The first laparoscopic hysterectomy for benign diseases was published in 1989 by Reich et al. [3]. Subsequently, laparoscopy was preferentially used in gynecologic oncology to convert radical abdominal hysterectomy into radical vaginal hysterectomy [4–6]. In 1990, Canis et al. [7] and in 1992, Nezhat et al. [8] described for the first time radical hysterectomy performed using the laparoscopic route. During the 90's various clinical series with a limited number of patients showed the possibility of performing radical resections with lymphadenectomy using the laparoscopic approach [9–13]. Different groups have published their experiences showing the feasibility and safety of the procedure and suggesting that prognosis or survival is not adversely affected by the procedure. However, there are few publications on the morbidity and long-term survival of laparoscopic radical hysterectomy.

Terminology

The term radical hysterectomy implies resection of a vaginal cuff and paracervical tissues besides the uterus. Pelvic lymphadenectomy also constitutes a part of the surgical procedure for early invasive cervical cancer, although it is not included in the current International Federation of Gynecology and Obstetrics (FIGO) staging classification [14]. The operation can be more or less radical according to the tumor size and involvement of paracervical tissue or of the vaginal tissue. Extension to the pelvic wall is performed through the paracervix, usually with involvement of lymph vessels and lymph nodes at this level.

In 1974, Piver et al. [15] pointed out that the term radical hysterectomy involves 'many different operations' and described five classes of extended hysterectomies that have been later summarized or adapted to the two types of radical hysterectomies: proximal, modified or Piver type II hysterectomy (resection of the medial paracervix proximal to the ureters and medial section of uterosacral ligaments) and distal or Piver type III/IV hysterectomy (distal resection of the paracervix at the level of the pelvic wall and removal of the uterosacral ligaments) (see Table 40.1).

In 2008, Querleu and Morrow [16] (Q-M) proposed a new classification of radical hysterectomy based on the lateral extent of resection. Four types of radical hysterectomy (A-D) were described, adding when necessary a few subtypes that look at nerve preservation and paracervical

Table 40.1 Types of radical hysterectomy

Querleu/Morrow type (2008/2011) [16, 17]	EORTC type (Piver 1974) [15]
Type A The fascia of the cervix and lower uterine segment is removed with the uterus	**Type I** Extrafascial hysterectomy
Type B Removes the cervix, proximal vagina, and parametrial and paracervical tissue The radicality of this operation can be improved by lymph-node dissection of the lateral part of the paracervix. Thus defining two subtypes: B1 and B2, with additional removal of the lateral paracervical lymph nodes.	**Type II** Modified radical hysterectomy
Type C Requires greater resection of the parametria The issue of nerve preservation is crucial. Two subcategories are defined: **C1 with nerve preservation** Uterosacral ligaments were transected after separation of both hypogastric nerves. The paracervix tissue was transected up to the deep uterine vein. The inferior hypogastric plexus with the splanchnic nerves are identified systematically . Then the bladder branches of the pelvic plexus were identified and preserved in the lateral ligament of the bladder **C2 with a complete parametrial resection** The paracervix is transected completely, including the part caudal to the deep uterine vein	**Type III** Radical hysterectomy
Type D Differs from type C2 in a feature additional ultraradical procedures, mostly indicated at the time of pelvic exenteration. Excision extends to the pelvic sidewall D1 is resection of the entire paracervix at the pelvic sidewall along with the hypogastric vessels, exposing the roots of the sciatic nerve D2 is D1 plus resection of the entire paracervix with the hypogastric vessels and adjacent fascial or muscular structures	**Type IV** Radical hysterectomy
	Type V **Pelvic Exanteration**

lymphadenectomy. Lymph node dissection was considered separately and four areas or levels were defined according to corresponding arterial anatomy and radicality of the procedure: level 1, external and internal iliac; level 2, common iliac (including presacral); level 3, aortic infra-mesenteric; and level 4, aortic infrarenal. In addition, it can be adapted to the different types of surgical approaches and is useful for open abdominal, laparoscopic or robotic, and vaginal routes.

More recently, in 2011, Cibula et al. proposed a classification system based on the proposal published by Querleu and Morrow but specifying anatomical landmarks for all types of radical hysterectomy in three dimensions [17].

Types of Radical Hysterectomy (Querleu-Morrow Classification Plus Cibula et al.)

Type A

This type corresponds to the extrafascial hysterectomy, which guarantees full removal of the pericervical tissue up to the attachment of the vaginal fornices. The paracervix is transected medial to the ureter, but lateral to the cervix. The uterosacral and vesicouterine ligaments are not transected at a distance from the uterus. Vaginal resection is generally at a minimum, routinely less than 10 mm, without removal of the vaginal part of the paracervix (paracolpos). The autonomic nerves remain fully preserved.

Type B

This type corresponds to the modified or proximal radical hysterectomy. Partial resection of the uterosacral and vesicouterine ligaments is a standard part. The ureter is only unroofed, dissected from the cervix and displaced laterally, permiting transaction of the paracervix at the level of the ureteral tunel. The nerve supply to the bladder is not treated because the paracervix is not resected caudal to the uterine vein, thereby nerve supply is conserved. At least 10 mm of the vagina from the cervix or tumour is resected.

The radicality of this operation can be improved without increasing postoperative morbidity by lymph-node dissection of the lateral part of the paracervix, thus defining two subtypes: B1 (as described); and B2, with additional removal of the lateral paracervical lymph nodes.

Type C

Type C corresponds to variants of classical radical hysterectomy. This type is transection of the uterosacral ligament at

the rectum and vesicouterine ligament at the bladder. The ureter is mobilised completely. 15–20 mm of vagina from the tumour or cervix and the corresponding paracolpos is resected routinely. The Q–M classification system distinguishes between a type C1 procedure, which corresponds to the nerve-sparing modification, and the type C2, which aims for a complete parametrial resection.

In type C1, the uterosacral ligaments were transected after separation of both hypogastric nerves and ureters. The paracervix tissue was transected up to the deep uterine vein. The inferior hypogastric plexus with the splanchnic nerves are identified systematically and preserved (Fig. 40.1). Then the bladder branches of the pelvic plexus were identified and preserved in the lateral ligament of the bladder (Fig. 40.2).

In the C2 type, the paracervix is transected completely, including the part caudal to the deep uterine vein (Fig. 40.3).

Type D

Type D1 is resection of the entire paracervix at the pelvic sidewall along with the hypogastric vessels, exposing the roots of the sciatic nerve. There is total resection of the vessels of the lateral part of the paracervix. Type D2 is D1 plus resection of the entire paracervix with the hypogastric vessels and adjacent fascial or muscular structures. This resection corresponds to the LEER (laterally extended endopelvic resection) procedure.

Surgical Procedure Step by Step [18]

Combined general and epidural anesthesia can be used. Patients should undergo bowel preparation and perioperative antibiotics (2 gr of cefazolin intravenously) and low-molecular-weight enoxaparin (40 mg/24 h subcutaneously) should be administered. A uterine manipulator is used. A four-trocar

transperitoneal approach is normally used. The laparoscope is introduced through an 11-mm umbilical trocar with a direct-puncture technique (or open technique using a Hasson trocar), and three other trocars are inserted with the patient in the 25–30-degree Trendelenburg position. Two accessory 12 and 5-mm trocars are then placed under direct visualization in the iliac fossas, and one 5-mm accessory trocar is placed at the midline between the umbilicus and the left subcostal margin (Fig. 40.4).

The abdominal cavity is inspected, and the retroperitoneal spaces are opened. The paravesical, pararectal, rectovaginal, and vesicovaginal spaces are developed, thereby delineating the uterosacral ligaments and the parametria (Fig. 40.5).

The pelvic lymph nodes are divided into external iliac, internal iliac or hypogastric, obturator, common iliac and presacral. External iliac nodes are superior and lateral to the external iliac vessels, from the deep iliac circumflex artery to the bifurcation of the common iliac artery. The internal iliac nodes are at the top and side of the internal iliac artery. The obturator nodes are in the obturator fossa below the external iliac vein and above the obturator nerve. Common iliac nodes extend from the bifurcation of the common iliac vessels to the bifurcation of the aorta. Presacral nodes are located below the bifurcation of the aorta and over the left common iliac vein. Lymphs located outside these anatomical areas are usually not involved in the lymphatic spread of uterine malignancies, so their systematic dissection is not justified.

Systematic bilateral pelvic lymphadenectomy is performed with blunt dissection and monopolar/bipolar coagulation from the common iliac artery to the inferior boundary of the circumflex iliac vein. On special occasions we use sealing vessels. Common, internal and external iliac nodes, as well as obturator and presacral lymph nodes, are removed (Fig. 40.6).

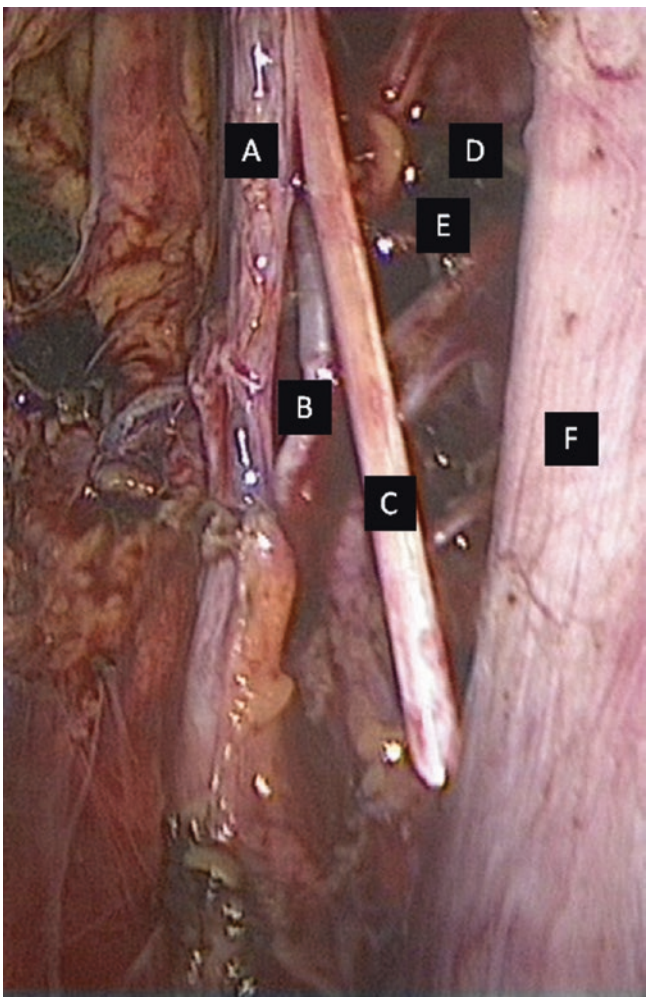

Fig. 40.6 Pelvic lymphadenectomy (*right side*). *A* Superior vesical artery *B* Obturator vein *C* Obturator nerve *D* Intern obturator muscle *E* Obturator fossa *F* External iliac vein

Uterine vessels are identified and cut at their origin from the hypogastric vessels. The uterosacral ligaments are transected after separation of both hypogastric nerves and ureters. The paracervix tissue is transected up to the deep uterine vein (Fig. 40.7).

Dissection of the ureteral tunnel, urinary bladder, and ureteral separation is accomplished with monopolar coagulation using a blunt dissector and with the aid of sealing vessels (Fig. 40.8).

Resection of the proximal paracervical tissues is performed with sealing vessels or monopolar/bipolar coagulation. At the point where the vaginal fornices are encountered bilaterally, the vagina is transected with monopolar coagulation, and the specimen is removed vaginally (Fig. 40.9)

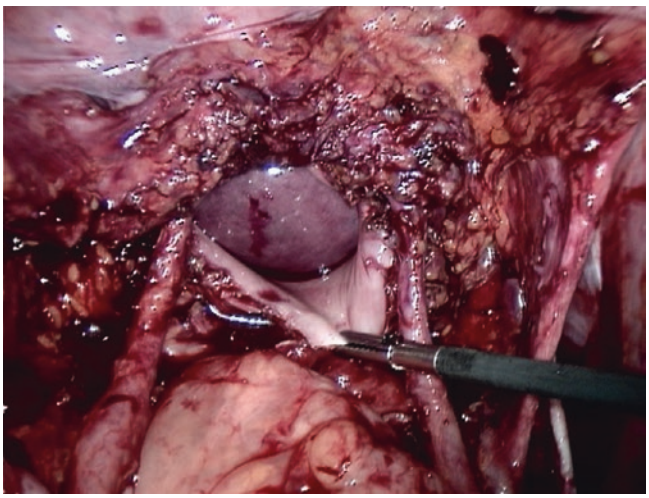

Fig. 40.10 Vaginal cuff before suture through the laparoscopic route

The vaginal cuff is then closed laparoscopically with 2-0 polyglactin continuous sutures. After completing the vaginal procedure, we check for hemostasis and intact ureters, and the peritoneal cavity is thoroughly irrigated and lavaged (Fig. 40.10).

Laparoscopy Radical Hysterectomy Compared with Laparotomy

There have been several studies in the last 10 years in which laparoscopy and laparotomy radical hysterectomy with pelvic lymphadenectomy for the treatment of early invasive Cervical Cancer have been compared.

Duration of Operation

As shown in Tables 40.2 and 40.3, duration of a laparoscopic radical hysterectomy type C operation ranged from 196 min

in the series of Malzoni [26] to 344 min in the study of Frumovitz [23, 24]. Other groups reporting short operative times are Li et al. [22] and Diaz-Feijoo et al. [25], in which procedures were totally performed using the laparoscopic route.

In a clinical series of 12 patients undergoing laparoscopic radical hysterectomy and lymphadenectomy with intraoperative detection of the sentinel node, Gil-Moreno et al. [28] reported a mean time of 271 min, which is shorter than results published in other series in which the technique of sentinel node detection was not included in the procedure. This study includes patients operated on from March 2001. In the same year, the same group [18], published their experience with laparoscopic radical hysterectomy and pelvis lymphadenectomy in which 27 patients were described (with detection of the sentinel node in 10) and the mean operative time was 285 min. However, patients in this study were included from September 1999, so it can be deduced that the technique of intraoperative sentinel node detection was not

initiated until the learning curve of radical hysterectomy with pelvic lymphadenectomy was accomplished.

Regarding the experience of the surgical team and the learning curve for this type of laparoscopic surgery, the study of Pomel et al. [29] provides interesting data. In a group of 50 patients, a mean operative time of 258 min (range 114–540 min, 39 radical hysterectomies type C and 11 type B) was reported. The operative time was not significantly different in patients with and without previous surgery, preoperative brachytherapy or even in relation to body mass index. But the effect of the learning curve was evident. In the first 25 patients, the mean operative time was 290 min, whereas for the last 25 patients, the mean time was 226 min ($P = 0.01$). Moreover, in the last ten patients, the mean operative time decreased to 135 min (range 114–180 min).

In 1995, Sedlacek et al. [30], compared a series of 14 patients undergoing laparoscopic radical hysterectomy type III with lymphadenectomy *vs* the historical group of patients treated in the past 3 years using the laparotomic route, showing a duration of operation of 7 h for the laparoscopy group and 4 h for the laparotomy group, although neither the influence of the surgical experience or the learning curve was considered. Lin [19] published preliminary findings of a prospective and non-randomized study. In the laparoscopic group of ten patients, the mean operative time was 159 min *vs* 165.7 min in the open surgery group (39 patients). It should be noted that the type of hysterectomy was a radical hysterectomy type B and that the procedure was completed by the vaginal route but the surgical time in the two approaches was the same. Abu-Rustum et al. [20] in 2003, carried out a retrospective comparative study of 19 patients undergoing laparoscopic radical hysterectomy with pelvic lymphadenectomy with argon beam coagulation (there were two conversions to open laparotomy, the operative times of which were not included) *vs* a historical cohort of 195 patients who underwent standard laparotomy over an 11-year period. The mean operative time was 296 min in the historical cohort and 371 in the laparoscopy group ($P < 0.01$), but again the learning curve should be taken into account.

Frumovitz and co-workers [23, 24] from the University of Texas M.D. Anderson Cancer Center compared 35 patients operated using the laparoscopic route (two conversions to open laparotomy) with 54 patients undergoing hysterectomy by laparotomy. Surgical times were significantly longer for the laparoscopic group (344 min *vs* 307 min, $P = 0.03$). The authors had two different explanations. Firstly, the learning curve because this was a new technique for the surgical team, and secondly, by the fact that the institution is a teaching center both for gynecologists that want to become specialists in gynecologic oncology and residents that participate in all surgeries. These surgical times are similar to those reported on in the Memorial Sloan-Kettering Cancer Center [20], which is also a university-affiliated hospital. The group of Zakashansky and Nezhat [21] published the results of a

case-control study in which 30 laparoscopically-operated patients (the procedure was completed by the vaginal route) were compared with 30 patients operated via laparotomy, emphasizing that the study was performed in a teaching center (with a teaching program for advanced laparoscopic procedures). This is an interesting study because it shows the curve of surgical time by academic year, showing a plateau of 310 min that was not able to be reduced with the experience of the surgeons. When the experience in a teaching program was analyzed, there was an increase in the mean operative time for the laparoscopic procedure *vs* the open route in radical hysterectomies performed by the same alumni. The duration of operation is slightly longer as compared with the same procedure performed by expert surgeons in other series, and approximately coincides with data from other studies of hospitals teaching these procedures [20, 31]. Li et al. [22] compared a group of 90 patients undergoing laparoscopic hysterectomy with suture of the vaginal cuff vaginally with 35 patients operated using the conventional laparotomy approach. The mean surgical time was 263 min *vs* 217 min, respectively ($P = 0.001$). The difference in favor of the laparotomy group was attributed to the learning curve since the duration of operation decreased significantly from 281 min for the first 48 patients to 244 for the last 45 patients ($P = 0.009$).

In 2008, Díaz-Feijoo et al. [25] reported the results of a retrospective non randomized study in which 50 consecutive patients with FIGO stage IA_2, IB_1, and AII disease less than 4 cm underwent radical hysterectomy and lymphadenectomy with intraoperative sentinel lymph node biopsy. The operation was performed entirely by laparoscopy in 20 patients and using the conventional abdominal route in 30. The mean duration of operation was 272.5 min and 240 min. for the laparoscopic and laparotomy groups, respectively ($P = 0.001$).

All studies are consistent with a longer duration of operation for the laparoscopic approach, although the operative time decreases with the surgeon's experience and when the learning curve has been surpassed. However, the laparoscopic technique involves some steps, such as extraction of the lymph nodes using a bag device and insertion of the uterine manipulator and other laparoscopic instruments which increase the overall operating time.

Intraoperative Blood Loss

A review of the different series published in the literature revealed a mean intraoperative blood loss of 200 mL (see Table 40.2). The learning curve is important to decrease blood loss at the time of surgery. Blood loss in the laparoscopic technique is minimized by a better visualization of the small vessels through magnification of the current optical systems, which allows a careful hemostasis of the operative field [24].

In the first case described by Nezhat et al. [8] in 1992, the estimated blood loss was 30 mL, and in the case reported by Jobling and Wood [32] in 1993, the amount of blood loss was 100 mL. These blood losses were very small bearing in mind the long operating time (420 and 460 min, respectively) and given that procedures were completed by the vaginal route. It is probable that hemostasis was carefully controlled.

When the laparoscopy and the laparotomy routes are compared (Table 40.2), all the studies reported a significantly lower blood loss in the laparoscopic route. Although the significant difference in blood loss (in ml.) may not be clinically important. The clinically important difference is the transfusion rate. Historically, 40–80 % of patients undergoing radical hysterectomy via abdominal laparotomy received blood transfusion.

In the study of Pomel et al. [29] (50 patients) only one patient required blood transfusion in the laparoscopic arm. In the study of Zakashansky et al. [21] published in 2007 (30 patients, procedure completed through the vaginal route), no transfusions were reported. In the study of Malzoni et al. [26], the estimated blood loss was 55 mL and no transfusions were needed. In the study of Díaz-Feijoo et al. [25], the mean blood loss was 623 mL in the laparotomy group and 400 mL in the laparoscopy group ($P = 0.001$). Five patients in the laparotomy group required blood transfusion compared with one patient in the laparoscopy group. In relation to the learning curve, in the largest series of laparoscopic radical hysterectomies lower rates of blood transfusion are generally reported. In the study of Spirtos et al. [33] of 78 patients, the transfusion rate was 1.3 % and in the study of Pomel et al. [29] 2 %.

Pelvic Nodes

The number of pelvic nodes obtained in the different studies published in the literature ranges from 7 to 41. In the largest series, the mean number of nodes removed in the laparoscopic route is around 20 (23.5 in the study of Malzoni et al. [26] with 65 patients, 21.3 in the study of Li et al. [22] with 90 patients and 25.5 in the study of AbuRustum et al. [20] with 197 patients). In other studies, the mean number of lymph nodes obtained is smaller (16.8 in the study of Lin et al. [19] with ten patients) or greater such as 31 in the study of Zakashansky et al. [21] with 30 patients (Table 40.2).

Abu-Rustum et al. [20], reported a mean of 25.5 nodes in the laparoscopic group *vs* 30.7 in the laparotomy group, although significant differences were not found. Malzoni et al. [26] also observed a higher number of nodes obtained in open surgery (25.2) than in laparoscopic surgery (23.5), including a difference in the number of aortic nodes in favor of laparotomy. In the study of Frumovitz et al. [23], a mean of 19 pelvic nodes were obtained during abdominal radical hysterectomy compared with 14 during total laparoscopic radical hysterectomy ($P = 0.001$). However, in the study of Li et al. [22] the mean number of nodes obtained was similar (21.3 laparoscopy *vs* 18.8 laparotomy), whereas Zakashansky

et al. [21] showed a significantly higher number in laparoscopic radical hysterectomy than in open abdominal surgery (31 *vs* 21.8, P = 0.01) (Table 40.2).

The decision to perform laparoscopic lymphadenectomy depends on the experience and protocols of each working group. There are, currently, controversial opinions regarding the posibility of comparing the results obtained for each of the different techniques, due to the absence of comparative prospective randomized studies on the effectiveness of each and influence on survival in each type of genital neoplasia.

However, there is not a consensus on the minimal number of nodes which should be removed at the time of a systematic pelvic lymphadenectomy or even if the lymphadenectomy has a therapeutic effect in cervical cancer. With this objective, Suprasert *et al.* [34]retrospectively included 826 patients who were divided into four groups according to the number of nodes removed (with at least 11 pelvic nodes removed). They concluded that the number of removed pelvic nodes was not associated with 5-year disease-free survival nor when stratified by nodal status. These results are opposite to those from the study of Shah et al. [35] who analyzed 5522 women included in the SEER. It concluded that among node-negative women, survival is improved when a greater number of lymph nodes are removed suggesting that the extent of lymphadenectomy in node negative patient influences survival. This could be explained because a greater number of removed nodes could give a better way to detect metastasis or to extract micrometastasis.

Sentinel Lymp Node (SLN)

The sentinel lymph node is defined as the first draining lymph node of an anatomical region, so that a histologically negative sentinel lymph node would predict the absence of tumor metastases in the other non-sentinel lymph nodes. In cervical carcinoma patients, lymph node status is a major prognostic factor and is a decision criterion for adjuvant therapy. In patients with early cervical cancer, pelvic or paraaortic lymph node metastases are detected in only 8 % of women with stage IA2 and in 26 % of women with stage IIA no bulky [36].Thus, many of these patients derive no benefit from pelvic lymphadenectomy. SLN dissections have been associated with decreased short-term and long-term morbidity when compared with complete lymph node dissection such as lymphedema [37]. We should remember that 34.5 % of patients with lymphadenectomy for a gynecological cancer will develop symptomatic linfocysts and 11.4 % a lower-limb lymphedema [38]. Eiriksson and Covens reviewed the reports published on 2333 patients with early cervical cancer and sentinel node dissection. The sensibility was 98.2 % and the predictive negative value was 99.6 %. They suggested that it may be possible that systematic lymphadenectomy can be substituted by detection and analysis of the sentinel node as many groups are making nowadays [39]. The study

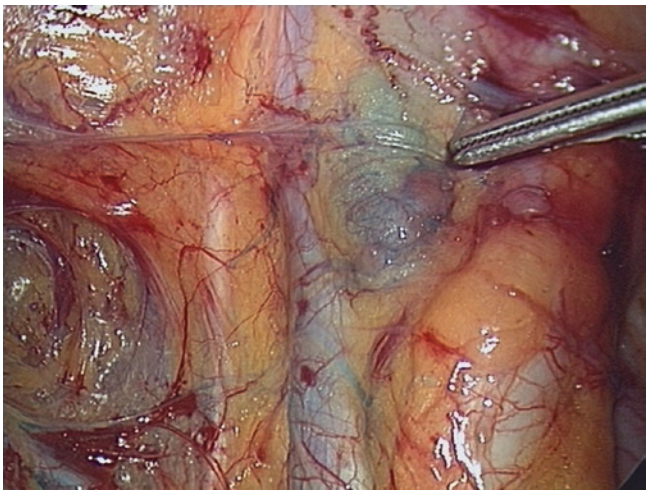

Fig. 40.11 Identification of a blue-positive sentinel lymph node

published by Gil-Moreno et al. in 2005 showed the feasibility of the combination of laparoscopic intraoperative sentinel node mapping and laparoscopic radical surgery in the context of minimally invasive surgery for the management of patients with early cervical cancer [18]. Intraoperative detection of sentinel lymph node status may have significant implications from a clinical management point of view. If the node is positive for tumor metastasis, a radical hysterectomy could be omitted, and adjuvant chemoradiation is commonly given (Fig. 40.11) [40].

Intraoperative Complications

Intraoperative complications reported on in the different studies are shown in Table 40.3. Conversion to open surgery has been mostly described in association with vascular injuries [10, 20, 22, 23, 33, 41], bladder injuries [9, 20, 27, 33], pelvic adhesions [9, 20], large uterus [9], or difficulties in maintaining the pneumoperitoneum for technical reasons [18, 25, 33].

Vascular injuries during laparoscopic procedures, including trocar injury at the start of the procedure [23] is one of the most common complications requiring immediate conversion to open surgery and/or blood transfusion, with the external and internal iliac veins [20, 22, 23, 41, 42] and vascular lesions of the abdominal wall being the most frequent. Blood transfusion at the time of surgery or in the immediate postoperative period is also a common complication. Although in the majority of studies higher blood losses are usually reported for conventional laparotomy [20, 21, 23, 25]. A case of secondary hemorrhage requiring relaparoscopy has been also reported [42]. A venotomy of the inferior vena cava during lymph node dissection in the laparotomy group was described by Zakashansky et al. [21].

Intraoperative injuries of the bladder (mostly repaired during the laparoscopic procedure) [23, 27, 29, 31, 33, 41, 42]

and less frequently of the ureters [9, 29, 30, 41, 42] (sometimes documented in the postoperative period) [42] are relatively frequent intraoperative complications. In a review of intraoperative urinary tract lesions in laparoscopic surgery (50 patients) and open surgery (48 patients), no statistically significant differences were observed [43].

Other less frequent intraoperative complications include intestinal damage [41, 42] ,a case of pneumomediastinum immediately following surgery [31], and hypercapnia [41].

In one large serie of laparoscopic radical hysterectomy and lymphadenectomy procedures for invasive cervical carcinoma that included 317 patients, Xu et al. [41] examined complications and analyzed factors associated with conversion to an open surgical procedure. The overall conversion rate was 1.3 % (n = 4). Major and minor intraoperative complications occurred in 4.4 % (n = 14) of the patients. Seven patients had vessel injuries, five of which were repaired or treated laparoscopically. One left external iliac vein required laparotomy, and one patient underwent laparotomy to control bleeding sites. Operative cystotomies occurred in five patients, which were repaired laparoscopically. Two patients underwent laparotomy because of hypercapnia and colon injury. The authors emphasized that these complications were developed in the first 50 laparoscopic procedures, and after those, no intestinal or vascular injuries occurred.

In the majority of studies in which the laparoscopic procedure and open surgery has been compared (see Table 40.3), differences in the rate of intraoperative complications were not found except in the study of Zakashansky et al. [21] regarding the number of patients requiring blood transfusion. Some studies even showed a trend towards a higher number of complications in the laparotomy group [21, 25]. In the laparotomy group in the study of Díaz-Feijoo et al. [25], ureteral injury occurred in one patient and disseminated intravascular coagulation in another. In the laparoscopy group, conversion to open surgery was necessary in one patient.

Postoperative Complications

Postoperative complications are also summarized in Table 40.3. Most relate to infections [12, 20, 21, 23, 28, 29, 33, 42] and bladder dysfunction, as classically reported after radical hysterectomy [12, 18, 21–23, 25, 28, 29, 32, 33, 41, 42]. Voiding difficulties, sometimes requiring intermittent catheterization, may occur between 2 weeks and 6 months postoperatively.

Infectious morbidity is mainly related to urinary tract infection, pelvic abscesses, and abscesses of the vaginal cuff, as well as some cases of fever of unknown origin. Cases of urologic-related sepsis have also been described. Frumovitz et al. [23] showed a higher percentage of postoperative infections in patients undergoing open surgery (53 %) than in those treated laparoscopically (18 %).

Ureterovaginal fistulas and to a lesser extent vesicovaginal fistulas, are also reported on in many studies [12, 22, 29–31, 41, 42, 44]. Surgical repair was necessary in most cases, although some patients have been treated conservatively [44]. In the study of Uccella et al. [43], the rate of postoperative urological complication was similar in laparoscopic and open surgery.

Other uncommon complications include deep venous thrombosis [21, 33, 41], which was reported as the cause of fatal and nonfatal pulmonary thromboembolism [21, 23, 31]. Early mobilization of the patients is highly recommended for the prophylaxis of deep venous thrombosis and pulmonary embolism. However, embolism of the right external iliac artery is a rare postoperative complication of laparoscopic radical hysterectomy [41].

In the study of Díaz-Feijoo et al. [25], 3 months after radical hysterectomy, vagina cuff separation with bowel prolapse after the first sexual intercourse (successfully repaired vaginally)was reported on in three patients in the laparoscopy group. Similar cases have been also described by other authors [29, 31, 44].

Lymphocele is a relatively common complication [22, 31, 33, 41], although most cases are asymptomatic and no treatment is required. Symptomatic lymphocele may be treated by percutaneous puncture, guided by ultrasound or compute tomography. Other complications described in the studies are lymphedema of the lower extremities [12, 41], transient sensory disturbances [29, 41], and colitis caused by *Clostridium difficile* reported both in laparoscopy surgery [21] and in open surgery [20].

Length of Hospital Stay and Costs

Laparoscopic surgery is usually associated with a short hospital stay, ranging between 1 day [31] and 13.8 days [22], although in most studies the mean length of stay varies between 2 and 5 days [8, 13, 18–21, 23–26, 31–33, 44]. (Table 40.2). Studies in which laparoscopy and laparotomy approaches were compared, length of hospitalization was usually shorter for the laparoscopic procedure [11, 19–21, 23, 25, 27] partly, due to early postoperative intestinal motility. In the study of Li et al. [22] there were differences in the bowel recovery time between the open surgery group (2.4 days) and the laparoscopy group (1.96 days) (P = 0.025). Advantages of the laparoscopic procedure include early mobilization and lower pain intensity. On the other hand, Li et al. reported similar lengths of hospital stay for the laparoscopic and open abdominal surgery groups (13.8 *vs* 13.7 days) and argued that patients wanted to be discharged after complete recovery. Moreover, differences in health care delivery systems and culture may account for a large variation in the average hospital stay. Also insurance companies may not be concerned about the duration of hospital stay in cancer patients.

In 1994, Sedlacek et al. [11] estimated the cost of laparoscopic radical hysterectomy as $12,594 in comparison with $12,905 of the open procedure. Reduced costs of laparoscopy were especially associated with a shorter hospital stay.

Outcome and Recurrence

A few cases of port-site metastasis have been reported [42, 44]. Preventive measures include irrigation of port sites with cytotoxic agents, careful tumor manipulation, and use of extraction bags for any suspicious tissue.

Definitive data regarding differences in overall survival, disease-free survival, and recurrence between the laparoscopic approach and conventional open surgery are lacking. Comparative studies of both procedures include small series of patients with relatively short duration of follow-up (Table 40.3). In the study of Li et al. [22], after a mean follow-up of 26 months, the overall mortality in the laparoscopy group was 10 % *vs* 8 % in the laparotomy group, and there was a recurrence rate of 13.7 % and 12 %, respectively. In the study of Frumovitz et al. [23], one recurrence in the laparoscopy group (n = 35) after a mean follow-up of 7.2 months and two recurrences in the laparotomy group (n = 44) after a mean follow-up of 15.2 months was reported. In the series of Díaz-Feijoo et al. [25], the disease-free survival was 100 % in the laparoscopy group after a follow-up of 23.3 months and 86.7 % in the laparotomy group after a mean follow-up of 34.6 months, with an overall survival of 90 %. In the study of Ditto et al. [27] in 2015, the recurrence rate was 3 % in the laparoscopic arm (31 months of follow up) and 8 % in the laparotomy arm (48.7 months of follow up).

Further studies, particularly prospective randomizes studies, with larger study samples and longer follow-up periods are needed to assess the outcome of patients with early-stage cervical cancer undergoing radical hysterectomy with pelvic lymphadenectomy through the laparoscopic approach or conventional open surgery.

Conclusions

In comparison with the conventional abdominal laparotomy, the laparoscopy approach is associated with a lower surgical morbidity in terms of intraoperative blood loss, shorter hospital stay and early resumption of daily activities with an increase in quality of life [25]. Recent advances in laparoscopic instruments simplify training and improve outcomes. Probably magnification yields a better surgical field and shorten operative times by enabling better hemostasis with less tissue damage and easier manipulation. With advances in surgical robotics [45–50], continuation of these trends can be anticipated.

Evidence presented here shows that laparoscopic radical hysterectomy with endoscopic pelvic lymphadenectomy is a safe surgical option in the treatment and staging of early invasive cervical cancer regarding the surgical technique, surgical risk, intraoperative bleeding, perioperative and postoperative complications, and patient's recovery. A decrease in operative time as more procedures are performed and surgeons become more familiar with the procedure may be expected. The laparoscopic technique is more expensive than laparotomy due primarily to laparoscopic instrumentation but the disadvantage of cost is counterbalanced by shorter hospital stay, prompt postoperative recovery, and early resumption of daily activities [11, 30].

In our opinion, minimally invasive surgery (conventional laparoscopy or robotically assisted) should be the standard approach for the surgical treatment of patients with early cervical cancer.

Total Laparoscopic Nerve-Sparing Radical Hysterectomy

41

Hiroyuki Kanao and Nobuhiro Takeshima

Introduction

Total laparoscopic radical hysterectomy for cervical carcinoma is currently an accepted surgical procedure not only because of its technical feasibility, but also because of its favorable oncologic outcome [1–6]. However, bladder dysfunction after a laparoscopic radical hysterectomy is likely to decrease the patient's quality of life because of the physical and mental stress that accompany post-operative disorders. The main cause is damage to the pelvic nerve plexus (inferior hypogastric plexus) and its vesical branches during this procedure. These nerve circuits are important for neurogenic bladder control [7–9].

Total laparoscopic nerve-sparing radical hysterectomy has been developed recently for early stage cervical carcinoma using a previously established technical procedure.. The principal features of this technique can be summarized by describing the procedure as one in which the hypogastric nerves, instead of the pelvic nerve plexus and its vesical branches, are preserved at several steps during a classical radical hysterectomy [10, 11]. Consequently, the hypogastric nerves are regarded as the main anatomical landmark of the nerve-sparing radical hysterectomy because they act as the upper limit of the pelvic nerve plexus and the vesical branches.

In this chapter, step-by-step surgical instructions for total laparoscopic nerve-sparing radical hysterectomy are described (with a special focus on the nerve-sparing techniques) and our original research regarding the correlations between the preserved pelvic nerve networks and bladder functions after total laparoscopic nerve sparing radical hysterectomy are introduced.

Surgical Procedures

Creation of the Vaginal Cuff

Prior to laparoscopic (LAP) surgery, a vaginal cuff is created (Fig. 41.1). In LAP surgery, an excision of suitable length of the vagina (2 cm from the tumor) is quite difficult due to the loss of tactile sensation; therefore, the creation of a vaginal cuff is essential for an accurate excision of the vagina. Moreover, the creation of a vaginal cuff is also quite useful to prevent the spillage of cancer cells during LAP surgery.

The patient is placed in the lithotomy position. First, 12–15 sutures are placed circumferentially approximately 2 cm from the tumor, and the sutures are pulled to reveal the incision line. Adrenaline at a dilution of 1:1,000,000 is injected into the incision line to reduce bleeding. The vaginal mucosa is then incised circumferentially using electrocautery and the vaginal cuff is doubly closed in a continuous fashion. When the margin of the tumor is difficult to determine, visual inspection with the Schiller test is essential.

Positioning of the Patient and Configuration of the Trocars

The patient is placed in the mild lithotomy position. The legs of the patient are extended slightly and the patent is tilted about 10 ° (Fig. 41.2a). A 12-mm trocar is placed in the umbilicus for a camera port and three 5-mm trocars for forceps are placed as in Fig. 41.2b. A 5-mm extra-long trocar (150 mm length) is placed at the posterior vaginal fornix, and a forceps placed through this port is used as a uterine manipulator. A 1-0 vicryl suture is placed around the uterine body and the uterus is manipulated by a pulling-and-pushing technique of the 1-0 vicryl suture with forceps through the vaginal trocar. In our procedure, a vaginal cuff is created prior to the LAP surgery, thus overcoming the problem of using a uterine manipulator (Fig. 41.2c).

(**b**) Incision of vaginal mucosa is made around the sutures and the vaginal cuff closure is started. (**c**) Vaginal cuff closure is completed

Pelvic Lymphadenectomy

Pelvic lymphadenectomy is started by opening the pelvic sidewall triangle, which is the area between the round ligament, the infundibulopelvic ligament, and the external iliac vessels. At first, a wide opening of the pararectal space and paravesical space is developed allowing the exposure of the cardinal ligament between these spaces. These spaces are avascular spaces; therefore, a blunt dissection is sufficient for development. In order to maintain a good surgical view around the paravesical space (and obturator fossa), we suspend an umbilical ligament to the abdominal wall (Fig. 41.3 1).

Next, the space between the psoas muscle and the external iliac vessels is developed widely in order to expose the obturator nerve and vessels (Fig. 41.3 2). The lymphofatty tissue is easily dissected from the obturator nerve and vessels using a blunt dissection technique and the upper end of the lymphofatty tissue (around the common iliac lesion) is clipped and transected (Fig. 41.3 3). The clipping of the cut end of lymph node is particularly important to prevent lymphocele after the surgery. Following the transection of the upper end, the lymphofatty tissue is easily stripped off the external and internal iliac vessels en block (Fig. 41.3 4–6).

For a total laparoscopic nerve-sparing radical hysterectomy, the complete exposure of the pelvic nerve networks (hypogastric nerves, pelvic splanchnic nerves, pelvic nerve plexus, and their vesical branches) is essential; and in order to achieve complete exposure it is very important to perform lymphadenectomy adjacent to the internal iliac region.

After developing a wide pararectal space, the hypogastric nerves can be observed easily along the lateral sides of the mesorectum. The lymph node tissue around the internal iliac region is removed completely; then, the S2–3 roots are identifiable beneath the fascia of the piriformis muscle. Additionally the pelvic splanchnic nerves, which join the pelvic nerve plexus, are visible as visceral branches originating

from the S2–3 roots after the lymph node tissue around the cardinal ligament is meticulously removed (Fig. 41.4). After all lymph nodes are harvested, the nodes are removed with a plastic bag to prevent the scattering of the specimen.

The Transection of Upper Ligaments

The infundibulopelvic ligament or the adnexal ligament (if the patient wants to preserve her ovaries) is desiccated and transected. The round ligament is also desiccated and divided.

The Dissection of the Bladder

The bladder peritoneum is incised using a monopolar knife and the bladder is dissected from the cervix. When the bladder is lifted ventrally enough, an avascular area between the bladder and the cervix can be visualized, and then the dissection of the bladder can easily be performed.

The Transection of the Uterine Artery and the Unroofing of the Ureter

The uterine artery has already been isolated at the pelvic lymphadenectomy step described above; therefore, the transection of the uterine artery is easily performed using a hemoclip. Lifting the end of the uterine artery medially, a branch to the bladder (middle vesical artery) is isolated. After transecting this branch, the uterine artery can be isolated from the ureter completely, and the ureter tunnel can be developed median of the ureter. The bladder pillar is dissected meticulously thus allowing a small vessel to be isolated (cervico-vesical vessels). After transecting these cervico-vesical vessels, the unroofing of the ureter is accomplished.

Steps 4–6 are identical to those of total laparoscopic radical hysterectomy (non nerve-sparing techniques); therefore please refer to the relevant chapter for further details.

The Transection of the Cardinal Ligament

At the pelvic lymphadenectomy step described above, the lymph node of the cardinal ligament is removed; therefore, the vessels and nerves around the cardinal ligament are already isolated at this point. In nerve-sparing procedure described here, only the deep uterine vein is clipped and transected at the pelvic sidewall, and the stump of the deep uterine vein is scraped up to the level of the hypogastric nerves (i.e., the upper end of pelvic nerve networks).

The Transection of the Posterior Layer of the Vesico-Uterine Ligament

This step is essential for the preservation of the vesical branches of the pelvic nerve networks. At the posterior layer of the vesico-uterine ligament, the vesical vessels, nerves, and

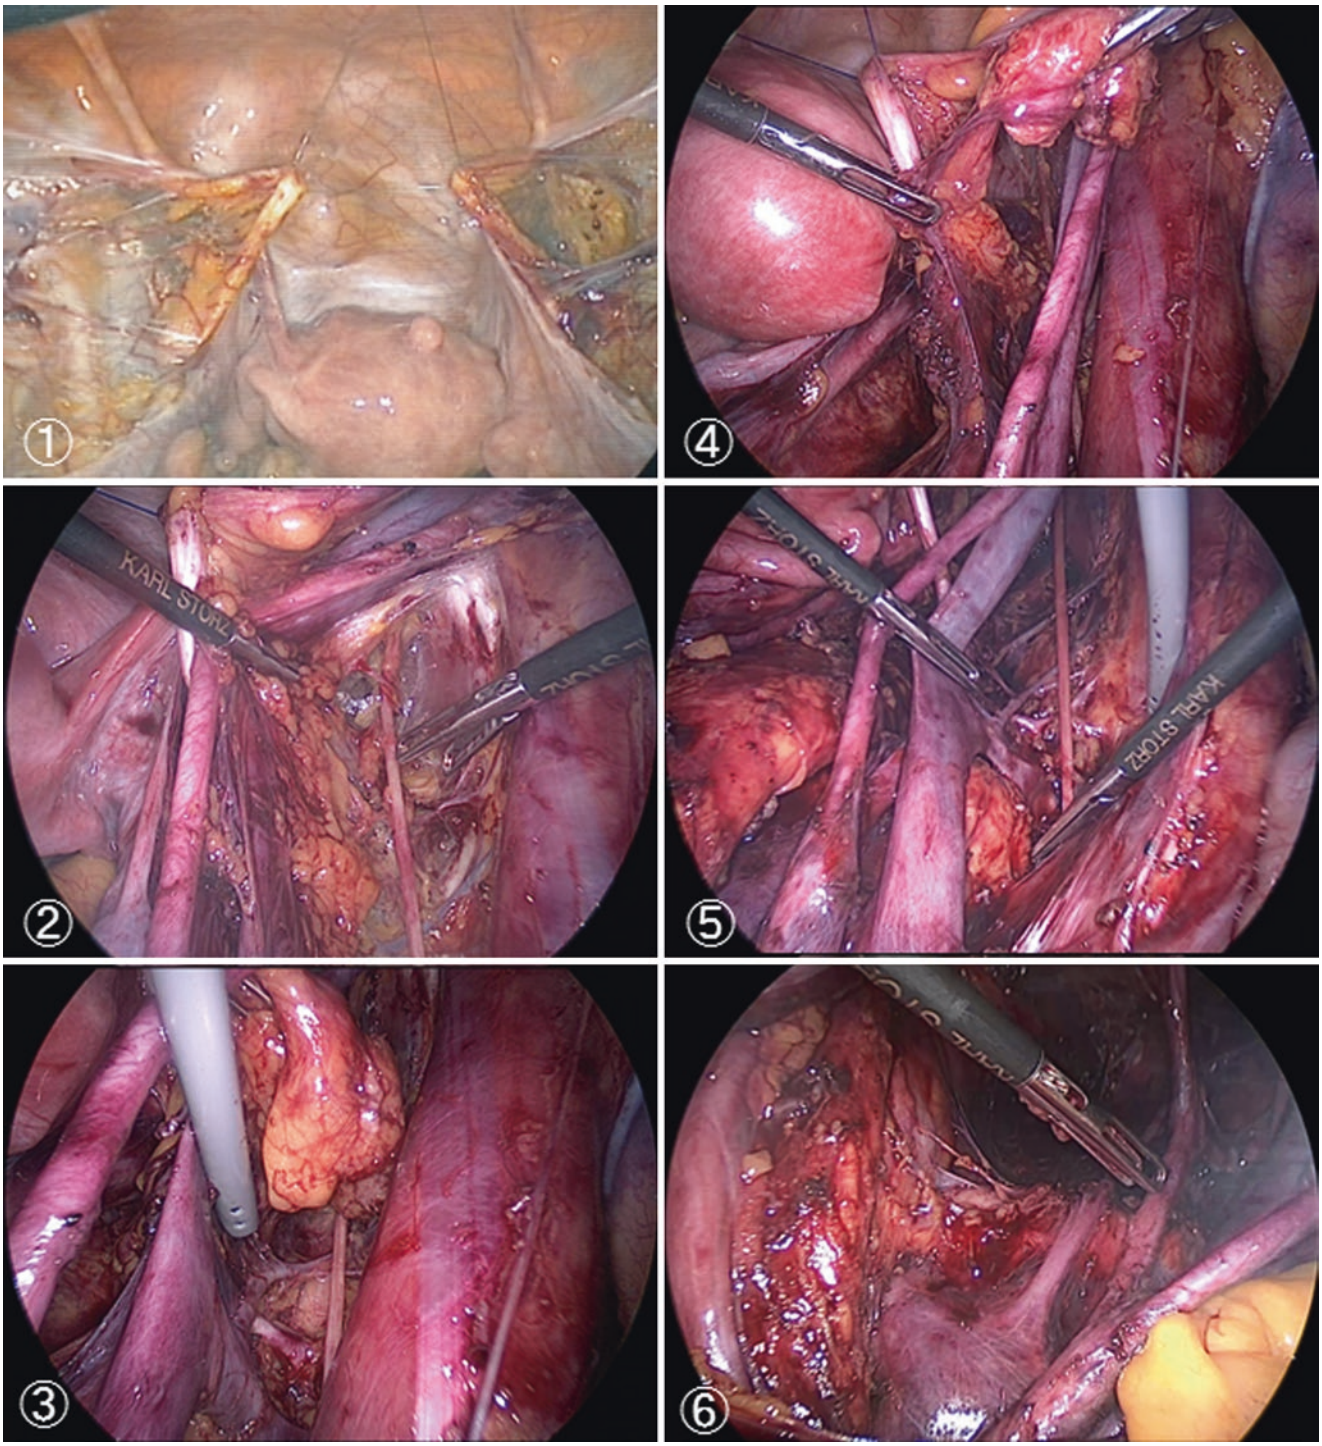

Fig. 41.3 Pelvic lymphadenectomy. (*1*) The umbilical ligament is suspended to the abdominal wall to maintain the good surgical view. (*2*) The space between the psoas muscle and the external iliac vessels is developed widely until the obturator nerve and vessels are exposed. (*3*) The upper end of the lymphofatty tissue(around the common iliac lesion) is clipped and transected. (*4*) Pelvic lymphnode is removed en block. (*5*, *6*) Final view of pelvic lymphadenectomy

adipose tissue are packed by a membrane, therefore a meticulous dissection or "demembranation" is required to expose the two or three vesical veins, which flow into the deep uterine vein; these veins are clipped and transected. The remnant after the transection of these vesical vessels at the posterior layer of the vesico-uterine ligament contains the vesical branches of the pelvic nerve networks. For complete preservation of the function of vesical branches, it is essential to

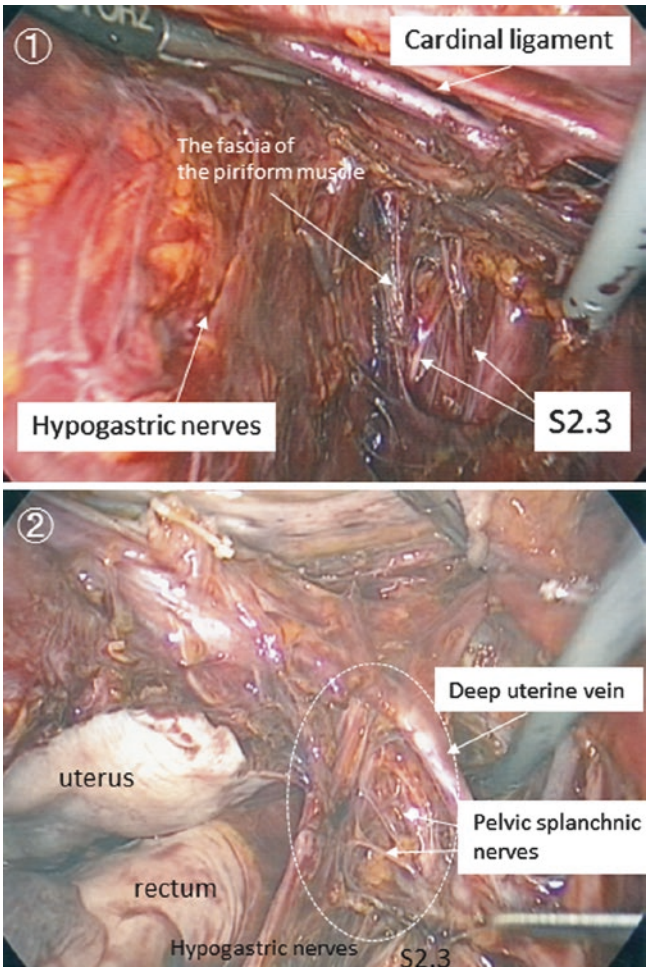

Fig. 41.4 Complete exposure of pelvic nerve networks. (*1*) The lymph node tissue around the internal iliac region is removed completely, then the S2–3 roots are identifiable beneath the fascia of the piriform muscle. (*2*) The complete structure of pelvic nerve plexus is marked by a dotted circle. They are consisted by hypogastric nerves and pelvic splanchnic nerves

prevent thermal injury; therefore, the vesical veins are transected using clips and scissors (Fig. 41.5 1–4).

Transection of the Paracolpium and Sacrouterine Ligament

The Douglas peritoneum is incised and the rectum is dissected until the posterior vaginal wall is exposed. Sometimes, the vaginal wall is opened at this stage because the vaginal cuff has already been created. After dissecting the rectum, the sacrouterine ligament can be exposed. To preserve the pelvic nerve networks, the uterosacral ligament and paracolpium tissue are transected just above the hypogastric nerves.

At this stage, the paracolpium tissue is sutured and ligated to reduce the usage of the energy device and to prevent thermal injury (Fig. 41.5a).

Transection of the Vagina

A vaginal pipe is inserted to extend the vaginal wall. The vaginal cuff has already been created at the first step of this surgery, thus after the transection of rectovaginal ligament, the vaginal wall can easily be transected.

Closure of the Vagina

The specimen is retrieved vaginally. To prevent the scattering of cancer cells, a plastic bag is used for the retrieval of the specimen (Fig. 41.6). The vaginal stump is closed using a 1-0 vicryl interrupted suture. The central part of the peritoneum is closed using a 2-0 vicryl suture, and the lateral part is opened to reduce the occurrence of lymphocyst following the surgery. The drainage tube is placed at the Douglas space.

Figure 41.7 shows the final view of the total laparoscopic nerve-sparing radical hysterectomy for stage Ib2 cervical cancer.

Discussion

Bladder function following conventional total laparoscopic nerve-sparing radical hysterectomy is quite good. However, the degree of radicality of this procedure is insufficient in some cases. Therefore, the applicability of this procedure is expected to be limited to early stage cervical carcinoma [12]. For intermediate-stage or advanced-stage cervical carcinoma, a more radical procedure is necessary. In such cases, nerve-sparing techniques have never been applied. However, in some intermediate-risk cervical carcinoma cases, non-nerve-sparing radical hysterectomy tends to result in overtreatment. We suggest that a different nerve-sparing technique be applied for these cases.

The pelvic nerve plexus appears as a mesh and consists mainly of hypogastric nerves and pelvic splanchnic nerves. The hypogastric nerves are located at the ventral edge and pelvic splanchnic nerves are located at the dorsal edge of the pelvic nerve plexus [13]. Therefore, the pelvic nerve plexus has a somewhat definable anatomical width. In this case, it is possible to apply a different nerve sparing technique, which would likely consist of a more radical procedure than conventional nerve-sparing radical hysterectomy.

To accomplish the innovative nerve sparing technique described here, the complete exposure of the pelvic nerve plexus is necessary. As explained above, the complete exposure of pelvic nerve networks is possible and enables to control the degree of radicality to the point where the uterosacral ligament and paracolpium tissue can be transected. Furthermore, laparoscopic radical hysterectomies can be

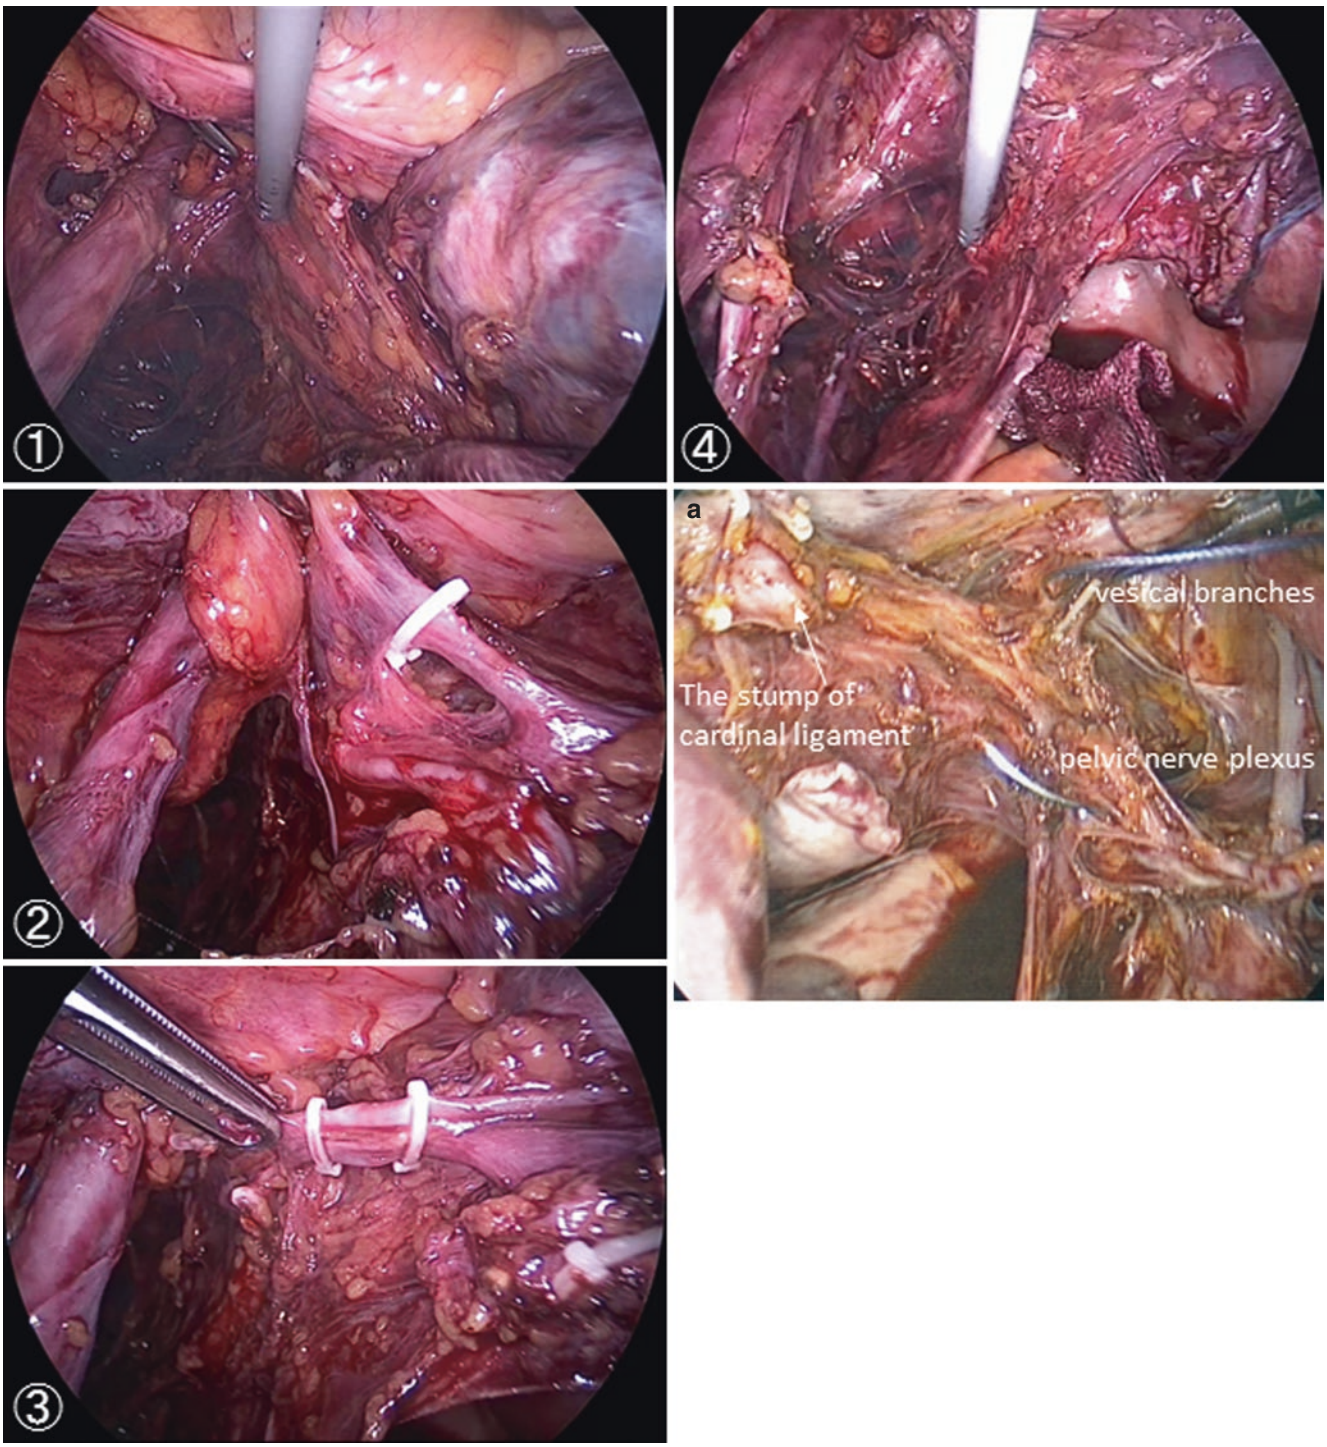

Fig. 41.5 Transection of posterior layer of vesico-uterine ligament and paracolpium tissue. ① The posterior layer of vesico-uterine ligament of left side. Veins, nerves and adipose tissue are packed by a membrane.②③ "Demembranation" expose two or three vesical veins. They are isolated and transected one by one.④ After transection of the posterior layer of vesico-uterine ligament, pelvic nerve networks are exposed. (**a**) To preserved the pelvic nerve networks, the uterosacral ligament and paracolpium tissue are transected just above the hypogastric nerves. At this stage, we suture and ligate the paracolpium tissue to reduce the usage of energy device and to prevent thermal injury

categorized into three types depending on the status of the preserved nerve network. The uterosacral ligament and the paracolpium tissue are transected above the hypogastric nerves for the conventional nerve-sparing procedure (group A), between the hypogastric nerves and pelvic splanchnic nerves for the radical nerve-sparing procedure (group B), or below the pelvic splanchnic nerves in the case of nerve-sacrificed radical hysterectomy (group C). We performed 27 cases belonging to group A, 13 cases to group B and 13 cases to group C (Fig. 41.8). Bladder function after these procedures was evaluated using urodynamic studies. Finally, we identified a correlation between the preserved pelvic nerve networks and bladder function after laparoscopic nerve-sparing radical hysterectomy.

Several studies have conducted urodynamic analyses after radical hysterectomy, but no consensus on these procedures has been reached, perhaps because around 80 % of patients with cervical carcinoma already had some degree of bladder dysfunction before the procedure was performed. It is therefore extremely difficult to evaluate the effects of nerve sparing techniques accurately [14]. In this study, we defined our original index (Function Ratio) to control for the scattering of data from urodynamic studies before surgical procedures. Urodynamic studies have many parameters, and among these parameters, the detrusor contraction pressure at maximum flow (PdetQmax) has been chosen to evaluate the motor function of the bladder, and the first desire to void (FDV) to evaluate sensory function, these are defined as:

Function Ratio (FDV) = FDV pre-operative / FDV post-operative.

Function Ratio (PdetQmax) = PdetQmax post-operative / PdetQmax pre-operative.

In fact, the PdetQmax is expected to be proportional to bladder function, and the FDV is expected to be inversely proportional to bladder function. Therefore, the function ratio formulas (FDV, PdetQmax) differ.

Ralph et al. reported that bladder function after radical hysterectomy could improve within 12 months after surgery [15]. Therefore, we analyzed data at 12 months after the operation to ascertain the correlation between the preserved pelvic nerve networks and bladder function after laparoscopic nerve-sparing radical hysterectomy (Fig. 41.9).

Based on the results of this study, it is possible to suggest that the distributions of sensory nerves and motor nerves differ. The sensory nerve is distributed predominantly at the lower (dorsal) half of the pelvic nerve networks. Thus, the sensory functions of group A and B are statistically equivalent, and the sensory function of group C is significantly lower than that of group A or B.

In contrast, the motor nerve is distributed predominantly at the upper (ventral) half of the pelvic nerve networks. Hence, the motor function of group A was significantly more preserved compared to that of either group B or C. The motor functions of groups B and C were damaged to same extent, and thus showed no mutually significant difference. Through this study, we conclude that various types of total laparoscopic nerve-sparing radical hysterectomy are technically feasible, and the sensory and motor functions of the bladder following the operation can be tailored depending on the patient's risk of cervical cancer.

Modified Nerve-Sparing Radical-Like Hysterectomy for Deep Infiltrating Endometriosis

42

Stefano Uccella, Jvan Casarin, and Fabio Ghezzi

Introduction

Endometriosis is a common disease characterized by the presence of ectopic endometrial glands and stroma outside the uterine cavity. This heterotopic tissue has the same cyclic estrogen-dependent changes of the eutopic endometrium, according to the various phases of the menstrual cycle.

Endometriosis typically affects young women in their fertile age, being extremely uncommon before menarche and after menopause. The real incidence of this condition is a matter of debate and it is probably underestimated, due to the possible presence of asymptomatic, clinically silent lesions. A large population-based study has shown that this disease affects approximately 11 % of premenopausal women [1]. The average age at diagnosis ranges from 25 to 30 years [2], and it has been estimated that the incidence raises up to 50 % among infertile females [3].

The main symptoms and signs of endometriosis include chronic pelvic pain, dysmenorrhea, dyspareunia, and infertility. The disease can be potentially ubiquitous, but its preferential location is obviously the pelvis. Three different forms of disease have been historically described, according to the site and invasiveness of the implants: peritoneal disease, ovarian endometriomas and deep infiltrating endometriosis (DIE) [4].

In its deeply invasive form, endometriosis grows mainly in the retroperitoneum, and has the potential to infiltrate organs and structures, including the recto-vaginal septum, the lateral parametria (also known as cardinal ligaments or lateral paracervix), the utero-sacral ligaments, the rectosigmoid, the ureters and the bladder. The clinical presentation of DIE is usually characterized by severe chronic pelvic pain, neurologic pain, dyschezia, dysuria, and deep dyspareunia. These symptoms have obvious debilitating consequences on the health and quality of life of reproductive age women.

Complete surgical excision of infiltrative endometriotic lesions by laparoscopy is possible and offers good long-term symptomatic relief, especially in case of failure of pharmacological treatment [5–10].

However, it must be kept in mind that the common locations of DIE are in contiguity with several autonomic nervous structures that exert their control on the function of many pelvic organs. In particular, the pelvic sympathetic and parasympathetic neural pathways (which run through the pelvic ligaments) regulate rectal, bladder, and sexual physiologic activities. Eradication of DIE may therefore disrupt neural fibers, and consequently impair (sometimes definitively) the autonomic control of important vegetative functions.

Rationale for Nerve Sparing

The anatomic proximity of DIE and pelvic autonomic nerves is witnessed by preliminary data from a recent study [11], which show that patients affected by endometriosis involving the recto-vaginal septum and the utero-sacral ligaments have a very high (>90 %) probability of a pre-operative urodynamic diagnosis of detrusor overactivity, even in the absence of bladder symptoms. These results corroborate the observation that pelvic sympathetic and parasympathetic nerves may be encapsulated or at least involved by endometriotic lesions [12]. As a consequence, preservation of neural structures and vegetative functions appears difficult, and may not always be possible at the time of radical surgery for DIE.

However (when neural fibers are not already disrupted pre-operatively), a deep and thorough anatomical knowledge about the routes of the neurogenic control of the pelvis is crucial to try to preserve as much as possible the inervation of the bladder, the rectum and the vagina.

The nerve-sparing approach to hysterectomy for deep infiltrating endometriosis implies the identification and meticulous isolation of the nerves and neural fibers that run

in the pelvic ligaments, in order to separate them from the DIE lesions that must be removed [13].

Unfortunately, while the majority of the knowledge on nerve supply to the pelvis relies on anatomical studies on cadavers, the identification of nervous fibers is much more difficult in the operating room.

Autonomic Innervation of the Pelvis [14]

Orthosympathetic Nerves

The efferent orthosympathetic nervous fibers that reach the pelvis take their origin from the inferior thoracic and the superior lumbar (L1-L2) segments of the spine. These descendent branches are accompanied by afferent, ascendant fibers from the same innervated regions and organs.

The first structure contributing to the orthosympathetic innervation of the pelvis, is the inferior mesenteric plexus (IMP). This is a plexyphorm net of sympathetic fibers, covering the aorta from the origin of the inferior mesenteric artery until the promontorium of the sacral bone. At its inferior boundary, the IMP joins with the superior hypogastric plexus (SHP), which is a triangular-shaped net of sympathetic fibers lying in the presacral, retro-rectal space, just in front of the promontorium.

The inferior part of the SHP gives origin to the right and left hypogastric nerves (HN), which first descend laterally to the mesorectum, then they lie in the lateral part of the uterosacral ligament, following the ureteral course in a dorsal and caudal position. The tissue below the ureter is named "mesoureter" and should be preserved during dissection, since it contains not only the hypogastric nerves, but also the majority of the parasympathetic neural supply to the pelvis (Fig. 42.1).

Parasympathetic Nerves

The parasympathetic innervation of the pelvic viscera, the bladder and urethra, the rectosigmoid and anal canal and the vagina is supplied by the pelvic splancnic nerves (PSN). These tiny neural branches take origin from the anterior rami of the sacral roots between S2 and S4. Lateral to the mesorectum and approximately 3–4 cm laterally and 2–4 cm caudally from the pouch of Douglas, a variable number of parasympathetic PSNs (3–5) pierce the parietal endopelvic fascial sheet covering the ventral aspect of the piriformis muscle. After running in the posterior-lateral aspect of the uterosacral ligaments, below the level of the orthosympathetic routes, the PSNs join the HNs, forming the mixed (orthosympathetic and parasympathetic) inferior hypogastric plexus, also known as pelvic plexus (Fig. 42.2).

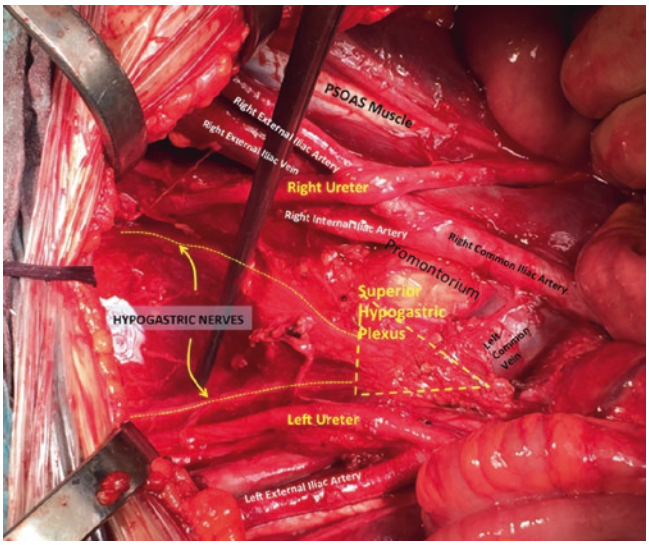

Fig. 42.1 The inferior mesenteric, the superior hypogastric plexus (with its triangular shape) and the two hypogastric nerves running to the pelvis bilaterally

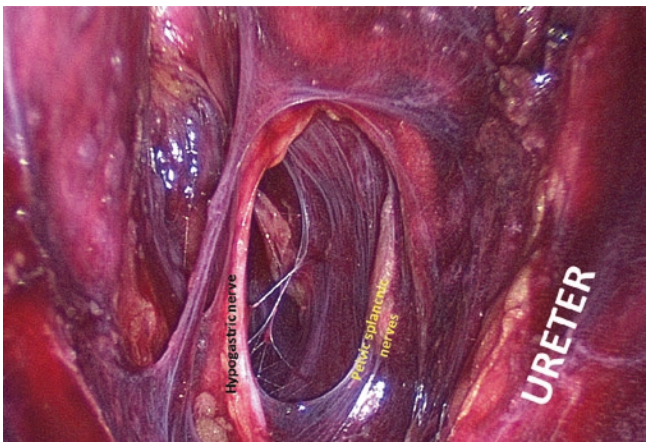

Fig. 42.2 The right inferior hypogastric plexus (also called "pelvic plexus") with its mixed (orthosympathetic and parasympathetic) fibers. The right ureter is lateralized, to expose the hypogastric nerve and the pelvic splancnic nerves, forming the plexus

Pelvic Plexus, Rectal, Bladder and Vaginal Neural Branches

The pelvic plexus is a pyramid-shaped plexus which is bilaterally located between the posterolateral vaginal fornix and the rectum, ventrally and caudally to the lateral rectal ligaments. This neural network receives ortho- and parasympathetic fibers both descending from the spine and ascending from the pelvic organs. From this anatomical structure, several fine neural branches reach the pelvic organs, mainly following the ligaments and supporting structures of the organs innervated. In particular, neural fibers reach the uterus and

the vagina through the parametria and paracolpia; anteriorly, ascending fibers deliver their neural supply to the bladder, running in the vesico-uterine ligaments (bladder branches); posteriorly, the innervation of the recto-sigmoid is delivered by fibers contained in the lateral rectal ligaments (also known as rectal wings).

The deep uterine vein is considered as the limit dividing the vascular part of the parametria (above its level), from their neural portion (below the deep uterine vein), where the pelvic plexus is located. To perform a nerve-sparing procedure that preserves the pelvic plexus, the deep uterine vein is to be identified, and resection should not exceed inferiorly this crucial anatomical landmark.

Pelvic Surgical Spaces for Radical Hysterectomy (Fig. 42.3)

In the pelvis, different anatomical spaces have been described. The knowledge of these regions is of paramount importance to obtain a safe and radical dissection of several oncological and non-oncological diseases in gynecology. In particular, we can recognize two median spaces (the Retzius space in front of the bladder and the presacral retrorectal space behind the rectum), and eight lateral spaces (the median and lateral paravesical and pararectal spaces) bilaterally, for a total of ten different and relatively avascular areas. To perform a radical hysterectomy, the paravesical and pararectal fossae have to be dissected. These virtual spaces must be carefully opened and developed by the surgeon, to make the anatomic landmarks clearer and also to allow a nerve-sparing procedure.

Paravesical Space

The boundaries of the paravesical space are the bladder and the upper part of the vagina, medially, and the obturator internus muscle, the obturator nerve, artery and vein (just beneath the bony arcuate ridge of the ileum), laterally.

This space is created by dissecting, both in dorsal and caudal direction, the loose connective tissue under the peritoneum, laterally to the bladder, until the levator ani muscle is reached. At this level, the external iliac vessels and the obturator nodes made up the lateral wall, while the bladder constitutes the medial landmark.

A useful tip to perform a safe and efficient dissection, is to identify the umbilical obliterated artery, and to develop the tissue laterally to it in a caudal direction. During the development of this space, surgeons have always to look for accessory obturator arteries and veins, which are often present in this area, in order not to damage them during dissection, in particular they have to pay attention to a anastomotic vein between the external iliac vein and the obturator vein, which in surgical jargon is called *corona mortis*.

The longitudinal course of the ureter is the reference for dividing the paravesical space in two different areas, the medial (also known as Yabuki's space) and the lateral paravesical fossa (Fig. 42.4).

Pararectal Space

The pararectal space is a potential space, lateral to the rectum. Dissection of this area usually starts with the development of the retroperitoneum medial to the internal iliac vessels. It is a triangular-shaped space, with an anterior base, represented by

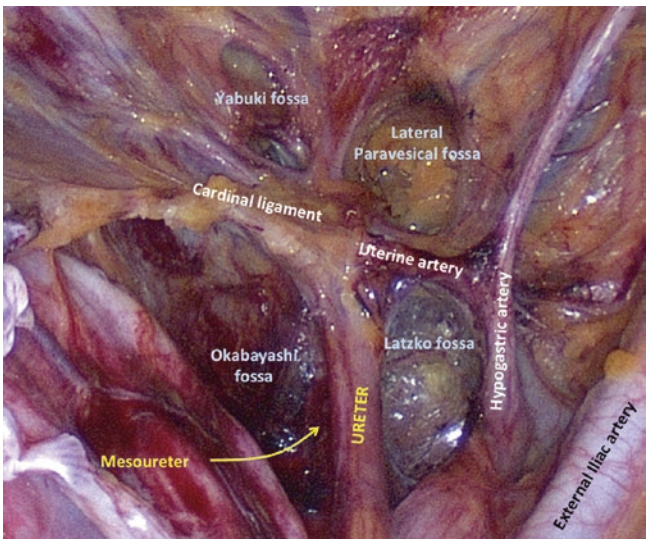

Fig. 42.3 The right paravesical and pararectal spaces, with the course of the ureter and mesoureter, the cardinal ligament and parametrium

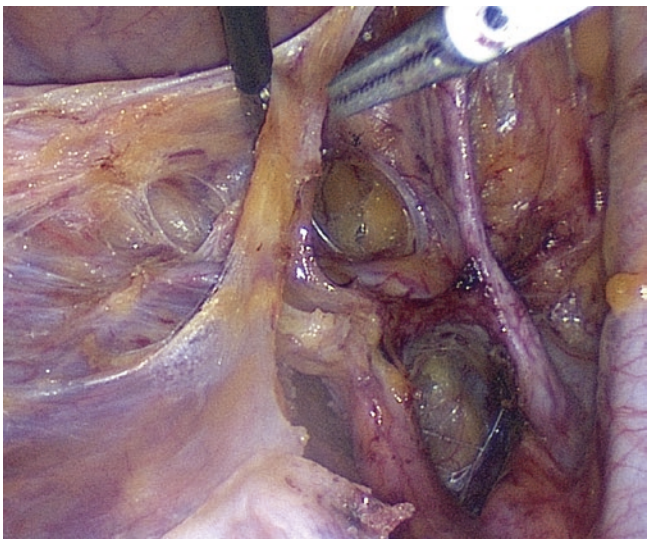

Fig. 42.4 The right lateral and medial paravesical spaces

the cardinal ligament; the medial border is represented by the vagina anteriorly, the peritoneum of the posterior sheet of the broad ligament superiorly, the utero-sacral ligament inferiorly and the rectum posteriorly; the lateral boundary corresponds to the internal iliac artery and vein with their collaterals. The ureter and the mesoureter divide the lateral aspect of the pararectal space (the so-called Latzko's fossa) from its medial aspect (Okabayashi's fossa) (Fig. 42.5).

The identification and development of the paravesical and pararectal spaces with their medial and lateral aspects is the first step to correctly identify the main anatomical structures in the pelvis and to perform a nerve-sparing radical hysterectomy, for both malignancies and endometriosis. Once the ureter with the mesoureter, the internal and external iliac vessels, the cardinal ligament with the uterine artery and veins and the utero-sacral ligament have been identified, the neural fibers of the hypogastric nerves, of the pelvic splancnic nerves and of the pelvic plexus can be localized and possibly spared, if not involved by the disease (Fig. 42.3).

Pre-operative Assessment

Preoperatively, all women should undergo a thorough gynecological examination, including complete medical and surgical history, bimanual visit, pelvic transvaginal and transabdominal ultrasound, to rule out the presence and exact location of the endometriotic lesions, and their relationships with the pelvic organs. In order to evaluate the extent of possible bowel, bladder and ureteral involvement and to better plan the correct surgical approach, pelvic and abdominal MRI with contrast medium may be useful. The administration of colon water distension during MRI is a possible adjunction that allows better visualization of the presence and depth of bowel wall infiltration. Ultrasound scan of the urinary tract may be useful, in order to recognize and quantify the possible presence of hydronephrosis, ureteral dilatation or bladder nodules. Anterograde pyleography is not performed on a routine basis at our department.

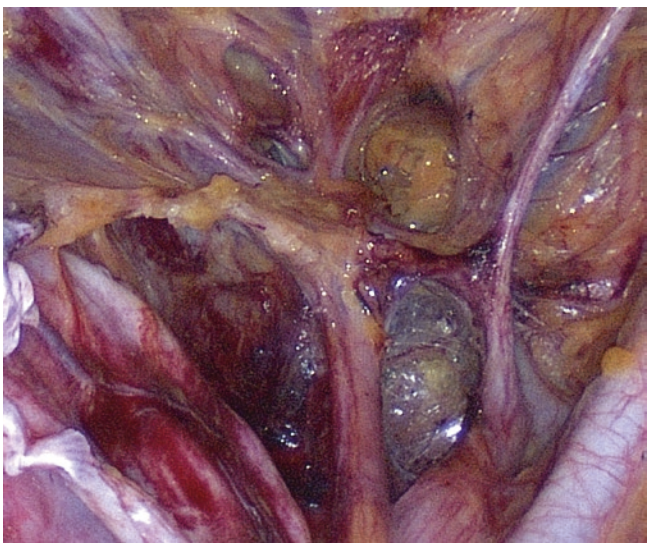

Fig. 42.5 The right lateral and medial pararectal spaces

Women receive one dose of prophylactic antibiotic 1 h before the intervention; antithrombotic prophylaxis is administered with low–molecular-weight heparin (7 days) and compression stockings (until full mobilization). Bowel preparation is not administered on a routine basis, unless bowel resection is planned.

Due to the intrinsic risks of this type of procedures, consisting in difficult recognition and isolation of the anatomical structures, and in the presence of dense adhesions and firm fibrotic nodules that complicate dissection of the surgical planes, pre-operative work-out should include the recognition of the most difficult cases of severe deep infiltrating endometriosis, in order to organize a surgical team of operators with extensive experience in both laparoscopic and open gynecological and intestinal procedures.

Instruments

The list of instruments for laparoscopic modified nerve-sparing radical-like hysterectomy in case of deep endometriosis should include:

- a uterine manipulator (we preferentially use a Rumi uterine manipulator used in conjunction with a Koh cup colpotomizer, [Koh Colpotomizer System; Cooper Surgical, Trimbull, CT]) to allow a safe dissection of the vesico-uterine fold, the delineation of the vaginal fornices and the lateralization of the ureters, obtained by cranial pressure on the instrument.
- Four 5-mm trocars, inserted one through the umbilicus and three suprapubically.
- A 0-degrees laparoscope.
- Scissors.
- Traumatic (Manes forceps) and atraumatic (Matkovic) graspers.
- Bipolar forceps.
- Monopolar hook or spatula.
- A suction-irrigation-system.

The entire procedure may be accomplished with reusable instruments. Only in very particular cases, a disposable combined coagulating/cutting device may be useful.

Surgical Technique

The patient must lie supine in lithotomic position. General endotracheal anesthesia is performed, and during the procedure, Trendelenburg position is maintained, to allow cranial

displacement of the bowel loops and optimal exposure of the pelvic organs. The uterine manipulator is positioned vaginally. A Veress needle is inserted in the abdominal cavity and CO_2 is insufflated. After creation of the pneumoperitoneum (10–15 mmHg pressure), a 5-mm trocar is inserted transumbilically for the laparoscope. Under direct visualization, three 5-mm ancillary trocars are positioned suprapubically: one at the level of the midline and two laterally to the epigastric arteries in the left and right lower abdominal quadrants, respectively. The entire abdominal cavity is then inspected.

The third operator, sitting between the legs of the patient, helps the first operator by mobilizing the uterus with the uterine manipulator.

In cases of severe deep infiltrating endometriosis, the pelvis is almost invariably "frozen" by dense adhesions. As a consequence, the procedure starts with meticulous adhesiolysis and adnexal surgery (cystectomy, stripping of endometriomas), if needed. One of the most important rules while performing surgery for DIE is to try to work in healthy tissue, surrounding the disease.

Development of the anatomical spaces is started coagulating and sectioning the round ligament, while the assistant grasps it and pulls it medially to obtain adequate countertraction and exposure. The anterior leaf of the broad ligament is coagulated with bipolar forceps and sectioned, starting from the round ligament up to the vesicouterine fold.

The retroperitoneum is then entered as follows: an incision is made on the peritoneum lateral and parallel to the infundibulopelvic ligamnents and the ureter is identified lateral to the ovarian vessels, when it crosses the iliac bifurcation and enters the pelvis at the level of the pelvic brim.

The lateral pararectal space is dissected medial to the internal iliac artery, and the uterine vessels are identified at their origin from the hypogastric artery and vein. The Okabayashi fossa is then developed by opening the virtual space between the ureter (laterally) and the peritoneum (medially), the cardinal ligament and uterine artery (anteriorly) and the rectum (posteriorly). While moving caudally in the dissection, the medial, fibrous part of the utero-sacral ligament should be separated by its lateral aspect, which contains the neural fibers of the hypogastric nerves and pelvic splancnic nerves. Once the Okabayashi and Latzko fossae have been prepared, the ureter is isolated and the mesoureter is identified and preserved, in order to spare the nervous fibers (hypogastric nerve, pelvic splancnic nerves and pelvic plexus) running in it (Fig. 42.6). If ureteral endometriosis is present, ureterolysis should be accomplished, with the intent of shaving and preserving the ureter whenever possible [5, 7]. Particular attention should be paid during isolation of the ureter to avoid damage to its peri-adventitial vessels, that provide blood supply to this organ, in order to prevent ischemic necrosis and consequent fistulas.

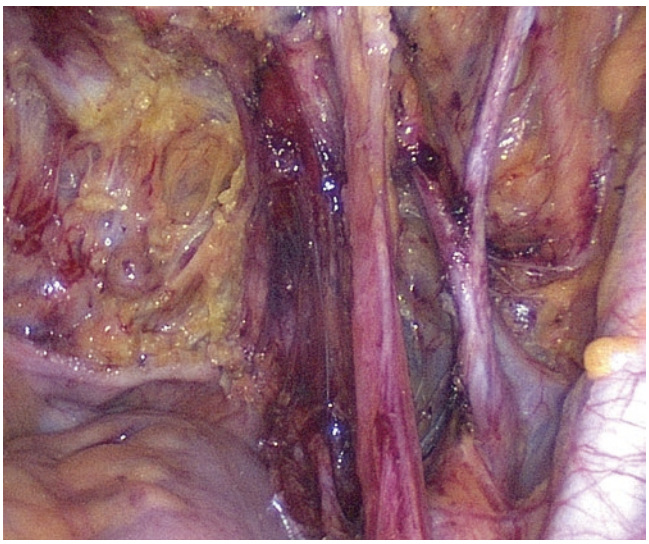

Fig. 42.6 The right ureter and the mesoureter isolated during a modified radical-like hysterectomy for deep endometriosis (the nervous fibers of the hypogastric nerves, pelvic splancnic nerves and pelvic plexus have been identified and spared)

The vesico-vaginal space is dissected and the space of Yabuki is developed only in case of vesical nodules or when the upper part of the anterior vaginal wall has to be removed.

In case of adnexectomy, coagulation and section of the infundibulopelvic ligament is accomplished. If the ovaries have to be preserved, coagulation and section is performed at the level of the tube and utero-ovarian ligament. The posterior leaf of the broad ligament is then opened, down to the level of the uterosacral ligaments.

When the cardinal ligament is involved, partial or total sacrifice of the uterine artery and/or some branches of the internal iliac artery may be necessary before its resection. Resection of the involved cardinal ligament is performed at this time, tailoring the radicality on the basis of the extension of the disease and the anatomical conditions of the patient.

If possible, isolation and preservation of the uterine vessels at the intersection with the ureter is performed. The dissection must never be extended below the level of the deep uterine vein (the border between the vascular portion and the neural portion of the parametrium), in order to spare the hypogastric nerves and the pelvic plexus, unless massive infiltration by the endometriotic process is present below this level.

When a rectovaginal nodule is present, the virtual space between the rectum and the vagina must be opened, starting from the medial pararectal spaces. The decision as to whether bowel resection is necessary, has to be taken on the basis of the percentage of infiltration of the recto-sigmoid wall by the endometriotic lesion. In case of bowel preservation, rectal shaving is accomplished and the nodule is mobilized from the anterior surface of the rectum, leaving it attached to the posterior vaginal wall.

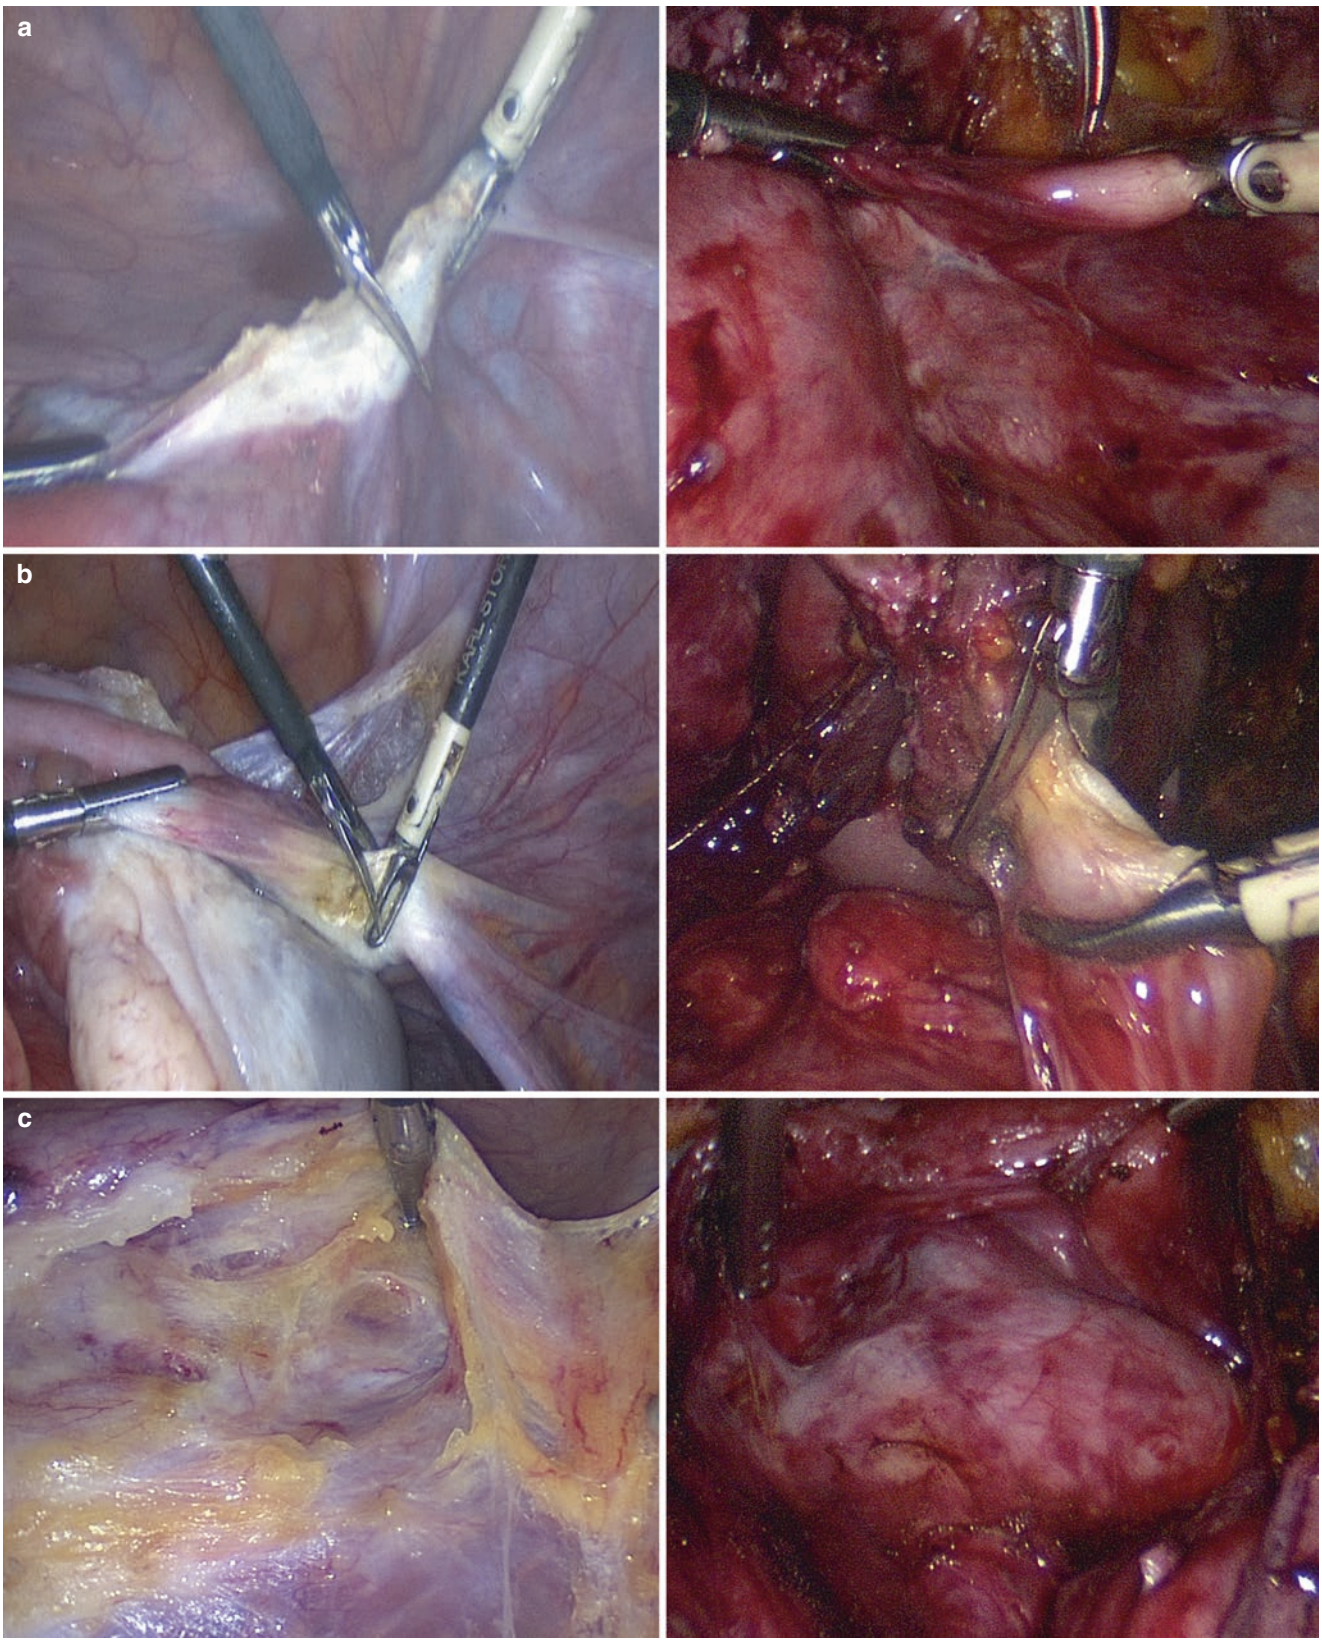

Fig. 42.7 (**a**) Coagulation and section of the round ligament; (**b**) Coagulation and section of the infundibulo-pelvic ligament; (**c**) Development of the vesical flap. Comparison between women without (*left*) and with (*right*) endometriosis. The recognition and dissection of the anatomical structures is more difficult in case of DIE

All the steps described are performed in the same way on both sides.

Once the uterus has been completely detached from its supporting structures, and complete dissection and isolation of the endometriotic process has been accomplished, colpotomy is performed using a monopolar spatula or hook. A colpo-pneumo-occluder inserted through the vagina before the procedure, is useful to prevent loss of pneumoperitoneum during this step of the procedure. Supplementary hemostasis of the vaginal vault with a bipolar forceps could be needed in cases of bleeding during colpotomy.

The extraction is usually performed *en-bloc* through the vagina; in some cases, transvaginal morcellation with cold knife could be necessary.

Once the specimen is extracted, the vaginal vault can be closed by continuous suture either transvaginally or endoscopically [15].

Before trocar extraction, an additional control of the hemostasis should be performed.

Figure 42.7 describes some of the steps of radical hysterectomy, highlighting the differences and the difficulties in the correct recognition of the anatomical structures in patients with vs. without endometriosis.

Post-operative Course

Although the common perception of the operators involved in this type of surgery is that hysterectomy for deep infiltrating endometriosis is associated with a higher likelihood of complications, compared to simple hysterectomy for benign gynecological conditions, the literature is devoid of clear information regarding this specific issue.

Normal post-operative management should include monitoring of the most common post-operative complications. A brief list of specific adverse events possibly related to modified-radical hysterectomy for deep endometriosis include: bladder and ureteral lesions/fistula (usually occurring 7–21 days after surgery), bowel perforation, and urinary, sexual or anal dysfunction, due to failure of nerve-sparing and denervation of the organs involved.

Summary of Key Steps for Modified Nerve-Sparing Approach to Radical Hysterectomy for Deep Infiltrating Endometriosis

- Opening of the retroperitoneum and development of the pararectal and paravesical spaces.
- Isolation of the ureter with preservation of the meso-ureter (in order to spare the hypogastric nerves, the pelvic splancnic nerves and the pelvic plexus).
- Separation of the lateral aspect of the utero-sacral ligament (containing the nervous fibers running to and from the pelvis), from its medial fibrous part, which may be transected, according to the extension of the endometriotic lesion.
- Avoid transection of the cardinal ligament below the level of the deep uterine vein (if possible), in order to preserve the mixed orthosympathetic and parasympathetic pelvic plexus.
- Try to work in healthy tissue surrounding the disease.

Laparoscopic Total Mesometrial Resection (L-TMMR)

43

Vito Chiantera, Alessandro Lucidi, and Giuseppe Vizzielli

Oncological Philosophy

Abdominal radical hysterectomy and pelvic lymph node dissection as introduced by Wertheim and Meigs [1–2] first in the beginning of the century is still regarded as "gold standard" in the surgical treatment of the uterine cervix carcinoma, FIGO stages IA2-IB and IIA. The resection of the parametrial and paracervical tissues proposed by the.

conventional radical hysterectomy is based on a "centrifugal diffusion" from the center of the tumor on the direction of the parametrial (dorsal, lateral and ventral) highways.

This imply a classic functional and ligament-focused view of the surgical anatomy.

Local spread of an invasive tumor is currently regarded as an isotropic process of tissue infiltration, irrespective of anatomic boundaries. Malignant solid tumors are thought to permeate locally by invasion of the interstitium or intravasion of lymphatic and venous channels and perineural spread. The conventional oncological surgical practice derived from these concept is a "wide tumor excision" as removal of the malignant tumor with a metrically defined radial margin of macroscopically and microscopically tumor-free tissue. However, despite histopathology confirmed resection within clear margins (R0), local recurrence rate (LRR) in cervical cancer patients still occurs in 10–25 % of the patients [3].

As consequence the clinical results obtained are favorable for small tumor, vascular space negative and free pelvic nodes remaining the necessity of adding adjuvant chemoradiation therapy in patients with histopathology high-risk features.

Those high and intermediate risk patients requiring adjuvant treatment may exceed 50 % in current series with moderate and severe treatment-related morbidity reported for a big percentage of them [4].

Hockel theory is based on the concept that local tumor spreads not completely random but follows for a long period of the malignant progression into a permissive compartment morphologically deduced from the embryologic development of the affected organ. Although tumor propagation increase within that compartment during the malignant progression the neoplasm respects the compartment borders for a long period of progression. Only very late adjacent compartments deriving from different embryological origins are invaded and even in these late stages a hierarchy of embryological kinship is maintained.

The logic consequence of this developmental view is a *"Compartment Resection"* as a new principle of radical surgery for local tumor control aiming to a high local tumor control rate without additional post operative radiation.

Höckel et al. first investigated embryonic development of the female reproductive tract with respect to embryological different compartments [5–8] and were able to define three different primordial tissue complexes from cranial to caudal:

- The paramesonephric–mesonephric–Müllerian tubercle complex
- The deep urogenital sinus (UGS) vaginal plate complex
- The superficial UGS-genital folds and tubercle

The pelvic viscera-parietal compartments deduced from the embryonic development define the following pelvic parietal lymph-node basins:

- External iliac
- Paravisceral (i.e.: anterior internal iliac, supraobturator and infraobturator, presciatic)
- Common iliac (including the superior gluteal)
- Presacral (i.e.: posterior internal iliac, aortic, and caval bifurcation)

The high rate of local tumor control following Total Mesometrial Resection (TMMR) without any subsequent

adjuvant radiotherapy in patients with early cervical cancer is impressive [9, 10]. Part of this outcome is achieved with a ultra radical pelvic lymphadenectomy (tLNE), called *"therapeutic lymphadenectomy"*, this differs from the classic staging pelvic LNE where the nodes are removed with the idea to obtain a precise hysto-patological information in order to individualize the adjuvant treatment.

In this version of the pelvic lymphadenectomy the aim of the procedure is to remove every macro or micro metastasis in order to "sterilize" the lateral pelvic surgical field and avoid any necessity of adjuvant treatment. To obtain this a ultra-radical dissection is performed with removing of the external iliac, the superficial obturator and the deep obturator nodes as well as the deep gluteal, pre ischiatic (at the level of the ischial spine), pre sacral (ventrally to the lateral sacral fascia), and internal iliac nodes [10].

Following this theory, the proposed uterovaginal (Müllerian) compartment, identified by bottom-up sectional anatomy as the final differentiation product of the Müllerian structures, as described in previous published data by Höckel et al. [8] are:

(a) The cranial part of the compartment located intraperitoneal that consists of the Fallopian tubes, the mesosalpinx, the uterine corpus with the broad ligament where the latter corresponds to the peritoneal mesometrium
(b) The sub-peritoneal part of the Müllerian compartment (i.e.: the subperitoneal mesometrium) tapers off with bilateral wings made up of dorso-laterally directed supply tissue with the uterine vaginal arteries and veins, lymphatic drainage, and a few lymph nodes (referred to as vascular mesometrium), and dorsally directed suspensory and fatty tissue fused to the anterior and lateral mesorectum continuous with the endopelvic fascia overlying the coccygeus muscles (referred to as ligamentous mesometrium).

Due to the systematic and complete resection of those compartments Hockel achieved impressive results: with a median follow-up of 41 months only three pelvic, two pelvic/distant and five distant recurrences were recorded. A recurrence-free survival of 94 % (95 % CI 91–98) and overall survival of 96 % (93–99) was noticed.

Even more, with the absence of any adjuvant radiation therapy applied to those patients a very low treatment-related morbidity as much as 9 % was reported.

Although it has been questioned whether the confirmation of these findings could change the classification of radical hysterectomy and the indication for adjuvant radiotherapy in early stage cervical cancer [11], various authors have recently described the TMMR as an attractive therapeutic option for the management of this subset of patients [12–15].

The TMMR as a open surgical technique is perfectly standardized and systematic described, Kimmig et al. showed that the principle of compartment based surgery combined with therapeutic lymphadenectomy (tLNE) as described by M. Höckel can systematically be translated to minimally invasive robotic procedures (rTMMR and rtLNE). The method appeared to be feasible and safe. Although the mean follow-up time (18 months) was limited, the number of patients was small and there was some "lack of homogeneity" in the patients' sample composition (six patients at FIGO stage IA and three patients who had prior radiotherapy), it should be noticed that there were no loco-regional tumor recurrence during the observation period.

We have recently reported in a large prospective multicentric experience that compartment based surgery performed as Total Mesometrial Resection combined with therapeutic lymphadenectomy can systematically be translated to laparoscopic procedure (L-TMMR) [16]. Combining the information gained in this two minimal invasive study and despite the limited number of patients or the short follow-up, it should be noticed that altogether only two (2.8 %) early loco-regional tumor recurrences were observed, thus suggesting that LTMMR and R-TMMR techniques may be safe with respect to local tumor control and should be considered at least equivalent to open surgery in term of radicalness.

More in depth, regarding to specific endoscopic surgical procedures, it should be underlined that, exposure of the tumor into the surgical field must strictly be avoided in order to diminishing the risks for a vaginal cuff recurrence and intraperitoneal tumor dissemination.

Regarding the operating time of L-TMMR, it should be noted that it was longer than other series of radical hysterectomy previously published according to the Querleu–Morrow classification [17].

Moreover, especially two steps of the TMMR are particularly demanding if performed laparoscopically: the natural complex eradication of some lymph node stations by laparoscopy (i.e. in the lumbosacral fossa) and the difficulty to obtain the right traction simultaneously both on the uterus, the rectum and the mesometrium in order to complete the dorsal part of the operation. Thus the difference with open surgery in exposing the posterior compartment cannot be neglected. On the other hand, the shorter operating time compared with the historical series by Höckel [5–8] performed by open technique, supports the idea that laparoscopic procedures are time-sparing compared to open technique, especially if performed by a surgical team with a deep experience in the endoscopic approach. Moreover, the two severe postoperative complications reported in the urinary tract and the sole vascular compartment damage are in line with an initial experience on this endoscopic surgical procedure and suggest next future improvements with the increasing of the specific surgical experience. In addition, the low grade post-operative autonomic urinary complications (9.8 %) reported could be justified considering that the L-TMMR technique spares the

pelvic nerves that supply the bladder both in the sympathetic and parasympathetic system.

Finally, laparoscopical as well as robotic approach, allowing to finely prepare and completely remove compartment-associated tissue without injuring adjacent structures by respecting the filmy septa at the compartment borders, enables to develop and dissect structures with higher "optical" accuracy than open technique. In our previous experience, laparoscopic elective dissection of the bladder and rectal splanchnic pelvic nerves and consequently, development of a parasympathetic nerve-sparing technique were technically feasible [18]. We believe that this L-TMMR technique is not inferior in terms of *"nerve sparing"* than the previous described laparoscopic approach.

Moreover, compared with the conventional open technique in the L-TMMR patients a notable reduction in global postoperative functional morbidity was demonstrated.

As next step we have compared, with a double-institution case-control study, peri-operative outcomes of R-TMMR and L-TMMR in early stage cervical cancer patients [19]. The few differences registered in this study did not seem clinically relevant, thus making the two procedures comparable, in terms of operative time, estimated blood loss and conversion or complication's rate.

Surgical Procedure

The objective of this chapter is to describe step-by-step the L-TMMR, a modified surgical technique according to the compartment theory based on ontogenetic anatomy proposed by Hockel. The laparoscopic procedure is performed in the modified dorsolithotomy position under endotracheal general anesthesia. A Veress needle is inserted through the umbilicus and the abdomen is insufflated. After pneumoperitoneum and insertion of the laparoscope through an umbilical 10 mm trocar, three suprapubic 5 mm trocars are introduced for ancillary instruments.

Step 1 An initial vaginal step was performed with *"vaginal manchette"* creation in order to encapsulate tumor lesion and reduce tumor spread during uterine manipulation, according to previous published data [20]. To preserve pneumoperitoneum, a wet surgical towel is placed into the vagina caudally to the performed manchette (Fig. 43.1).

Tips

The dissection of vescico-vaginal and retto-vaginal septum should be performed without opening of the peritoneum.

Step 2 Exploration of pelvic and abdominal intraperitoneal structures. With the exception of the recto-sigmoid colon, all bowel organs are retracted ventrally and placed in the right upper abdomen. The abdominal retroperitoneum is opened by incising peritoneum at the psoas muscle parallel to the infundibulopelvic ligaments.

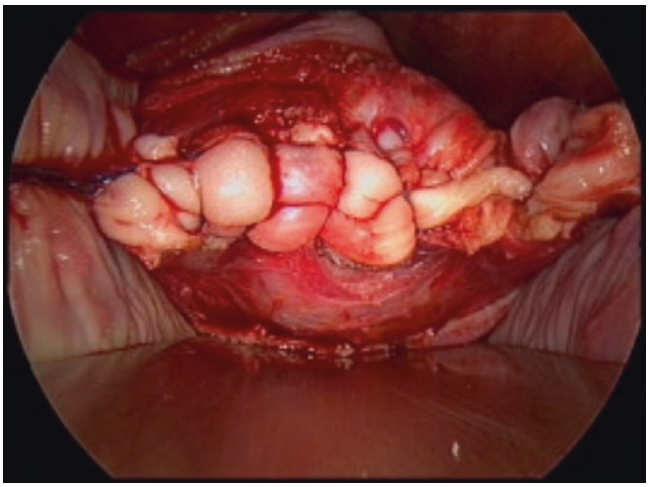

Fig. 43.1 Creation of tumor-adapted vaginal manchette

Step 3 Exposition of the urogenital mesentery developing anteriorly the paravisceral space with the umbilical artery and the lamina vesicalis dissected from the pelvic wall and tractioned medially

Step 4 Therapeutic systematic pelvic lymphadenectomy [tLNE] according to Höckel is performed and lymph-nodes are examined under frozen section [10]. The parietal nodes of the anterior pelvic compartments (external, internal iliac and obturator) are removed by completely stripping the external and internal iliac artery and vein. The deep pelvic lymph nodes are also removed exposing the proximal sciatic nerves and the lumbar rami of the sacral plexus and removing the paravisceral fat pads up to the sciatic spine (Figs. 43.2 and 43.3). Para-aortic lymph-node dissection is performed in any FIGO stage just in case of pre-operative radiological suspicious or with pelvic positive nodes at frozen section.

Step 5 The infundibulopelvic ligament is coagulated and cut in case of adenocarcinoma histology. In order to obtain more space in the pelvis the uterus–ovarian ligament is cut with separation of the adnexa from the uterus. The adnexa are placed in a bag outside the pelvis and are retained later. Otherwise if conservation of the adnexa were planned, the adnexa are separated form the uterus and dislocated in the upper abdomen at the level of the paracolic spaces on both side. In this case the whole *"peritoneal mesometrium"* (Falloppian tube, mesosalpinx and part of the broad ligament) is accurately dissected and removed separately.

Step 6 The peritoneum is incised again at the level of the right promontorium. The sigmoid colon is mobilized contra-

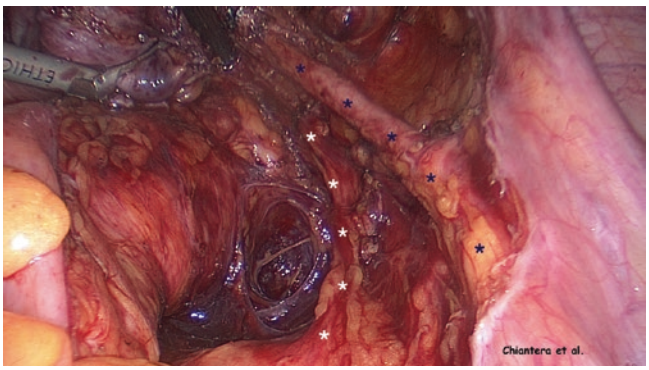

Fig. 43.5 Following the right hypogastric nerve the caudal and dorsal part of the parasacral space is developed up to the lateral border of the dorsal mesometrium.
Black stars: right ureter. *White stars*: right hypogastric nerve

lateral and the hypogastric plexus is identified just caudal the aortic bifurcation. The superior hypogastric plexus is identified at this level and the origin of the two hypogastric nerves is underlined (Fig. 43.4).

Tips

If difficult occurs in the identification of the superior hypogastric plexus the dissection can be further cranially developed up the the level of the aortic bifurcation where the dense tissue of the plexus is easier to identify.

Step 7 Development of the right pre-sacral fossa dorsally the Waldeyer's fascia and ventrally the parietal sacral fascia. Identification and isolation of the right hypogastric nerve adhering medially to the mesorectum (Fig. 43.5).

Step 8 The hypogastric nerve is lateralized in order to completely expose the ligamentous mesometrium. This maneuver is carried out down to the level where the pelvic splanchnic nerves join the right hypogastric nerves to form the right inferior hypogastric plexus.

The proximal inferior hypogastric plexus is mobilized from the lateral surface of the dense subperitoneal connective tissue which encases the rectum enabling the transection of the latter without nerve damage (Figs. 43.6, 43.7, 43.8 and 43.9).

Step 9 A complete uterus anti-version is obtained with the assistant instrument positioned behind the cervix. The Douglas peritoneum is now incised and the recto-vaginal septum is developed up to the level were the previous vaginal dissection was carried. Once the correct traction is obtained and the hypogastric nerves are lateralized, the ligamentum

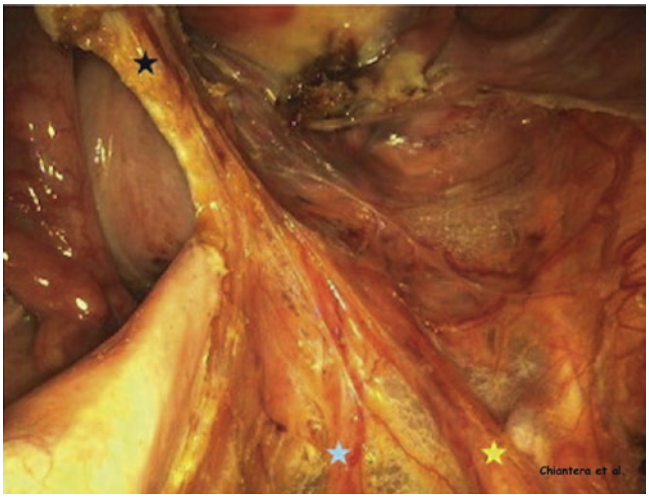

Fig. 43.6 The right hypogastric nerve is lateralized and divided from the posterior mesometrium. Thus the cranial aspect of the dorsal mesometrium is developed. *Black star*: mesometrium. *Yellow star*: right ureter. *Light blue star*: right hypogastric nerve

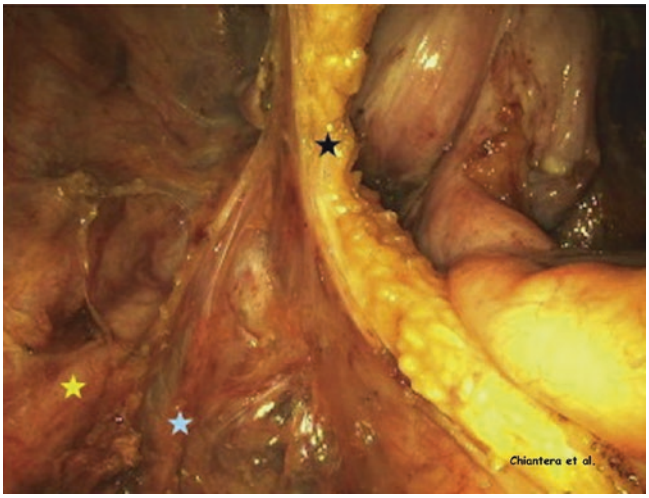

Fig. 43.8 Further lateralization of the left hypogastric nerve from the dorsal mesometrium. *Black star*: mesometrium. *Yellow star*: left ureter. *Light blue star*: left hypogastric nerve

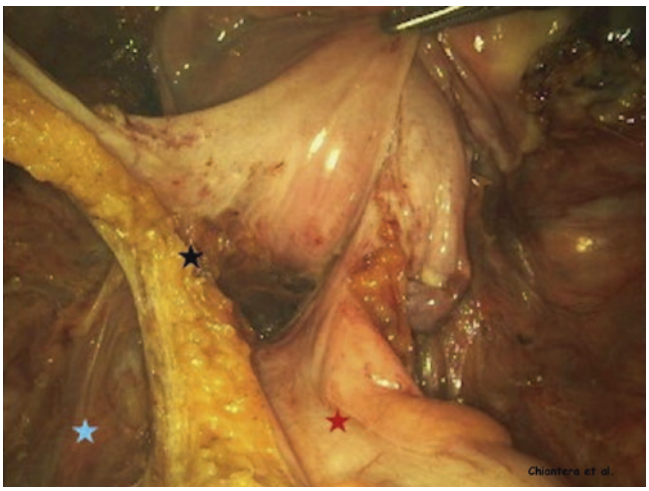

Fig. 43.7 On the left side the same preparation is carried out, the rectovaginal space is cranially dissected at this point. *Black star*: Mesometrium. *Red star*: Rectum. *Light blue star*: right hypogastric nerve

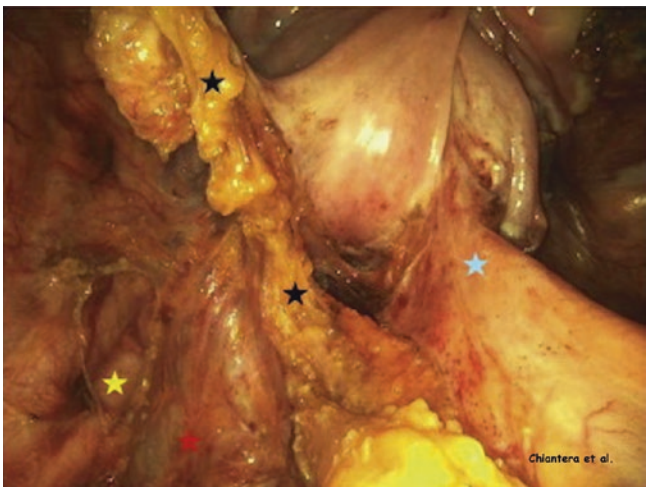

Fig. 43.9 The cranial and caudal part of the dorsal mesometrium is completely divided from the right hypogastric nerve. *Black stars*: cranial and caudal mesometrium. *Yellow star*: left ureter. *Red star*: left hypogastric nerve. *Light blue star*: Rectum

mesometrium. Is transected directly at the level of the anterior surface of the rectum (Fig. 43.10).

Tips

If necessary the rectum is pulled cranial-contralateral and suspended with a suture transfixed into the abdominal wall. Alternatively, the uterus can be suspended ventrally to the abdominal wall with two transfix suture and the assistant can pull the rectum at the level of the promontorium. One of this option is often required in order to obtain the necessary traction thus miming the exposure of the two posterior wings containing the posterior mesometrium as made by laparotomy.

Step 10 The dorsal part of the operation is now concluded (Fig. 43.11), proceeding ventrally the ureter is exposed and its route is completely exhibited until the cross with the uterine vessels (Fig. 43.12).

Step 11 Incision of peritoneum at the level of the vescicouterine septum with separation of bladder from the anterior cervix and the proximal vagina up to the level of the previous vaginal preparation.

Tips

The vescico uterine septum should be prepared just in his medial aspect in order not to detach the anterior mesometrium from the vescical fascia that has to be keep untouched

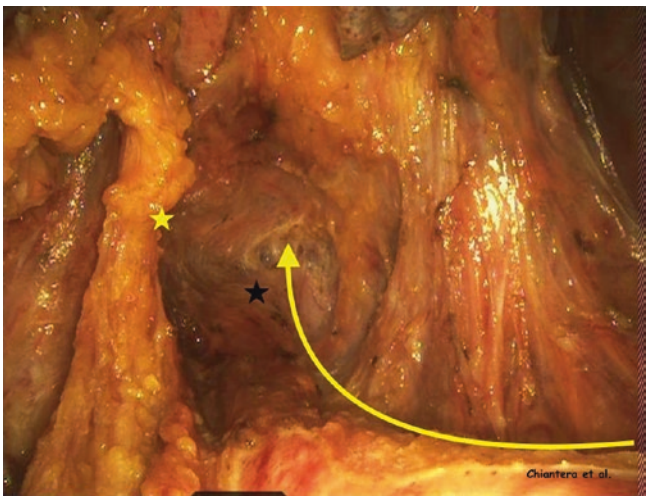

Fig. 43.10 Caudal preparation of the rectovaginal space up to the level of the dorsal vagina, this deep preparation allows a compete explosion of the caudal mesometrium. *Black star*: rectum. *Yellow star*: mesometrium. *Yellow arrow*: line resection of the mesometrium

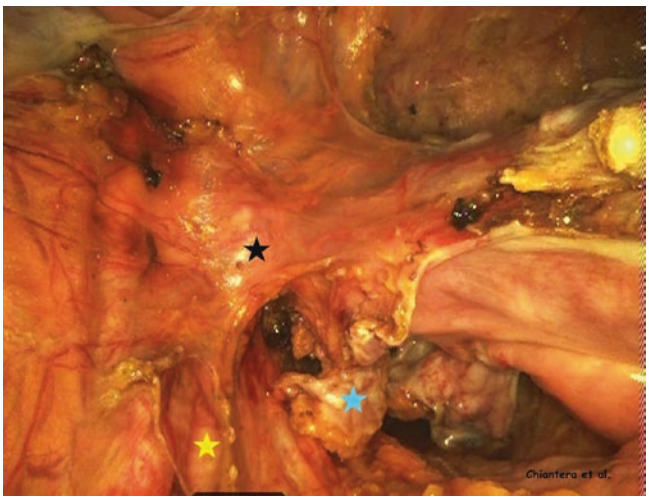

Fig. 43.12 Left vascular mesometrial preparation. *Yellow star*: ureter. *Black star*: vascular mesometrium. *Light blue star*: posterior mesometrium

Fig. 43.11 Right side at the end of the dorsal parametrectomy with cranial and caudal mesometrial preparation. Anatomical relations between the ureter, the right nerve and the dorsal mesometrium. *Blue circle*: divided Mesometrium. *Yellow star*: dorsal aspect of the Parasacral space. *Blue star*: sacral promontorium. *Yellow dotted line*: hypogastric nerve and plexus. *Blue dotted line*: right ureter

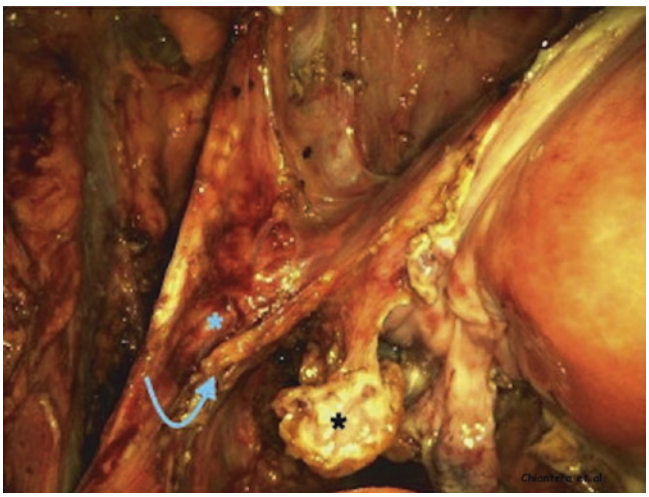

Fig. 43.13 Left vascular mesometrial preparation. *Light blue star*: left ureter. *Light blue arrow*: left vascular mesometrium. *Black star*: posterior mesometrium

until the sharp preparation of the space between the mesometrium and the lateral bladder is completed.

Step 12 The umbilical artery together with the superior bladder mesentery is separated from the anterior mesometrium with sharp dissection in order to isolate the lateral meometrium from the anterior one (Figs. 43.13 and 43.14).

Tips

Differently from the "classic" radical hysterectomy neither the lateral pararectal fossa after Latzko neither the medial one after Okabayashi are developed.

Step 13 The uterine arteries and veins are now coagulated and cut at their origins, this allow the vascular mesometrium to be flipped medially. The lateral mesometrium is mobilized from its origin at the site of the already transected uterine artery and vein(s) towards the uterus beyond the superior surface of the ureter (Figs. 43.15 and 43.16).

Fig. 43.14 Left vascular mesometrial preparation. *Light blue star*: left uterine artery. *Black arrow*: left ureter. *Yellow star*: ureteral tunnel

Fig. 43.16 Left vascular mesometrial preparation after the flipping. *Black arrow*: left ureter. *Yellow star*: rolled vascular mesometrium

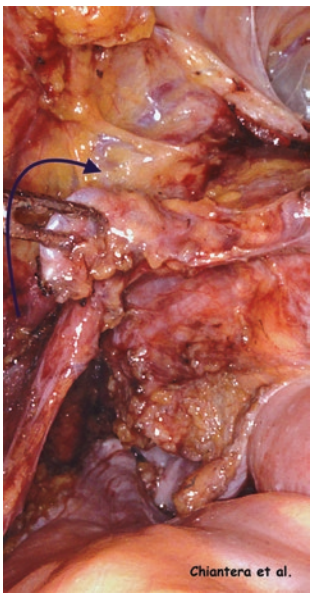

Fig. 43.15 Left vascular mesometrial preparation. Flipping of the vascular mesometrium above the ureter

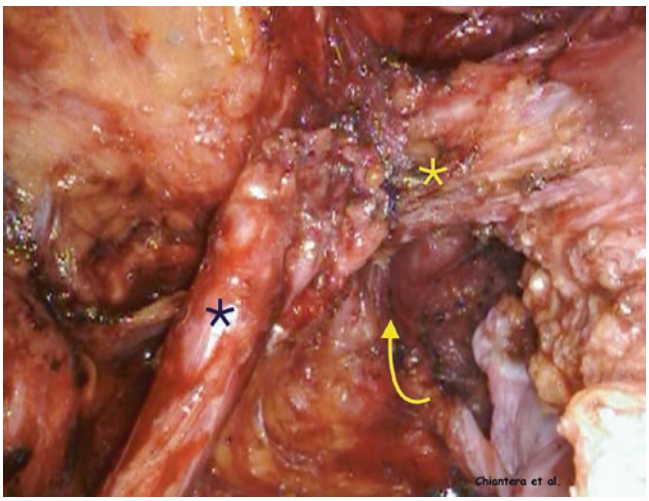

Fig. 43.17 Left vascular mesometrial preparation. Dividing the paravaginal tissue medially to the hypogastric nerve and plexus. *Blue Star: Ureter*, *Yellow Star*: paravaginal tissue, *Yellow arrow*: direction of the hypogastric nerve and plexus

Tips

The mesoureter has to be divided at the level of the lateral mesometrium in order to permit the medial rotation of the uterine artery and vein above and behind the ureter.

Step 14 The operation proceeds now in the anterior compartment. The vescico-vaginal venous plexus together with the dense subperitoneal connective tissue above the prevesical segment of the ureter is coagulated and divided. After cutting the remaining dorsal attachments the ureter can be completely mobilized laterally together with the dorsal part of the dense vescico caginal tissue containing the bladder branch of the pelvic parasympathetic nerve (Fig. 43.17).

Step 15 The paracolpium placed immediately lateral the initial "manchette" is transected connecting the anterior vescico-vaginal space with the posterior retto-vaginal one (Fig. 43.18).

Step 16 The TMMR-specimen is removed through the vagina and the vaginal stump is closed with laparoscopical sutures (Fig. 43.19).

According to Höckel approach no adjuvant radiotherapy should be indicated; although patients with lymph-node

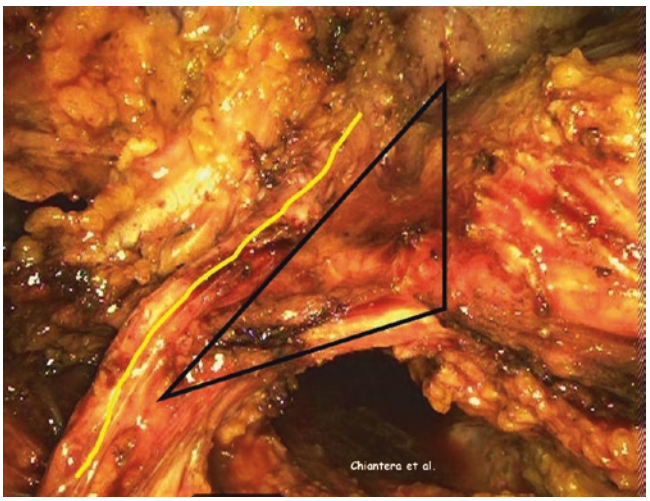

Fig. 43.18 Left vascular mesometrial preparation. Dividing the paravaginal tissue medially to the hypogastric nerve and plexus. *Yellow line*: left ureter. *Black triangle*: left paravaginal tissue

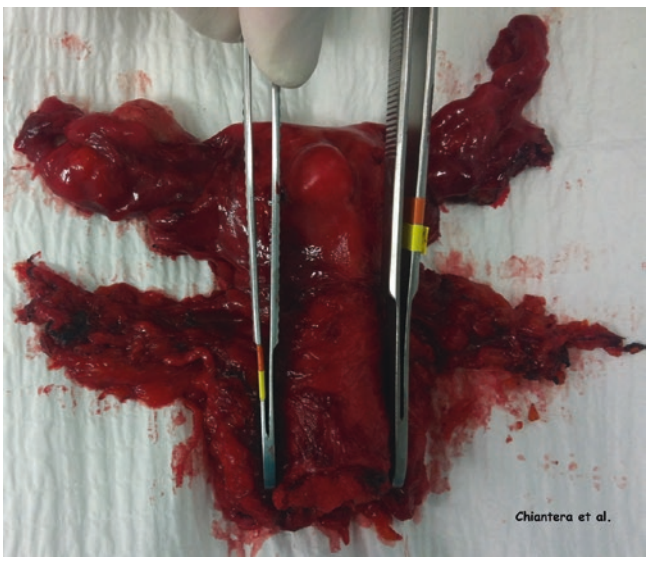

Fig. 43.19 The TMMR surgical specimen with the two of the four "wings"

metastases should be suggested to receive adjuvant chemotherapy with 75 mg/m^2 cisplatin for up to six 3-week cycles, because it had been demonstrated that adjuvant chemotherapy after conventional radical hysterectomy also reduced the incidence of distant metastases in patients with pN1 tumors [21].

Patients should be enrolled in a follow-up program of assessments at 3-month intervals for the first 2 years after surgery, and should be assessed at 6-month intervals thereafter.

It has to be acknowledged that the level of evidence supporting the oncological role of TMMR is still low. The introduction of the ontological surgery in the standard treatment of cervical cancer will probably need more support from the scientific community and further prospective randomized data. However, although the role of TMMR in cervical cancer remains to be definitively established, compelling data from retrospective and prospective series support its role in this clinical setting [11–15]. In conclusion, further larger prospective studies are needed in order to confirm these promising results and to compare this results to the outcome of the classical radical hysterectomy as well as to better define the laparoscopic surgical steps and the subsequent oncological outcome of patients undergoing TMMR compared to a classical open surgical approach.

Laparoscopic Radical Hysterectomy for Malignant Indications: Laparoscopic Trachelectomy

44

Vito Chiantera, Alessandro Lucidi, and Marco Petrillo

Cervical cancer is the third most common female cancer and the fourth leading cause of female cancer death worldwide [1]. Approximately 15 % of all cervical cancers are diagnosed in women under the age of 40 years who wish to preserve their fertility [2, 3]. For these reasons, although radical hysterectomy with lymph node dissection represents the standard treatment for early-stage cervical cancer, alternative surgical approaches able to spare reproductive organs have been developed.

In this context, vaginal radical trachelectomy (VRT) with laparoscopic lymphadenectomy represents the gold standard for fertility sparing surgery in early stage cervical cancer patients. This surgical technique was firstly described by Dargent [4] in the 1980s, and to date more than 1000 cases of VRT have been published, with a global pregnancy rate (total number of women who conceived of all who retained fertility) of 24 % [5], and a relapse and death rate of 4.2 % and 2.9 %; respectively [6].

Radical trachelectomy is a surgical procedure in which is removed the cervix with parametria, the upper part of the vagina and pelvic lymph nodes.

Criteria used to select candidates for radical vaginal hysterectomy are:

1. Confirmed invasive cervical cancer: squamous, adenocarcinoma, or adenosquamous
2. FIGO stage IA1 with lymphovascular space involvement, FIGO IA2 L0 or L1 V0 to IB1 L0 or L1 V0
3. Desire to preserve fertility
4. Lesion size < 2 cm
5. No previous history of infertility
6. Limited endocervical involvement at colposcopy (R0 resection possible with surgical margin >5 mm)
7. Estimated length of remaining cervix >1 cm
8. Post-conization adequate resolution of acute inflammation required (usually a 6-week interval between conization and RT)
9. Negative pelvic lymph node status

In this context, although VRT still represents the best surgical approach, only in selected cases laparoscopic radical trachelectomy (LRT) may offer specific advantages.

It has been considered that the age of first pregnancy is progressively increasing; therefore the vast majority of women receiving fertility sparing surgery are nulliparous at the time of surgery.

In these cases, RVT can be technically complex, and the laparoscopic route can be a more reliable strategy. Moreover, LRT represents an alternative to RVT for several gynecologic oncologists who are not proficient in vaginal radical surgery.

In addition, LRT ensures an easier identification of the uterine artery and the hypogastric nerve compared with the vaginal approach, thus allowing a more precious dissection of the parametrium. Therefore, using the laparoscopic route surgeons can better tailor the width of parametrium resection compared with the vaginal approach. In this context, it has to be considered that a novel surgical technique, the total mesometrial resection (TMMR) has been recently proposed as an affective therapeutic strategy in early stage cervical cancer patients [7], with recently published evidences suggesting the feasibility of laparoscopic TMMR [8]. Therefore, LRT may represent an attracting strategy in order to remove mesometrium according with Hockel technique which is not applicable with the vaginal approach.

For these reasons, LRT may be considered in women with tumor dimension > 2 cm receiving fertility sparing surgery which may require a wider parametrial resection. In these

cases, LRT may be considered only in the context of controlled clinical trials in which a fertility sparing surgical treatment is proposed after neoadjuvant chemotherapy [9]. In this regard, too many case reports and retrospective studies have been presented in literature proposing abdominal trachelectomy as surgical option for patients with tumor dimension >2 cm [10].

In conclusion, we have to point out that for tumor >2 cm LTR may be considered only in the context of controlled clinical trials and at the same time we have to remember that even in patients with tumor dimension <2 cm the real advantage of LRT compared to VRT must be proved necessarily and exclusively through a randomized prospective clinical trial.

In this context, it has to be emphasized that to safely complete LRT is mandatory to perform vaginal manchette to avoid intraperitoneal diffusion of cancer cells during specimen's removal after surgery. We believe that to cure women diagnosed with cervical cancer by fertility-preserving surgery, correct indication and oncologic precautions are more important than the type of approach. During surgical procedures the tumor may be inadvertently manipulated and the tumor cells may have been mobilized [11]. Although it has not yet been demonstrated worsening oncological outcome in cases in which vaginal cuff closure is not performed we consider this procedure essential more so in patients receiving LRT. Indeed, in these cases uterine cervix is exposed in the abdominal cavity to be transected allowing not only a vaginal tumor cell contamination (as for standard radical hysterectomy) but also an intraabdominal tumor spread.

Looking at the literature, a recent review including 485 abdominal radical trachelectomies reported a relapse and death rates of 3.8 % and 2.9 %, respectively [5]; which appears comparable with the results reported for VRT. In particular focusing on the laparoscopic approach, 140 LRT have been described in the literatures (Table 44.1). The operative outcomes are summarized in Table 44.2. The analysis of combined data demonstrates a low average intraoperative complication rate of 0.7 % with an incidence of postoperative complications around 6.4 %. The most common intraoperative complication is represented by the injury of uterine artery occurring during pelvic lymphadenectomy. On the other hand, the most frequent post-operative complications are represented by cervical stenosis, and bladder hypotonia due to the surgical-related damage of the sympathetic and parasympathetic branches of the pelvic autonomic nerve system.

Rates of conversions to laparotomy or secondary surgeries for parametrial bleeding, blood vessel injury, lymphocele, suprapubic, or vulvar hematoma range between 0 %

and 9 %. Postoperative complications such as dysmenorrhea (24 %), dyspareunia (20 %), menstrual abnormalities (17 %), excessive vaginal discharge (14 %), recurrent candidiasis (14 %), bladder hypotonia (4–16 %), vulvar edema (12 %), lymphocele (3–11 %), chronic pelvic pain (10 %), isthmic stenosis (10 %), amenorrhea (7 %), vulvar hematoma (7 %), suprapubic hematoma (4 %), lymphedema (3 %), urinary tract infection (2 %), and femoro-cutaneous nerve palsy (1 %) are reported.

Focusing on oncologic outcome, the tumour recurrence rate reported with LRT is 2.9 %, which appears superimposable or even lower compared with data reported for VRT (4.2–5.3 %), and abdominal radical trachelectomy (3.8 %) [5, 20]. Furthermore, the risk of recurrence does not seem to be greater after LRT for adenocarcinoma compared with squamous cell carcinoma (2.8 vs. 2.9 %), thus suggesting that tumor histotype does not represent a contraindication to the use of the laparoscopic route.

The obstetric outcomes after LRT for early-stage cervical cancer in the available literature are presented in Table 44.3. Overall, 59 patients attempted to conceive after LRT, and 46 patients successful deliveries were recorded, with a pregnancy rate of 78 % (46/59). Seventeen miscarriages, 14 preterm births and 11 term births have been described. On the other hand, the pregnancy rate in patients attempting to conceive after VRT is 52.8 % [5, 21], thus suggesting that the pregnancy rate after LRT is not lower compared with VRT. Similarly, the pregnancy loss rate is superimposable between vaginal and laparoscopic approach, accounting for 24 % [5, 21]. Unfortunately, regardless of the used surgical strategy, the pregnancy loss rates are significantly higher than that of the general population (12 %) [22]. The preterm birth rate of patients who gave birth after vaginal or abdominal radical trachelectomy is 24.7 %, and 38.7 % respectively. The preterm birth rate after LRT was 24 % in all the published studies, which appears again higher than general population, but superimposable with the vaginal approach [23]. Further investigations are required to establish definitive guideline for preterm birth prevention following radical trachelectomy.

Surgical Procedure

The surgical procedure is similar to that for laparoscopic nerve-sparing radical hysterectomy as described by Querleu [24]. In this chapter we describe our surgical modified technique according to the compartment theory besed on ontogenetic anatomy proposed by Hockel. The laparoscopic procedure is performed in the modified dorsolithotomy position under endotracheal general anesthesia. A Veress needle is inserted through the umbilicus and the abdomen is insufflated. After pneumoperitoneum and insertion of the laparoscope through an umbilical 10 mm trocar, three suprapubic 5 mm trocars are introduced for ancillary instruments.

Step 1 Preserving the integrity of the round ligament, the retroperitoneal space is entered along the lateral pelvic wall, thereby exposing the common iliac, external iliac, internal iliac and umbilical arteries. The pelvic visceroparietal ground plan is exposed by dissecting the areolar fibrous tissue to create a "paravisceral space" down to the pubo- and iliococcygeus muscles and a "presacral space" to the ventral margin of the inferior hypogastric plexus separated by the urogenital mesentery. Laterally to the external iliac vessels the obturator and lumbosacral fossa are developed. We proceed with the identification of the obturator nerves, the lumbosacral trunc, the gluteal vessels and the sciatic nerve. The lymph node dissection include the external and internal iliac nodes and the superficial and deep obturator nodes. We extend the radicality of our lymphadenectomy to the gluteal and pre-ischiatic nodes according to the therapeutic lymphadenectomy described by Hockel (Fig. 44.1) [7]. Lymph nodes are extracted in endoscopic bags through

the 10-mm sheath for perioperative histological examination. If the lymph nodes are negative, the procedure is continued.

Tip The pararectal fossa during this step is not developed to avoid uterine artery injury during lymphadenectomy. We proceed with this step later when we have a complete exposition of the pelvic retroperitoneum.

Step 2 A vaginal step is performed with vaginal "manchette" creation (Fig. 44.2a, b) in order to encapsulate tumor lesion and reduce tumor spread during uterine manipulation, according to previous published data [25]. The vescico-vaginal and recto-vaginal septum are opened without peritoneal incision.

Tip A sterile gauze is placed inside the developed septum for a easier identification of the developed space during laparoscopy. A sterile glove with a gauze inside are placed into the vagina to prevent gas loss during laparoscopy.

Step 3 The development of the medial and lateral pararectal space is then performed (Fig. 44.3). The lateral pararectal fossa (Latzko's fossa) is developed until the plan of uterine vein.

Tip Differently from what we have previously reported for radical hysterectomy [26] the parasympathetic nerves plan is not reached and the sacral fascia remains intact along the surface of the sacral root.

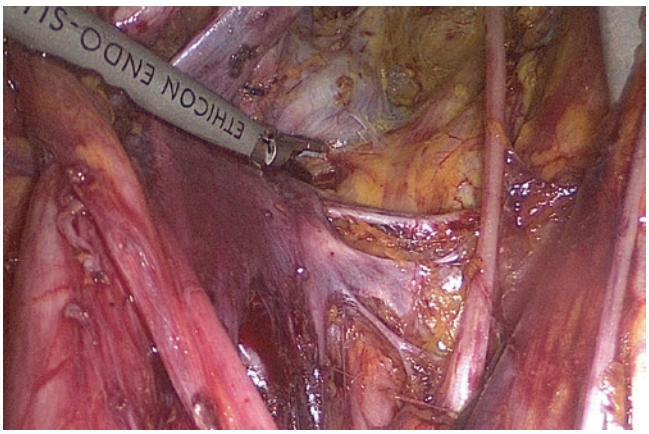

Fig. 44.1 Pelvic side wall after radical lymphadenectomy according to Hockel

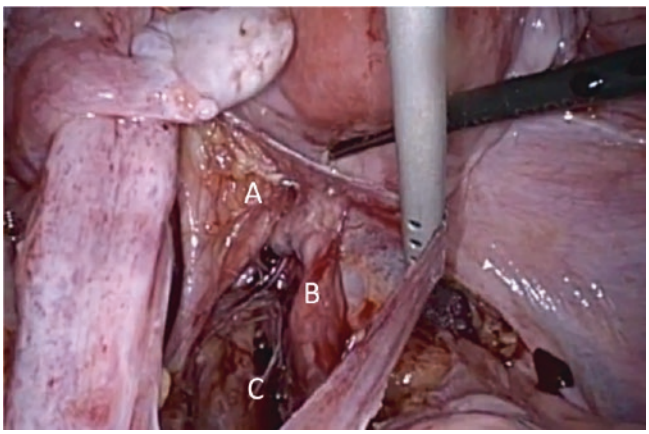

Fig. 44.3 Uterine artery (*A*); Ureter (*B*), Pararectal space (*C*)

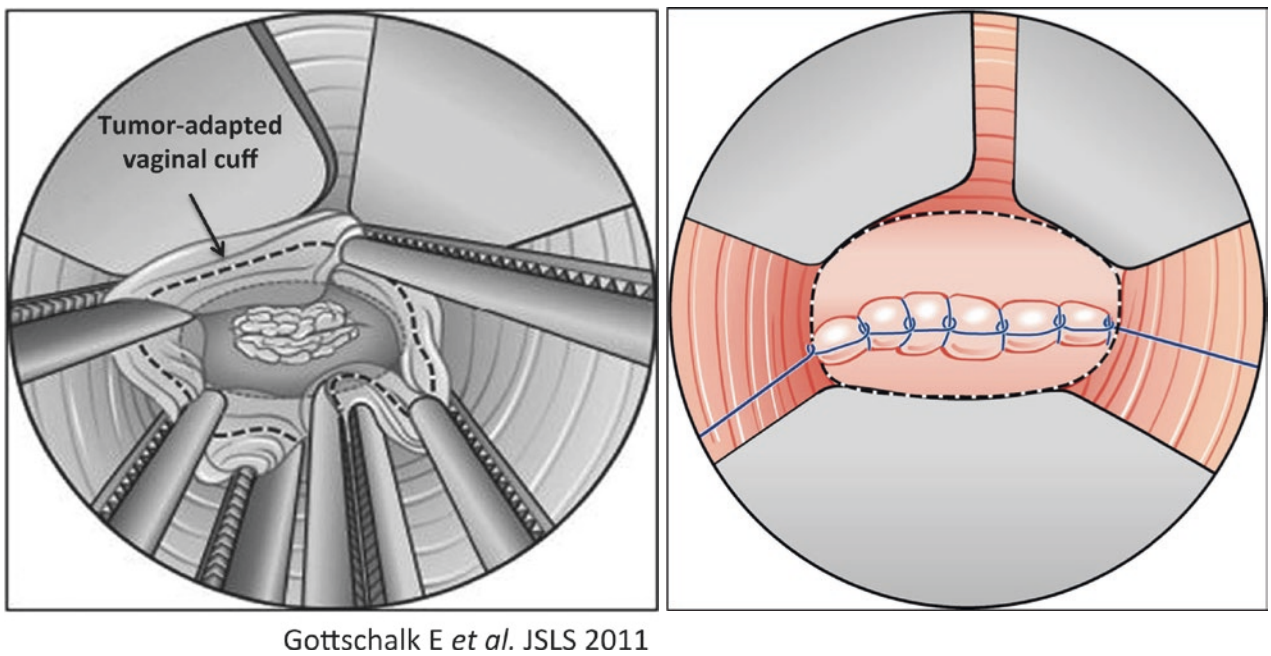

Fig. 44.2 Vaginal manchette

Step 4 The superior hypogastric plexus is isolated at the level of the sacral promontory and the right hypogastric nerve is identified (Fig. 44.4) with the development of the parasacral fossa.

Step 5 A peritoneal incision on the left side is performed at the level of the common iliac artery. The hypogastric plexus and the left hypogastric nerve are identified and the parasacral fossa is developed with reunification on the contralateral space (Fig. 44.5).

Tip At this point the rectum should be cranially pulled. We generally anchored it to the abdominal wall by placing a stitch on the rectal tenia.

Step 6 Hypogastric nerves are bilaterally lateralized and the peritoneum is transected medially to the ureter until the posterior mesometrium (Fig. 44.6) which is then transected at the level of the vaginal manchette (Fig. 44.7).

Tip Before the mesometrial transection Douglas peritoneum should be opened in order to identify the gauze previously positioned during the vaginal step.

Step 7 The pelvic ureter is separated from the broad ligament to the crossing of the uterine artery, and the hypogastric nerve is identified in the space created between the broad ligament and the mesoureter (Fig. 44.8).

Step 8 The uterine vessels and ureters are identified bilaterally (Fig. 44.9). The ascending and descending branches of

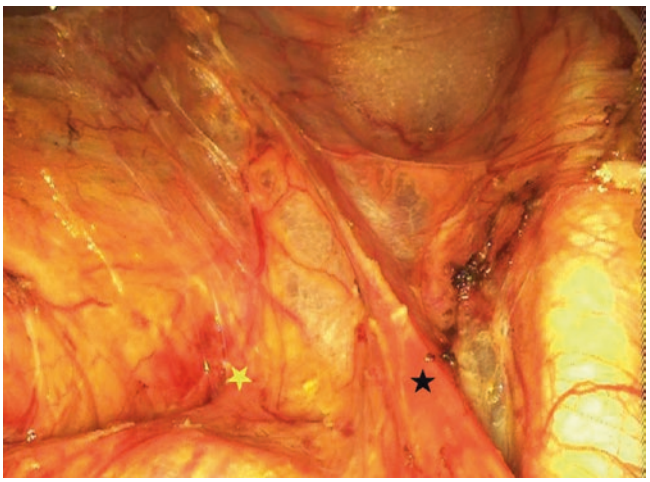

Fig. 44.4 *Black star*: right ureter. *Yellow star*: right hypogastric nerve

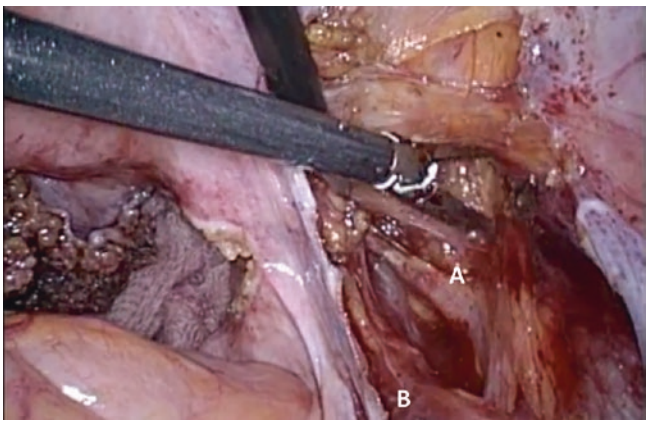

Fig. 44.9 Uterine artery (*A*); Ureter (*B*)

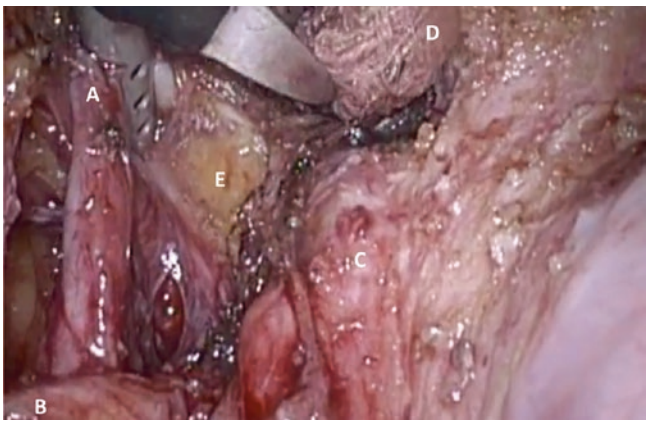

Fig. 44.11 Ureter (*A*); Uterine artery (*B*); Cervix (*C*); Vagina (*D*); Vescico-uterine ligament (*E*)

uterine artery are identified and in our technique uterine artery with both branches is preserved till to final cervical resection from the uterine corpus. The lateral parametrium is resected below (dorsally) the uterine artery (Fig. 44.10). The uterine vein is sectioned at the origin and then the parametrium is rotated below the ureter.

Tip In contrast to our classic radical hysterectomy where the mesouretere remains intact and the parametrium (including uterine artery) is rotated above and medially to the ureter, we prefer to dissect the mesouretere sliding the parametrium (with the uterine artery intact) below ureter.

Step 9 The vescico-vaginal space is opened with the identification of the gauze previously positioned during vaginal step (Fig 44.11).

Tip The two bladder corners are pulled ventrally positioning two stitches through the abdominal wall.

Step 10 The dissection of vescicouterine ligament is performed defining a section plane between the cervix (medially) and the terminal ureter (externally) with the bladder positioned ventraly and the uterine artery dorsally (Fig. 44.11).

Step 11 The uretere is isolated caudally to the uterine artery, surrounded by a rubber strip and anchored to the abdominal wall (Fig. 44.12). In this way we create a kneeling of the uretere caudally to the uterine artery.

Step 12 The infraureteral anterior parametrium, the anterior and lateral paracolpium are transected dorsally to the pulled ureter (Fig. 44.13).

Tip At this point the anterior (vescico-vaginale), lateral and posterior (recto-vaginal) spaces are in communication and the cervix remains pegged to the posterior paracolpium.

Step 13 The remaining paracolpium (Fig. 44.14) is transected caudally to the vaginal manchette.

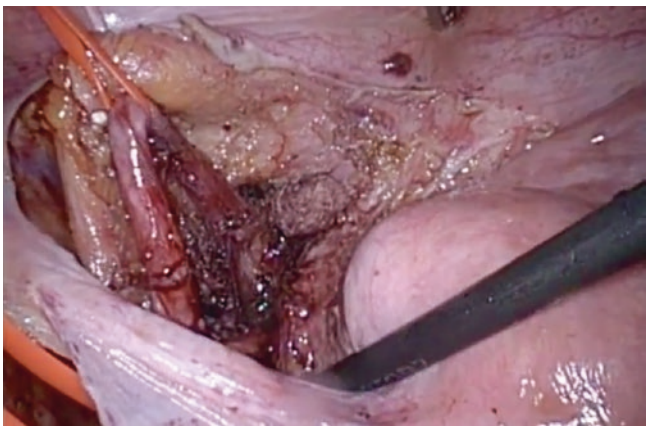

Fig. 44.12 Anchored ureter

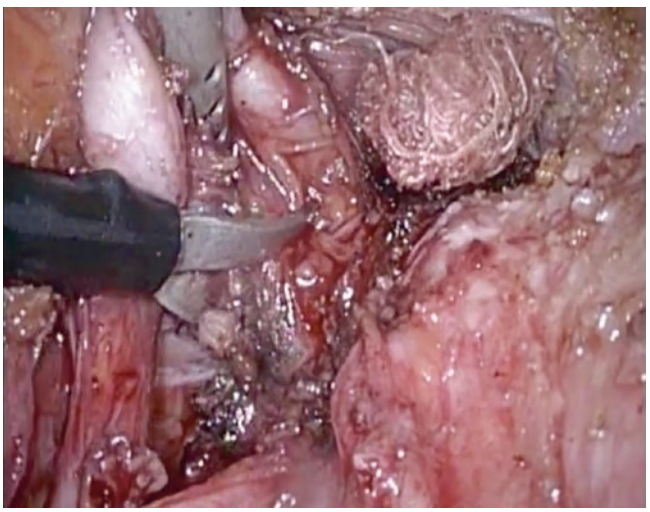

Fig. 44.13 Infraureteral anterior parametrium

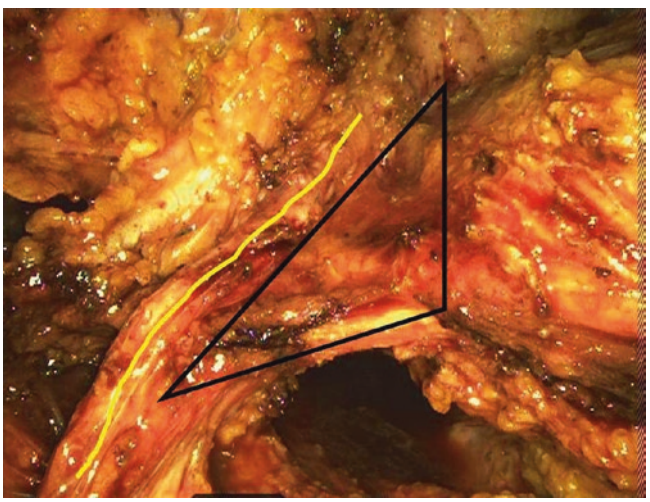

Fig. 44.14 *Yellow line*: left ureter. *Black triangle*: left paracolpium

Step 14 All these steps are performed bilaterally.

Tip The uterus at this point is held in place by the round ligaments, the uterine arteries and the pelvic infundibula.

Step 15 The vaginal manchette is rotated ventrally in order to expose the isthmus (Fig. 44.15).

Step 11 The descending branch of uterine artery is coagulated, whereas the ascending branch is preserved, then the cervix is then transected approximately few millimetres below the insertion of the uterine artery (Fig. 44.16). The excised cervix is marked and sent for frozen section for the evaluation of surgical margins.

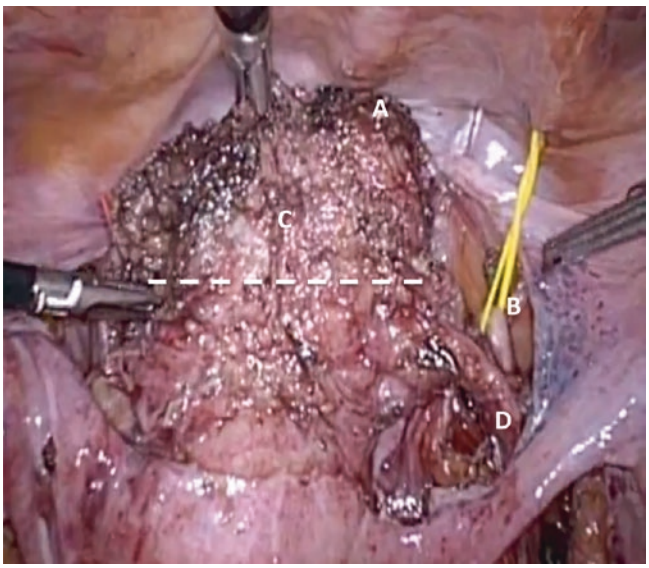

Fig. 44.15 Vaginal manchette (*A*); Ureter (*B*); Cervix (*C*); Uterine artery (*D*)

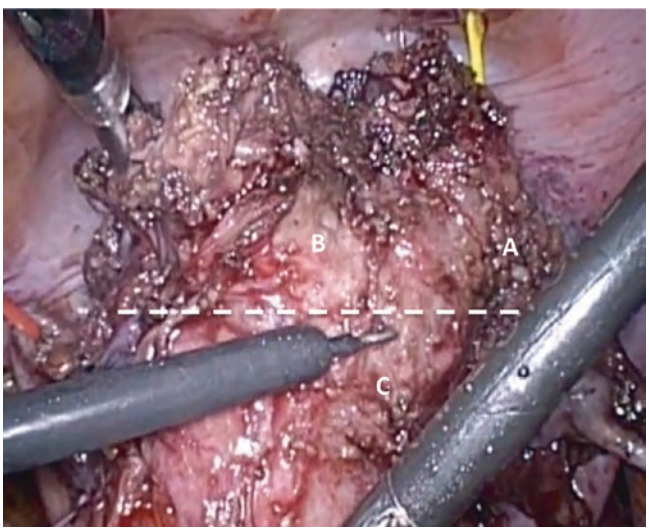

Fig. 44.16 Parametrium (*A*); Cervix (*B*); Isthmus (*C*)

Step 12 Reanastomosis of the uterine corpus and upper vagina is then laparoscopically performed and eight separated stiches are placed (Fig. 44.17).

Step 13 The specimen is sent for extemporaneous histological examination in order to evaluate the the margins of resection (Fig. 44.18).

A Foley catheter is always placed in the isthmus at the end of the surgical procedure.

After LVT, we recommended contraception with oral contraceptives for 6–12 months in patients with squamous cell carcinoma. Patients with adenocarcinomas were recommended non-hormonal contraception. During pregnancy following LVT, we recommended regular visits in short intervals such as in risk pregnancies. Cervical length was assessed on every visit or at least every 2 weeks. In the event of cervical shortening or funnel building, we recommended the Saling procedure between weeks 12 and 14. We recommended examining microbiologic vaginal smears every second week to detect vaginal infection as soon as possible. We advised women to check their vaginal pH twice a week starting in the second trimester. If a patient showed signs of cervical insufficiency, we recommended bed rest and hospitalization. We recommended routinely administering steroid and antibiotic prophylaxis before the 34th week to prevent acute respiratory distress syndrome and premature rupture of membranes (PROM) in patients with cervical insufficiency or suspicious microbiologic smears.

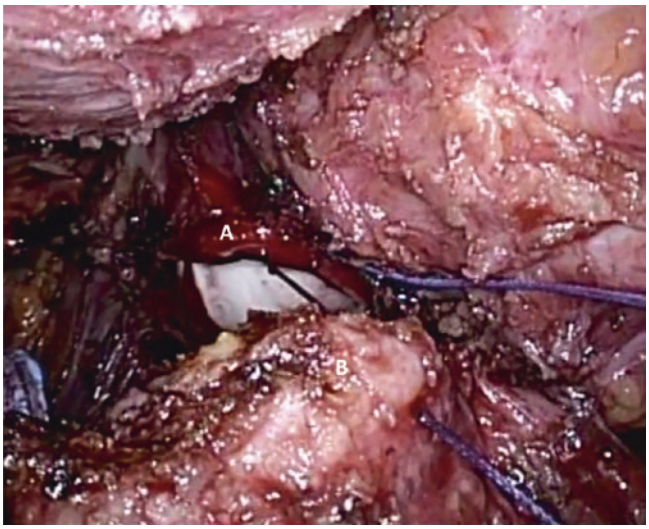

Fig. 44.17 Vagina (*A*); Uterine corpus (*B*)

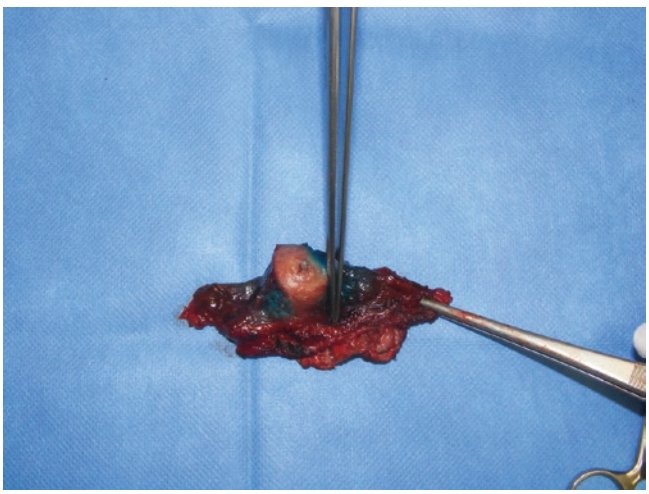

Fig. 44.18 Final surgical specimen

LRT does appear to be a well tolerated treatment for carefully selected patients. The advantages of minimally invasive approaches are visual enhancement, more precise dissection, less blood loss, fewer complications and shorter recovery time. The review of the literature indicates that pregnancy rates are high; however, preterm birth is common. LRT allows a more precious dissection of the parametrium and a wider parametrial resection; however "not always bigger means better". Therefore, VRT remains the gold standard, and LRT should be considered only in the context of clinical trial as an additional surgical approach for selected cases. In tertiary referral centers both surgical techniques must be available to properly tailor surgical management.

45 Laparoscopic Radical Hysterectomy with Anterior and Posterior Exenteration – Gynecological Perspectives

Shailesh P. Puntambekar, Yamini M. Gadkari, Vikrant C. Sharma, Suyash S. Naval, Seema S. Puntambekar, and Natasha U. Singbal

Introduction

Uterine malignancies are a common cause of cancer death amongst women. The incidence has risen in the recent years because of increasing awareness and screening [1, 2]. Radical hysterectomy continues to be the most common surgical approach in treatment of an early stage carcinoma of the cervix and endometrium.

The role of laparoscopy in this setting is to offer all the benefits of a minimally invasive approach, while maintaining equivocal oncological outcomes of an open approach. Since the first radical hysterectomy performed by Clark in 1895 and the Wertheim's technique of radical hysterectomy in 1898 [2], the radical hysterectomy has evolved into a simpler procedure and the surgical approach has evolved over a period of time into a highly specialized and minimally invasive modality. With technological advances we now can perform the radical hysterectomy with minimally invasive techniques like laparoscopy and robotics [3].

Here the author describes his "Pune technique" of laparoscopic radical hysterectomy with operative steps which are standardized. This makes this technique universally acceptable as it is easily duplicable [3].

Advantages of laparoscopic surgery are shorter hospital stay, less postoperative pain, quicker postoperative recovery, cosmetically better, enables the patient to start adjuvant treatment as early as possible. Hence, the acceptance of minimally access surgery in the recent years has increased [2, 3].

Laparoscopic Radical Hysterectomy [2, 3]

Indications

1. Cervical cancer stage IA2 to stage IIA2
2. Endometrial cancer stage II

Preoperative radiation therapy is not a contra-indication for the laparoscopic procedure.

Contraindications

1. Evidence of peritoneal carcinomatosis or distant metastatic disease
2. Evidence of grossly involved lymph nodes

Preoperative

Liquid diet a day prior to the surgery.

Mechanical Bowel Preparation: Polyethylene glycol night before the operative to clear the bowels so as to keep them away from the operative field.

Enema and bowel wash should be avoided as this leads to dilatation of sigmoid colon.

Anaesthesia

Combined regional and general anaesthesia. The regional anaesthesia acts by blocking the sympathetic activity, contracts the small bowel and keeps it away from the operative field.

Patient Position

Patient is placed in modified Lloyd Davis position. A bolster is placed at the level of the anterior superior iliac spine which

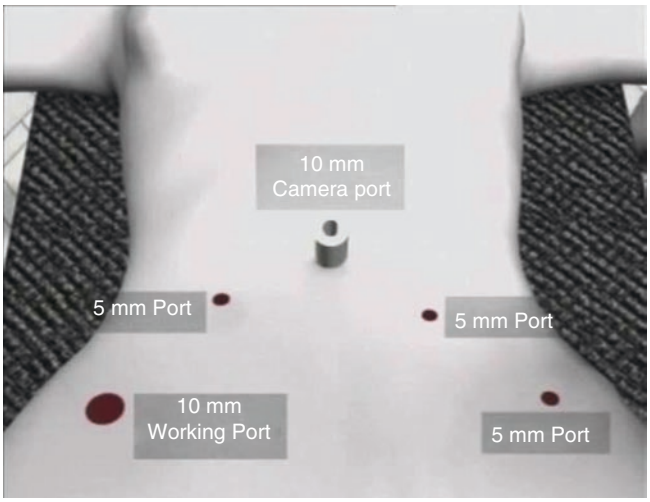

Fig. 45.1 Port positions

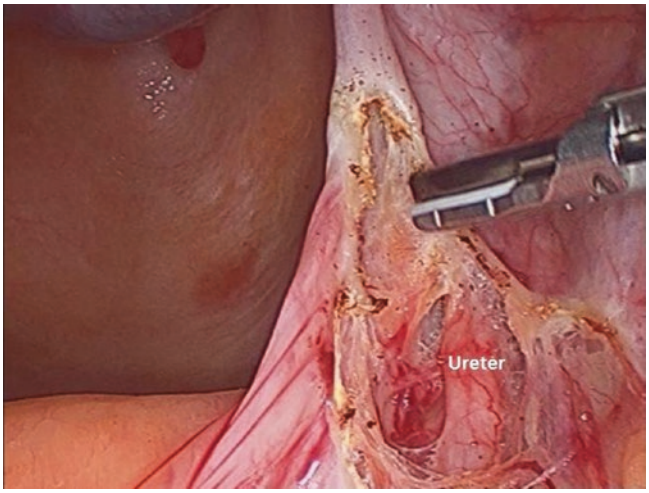

Fig. 45.2 Opening of peritoneum at the level of sacral promontory to expose ureter

causes elevation of the pelvis and results in a drop of the intestines cephalad. A gauze piece is kept in the vagina to prevent the loss of pneumoperitoneum after colpotomy.

Port Positions (Fig. 45.1)

A total of five ports are used.

A 10 mm camera port at the umbilicus.

A 10 mm working port at the Mcburney's point on the right side.

A 5 mm port pararectally (at rectus muscle margin) at the midclavicular line at the level of the umbilicus.

A set of two 5 mm ports are inserted as a mirror image of right side on the left side.

The surgeon stands on the right side, the assistant surgeon on the left side and the camera surgeon also stands on the left side, at the head end.

Procedure

The uterus is manipulated with a myoma screw in cervical malignancy. The myoma screw is introduced from the 5 mm left pararectal port and inserted into the fundus.The uterus is manipulated with a tenaculum in cases of endometrial malignancy.

Step 1: Posterior U- Cut

Uterus is anteverted. The rectum is retracted towards the left side. The right ureter is identified underneath the peritoneum at the level of sacral promontory. The peritoneum is opened medial to infundibulopelvic ligament with the help of harmonic shears to expose the ureter (Fig. 45.2). This cut is extended downwards into the Pouch of Douglas upto the level of uterosacral ligament

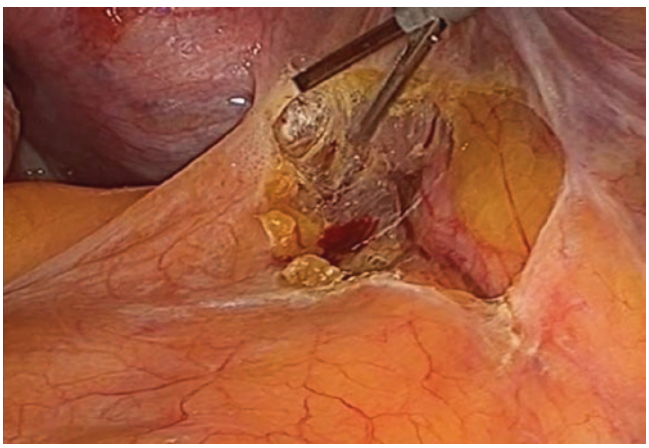

Fig. 45.3 Extending the peritoneal cut towards the Pouch of Douglas

(Fig. 45.3).The ureter should be on the lateral side and constantly under vision. The same steps are repeated on the left side and both the peritoneal cuts are joined in the Pouch of Douglas forming the posterior U- cut (Fig. 45.4**).**

Step 2: Dissection of Rectovaginal Space (Fig. 45.5)

The peritoneum in the Pouch of Douglas is pulled cephalad and the rectum is dissected off the posterior vaginal wall by remaining in between the two layers of Denonvillier's fascia. The plane between the fat and the posterior vaginal wall is dissected keeping in mind the dictum **"the fat belongs to rectum".**

Step 3: Dissection of Pararectal Space

The left ureter is retracted medially, and the posterior leaf of the broad ligament above the ureter is cut. A window is made in the anterior leaf of broad ligament. The ureter is now retracted

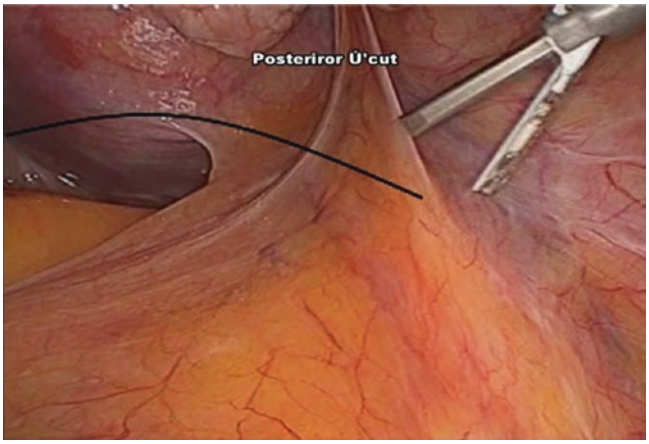

Fig. 45.4 Posterior U-cut

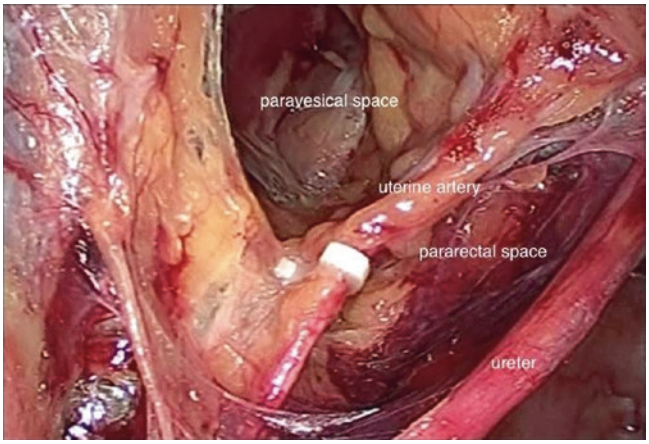

Fig. 45.6 Left pararectal space

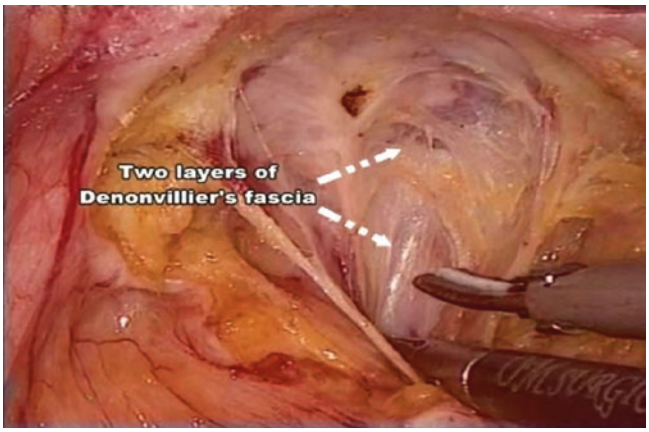

Fig. 45.5 Dissection of rectovaginal space

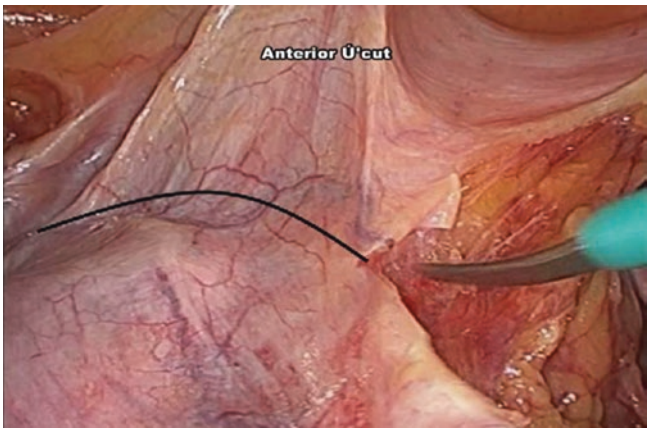

Fig. 45.7 Anterior U-cut

medially and the pararectal space is opened by remaining parallel and lateral to the ureter. The internal iliac artery forms the lateral boundary of this space and is then visualised. The only structure which crosses the pararectal space transversely is the uterine artery (Fig. 45.6). The space anterior to the uterine artery and medial to the obliterated hypogastric artery is dissected. The dissection is continued caudally by remaining parallel to the uterine artery to open the paravesical space upto the levator ani muscle. The uterine vein is seen below the ureter. The ureter always lies in the fork formed by the uterine artery anteriorly and the uterine vein posteriorly. Both the artery and the vein are individually clipped or ligated and then cut. This allows the visualization of the uterosacrals and the mackenrodt's ligament from their origin. The ureter is now retracted upwards and laterally and these ligaments are cut either with the harmonic or ligasure, as laterally as possible. The paracolpos which is continuation with the mackenrodt's ligaments is thus reached. This is divided up to the levator ani muscle. Similar steps are repeated on the right side.

Step 4: Anterior U- Cut

The uterus is retroverted. The peritoneum over the uterovesical fold is cut starting from the round ligament on right side to the left side forming the anterior U- cut (Fig. 45.7)**.**The bladder is dissected off the uterus and cervix by remaining below the fat and above the pubocervicovesical fascia.The dictum used is **"fat belongs to the bladder"**(Fig. 45.8). The peritoneal cut is further extended up to the infundibulopelvic ligaments.

Step 5: Dissection of Ureteric Tunnel (Fig. 45.9)

The uterus is pulled to the left. The right ureter is traced along its entire course towards the bladder. The bladder peritoneum is held and the bladder is retracted upwards by the assistant. The cervicovesical ligaments, also known as the ureteric tunnel, is dissected with the help of Maryland's forceps (Fig. 45.10).There are two veins in the anterior cervicovesical ligament which is clipped and then cut. Similarly the posterior cervicovesical ligament is also clipped and cut. The

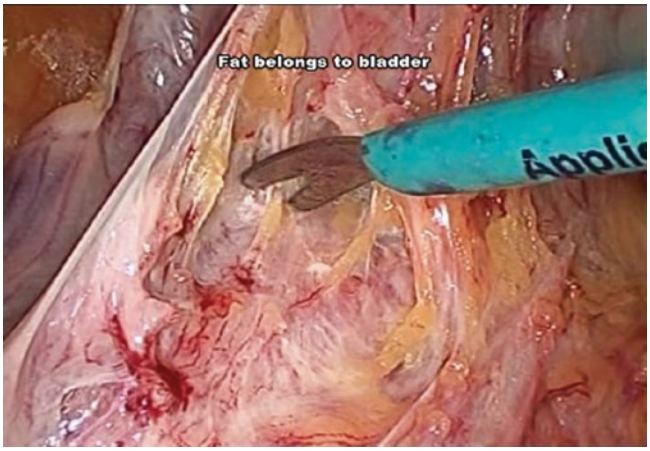

Fig. 45.8 Bladder dissection

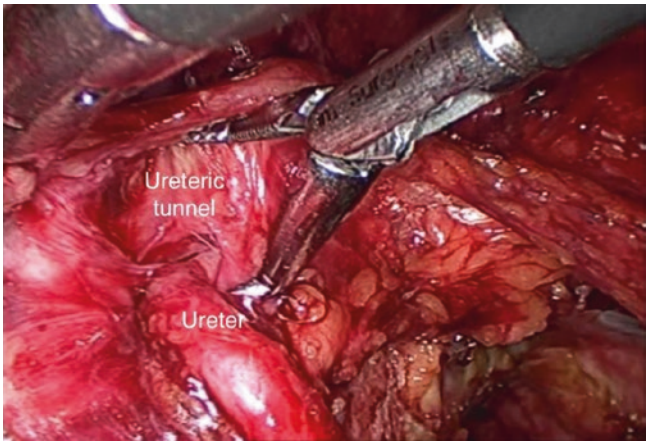

Fig. 45.10 Ureteric tunnel

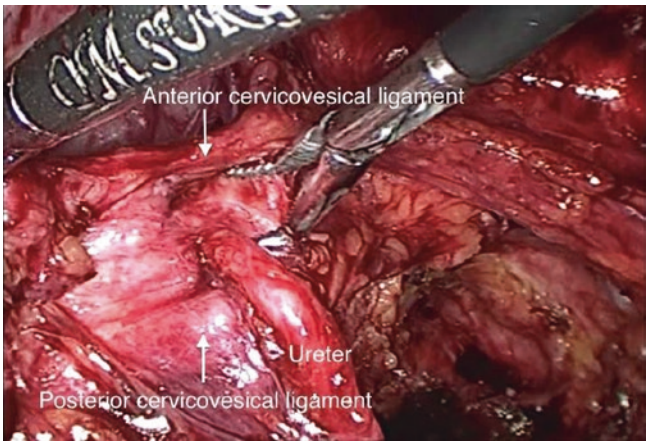

Fig. 45.9 Anterior and posterior cervicovesical ligament

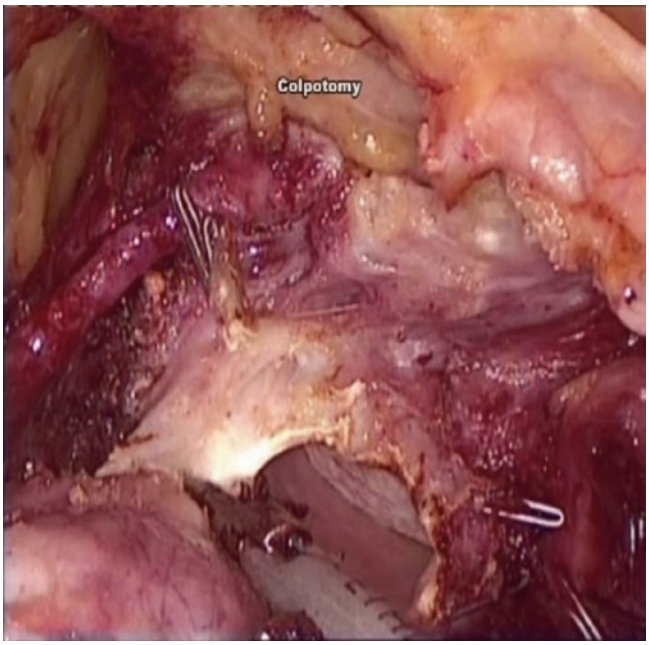

Fig. 45.11 Colpotomy

strands of endopelvic fascia which hold the ureter are cut on the medial side which further lateralises the ureter. The ureter can be seen upto its entry into the bladder. The bladder is pushed further down to achieve a good vaginal cuff, below the growth. The paracolpos is then cut as laterally as possible. These steps ensure that we can obtain maximum amount of paracolpos and the vaginal margin. The same steps are repeated on the left side making the trigonal area visible. Colpotomy is done above this level with the help of harmonic shears (Fig. 45.11). The infundibulopelvic ligaments are then cut and the entire specimen is separated and placed in an endobag.

Step 6: Lymph Node Dissection (Fig. 45.12)

The lymph node dissection is started at the bifurcation of common iliac artery (Fig. 45.13). All the fibrofatty tissue along the external iliac vein and artery is dissected, remaining in a direction parallel to the vessels upto the iliac bone which forms the lateral limit of the dissection. The medial limit is formed by the internal iliac artery and the lower limit is the obturator nerve (Fig. 45.14).Similar dissection is done on the opposite side. The entire nodal tissue obtained is put in the endobag (Fig. 45.15). The endobag is removed vaginally. Haemostatsis is achieved. Vault is closed with continuous locking intracorporeal suturing with vicryl 2–0, which is introduced through the 10 mm working port. Wound is irrigated with normal saline. It is not necessary to use any intra-abdominal drain. The ports are removed under vision and the port sites closed.

The Specimen This technique achieves a Pivers Type III [4]/ Querleu and Morrow [5] Type C Radical Hysterectomy,

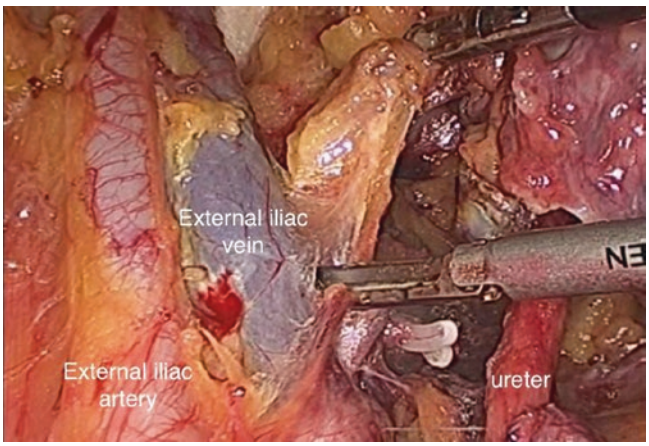

Fig. 45.12 Ilioobturator lymph node dissection

Complications

Haemorrhage
Bladder injury
Ureteric injury
Bowel injury
Fistulas

Laparoscopic Nerve Sparing Radical Hysterectomy [6, 7]

The main disadvantage of laproscopic radical hysterectomy is the bladder dysfunction. This is caused due to autonomic nerve disruption with loss of anatomical bladder neck support and over distension of the bladder. A nerve sparing radical hysterectomy is involves the preservation of superior and inferior hypogastric and the pelvic splanchnic plexus, thus overcoming the complication of bladder dysfunction.

The procedure is the similar as that of laparoscopic radical hysterectomy. The hypogastric plexus lies lateral to the uterosacral ligaments. Thus the dissection at the level of uteroscarals is done carefully. The nerves are identified lateral to the uterosacrals and medial to the ureter.

The branches of the hypogastric nerve going to the uterus are identified in the connective tissue just posterolateral to the vagina and these branches are selectively cut and the nerve plane is lateralized on the posterior side. The bladder branch of the inferior hypogastric plexus is spared by lateralizing the nerve plane and the ureter. The posterior leaf of the vesicouterine ligament contains vesical veins that drain into the deep uterine veins which are individually clipped and cut. The bladder branch that passes just below the inferior vesical vein is also spared. The uterine and cervical branches

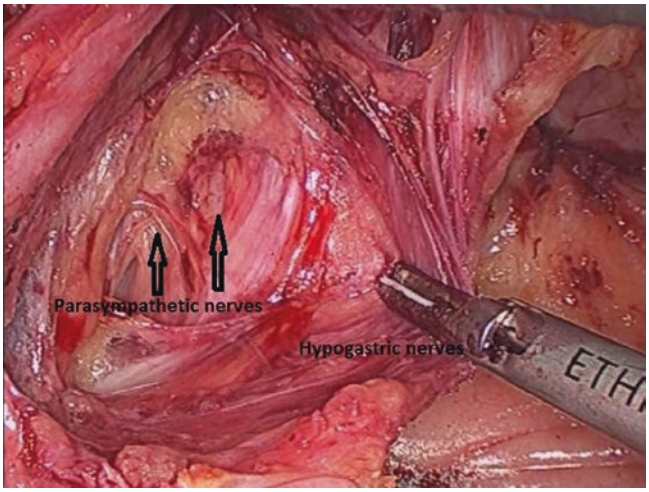

Fig. 45.16 Inferior hypogastric plexus

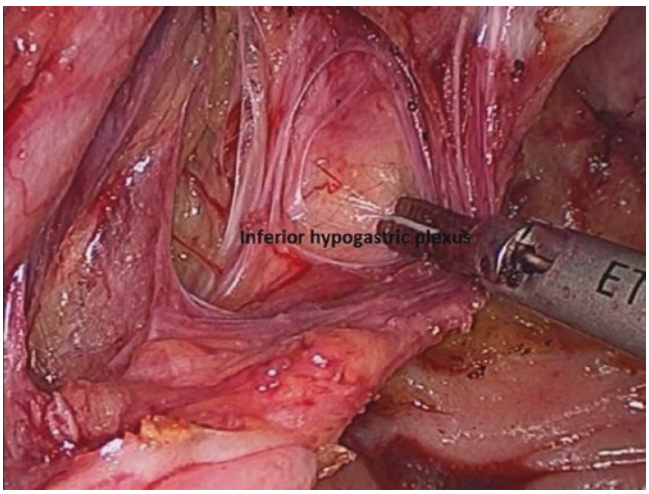

Fig. 45.17 Inferior hypogastric plexus

of the inferior hypogastric plexus in the anterior part are also selectively cut (Figs. 45.16 and 45.17).

The key structure in a nerve sparing radical hysterectomy is the uterine vein. The uterine vein should be cauterised and cut medial to the ureter in order to preserve the nerves.During colpotomy the nerve is lateral to ureter whereas in the initial stages of the dissection the hypogastric nerve and inferior hypogastric plexus were anatomically posteromedial to the ureter. The rest of the procedure is completed in the same way as the laparoscopic radical hysterectomy explained earlier.

Postoperatively the Foley's catheter is removes after 48 h. If urinary retention occurs Foley's catheterization is done again and patient is reassessed every 7 days.

Anterior Exenteration

Currently anterior exenteration is used as one of the modality for treatment of locally advanced cancers of the cervix.The anterior exenteration includes the removal of bladder, lower ureters, perivesical stump, uterus, ovaries and ilioobturator and iliac lymph nodes [8].

The following criteria should be used to decide the operability [9]:

1. Histological documentation of cancer in the palpable mass.
2. Absence of tumour extension to parametrium or pelvic sidewalls.
3. No involvement of the rectum by the growth.
4. Absence of gross pelvic or para aortic lymph node enlargement.
5. No peritoneal implants or bowel involvement.
6. No evidence of distant metastasis.

The absolute contraindications for surgery are:

1. Unilateral or bilateral pedal edema.
2. Sciatica or bone pain.
3. Poor medical condition.

Preoperative Workup

1. Computed tomography of the abdomen and pelvis
2. Chest radiography
3. Liver function tests
4. Cystoscopy

Procedure [10, 11, 12]

Anaesthesia, patient position and port positions are same as laparoscopic radical hysterectomy.

Steps 1 ,2, 3 remain the same as at radical hysterectomy (Fig. 45.18).

Step 4

The anterior dissection is begun by cutting right round ligament and then the anterior leaf of the broad ligament is cut. The peritoneum medial to the obliterated hypogastric artery is cut and the peritoneal cut is extended to the anterior abdominal wall, to separate the bladder from the anterior abdominal wall. Similar steps repeated on the left side.

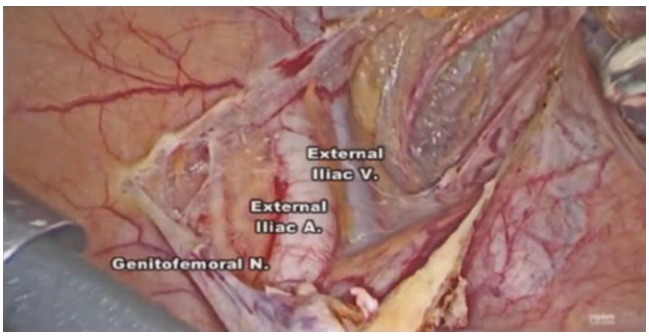

Fig. 45.18 External iliac vessels

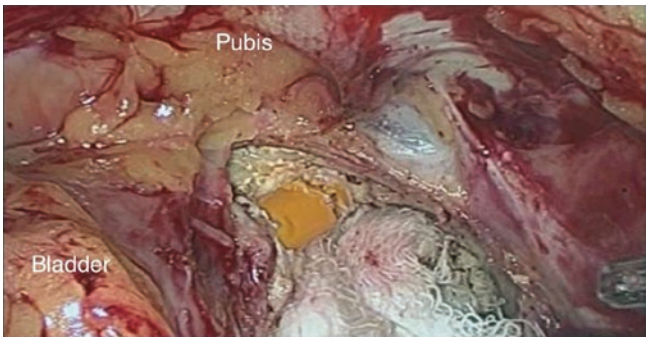

Fig. 45.20 Urethra being cut

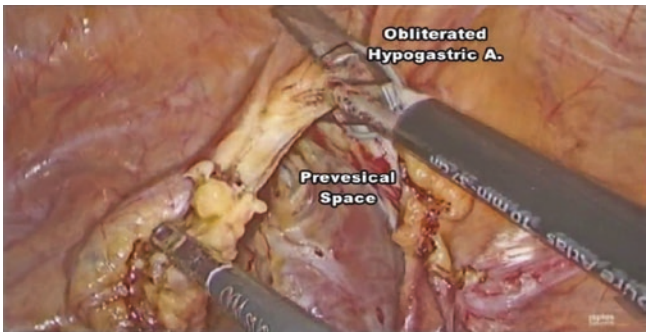

Fig. 45.19 Prevesical space

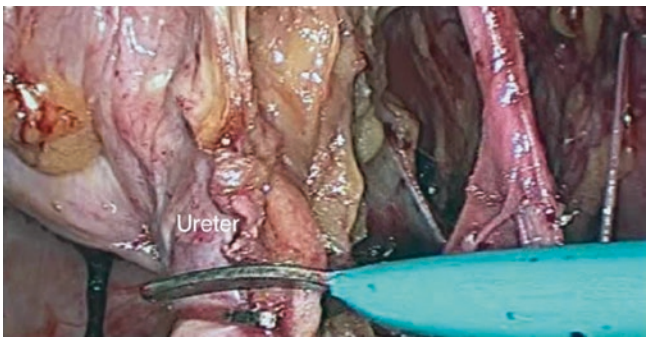

Fig. 45.21 Ureter being clipped and cut

Step 5

The bladder is then brought down from the anterior abdominal wall to enter the retro-pubic space i.e. the Cave of Retzius (Fig. 45.19) The tissue which is anterior and lateral to the urethra and vagina is cut. The urethra is accessed anteriorly (Fig. 45.20). The posterior urethral wall and the anterior vaginal wall are cut. A good length of vagina below the growth is exposed. The aim is to have a distal vaginal cuff of 3 cms.

Step 6

Colpotomy is done. Ilio obturator nodal dissection is done on both the sides and the tissue put in an endobag. Specimen is removed vaginally.

The type of urinary diversion plays an important role in the quality of life.

The various type of urinary diversions which can be done are

- ileal conduit
- ureterosigmoidostomy
- orthotropic illeal neo bladders
- Indiana pouch.

Ureterosigmoidostomy and ileal conduit can be done entirely laparoscopically while Indiana pouch and neo bladder have to be done by opening the abdomen. Here the author describes the ureterosigmoid anastomosis.

Step 7

The right ureter is cut (Fig. 45.21) and transfixed to the sigmoid colon anteriorly over the taenia coli. The end of the suture is held up for better visualization. A cut is made on the ureter which is fashioned into a fish mouth. A cut is also made on the sigmoid, anteriorly overlying the taenia coli (Fig. 45.22). A proximal full thickness stitch is taken, outside-in on colon and is continued inside-out on ureter. Infant feeding tube no. 5 or 6 is inserted in it, to act as a stent across the anastomosis (Fig. 45.23). It is proximally put into the ureter upto the renal pelvis. A note is made of the presence of flowing urine in the tube, to confirm proper placement. It is distally inserted into the opening made in the sigmoid colon. Once the stent is in place, the ureter edges are sutured with a 3:0 vicryl continuous suture. A full thickness continuous suture is taken on one side of the anastomosis, going from proximal to distal. The same suture is taken around and continued from distal to proximal end on the opposite side of the anastomosis. Right edge of ureterosigmoid anastomosis is sutured (Fig. 45.24). The suture is brought around from below the ureter, to be tied to its tail on the left side. A transfixation suture (hypnotic) is taken. The excess tip of ureter is trimmed. The left ureter is brought under the colon and then to the right side.

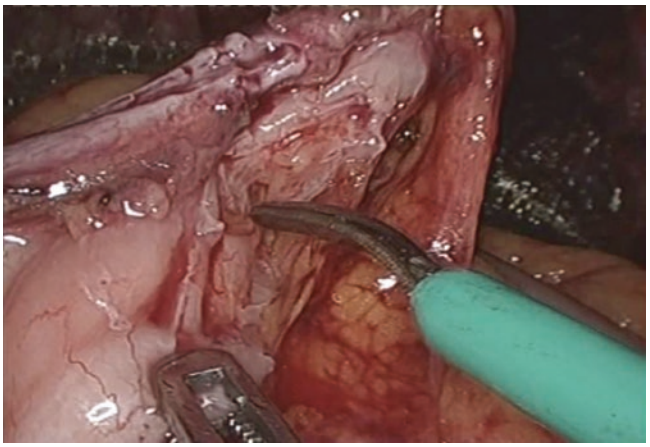

Fig. 45.22 A cut is being made on the sigmoid, anteriorly overlying the taenia coli

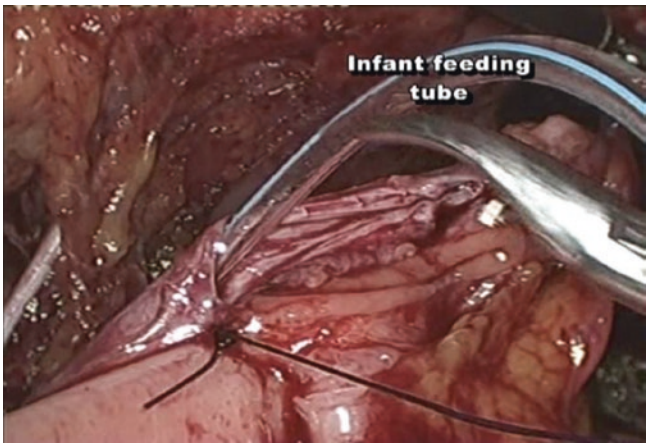

Fig. 45.23 Infant feeding tube no. 5 or 6 is inserted in the ureter to act as a stent across the anastomosis

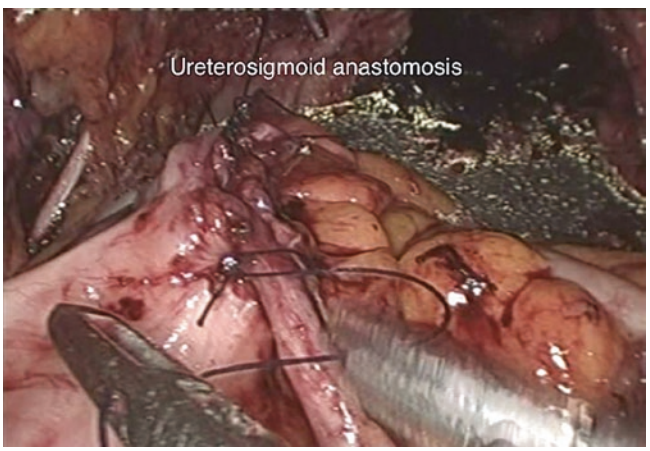

Fig. 45.24 Ureterosigmoid anastomosis

Step 8

The vagina is then sutured with 2:0 vicryl continuous intracorporeal suturing. Haemostasis achieved. An abdominal drain is placed in the pelvis. The ports are then removed under vision and closed.

Posterior Exenteration

Posterior exenteration is one of the treatments described for advanced cancers of the cervix, uterus, ovary, and rectum. Until recently, due to the complexity of the surgery, only the open method was used, however, minimally invasive surgery is now being used as a modality of surgery.

Preoperative Workup

1. Computed tomography of the abdomen and pelvis,
2. Chest radiography,
3. Liver function tests,
4. Cystoscopy
5. Proctoscopy.

All patients are examined under anesthesia before the procedure to confirm the extent of rectal involvement and to assess the feasibility of a stapled colorectal anastomosis.

The need for a temporary colostomy and the possibility of a permanent colostomy is also to be considered and discussed with the patients. The final decision is made at laparoscopy.

Inclusion Criteria

1. Ovarian cancer involving pouch of Douglas
2. Postradiation cervical cancer recurrence localized posteriorly
3. Cervical cancer with rectovaginal fistula
4. Vaginal cancer with rectal involvement

Exclusion Criteria

1. Extrapelvic spread
2. Distant metastasis including para-aortic nodes
3. Involvement of urinary bladder
4. Involvement of ureters
5. Limb edema or sciatic pain
6. Patient medically unfit

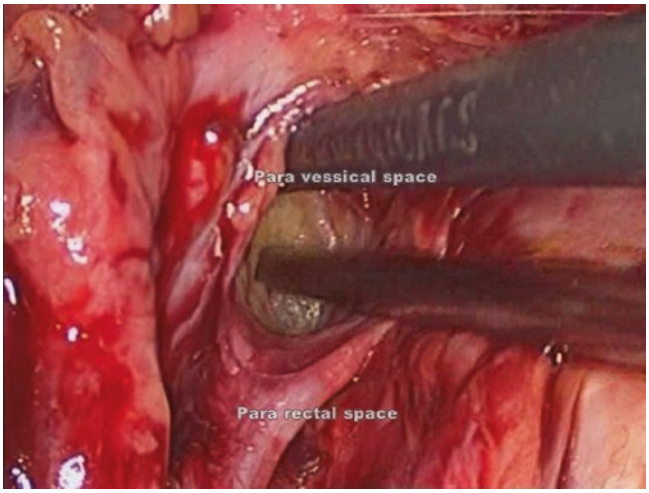

Fig. 45.25 Pararectal and paravesical spaces

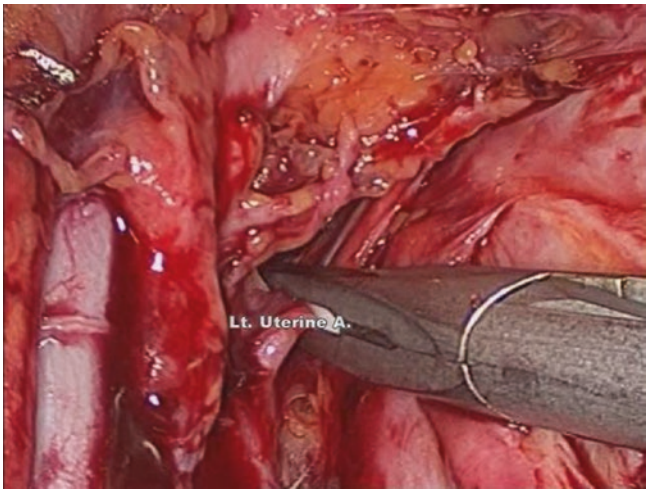

Fig. 45.26 Uterine artery being clipped

Preoperative Bowel Preparation

Routine bowel preparation was with 1 L of oral isosmotic solution (Peglec) taken the night before surgery.

Anaesthesia, patient position, port positions and surgeon position is same as laparoscopic radical hysterectomy.

Procedure [13]

The uterus can be manipulated with the help of a myoma screw or uterine hitch [14].

Step 1

The dissection is begun at the level of sacral promontory after identifying the external iliac vessels and ureters on the left side. A fold of peritoneum is opened and the ureters are lateralised. Infundibulopelvic ligament is skeletonised, clipped and cut.

Step 2

The pararectal spaces on both sides are dissected, remaining parallel and lateral to the ureter. Dissection proceedes anteriorly into the paravesical spaces upto the levator ani, which is used as the distal limit of dissection (Fig. 45.25). The uterine arteries and veins are clipped or ligated (Fig. 45.26). The ureter is further lateralised by dissecting the endopelvic fascia on the medial side. Similar steps are followed on the opposite side.

Step 3

Anterior U cut is made and the urinary bladder is dissected from the uterine cervix(Fig. 45.27).

Involvement of the urinary bladder at this stage would require a total pelvic exenteration.

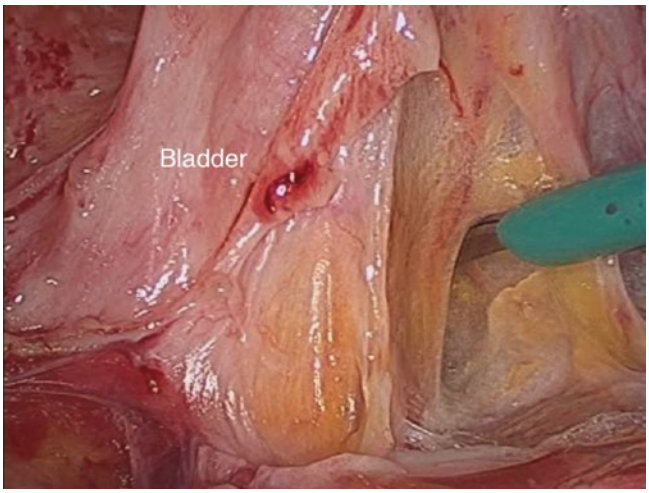

Fig. 45.27 Bladder being dissected using the principle of fat belongs to the bladder

Step 4

The presacral space is dissected between the rectum (Fig. 45.28) and the presacral fascia by following the dictam fat belongs to the rectum (Fig. 45.29). This is an avascular plane, and following this plane distally reveals the levator ani as its inferior limit. The virgin plane is entered between the vaginal wall and the rectum below the level of the Pouch of Douglas. The distal level of rectal involvement is the criterion to decide whether supralevator or infralevator posterior extenteration is to be used.

In supralevator cases rectal continuity be made using endostaping device. In patients with involvement of the sphincter complex, tumor involvement extending very low in the rectum and low malignant rectovaginal fistula require infralevator resection with a permanent colostomy.

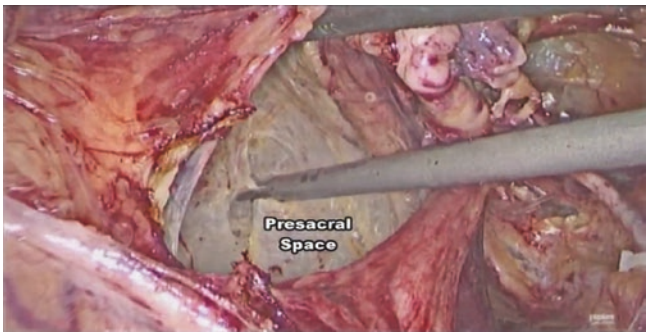

Fig. 45.28 Presacral space

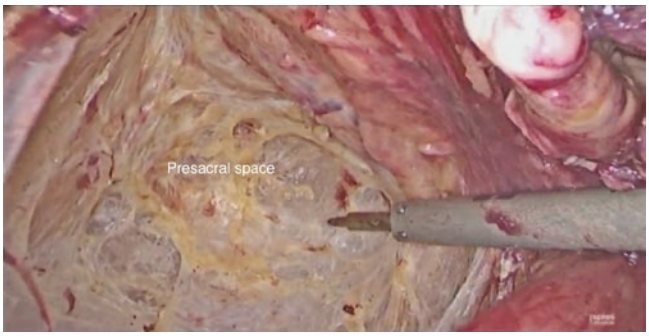

Fig. 45.29 Presacral space opened up using the principle of fat blongs to the rectum

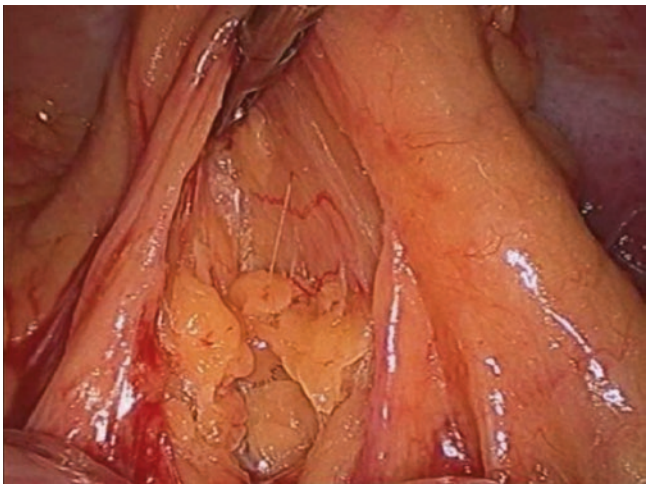

Fig. 45.30 Large bowel being mobilized

Step 5

A low colpotomy is performed.

Step 6

The proximal large bowel is mobilized (Fig. 45.30). The inferior mesenteric artery is clipped and cut at its origin (Fig. 45.31). The rectum distal to the tumor is visualized, which enables transection with the endostapling device (Fig. 45.32).

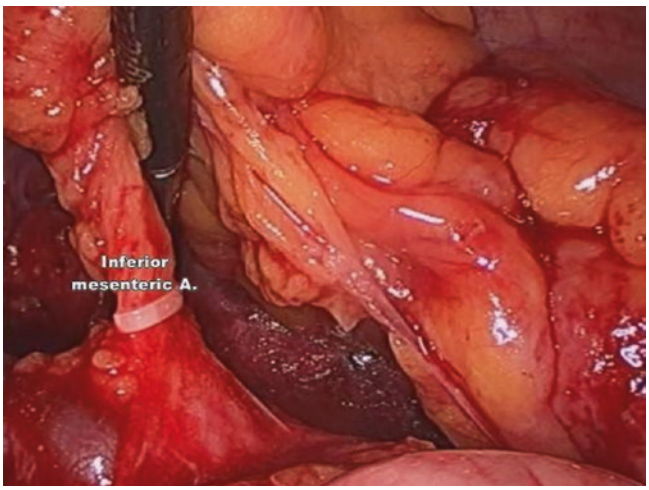

Fig. 45.31 Inferior mesenteric artery being clipped

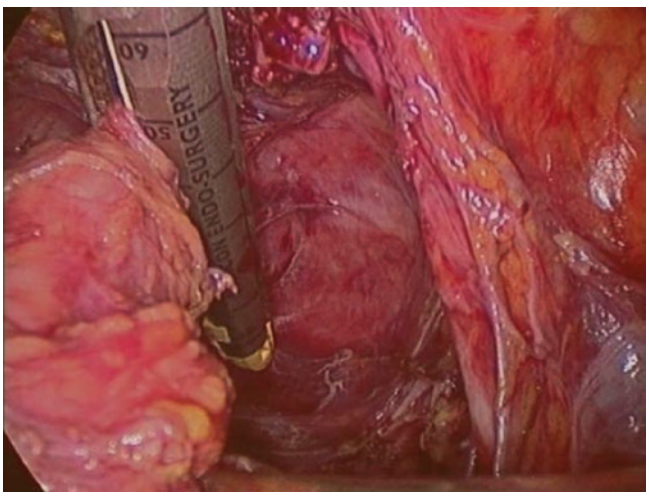

Fig. 45.32 Endostapler

Step 7

Although extraction of the specimen (Fig. 45.33)is possible vaginally, insertion of the anvil of the stapler in the colon is difficult via that route; thus, a suprapubic minilaparotomy of approximately 3 cm is used for specimen extraction. The remainder of the procedure was performed laparoscopically.

Thus, laparotomy is used for specimen extraction, proximal bowel transection and placement of the anvil of the end-to-end anastomotic stapler in the mobilized proximal colon. Circular stapled anastomosis was performed (Fig. 45.34) as well as temporary colostomy. Thus, posterior exenteration involves removal of the rectum, uterus, and vagina, and vulva if necessary.

Step 8

Fibrofatty lymphovascular tissue along the external iliac veins and the obturator nerves is removed (Fig. 45.35). The type of radical hysterectomy performed according to the new classification for radical surgery was type C2.

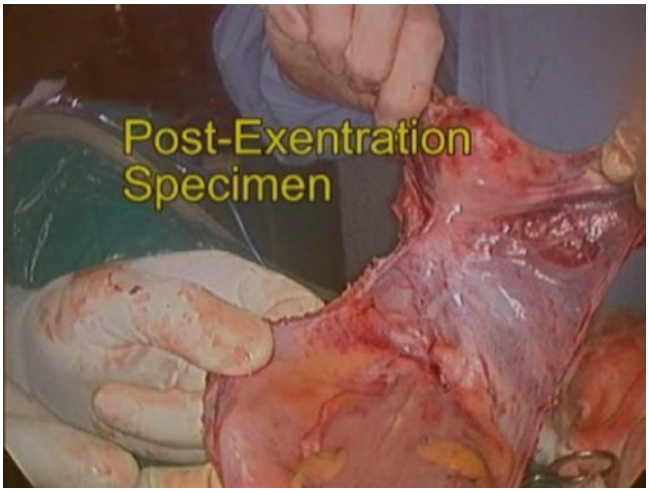

Fig. 45.33 Specimen of posterior exenteration

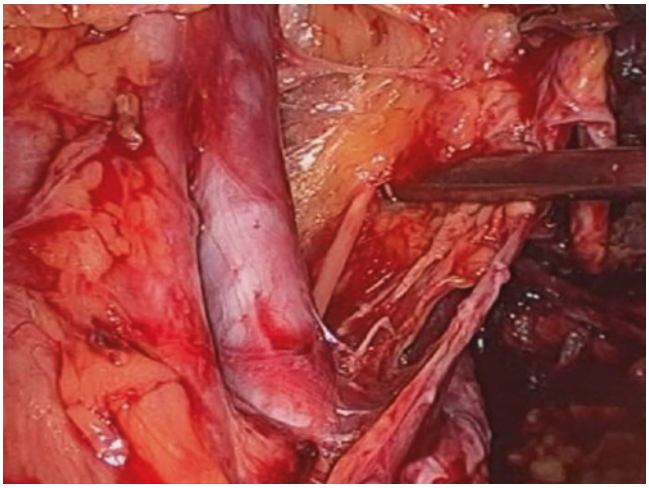

Fig. 45.35 Ilioobturator lymph node dissection

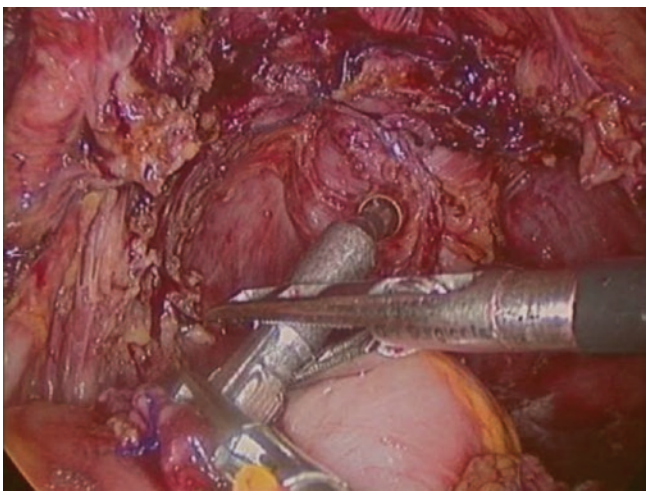

Fig. 45.34 Circular stapler

Complications

- Delayed bladder recovery
- Surgical site infection
- Anastamotic leak
- Prolonged ileus

Successful colostomy reversal is performed after 4–6 weeks in six patients with a temporary colostomy.

Laparoscopic Radical Hysterectomy (LRH) with Anterior and Posterior Exenteration: Urological Perspectives

46

Jens J. Rassweiler, Ali S. Gözen, Marcel Fiedler, and Jan T. Klein

Introduction

Laparoscopic and robot-assisted radical cystectomy has become an established procedure in the management of muscle-invasive bladder cancer and even accepted in the actual EAU-guidelines [1]. In a recent study coordinated by the EAU-section of uro-technology (ESUT) 18 % of patients were female [2], but the number is increasing due to the higher proportion of smoking women. Even, if there are forms of uterus-sparing of radical cystectomy, the vast majority of women undergo *anterior exenteration* with and without ovarectomy depending on the age of the patient. Based on this, the urologist is familiar with the anatomic details of such an operation regardless whether it is open, laparoscopic or robot-assisted [2, 3]. In gynaecology, the main indications include invasive carcinoma of cervix stage IVA and IVB, respectively advanced endometrial cancer with isolated invasion in the bladder (FIGO IVA) and stage T3 (FIGO III) of vulvar cancer [4–9].

In contrast, *posterior exenteration* is performed very rarely in patients suffering from advanced bladder cancer because the vagina represents an anatomical barrier for tumour infiltration. Such procedures are usually indicated as a salvage procedure (i.e. following radiotherapy of cervix carcinoma; advanced carcinoma of cervix or endometrium with invasion of bladder and rectum (FIGO IVA). Due to the complexity of this operation, it is mainly performed by open surgery in cooperation with a team of abdominal surgeons rather than by means of minimally invasive surgery [10, 11].

Therefore, we want to focus on technical aspects and outcome of *laparoscopic anterior exenteration*, which might be also indicated in advanced stages of cervical and endometrial cancers as well as in rare cases of carcinoma of the vulva respectively other tunours invading the vulva such as melanoma in combination with vulvectomy [6].

Beside the ablative part, the *form of urinary diversion* becomes an important factor with significant impact on the quality of life for the patient, but also regarding complexity and morbidity of the procedure particularly when performed laparoscopically [12–14]. There is an increasing experience with laparoscopic or robot-assisted ileal conduit and neobladders in the literature. Whereas advantages of the ablative part of operation have been demonstrated, it is still controversial about benefits of the complete intra-corporeal technique versus an extracorporeal approach extending the incision required for removal of the specimen [14, 15]. In women, however, the specimen can be extracted via the opening of the vagina [12]. Nevertheless, until now, there is no consensus, which approach offers the best option for the patients.

Indications for Laparoscopic Anterior Exenteration

Since recently, similar oncological outcome could be shown in a large European trial, there are no differ from those of open surgery, including T1–3 stages of bladder cancer. In gynaecology, anterior exenteration is only indicated for advanced stages (FIGO IV) of carcinoma of the cervix uteri, endometrial cancers, as well as vulva carcinoma (FIGO III) respectively as salvage therapy following irradiation and local progression, vesico-bladder fistula [4–9].

Type of Urinary Diversion

The choice of the type of urinary diversion depends on various factors, such as age, compliance, local extension of disease. Basically one has to distinguish between

Table 46.1 Laparoscopic urinary diversion following anterior exenteration– technical steps and options

Operative step	Options	Comments
Transposition of ureter	Ileal-Conduit	Not for sigmoid-bladder
	Ileal-Neobladder (Studer)	Or ureterosigmoidectomy
		Not for Ileal-Neobladder (Hautmann)
Creation of reservoir	Intracorporeally	Technically difficult
		Stapler for GI-Anastomosis
		V-lock for neo-bladder
	Extracorporeally	Via mid-line incision
		Open technique
Conduit in females	Intracorporeally	Stapler for GI-Anastomosis
		Laparoscopic suture
	Extracorporeally (lap-assisted)	Via mid-line incision
		Open technique
Ureteral anastomosis	Intracorporeally	Sigmoid/Ileal-neobladder
		Sigmoid-pouch
		Ileal conduit
	Extracorporeally	Ileal neobladder (Studer)
		Ileal-pouch
Urethral anatomosis	Intracorporeally	All continent diversions (as first step)
		After re-insufflation (as last step)
	Extracorporeally	With laparoscopic pre-placed stitches

continent and incontinent diversion. The most popular form of incontinent diversion represents the ileal conduit. In selected case with one functioning kidney, ureterocutaneostomy might be an option. Continent urinary diversion includes a modified ureterosigmoidostomy with creation of a reservoir (Mainz-Pouch II), ileal neobladder, and various forms of catherizable pouches attached to the umbilicus (Table 46.1).

Whereas ileal conduit can be performed in almost every patient, ileal (sigmoid) neo-bladder requires some preliminaries: (i) the tumour has not infiltrated the bladder neck, (ii) the patient is able to manage the use of the neo-bladder including possibility to self-catheterize. A pouch can be also performed is almost all situation, however, represents a complex procedure and requires also the ability to self-catheterize [12, 16].

The patient has to be informed about all variation of urinary diversion. For this purpose, we administer an enema of 300 cm^3 of physiologic sodium chloride solution transanally and recod the time, the patient can hold this in the rectum. If the holding time is below 60 min, the patient should not undergo a continent diversion using a sigmoid pouch (ie Mainz-Pouch II). The use of ureterosigmodostomy without pouch has been abandoned. Additionally, we place a urostoma bag filled with 200 cm^3 of normal saline on the right side of the body to check the appropriate position of the stoma of an ileal conduit (Fig. 46.1). Since the rate of hypercontince of a neobladder in women may reach up to 30 %, women should be mentally and physically able to perform self-catheterization.

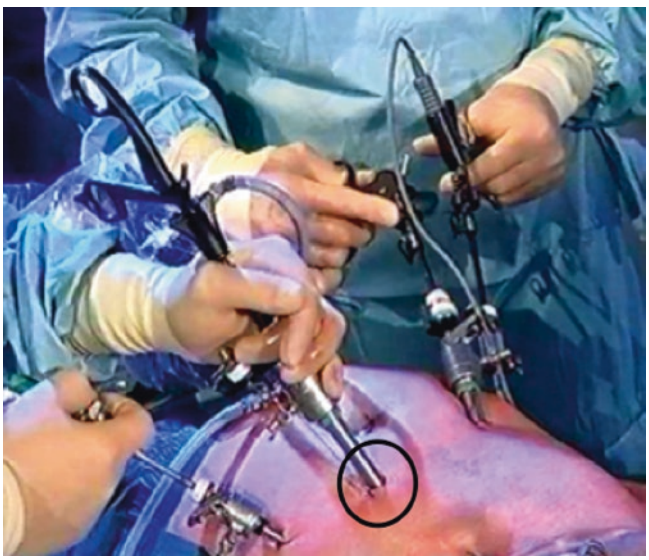

Fig. 46.1 Port placement for laparoscopic anterior exenteration – the right medial trocar entrance is used for the urostoma (*black circle*)

Patient Preparation

Initially, the bowel was prepared by oral self-administration of 2 l of electrolyte lavage solution during two days before the surgical procedure. However, we have changed this to a classical form of bowel preparation by administration of laxatives. It is important to hydrate the patient during the preoperative night (ie. 1500 ml electrolyte solution i.v) to

improve renal function during the procedure and minimize the risk of hyperhydration by the anaethesiologist, which has a negative impact on the healing of bowel anatomosis.

Antibiotic prophylaxis with a cephalosporin (2 × 2g) and metronidazole (3x500 mg) is performed from day 1–5 and low molecular weight heparin (4000 units) is administered preoperatively and until the postoperative day 15. Compression stockings are applied as the patient is placed in supine position with the legs apart to allow free access to the vagina. The table is set to a 30 ° Trendelenburg position. An 18F-Foley catheter is inserted to drain the bladder and a nasogastric tube is positioned. As the lower limbs are carefully strapped to the table without compressions, no shoulder pads are necessary.

Technique of Laparoscopic Anterior Exenteration

Equipment

The technique is challenging, requiring state-of-the-art laparoscopic infrastructure and expertise. Using a five- or six-port transperitoneal approach (Fig. 46.1) anterior exenteration in combination with extended pelvic lymph node dissection is performed. Standard laparoscopic surgical equipment with few special instruments is required (Table 46.2). This may include an endoscopic stapler (i.e. Endo-GIA) for control of the pedicles of the bladder and eventually for the intracorporeally performed intestinal anastomosis. The use of an ergonomic chair like ETHOS might be very useful during the procedure (Fig. 46.2).

	1

Fig. 46.2 Use of ergonomic chair (ETHOS, United States) with arm rest an chest support during laparoscopic anterior exenteration. The surgeons sits over the head of the patient

Trocar Placement

The patient is in supine position, with the lower limbs slightly (15 °) abducted. A 30 ° flexion is given to the knees, to define accordingly the value of Trendelenburg position. Extension of the hips should be avoided to prevent any backache. In male patients, the technique can be also performed with the legs in a paralell, non-abducted position.

The first 10 or 13 mm trocar is placed 1 cm above the umbilicus, using an open Hasson-technique through a mini-laparotomy. This trocar is reserved for the 30 °-laparoscope. The remaining four ports are placed under endoscopic control after establishment of the pneumoperitoneum (12–15 mmHg, high flow; AirSeal-Insufflator, Dach Medical Group, Freilassing. Germany).

At the « left Mac Burney » point a 12 mm diameter port is used, which can also be used to ease the retrieval of pelvic lymph nodes after dissection. At the true right Mac Burney point, another 12 mm trocar is placed to accept larger instruments (i.e. 10 mm-clip-applicator, right-angle dissector, needle with reducer-sheath, Endoscopic stapler) if necessary. Two 5 mm trocars are placed at the horizontal level of the navel, lateral to the 10/12 mm trocars. Optionally, on the midline, a 5 mm trocar is placed,.

During diagnostic laparoscopy the abdomen and pelvis are inspected focussing on possible peritoneal metastases. If necessary, intestinal adhesions are released by blunt and sharp dissection.

Posterior Dissection

The posterior dissection starts at the level of the recto vaginal space. As described in laparoscopic surgery for prolapse, the posterior vaginal bottom is lifted by the second assistant with a curved metal retractor, exposing immediately the recto- vaginal space to blunt and sharp dissection (Fig. 46.3a). This dissection is extended laterally to the ischio-rectal fossae (Fig. 46.3b).

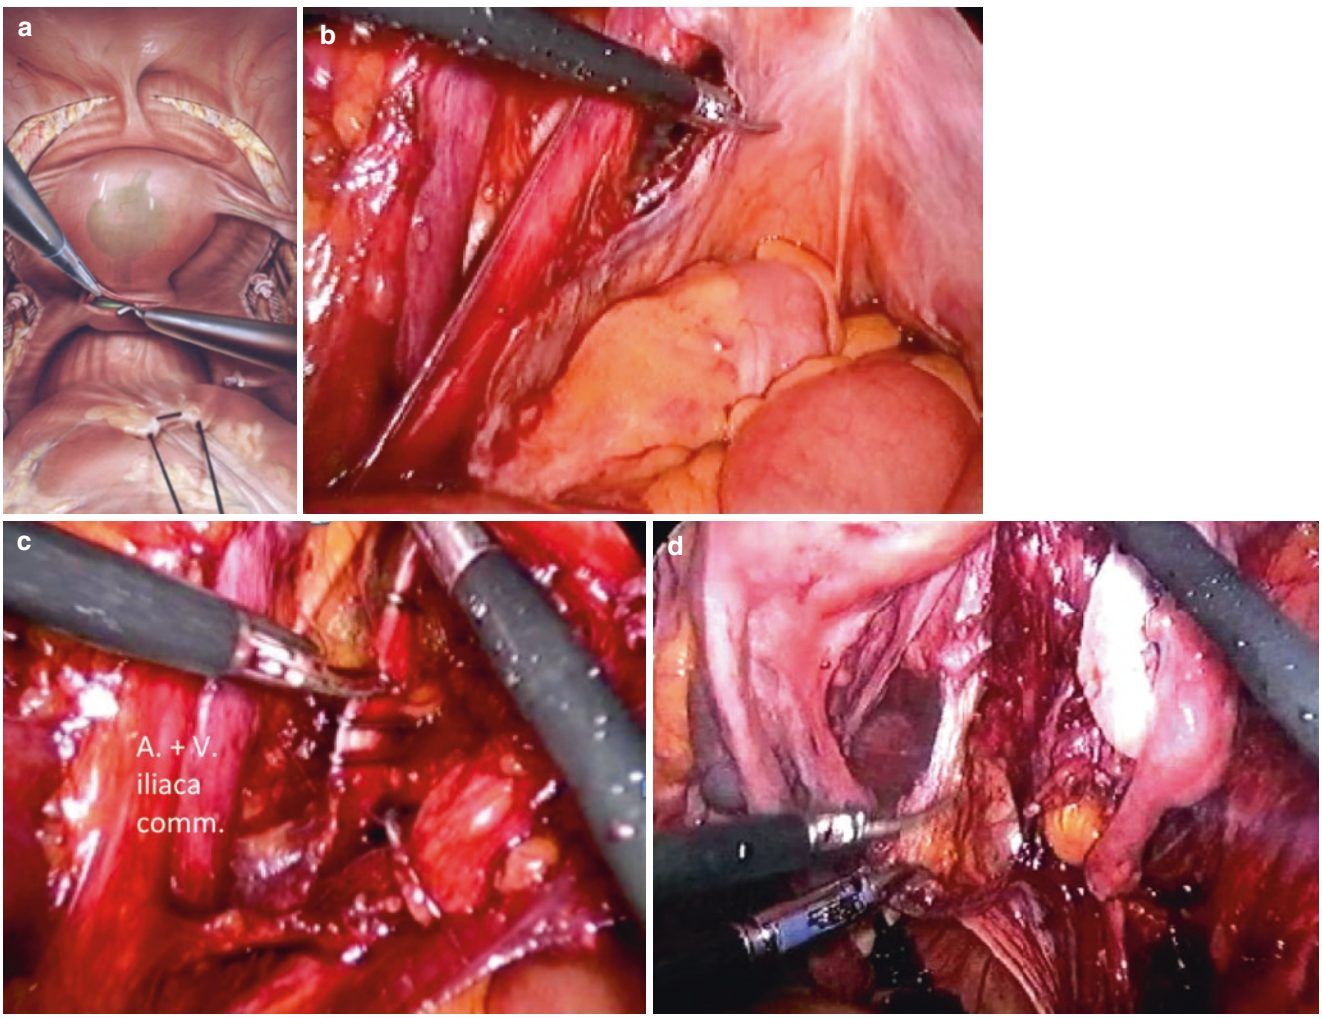

Fig. 46.3 Technical steps of laparoscopic anterior exenteration. (**a**) Posterior approach to the cul de sac, uterus and vagina. Note retraction stich of the sigmoid. (**b**) Incision of the peritoneum cranial to the sigmoid. (**c**) Division of the proximal pedicle (A. vesicalis sup.) on the right side between 10 mm Titanium-clips. (**d**) Transection of adherences between sigmoid and vagina. Both ovaries are included en-bloc in the specimen. Both uterine arteries have been clipped and divided

Table 46.3 Laparoscopic anterior exenteration–technical steps and options

Operative step	Options	Comments
Positioning of Patient	Deflected Supine Lithotomy	For all female patients
Trocar arrangement	Semilunar W-shaped	In case of ileal conduit one port = Urostoma
Transperitoneal access	None	Similar to open surgery
Incision of Douglas Pouch and retrovesical dissection	None	None
Pelvic lymph node dissection	Extended	According to indication
Division of ureters	None	None
Division of ovarian and uterine vessels	Endo-clips	For female patients
Division of umbilical ligaments and pedicles	Endo-GIA Hem-o-lock® Ligasure® Ultracision®	According to surgeon
Suturing of dorsal vein	None	None
Division of urethra	Closed by catheter Closed by clip	According to technique
Incision of anterior vagina	None	None
Entrapment of specimen	Organ-bag intra-abdominally Transrectally	None
Retrieval of specimen	Mini-laparotomy Transvaginal	Periumbilical, mid-line Pararectal Preferable in women

Exposure of Ureter and Iliac Vessels

If pelvic lymph node dissection is done primarily, the peritoneal incision starts at the level of the first peritoneal fold to find and dissect the ureters. The lateral incisions of the parietal peritoneum are extended to the internal inguinal ring. Then, both ligamenta teres are divided and retracted medially to expose the medial aspect of the external iliac vessels. Pelvic lymph node dissection is done on each side, as already described in view of frozen sections. The subsequent dissection and antegrade division of ureters and upper vesical pedicles are then carried out (Fig. 46.3c). In case of an anterior exenteration, removing the bladder and uterus together with the ovaries (Fig. 46.3d), this step includes the division of the ovarian vein (Table 46.3).

Anterior Dissection

Umbilical ligaments and urachus are divided and the prevesical space is opened and bluntly dissected to expose the anterior aspect of the bladder until the bladder neck, urethra and anterior wall of the vagina. Opening of the endopelvic fascia allows the dissection to be continued until the lateral aspects of the urethra, which is dissected completely, secured between clips and transected. A metal retractor might be moved to the anterior vaginal bottom to enable the dissection of the urethro-vaginal space, which is developed in a retrograde way after section of the urethra. Preoperative packing of the vagina can be used for the same purpose.

If an *orthotopic bladder replacement* is planned, a maximal urethral stump is then preserved in view of the anastomosis (Fig. 46.4a–e). According to patient's age and expectations, cystectomy may be carried out with vaginal and uterine preservation [16]. More often, according to the tumour burden and stage, the uterus and part of the vagina may need to be taken with the bladder.

The section of the vaginal anterior wall is carried out with the help of the retractor, giving a flat horizontal shape to vagina ; the gas leak during section of the vagina is prevented by packing the vagina or by the fingers of the assistant. The use of a high-flow insufflator (ie. AirSeal, Dach Medical Group, Freilassing. Germany) is very helpful. Then, the specimen can be extracted transvaginally preferably in an Endobag.

Removal of the Specimen

In advanced cases, even for this manoeuver entrapment of the specimen in an organ-bag is recommended to minimize the risk of tumour cell spillage. Finally, the vagina is repaired and closed with continuous sutures (Fig. 46.5 ; i.e. V-lock, 30 cm, SH-needle).

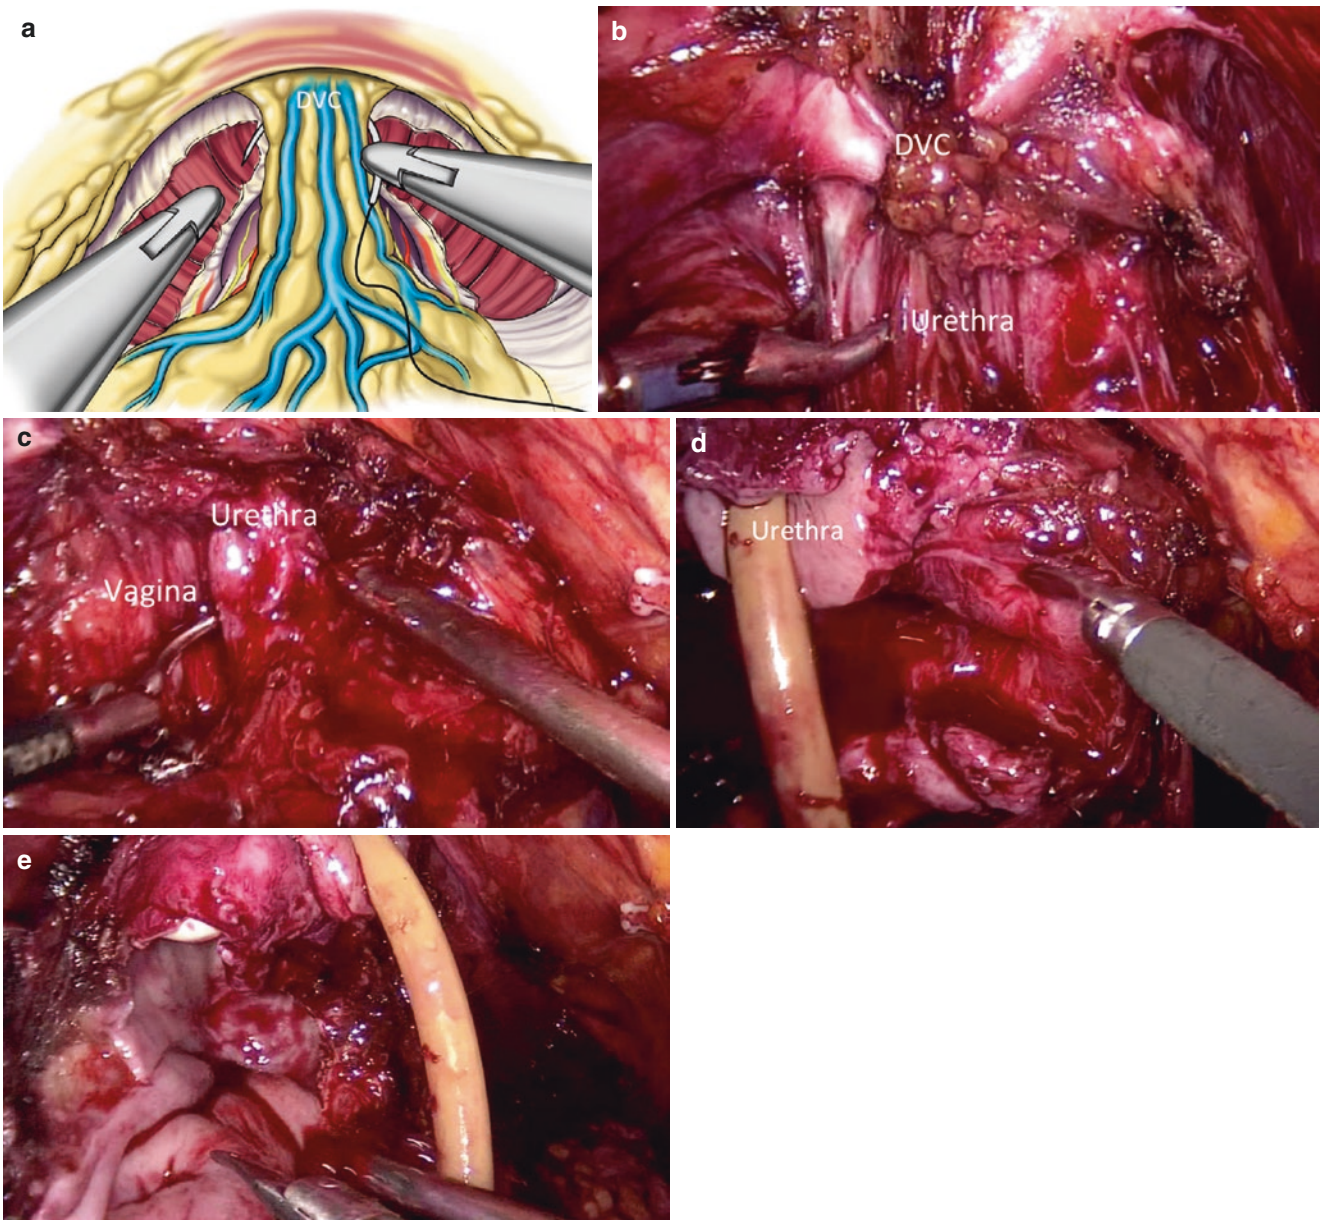

Fig. 46.4 Technical steps of dissection around the urethra during laparoscopic exenteration with formation of an ileal neo-bladder. (**a**) Suturing of the dorsal vein (Santorini's plexus) with an MH-needle (Vicryl, 15 cm or using a barbed suture (V-lock, 30 cm, SH-needle; Ethicon, Conneticut, United States). (**b**) Preservation of pubo-vesical collar and levator fascia lateral to the urethra to improve postoperative continence due to reduced injury to intrapelvic branches of pudendal nerve. (**c**) Posterior dissection of the urethra providing a long urethral stump. (**d**) Transection of the urethra at the level of the bladder neck with indwelling Foley catheter. (**e**) Opening of the vagina preserving a long anterior part. Note the finger of the assistant exposing the urethra and providing sealing of the vagina to minimize loss of carbondioxide

Table 46.4 Distribution of urinary diversion in the ESUT-study on laparoscopic cystectomy

Urinary diversion	
Bricker	345 (69 %)
Ureterocutanostomy	10 (2 %)
Mainz II	8 (2 %)
Orthotopic neobladder	128 (25 %)
Continent pouch (Kock, Indiana)	12 (2 %)

Urinary Diversion

Depending on the gender, age of the patient as well as on the specific indication several types and techniques of urinary diversion can be performed (Table 46.4).

Laparoscopic Assisted Ileal Conduit

Completely Intra-Corporeally Construction of Ileal Conduit

In the female patient, following closure of the vagina (Fig. 46.5), the formation of an ileal conduit can be carried out completely laparoscopically. First step represents the transposition of the left ureter (Fig. 46.6a, b). Subsequently a 20-cm ileal segment is isolated by use of an endoscopic stapler (Fig. 46.6c). The ileo-ileal anastomosis is performed with antimesenteric side-to-side stapling and closure of the remaining opening by endoscopic suturing. Then, the distal end of the ileal segment is pulled out via an enlarged trocar incision in the right lower abdomen and sutured to the skin (Fig. 46.6d). Via the so created urostoma, single-J-stents can be introduced, and both ureters are stented and sutured to the ileal conduit in a modified Wallace-type (Fig. 46.6e) technique or individually using interrupted sutures, according to the Bricker's technique (Fig. 46.6d).

Extracorporeal Creation of Ileal Conduit

For most patients, the ileal conduit usually is performed laparoscopically assisted. The extended peri-umbilical mini-laparotomy for retrieval of the specimen is used for the isolation of the 20-cm segment of the distal ileum in an open technique (Fig. 46.7a, b). The ileo-ileal anastomosis is performed by interrupted seromuscular stitches, and the ileum is brought back into the abdominal cavity. Next step represent the uretero-ileal anastomosis using an open technique (Fig. 46.7c). Subsequently, the 10 mm trocar incision in the right lower abdomen is used as ileostoma (Fig. 46.7d): the trocar incision has to be enlarged allowing the pulling of the distal conduit end through the wound, and suture it to the rectus fascia and skin. After placement of two single-J-stents the ileal segment is manipulated back into the abdominal cavity, the periumbilical incision is closed, and the pneumoperitoneum re-established. The separate use of two trocar incisions offers the advantage of a better cosmetic result of the urostoma, and thus minimal problems with the adhesive plates.

Intracorporeal Uretero-Ileal Anastomosis

Alternatively the uretero-ileal anastomosis can be performed laparoscopically, the already transposed left ureter is sutured to the right one in a Wallace fashion (i.e. Vicryl 3/0, RB1-needle). Then both ureters are stented by insertion of the single-J-stents, and sutured to the ileal conduit using interrupted or continuous sutures.

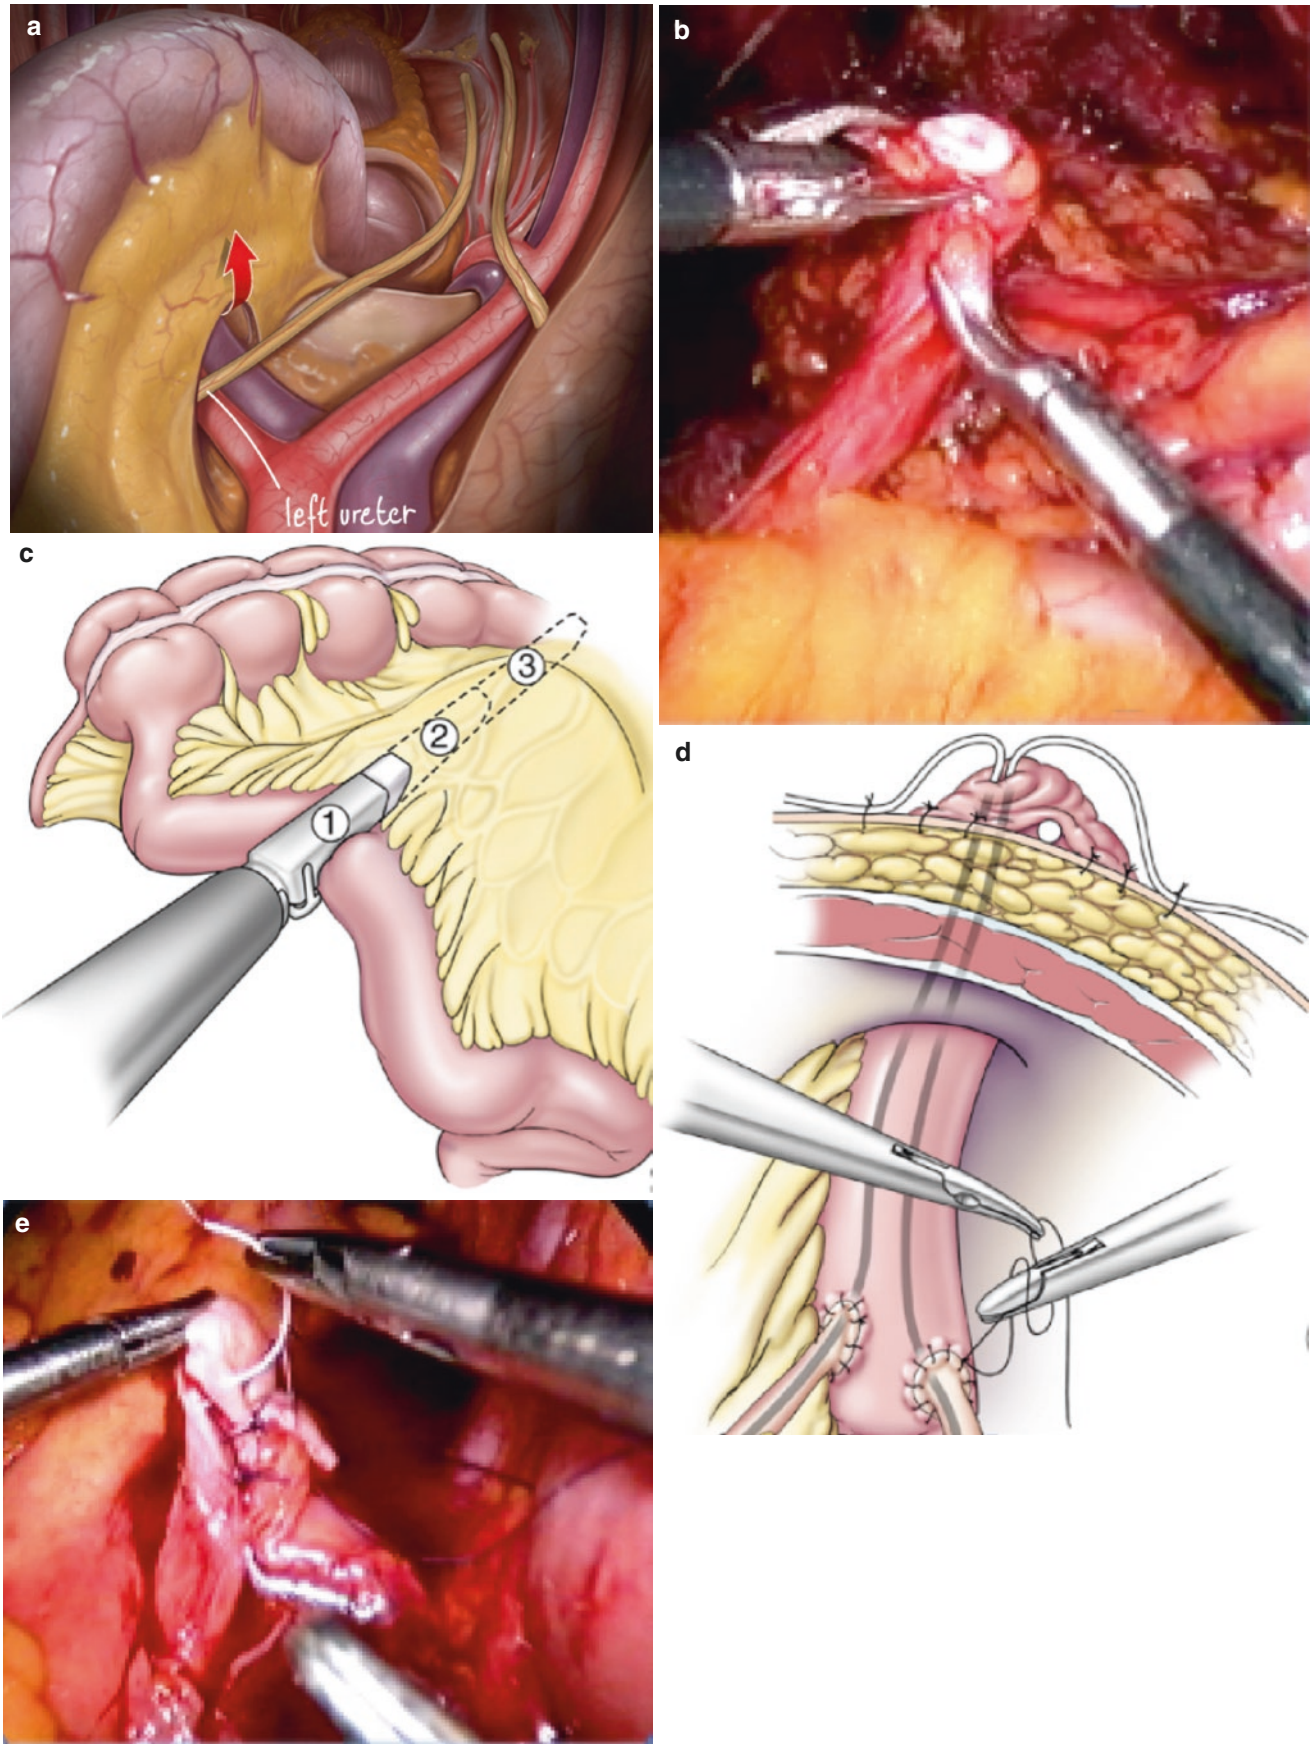

Fig. 46.6 Technical steps of laparoscopic intra-corporeal ileal-conduit. (**a**) Transposition of the left ureter under the meso-sigma, which is facilitated by the previous extended pelvic lymph node dissection (Level I and II). (**b**) Spatulation of the ureter. (**c**) Isolation 20 cm terminal ileum using endoscopic stapler. (**d**) Wallace end-to-side anastomosis of both ureters. (**e**) Fixation of the conduit at the skin; here use of to individual uretero-ileal implantation sites

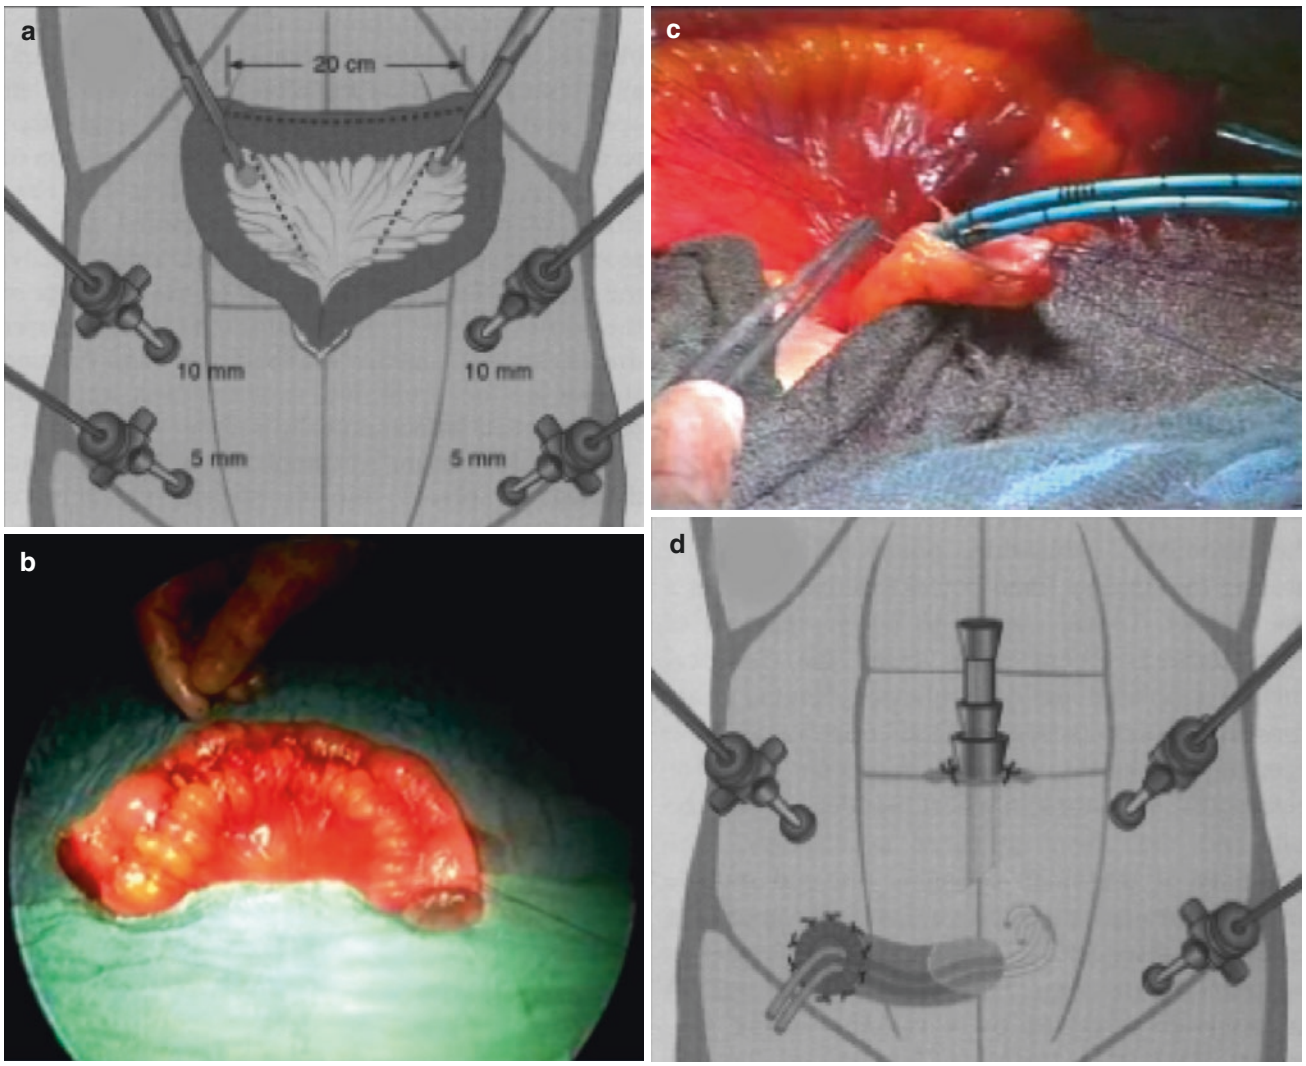

Fig. 46.7 Technical steps of laparoscopic-assisted extra-corporeal ileal-conduit. (**a**) Isolation of the ileal segment via a sub-umbilical incision using open technique. (**b**) Isolated ileal segment, the ileo-ileal end-to-end anastomosis has been performed and the restored ileum carefully replaced intraabdominally. (**c**) Uretero-ileal anastomosis performed in an open technique. (**d**) After accomplishing the urostoma, the abdomen is reinsufflated to check the correct position of conduit and anastomosis

Laparoscopic Assisted Orthotopic Neo-Bladder

This procedure represents the most frequently applied technique of urinary diversion following laparoscopic radical cystectomy, however in the advanced indications in gynaecology they cannot be applied in most cases due to involvement of the bladder neck and urethra.

Extra-abdominal Construction of the Ileal Neobladder

The orthotopic neobladder pouch is created by suturing opened small bowel together to form a new bladder. Like usually, a 55- to 60-cm segment of ileum located 15 cm away from the ileocecal junction is isolated and detubularized, leaving intact a proximal 10-cm isoperistaltic afferent Studer limb segment. As a function of surgeon's skills or preferences, an Hautmann's ileal bladder can be built as well and the bowel prepared accordingly. The continuity of the small bowel is restored outside the body through the incision made for specimen retrieval. Subsequently, a spherical neobladder is constructed extracorporeally. The anterior wall of the reservoir is closed by a running suture (i.e. PDS 3/0 with straight needle; Vicryl 3/0 ; SH-needle) ; the caudal part of this closure is left open in view of the neo-vesico-urethral anastomosis.

Uretero-Ileal-Anastomosis

A termino-terminal uretero-ileal anastomosis is then performed through the same incision, according to Wallace or to Bricker. Ureters are intubated with 8 Fr. smooth catheters

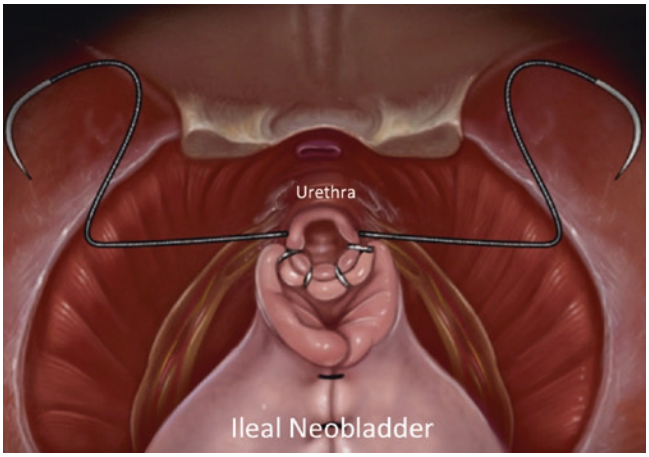

Fig. 46.8 Laparoscopic assisted extracorporeal neo-bladder: urethra-vesical anastomosis using van Veltoven-technique as last step of the procedure

temporarily attached to the posterior wall of the pouch with quickly absorbable sutures (Vicryl rapid ® *2/0)*. Both catheters are exteriorized through the anterior wall of the pouch, and subsequently, will be passed through the abdominal wall.

Urethral Anastomosis

When the pouch is ready, it is placed into the abdomen and the mini-laparotomy is closed classically. The 10 mm trocar is replaced for the telescope in an infraumbilical position and the pneumo-peritoneum re-insufflated.

After appropriate positioning of the ileal neo-bladder in its orthotopic position a « vesico » urethral anastomosis is started between the ileal orifice left open and the urethral stump using a single-knot technique (van Velthoven) minimizing the tension of the tissue (Fig. 46.8). The suture is started at six o'clock on the ileal edge of the suture ; two 6–7 in. of 2/0 PGA monolayer threads knotted together are used ; two hemi-running sutures are then built until twelve o'clock where the only knot tied intracorporeally is done.

When this suture is completed, a Jackson-Pratt drainage is placed into the pelvis ; the tube is exteriorized through a trocar hole in the right fossa. Fascial incisions of 10 mm are closed with interrupted sutures. The skin is closed with surgical staples.

Intra-corporeal Laparoscopic or Robot-Assisted Neo-Bladder

The entire neo-bladder can be also performed laparoscopically as a sigmoid-neobladder [12]. However, most experience exists with the ileal-neobladder replicating the Studer-neobladder. This includes mainly seven steps (Table 46.5). Evidently, this represents a very complicated procedure

Table 46.5 Surgical steps of robot-assisted intra-corporeal laparoscopic orthotopic neo-bladder

Choice of longest ileal segment and urethro-ileal anastomosis
Isolation of 60 cm ileal segment using endoscopic stapler
Ileao-ileal anastomosis using endoscopic stapler
Anti-mesenterial incision of ileal segment preserving the distal end for uretero-ileal anastomosis
Continuous suture of posterior wall of neo-bladder
Closure of anterior wall of neo-bladder
Stenting of both ureters
Uretero-ileal anastomosis

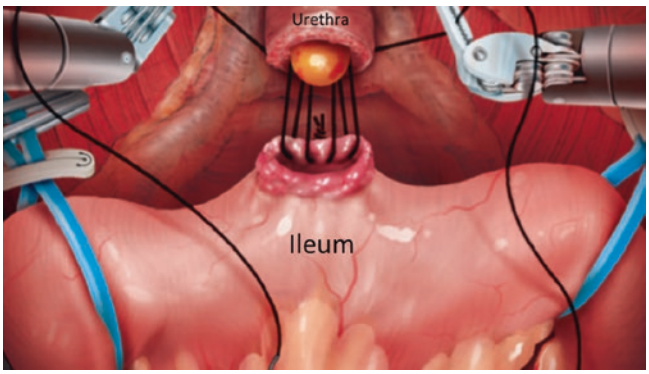

Fig. 46.9 Robot-assisted intracorporeal neo-bladder: anastomosis between urethra and ileal loop ad first step of urinary diversion

even with the assistance of the Da-Vinci-robot [17]. The main advantage represents the fact, that the first step includes urethro-ileal anastomosis (Fig. 46.9) thus minimizing the tension on anastomosis.

Laparoscopic Assisted Sigmoid-Pouch (Mainz-Pouch II)

The Mainz-Pouch II has been used frequently in women, due to the problems of "hypercontinence" with ileal neo-bladders ranging up to 30 % of the patients. However, this technique requires adequate control of the anal sphincter. The procedure can be performed completely laparoscopic or laparoscopic-assisted creating the sigmoid-pouch via a 10 cm- midline incision respectively using a Pfannenstiel incision.

Postoperative Management

In the first night, all patients were monitored on the intensive care unit for vital parameters monitoring and adequate pain management. Parenteral nutrition was continued until complete oral feeding (i.e. day 3–5). The drains are removed

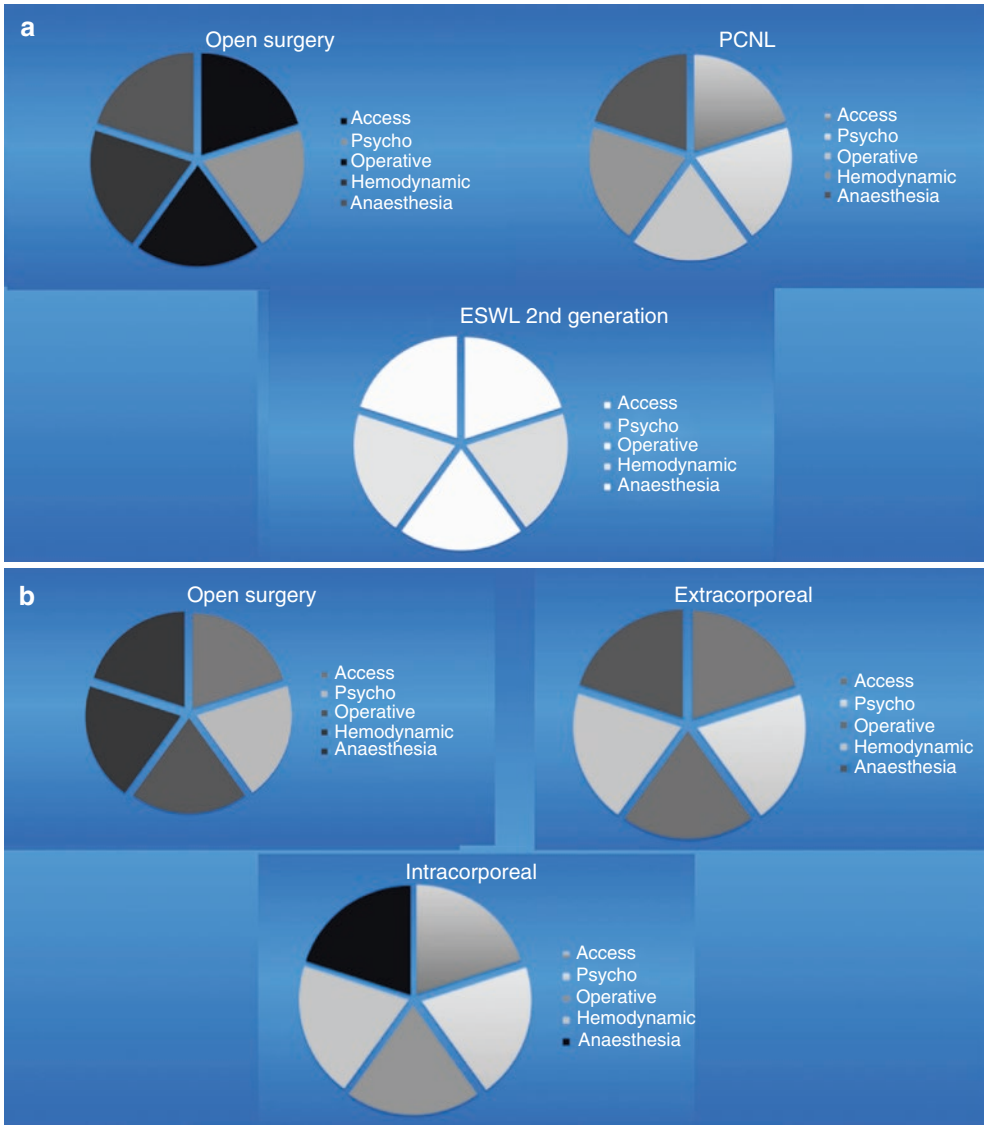

Fig. 46.10 The impact of minimally invasive techniques on the outcome of the procedure (according to Wickham 1991). (**a**) The introduction of percutaneous nephrolithtomy (PCNL) and extracorporeal shock wave lithotripsy (ESWL) significantly improved all five relevant aspects of a surgical procedure (*white* = no problems, *black* = significant problems). (**b**) The introduction of extracorporeal and intracorporeal radical cystectomy with urinary diversion has also reduced some of the five aspects, but on the other hand the associated morbidity might be increased (*white* = no problems, *black* = significant problems)

after reduction of secretion below 50–100 ml. On day 10 and 11, the ureteral stents are removed. Following a cystogram, the urethral catheter of neo-bladders is removed on postoperative day 14–18 (Fig. 46.10), after 48 h of intermittent clamping every 2 h.

Results

Of note, median LN retrieval in the *European Study* was 14 nodes (IQR 9–17). Positive surgical margins (PSM) were detected in 29 specimens (5.8 %): 26/29 PSM were found in patients harboring extravesical disease (11 had pT3, 15 pT4). This underlines, hat laparoscopic technique allows to perform adequate pelvic lymph node dissection.

Minor complications (Clavien I-II) occurred in 39 % (195/503) of patients, with post-operative infections requiring antibiotic therapy being the most frequent (Table 46.6). Major complications instead (Clavien IIIa-IVb) were found in 17 % (85/503) of patients in the early (<30 days) post-operative period. Specifically, 60 patients (12 %) underwent a second surgical operation of which 18 (4 %) due to bowel leak/peritonitis, 8 (2 %) for a urinary leak/fistula, 6 (1 %) for operative management of abdominal wall defects, 5 (1 %) for adhesiolysis due to occlusive syndrome, 3 (0.5 %) for surgical drainage of infected intraabdominal collection and 2 (0.5 %) for post-operative bleeding. Finally six patients (1 %) were re-operated for other causes (including endoarterectomy, ureteral reimplantation, fasciotomy, preputium necrosis), and in 12 patients the cause of re-operation was unknown. Clavien IV complications occurred in five patients (1 %), notably 2 acute respiratory failures (IVa), 1 acute renal failure (IVa), 1 septic multi-organ failure (IVb) and finally 1 patient experiencing both a Clavien IVa (respiratory distress)

Table 46.6 Postoperative complications of European Study on Laparoscopic Cystectomy

Post-op complications	
Clavien I	71 (14 %)
Clavien II	140 (28 %)
Clavien IIIa	29 (6 %)
Clavien IIIb	60 (12 %)
Clavien IVa	4 (1 %)
Hospital stay*(days)*	14 (10–20)
Median (IQR)	18 ± 15

and a Clavien IVb (septic multiorgan failure) complication. The rate of Clavien V complications was estimated at 2 %, with ten patients dying in the early postoperative period principally as a consequence of septic multi-organ failure. Conversion to an open procedure occurred in 12 cases (3.4 %), and depended on different factors ranging from extensive intra-abdominal adhesions to uncontrollable bleeding.

Oncologic Outcomes

There is no doubt, that the prognosis of anterior exenteration for advanced disease (FIGO IV; T4 TCC) is poor. Even in the European Study of laparoscopic cystectomy with D a median follow-up 52 months, 134 recurrences were detected and 118 (23 %) were due to metastatic disease, 14 (3 %) were local and 2 (0.5 %) urethral recurrences. 343 patients are alive and free from disease, 108 died as a consequence of bladder cancer (10 in the early post operative period, 98 due to disease progression), and 52 died of non-cancer specific causes. Actuarial RFS, CSS and OS rates were calculated at 74 %, 82 % and 79 % after 2 years; 66 %, 75 % and 62 % at 5 years; 62 %, 55 % and 38 % at 10 years. Patients with positive surgical margins experienced the worst survival outcomes, with 2- and 5 year OS rates of 31 % and 16 %, respectively. Tumor stage and node involvement were significant predictors of RFS, CSS and OS (all $p < 0.0001$). Notably, no port-site metastases were detected during the entire follow-up of this cohort.

Discussion

Anterior exenteration plays an important role in the management of muscle-invasive bladder cancer in women, representing 18–20 % of patient population [2]. In rare cases of advanced gynaecological tumours stage FIGO IV it may be also indicated [7, 8]. The procedure can be accomplished laparoscopically, but it represents a challenging operation. On the other site, laparoscopy in experienced hands has significantly reduced blood loss of this procedure. Most of the serious complications (Clavien III–IV) are not related to the ablative part, but to the urinary diversion ([7]; Table 46.6).

There is still the debate, whether the urinary diversion should be performed completely intracorporeally or extracorporeally extending the incision required for removal of the specimen. In women, the specimen can be extracted transvaginally. Thus, an additional incision becomes necessary. The main argument against the entire laparoscopic approach represents the technical difficulty of the procedure including bowel anastomosis, uretero-intestinal-anastomosis, stent placement which may be very time-consuming with the hazard of severe postoperative complications (Table 46.6). Even in the hand of the most experienced surgeons the OR-times are very long, which also adds to the associate trauma of the procedure [18].

In case of anterior exenteration for gynaecological indications, usually a neo-bladder is not indicated. This means, that an ileal conduit will be mostly performed. This might be easier, however, we still encountered some complications when doing the procedure intracorporeally, such as a fistula between conduit and ileum at site of intestinal anastomosis. Moreover, it is important to follow all surgical steps established in open surgery to minimize the risk of complications [18]. When using a sigmoid-pouch (Mainz-Pouch) for urinary diversion, we did not perform a sacropexy of the pouch, which resulted in formation of a sigmoidal-vaginal fistula. On the other side, to perform urinary diversion extracorporeally has the advantage of a significantly shorter operating time. Thus, the combination of laparoscopic anterior exenteration with extracorporeal ileal conduit may represent an ideal form of minimally invasive surgery for such extended cases. This can be nicely demonstrated when using the Wickham Wheel ([19]; Fig. 46.10).

In the future, further experience with robot-assisted radical cystectomy and urinary diversion may alleviate to perform the procedure [5, 17, 20]. This could include the use of easier-to construct neo-bladders (i.e. T-pouch, Y-pouch), the use of absorbable staplers and better suturing techniques. Actually, robot-assisted anterior exenteration with intracorporeally urinary diversion is still experimentally.

LRH with Anterior and Posterior Exenteration: Surgical Perspectives

47

Gwenael Ferron, Juan J. Torrent, Christophe Pomel, Bernard Malavaud, D. Querleu, and Alejandra Martinez

Introduction

Pelvic exenteration (PE) is the most radical surgery performed in gynecologic oncology. Pelvic exenteration is the only therapeutic approach for the management of pelvic relapse within irradiated fields or in locally advanced tumors resistant to radiochemotherapy.

Over the last decade, the selection criteria have been refined. The surgical technique has substantially evolved, with the development of new haemostatic devices, description of laterally extended endopelvic resection and mainly to the systematization of complex reconstruction techniques of the vagina, perineum, urinary and digestive tract.

Indeed, many reconstructive surgical techniques are available to re-establish pelvic functions lost after an exenterative procedure. Surgical methods have been developed and validated to increase quality of life, enabling assessment of the relevance of reconstructive surgery for patient's well-being. In addition, reconstruction procedures contribute to avoid the empty pelvis syndrome and therefore result in an additional benefit in reducing the pelvic complication rate.

This complex surgery requires highly qualified surgical, anaesthesiology, and paramedical teams. It is associated with a high complication rate and a consequently a long average hospital stay.

The denudated and irradiated pelvis represents the source of complications, such as bowel obstruction and bowel fistula formation. However, the use of non-irradiated colon for urinary diversion decreases fistula rate, and the pelvis filled by a musculocutaneous flap also greatly reduces complications like fistula or abcess. Association of complex reconstruction techniques (myocutaneous flap for vaginal reconstruction associated to a continent colic urinary diversion and digestive's restoration) improves quality of life and also postoperative courses.

Patient Selection for Pelvic Exenteration

An evaluation of the potential oncologic benefit is mandatory before proposing a patient pelvic exenteration, which is a mutilative procedure. Except in rare palliative indications for complex fistulas, only patients with relatively favorable long-term prognosis should be selected. The presence of extrapelvic visceral metastasis, of peritoneal disease, and/or macroscopic aortic lymph nodes metastasis are associated with a poor short-term prognosis and therefore are generally considered as a contraindication.

The objective of the surgery is to achieve free margins. The hypothesis of a residual tumor (R1 or R2) at the end of the surgery must be minimized. The contribution of new imaging techniques such as MRI and PET-CT has improved the preoperative assessment of tumor extent and the detection of distant metastases. Although preoperative imaging is helpful in detecting obvious contra-indications to exenteration, preoperative laparoscopic staging possibly associated with aortic lymph node dissection may be useful to further decrease the rate of abortive surgery.

The type of excision and organ removal must be adapted to the tumor location. The term 'exenteration" encompasses

© Springer International Publishing Switzerland 2018

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_47

a variety of surgeries, depending on the involvement of the pelvic organs and the required level of pelvic floor resection. Anterior, posterior, or total exenteration, with or without removal of the pelvic floor and perineum (supralevator, infralevator or extended) are described in the Magrina's classification [1].

Preoperative Preparation of the Patients

The extent of planned surgery determines the information given to the patient. The patient must be informed about potential resections, functional consequences and expected complications, including both body image and sexual function alteration. The available reconstruction techniques, the associated complications and potential benefit must be addressed. Information regarding the day-to-day management of diversion must be provided. Support of a nursing team, stomatologist, dietician and psychologist is mandatory. Placement of stomas must be decided with the patient before the surgery according to her morphotype and clothing habits. In case of continent pouch, urostomy is often placed in the umbilicus.

Even though it is not generally recommended in elective colic surgery, bowel preparation may be useful, particularly in the case of the creation of a continent urinary pouch.

Thorough preoperative assessment of the medical condition of the patient, active anesthesiologic management, including invasive monitoring and peridural analgesia are mandatory. Routine respiratory physiotherapy and early enteral and oral feeding have been found to shorten the postoperative stay.

Patient Selection for Laparoscopic Pelvic Exenteration

Pelvic exenteration as well as reconstruction techniques are feasable by laparoscopy [2]. The contribution of perineal approach to the laparoscopy allows to reduce the mean surgical time as well as to adapt perineal approach to oncologic rules [3].

The use of both new haemostatic tools and automatic suture devices allows to manage in well selected cases this type of surgery with reasonable mean surgical time.

Although the use of this technique is currently undertaken by only a few surgeons**,** its reproductibility is assured for the ablative phase and also for reconstruction techniques such as Miami continent pouch or ileal loop derivation.

Techniques of vaginal reconstruction are limited in laparoscopic approach with the impossibility to use the current reference rectus abdominis myocutaneous flap.

Indications for lparoscopic approach for PE must be limited to:

- patients with a locally advanced tumor or a small size isolated centro-pelvic relapse.
- non sexually active patients, without the need of "optimal" vaginal reconstruction. For young and sexually active patients, we believe that open surgery with rectus abdomininis flap (or vertical DIEP flap) represents the best option [4].

Gynecologists must keep in mind that such a technically challenging procedure needs to be used with caution, as special laparoscopic and oncologic experience is required.

In this chapter, we report our stepwise surgical procedure of laparoscopic supralevatori anterior (and middle, with complete vaginectomy) pelvic exenteration. In addition, specific steps for rectal resection in case of total PE are described. Lymp nodes dissection are not described here. Indications of pelvic and aortic nodes dissection are depending to results of PET-CT and to the patient medical history. In case of pelvic recurrence, lymphadenectomies have been routenelly previously performed.

Laparoscopic Pelvic Exenteration: A Three Step Procedure

Description of laparoscopic PE can be divided into three different phases [2, 3]:

Step 1: Laparoscopic Ablative Phase

Like in open surgery, anterior (and middle) PE with total vaginectomy represents a multimesovisceral resection including a total mesometrial resection and removal of the ureterovesical compartment. The dissection plans of PE have to be adjusted to the borders of pelvic compartments [5].

The dissection is stopped as soon as laparoscopic dissection is deemed sufficiently complete to later allow en-bloc removal of the specimen via perineal or vaginal approach. Additional steps adapted to each individual case are then performed before the loss of pneumoperitoneum secondary to later removal of the specimen.

Step 2: Laparoscopic Reconstructive Phase with Urinary Diversion Construction (Continent or Not) and Omental J Flap Harvesting

After a complete laparoscopic mobilization of the right colon and both ureters, the urinary diversion is created extracorporeally

through a small 5 cm medial minilaparotomy adjacent to the umbilicus or a 5 cm minilaparotomy over the right 10 mm port site.

Step 3: Perineal or Vaginal Approach

The en-bloc specimen is removed through the vagina or after perineal excision adapted to the tumor location.

The vaginal reconstruction is done by using the omental J flap and if needed, additional local flaps.

New haemostatic devices such as vessel sealing combined with ultrasonic and advanced bipolar energy are used to reduce bleeding and instrument changing. Endo-GIA staplers are necessary for bowel section.

Standard laparoscopic instruments are used during this procedure: two non-traumatic graspers, one Leriche dissector, and one needle holder.

Specific instrumentation is required for the continent pouch construction similar to open surgery [6, 7].

Patient Position

The patient is placed in a lithotomy position, with the legs at the same level than the abdomen with complete access to the perineum.

Both arms are placed along the abdomen to facilitate the laparoscopic procedure.

The surgeon operates from the left side and the assistant is on the right. The surgeon can move between both legs to easily access the upper part of the abdomen during omental J flap harvesting and mobilization of the right colon.

Laparoscopic Ports Placement

The umbilicus is used as the port site for the laparoscope. Four operative trocars are placed:

- one 5 mm on each iliac fossa.
- one 10 mm in the placement of preoperative marked stoma site.

Altogether, five trocars are placed. (Fig. 47.1).

Ergonomic placement of trocars is mandatory to access the entire peritoneal cavity, and allows pelvic and supraabdominal procedure with the same ports.

The absence of undefined preoperative intra-abdominal metastatic disease should be confirmed at this time. Since R0 resection is the goal of surgery, and undiagnosed peritoneal or visceral metastases are often unresectable, definitive surgery should be avoided in these cases, except for palliative surgery.

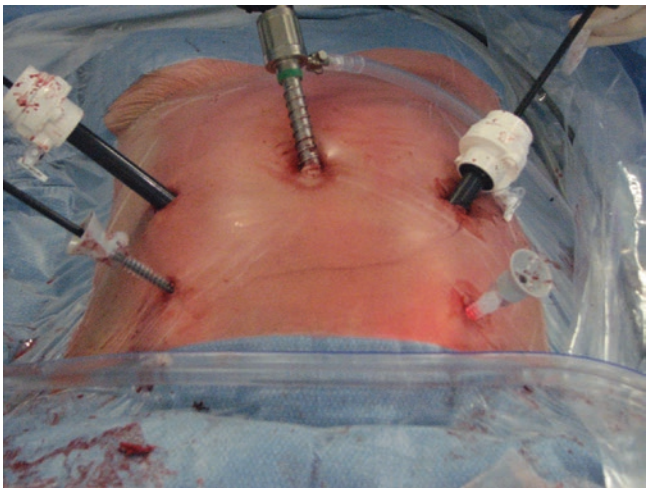

Fig. 47.1 Laparoscopic ports placement

Laparoscopic PE Phase

The abdominal phase is completely performed by laparoscopy.

The patient is placed in Trendelenburg position. Optimal pelvic exposure is required. The small intestine is packed in the upper quadrant after a right paracolic guttier incision.

If necessary, the sigmoid is attached to the left paracolic guttier to empty the posterior pelvis.

Dissection of Retzius and Pelvic Spaces

The anterior visceral peritoneum of the bladder is incised (Fig. 47.2), and the space of Retzius is opened. Both paravesical (Fig. 47.3) and pararectal (Fig. 47.4) spaces are developed.

During this dissection, the ureters still attached to the peritoneum are pouched medially or laterally to widely open the pararectal space.

The pelvic side peritoneum is incised laterally to the rectum.

Ureters Dissection

The infundibulopelvic ligaments are divided. The ureters are obstructed using hemoloks ® then transsected as low as possible in the pelvis (Fig. 47.5).

Of note, the ureters are often located medially in patients who have previously undergone surgery. Preoperative placement of ureteral stents is not required.

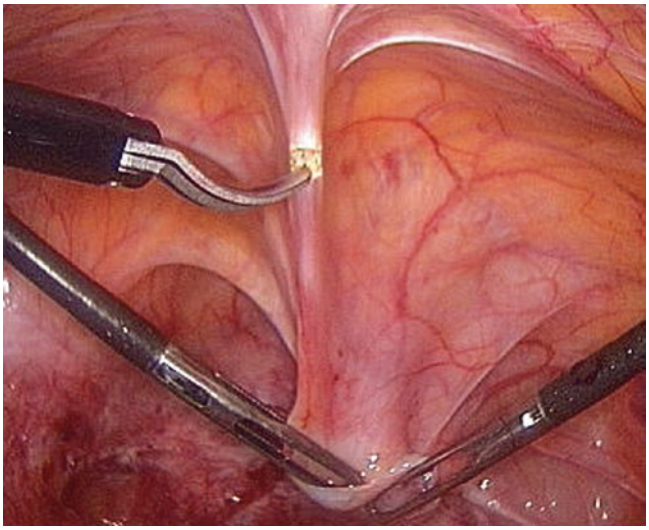

Fig. 47.2 Incision of the anterior visceral peritoneum of the bladder

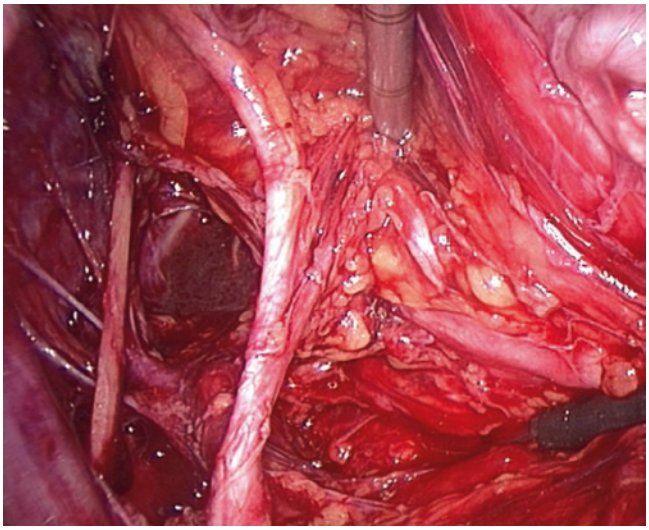

Fig. 47.4 Development of pararectal space

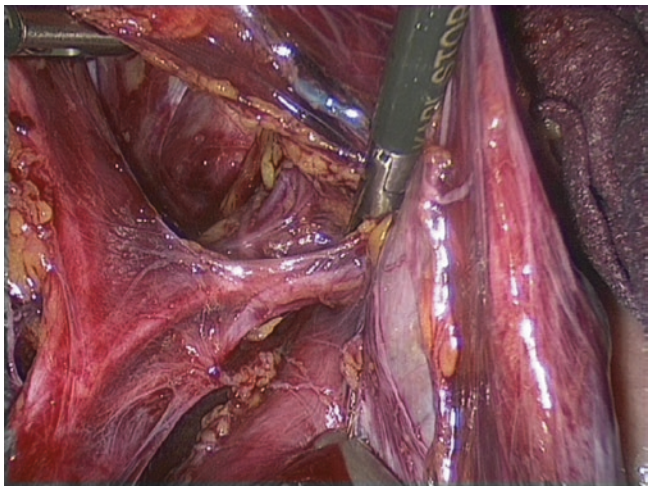

Fig. 47.3 Opening of the Retzius space

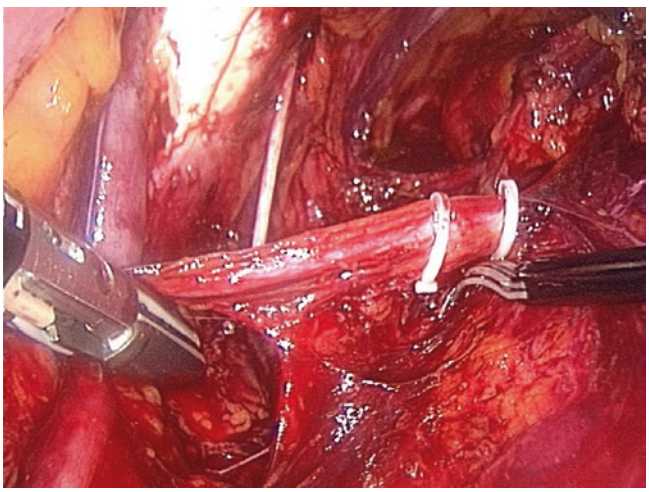

Fig. 47.5 Transsection of the left ureter

Dissection of the Rectovaginal Septa

The peritoneal incision is extended into the Douglas pouch (Fig. 47.6). The anterior aspect of the rectum is separated from the posterior vaginal wall with a blunt dissection (Fig. 47.7).

Coagulation and Section of the Parametrium

The entire specimen is pushed to one side by the assistant. The dissection is started in the pararectal space. The uterine artery and the superior vesical artery are coagulated or clipped (Fig. 47.8). The dissection is carried caudally and medial to the hypogastric pedicle.

The same step is then carried out on the other side.

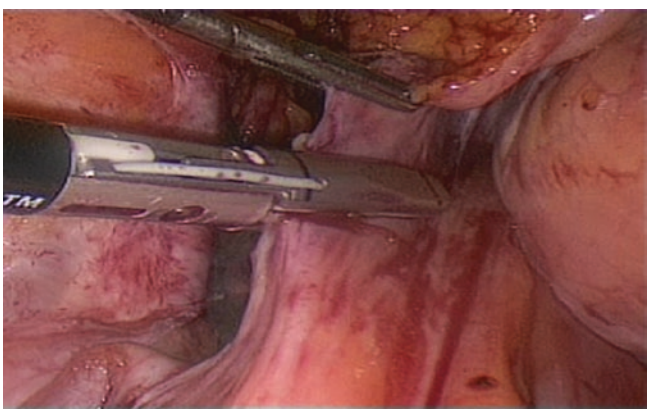

Fig. 47.6 Incision of the peritoneum into the Douglas pouch

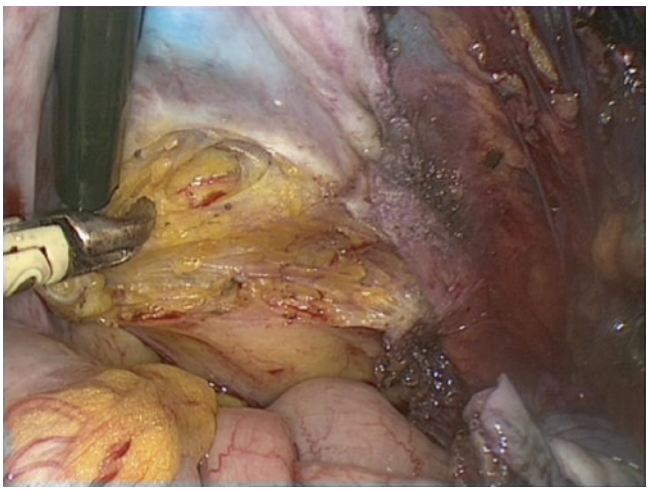

Fig. 47.7 Blunt dissection between the anterior aspect of the rectum and the posterior vaginal wall

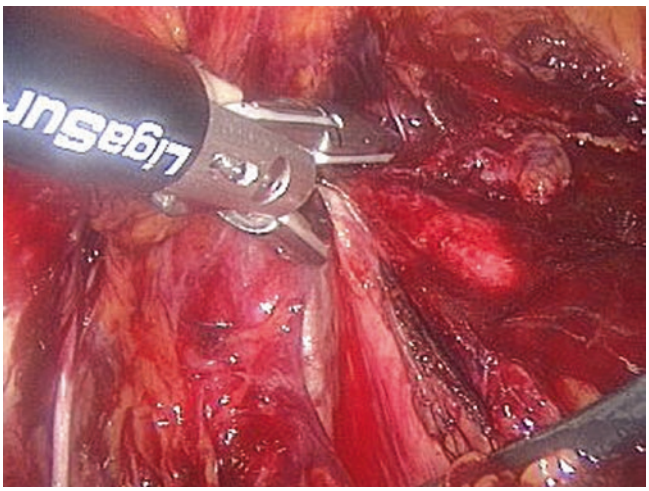

Fig. 47.9 Transsection of the uterosacral ligaments and paracolpos

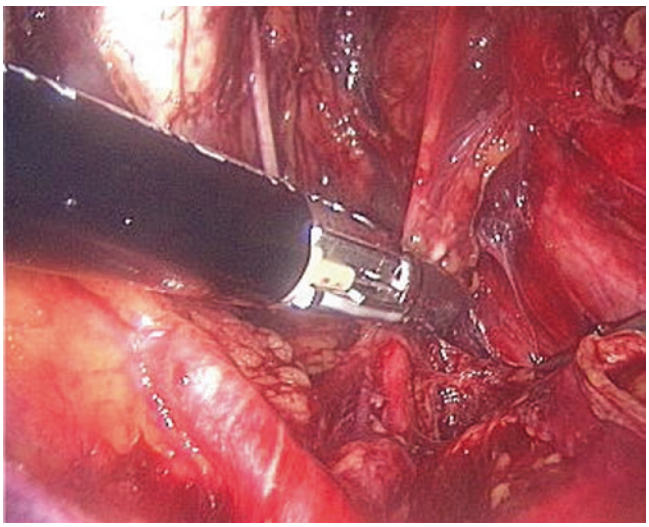

Fig. 47.8 Coagulation of the uterine artery and the superior vesical artery

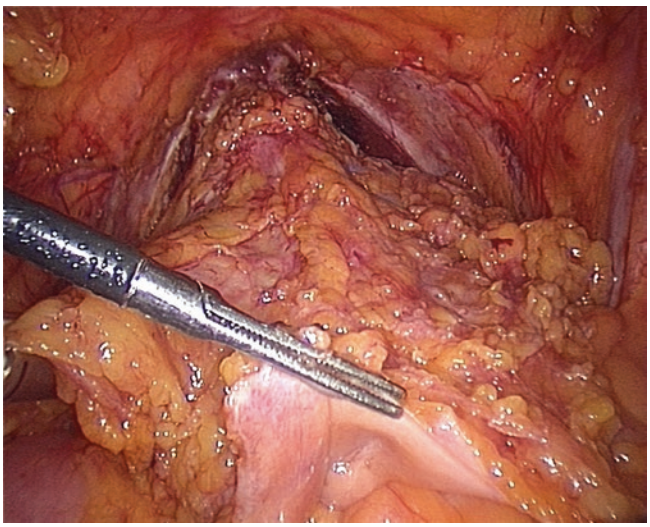

Fig. 47.10 Opening of the endopelvic fascia

Coagulation and Section of Paracervix and Paravaginal Tissue to the Pelvic Floor, and Identifying the Levator Ani

Uterosacral ligaments and paracolpos are transected as laterally as possible according to a complete mesometrial compartmentectomy and removal of the ureterovesical compartment (Fig. 47.9).

The endopelvic fascia is cleaned, and opened in case of infralevator or extended PE (Fig. 47.10).

In Case of Total PE

The rectum is dissected off the sacrum and coccyx by blunt dissection. This is performed by retracting the uterus and distal segment of the rectum anterior and cephalad, inserting an instrument behind the rectum in the presacral space, and freeing the rectum down to the coccyx.

In order to perform a colo-anal or colorectal anastomosis without tension, the left colon including the spleen flexure is widely mobilized.

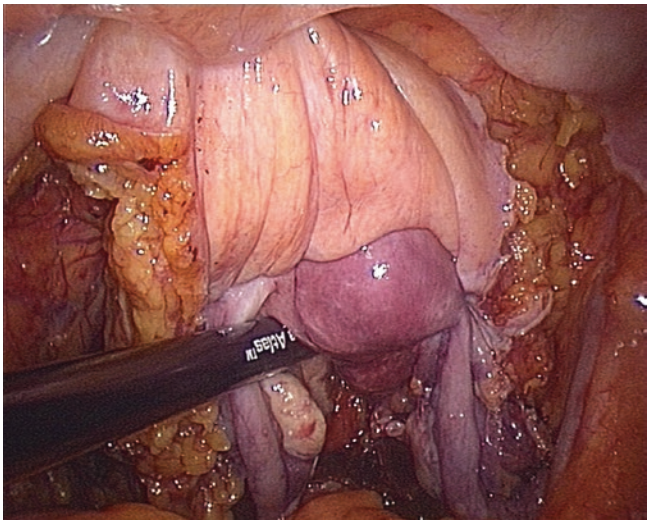

Fig. 47.11 Final laparoscopic view before en-bloc removal via perineal or vaginal approach

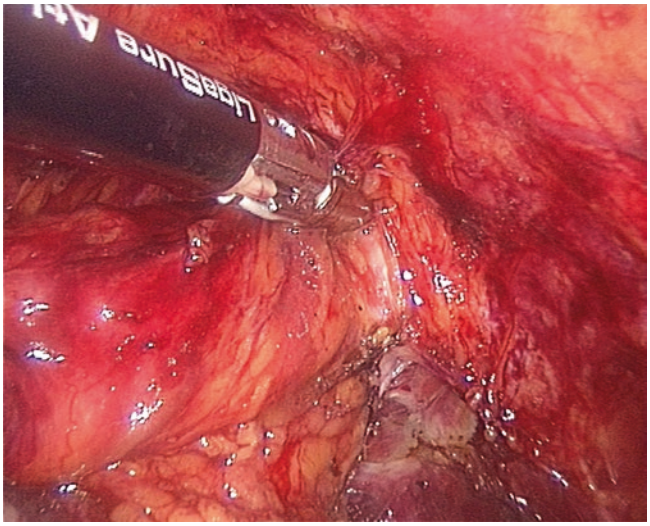

Fig. 47.12 Coagulation of paravesical plexus

The inferior mesenteric artery is transected at the origin and if necessary the inferior mesenteric vein close to the inferior aspect of the pancreas.

The rectum and the descending colon can be transected by laparoscpy using Endo-GIA staplers or outside after removal of the specimen (see next step).

Later Removal of the Specimen

The dissection is stopped as soon as laparoscopic dissection is deemed sufficiently complete to later allow en-bloc removal of the specimen via perineal or vaginal approach (Fig. 47.11).

By cephalad traction, the urethra can be exposed and transected at this time after coagulation of paravesical plexus (Fig. 47.12).

Additional steps adapted to each individual case are then performed before the loss of pneumoperitoneum, secondary to later removal of the specimen.

In the case of supralevatori PE, some authors have proposed to transect the vagina and remove the entire specimen through the vagina [2, 8]. The vagina is then packed to prevent pneumoperitoneum leakage.

Reconstructive Phase: Urinary Diversion (Bricker Diversion)

Mobilization of Both Ureters

The right ureter is mobilized up to the lower renal pole (Fig. 47.13), whereas for the left, it is dissected above the level of the inferior mesenteric artery and brought across the midline to the right without tension through a window created in the mesentery above the inferior mesenteric artery (Fig. 47.14). This step is facilitated in case of simultaneous aortic lymphadenectomy.

Creation of the Diversion

A 5 cm median incision starting from the umbilical trocar site is performed.

A segment of ileum is mobilized and exteriorized through the incision (Fig. 47.15). A 10 cm ileal segment 15 cm away from the ileocecal junction is isolated to construct the urinary diversion.

Bowel continuity is restored with stapled side-to-side ileo-ileal anastomosis.

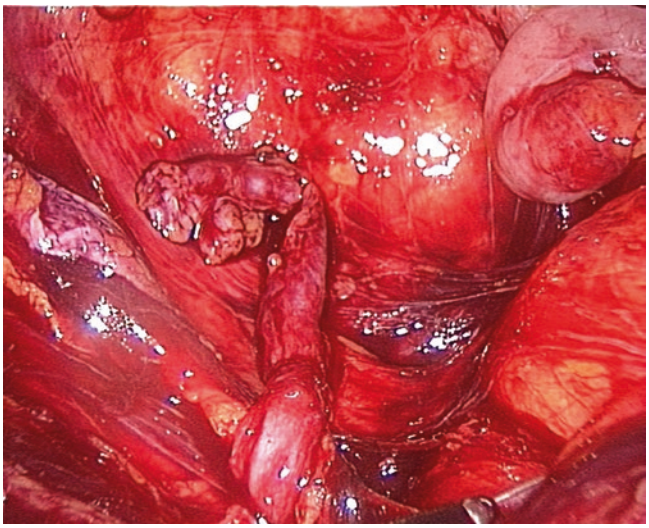

Fig. 47.13 Mobilization of the right ureter

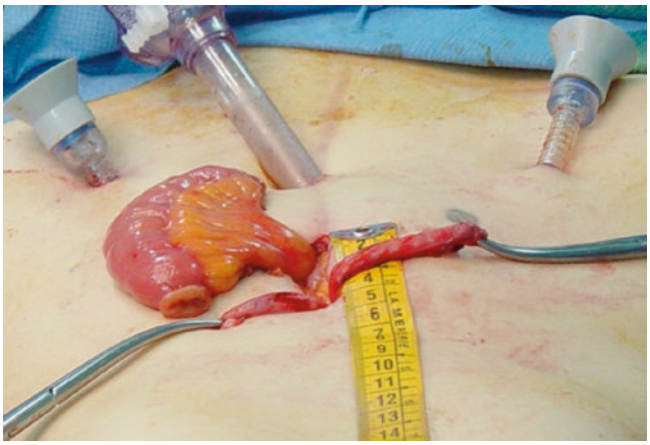

Fig. 47.15 Exteriorization of a segment of the ileum and the both ureters through the ombilical incision before creation of the Bricker diversion

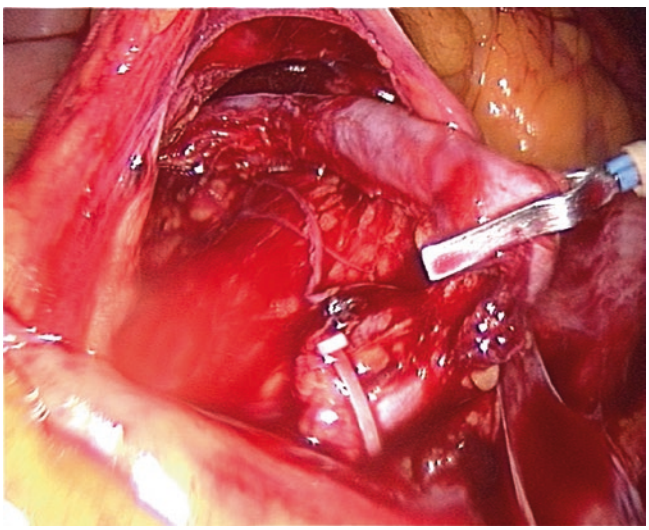

Fig. 47.14 Mobilization of the left ureter after creation of a peritoneal window above the level of the inferior mesenteric artery

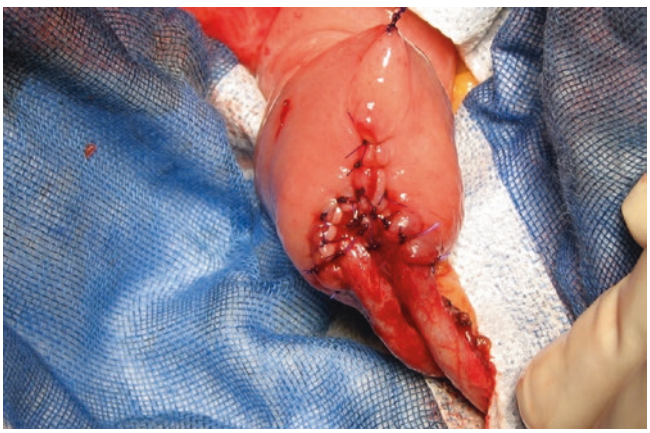

Fig. 47.16 Ileo-ureteral anastomoses in a wallace faction

Ileo-ureteral anastomoses in a Wallace faction are performed extracoporeally (Fig. 47.16). They are bilateral stented (8F Double JJ).

Finally the conduit stoma is fashioned: the end of the ileum is then brought out through a 10 mm port site previously placed in a preoperative marked stoma site.

Reconstructive Phase: Continent Miami Pouch

Right colon Mobilization Up to the Hepatic Flexure and Omental J Flap Harvesting

The patient is then positioned in a 15 ° reversed Trendelenburg with 15 ° left sided rotation to facilitate the mobilization of the ascending and the hepatic flexure of the colon.

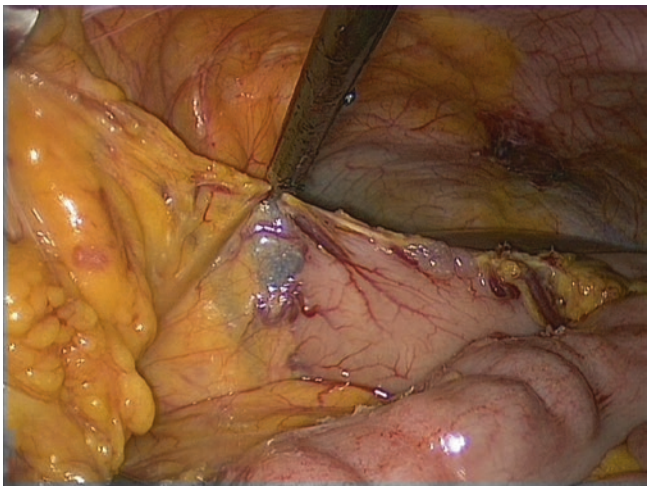

Fig. 47.17 Transection of the omentum off the greater curvature of the stomach

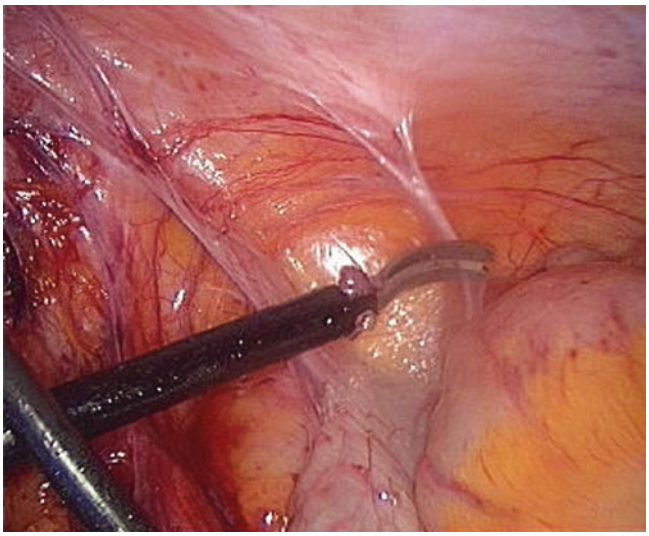

Fig. 47.19 Mobilization of the hepatic flexure

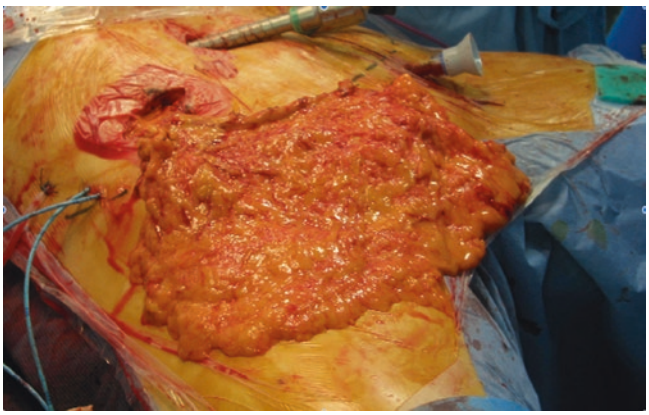

Fig. 47.18 Exteriorization of the omental J flap through the 5-cm iliac incision for neovaginal creation

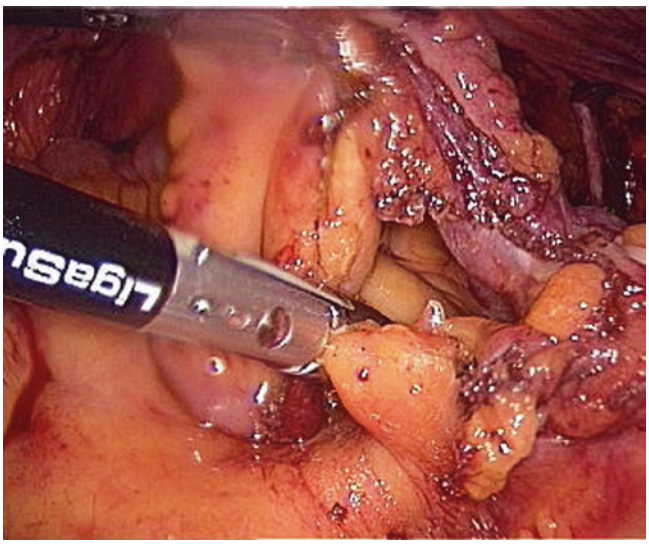

Fig. 47.20 Coagulation of the mesentery

The omentum is liberated from the transverse colon. Omental J flap is harvested at this time, after opening the omental bursa. The omentum is tipped over the anterior aspect of the stomach. The omental J flap is initiated by transecting the omentum off the greater curvature of the stomach (Fig. 47.17). The right gastroepiploic pedicle is skeletonized for the flap vascular supply. The omental J flap is stored at the upper part of the abdomen for the vaginal reconstruction. It will be transferred into the pelvis during the last phase after the removal of the specimen to fill the pelvis and optionally reconstruct the vagina (Fig. 47.18).

Then, the right part of the colon up to and including the hepatic flexure is mobilized (Fig. 47.19). This is to facilitate harvesting of an appropriate length of colon as well as entry into the retroperitoneal space to mobilize the ureters. The colon is transected proximaly to the middle colic artery, thus preserving an important blood supply. Transillumination through the right lower port with a 5 mm endoscope can be useful in identifying this important vessel in obese patients. It is also important to identify the position of the ileocolic artery before dividing the ileal mesentery, because this will be the main blood supply for the pouch. The colon and ileum are skeletonized (Fig. 47.20) and defatted before transection with EndoGIA staplers. 25 cm of colon and 15 cm of the terminal ileum are necessary to create a 250 cc volume pouch.

Mobilization of both ureters:

The right ureter is mobilized up to the lower renal pole, whereas for the left, it is dissected above the level of the

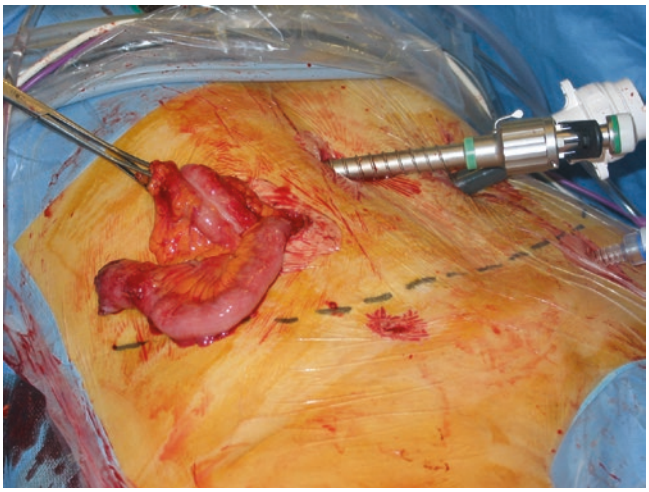

Fig. 47.21 Exteriorization of the ileum and the transverse colon before extracorporeally side-to-side anastomosis

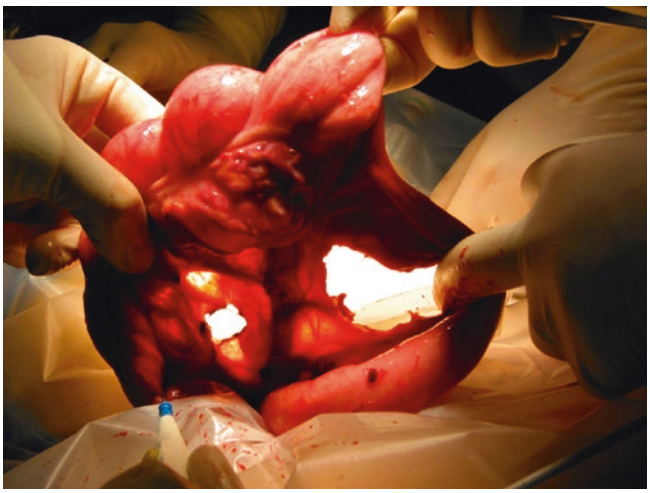

Fig. 47.22 Transillumination of the ileocolic conduit.

inferior mesenteric artery and brought across the midline to the right without tension through a window created in the mesentery above the inferior mesenteric artery. At this point, we prefer to fix the two ureteric ends with sutures near the site for the minilaparotomy to facilitate the exteriorization of the ureters during the next step.

Creation of a 5 cm Lateral Minilaparotomy

Through this, the transected intestinal ends are exteriorized, and a standard ileotransverse anastomosis is performed to restore bowel continuity (Fig. 47.21). We employ a side-to-side technique using two GIA 80 linear staplers.

Exteriorization of Ureters and Ileocolic Conduit (Fig. 47.22)

An appendicectomy is performed if it is present.

Creation of the Reservoir

The colon is folded on itself in a « U » configuration, and two sutures are used to maintain the alignment. Two 2 cm colostomies are made at the medial tip of both ends, and detubularization is done with resorbable staples (Poly-GIA) (Fig. 47.23).

The pouch is then unfolded and the detubularization is completed with a second resorbable stapler, thus creating a pouch (Fig. 47.24).

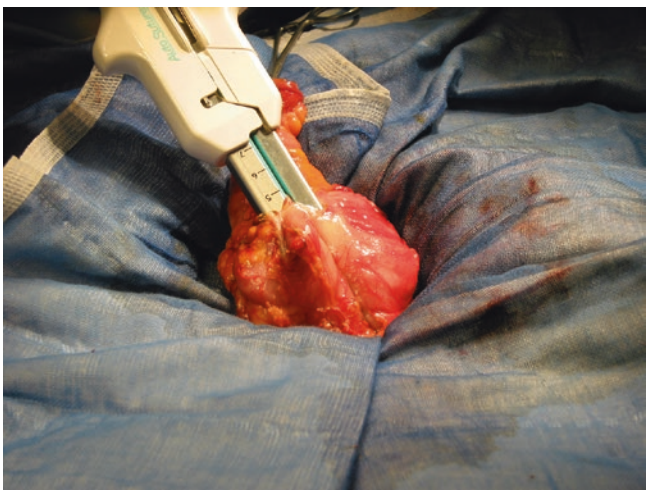

Fig. 47.23 Construction of the reservoir using resorbable staplers

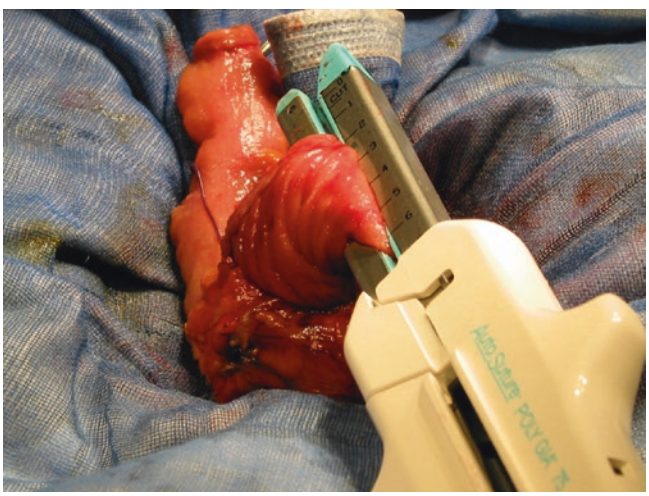

Fig. 47.24 Application of the second resorbable stapler to achieve the detubularization

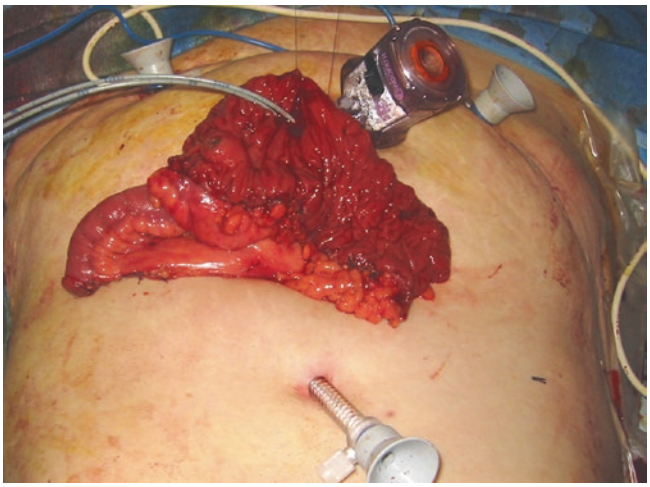

Fig. 47.25 Ureteric anastomosis to continent pouch

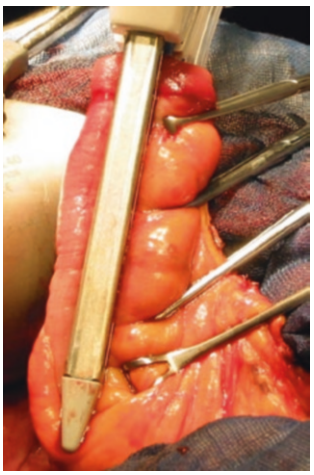

Fig. 47.26 Construction of continent mechanism by tapering of the distal ileal segment

Ureteric Anastomosis to Continent Pouch

Initialy, the ureteric ends were simply spatulated and anastomosed mucosa to mucosa at the base of the pouch with interrupted 4-O PDS sutures (Fig. 47.25).

Currently, in order to provide an efficient antireflux mechanism with a intraluminal valve, the 2 cm end of both ureters are left free into the reservoir and suturred serosa to mucosa at the pouch.

Single J stents (8F) are inserted, and their free ends are tunneled through the right lower abdominal wall to prevent obstruction by irrigation during early postoperative course.

Closure of the Pouch

After the placement of stents, the pouch is closed by a running suture.

Construction of Continent Mechanism: Tapering of the Distal Ileal Segment

A 14F catheter is placed through the ileum, and the ileum is narrowed with a GIA stapler. To obtain an optimal diameter, the 14F catheter is maintained with three or four Babcock forceps on the mesenteric side of the ileum (Fig. 47.26).

Checking the Continence and Integrity of the Pouch

200 mL of blue dye is infused to check for continence and the integrity of the pouch.

Continent Pouch Placement

The pouch is then replaced back into the cavity. The base is sutured to the posterior aspect of the abdominal wall to prevent displacement and torsion of the pouch. The minilaparotomy is then closed, and once the perineal and laparoscopic phases are completed, the ileal conduit is brought through and sutured at the umbilicus.

Specific Post Operative Care

Standard postoperative care includes the use of regular pouch irrigation to prevent mucus accumulation. Permeability of J stents have to be regulary controled and irrigation performed in case of obstruction.

A pouchogram is performed routinely on day 10 to confirm that there is no leakage before removing the J stents and the 14F Foley catheter.

All patients are taught how to self-catheterize with the 14F single-use urinary catheter.

En Bloc Removal of the Specimen Via Perineal or Vaginal Approach Phase

After completion of all required laparoscopic steps, a vaginal approach in type I–II or perineal approach in type III exenterations is used to complete the removal of the specimen.

Vaginal and perineal incision adapted to the extent of disease is followed by dissection with a haemostic device of the attachments of the urethra or vagina to the pelvic wall (Figs. 47.27 and 47.28).

Fig. 47.27 Vaginal and perineal incision adapted to the extent of disease

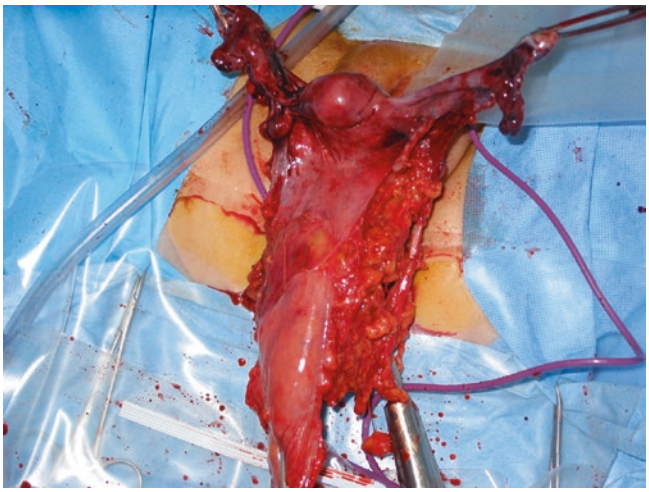

Fig. 47.28 Exteriorization of the anterior and middle PE specimen

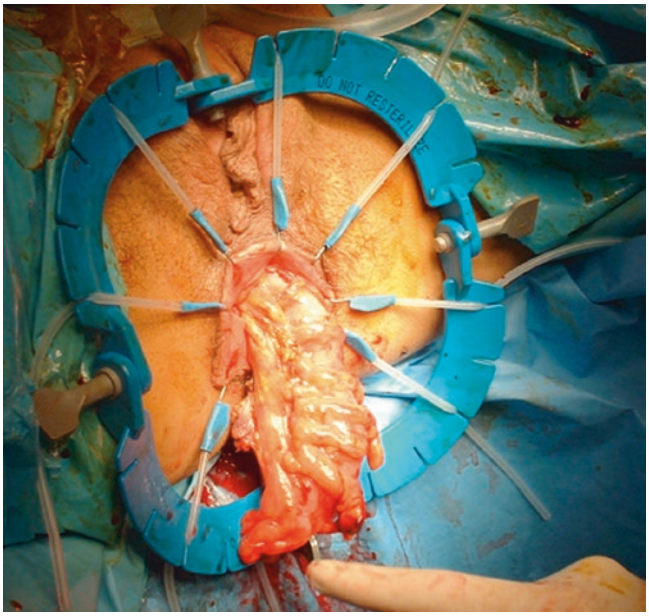

Fig. 47.29 Coloanal anastomosis

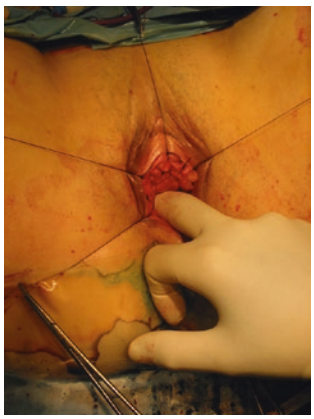

Fig. 47.30 Vaginal reconstruction using an omental J flap

Restoration of Bowel Continuity

The left colon is exteriorized through the anal sphincter to facilitate the colo-anal anastomosis (Fig. 47.29).

If the remain rectum is long, a colorectal anastomosis is performed by laparoscopy using EEA staplers.

A loop ileostomy is performed on left iliac fossa to protect both ileal and colo-anal anastomosis.

Vaginal Reconstruction

The omental J flap, harvested during the previous surgical phase is transferred into the pelvis. It is tubularized and sutured to the introitus or the remaining vagina (Fig. 47.30).

The use of vicryl or biological mesh combined with an omental flap have been described by some authors to reduce the rate of neovaginal prolapse [9].

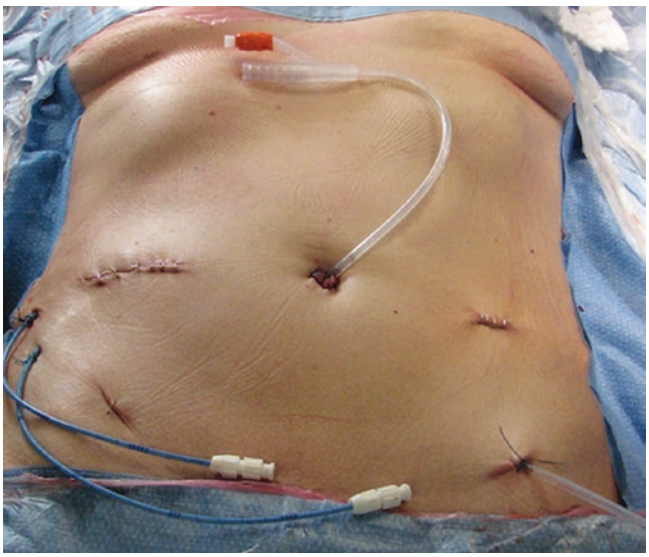

Fig. 47.31 Final view after anterior and middle PE with placement of the urostomy through the umbilicus. Drainage

A vaginal mold is placed and removed each day for irrigation. In our experience, split thickness skin graft is not needed, as spontaneous reepidermization will be completed after several weeks.

An additional local myocutaneous flap can be used if necessary.

Drainage

Abdominal drainage is achieved through the upper umbilical port site and a second one through the vaginal suture (Insert Fig. 47.31).

Hysterectomy in the Surgical Management of Endometriosis

48

Rouba Murtada, Gabriele Centini, Karolina Afors, and Arnaud Wattiez

Endometriosis is the ectopic presence of endometrial glandular and stromal tissue. It affects 10–20 % of women, and up to 60 % of women suffering from dysmenorrhea [1–4]. As a hormone dependent condition, menopause usually brings an end to its evolution. Infertility and pain are its two major symptoms. The pains most frequently linked to endometriosis are dysmenorrhea, non-menstrual chronic pelvic pain, dyschezia, dysuria and dyspareunia. In certain patients, the severity of symptoms is such that it can cause a significant impact on quality of life, sexual function and psychological physical well-being.

The treatment of endometriosis relies on 2 pillars: hormonal treatment and surgery. In the surgical management of endometriosis, hysterectomy is one of the options. It is generally considered a last resort solution which is to be reserved for severe symptoms, only after failure of other treatments or procedures and after the patient has accomplished her family project.

Few publications are dedicated to the place of hysterectomy in endometriosis. Nevertheless there is evidence to support both the rationale of performing a hysterectomy in endometriosis, and its efficiency in treating painful symptoms.

The Rationale of Hysterectomy for Endometriosis

The Innervation of Eutopic Endometrium

It was demonstrated by Tokushige et al. that patients with endometriosis have a greater density of nervous fibers whithin the eutopic endometrium and myometrium when compared to patients without endometriosis [5].

The same team demonstrated that hormonal treatment significantly decreases the density of nervous fibers within the eutopic endometrium and myometrium, supplying an explanation for their efficacy in treating pelvic pain attributed to endometriosis [6].

Al Jefout et al. went as far as suggesting the immunohistochemical detection of nervous fibers on endometrial biopsy as a diagnostic technique for endometriosis [7]. In a population of 99 women presenting with pelvic pain and/or infertility, they found that this technique had a sensibility and specificity of 83 % and 98 %, and a positive and negative predictive strength of 91 % and 96 %, respectively. Women with endometriosis and pelvic pain had significantly higher density of nervous fibers than women with endometriosis but without pelvic pain (2.3 vs 0.8 /mm2, p = 0.005).

These elements are in favor of a participation of the uterus to nocicetive mechanisms implicated in endometriosis pain.

Nevertheless, Zhang et al. studied the density of nervous fibers in the endometrium of 30 patients with endometriosis, 40 women with adenomyosis, 41 women with uterine fibroids and 47 women with endometriosis and adenomyosis. They demonstrated a greater density in women presenting with pelvic pain as compared to those without painful symptoms, whichever the pathology [8].

Retrograde Menstruation Theory

It is one of the theories concerning the genesis of endometriosis. The persistence of menstrual reflux could contribute

© Springer International Publishing Switzerland 2018

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_48

to the maintaining of endometriosis, and its suppression could decrease the genesis of new lesions. Women with endometriosis could have heavier menstrual flux than other women [9, 10]. Also, high levels of prostaglandins have been found in the menstrual flux of women with dysmenorrhea and their recurring outpour into the abdominal cavity could contribute to inflammation and a mechanism of peripheral sensitization [11].

Uterine Dyssynergia

Physiologically, uterine contractions spread from the fundus to the uterine cervix during the menstrual period, which allows the evacuation of uterine debris [12]. These contractions don't occur in women under oral contractives, suggesting a hormonal participation in this phenomenon [13].

These contractions could also occur differently in women with endometriosis, with a hyperkinesia or dyskinesia that could contribute to dysmenorrhea as well as reduce the efficacy of evacuation of the menstrual flux. The pressure of contractions and their frequency were significantly increased in 16 patients with endometriosis in comparison to 14 control patients in a study by Bulletti et al. This inefficacy of uterine contractions resulted in retrograde menstruation, with the previously cited consequences [14].

Adenomyosis Associated to Endometriosis

Adenomyosis, previously called internal endometriosis is the presence of endometriosis within the myometrium. It is a pathology of the fourth and fifth decade and is revealed by menorragia and/or pelvic pain. An association between adenomyosis and endometriosis has been found. It is particularly the case of external adenomyosis, whereby endometriotic lesions principally recto-vaginal nodules, are contiguous to adenomyosis within the myometrium, with a similar histological structure in both lesions [15].

In a radiological study, Kunz et al. found aprevalence in adenomyosis (based on the thickening of the junctional zone) of 79 % in a population of 160 women with endometriosis [16]. Larsen et al. after pathological study of hysterectomy specimens found a prevalence of adenomyosis of 34.6 % in a group of 153 patients with endometriosis, vs 19.4 % in a control group ($p < 0.05$) [17]. Moreover, there was a tendency towards an increase in the prevalence of adenomyosis with the severity of endometriosis: 42,8 % in the ASRM IV group vs 29.4 % in the ASRM I, II and III (NS, $p = 0.10$), as well as in the depth of infiltration of adenomyosis in the myometrium (NS, $p > 0.05$).

The participation of adenomyosis in the persistence of pain after excisional surgery for endometriosis has been studied. Parker et al. studied the thickness of the myometrial junctional zone on MRI, as an indicator for adenomyosis, in 53 patients suffering from pelvic pain [18]. After surgery 40 had histologically proven endometriosis. In these patients, dysmenorrhea and non-menstrual pelvic pain were significantly and three times more likely to persist after surgery when thickness was superior to 11 mm on pre-operative MRI.

Ferrero et al. performed a similar study in women with bowel endometriosis, with or without associated adenomyosis (diagnosis was based on MRI findings) [19]. Dysmenorrhea was significantly improved in patients without adenomyosis or those in whom an excision of focal adenomyosis had been performed, on an 18 months study period. No improvement of dysmenorrhea was obtained when adenomyosis was left untreated. Deep dyspareunia and non menstrual pelvic pain were improved in all groups, as well as specific bowel symptoms.

The presence of adenomyosis could be responsible for an incomplete resolution of painful symptoms in endometriosis after conservative surgery, in particular with the persistence of dysmenorrhea.

The Place of Hysterectomy in Endometriosis

Performing a hysterectomy for a benign condition, all conditions included, generally yields favourable results [20]. Nevertheless, the results of hysterectomy for chronic pelvic pain seem inferior to those obtained in other benign conditions. Indeed, pre-operative pain is a risk factor for post-operative pain in hysterectomy.

In a 2004 study by Hartmann et al. on 1200 patients having undergone a hysterectomy for a benign condition, all indications included, the group of patients presenting with pelvic pain and depression was identified as having a three to five times greater risk of suffering from altered quality of life, dyspareunia and pelvic pain [21]. Nonetheless an improvement was reported in 78–86 % of patients in this sub-group. This observation was again found in a Danish study in 2007 where a questionnaire was sent to 1299 1 year after they had undergone a hysterectomy. It was found that pre-operative pain, as well as pain as an indication for surgery, were risk factors for post-operative pain with respectively odd-ratios of 3.25 and 2.98 [22].

Hysterectomy Is Efficient for Pain Improvement Rather than Pain Resolution

In 1990, Stovall et al. reported the results of hysterectomy by laparotomy for chronic pelvic pain attributed to a uterine cause (leimyomatosis, adenomyosis) one year after surgery

[23]. Pelvic endometriosis cases were excluded. They were surprised to find lower results than expected. 22.2 % of patients had persisting pain, of which 5 % had increased pain. They concluded in the efficacy of hysterectomy for pain improvement, rather than pain resolution. In 1995, Hillis et al. in a serie of 388 patients having undergone a hysterectomy reported similar results with 74 % of pain resolution, 21 % of pain decrease and 5 % of pain increase [24]. A high-risk subgroup, with 40 % of persistent pain, was identified and included patients younger than 30 years, without medical insurance, without an identified pelvic pathology, or with a history of pelvic inflammatory disease.

Hysterectomy Is Efficient in the Treatment of Pain Related to Endometriosis

Endometriosis is one of the causes of chronic pelvic pain. It affects young women, and therefore the surgical management of endometriosis is often focused towards uterine conservation and fertility preservation. Few studies have been dedicated to hysterectomy in endometriosis. Its results are often merged with those of hysterectomy for other indications, and the outcome measures used are heterogeneous throughout literature.

In the study of Hillis et al., the subgroup of patients with histologically proven endometriosis without mention of severity or stage, 81.3 % of patients (n = 13) had no pelvic pain at one year after surgery, 18.7 % had decreased but persistent pelvic pain, and no patient reported increased pain [24]. In a study by Berner et al. on the results of subtotal laparoscopic hysterectomy, all indications included, 37 patients had undergone the procedure for pelvic pain attributed to endometriosis [25]. A significant decrease in pain scores measured on a visual analogic scale was reported at 3 years of surgery, with a mean of 4.01 points. Thirty one percent of patients had residual pain. Nevertheless, the residual pain score was significantly greater than in other pathologies (3.46 vs 0.94, $p < 0.001$).

Despite Imperfect Results, There Is Evidence That Hysterectomy Is Superior to Conservative Surgery in the Treatment of Endometriosis-Related Pain

Hysterectomy in general seems more efficient than conservative procedures. In an observational study of a cohort of 1503 patients reporting a pelvic problem (uterine bleeding, chronic pelvic pain, symptomatic fibroid tumor), Kuppermann et al. studied the impact of hysterectomy, uterine-preserving surgery and non-surgical treatments on health-related quality of life [20]. 13.8 % of patients had undergone a hysterectomy and 9 % a uterine-preserving surgery. An improvement was registered in all parameters of the quality of life questionnaire, in all three categories. Improvement was greater after hysterectomy.

In endometriosis specifically, there is also direct and indirect evidence that hysterectomy is more efficient than conservative surgery for the treatment of pain.

An indirect argument was provided by Weir et al. who studied on a 4 year period the rate of readmission in a population of 7993 patients having undergone surgery for endometriosis [26]. 27 % of patients were readmitted at some point after conservative surgery and 12 % after hysterectomy. Shakiba et al. studied the rate of reoperation in three groups: 107 patients who had uterine preserving surgery, 47 patients who had hysterectomy without oophorectomy and 50 patients who had hysterectomy with oophorectomy [27]. Hysterectomy was performed by laparotomy, laparoscopy or laparoscopically-assisted vaginal way. Patients who had a hysterectomy had a significantly lower rate of reoperation for pelvic pain as compared to the conservative treatment group. At, 2, 5 and 7 years, the percentage of reoperation-free patients was respectively of 79.4, 53.3 and 44.6 % for conservative surgery, 95.7, 86.6 and 77 % for hysterectomy without oophorectomy, 96, 91.7 and 91.7 % for hysterectomy with oophorectomy.

A study by Sinaii et al. compared 802 conservative laparoscopic surgeries for endometriosis to 230 oophorectomies, 209 hysterectomies with ovarian preservation, and 144 hysterectomies without ovarian preservation [28]. 94.6 % of patients had pelvic pain at time of surgery. In the isolated hysterectomy group, 45.9 % of patients considered their procedure to be a complete success for 30.4 % in the conservative surgery group ($p < 0.001$), 37.8 % in the oophorectomy group and 40.3 % in the hysterectomy with oophorectomy group.

Hysterectomy for Endometriosis-Related Pain Should be Part of a Radical Approach

For a long time, hysterectomy with bilateral salpingo-oophorectomy was considered the definitive treatment of endometriosis in that it associates a surgical effect with a hormonal effect due to the removal of the ovaries. Other endometriotic locations were sometimes overlooked, with the idea that the disease would regress after menopause was induced.

There is nevertheless data in favor of the radicality of excision when performing a hysterectomy as the definitive treatment of endometriosis. Fedele et al. compared the results of laparotomic extra-fascial hysterectomy (n = 26) with those of radical hysterectomy comprising a parametrectomy (n = 12) in treating patients presenting with endometriosis

and pelvic pain [29]. Pain recurrence occurred in 30 % of patients of the former group and none of the latter. Redwine reported 75 cases of endometriosis occurring after ovarian castration and requiring repeat surgery for excision due to pain recurrence. He concluded that no endometriosis should be left untreated at castration [30].

There Is Conflicting Data on the Importance of Concomittant Bilateral Salpingo-Oophorectomy When Performing a Hysterectomy for Endometriosis

Namnoum et al. compared the results of laparotomic hysterectomy for endometriosis in 29 patients with ovarian preservation and 109 without [31]. They reported a rate of pain recurrence of 62 % in patients of the first group and 10 % in the second, with a reoperation rate of respectively 31 % and 3.7 %. Patients with ovarian preservation had a 6.1 relative risk of painful recurrence and 8.1 of reoperation. In the study of Shakiba et al. the relative risk of reoperation in case of ovarian preservation was of 2,44, although not statistically significant [27]. On the other hand, in the sub-group of patients of ages 30–39 years, BSO did not significantly increase the interval between initial and repeat surgery.

It is also to be taken into consideration that ovarian preservation is preferable in the young patient because of the cardio-vascular risk that comes with early menopause.

For that purpose, bilateral salpingo-oophorectomy is not systematic in our institution when performing a hysterectomy for endometriosis. The adnexae is only considered to be another potential site of involvement, requiring excision only when affected.

Despite Imperfect Results, Hysterectomy for Endometriosis Yields a High Level of Satisfaction

In a personal series of 39 patients having undergone hysterectomy with or without BSO for pain attributed to endometriosis between 2006 and 2012, 30 % responded to being "satisfied" of having had the procedure, and 53 % were "very satisfied", as opposed to "quite satisfied" (7.7 %) and dissatisfied (5.1 %). This came in spite of high rates of significant residual pain, defined by pain described as "important" or "unbearable" in intensity, with nearly 40 % at one year post-operatively and 30 % at 2 years.

Predictors of a high level of satisfaction were patient age, as older patients were more likely to be "very satisfied" and patient request, as patient who had requested the surgery were 50 times more likely to be "very" satisfied.

Predictors of long-term significant residual pain were age and BMI, as a patient was more likely to have pain described as "important" or "unbearable" if she was younger or with a lower BMI.

Age as a predictor is consistent with previously published data whereby age is recurrently stated as being a pejorative factor, whether in conservative surgery for endometriosis, hysterectomy for endometriosis or hysterectomy for pelvic pain in relation to a pathology other than endometriosis. Mac Donald et al. compared the results of hysterectomy for endometriosis related pain in 16 patients of age less than 30 years and 27 patients of age above 40 years [32]. In the two groups, a similar proportion of women considered themselves to be completely treated (80 %). There was no difference with regards to residual dyschezia but dyspareunia persisted in 50 % of patients younger than 30 years versus 17.4 % of patients in the other group ($p = 0.035$). There was no significant difference in the proportion patients regretting having had the procedure. Younger patients had a greater sense of loss.

Far from concluding that hysterectomy for endometriosis should be restricted to women approaching menopause, it does call for a particularly extensive information on the benefits to be expected of the surgery and its imperfect but significant impact on pain. Before performing a surgery marking the end to fertility, the surgeon should be certain that the patient is fully convinced of its usefulness. Performing a hysterectomy at the patient's request was a strong predictor of satisfaction. Therefore, hysterectomy should be suggested with caution to the younger patient, and after a reflection period.

In conclusion, hysterectomy does deserve its attribute of "definitive surgery" in that it is more efficient on chronic pain than conservative surgery, with the lowest reoperation rates. This is true only if hysterectomy is part of a radical approach of the surgical management of endometriosis and is paired with the resection of all associated lesions. The role of concomitant BSO remains to be clarified and its usefulness balanced with its potential morbidity.

Hysterectomy yields a high level of satisfaction from patients, despite an imperfect resolution of pain. Its impact on pain is significant and covers all types of pains associated with endometriosis. Hysterectomy should be suggested to patients older than 40 years as an interim solution before menopause can bring an end to the active phase of the disease. It should be performed with caution in the young patient, even when she no longer wishes to retain fertility. A strong demand coming from the patient is a good indicator of an adherence to the treatment plan and a factor of high level of satisfaction.

Surgical Strategy in Hysterectomy for Endometriosis

Endometriosis is a complex disease which can cause considerable anatomical distortion. It is multicentric and can affect the anterior and posterior compartments of the pelvis as well as the adnexaes and the urinary tract laterally.

In a normal anatomical context, performing a hysterectomy entails the application of a specific surgical approach with reproducible key steps. In case of endometriosis the surgery is a variation on this approach made to include a general strategy. The purpose of this general strategy is three-fold: restore the anatomy, identify landmarks to preserve during dissection (most importantly the ureter) and separate diseased tissue from in sano tissue. Only once these conditions have been fulfilled can the hysterectomy be performed.

The first step is exploratory for a proper assessment of lesions. This starts with a vaginal examination to search for a palpable nodule, and will serve as a benchmark for sequential examination as the nodule is dissected.

A uterine manipulator is placed, and the patient is placed in Trendelenbourg position. Thorough examination of the intra-abdominal cavity is carried. Adhesiolysis is performed, ovaries are liberated from the ovarian fossa and endometriotic cysts are drained. If ovarian preservation is decided their treatment is delayed to the end of the surgery in order to prevent blood spillage from polluting the operative field.

At this point, before undertaking the regular steps of hysterectomy, the ureters should be identified. What is usually achieved through transperitoneal direct visualization isn't possible in the context of severe endometriosis. On the left side it is made possible by removing the physiological attachment of the sigmoid to the left parietal wall. There are four advantages to this step:

1. It allows to mobilize the colon and displace it cranially in order to enhance the working space.
2. It gives direct access to the left adnexae and allows to properly identify the infundibulo-pelvic ligament.
3. The course of the ureter is visualized. This is key in deep endometriosis where it is typically medialized as a result of fibrotic retraction. It is the first structure medial to the infundibulo-pelvic ligament. It can then be lateralized and its distance with the uterus increased during central dissection.
4. It gives access to the left pararectal fossa, an avascular plane which is developed in the case of rectovaginal nodule and/or bowel involvement, or in case of a simple ventral retraction of the rectum with an adhesion to the uterine torus (posterior aspect of the uterus). This space is developed starting at the level of the pelvic brim, or more caudally, laterally to the rectovaginal space, in the absence of anatomic distortion.

During this dissection, special care should be taken in individualizing and preserving the hypogastric nerve which is found immediately underlying the peritoneum.

Once this general strategic sequence has been completed, a specific strategy is adopted depending on the organs affected.

The twin goals of this strategy are: to isolate the uterus from the affected organs in order to perform the hysterectomy, then secondarily remove the residual disease as part of a radical approach. This is the exact opposite of en bloc resection used in oncological cases, and allows a radical but economical approach disregarding the notion of safe margins. Only when the involvement is contiguous to the uterus, such as in the case of a vaginal nodule, can the resection line be displaced in order to include the immediately adjacent disease.

Case 1

The first laparoscopic view (Fig. 48.1) is of a uterus without sign of adenomyosis, but with a retracted left adnexae bearing an endometriotic cyst as well as a hydrosalpynx, adherent to the mesosigmoid. The contralateral adnexae is normal. The first step consists in performing adhesiolysis in order to first liberate the left adnexae from the mesosigmoid through simple cutting action (Fig. 48.2). This reveals fully the endometrioma which is impacted in the ovarian fossa as it is usually the case. The aspiration device is used along with the bipolar to liberate it (Fig. 48.3) and in doing so a spontaneous rupture occurs and the typical chocolate fluid is immediately and progressively aspirated (Fig. 48.4) so as to prevent it from polluting the spaces. For this reason the ovariolysis is always performed with aspirating device in hand. Once the endometrioma has been emptied, a fibrotic retration of the left adnexae is better revealed. At this point, the ureter isn't

Fig. 48.1 Initial laparoscopic view: endometriosis affects the left lateral compartment

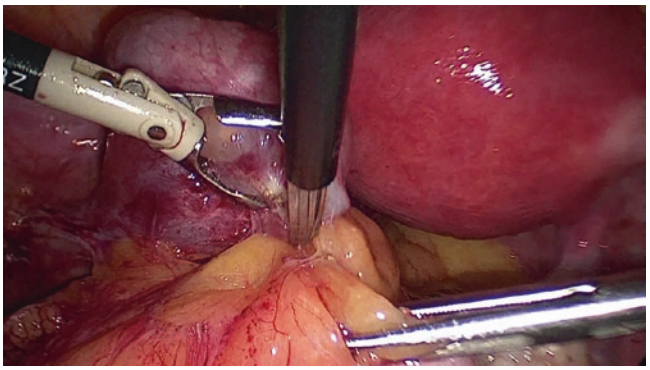

Fig. 48.2 The first step is adhesiolysis: the attachment of the mesosigmoid to the left adnexae is removed

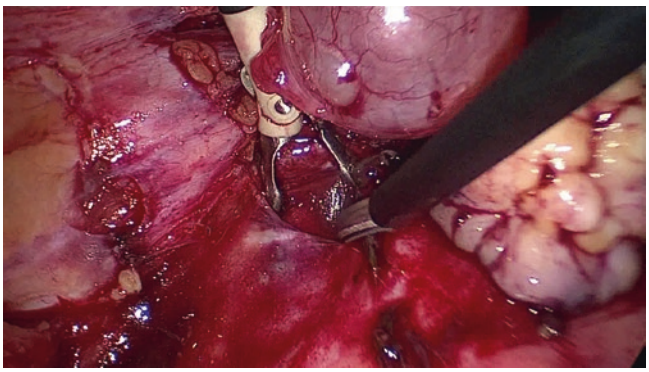

Fig. 48.5 Identify the ureter: the peritoneum is opened at the level of the IP ligament

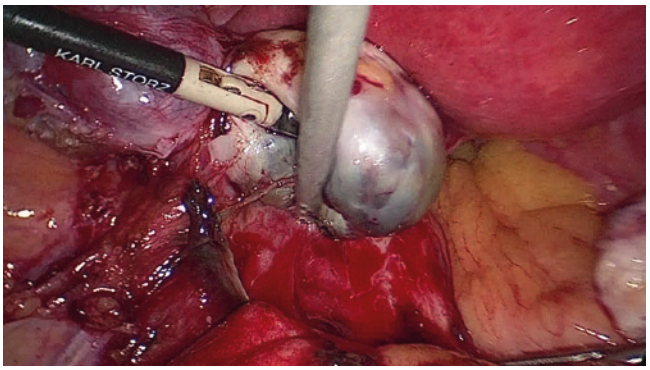

Fig. 48.3 Ovariolysis: the left endometrioma is liberated from the ovarian fossa

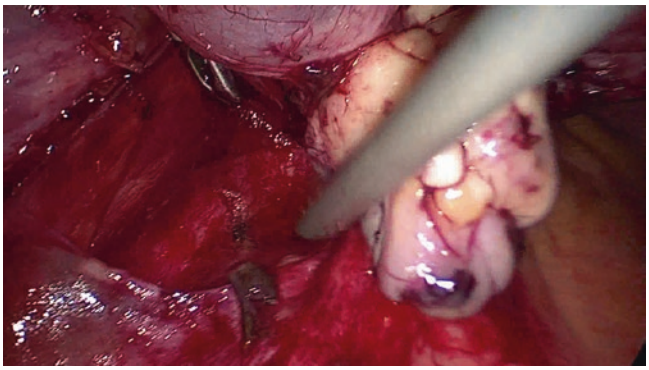

Fig. 48.6 Dividing tissues using divergent forces reveals the ureter, medial to the IP ligament

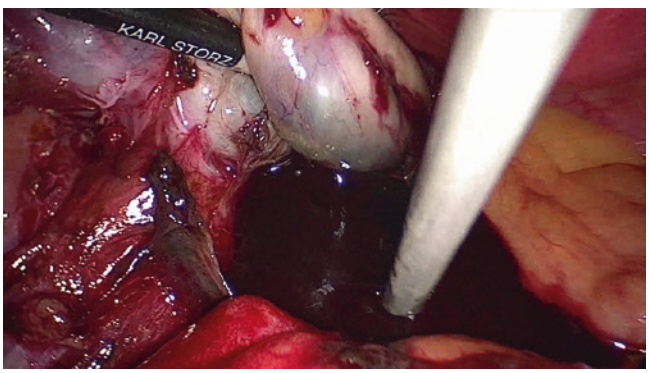

Fig. 48.4 Aspitation of typical chocolate liquid

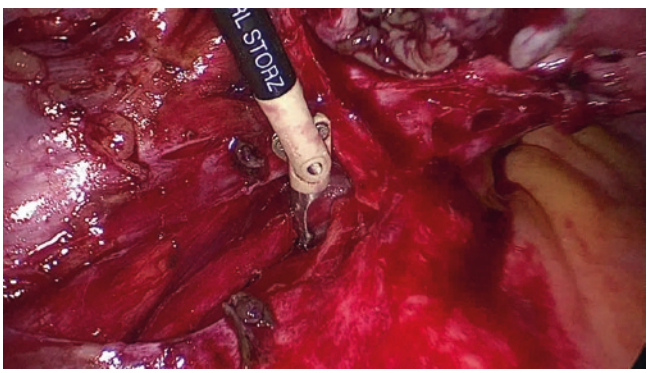

Fig. 48.7 Dissection progresses caudally and left pararectal fossa is entered

identified and it is crucial to individualize it in order to preserve it during further dissection. The peritoneum is opened at the level of infundibulo-pelvic (IP) ligament (Figs. 48.5 and 48.6). Tissues are divided until the ureter becomed apparent, medial to the IP ligament (Fig. 48.7). Dissection is carried caudally and the pararectal fossa is entered (Fig. 48.8). In doing so the ureter is reclined laterally and the bowel is separated from the adnexae. Further ureterolysis is performed to separate it from the IP ligament (Fig. 48.9). Once this preparatory step has been achieved, the hysterectomy can be started as usual with the section-coagulation of the round ligament (Fig. 48.10) and the division of the anterior peritoneum towards the isthmus (Fig. 48.11). Due to the retraction of the adnexae, the IP ligament is not as easily skeletonised as usual, and a further division of the anterior peritoneum is carried

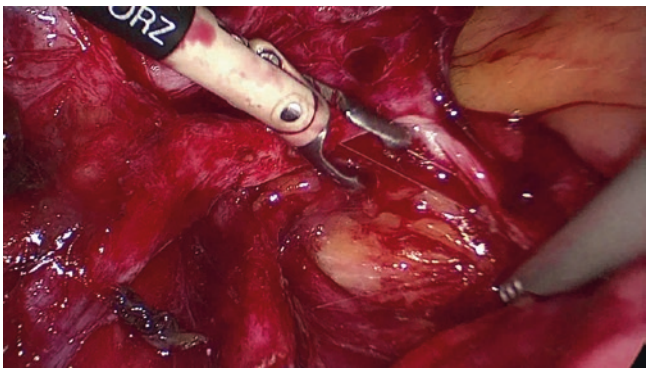

Fig. 48.8 Ureter is reclined laterally, separated from the bowel

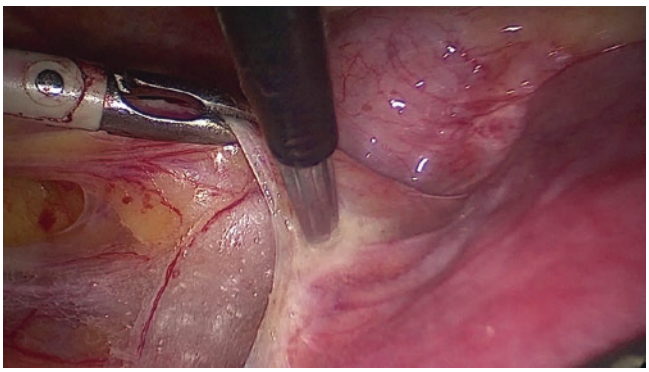

Fig. 48.11 Division of the anterior peritoneum of the broad ligament

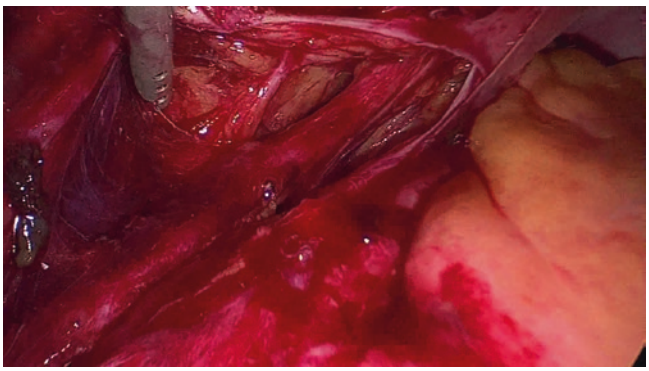

Fig. 48.9 Ureterolysis is pursued in order to separate it from the IP ligament

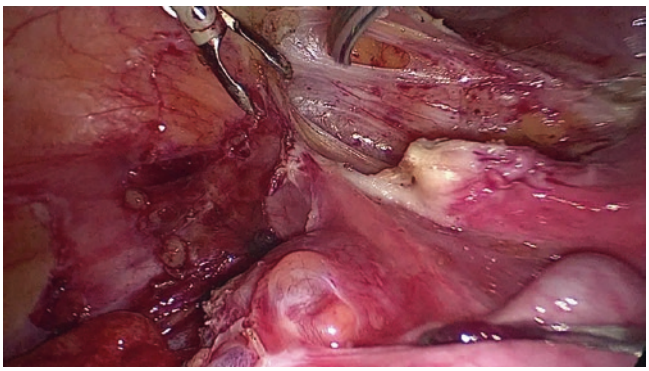

Fig. 48.12 Further division of the anterior fold, cranially, parallel to the IP ligament

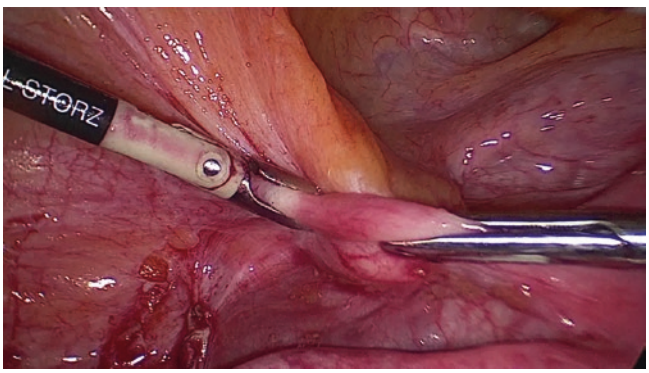

Fig. 48.10 Once the preparatory step has been achieved, the usual steps of hysterectomy can be performed: the round ligament is divided

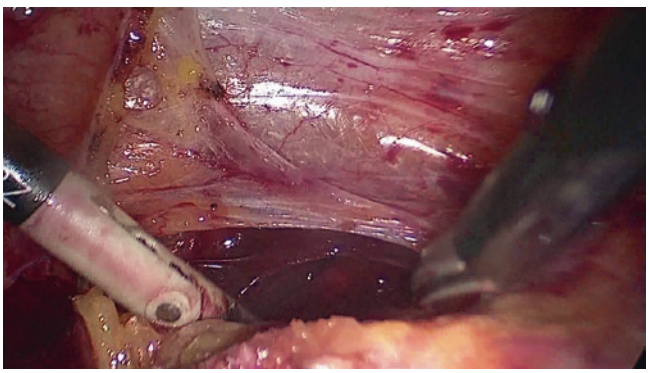

Fig. 48.13 Fenestration of the broad ligament allows to skeletonize the IP ligament

cranially, parallel to the IP ligament in order to better identify it (Fig. 48.12). The posterior peritoneum is fenestrated as usual (Figs. 48.13 and 48.14) and as a further verification measure the bipolar is passed through the opening and to the other side (Fig. 48.15). It then becomes apparent that the ureter is at a safe distance and the section-coagulation of the IP ligament can be performed safely. The rest of the hysterectomy is achieved through the classical steps.

Case 2

In this case, the endometriotic involvement is at the level of the anterior compartment with a retraction of the vesico-uterine peritoneum (Fig. 48.16). It is uncertain whether the endometriotic nodule affects the bladder or merely the anterior aspect of the uterus. Two thick lateral folds in the peritoneum are a consequence of the retraction. The dissection is initiated laterally at their level, at a safe distance

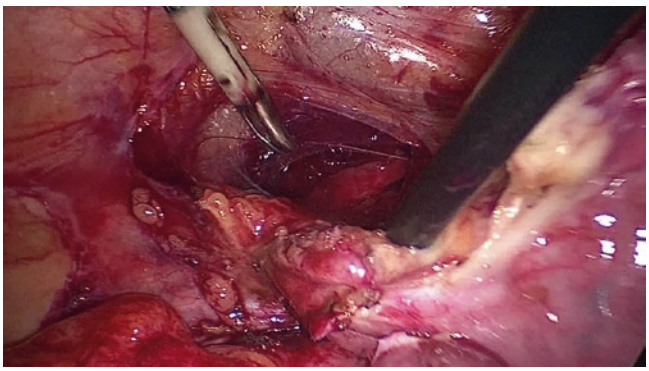

Fig. 48.14 Fenestration is achieved applying divergent forces

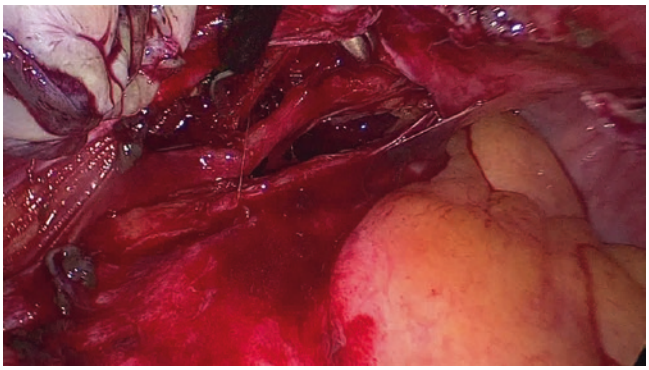

Fig. 48.15 Prior to sectioning the IP ligament, an instrument is passed through the window created in the broad ligament, and seen at a safe distance from the ureter

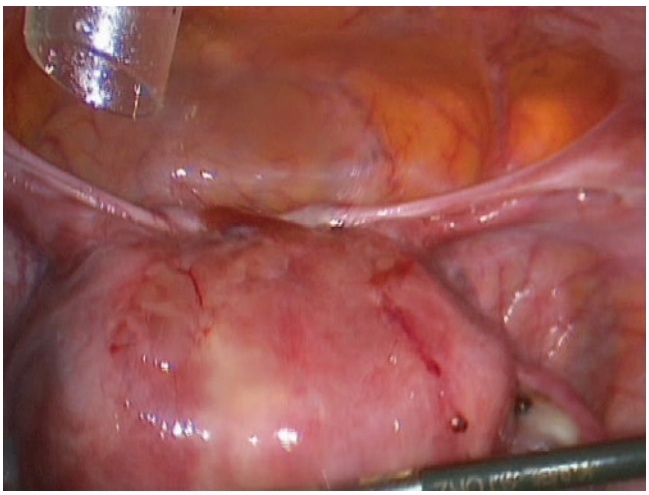

Fig. 48.16 Initial laparoscopic view: endometriotic retraction affecting the anterior compartment

from the bladder (Fig. 48.17). The peritoneum is incised and through pneumodissection, the bubble effect is seen at the level of the paravesical space (Fig. 48.18). The vesico-uterine peritoneum is divided medially (Fig. 48.19),

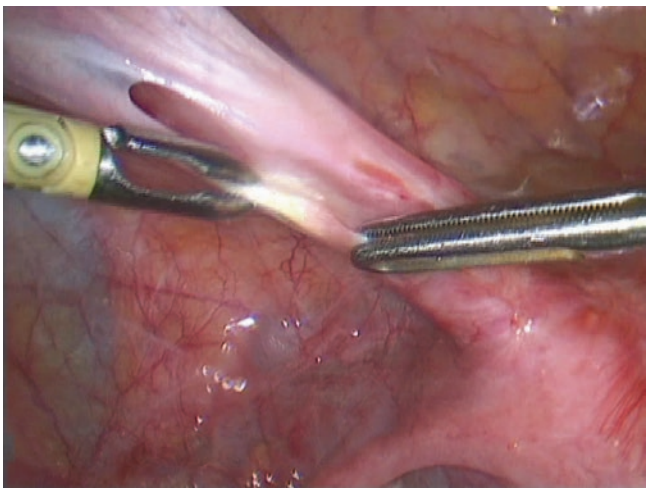

Fig. 48.17 Dissection is initiated laterally in the peritoneal retractile folds, at a safe distance from the bladder

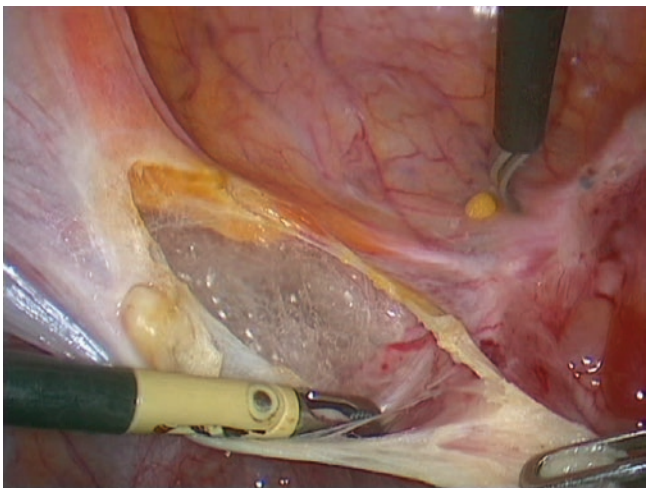

Fig. 48.18 Pneumodissection creating a bubble effect in the left paravesical fossa

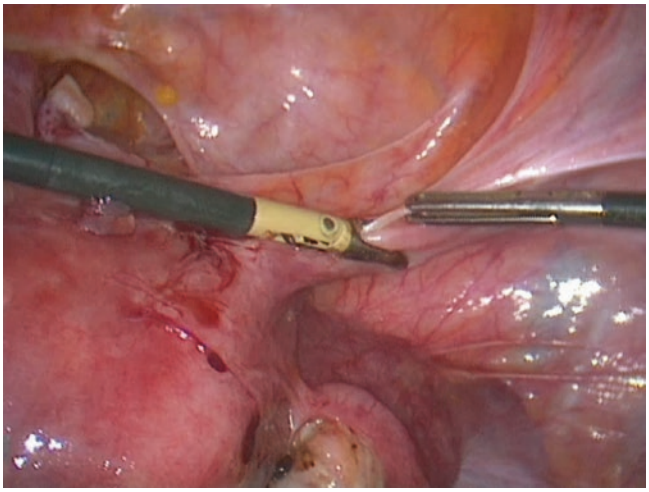

Fig. 48.20 Contralateral dissection

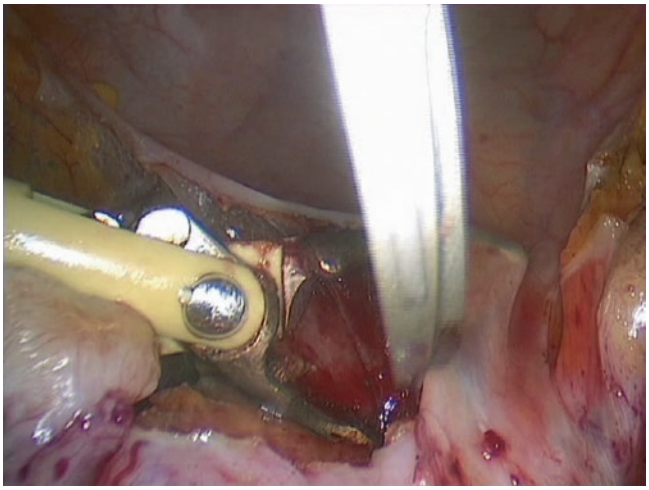

Fig. 48.22 Peritoneum dissected away from the bladder

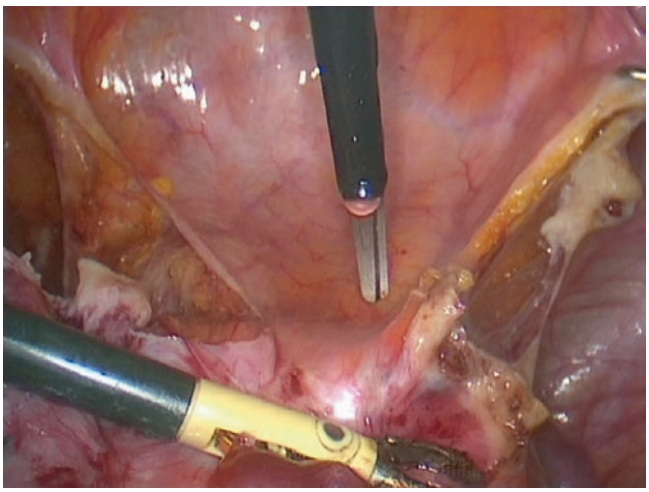

Fig. 48.21 A peritoneal bridge at the level of the bladder lays remnant after bilateral dissection

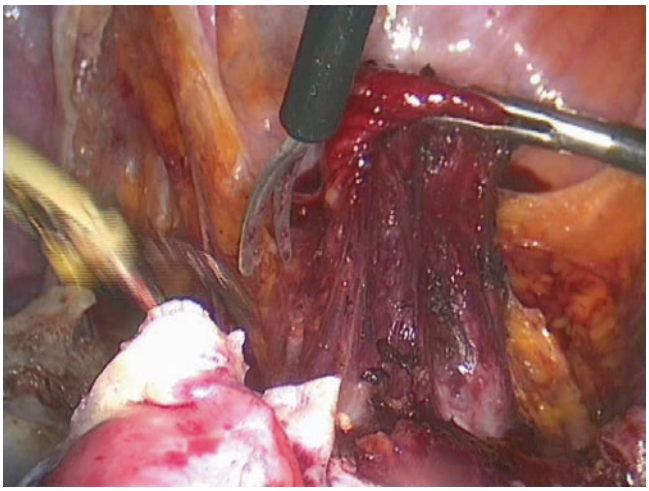

Fig. 48.23 Usual dissection of the vesico-uterine space, the endometriosis affecting the anterior aspect of the uterus, and sparing the bladder

without fully reaching the midline. The dissection is then initiated contra-laterally with the section-coagulation of the right round ligament and safely carried medially (Fig. 48.20). A peritoneal bridge then lays between the two lateral spaces of dissection (Fig. 48.21), close to the bladder. Through divergent movements of the bipolar jaws (Fig. 48.22), the peritoneum is progressively separated from the bladder then divided. It is at that point apparent that the bladder is unaffected. The bladder is seized and the vesico-uterine space is dissected in the usual manner (Fig. 48.23). At the end of the dissection, the endometriotic retraction has been fully separated from the bladder and is entirely on the anterior aspect of the uterus (Fig. 48.24). At that level, the colpotomy will be displaced caudally in order to include the disease. The rest of the hysterectomy can be carried through the usual steps.

In conclusion of these two cases, the usual steps of the hysterectomy apply, but depending on the location of the

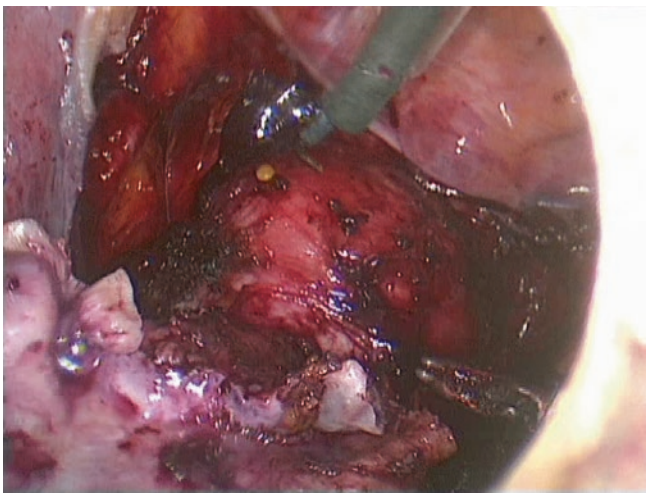

Fig. 48.24 Initiation of colpotomy. The line will be displaced caudally for the hysterectomy to entirely include the endometriotic tissue

endometriosis, a preparatory operative step is necessary. It aims to identify and keep the adjacent organs at a safe distance.

Laparoscopic Hysterectomy (TLH) in Obese Patients

49

Raffaele Tinelli and Ettore Cicinelli

Introduction

Several studies showed that LPS treatment of obese women with endometrial pathologies offers many advantages compared to the open approach [1–4] primarily considering the less postoperative pain, better visibility of the operative field, and shorter hospital stay as the main benefit [5, 6]; postoperative complications after LPS treatment seems to be reduced or similar [1, 3], likely related to the laparoscopic expertise of the operating surgeons and the patient's co-morbidities.

However, this procedure does not seem to modify the incidence of intra-operative and post-operative complications [3, 7].

It appears from data of several studies that LPS hysterectomy may offer significant advantages over LPT in the comprehensive surgical management of extremely obese women, but it should be performed by advanced laparoscopic gynaecologic surgeons [7].

Surgical Technique of Laparoscopic Hysterectomy

After dilatation with a Hegar dilator (no. 7.5), an uterine manipulator (*Clermont-Ferrand,* Karl Storz, Tuttlingen, Germany) is inserted.

A 11 mm Endopath XCEL® trocar (Ethicon, Johnson & Johnson, USA) that incorporates the zero-degree laparoscope (Karl Storz, Tuttlingen, Germany) was inserted through an umbilical vertical incision, after pneumoperitoneum by Veress needle (Covidien Cares, Minneapolis, MN) has been induced at the level of umbilicus.

Difficulties of entry into the abdomen in obese patients are often associated with the expanded thick fatty layer of the abdominal wall, especially with translocation of the umbilicus which is more caudal to the normal umbilical site and just below the aortic bifurcation.

In our technique, an 11 mm skin incision is created at the superior crease of the umbilical fold, and the underlying subcutaneous adipose tissue is bluntly dissected using the tip of a fine clamp until the umbilical stalk is isolated at the inferior and central part of the incision.

There is a concern that rare but life-threatening complications can occur, including severe bleeding due to damages of major abdominal vessels, as well as other injuries related to bowel and bladder trauma, subcutaneous emphysema and postsurgical infections.

To prevent these complications and risks, the abdominal wall is elevated by upward traction. In obese patients the Veress needle is then inserted nearly perpendicular to the incision and turned toward the pelvis "immediately" after resistance to the needle has been lost.

Three suprapubic ancillary trocars were used: one 5 mm Endopath XCEL® trocar (Ethicon, Johnson & Johnson, USA) trocar was inserted in the midline 3 cm under the umbilicus, and one in each iliac fossa (11 mm on the left side and 5 mm on the right size) laterally to inferior epigastric vessels, respectively.

Before the operative procedure, all the pelvic structures are inspected and the abdomen explored through the laparoscope in a clockwise fashion.

Laparoscopic hysterectomy is performed with the patient in an approximately 30 ° Trendelenburg position to facilitate retroperitoneal exposure by retaining the small intestine in the mid and upper abdomen using gravity and gentle instrumentation. In patients with a prior midline incision, the initial entry into the abdominal cavity was made approximately 2 cm below the left costal margin at the level of the midclavicular line to avoid injury to bowel adherent to the anterior abdominal wall.

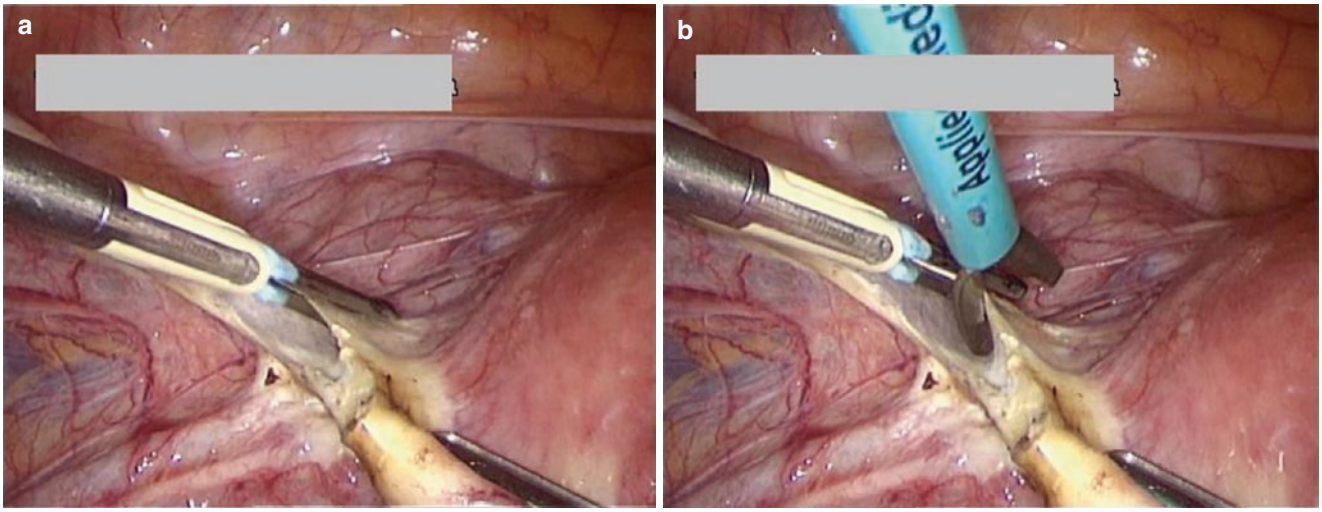

Fig. 49.1 (**a**, **b**) The round ligament is coagulated and transected with endoscopic shears

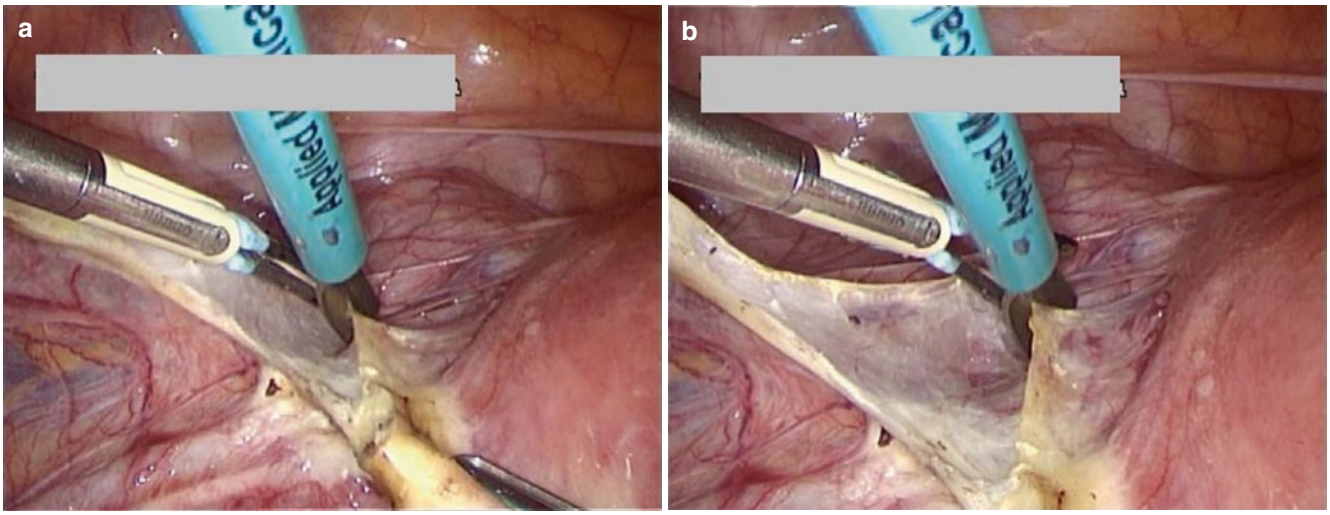

Fig. 49.2 (**a**, **b**) The vesico-uterine fold is grasped and incised

A MiniPort 2 mm single use introducer (MiniPort-Auto-Suture, USSC, Norwalk, CT) and a stopcock for insufflation and desufflation were used to establish the pneumoperitoneum.

The obturator had a spring-loaded, blunt stylet similar in function to a Veress needle. A circular adjustable stopper located on the sleeve of the miniport allowed for adjustment of depth in the cavity. The system was used to establish and maintain the pneumoperitoneum in the abdomen while providing access for a minilaparoscope with a diameter of 1.9 mm and a length of 10 or 12 cm (Karl Storz, Tuttlingen, Germany).

The round ligament is coagulated and transected with endoscopic shears (Fig. 49.1). The vesico-uterine fold is grasped and incised (Fig. 49.2) while the bladder is isolated: after dividing the vesico-uterine fold (Fig. 49.3, the suction-irrigator probe pushes the bladder completely from the upper vagina (Fig. 49.4).

The anterior and posterior peritoneal layers of the broad ligament are opened and the ureter is identified at the pelvic brim, traced into the pelvis and freed from the posterior leaf of the broad ligament. The ovarian ligament is coagulated (Fig. 49.5) with bipolar forceps and transacted with scissors. The uterine vessels are identified allowing an excellent skeletonization of the obliterated artery by preparing the anterior and posterior web. The uterine artery is coagulated and transected.

The vagina is visualized and the vaginal cuff around the cervix is transected with the monopolar needle (Fig. 49.6), incising the vagina circumferentially using the

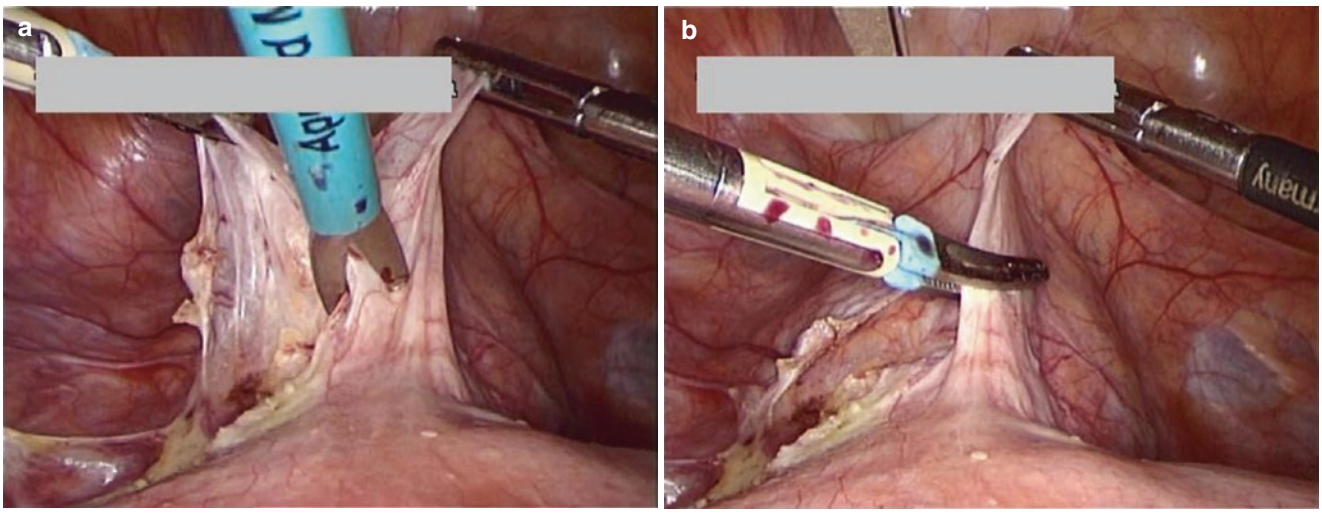

Fig. 49.3 (**a**, **b**) The bladder is isolated after dividing the vesico-uterine fold

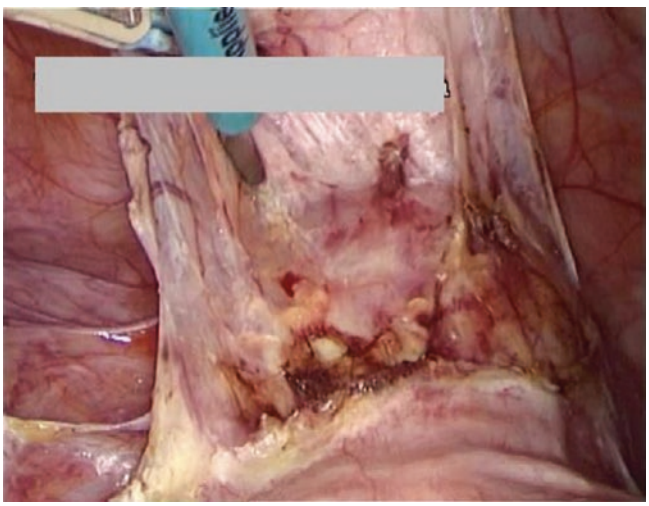

Fig. 49.4 The endoscopic sheras pushes the bladder completely from the upper vagina

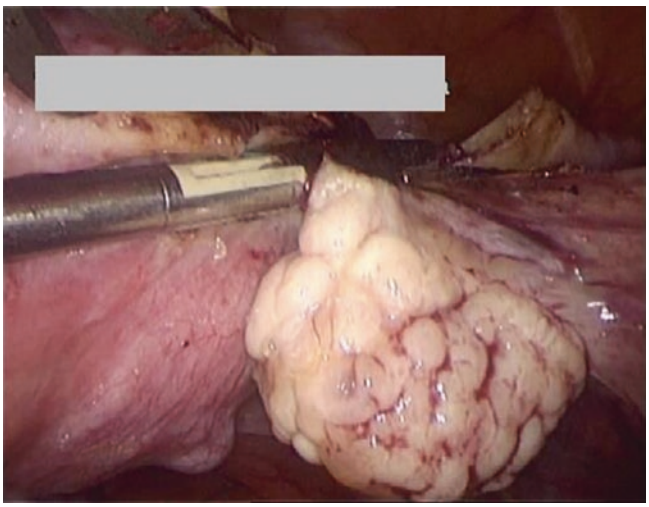

Fig. 49.5 The ovarian ligament is coagulated with bipolar forceps and transacted with scissors

porcelain-valve of the uterine manipulator as a guide; the uterus is removed vaginally. The vaginal vault is closed with continuous 0-polysorb sutures by laparoscopic access and after the laparoscopic control of the haemostasis is performed (Fig. 49.7). The 5- and 10-mm incisions are closed with mattress sutures of 2–0 Rapide Vycril. At the conclusion of the surgical procedure we deflated the abdomen before removing the trocars.

During laparoscopic surgery in obese patients, sufficient intraabdominal workspace is important for the surgeon. Therefore, most surgeons request that their patients be placed in an adequate Trendelenburg position to facilitate retroperitoneal exposure in the case of lymphadenectomy. This leads to retention of the small intestine in the mid and upper abdomen using gravity and gentle instrumentation and reduces bowel injury; however, the effect of an increased workspace is not always sufficient.

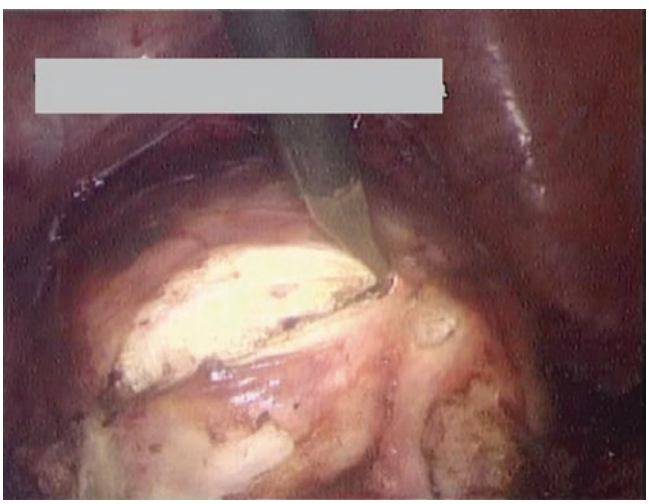

Fig. 49.6 The vagina is visualizated and vaginal cuff around the cervix is transected with monopolar needle

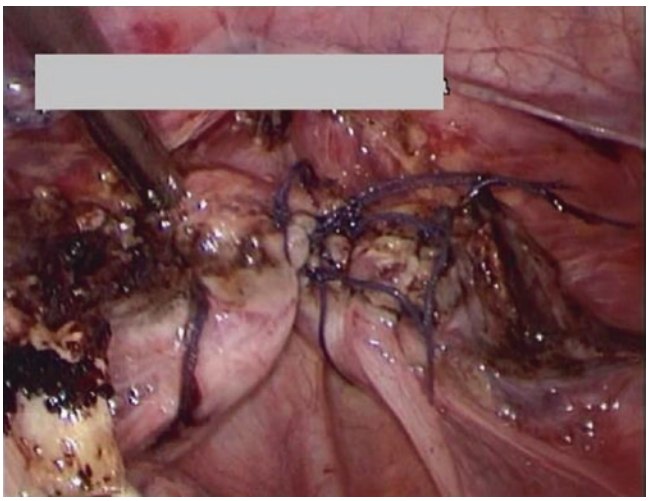

Fig. 49.7 The vaginal vault is closed with continuous 0-polysorb sutures by laparoscopic access and after the laparoscopic control of the hemostasis is performed

Discussion

Obese patients with endometrial cancer patients exhibit a large accumulation and abnormal distribution of abdominal fat; these characteristics seriously affect the exposure of the operative field. In addition, perivascular fat parcels and lipid deposition on vascular walls lead to increased vascular fragility; as a result, slight stretching of blood vessels can easily lead to vascular rupture and bleeding, which severely affect the surgical process and increase surgical difficulty and risk. Furthermore, obesity is frequently associated with many cardiopulmonary and other chronic diseases that decrease operational tolerance.

Many patients with gynaecologic pathologies present with co-morbidity such as obesity, hypertension, and diabetes [8]. Abdominal surgery is therefore exposing patients into increased risk of complications [9].

The role of minimally invasive surgical staging in the management of extremely obese patients with gynaecologic pathologies continues to evolve. Recently, several studies concluded, as others, that the post-operative complications after LPS treatment are reduced or similar [5, 9–12].

Brezina et al. compared the surgical outcomes of 293 obese women undergoing hysterectomy (LPT, vaginal, or LPS). No significant difference was found in obese women between LPS and LPT hysterectomy for operative time and anaesthesia. They concluded that in obese patients for whom vaginal hysterectomy is not possible, LPS hysterectomy should be considered before LPT hysterectomy because the LPS route reduced hospital time and blood loss [13].

Nawfal et al. estimated the impact of body mass index (BMI) on the surgical outcomes of 135 patients undergoing robotic-assisted total LPS hysterectomy for benign indications. They concluded that BMI is not associated with blood loss, duration of surgery, length of stay, or complication rates in patients undergoing robotic-assisted total LPS hysterectomy. Robotic assistance may help surgeons overcome adverse outcomes sometimes found in obese patients [14].

Bardens et al. investigated the influence of the body mass index (BMI) on 200 patients who underwent LPS hysterectomy for benign disease. The group of overweight women had the highest rate of complications and the group of obese women had the lowest. However, the rate of women who required readmission and reoperation was not elevated in the overweight group. They concluded that LPS hysterectomy is a safe and feasible method even in obese and morbidly obese patients. Overweight and obesity increase the time needed to perform LPS hysterectomy but do not seem to relevantly influence the rate of major intra and postoperative complications [15].

Harmanli et al. compared the effect of obesity on perioperative outcomes in women undergoing LPS supracervical hysterectomy (LSH) or LPS total hysterectomy (TLH) for benign conditions in obese (body mass index > or = 30 kg/m^2) and non-obese women. The rates of urinary tract injury, vaginal cuff dehiscence, postoperative fever, and ileus were similar between the groups. Of all seven cuff dehiscences, 5 (71 %) occurred in non-obese women undergoing TLH. They concluded that obesity increased the risk of bleeding requiring transfusion and conversion to laparotomy but did not influence the other perioperative complications. LSH in non-obese women seems to result in best outcomes [16].

In a recent study by Fanfani et al. they analysed perioperative outcomes of Laparo-Endoscopic Single-Site (LESS) hysterectomy in obese and non-obese women in a multicentric retrospective case-control study on 115 women who underwent LESS hysterectomy and were divided into two groups: obese (n = 43, BMI $\geq$ 30 kg/m^2) and non-obese (n = 72, BMI < 30 kg/m^2). No statistical differences regarding perioperative outcomes were observed between the two groups. Conversion to laparotomy occurred in 1 obese (2.3 %) and 3 (4.2 %) non-obese women. Intraoperative complication rate was 11.6 % and 9.6 % in obese and non-obese women, respectively. The early postoperative complication rate was 6.9 % in obese and 4.1 % in non-obese women. This study suggested that obesity (BMI $\geq$ 30) does not preclude successful completion of total LESS hysterectomy [17].

In a recent retrospective study Tinelli et al. compared the safety, complication and recurrence rate after total LPS hysterectomy with lymphadenectomy and LPT hysterectomy with lymphadenectomy for early stage endometrial carcinoma in a series of 75 extremely obese women (BMI > 35).

They performed a multicenter study of all the complications after treatment of 75 consecutive extremely obese patients with clinical stage I endometrial cancer who

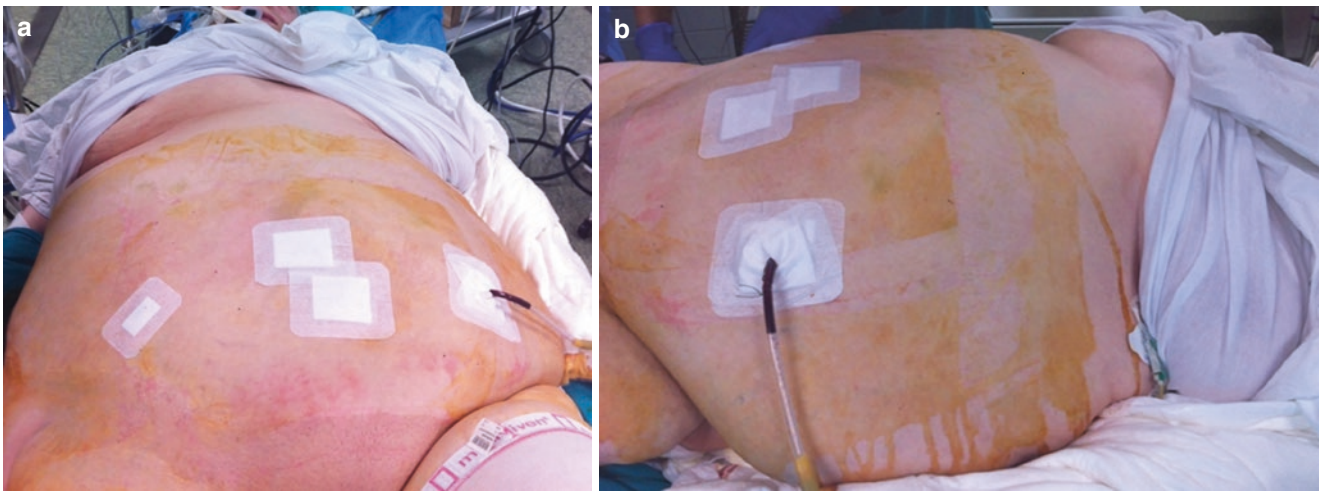

Fig. 49.8 (**a**, **b**) LPS procedures were successfully completed without conversion to LPT and no patient of the two groups required an intraoperative or postoperative blood transfusion

underwent LPS hysterectomy (45 cases) or LPT hysterectomy (30 cases) with pelvic and aortic lymph node dissection.

According to the FIGO staging system, all the patients underwent surgical staging consisting of total hysterectomy, bilateral salpingo-oophorectomy, and in all cases systematic bilateral pelvic lymphadenectomy was performed. In three patients of the LPT group they observed a dehiscence of the abdominal suture with surgical site infection in the first week after surgery that was resutured with interrupted sutured with no sequelae. Postoperative fever was reported in 6 (20 %) patients of the LPT group and in 2 patient of LPS (4.4 %) group.

No case of port-site metastasis, no vascular injury and no wound complications were detected.

In all cases the LPS procedures were successfully completed without conversion to LPT and no patient of the two groups required an intra-operative or postoperative blood transfusion (Fig. 49.8).

One case of bladder injury occurred in the LPS group at the time of utero-vesical fold incision that was laparoscopically sutured.

In this multicentre study, no significant difference in intra-operative complications was observed between groups, whereas postoperative were significantly less common in the LPS than in the LPT group.

We can speculate that LPS hysterectomy in extremely obese women is associated with safety and efficacy outcomes that are similar to those that have been reported for LPT hysterectomy for the treatment of endometrial pathologies [18, 19].

In fact, in almost cases the LPS procedures were successfully completed without conversion to LPT and no patient of the two groups required an intra-operative or postoperative blood transfusion.

Therefore, it appears from data of our studies that LPS hysterectomy may offer significant advantages over LPT in the comprehensive surgical management of extremely obese women, but it should be performed by advanced laparoscopic gynaecologic surgeons.

In fact, a totally LPS hysterectomy is more difficult in the morbidly obese and other patient factors such as associated co-morbidities, adhesive disease, large uteri, fatty mesentery, and inability to tolerate steep Trendelenburg have limited widespread use of this approach in the treatment of uterine pathologies [3–7, 20].

The obese patients with associated co-morbidities had the most to gain from a successfully completed minimally invasive procedure, but also offered the surgeon the greatest challenges to complete the case [21–24].

Moreover, the LPS permits a better exposure of the operative field in association with the advancement of the LPS techniques allowing better dissection of the pelvic spaces; however, it should be outlined that LPS procedures have to be always performed by the same surgical team [4, 7, 12].

Several studies confirm that LPS hysterectomy remains, in expert hands, the procedure better related to the best short-term outcomes in obese women [13–19, 25].

In fact, LPS hysterectomy was associated with a shorter time of post-operative ileus, shorter hospitalization, lower cases of dehiscence of the suture with surgical site infection, reduced cases of postoperative fever, and a reduced time of discharge when compared with LPT fever reducing the costs.

Conclusion

Our data confirm that LPS hysterectomy in extremely obese women improves quality of life in the postoperative period with reduced time of discharge.

The low intra-operative and post-operative complications rate observed in the LPS group highlights the feasibility, safety and efficacy of this surgical approach for the obese patients.

LPS hysterectomy can be considered a safe and effective therapeutic approach for management of e obese women with a better visibility of the operative field, lower postoperative pain, and a significantly lower blood loss, although multicentre randomized trials, long-term follow-up and cost-benefit analyses are required to determine if the use of LPS improves outcomes over standard LPT in obese women and if the advantages of this technique could be extended to a larger proportion of patients.

Laparoendoscopic Single-Site (LESS) Hysterectomy

50

Anna Fagotti, Cristiano Rossitto, Francesco Fanfani, and Giovanni Scambia

Introduction

Since its introduction laparoscopic surgery has undergone several advancements. More minimally invasive approaches to further reduce surgical morbidity represent a recent progress in laparoscopy. They consist of a reduction either in port's dimension or in port's number. This last option is called single-site surgery. This approach is performed through a single trans-umbilical multiport device. A multidisciplinary consortium of surgeons, who met at the Cleveland Clinic in July 2008, coined the acronyms of laparoendoscopic single-site surgery (LESS) that included all the techniques performed with a single transumbilical skin incision [1]. Since its first reports [2–5], there has been a considerable surge of interest in LESS as a virtually scarless procedure for a variety of surgical indications in different fields. LESS has been utilized to successfully perform a large number of procedures also in general surgery [6–8]. It was first reported for gynecological procedures in the 1970s for laparoscopic tubal ligations [9]. However, this procedure did not initially gain popularity because of technical challenges. In the last decade, technological advances in flexible optical and coagulation devices allowed performing more advanced procedures, such as total LESS hysterectomy and pelvic/aortic lymphadenectomy. In this period several reports have come out to demonstrate the feasibility and reproducibility of this approach for benign and malignant uterine disease [1, 3, 4, 10, 11].

e-mail: francesco.fanfani@unich.it

The benefits of single-site surgery seem superior to those reported for standard laparoscopy, including faster recovery, and lower postoperative analgesic requirements and better cosmetic results [12–14].

Or Set-Up and Patient's Positioning

Since single port surgery is a technically complex approach even in case of simple operations, the operating room set up needs to be modified to make the surgeon drive in the most ergonomic position. To this purpose, every single detail should not be overlooked, to avoid difficulties during surgery.

We demonstrated that the OR staff must move around the patient, in an anti clockwise of about half an hour. Accordingly, the first surgeon is positioned at the head of the patient, the first assistant is sitting at her right side, and the second assistant is sitting and moving the uterine manipulator between the patient's legs [10]. The anaesthesiologist and his instrumentation are located between the surgeon and the assistant. The nurse is at the left side of the patients, to easily switch the surgeon's instruments. Finally, two monitors should be positioned at the head and legs of the patient, respectively (Fig. 50.1).

Following the induction of general anaesthesia, the patient is positioned in the dorsal lithotomic position with both legs supported in stirrups with a steep Trendelenburg tilt. In this way, the head of the patient is located at the level of the surgeon's legs. This position allows a number of benefits: (1) small bowel ansae are easily dislocated outside the pelvis; (2) the distance between the working instruments at the umbilicus and surgeon's hands is significantly reduced; (3) the surgeon achieves a very ergonomic position, thanks to the 90 ° angle between the surgeon's arm and forearms.

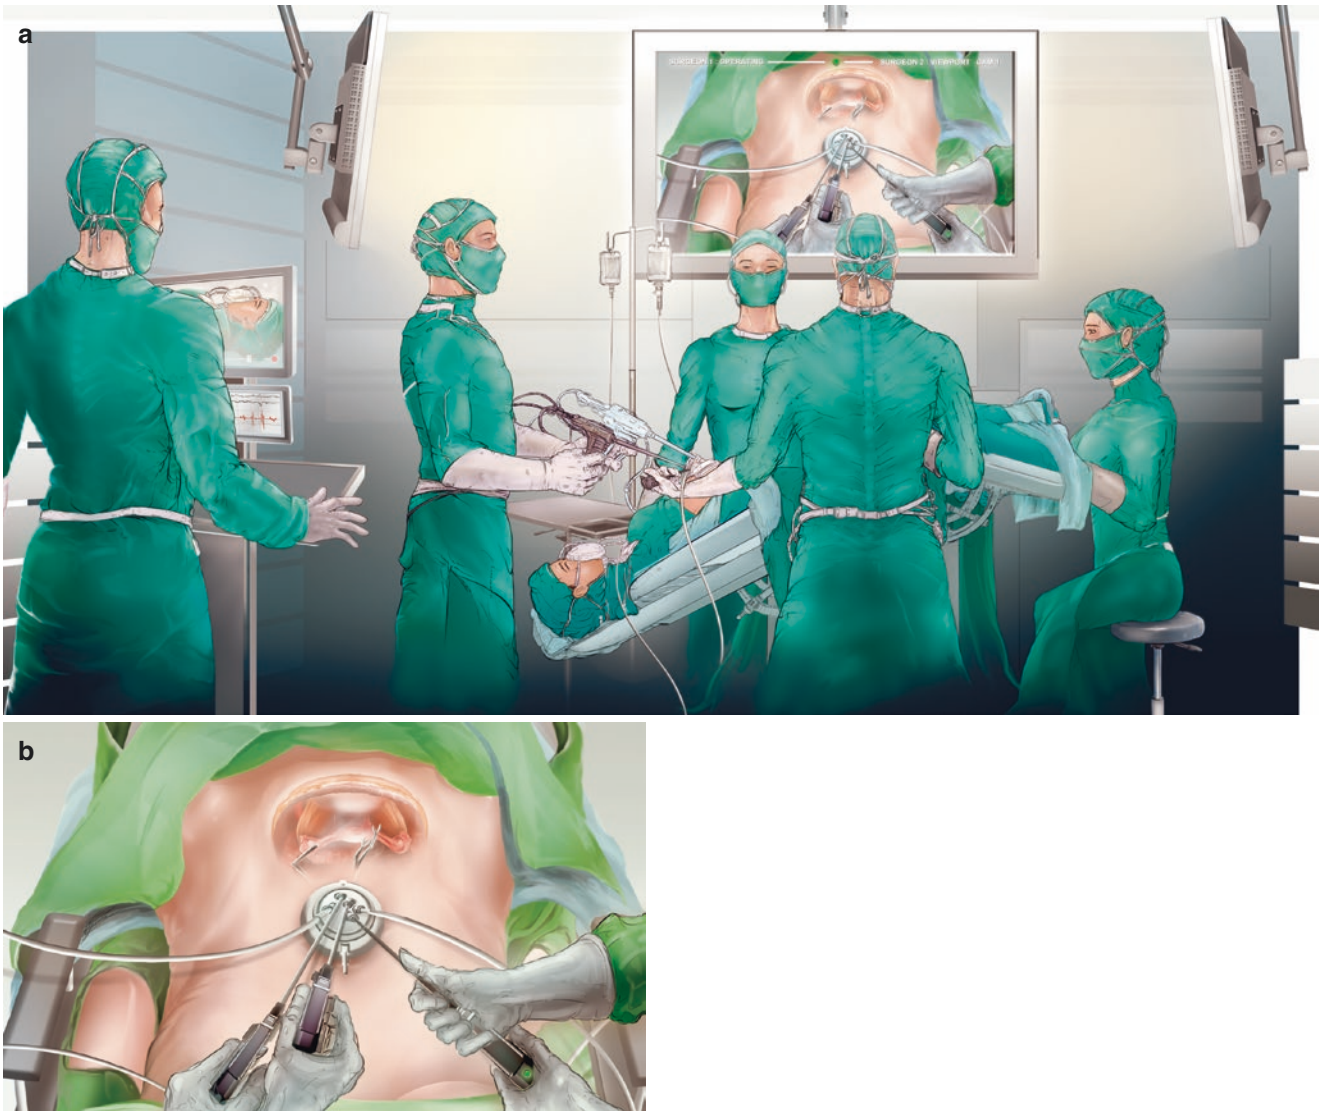

Fig. 50.1 (**a**) OR setting, (**b**) Surgeon's point of view on LESS approach

Instruments

The insertion of the single trocar is obtained by a skin incision within the umbilical scar of about 1.5–2 cm. We suggest performing a larger incision (2.5 cm) in the underlying abdominal fascia in order to avoid any clashing between the instruments and the optic [10]. Single port trocar may have different numbers and sizes of ports for the insertion of the instruments. However, a minimum of three 5 mm ports is required to perform SS hysterectomy.

Dedicated optics to single port surgery allow the best balance between an excellent intra abdominal visualization and no conflict between the camera and the instruments outside the patient. To this purpose, they are usually 5 mm HD telescopes, either with a long and flexible external arm and a 30 ° optic, or with a flexible internal tip and a 0 ° optic.

We strongly suggest using the uterine manipulator to perform single-site hysterectomy. It may partially replace the *third missing hand* with single port surgery, making the indispensable traction on the uterus, and thus resulting much more helpful than in traditional laparoscopy.

Working 5-mm instruments are inserted into the remaining ports, choosing among graspers, bipolar coagulator, cold scissors, suction/irrigation, and a multifunctional device, which grasps, coagulates and transects, simultaneously.

To prevent clashing between instruments and surgeon's hands and to facilitate surgical manoeuvres, the combination of one 33-cm-long instrument with a 43-cm-long straight instrument is suggested. Alternatively, one double bended and one straight instrument could be adopted.

In our opinion, the standard equipment to perform LESS hysterectomy should consist of a 5 mm HD 0 degree optic

Fig. 50.2 Standard equipment to perform LESS hysterectomy

with flexible tip, a 43 cm long bipolar grasper, a standard multifunctional device, a 43 cm long suction/irrigation, and a uterine manipulator. This set allows the best performances in terms of intra-operative visualization, safe and effective coagulation and cutting, which reflects in a shorter operating time, and lower complication rate (Fig. 50.2)**.**

Surgical Steps and Technique

Surgical steps during LESS hysterectomy should not differ from those described for any abdominal hysterectomy (either laparotomy and traditional laparoscopy). This avoids potential confusion, which may lead to serious intra- and post-operative complications.

Here we present the CUSH (Catholic University of the Sacred Heart) technique for total extrafascial hysterectomy (class A according to Querleu and Morrow) [15].

Coagulation and Section of the Round Ligament

The cutting landmark is the perpendicular projection of the obliterated umbilical artery on the ligament itself (Fig. 50.3). The identification of the correct point allows a safe access to the pelvic retro-peritoneum, through an avascular space, thus avoiding unnecessary bleeding from the small vessels of the broad ligament.

Access to the Pelvic Retro-Peritoneum

Once the round ligament has been sectioned, the wide ligament is opened in a dorso-caudal direction through the surgeon's forceps and CO2 (Fig. 50.4).

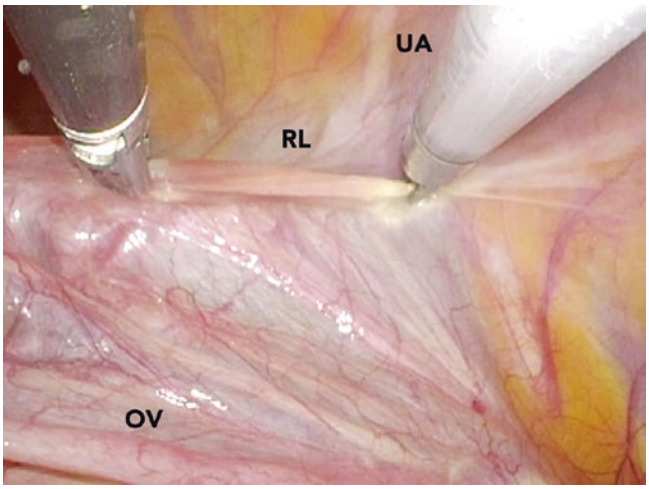

Fig. 50.3 Round ligament (*RL*), coagulated and resected along the vertical projection of the umbilical artery (*UA*). Ovarian vessels (*OV*)

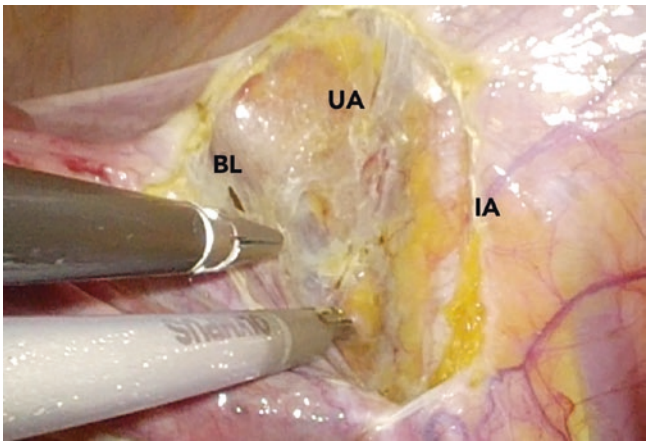

Fig. 50.4 Access to the pelvic retro-peritoneum on the right side. Umbilical artery (*UA*), iliac artery (*IA*), broad ligament (*BL*)

Identification of the Ureter

Through a gentle dissection of the loose connective tissue, the pelvic portion of the ureter is visualized at the posterior layer of the broad ligament. The peristaltic movement of the ureter may be helpful, for its correct identification (Fig. 50.5).

Identification and Closing of the Uterine Artery at Its Origin

In most cases, the uterine artery is the first branch of the obliterated umbilical artery, which is, in turn, a branch of the internal iliac artery. In a small percentage of anatomical variants (about 10 %), it can come directly from the internal iliac or hypogastric iliac artery.

Closing with metal clips the uterine artery at its origin, laterally to the ureter, may serve either as effective haemostats as well as an indirect landmark for the ureter throughout the operation (Fig. 50.6).

Coagulation and Section of the Ovarian Vessels/Utero-Ovarian Ligament

In case of hysterectomy with adnexa removal, we suggest to create a peritoneal window between the ovarian vessels (upper) and the ureter (below) (Fig. 50.7). This procedure moves the ureter further away from the coagulating energy, thus avoiding any ureteral potential injury. The ovarian vessels should be coagulated with extreme caution to avoid any bleeding, in subsequent steps, by alternating between coagulations and cut of small parts of the vessels.

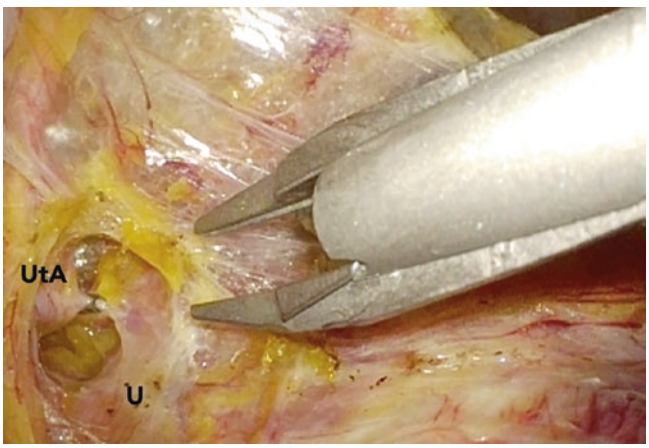

Fig. 50.5 Identification, dissection and closure of the uterine artery (*UtA*) at its origin. The ureter (*U*) passing below the arc drawn by the uterine artery.

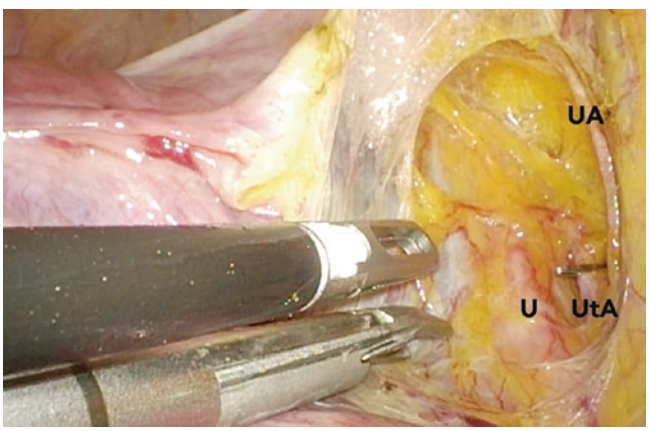

Fig. 50.6 Identification of the retro-peritoneal structures. Uterine artery (*UtA*) closed at the origin with haemostatic clip. Ureter (*U*). Umbilical artery (*UA*)

In case the adnexa will be conserved, the section of the ovarian vessels will be performed proximally to the uterus, at the level of the utero ovarian ligaments. They should be coagulated and cut, leaving 1–2 cm from the uterine body, in order to avoid any bleeding of the cervical branches of the uterine artery.

Section of the Utero-Sacral Ligaments

Detachment and section of the peritoneum covering the utero-sacral ligaments allows colpotomy to be performed more bloodlessly, moves the ureters further away from the energy application and avoids damage to the uterine vessels which remain in the lateral position (Fig. 50.8).

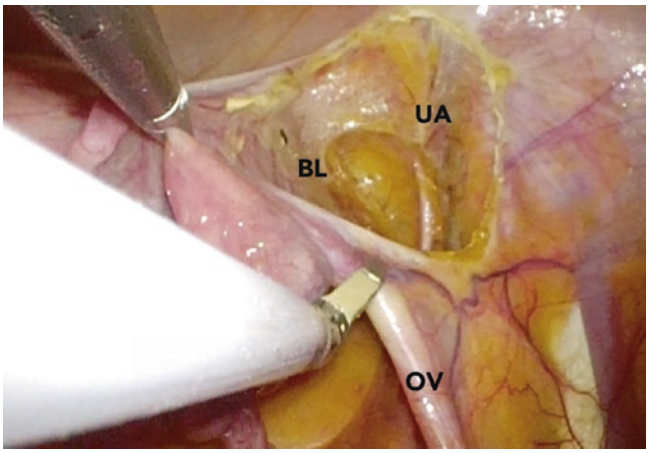

Fig. 50.7 Coagulation and section of the ovarian vessels (*OV*). Umbilical artery (*UA*). Broaf ligament (*BL*)

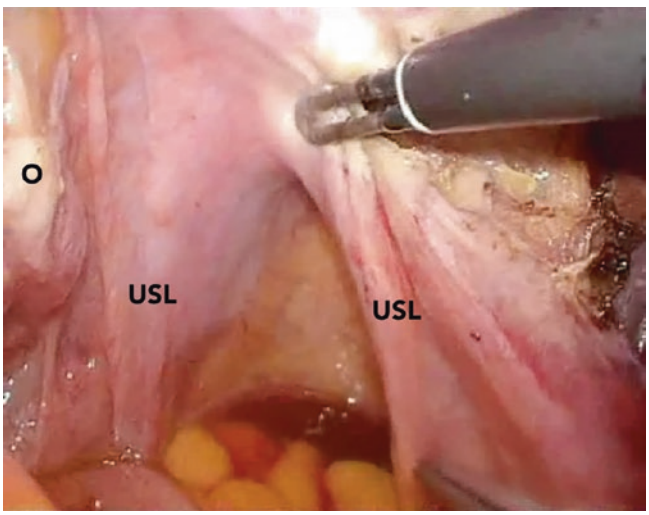

Fig. 50.8 Dissection along the posterior part of the broad ligament, to resect the uterosacral ligaments (*USL*). Ovary (*O*)

Development of the Vesico Uterine and Vesico Vaginal Spaces

Development of the anterior space requires the assistant to apply a strong tension to the uterus in a ventro-medial direction. This tension allows the surgeon to develop the anterior space, between the uterine vessels (dorsal – lateral), the cervix (caudal-medial) and the bladder (anterior). This step must be performed following a latero-medial direction, to avoid any potential risk of damaging the bladder, as in case of previous surgery at this level (i.e. caesarean section). The peritoneal reflection between cervix-vagina and bladder is often very clear. The dissection should be performed 1 cm caudally to this reflection, not to open the cervical fascia. After completing the lateral dissection, both on the right and the left side, the surgeon may grasp the bladder upwards to highlight the peritoneal passage during the central detachment (Fig. 50.9).

Identification, Coagulation and Section of the Uterine Vessels

The coagulation of the uterine vessels in the iuxta-uterine position entails their dissection, so that haemostasis is more precise and safe. After closing the uterine artery at its origin, the vessel coagulation shall be performed progressively since venous reflux bleeding can still occur from the cervical and vaginal branches (Fig. 50.10).

Colpotomy

Colpotomy is a circular incision of the vagina, which is performed closer to the cervix to reduce the vaginal border removal. Colpotomy can be performed with monopolar current (Hook or scissors) or with new multifunctional devices (advanced bipolar or ultrasonic). After closing of the uterine vessels and preparing the anterior and posterior peritoneal planes, this step will be virtually bloodless.

The uterine manipulator valve, introduced into the vagina, will help us to decide on the incision starting point and will guide the operator throughout the colpotomy (Fig. 50.11).

Removal of the Uterus and Closure of the Vaginal Cuff

In the case of histologically proven benign pathologies, the uterus can be removed vaginally, integrally or through cold morcellation. In the case of malignant disease, the uterus must be removed integrally, either through the vaginal approach or by mini-laparotomy (if vaginal removal is impossible). Vaginal suture can occur either laparoscopically or through the vaginal approach. Due to the waste of time, in the single port approach,

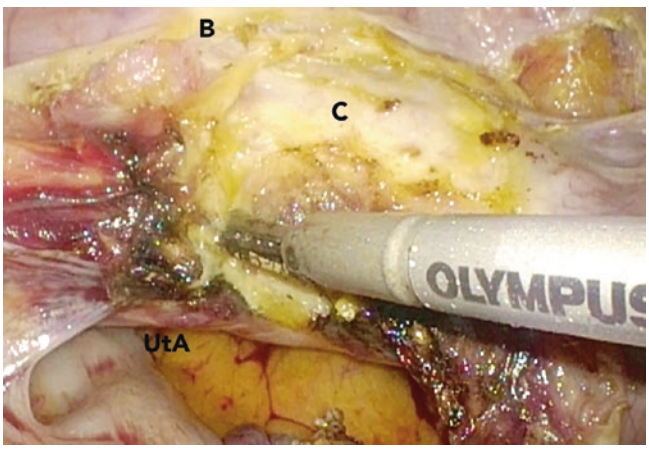

Fig. 50.10 Section and coagulation of the uterine artery (*UtA*), medially to the ureter, at the level of the cervix (*C*). Bladder (*B*)

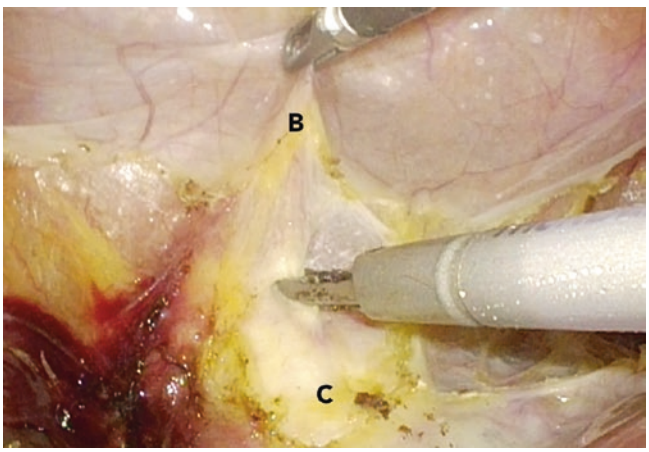

Fig. 50.9 Detachment of vesico-uterine peritoneal reflection. Bladder (*B*), cervix (*C*)

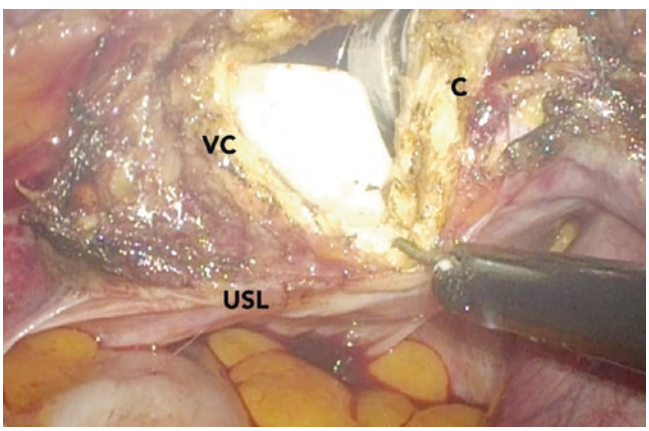

Fig. 50.11 Posterior colpotomy and section of the utero sacral ligament (*USL*). Vaginal cuff, cervix (*C*)

we prefer the vaginal suturing, using a stitch with 1 absorbable wire, first anchoring the vaginal angles and then suturing from right to left with a continuous suture.

Final Control

After suturing the vaginal vault, pneumoperitoneum is re-induced to check haemostats at the trigger points (ovarian pedicles, uterine arteries and utero-sacral ligaments), integrity of the ureter, and the bladder at the idropneumatic test. At the end of the procedure, complete CO2 essufflation should be obtained to avoid patient's pain complain after surgery. The umbilical fascia is closed with a figure-of-eight 0-Vicryl (Fig. 50.12).

Following these simple rules, each surgeon needs about twenty cases to complete his/her learning curve (Fig. 50.13)**.**

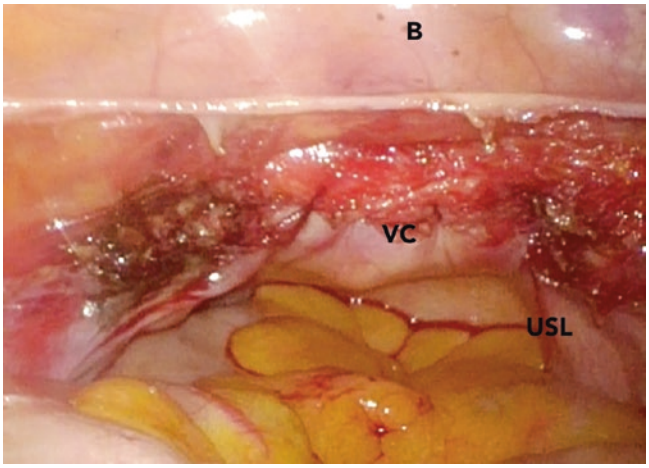

Fig. 50.12 Final imaging after removal of the uterus and vaginal colporrafy. Bladder (*B*), vaginal cuff (*VC*), utero sacral ligament (*USL*)

Laparoscopic Pelvic and Paraaortic Lymphonodectomy

51

Bernd Holthaus and Sven Becker

Current Significance of Lymphonodectomy in Gynecologic Oncology

Our current understanding of cancer has its roots in the nineteenth century. At that time the novel techniques of tissue staining – which incidentally have not changed much since – first allowed us to distinguish between normal cells and cancerous growth. The notion that cancer originates within a specific organ, invades locally but ultimately finds its way through the body to metastasize at distant sites remains one of the most fundamental tenements of current oncologic thought.

The question "How does the cancer get from A to B?" logically follows and only two pathways seem obvious: either the bloodstream or the lymphatic drainage system of the body.

It has been and remains exceptionally difficult to systematically detect cancer cells within the bloodstream and reliable technologies have only evolved over the past two decades, spurring a whole scientific industry involved with "Circulating Tumor Cells"and notions of "Liquid Biopsies". At this point, the presence of cancer cells in the bloodstream is documented, a relationship to the prognosis seems established, but the exact significance remains unclear.

The presence of supposedly "migrating" tumor cells within the lymphatic system and particularly within the lymphatic nodes has been documented for much longer. Virchow and his contemporaries were already able to discern these cells using standard hematoxylin-eosin staining.

Linking the presence of micrometastatic cancers cells in lymph nodes to a normally reduced prognosis was yet another milestone in our understanding of cancer.

It is important to stress how much this model or cancer progression, which has been the rock upon which all our treatment concepts have been built, is rooted in the mechanical view of the world that dominated the nineteenth century.

Viewing the cancer as a "runaway" renegade inevitably led to therapeutic concepts of "radical excision" and "removing the bad cells" wherever possible.

If cancerous cells are present in lymphatic nodes and if their presence there leads to a poorer prognosis, surely we can reverse this process by removing the affected lymph nodes.

Because lymphonodectomy is technically challenging and longer operating times only became possible after the introduction of endotracheal intubation after the Second World War, these pathophysiological concepts were not put into action until the 1950s. At this time Joe Vincent Meigs introduced lymph node dissection to the standard oncologic surgery of the day: the radical hysterectomy, originally pioneered by Wertheim, without lymphonodectomy. Hence the now commonly used term for the surgery: "Wertheim-Meigs-Okabayashi".

Lymphonodectomy, by and large, became the standard of all surgical oncologic procedures. Proper "staging" of the tumor became one of the most important advances in standardizing oncologic care, as multimodal treatment approaches depended on stratification to assess the exact treatment.

As a result, no tumor was deemed adequately diagnosed and treated, if the "TNM"-status (tumor, nodal, metastasis) status was not available.

Lost in this great leap forward with regard to overall quality of care was the question at the core of the presence of cancers cells within the lymphatics: Was their presence merely a prognostic marker or would their removal – by removing the "advancing" maximal border of the systemically spreading cancer – improve cure rates?

To this day, there appears to be no definitive answer. In breast cancer, the therapeutic significance of axillary lymph node dissection was unquestioned 20 years ago. Today, as

© Springer International Publishing Switzerland 2018

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_51

the molecular markers of the individual disease take the lead in treatment stratification, the removal even of affected lymph nodes has been called into question. Axillary lymph node dissection is now seen as a purely diagnostic procedure without any therapeutic effect.

In gynecologic cancers, the current evaluation of the significance of lymph node dissection is changing, but different approaches are emerging for the different disease entities: endometrial cancer, cervical cancer, ovarian cancer and vulvar cancer.

For the surgeon, deciding who to operate and how to operate, this basic knowledge is decisive as we balance the inherent surgical harm of what we do with the oncologic benefit, a balancing act that – while relying on guidelines and standards – must be made individually for each patient every day.

In endometrial cancer, the available literature – though far from uncontroversial – appears to support a clinical benefit of surgical staging in the form of pelvic and paraaortic lymphonodectomy for all high-risk endometrial cancers, i.e. FIGO IB and above, G3 and non-endometrial cancers irrespective of stage. Statistically, this approach makes sense, as a high proportion of "low-risk" cancers will have negative, non-cancerous lymph nodes.

There is little doubt that removing tumor-free lymph nodes will have no beneficial effect. This argument, however, ignores the fact that statistical probabilities mean little for the individual low-risk patient who is undertreated because she did not have a lymphonodectomy but just happens to be part of the unlucky few.

In fact, it is important to logically stratify the statement: Removing non-affected lymph nodes probably has no survival benefit. Does removal of affected lymph nodes provide a survival benefit, either because the patient will receive additional treatment or because the accessible cancer burden is actually decreased?

When lymph nodes are grossly positive, there is general agreement that they should be removed if possible. This will reduce the residual tumor burden but it might also improve long-term outcome after radiation therapy, as studies have shown that "bulky" lymph nodes larger than 3–4 cm often will not be sufficiently sterilized by radiation. Under these circumstances, laparoscopic – but not laparotomic – lymphonodectomy has the potential to improve the outcome of chemoradiation therapy.

Of course, overall, a reasonable balance between statistical surgical risk and statistical clinical benefit needs to be found. Contrary to chemotherapy or radiation therapy, which can be standardized, the risk of a surgical procedure depends mostly on the two variables "surgeon's skill" and "patient's disposition".

As already mentioned, particularly for cervical cancer, there exists data showing that the removal of grossly affected lymph nodes might confer a survival benefit. While the role of lymphonodectomy for adenocarcinomas such as breast cancer and endometrial cancer has been questioned, squamous lymphatic metastasis appears to be amenable to surgical treatment with curative intention. Furthermore, "oncologic tailoring", i.e. determining the radicality of parametrial resection inevitably depends on histopathologic lymph-node assessment. Because of this, contrary to endometrial cancer, lymphonodectomy remains an integral part of the treatment of all cervical cancers, with the exception of low-risk pT1a1-stages.

In fact, even for non-operable cervical cancer, evaluating lymph nodes, as a means to delineate the limits of the radiation field or to define additional need for systemic chemotherapy, continues to be evaluated.

The role of lymphonodectomy in ovarian cancer is under intense investigation. Laparoscopy does not play a generally accepted role in the staging of early ovarian cancer, where lymphonodectomy is called for under any circumstances. While the existing literature supports the oncologic equivalence of open vs. laparoscopic staging, fear of incompetent use of the difficult laparoscopic techniques has led to a great reluctance to accept the laparoscopic approach within the different national guidelines. Opinions differ along national society recommendations. Overall and globally speaking, laparoscopy is becoming more and more accepted as a staging tool in early ovarian cancer as well as a treatment-stratification tool in advanced ovarian cancer.

For vulva cancer, again a cancer of predominantly squamous histology, the therapeutic effect of adequate treatment of inguinal lymph nodes remains unquestioned – mostly because an inguinal recurrence is basically not treatable and will lead to inevitable death, often after extensive periods of suffering. Laparoscopic pelvic-lymphonodectomy is generally accepted to delineate the limits of subsequent radiation therapy.

Some Remarks About the Access

Laparoscopic pelvic and particularly laparoscopic paraaortic lymphonodectomy remain difficult "high-end" procedures within the spectrum of surgical laparoscopy. As safe laparoscopy relies heavily on patient setup as well as technical and anesthesiologic support, we will now review the key points of patient setup and laparoscopic access.

Adequate Positioning of the Patient

Proper, safe and stable positioning of the patient are key elements of successful laparoscopic surgery.

The patient should be in the regular supine position with adequate dorsal padding. The arms must be "tucked"

laterally, i.e. aligned to the body axis (Fig. 51.1a). In very obese patients, this sometimes is not possible, making particularly the pelvic LND much more challenging. Positioning with only one arm tucked to the body is unacceptable as a routine setup. The stability of the patient on the table is less crucial for lymphonodectomy than for hysterectomy, but as the two procedures are often combined and as the same routine positioning should apply to all laparoscopic procedures, the same rules should apply. As the patient needs to be placed in a Trendelenburg position for some time, it is essential to prevent cephalad slide (Fig. 51.1b, c). Consequently, we recommend the use of heavily padded, symmetrically placed shoulder pads (Fig. 51.1d, e). Legs should be in stirrups – the classic position for all gynecologic laparoscopy, allowing easy placement and management of the uterine manipulator. All exposed body parts, such as hands, fingers, elbows etc., need to be safely padded. Particular attention needs to be paid to possible changes of positioning during the surgery, when the patient is completely covered by sterile draping and can no longer been seen directly. Ideally, the patient setup is arranged by the trained scrub-nurse team and reviewed by the surgeon. Usually, the OR nurses are much

Fig. 51.1 (**a**) Positioning of the patient. Arms always tucked tightly – but well padded – parallel to the thorax. (**b**) Neutral positioning of the OR table. (**c**) "Head-down" >45° i.e. Trendelenburg position during surgery. (**d**) Shoulder padding to prevent positioning injuries. Side view. (**e**) Shoulder padding to prevent positioning injuries. View from *top*

Fig. 51.1 (Continued)

more competent with regard to positioning, but ultimate responsibility rests with the surgeon. Scrubbing the patient for laparoscopy should be no different than for any other patient, but the constant use of electrical energy makes "dry" scrubbing even more important: no amount of scrubbing liquid should run off the patient and moisten dorsal or gluteal parts that could serve as exit points for electrical currents. There are lots of different ways to drape a patient and only the general rules for draping should apply.

Proper Trocar Placement (Figs. 51.2 and 51.3)

As for all advanced laparoscopy, special rules apply to trocar placement. As laparoscopic surgeons are often used to suboptimal situations, they often do not realize the details that make their daily lives more difficult. The central trocar will be placed through the umbilicus after a small vertical incision at the bottom of the umbilical scar. Making this incision too big will lead to inward sliding of the optical trocar, making surgery miserable and more complicated. For all advanced laparoscopic surgery in the pelvis, the lateral trocars should be placed "high and lateral", almost at the level of the umbilicus (but never more than 1–2 cm below that transverse line), and far lateral, but never more medial than 3 cm medial of a sagittal line drawn through the anterior iliac spinal processus. There is less pain for the patient if the placement does not touch the rectal muscle. The working trocar should not be placed in the classic suprasymphysiary position as that inevitably means the surgeon will be working "towards" him

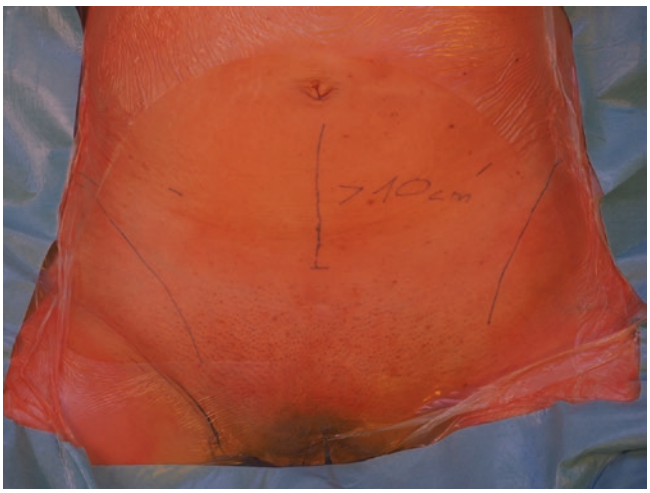

Fig. 51.2 Marking down the trocar positions. The middle, working trocar should be placed sufficiently away from the optical trocar to avoid interference, 10 cm is usually sufficient

or herself. It should be placed midway between the symphysis and the navel, taking care not to go too close to the optical trocar to avoid intraabdominal interference.

All available hands should be used. The first assistant or better the second surgeon should hold the camera and use the right lateral port to hold an atraumatic grasper and assist as the surgery demands. The surgeon should use both hands equally. The left lateral port for traumatic or atraumatic grasping and the medial trocar for cutting, dissection and thermocoagulation. For the surgeon to use the right and left lateral trocars creates unnecessary strain. This will work for

cysts, but even then it is awkward although many surgeons used to this approach do not notice this anymore. The use of electrical, harmonic and cutting force, i.e. the use of any potentially dangerous instrument, should be limited to the medial trocar placed between navel and symphysis. Of course, this recommendation needs to be applied reasonably as sometimes (but only rarely) the required angle for cutting will make lateral access better. Generally, however, the medial trocar is the safest access for all potentially dangerous instruments. Only here is the instrument observed in its entirety, irregularity in electrical currents can be immediately realized, and total control is guaranteed.

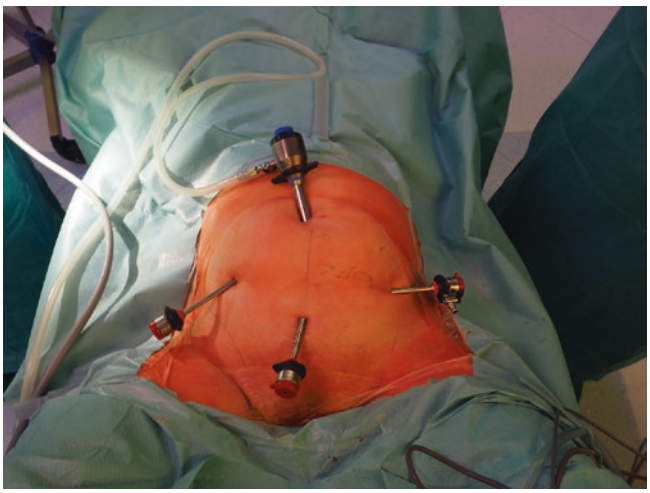

Fig. 51.3 Trocars placed

Very experienced surgeons will be able to use a coagulating grasper through the medial trocar and an electrified scissor through the lateral trocar, but the less experienced surgeon should be wary of such setups.

Having stated how the two authors place their trocars, it should be noted, that trocar placement is ultimately at the surgeon's discretion and will depend also on local traditions and simply on how the individual surgeon was taught. There is no and never will be any scientific evidence as to what is the best placement. An alternative would be the "Indian-Style" placement often seen in the United States, with the two main working trocars placed high and low on the left side of the patient's abdomen.

For removal of the (pelvic) lymph nodes, we recommend placement of a 10 mm trocar in the suprasymphysary position. This trocar will become necessary for placement of the camera during the retrograde approach for the paraaortic lymphonodectomy. An alternative in cases of hysterectomy is to take out the nodes through the opened vagina.

Optimal Positioning of the Surgical Team (Figs. 51.4 and 51.5)

"Optimal" is what works best, and that might very well vary for different surgeons and different teams. However, it is curious to observe how clearly inferior techniques remain long in use, simply because everyone has gotten used to them. Most laparoscopic surgeons were trained in the posi-

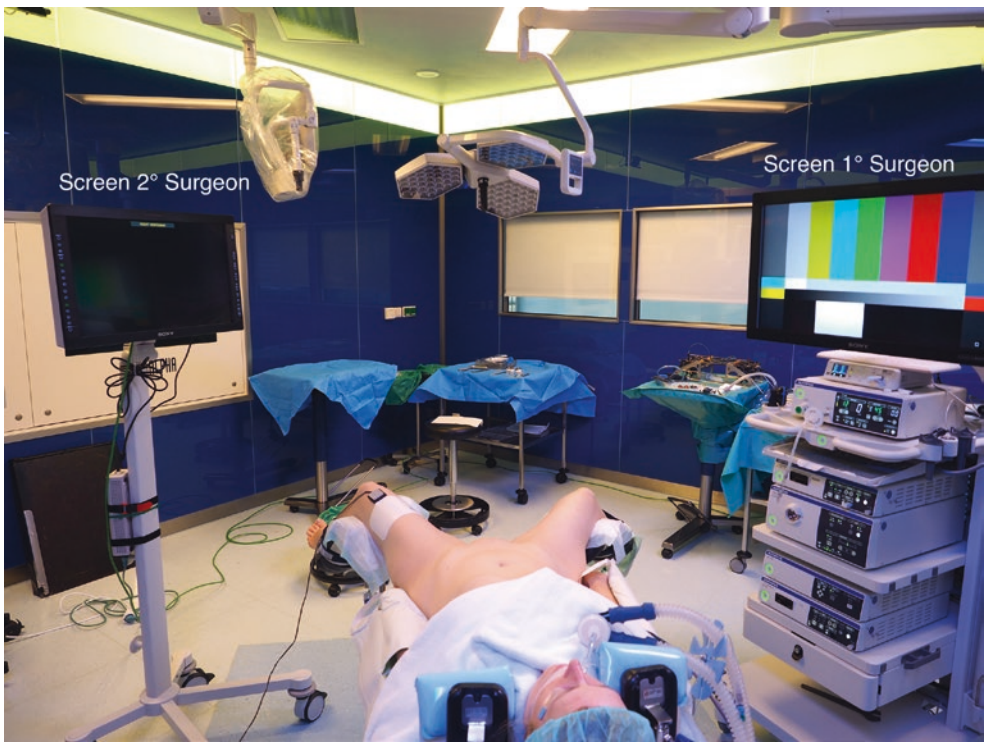

Fig. 51.4 Positioning of the monitors for the first and second surgeon

Fig. 51.5 Placement of the generator, insufflator

tion of the first assistant on the right side of the patient and as the responsible surgeon on the left side of the patient.

The second assistant if necessary should sit comfortably between the legs and follow the surgery on an extra monitor placed above the head of the surgeon. If there is a third assistant, ideally, anesthesia will allow for complete draping of the patient and the third assistant will be able to comfortably stand at the head of the patient and hold the camera with both hands. However, this way of draping sadly remains limited to a few centers with highly experienced anesthesia teams as superficially it limits access to the head of the patient although such access really remains immediate at all times by lifting up the drape.

Availability of Necessary Instruments and Video Equipment (Fig. 51.6)

The more complicated the surgery, the better the equipment needs to be. Both pelvic and paraaortic lymphonodectomy can be done using standard equipment: two atraumatic and two traumatic graspers, an Overholt-Clamp for dissection, a clamp for coagulation (curved clamp that can also be used for dissection such as the Kelly-clamp is to be preferred), regular scissors (keeping in mind that monopolar electricity should be used by experienced surgeons only) and suction-irrigation (to be used extremely judiciously and rarely. Particularly irrigation will inevitably make fine dissection more difficult). Any kind of advanced laparoscopy will be easier and speedier for the average laparoscopist if harmonic energy is available, such as Ethicon's Ultracision® or more recently Olympus' Thunderbeat®, the latter combining

Fig. 51.6 Used laparoscopic instruments for lymphadenectomy

harmonic and electric energy. With regard to optical instruments, we recommend the routine use of 30° optics, as they allow a better range of vision and a better evaluation, particularly of the field of vision in paraaortic lymphonodectomy, but both surgeries can also be done using zero degree optics. One monitor between the legs and one monitor above the head are the minimum setup required. Ideally, an integrated operating room is available. High resolution camera and video equipment should be available.

The availability of 3D vision systems will improve overall feasibility particularly of high-end laparoscopic procedures as an increasing body of literature continues to demonstrate.

Optimal Use of Surgical Instruments

Every surgeon will develop a highly individual approach to surgery. However, some principles should be considered: All laparoscopic surgery requires a much higher degree of

finesse than abdominal or vaginal surgery. Any kind of bleeding must be avoided during laparoscopy at any time and at all costs as bleeding will disturb the field of vision, obscure the anatomy, require dangerous coagulation, the more so the larger the bleeding. Also, bleeding will make the surgery less beautiful. What does "finesse" mean? The difference between good and bad laparoscopic surgery is the right balance between careful dissection, taking down the tissue sometimes millimeter by millimeter, never cutting were you cannot see, never cutting pedicles that are too thick. It means using the preformed anatomic spaces that can be opened without any sharp dissection at all. It means setting up the vascularized pedicles almost down to the actual artery and vein before sealing the vessels under direct view. It means using the peritoneum as a safe plane of preparation. But it also means doing these things swiftly and decisively to avoid stalling the surgery.

As in all surgery, it means finding the right balance between courage and caution, both based on skill and competence that only time and experience will teach.

Practical little tricks can be important: Try to avoid irrigation, as somehow the crispness of the un-irrigated surgical field will be irrevocably lost after one thorough rinsing. Use suction instead. Train your assistant to focus on proper camera management and sparing interference: "One person only moving" is a simple but important principle. Check the assistant at the uterine manipulator frequently. Uterine manipulation is in essence ureteral distancing and thus protects the single most vulnerable structure in your surgical field.

Technique of Laparoscopic Pelvic Lymphonodectomy

Ultimately, pelvic lymphonodectomy should lead to the representative removal of lymph nodes that reflect the lymphatic drainage of the uterus. This involves the lymphatic axis of the externa iliac vessels as well as the oburatoria fossa, the axis of the internal iliac vessels as well as the common iliac artery. Interestingly, literature looking at patterns of lymphatic spread along these different areas is practically non-existent.

While sentinel lymphonodectomy remains imperfect for endometrial cancer and not yet sufficiently standardized for cervical cancer, the extensive studies surrounding the identification of the pelvic sentinel node all point towards a node of fairly stable location at the bifurcation of common iliac artery to the external and internal iliac artery, towards the appearance of the obturator nerve when accessing the oburatoria fossa medially.

Equally unclear is the desired number of lymph nodes to be removed. Amazing differences exist between the written and unwritten standards of different countries.

We propose a standardized approach. What follows is first an outline of our approach, followed by a detailed explanation of the underlying rationale.

1. Normalization of anatomy – dissection of the ileocoecum cranially and resolution of the sigmoid adhesions in the pelvis
2. Opening of the pelvic sidewall by transecting the round ligament
3. Short extension of the peritoneal incision caudad and medial, towards the bladder
4. Long extension of the peritoneal incision in an arc transversing the external iliac vessels and opening the psoas space
5. Medialization of the infundibulopelvic ligament medially, exposing the ureter as it crosses the pelvic brim
6. Following and dissecting the ureter into the pelvis
7. Separation of the ureter and the internal iliac artery
8. Again moving to the anterior part of our dissection: Isolating the lateral umbilical ligament
9. Opening of the paravesical space
10. Opening of the Fossa obturatoria – Dissection of the obturator nerve
11. Complete lateralization of the axis internal iliac artery – Umbilical Artery/Lateral Umbilical ligament. Finding and dissecting this arterial axis is crucial because it will allow us to do the most important thing gynecologic surgeons do in the pelvic sidewall: Finding where the uterine artery branches off the internal iliac artery.
12. For beginners, managing the arterial axis often appears daunting; however, injuries to big arterial vessels are actually very rare. You really have to directly cut into or puncture these big muscular vessels. Blunt dissection on top of these arteries is easily possible. Of note: There are no significant structures leaving this arterial axis ventrally, laterally or even medially (until the branching of the uterine artery), so it can be used as a safe "preparation" street. In fact, the more vulnerable internal iliac vein lies "protected" behind the artery on both sides and will not be in danger until you have exposed more than half of the arterial circumference
13. Exposing the branching of the uterine artery off the internal iliac artery
14. Opening of the pararectal space
15. Start of the lymphonodectomy at the most distal part of the external iliac artery. Distal limit: Crossing of the circumflex vein. This vein does not need to be coagulated and it has no great significance. Because of the low intravenous pressure, it often appears as a flat, ligamentous structure crossing the artery. To us, it means: "far enough" with regard to the distal end of lymphonodectomy.
16. Avoid disturbing the lateral fatty tissue on the psoas muscle

17. Expose the external iliac artery and remove lymph nodes in a retrograde fashion, using a combination of blunt (80%) and sharp (20%) dissection
18. Try for en-bloc removal
19. At the distal end, expose the internal iliac vein
20. Find the pelvic bone directly "underneath", i.e. medial and dorsal of the internal iliac vein
21. Re-expose the obturator nerve
22. Start removal of the Fossa obturatory lymph nodes
23. Distance the external iliac vessels from the psoas muscle to expose the obturator fossa laterally
24. Use the obturator nerve as a guide to further remove the fossa obturatoria lymph nodes
25. Continue this dissection towards the internal iliac artery lymph nodes
26. Remove the bifurcation node (sentinel node)
27. Cut remaining attachments of the lymph nodes into the fossa obturatoria and to the lateral umbilical ligament
28. Expose branching of the internal iliac vein off the common iliac vein
29. Remove remaining and most proximal external iliac artery lymph nodes into the en-bloc resection tissue
30. Remove lymph nodes using an endobag if at all possible
31. Complete lymphonodectomy by removing the lymph node pads lateral to the common iliac artery (right side).

What follows is a more detailed explanation of the above mentioned step-by-step approach.

Normalization of anatomy – dissection of the ileocoecum cranially and resolution of the sigmoid adhesions in the pelvis (Fig. 51.7a–h)
Ultimately, dissection of the lymph nodes will require sufficient exposure laterally and cranially. If postoperative adhesions pulling the ileocaecum on the right side or the sigmoid colon on the left side towards the pelvis are not removed initially, it will have to be done later, when it tends to be more difficult as the planes are no longer as anatomically pristine.

Particularly the physiologic adhesions of the sigmoid colon towards the left pelvic sidewall are extremely varied. Taking them down requires a certain degree of practice. Opening of the retroperitoneum at this point needs to be avoided. The perfect dissection requires sharp scissors only. Excessive bleeding means the dissection plain is incorrect. Coagulation with electrocautery carries a high risk of thermal bowel injury.

Opening of the pelvic sidewall by transsecting the round ligament (Fig. 51.8a–f)
The classical step. The opening should be performed at the most lateral position. Normally, there are no vessels associated with the round ligament, even though in the English literature, a variable so-called "Sim's artery" is frequently mentioned. Using laparoscopy means the opening of the retroperitoneum allows immediate CO_2 access, leading to distention of this artificial space.

Short extension of the peritoneal incision caudad and medial, towards the bladder (Fig. 51.9a–d)
It is tempting to go further towards the bladder, particularly if a hysterectomy is part of the surgery; however, there is always a danger to run into bleeding or even to injure the bladder.

Long extension of the peritoneal incision in an arc transversing the external iliac vessels and opening the psoas space (Fig. 51.10a–c)
This is the key step at the start of the surgery. Limiting the incision to the peritoneal layer makes this move very safe. The psoas space is one of the "safe" areas. The only danger exists while crossing the external iliac vessels, which theoretically could be injured. Once the psoas space is reached, the incision now bends cranially, going up as far cephalad as possible. At this point, a previous meticulous dissection and removal of the ileocoecum on the right side and the sigmoid colon on the left side becomes crucial. Each further centimeter cephalad helps with the next step: mobilization of the infundibulopelvic ligament medially.

Medialization of the infundibulopelvic ligament medially, exposing the ureter as it crosses the pelvic brim (Fig. 51.11)
This step exposes the ureter. Dissecting the infundibulopelvic ligament always needs to be done with extreme caution. Aside from tearing the ovarian vein (which requires some force…) there are numerous smaller vessels that can tear and cause unnecessary bleeding. This step needs to be done more than once, bluntly, to carefully expose the ureter. This is easier on the right side (no sigmoid).

Following and dissecting the ureter into the pelvis (Fig. 51.12)
This can be either very easy (no previous surgery, no adhesions) or very difficult, when the tissue does not yield easily. Small peritoneal bleeders can be annoying and obscure. Ideally, the ureter is followed caudad easily, leading to the internal iliac artery as it stays close to the pelvic sidewall, while the ureter runs more medial towards the peritoneum of the Douglas space. There are slight differences with regard to the position of the ureter, but they are curiously difficult to describe. On the right side, the ureter sits more "on top" and medial of the internal iliac artery, while on the left side, it runs more laterally to the artery even at the pelvic brim.

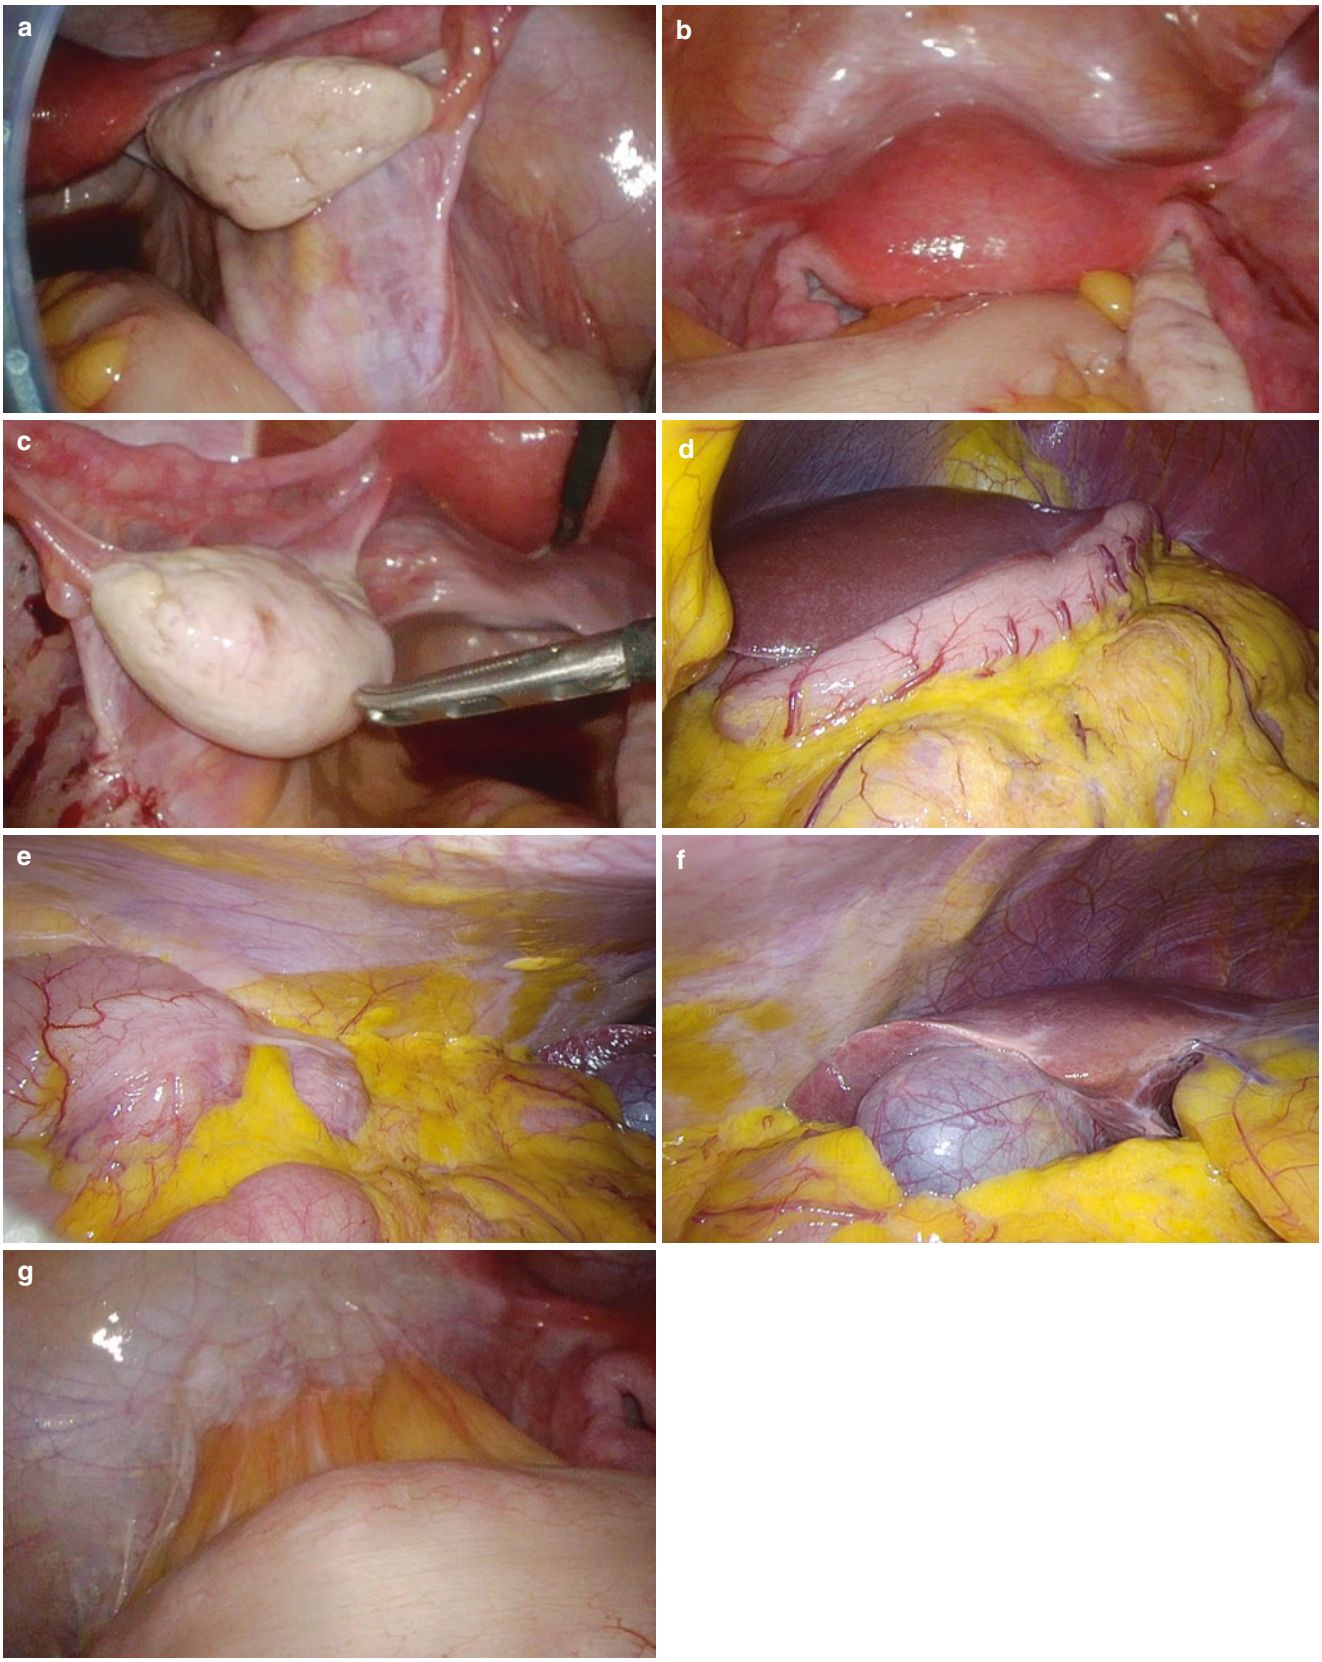

Fig. 51.7 (**a**) Inspection of the pelvis after Trendelenburg positioning. Right adnex. (**b**) Inspection of the pelvis after Trendelenburg positioning. Midline view. Uterus. (**b**) Pelvic lymphonodectomy on the right side. Exposition of the external illiac vessels and the psoas muscle. (**c**) Opening of the obturator fossa

If this step is overly difficult, attention can be given to the anterior aspect of the dissection, first.

Separation of the ureter and the internal iliac artery
As already mentioned above, this leads the way to the branching of the uterine artery. At the same time, it prepares access to the pararectal space (opening necessary only when a radical hysterectomy is planned).

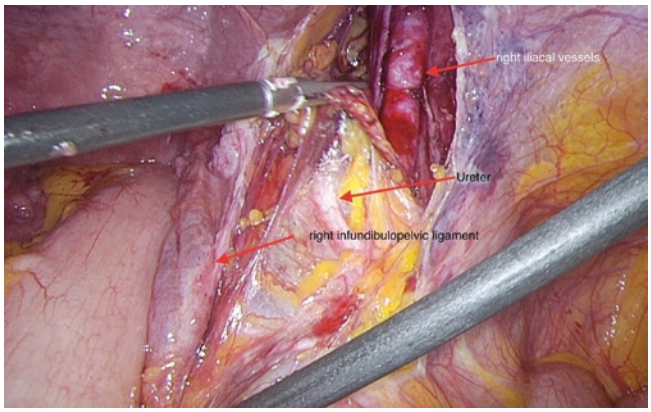

Fig. 51.11 Visualization of the ureter at the level of the right illiac artery bifurcation

Again moving to the anterior part of our dissection: Isolating the lateral umbilical ligament
This step can be performed at any time. Generally, the most important rule of "rules for dissection" is: every operative procedure is different. There is no point in persevering at a particularly difficult part, when other areas can be dealt with more easily. Often, magically, when returning to the difficult area, the anatomy has become kinder and the surgical procedure can move forward, where it was very difficult previously.

No matter how difficult the anatomy or how obese the patient, the lateral umbilical ligament can usually be found on the anterior abdominal wall and followed in a retrograde fashion cephalad, allowing for orientation in the most desperate pelvis.

Opening of the paravesical space (Fig. 51.13)
The paravesical space, immediately medial to the lateral umbilical ligament is the most accessible space of the pelvis. It should be dissected bluntly. The dissection can be carried down almost to the pelvic floor – where unnecessary bleeding awaits, so the last centimeter remains unnecessary and should be avoided. In thin patients, dissecting the paravesical space can sometimes lead to the obturator nerve laterally and the ureter posteriorly.

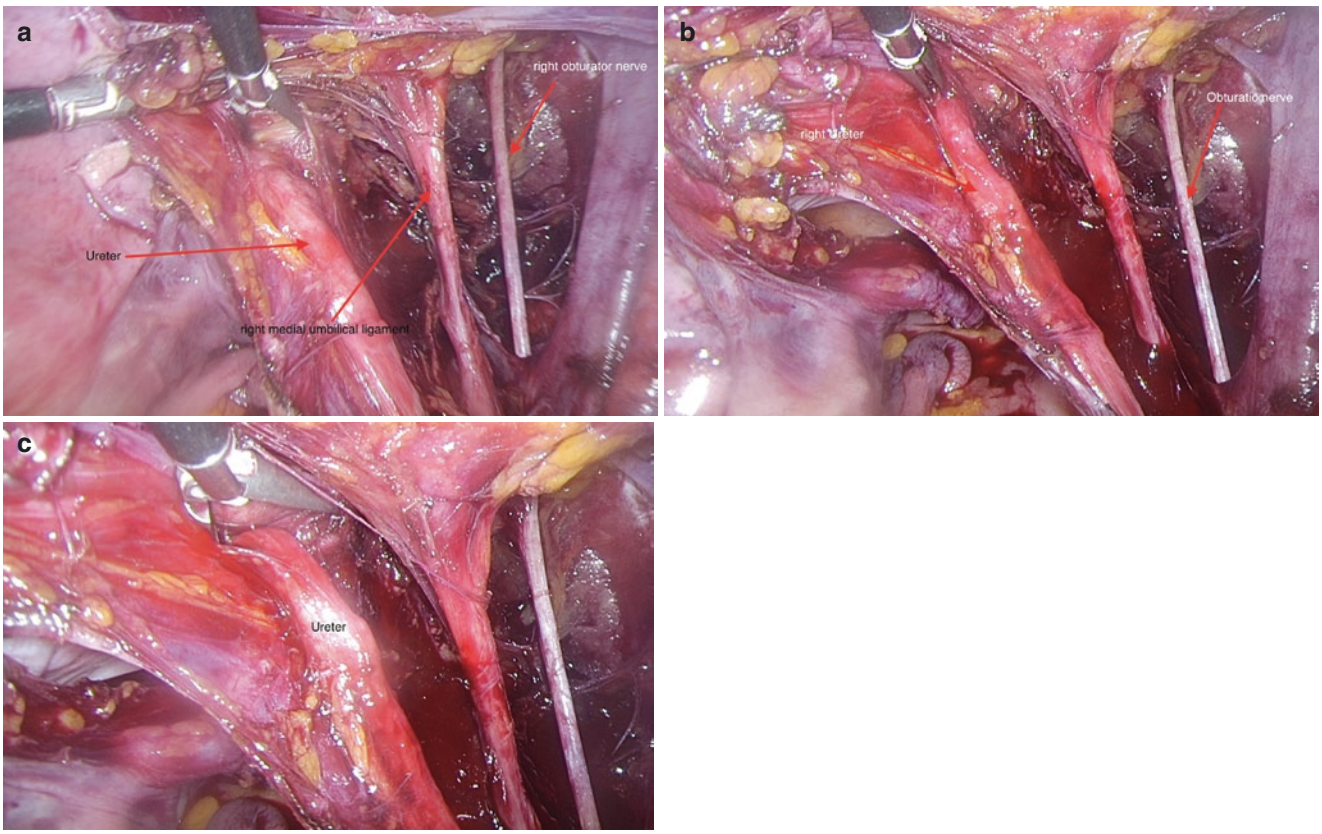

Fig. 51.12 (**a**) Dissection of the right ureter until it is crossed by the uterine artery. (**b**) Visualisation of the right obturator nerve. (**c**) Dissection of the crossing of ureter and uterine atrtery

Opening of the Fossa obturatoria – Dissection of the obturator nerve

Medial of the lateral umbilical ligament (containing the obliterated umbilical artery), the obturator fossa can be accessed. This sometimes requires some sharp dissection as the lateral umbilical ligament can be very lateral, almost attached to the adjacent structures, i.e. the external iliac vein. Because of this, the safe opening of this space should proceed directly lateral of the lateral umbilical ligament, as far away from the pelvic sidewall as possible. The "bottom" of the obturator fossa is the obturator nerve, which needs to be freed from surrounding fatty and lymphatic tissue over some distance to be truly visible during the rest of the surgery. The obturator nerve needs to be frequently checked for its location. It follows the old ureteral rule: "Now you see it, now you don't" and can be easily damaged with electrocautery, thermal energy or by sharp transection. The obturator nerve is the largest nerval structure normally dissected in the pelvis. It is accompanied by the obturator vessels, which rarely need to be coagulated, but can lead to unnecessary and annoying bleeding if not respected. The obturator vein often branches off the *external* iliac vein, in which case coagulation is advised to facilitate lymphonodectomy.

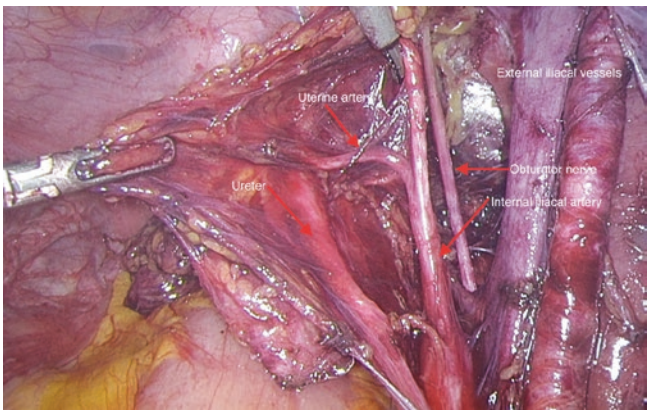

Fig. 51.13 Final view. Preparation and visualization of the crossing of the uterine artery and the ureter

Complete lateralization of the axis internal iliac artery – Umbilical Artery/Lateral Umbilical ligament (Fig. 51.14a)

After a successful approach from caudad and cephalad, this axis often remains attached to the pelvic sidewall. However, other than small peritoneal vessels, there remain no important vessels or other structures so that sharp dissection should carry the most dorsal part of the surgical field down to this vessel axis.

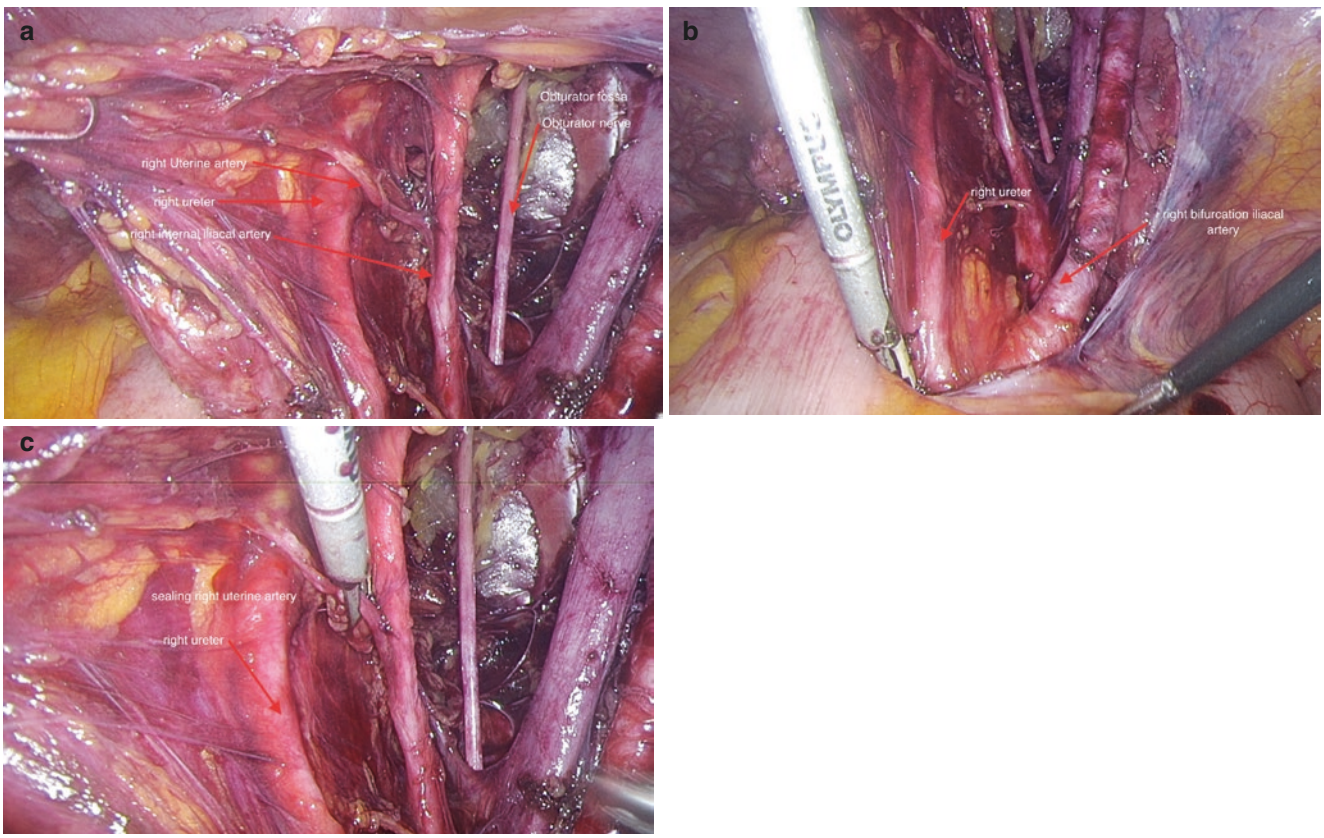

Fig. 51.14 (**a**) Preparation/dissection of the paravesical space. (**b**) Preparation/dissection of the pararectal space. (**c**) Coagulation of the uterine artery at its origin from the internal illiac artery (*right side*)

Exposing the branching of the uterine artery off the internal iliac artery (Fig. 51.14b)
Finding the uterine artery where it branches off (in an almost 90° angle) from the internal iliac artery remains the most critical skill to be mastered by the gynecologic surgeon. It is essential for radical hysterectomy, but extremely helpful in many challenging situations of benign gynecologic surgery. Essentially, it requires a sufficient dissection of the paravesical and the pararectal spaces which are separated by the uterine artery.

Opening the pararectal space (Fig. 51.14c)
Opening the pararectal space is not strictly necessary for pelvic lymphonodectomy, as is the isolation of the uterine artery. It would be necessary as part of the setup for a radical hysterectomy.

Start of the lymphonodectomy at the most distal part of the internal iliac artery (Fig. 51.15a)
Once all the relevant structures have ben delineated and all the spaces opened, lymphonodectomy can safely begin. Grasping of the lymph nodes is usually possible with atraumatic graspers. Lymph nodes tend to bleed, so caution is required. The guiding structure for this first part of the dissection is the external iliac artery.

Distal limit: Crossing of the circumflex vein (Fig. 51.15b)
Care should be take not to go too far into the inguinal canal. Exposing this vein, crossing the external iliac artery is sufficient for the distal limit of dissection.

Avoid disturbing the lateral fatty tissue on the psoas muscle (Fig. 51.16a–e)
Many surgeons believe that the all too easy removal of this lymph node-free fad-pad leads to an increased incidence of lymphoceles/lymph cysts. It certainly does not add to the lymph node count.

Expose the external iliac artery and remove lymph nodes in a retrograde fashion, using a combination of blunt (80 %) and sharp (20 %) dissection
The external iliac artery needs to be exposed and protected. However, it is a sturdy structure and lymph nodes can be "pulled" off the artery in a blunt fashion – as is done in open cases routinely.

Try for en-bloc removal
Particularly on the right side, en-bloc-removal is possible, making later removal from the abdominal cavity easier. However, it is not a goal in itself.

At the distal end, expose the internal iliac vein
After removing the lymph nodes overlying the external iliac artery, the move is medially, down on the very thin and often "empty" (because of the patient's Trendelenburg position) external iliac vein.

The key is to define the "lower" edge of the vein, to make sure that the paper-thin vessel is not accidently injured. The danger is that an injured but "empty" external iliac vein might not immediately bleed.

Find the pelvic bone directly "underneath", i.e. medial and dorsal of the internal iliac vein (Fig. 51.17)
This bony part of the pelvis is a key part of the dissection. It allows safe access to the lateral limits of the obturator space (obturator muscle) and further allows for the safe isolation of the obturator nerve.

Because the obturator lymphatic fat-pad can be easily dissected off the smooth bone, it is also a good starting point for the lymph node resection

Re-expose the obturator nerve
As mentioned above: Again and again, the obturator nerve needs to be visualized. However, this distal part is not the

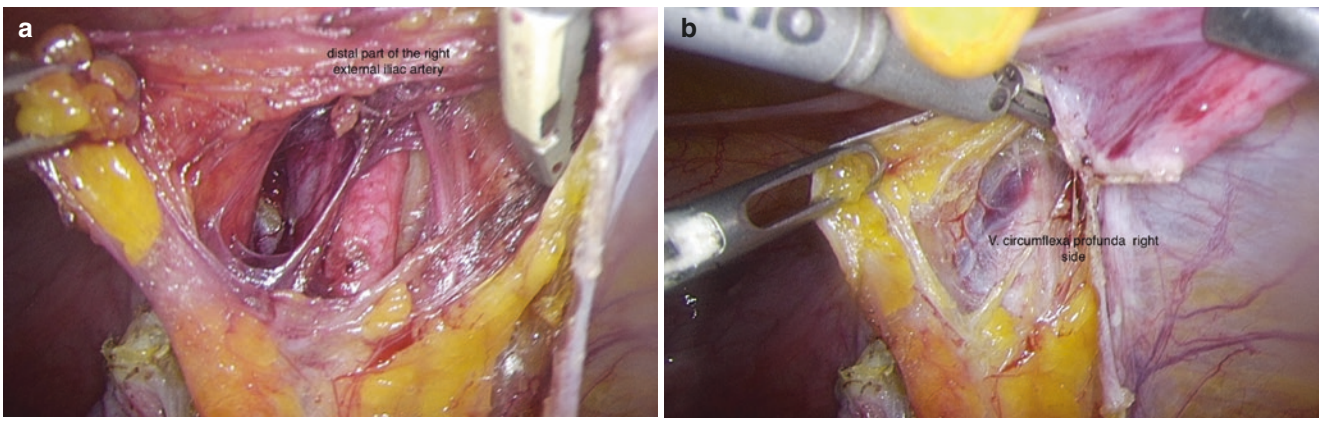

Fig. 51.15 (**a**) Distal limitation of the pelvic lymphonodectomy. Visualization of the distal part of the right external iliac artery. (**b**) Distal limitation of the pelvic lymphonodectomy. Visualization of the V. circumflexa profunda just cranial of the inguinal ligament

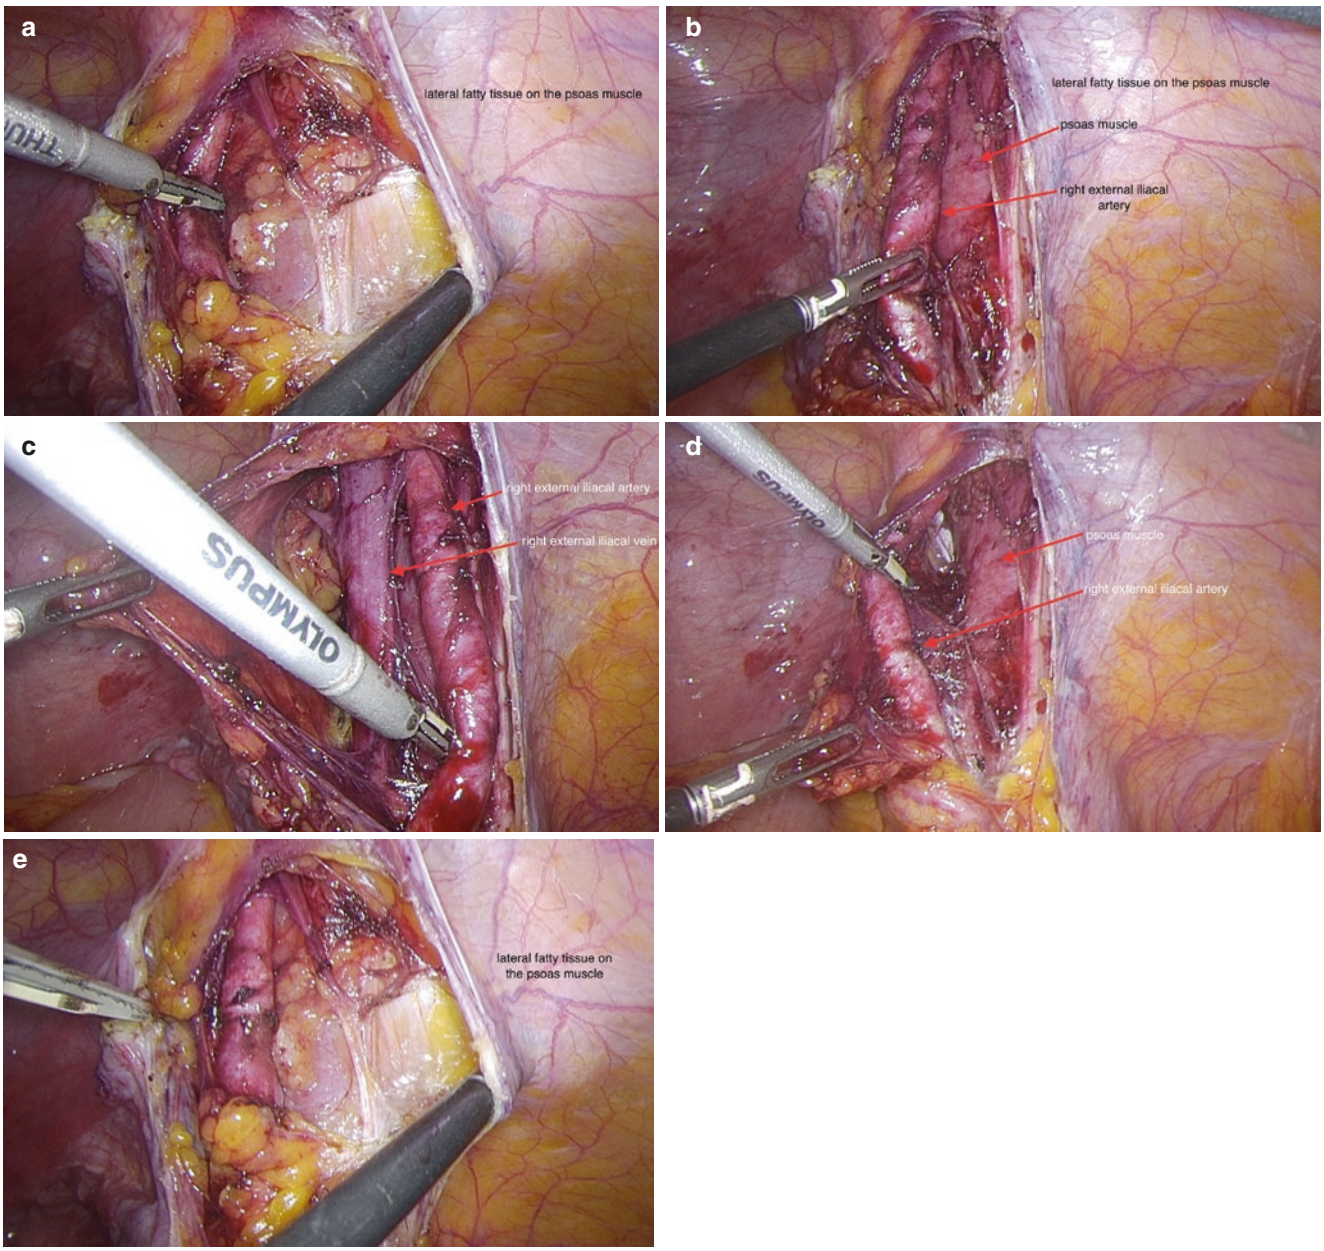

Fig. 51.16 (**a**) The lateral limits of the pelvic lymphonodectomy: psoas muscle and lateral adipose tissue which should not be removed. (**b**) The external illiac vessels are medialized bluntly away from the psoas muscle to allow optimal access to all lymphatic tissue. (**c**) Dissection of the right exteranl artery and vein. (**d**) "Lateral" access to the oburator fossa between psoas muscle and external vessels. (**e**) The lateral border of the lymphonodectomy: psoas muscle

part most likely to be injured. Injuries usually occur right where it appears underneath the external iliac vein into the obturator fossa.

Start removal of the fossa obturatory lymph nodes

(Fig. 51.18a–d)

With the external iliac vein safely away and the obturator nerve visualized, lymphonodectomy starts sharply, coagulating and cutting the incoming lymphatic vessels and then removing the lymph node tissue mostly bluntly. Aberrant obturator veins, branching of the external iliac vein need to be watched carefully and usually must be coagulated and transected.

Distance the external iliac vessels from the psoas muscle to expose the obturator fossa laterally

For the laparoscopist, this move does not add much and does not need to be performed at all costs. It allows for slightly better control if bleeding from the obturator muscle perforators occurs. A lot of traditional open surgeons, however, strongly believe that this is an essential part of the pelvic lymphonodectomy,

claiming that the lymph nodes just above the sacral nerves in the area are a common site of recurrence, particularly of cervical cancer, a claim never corroborated by solid evidence nor by the experience of the authors of this chapter.

Also, recent understanding about the lymphatic drainage of the uterus and cervix point to a common sentinel node at a completely different location.

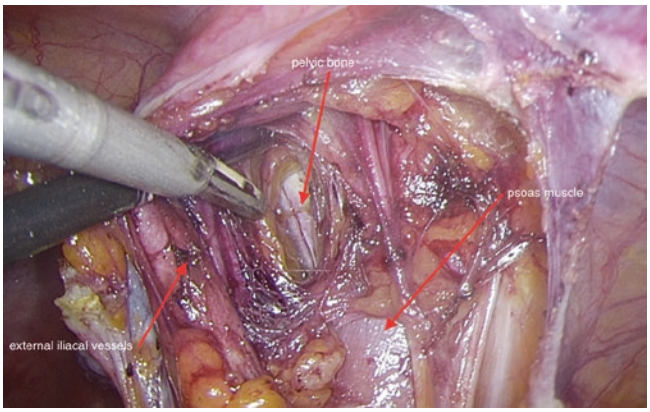

Fig. 51.17 The dorsal limit of the pelvic lymphonodectomy. Vizualisation of the pelvic bones

Still, it is a nice and fairly easy technique to master. Sometime, when all else fails, it might be the only way to find the obturator nerve.

Use the obturator nerve as a guide to further remove the fossa obturatoria lymph nodes

The nerve is a fairly strong structure as far as mechanical force is concerned. Overlying attachments, however, need to be carefully dissected, taking care not to injure the nerve thermally.

Continue this dissection towards the internal iliac artery lymph nodes (Fig. 51.19)

This lymph node, incidentally, is the sentinel node for both endometrial and cervical cancer, making sentinel lymphonodectomy in the area somewhat more tricky than in vulva and breast cancer.

Remove the bifurcation node (sentinel node) (Fig. 51.20a–c)

At this area, the obturator nerve is at its most vulnerable. It is the critical triangle, with strong lymphatic attachments, rich

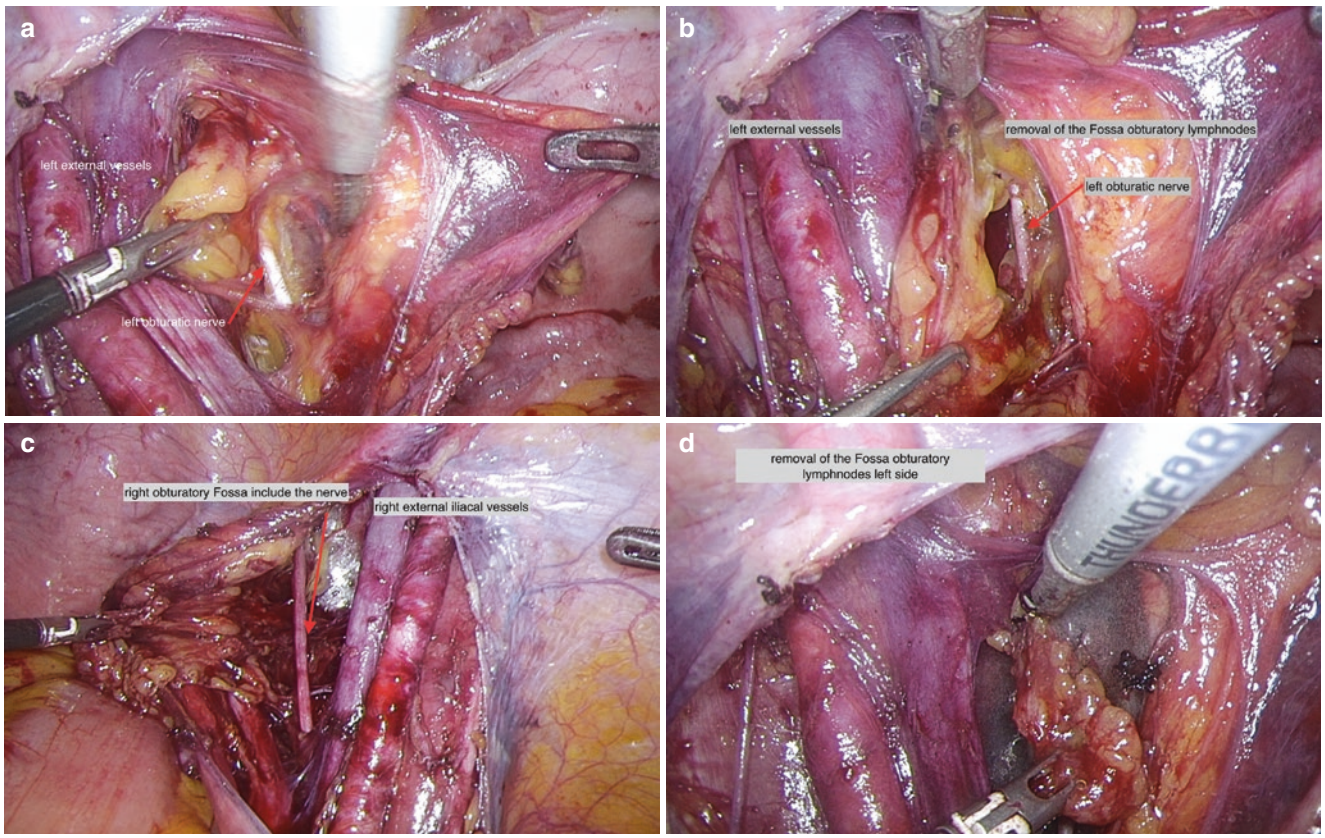

Fig. 51.18 (**a**) Opening of the obturator fossa and identification of the oburator nerve. (**b**) Dissection of the oburator nerve (*left side*). (c) Opening of the obturator fossa and identification of the oburator nerve. Dissection of the oburator nerve (*right side*). (**d**) The "lower" edge of the iliac vein needs to be well exposed before the lymph nodes are removed

microvasculature and numerous dangerous structures underneath or directly lateral (obturator nerve, internal iliac vein).

Cut remaining attachments of the lymph nodes into the fossa obturatoria and to the lateral umbilical ligament
With great caution and care. At this point, tendency is to pull the lymph node package medially, to make these attachments more visible. This, however, dangerously distorts the course of the obturator nerve which must be kept in mind.

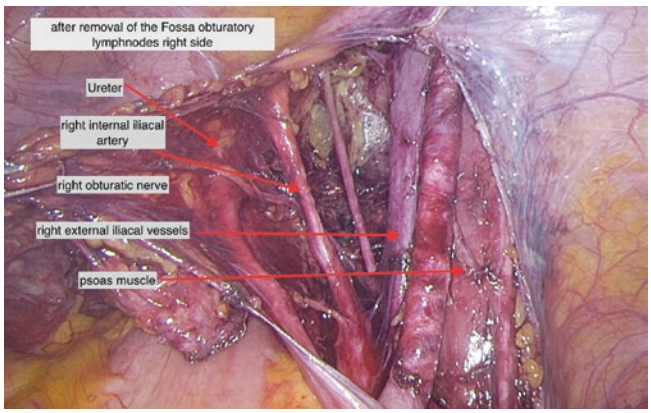

Fig. 51.19 Final view after completed right pelvic lymphonodectomy

Expose branching of the internal iliac vein off the common iliac vein
This is a quality step of the lymph node dissection. If you can actually see this branching, you have certainly done a thorough resection of the most relevant lymph nodes.

Remove remaining and most proximal external iliac artery lymph nodes into the en-bloc resection tissue
Here, the lymphatic chain continuing towards the common iliac artery must be cut at some point.

Remove lymph nodes using an endobag if at all possible (Fig. 51.21)
Other than being aesthetically more satisfying, it also keeps your suprasymphysary 10 mm trocar clean which will be important for the camera positioned there during the paraaortic lymph node dissection.

Complete lymphonodectomy by removing the lymph node pads lateral to the common iliac artery (right side)
Lymph node tissue in this area is usually somewhat flat and patchy. Some bleeding is common.

On the right side, at some point, the posterior limit becomes the inferior vena cava which is not to be injured inadvertently.

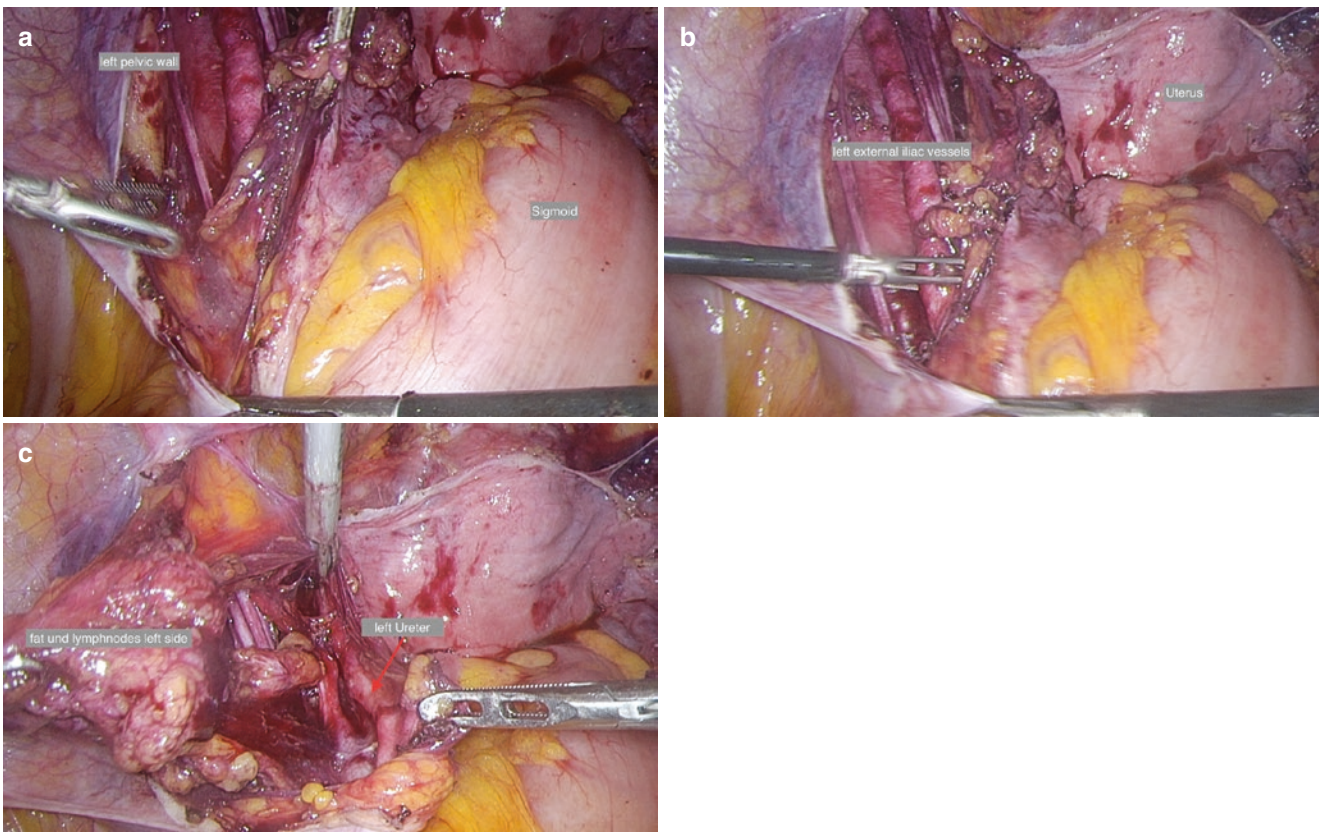

Fig. 51.20 (**a**–**c**) Identification of the left illiac vessels. (**b**) Identification of the ureter. (**c**) Removal of lymph nodes

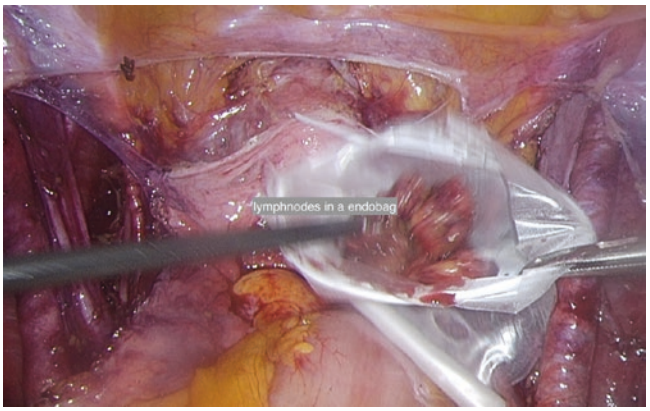

Fig. 51.21 The freed lymphatic tissue is removed separately using endobags

Technique of Laparoscopic Paraaortic Lymphonodectomy

1. Positioning. Retrograde laparoscopy. Camera in the additional suprasymphysary 10 mm port. Second assistant between the legs holding camera only. Surgeon on the patient's right side looking cephalad, First assistant on the patient's left side looking cephalad.
2. Exposing the pelvic brim – starting point is the common right iliac artery.
3. Moving the rectosigmoid to the left side of the abdominal wall and moving the small intestine towards the right side of the abdominal wall. Adjusting Trendelenburg position as needed.
4. Lifting up the peritoneal covering just above the right common iliac artery creates an opening into the retroperitoneal space.
5. Using the arterial trunk, the peritoneal incision is extended upward towards the ligament of Treitz, avoiding all vulnerable structures.
6. In essence, the preparation is about opening the peritoneal tent needed for the surgery.
7. The tent needs to be extended towards the patient's right side, where the ureter needs to be identified separately from the right ovarian vein
8. The right ureter needs to be distanced, exposing the psoas space directly to the right of the vena cava inferior.
9. Delineating the right edge of the vena cava, care must be taken to identify the branching of the ovarian vein – if necessary, the vein needs to be coagulated.
10. Similarly, the crossing of the small right ovarian artery needs to be identified, either to be respected or to be carefully coagulated and transected.
11. After securing the "right side" of the tent, the left side needs to be defined.
12. First, the branching of the interior mesenteric artery needs to be found. It is fairly constant midway between the aortic bifurcation and the crossing of the left renal vein and comes off slightly to the left side of the aorta.
13. Finding the crossing of the left renal vein is challenging. Dissection cannot be sharp: cutting into the lower edge of the left renal vein is a catastrophe that must not happen.
14. About 2 cm towards the left off the aorta, the left ovarian vein starts to descend from the left renal vein. This corner is the most difficult part of the paraaortic lymphonodectomy
15. The tent is now sufficiently defined.
16. Lymphonodectomy can be performed either from cranial to caudal or from caudal to cranial. The decision how to proceed is often situational and depends on the individual anatomy. Distal dissection tends to be more difficult and more dangerous and maybe therefore should be the first step.
17. Preparation on the aorta is unproblematic; dissecting off the vena cava needs to be slow and meticulous. Even pulling on the lymphatic tissue can lead to perforator veins tearing off the vena cave and possible cava bleeders.
18. Cava bleeders need to be closed with pressure immediately. About 90% of them can be stopped by applying sufficient pressure for at least 5 min. What still bleeds after prolonged pressure needs to be sutured with a 4-0 or 5-0 monofilament suture.
19. En-bloc lymphonodectomy down the paracaval and paraaortic spaces is challenging. We recommend a step-by-step approach that takes place in different spaces:
20. Paraaortic area cranial to inferior mesenteric artery (including the difficult angle between the left renal and left ovarian vein).
21. Paraaortic area inferior to the inferior mesenteric artery (careful, the ureter is very close towards the left lateral edge of the preparation and can be easily injured). Visualization of the left ureter remains one of the great challenges. Patient and mostly blunt dissection will eventually allow us to see this important structure. It is deeply imbedded in adipose tissue on the left and does not yield easily to blunt dissection, but sharp dissection is dangerous in this region.
22. Paracaval region, upper half – attention to crossing of the right ovarian artery, branching of the right ovarian vein.
23. Paracaval region, lower half – attention to the perforator veins which are increasing in frequency towards the caudad region.
24. Interaorto-caval region – careful not to injure the lumbar veins going off in a dorsal and downward manner.
25. Paracaval region towards the right side of cava – psoas space. Careful not to injure the right ureter.
26. The key to paraaortic lymphonodectomy is to avoid major bleeding, as it will often require laparotomy.

27. Lymph node tissue is often smaller and can be removed through the umbilical 10 mm trocar.

What follows is a more detailed explanation of the above mentioned step-by-step approach.

Positioning. Retrograde laparoscopy. Camera in the additional suprasymphysary 10 mm port. Second assistant between the legs holding camera only. Surgeon on the patient's right side looking cephalad, First assistant on the patients left side looking cephalad (Fig. 51.22).

These are recommendations only, of course. Each surgeon needs to find out his or her best approach. Some surgeons might want to stand between the legs. However, we strongly encourage our readers to try our approach.

Exposing the pelvic brim – starting point is the common right iliac artery (Fig. 51.23a, b)
This is a test also for the feasibility of this very challenging surgery. If the common right iliac artery cannot be dissected, the surgery might not be possible.

Fig. 51.22 Positioning of the surgeon. Surgeon on the patient's right side looking cephalad, First assistant on the patient's left side looking cephalad

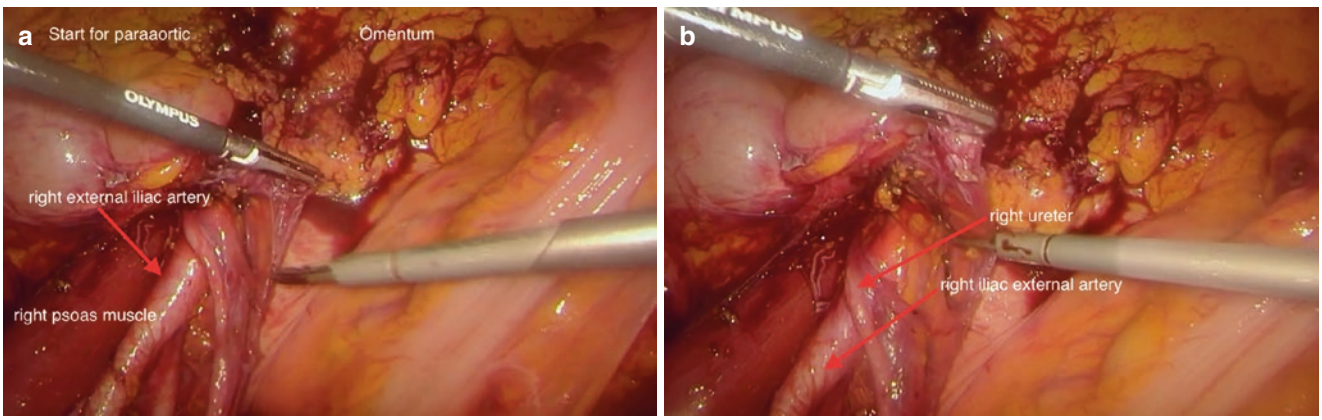

Fig. 51.23 (**a**) The bifurcation of the right common illiac artery is a good starting point for the paraaortic lymphonodectomy. (**b**) Always identify the ureter at this point

Moving the rectosigmoid to the left side of the abdominal wall and moving the small intestine towards the right side of the abdominal wall. Adjusting Trendelenburg position as needed (Fig. 51.24a, b)
At this point, we should discuss the order of the surgery. Oncologically speaking, it is nice to know, if the pelvic lymph nodes are affected. In cervical cancer this might be the reason for performing a paraaortic lymph node dissection. However, given the fact that the paraaortic dissection is the most challenging part of the surgery, with the highest conversion rate (though still very low in the hands of a skilled surgeon), one might consider starting out with this part of the surgery. The advantage is that if the surgeon starts with the paraaortic dissection, the attachments of the sigmoid colon to the left pelvic sidewall have not yet been taken down, helping in the lateralization.

Lifting up the peritoneal covering just above the right common iliac artery creates an opening into the retroperitoneal space
Most laparoscopic oncologic surgery can be done with almost any level of skill on the part of the first assistant. However, paraaortic dissection is different. The presence of at least a minimally skilled assistant is essential.

Using the arterial trunk, the peritoneal incision is extended upward towards the ligament of Treitz, avoiding all vulnerable structures
Again, these first steps are crucial. The oncologic context of the lymphonodectomy needs to be understood. If these first steps are not possible because of bowel obliteration of the field or because of extreme obesity, another, if necessary laparotomic approach must have been discussed with the patient. For this reason, too, the feasibility of the laparaoscopic approach must be established at the beginning of the procedure, just as it needs to be ascertained whether the uterus can be removed vaginally.

In essence, the preparation is about opening the peritoneal tent needed for the surgery (Fig. 51.25a–c)
The laparoscopic paraaortic dissection follows a two-tiered approach: first go upward to create the tent, then go upward to start the lymphonodectomy on the aorta.

The tent needs to be extended towards the patient's right side, where the ureter needs to be identified separately from the right ovarian vein
The difficulties on the right side are always the same: What is the ureter and what is the vein? They look surprisingly similar and waiting for the ureter can be time-consuming. Still, one has to be certain. Sometimes, just extending the dissection on the lateral edge of the vena cava more cranially will solve the problem.

The right ureter needs to be distanced, exposing the psoas space directly to the right of the vena cava inferior (Fig. 51.26a, b)
This space is easily opened and – one more time – the psoas space (this one much more cranial than the first one described during pelvic lymphonodectomy) offers safety.

Delineating the right edge of the vena cava, care must be taken to identify the branching of the ovarian vein – if necessary, the vein needs to be coagulated (Fig. 51.27)
Not coagulating the vein increases the risk of tearing it off, sometimes directly where it comes out of the vena cava, creating a hole that cannot be closed by pressure only.

Similarly, the crossing of the small right ovarian artery needs to be identified, either to be respected or to be carefully coagulated and transected
The ovarian arteries are quite small, but they bleed considerably. Sometimes their coagulation is not even noticed but the lack of coagulation is always apparent on transection. Their identification is not always possible, but they are always there.

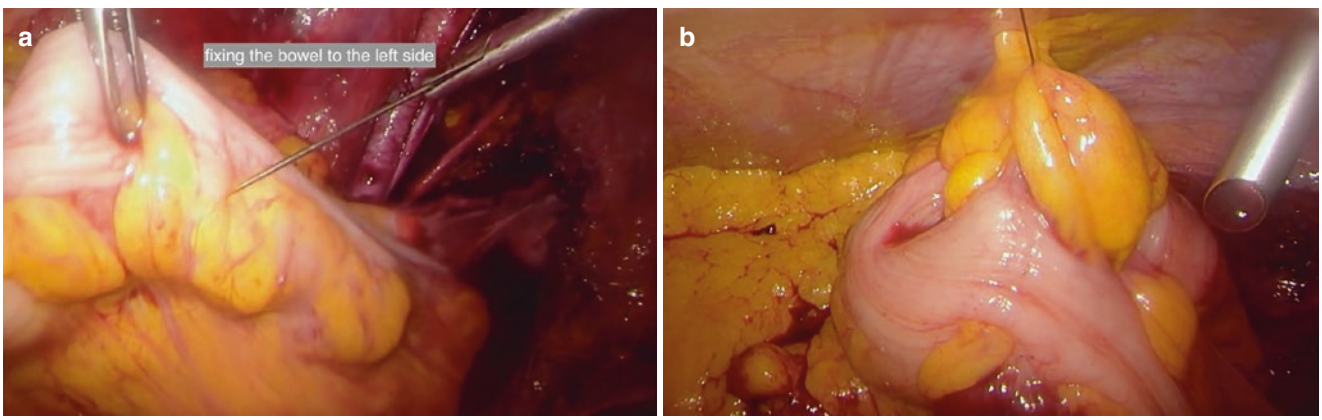

Fig. 51.24 (**a**) To allow optimal access to the aorta, the sigmoid colon is mobilised. (**b**) The sigmoid is fixed towards the left of the patient with a percutan suture

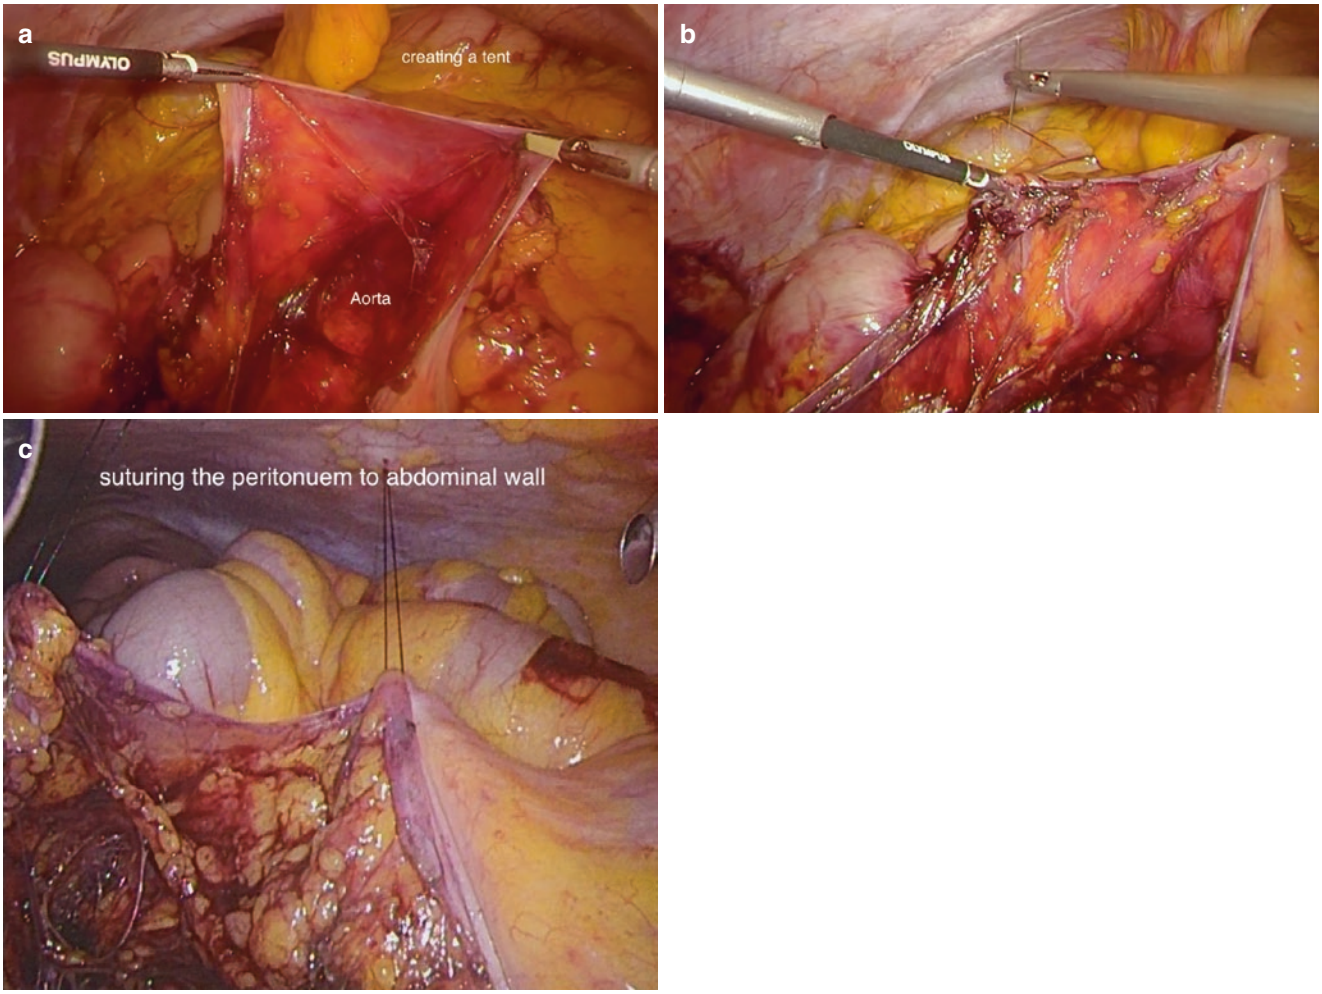

Fig. 51.25 (**a**–**c**) The peritoneum is opened up to the ligament of Treitz. (**b**) The peritoneum is then fixed towards the abdominal wall with percutaneus sutures. (**c**) The "tent" exposes the surgical field and keeps the small bowel in the upper abdomen

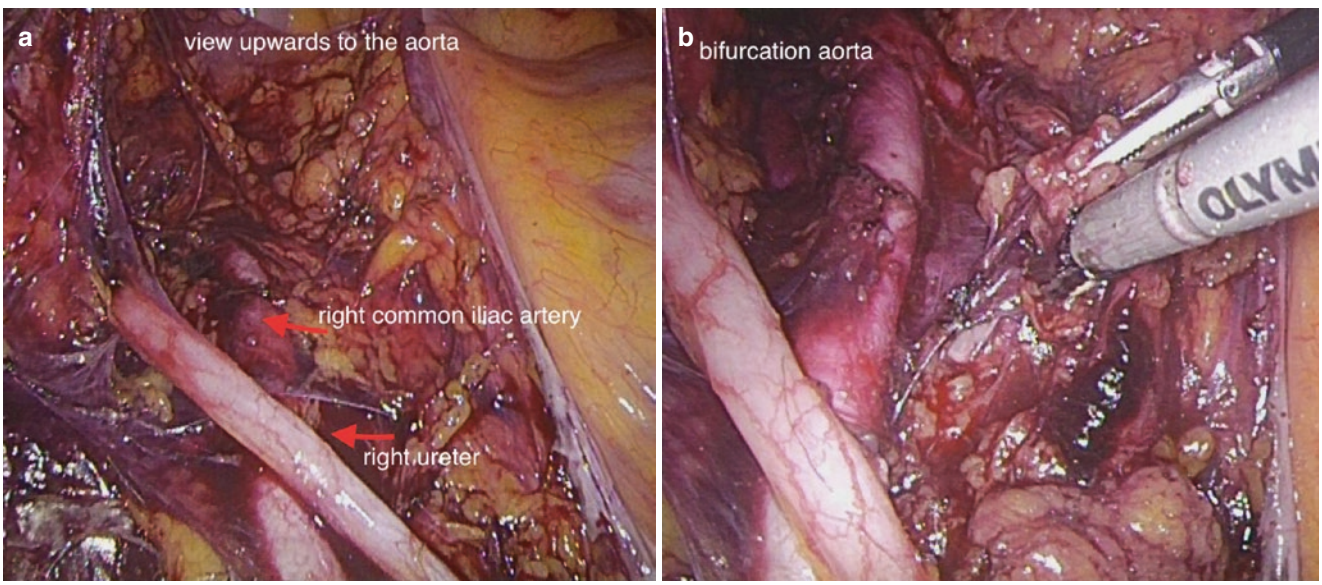

Fig. 51.26 (**a**) Dissection along the right common illiac artery, leading towards the aortic bifurcation. (**b**) The lymphatic tissue below the bifurcation should be removed carefully with the left common illiac vein just below

After securing the "right side" of the tent, the left side needs to be defined (Fig. 51.25c)
On the right side, particularly the right ureter is far more easily visualized than the left ureter.

First, the branching of the interior mesenteric artery needs to be found. It is fairly constant midway between the aortic bifurcation and the crossing of the left renal vein and comes off slightly to the left side of the aorta (Fig. 51.28)
Finding the branching of the inferior mesenteric artery, which serves as a sort of central reference point in the entire field of dissection is the key to all subsequent orientation. With more experience, one realizes that it is relatively constant. Sometimes it can be seen in its lateral trajectory, but ultimately, the branch directly off the aorta needs to be dissected by blunt preparation. We prefer to do this coming from the medial line of aortic preparation.

Finding the crossing of the left renal vein is challenging. Dissection cannot be sharp: cutting into the lower edge of the left renal vein is a catastrophe that must not happen (Fig. 51.29a, b)
The location of the left renal vein is about 4–5 cm cranial of the inferior mesenteric artery. Blunt dissection is essential, can, however, lead to small vessel bleeding which might require coagulation, obscuring the field and making further dissection more difficult. The learning curve of paraaortic laparoscopic lymphonodectomy takes several years, as shown by the group of Achim Schneider, and this is one of the reasons it take time to be comfortable in this region.

About 2 cm towards the left of the aorta, the left ovarian vein starts to descend from the left renal vein. This corner is the most difficult part of the paraaortic lymphonodectomy
Because of the lymphatic drainage of the corpus, these lymph nodes are of particular importance. If they are negative, the paraaortic lymphonodectomy has truly analyzed the complete lymphatic drainage of the uterus.

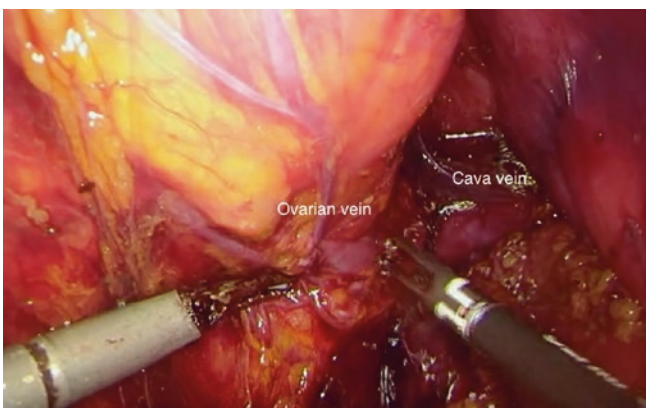

Fig. 51.27 Exposition and dissection of the right ovarian vein

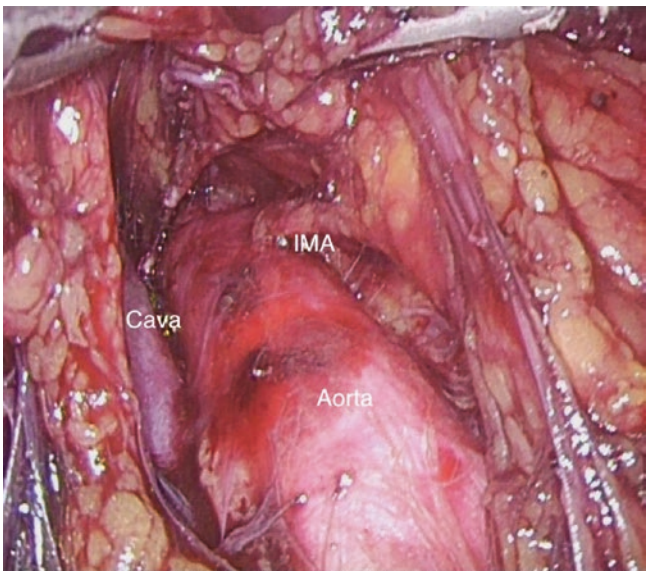

Fig. 51.28 Exposition of the aorta and delineation of the inferior mesenteric artery towards the left and the vena cava toward the right of the patient

The tent is now sufficiently defined
How to best hold the tent open is a matter of debate. We have had good experience with the first assistant opening the tent, as needed, with two blunt instruments. Some surgeons advocate suturing the peritoneal edge to the abdominal wall, others introduces a retractor through an additional trocar in the left upper quadrant.

Lymphonodectomy can be performed either from cranial to caudal or from caudal to cranial
In the end, the order depends on surgeon preference and the actual anatomical situation. Again: The steps of any surgery can be precisely described, but not necessarily their order.

Dissection on the aorta is unproblematic, dissecting off the vena cava needs to be slow and meticulous. Even pulling on the lymphatic tissue can lead to perforator veins tearing off the vena cave and possible cava bleeders (Fig. 51.30a–e)
The aorta is like a well-paved street easily traveled. Blunt dissection is possible. The vena cava tends to be more vulnerable, blunt dissection is to be avoided.

Cava bleeders need to be closed with pressure immediately. About 90 % of them can be stopped by applying sufficient pressure for at least 5 min. What still bleeds after prolonged pressure needs to be sutured with a 4-0 or 5-0 monofilament suture.
Pressure is the most effective hemostatic measure for small cava bleeders. Be careful using clips and sutures too early. Sometimes they make matters only worse.

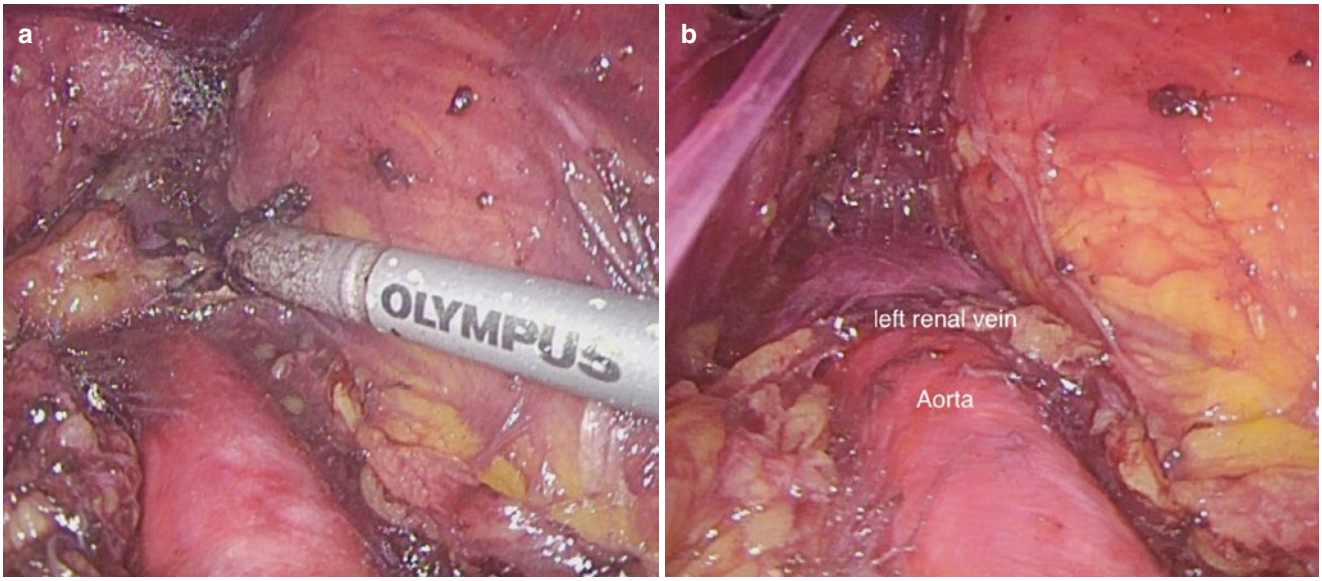

Fig. 51.29 (**a**) Further preparation "upward" i.e. cephalad until the left renal vein crossing the aorta is reached. (**b**) The left renal vein is the upper limit of the gynecologic paraaortic lymphonodectomy

En-bloc lymphonodectomy down the paracaval and paraaortic spaces is challenging. We recommend a step-by-step approach that takes place in different spaces
Lymph nodes should be removed as they become available through the 10 mm trocar at the umbilical position.

Paraaortic area cranial to inferior mesenteric artery (including the difficult angle between the left renal and left ovarian vein) Figs. 51.31 and 51.32a, b)
This is at the same time the most challenging and the most important area of dissection. Even very experienced surgeons continue to find this area very challenging.

Paraaortic area inferior to the inferior mesenteric artery (careful, the ureter is very close to the left lateral edge of the preparation and can be easily injured).
This area – rich in lymph nodes – should be assessed. It is crucial to identify the ureter towards the left lateral side.

Paracaval region, upper half - attention to crossing of the right ovarian artery, branching of the right ovarian vein
Careful dissection includes the identification, coagulation and transection of the above-mentioned structures. Vena cava perforators at this level are rare.

Paracaval region, lower half – attention to the perforator veins which are increasing in frequency towards the caudad region
In the Anglo-American medical community, these perforators are referred to as the "Fellow's veins", indicating that injury is mostly associated with lack of experience, However, here "experience" mostly teaches caution. Blunt dissection will inevitably lead to tearing of these small veins and to holes in the vena cava.

Interaorto-caval region – careful not to injure the lumbar veins going off in a dorsal and downward manner
This is a region rich in lymph nodes, but also rich in big and difficult-to-visualize vessels that are rarely encountered. Careful dissection and reassessment of the oncologic context are important.

Paracaval region towards the right side of cava – psoas space. Careful not to injure the right ureter
This remains one of the most challenging parts. Careful preparation is essential. Respect the trajectory of the inferior mesenteric artery which should remain lateral and cranial of the field. The ureter is difficult to visualize until you have dissected it. Still, it is an important area rich in lymphatic tissue.

The key to paraaortic lymphonodectomy is to avoid major bleeding as it will often require laparotomy
For this step, excellent visualization, using a 30° scope and optimal camera assistance are important. The big dangers are perforator bleeders from the inferior part of the vena cava, the left renal vein, if not exposed carefully, the ovarian veins and the lumbar veins if dissection is performed in a radical manner.

The most common serious source of bleeding will be small holes in the inferior part of the vena cava because of exaggerated pulling on lymphatic tissue, tearing off the small perforator veins. Ninety percent of these bleeders – which are easily diagnosed as venous bleeders because of the dark blue color of the blood – can be stopped by applying at least 5 min of direct pressure on the bleeding site. Patience is the key.

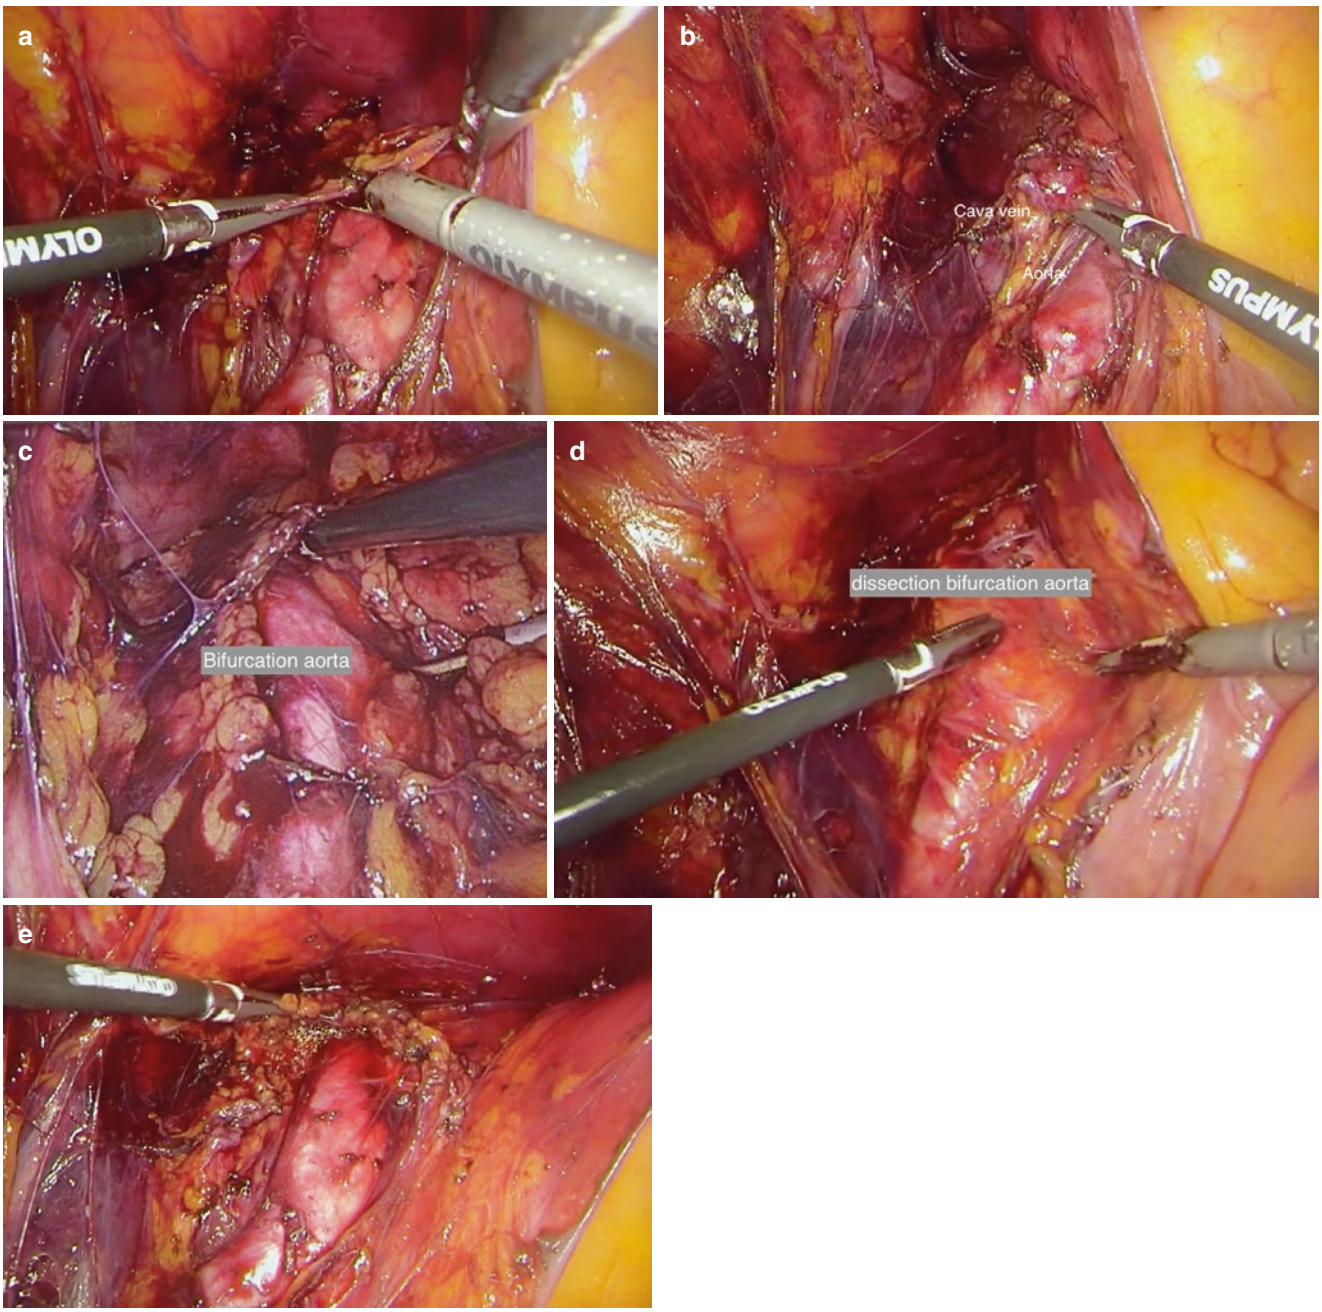

Fig. 51.30 (**a**) The dissection in the aorta is a sharp dissection. (**b**) Sharp dissection on the wall of the aorta. Attention to small perforating vessels. (**c**) First step is to clear the bifurcation of the aorta. (**d**) The use of vessle-sealing devices will facilitate the preparation. (**e**) The surgery follows exactly the course of the aorta

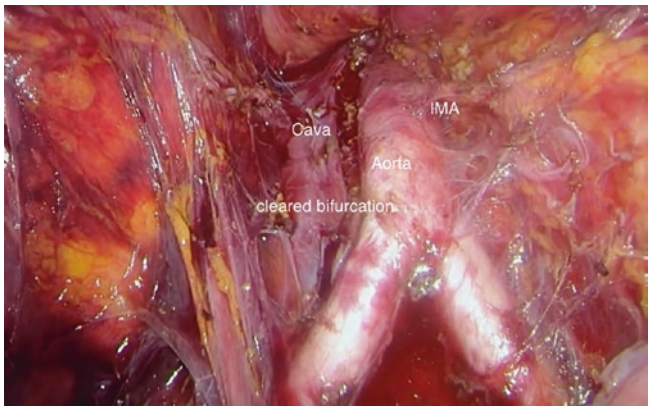

Fig. 51.31 Final view after exposing the aorta and the vena cava inferior

However, if the tear is too large, it needs to be closed with sutures. All venous defects – in fact all vascular defects – need to be closed with monofilament sutures, either 5-0 or 4-0 PDS or, as preferred by some surgeons, permanent sutures. Suturing the vena cava is not only difficult but also dangerous as tearing on the paper-thin venous wall has the potential to catastrophically enlarge the whole, necessitating immediate and urgent laparotomy. It is much better to avoid these bleeders than to control them.

Lymph node tissue is often smaller and can be removed through the 10 mm umbilical trocar

Do not leave small lymph nodes "waiting" in the abdominal cavity. Remove them immediately, lest they should be lost.

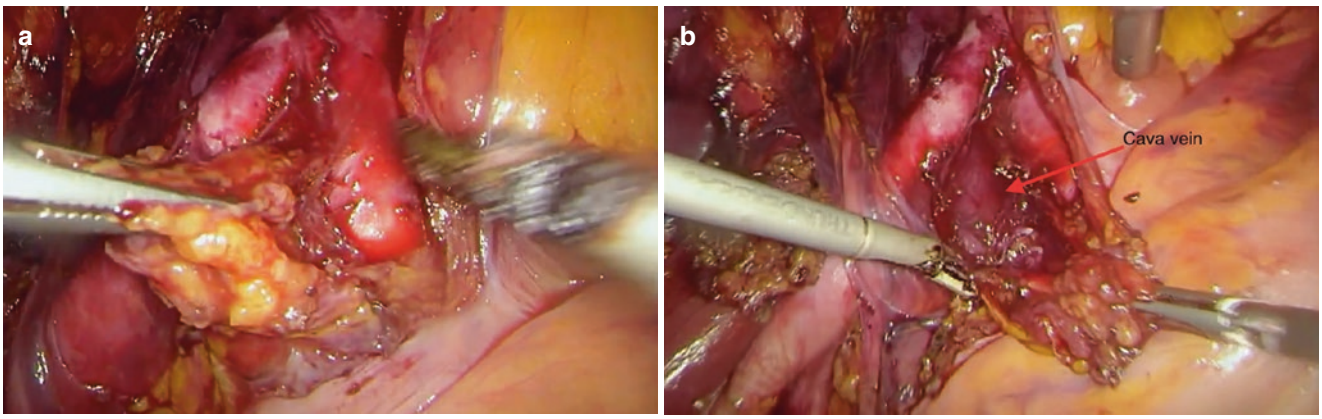

Fig. 51.32 (**a**) Dissesction of lymph nodes downwards the aortic bifurcation. (**b**) Attention! The cava vein is just below the aortic bifurcation

Surgical Techniques of Laparoscopic Omentectomy

52

Jun Ho Lee and Jieun Kim

Introduction

Omentectomy refers to the surgical removal of the omentum. It is usually performed in conditions of malignancies that are likely to transperitoneal metastasis. Omentectomy is a part of standard procedure during surgery for gastrointestinal and genitourinary malignancies like gastric cancer and ovarian cancer. It is a relatively safe procedure once you understand the anatomy and the avascular plane. It is important to be aware of the relationships with adjacent organs that are attached to the omentum to avoid injuries, such as colon, spleen, pancreas, stomach and duodenum. Finding avascular plane by proper traction is the key technique to perform safe omentectomy.

Anatomy and Functions

The greater omentum is a large double layered folds of peritoneum attached from the stomach hanging down to the transverse colon like an apron. It is made up of four layers. The anterior two layers descend from the greater curvature of the stomach and the proximal part of the duodenum, it passes down in front of the small intestines, sometimes as low down as the pelvis. Then they folded on itself and ascend again and attached to the transverse colon. The greater omentum is considered as composition of gastrocolic ligament and gastrosplenic ligament. It is continuous structure but named separately for descriptive purposes. The left border of the greater omentum continuous with the gastrosplenic ligament; and its right border extends as far as the proximal duodenum. Occasionally gastrocolic ligament itself is considered as synonym for "greater omentum" [1].

J.H. Lee, MD, PhD (✉) • J. Kim, MD

e-mail: gsjunholee@gmail.com; gskimji@gmail.com

The omentum has been known to play an immunologic role in defending the peritoneal cavity. It is a storage site for lipids, a regulator of peritoneal fluid transit, and a reservoir for immune cells in the peritoneal cavity. It serves as an antibacterial defense, provides hemostasis, reduces intestinal adhesion, and absorbs foreign material from peritoneal cavity. Yet, the omentum remains an understudied organ whose function and role in cancer is not completely understood. Role of omentum in immunology and cancer is still ongoing study [2].

Blood Supply and Lymphatic Drainage

The right and left gastroepiploic vessels provide the blood supply to the greater omentum (Fig. 52.1). The right gastroepiploic artery is a branch of the gastroduodenal artery, which is a branch of the common hepatic artery, which is a branch of the celiac trunk. It runs from right to left along the greater curvature of the stomach except at the pylorus. The left gastroepiploic artery is the largest branch of the splenic artery. It runs from left to right along the greater curvature of the stomach. These arteries lie about a fingerbreadth or more from the greater curvature and anastomose within the two layers of the anterior greater omentum [1, 3].

The right and left gastroepiploic vein run parallel to the same named artery. The right gastroepiploic vein is joined to the anterosuperior pancreaticoduodenal vein then drains into the superior mesenteric vein, and the left gastroepiploic vein drains into the splenic vein. And then, venous blood flow drains to the portal vein and entering the liver cycle.

Generally, the lymphatic drainage of the stomach parallels the vasculature. There are two lymph node groups: those along the left gastroepiploic vessels and those along the right gastroepiploic vessels [3]. Lymph nodes along the left gastroepiploic artey is defined as lymph node station 4sb by Japanese classification of gastric carcinoma [4]. Lymph nodes along the second branch and distal part of the right gastroepiploic artery is defined as lymph node station 4d.

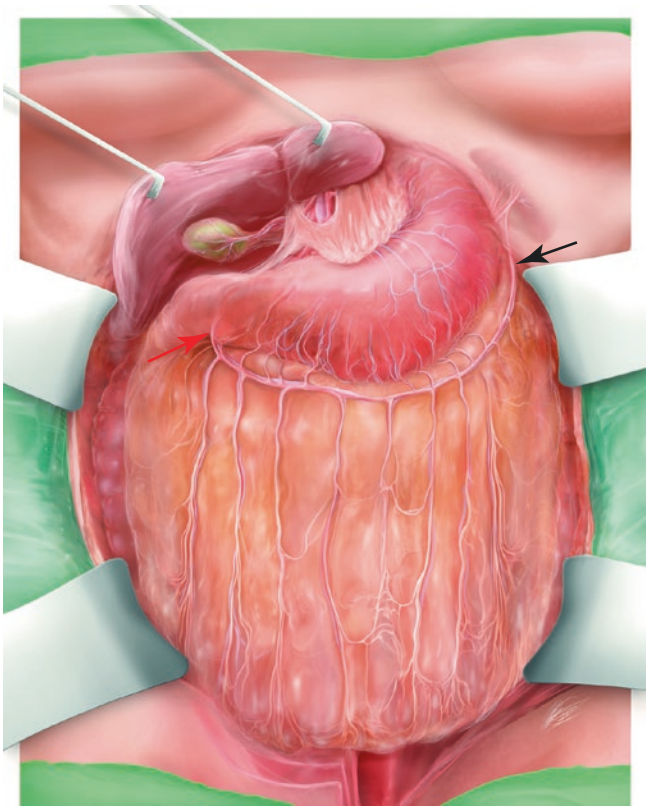

Fig. 52.1 Overview illustration of the omentum and the vessels

Lymph node stations of 4sb and 4d are regional gastric lymph nodes, which are essential for adequate lymph node dissection during curative resection for gastric cancer [4].

How to Perform Omentectomy

Dissection trough the avascular plane with proper counter traction of the transverse colon can lead to rapid and safe omentectomy during open surgery. In laparoscopic surgery, total omentectomy is time consuming procedure and has potential risk of injury to the adjacent organs. Surgeons not familiar with the upper abdominal anatomy in the laparoscopic view, limited working space, and loss of tactile sense might lead to inappropriate traction and it would make it difficult to find proper dissection plane through overlapped layers of omentum. We would like to introduce some tips to perform omentectomy without an assistant, which could be applied in single incision laparoscopic surgery as well [5].

Total Omentectomy

The patient can be placed in the supine position or lithotomy position, depending on the operator's preference. The operator should stand at either right side of the patient or between the legs of the patient if the patient is in the lithotomy position. After pneumoperitoneum is made and the laparoscopic trocars are in inserted (Fig. 52.2), greater omentum is easy to find in the center of abdominal cavity covering small bowel. Fifteen to twenty degree reverse Trendelenburg position would make a better view to start. Place patient in the left side up position while performing left side omentectomy, begin the procedure by removing all the omental adhesion to the parietal peritoneum. Grasp omentum attached to the parietal peritoneum, and gently pull to the medial side to find avascular white line by operator's left hand (Fig. 52.3). Adhesions can be easily divided with a scissors or electrocautery.

Identify splenocolic ligament by pulling down splenic flexure with operator's left hand (Fig. 52.4). Dividing dense splenocolic ligament could help find dissection plane. Sometimes dividing splenorenal ligament might be neces-

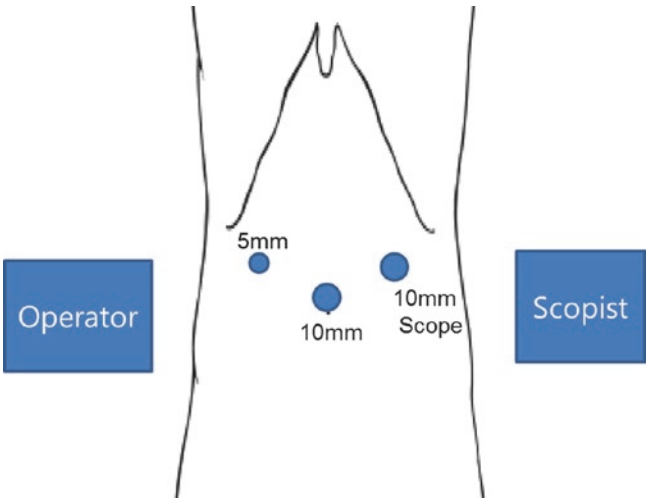

Fig. 52.2 Trocar placement. Five mm port is placed on the patient's right side of abdomen, 10 mm port is placed at the umbilicus, and another 10 mm port is placed at the left side. Five mm port is for the operator's left hand 10 mm port in umbilicus is used for operator's right hand

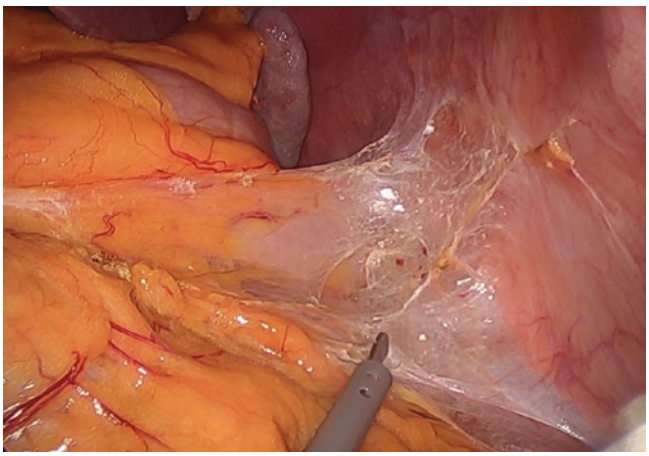

Fig. 52.3 Removing adhesions from the parietal peritoneum

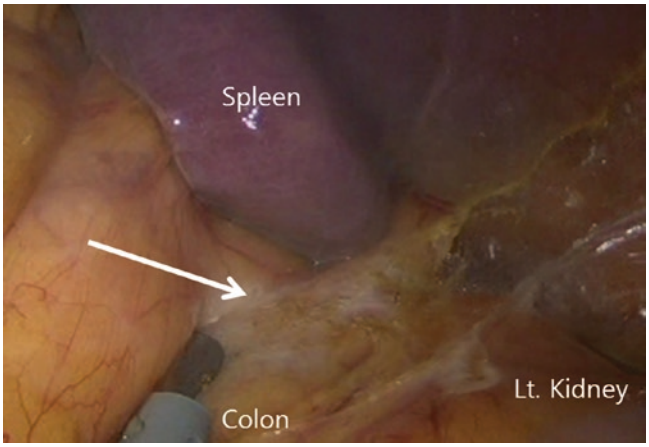

Fig. 52.4 Dividing splenocolic ligament. *Arrow*: splenocolic ligament

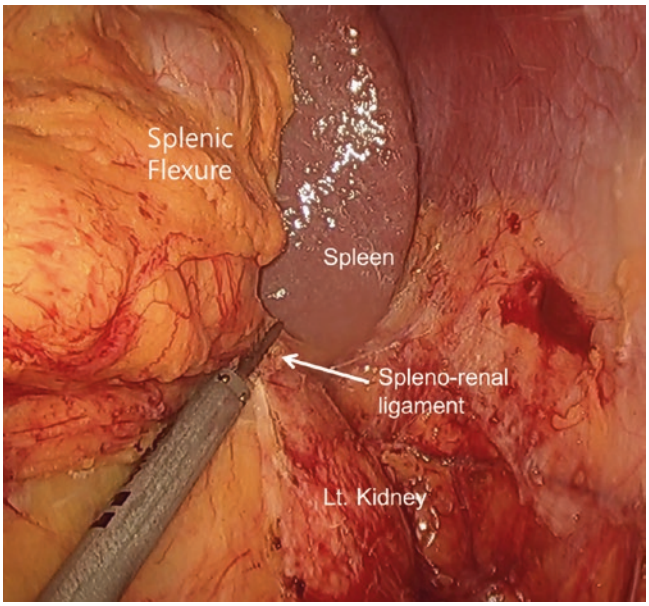

Fig. 52.5 Dividing splenorenal ligament. Left kidney is covered with Gerota's fascia

sary for a better view (Fig. 52.5). Grasp omental tissue 2–3 cm apart from the distal transverse colon with operator's left hand gently lift to the cranial, medial direction. Divide omentum with electrocautrery at the avascular plane just beside transverse colon (Fig. 52.6). Operater's left hand should stay upward direction while operator's right hand should press down transverse colon as if peeling the mesocolon off from the omentum. Continue until tail of the pancreas reveals then follow superior border of the pancreas to the lower pole of the spleen (Fig. 52.7). Occasionally, small vessel branching to inferior pole of the spleen needs to be divided. Careful dissection will identify the root of left gastroepiploic vessels coming up just behind the pancreas tail (Fig. 52.8). The left gastroepiploic vessels are ligated using the hemolock.

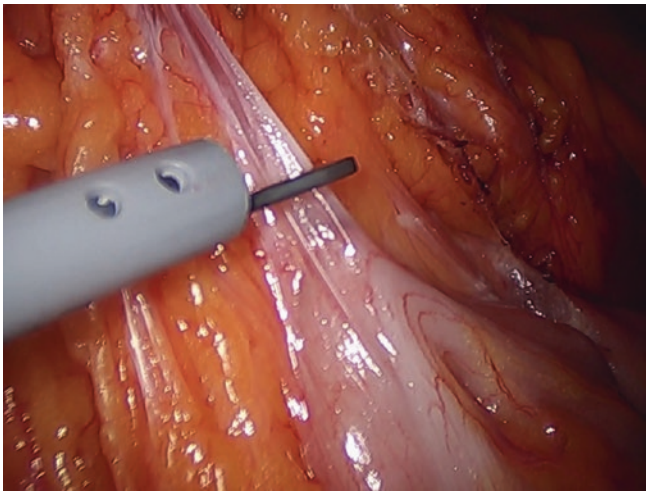

Fig. 52.6 Start dividing omentum with electrocautrery at the avascular plane just beside transverse colon

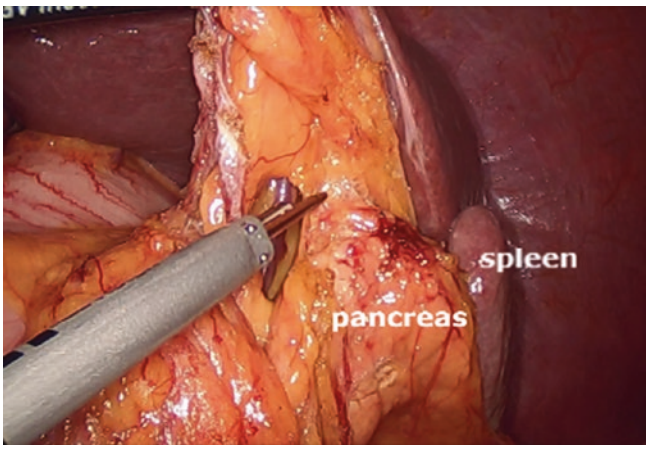

Fig. 52.7 Left side dissection following to the tail of the pancreas

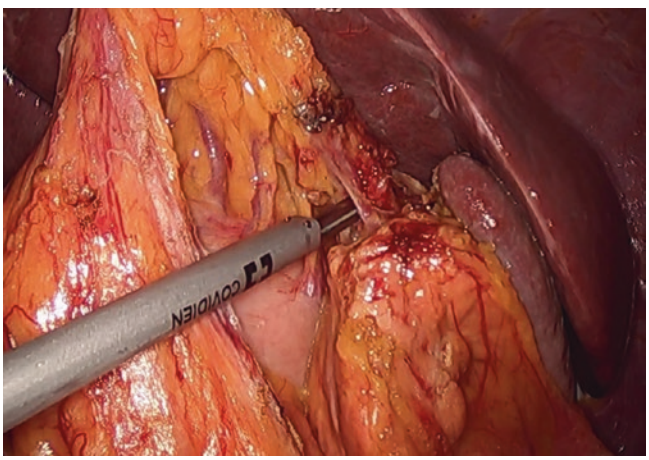

Fig. 52.8 Ligating left gastroepiploic vessels

Continue separating omentum from transverse colon from left to right direction. Keep on upward traction of the ometum with operator's left hand while pressing down

transverse colon as previously described (Fig. 52.9). This maneuver will help to minimize injury to the colon. Be careful of the thermal injury of the serosa of the colon by electrocautrery or active blade of ultrasonic shears (Fig. 52.10). If the thermal injury of the serosa is suspected, reinforce suture is needed. Once you divide white line attached to the tenia coli of the transverse colon with an electrocautery, strip off mesocolon from the omentum by gentle push and pull down maneuver with a blunt tip of the monopolar. If you encounter vessels in this layer, mostly it is vessels from mesocolon (Fig. 52.11). Trace the vessels and if it runs horizontal direction, it is vessel from the mesocolon, if the vessel trace up to the vertical direction it is a vessel to the omentum, which you should ligate with the energy device. Gentle press down layer just above the vessel will guide you to the next layer.

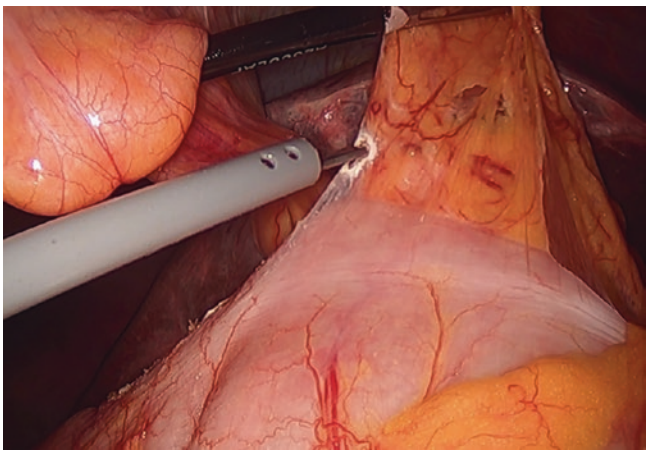

Fig. 52.9 Upward traction of the omentum with operator's left hand while pressing down transverse colon

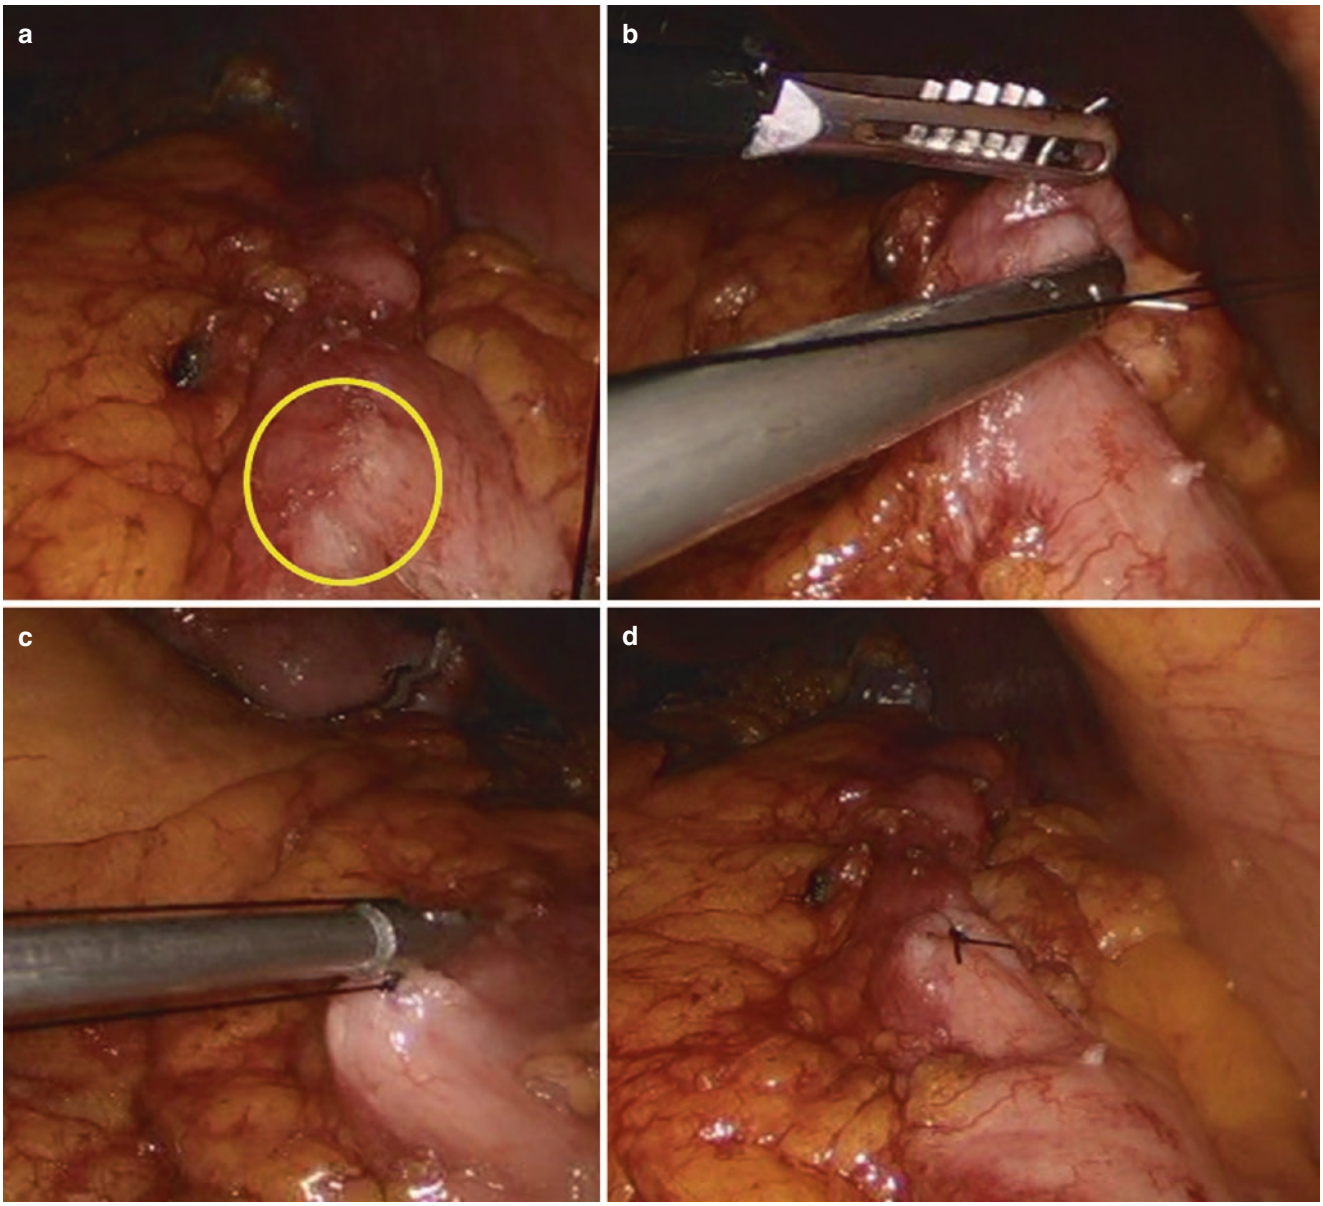

Fig. 52.10 (**a**) *Yellow circle*; Thermal injury to the colon wall. (**b**) Repairing serosa with interrupt suture. (**c**) Making knot with the knot-pusher. (**d**) Final view after serosa repair

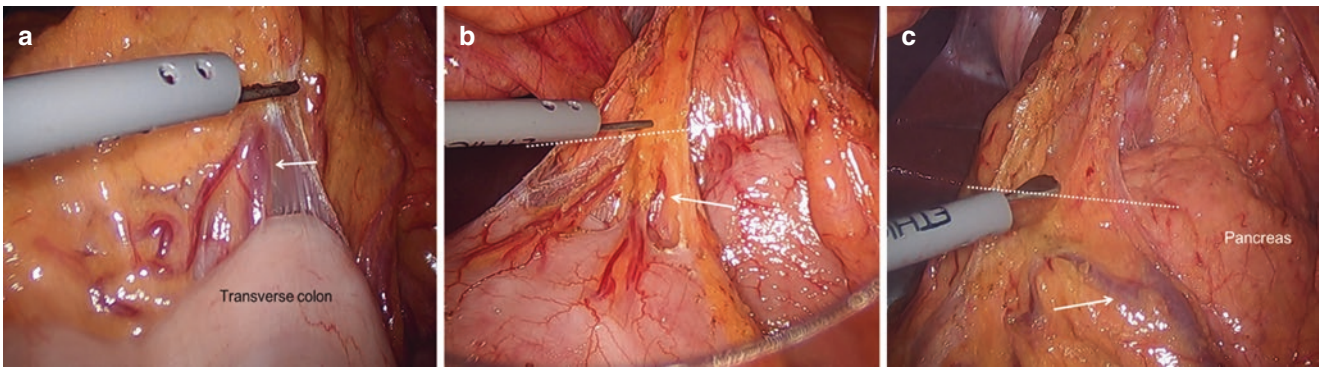

Fig. 52.11 Peeling off mesocolon from the omentum. Be aware of the mesocolic vessels (*arrow*). Dotted line: dissection plane

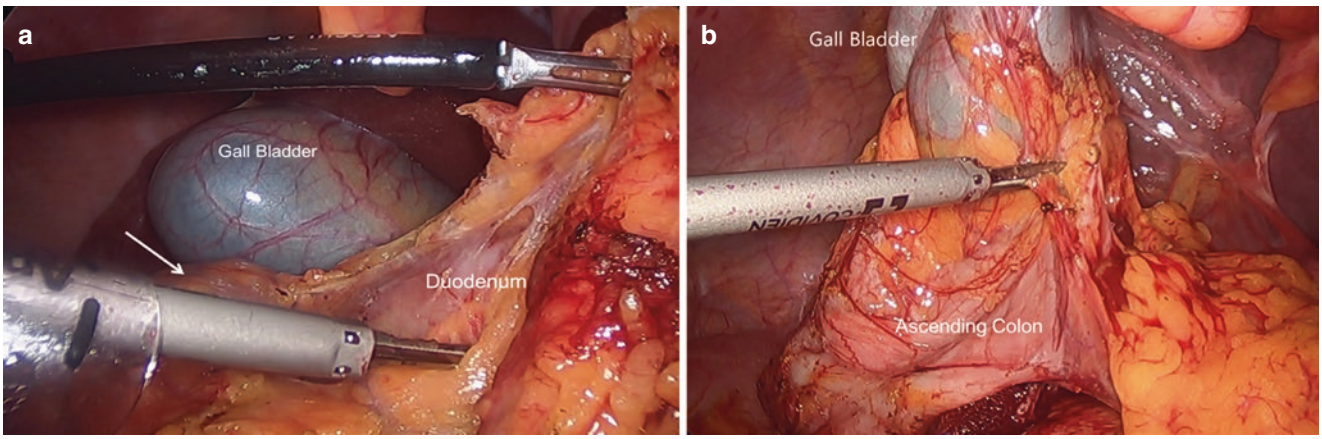

Fig. 52.12 (**a**) Right side omentectomy until the duodenum is seen. *Arrow*: ascending colon. (**b**) Adhesions between the ascending colon and the gall bladder

When you reach right side to the proximal transverse colon, unusual attachment of the omentum may be encounterd. Sometimes colon is folded in hide behind bulky fat tissue in this area. Track down colon until the second portion of the duodenum is seen (Fig. 52.12). Then trace duodenum and trim omentum to the pylorus level.

After separation of the omentum from the transverse colon, flip up the omentum and identify right gastroepiploic vessels arising vertically from the pancreas. Operator's left hand grasp pedicles of the gastroepiploic vessels and stretch to the cranial direction, careful dissection with right hand and ligation of the vessels with the hemolock just above the pancreas (Fig. 52.13). Too much tension before ligating vessels, might cause tearing or injuries to the vessels.

Follow ligated gastroepiploic vessels to the greater curvature of the stomach for trimming (Fig. 52.14). Be careful not to injure short gastric vessels inside the gastrosplenic ligament. Once you reach the greater curvature of the stomach, grasp omentum just 2–3 cm apart from the greater curvature with the operator's left hand and trim the greater curvature from left to the right direction with the operator's right hand with the energy device. Hold the omentum upward direction to maintain proper traction, gently pressing down the greater curvature as you divide omentum from the stomach from left to

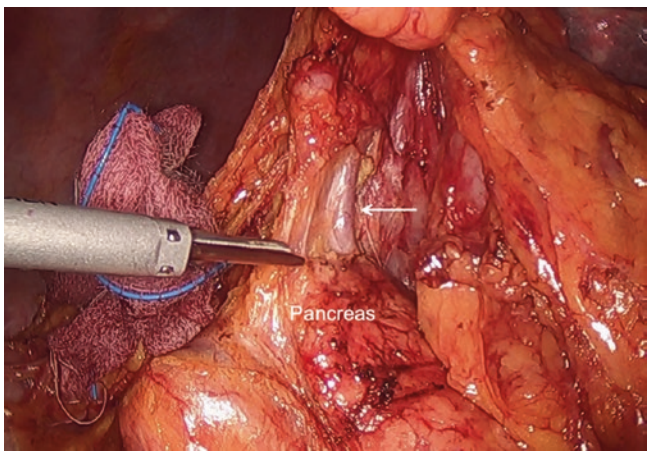

Fig. 52.13 Ligating the right gastroepiploic vessel. *Arrow*: right gastroepiploic artery

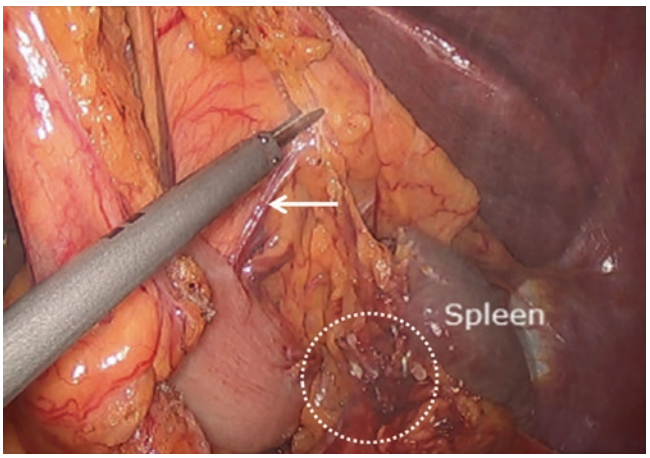

Fig. 52.14 Follow short gastric vessels toward stomach wall for trimming. Arrow: short gastric vessel, *Circle*: ligated left gastroepiploic vessels

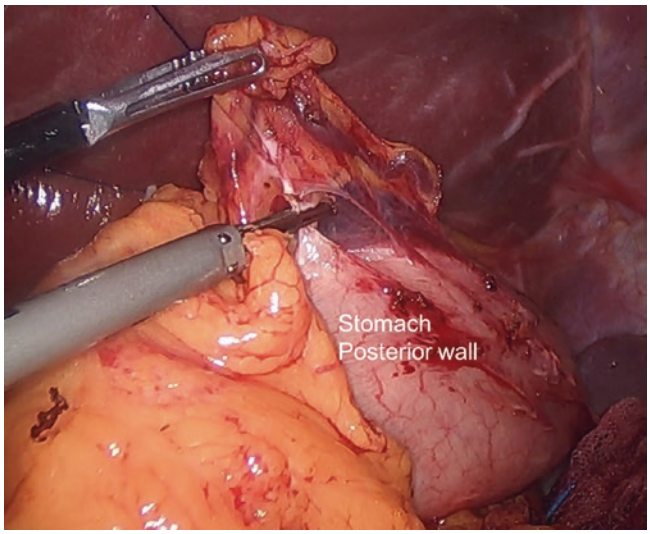

Fig. 52.15 Trimming of the omentum from the stomach

right (Fig. 52.15). This maneuver will show the layers of the dissection plane and minimize the injury of the stomach wall.

Partial Omentectomy

Partial omentectomy is the procedure literally removing only certain part of the omentum. For gastric surgery, partial omentectomy will be removal of the omentum attached to the greater curvature of the stomach including the arcades of the gastroepiploic vessels with the lymph node stations [6, 7]. For gynecologic surgery, terminology of infracolic omentectomy is used [8, 9]. For this case, arcades of the gastroepiploic vessels will be preserved, range of resection would be below gastroepiploic arcades and the rest of the gastrocolic ligament.

Either partial omentectomy or infracolic omentectomy, dissection line should be 4–5 cm apart from the greater curvature of the stomach. The omentum is divided 2–3 cm distance from the gastroepiploic vessels. First, start with making a window at 2–3 cm apart from the arc of the gastroepiploic vessels near lower to mid body of the stomach (Fig. 52.16). Operator's left hand grasp the greater curvature of the stomach and lift upward direction while operator's right hand divide omentum following the gastroepiploic vessels to the left side toward the lower pole of the spleen (Fig. 52.17). When approaching the lower pole of the spleen, it is important to identify the colon to prevent its injury. Make sure colon wall is not in the way of dissecting plane. The left gastroepiploic vessels are ligated as the same method as used for total omentectomy.

The right sided partial omentectomy is mostly same as previously described in the total omentectomy. Follow gastroepiploic vessels to the right side towards proximal duodenum, ligate the right gastroepiploic vessels

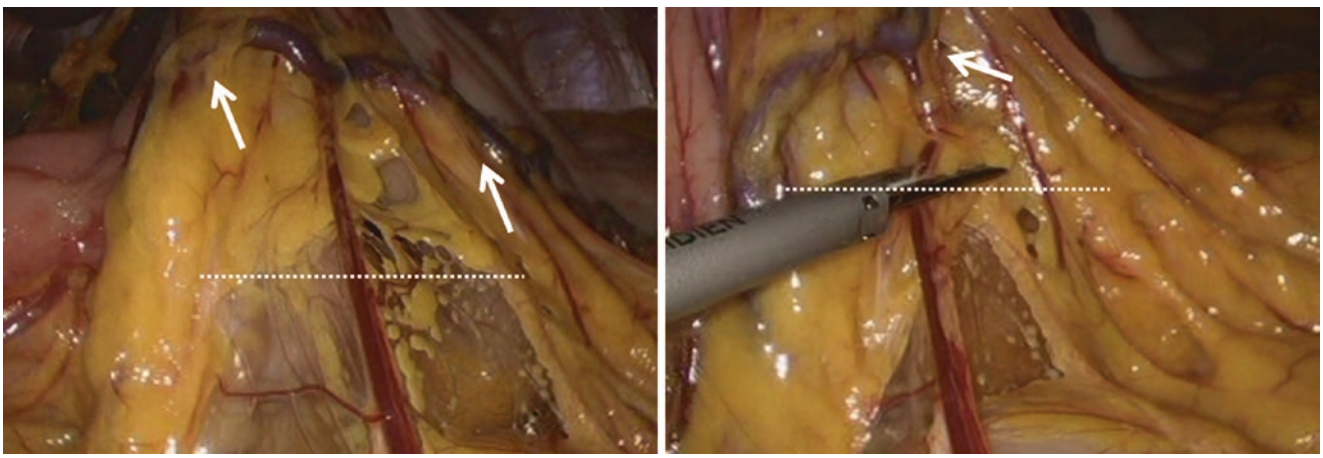

Fig. 52.16 Start partial omentectomy by making a window at 2–3 cm apart from the arc of the gastroepiploic vessels near lower to mid body of the stomach. *Arrow*: gastroepiploic arcade. *Dotted line*: dissection plane

Final Steps and Postoperative Considerations

53

Monika Martina Wölfler

Final Steps After Hysterectomy Via Laparoscopy

Upon finalizing the hysterectomy by removing the uterus transvaginally and closure of the culdotomy or removing the uterine corpus via morcellation in case of a subtotal hysterectomy, extensive lavage of the peritoneal cavity to remove debris and clots and inspection of the entire operating field are essential. Meticulous inspection of the culdotomy, the adnexal region or site of salpingoophrectomy, all peritoneal edges, blood vessels and vascular pedicles for bleeders and good hemostasis after irrigation and suction of fluids reduce the risk of postoperative hemorrhage.To identify small bleeders it might be helpful to temporarily reduce the intraperitoneal pressure. Bipolar electrocauterisation under direct vision is standard for steady hemostasis. Additionally, hemostatic agents, tissue sealants and compression suture clips can be used, however, good evidence is scarce [1].

Irrespective of the dimension of the operative procedure, be it a standard laparoscopic hysterectomy in an outpatient setting or major surgery for deep infiltrating endometriosis or a radical hysterectomy including lymphonodectomy, at the end of the procedure it is important to visualize normal ureteral peristalsis and document whether the urine is clear in the urinary catheter. Normal ureteral peristalsis is certainly not a proof for the absence of for instance thermic ureteral lesion, however, forensically it is substantial to at least address the macroscopic integrity of the ureter intraoperatively.

After major surgery the application of an intraperitoneal drain might be requested although there is no scientific evidence to favor the use of drains at all. Furthermore, data from randomized trials underline that routine use of drains does increase the risk of wound infection. In case drains are inserted they should be removed as soon as possible [2].

When finishing the laparoscopy, the removal of the accessory trocars should be carried out carefully and under direct vision. Small bleeders can mostly be controlled with pressure or electrocauterisation,otherwise a full thickness suture should be placed. For 12 mm accessory trocars and the laparoscope trocar fascial closure is required to prevent herniation. After removing the laparoscope, extensive deflation of carbon dioxide prior to removing the trocar avoids postoperative discomfort caused by residual gas [3].

For the closure of all cutaneous incisions intracutaneous absorbable monofilament sutures will guarantee for optimal aesthetic outcome. All wounds need to be covered with sterile dressings. Alternatively, for the small incisions tape strips and dressings or a skin adhesive dressing can be used.

Postoperative Considerations

The perioperative management was subject to major changes in recent decades, hence checklists for the prevention of complications and for the improvement of patients´ safety are nowadays standard in most clinics and are explicitly recommended by several gynecologic and surgical societies (see also Fig. 53.1 displaying the checklist used at our clinic as an example).Data from abdomino surgical studies underline the superiority of the “fast-track surgery” concept and enhanced postoperative recovery programs compared to traditional concepts in perioperative management [2, 4]. Data from these studies refer to major abdominal surgery and patients with mostly advanced morbidity. Since the majority of gynecologic patients scheduled for hysterectomy are American Society of Anesthesiologists category 1 or 2 (ASA1 healthy or ASA2 mild systemic disease) they might benefit even more from the “fast-track surgery” concept. For the postoperative management in particular several issues need to be addressed.

Fig. 53.1 (continued)

Analgesia

Effective analgesia that allows early mobilization is a fundamental prerequisite for improved postoperative recovery. Especially in case of extensive surgery epidural analgesia followed by multimodal non-opioid analgesia is the most effective evidence-based method [2]. Epidural analgesia, however, is not indicated in the vast majority of laparoscopic hysterectomies and can be replaced by opioid-sparing multimodal analgesia, including oral paracetamol, non-steroidal anti-inflammatory drugs, gabapentanoids and local anesthetics [5]. For vaginal hysterectomy recent data have shown that preemptive local analgesia prior to hysterectomy is associated with significantly lower pain scores and a reduction in narcotic use postoperatively [6, 7]. Patients undergoing laparoscopic hysterectomy might benefit from paracervical analgesia as well. Additionally, there is substantial evidence that transversus abdominis plane (TAP) blocks (see also Fig. 53.2) and local anesthetic infiltration of trocar insertion sites in several laparoscopic procedures result in reduced pain scores and analgesic requirement [8–10]. TAP block in laparoscopic hysterectomy in particular was associated with lower use of opioids in the postoperative phase [11]. A recent study on extended assisted ventilation with an open umbilical trocar valve after laparoscopic hysterectomy showed that this is an effective and safe method to reduce postoperative pain levels, in particular abdominal and shoulder pain [3].

For efficient postoperative pain treatment it is crucial that clinical standards of care provide anticipatory pain management and that the use of opioids is evited.

Postoperative Nausea and Vomiting (PONV)

Besides postoperative use of opioids, non-smoking status and history of PONV or motion sickness, female gender per se is a risk factor for PONV according to the Apfel risk score [12]. This risk score and an individual risk based multimodal PONV prophylaxis is advocated by evidence-based guidelines as standards of care. Tailored anesthesia and pain management in particular avoiding too liberal dosing of anesthetics and opioid analgesics is essential in order to reduce the risk for PONV [13].

Thus multi-modal opioid sparing analgesia and a risk-based prophylaxis should be provided to every patient

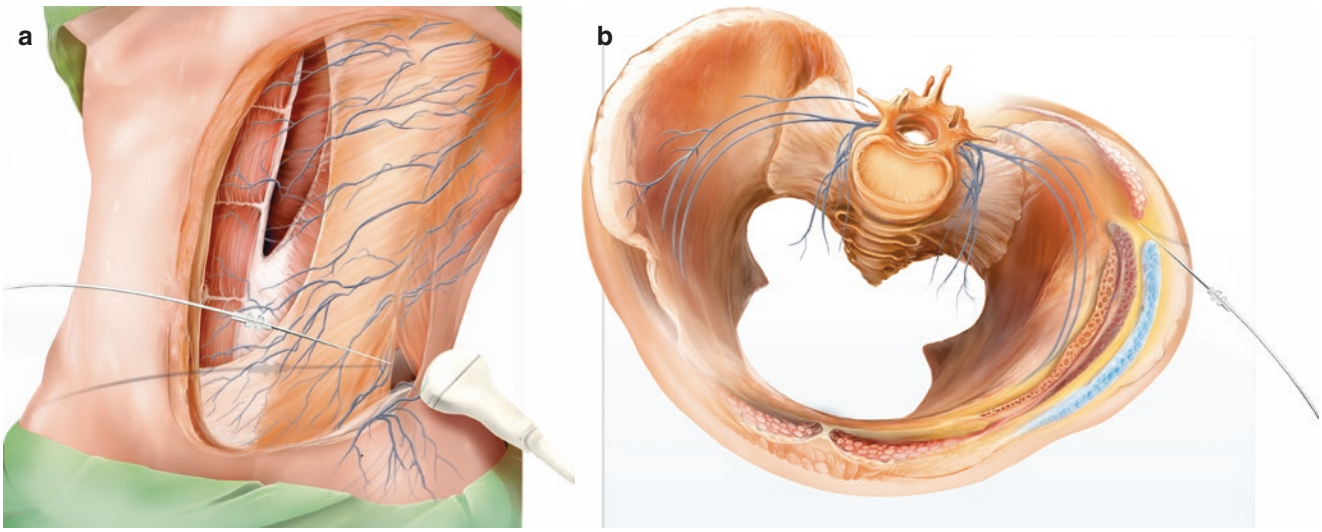

Fig. 53.2 The anatomical background for performing the transversus abdominis plane (TAP) block. The original technique described by Rafi et al. in 2001 [14] was a "blind" TAP block injecting a local anesthetic through the triangle of Petit on the lateral abdominal wall, whereas currently the ultrasound guided insertion of the needle is performed in an anterior to posterior manner to the plane of the rectus abdominis muscle [15]. Therefore, the ultrasound probe is placed diagonally over the lateral abdominal wall at the level of the mid axillary line (**a**). The extent of analgesia which can be achieved by TAP block is from the umbilical to the suprapubic region (block of the innervation of the anterior abdominal wall by the tenth thoracic intercostal nerve to first lumbar nerve) (**b**)

undergoing laparoscopic hysterectomy in order to minimize the occurrence of PONV.

Urinary Catheter, Drains and Tamponades

A recent meta-analysis of randomized controlled trials on immediate and delayed removal of urinary catheters following uncomplicated hysterectomy suggests that delayed catheter removal increases the incidence of postoperative bacteriuria and symptomatic urinary tract infection but reduces the risk of re-catheterization [16]. For laparoscopic radical hysterectomy and extensive resection of deep infiltrating endometriosis of the pelvis no such evidence is available albeit the removal of the urinary catheter upon mobilization is advisable. Functional bladder dysfunctions are common following nerve-sparing radical hysterectomy. Systematic bladder training, however, does not influence the rate of urinary retention or readmissions for bladder catheterization and is therefore not indicated [17].

There is no scientific evidence to favor the use of drains and tamponades. Several randomized trials addressing intraperitoneal drainage have shown that routine use of drains does increase the risk of wound infection, causes discomfort and postoperative pain and should therefore never be used routinely. In case drains are inserted they should be removed as soon as possible [2].

According to data from a recent Cochrane Database systematic review, patients with gynecological malignancies undergoing pelvic lymphadenectomy do not benefit form the placement of retroperitoneal tube drains to preventlymphocyst formation. When the pelvic peritoneum is left open, tube drain placement is associated with an even higher risk of short and long-term symptomatic lymphocyst formation [18].

Antibiotic Prophylaxis

There is no evidence for antibiotic prophylaxis in the postoperative phase. Antibiotic medication should only be initiated upon specific indication.

Venous Thromboembolic Event Prophylaxis

The rate of venous thromboembolic events (VTEs) including deep venous thrombosis and pulmonary embolism among women undergoing gynecologic surgery is high, particularly for women with a gynecologic malignancy. Current guidelines recommend VTE prophylaxis in the immediate postoperative period for patients undergoing open surgery. However, the VTE prophylaxis recommendations for women undergoing minimally invasive gynecologic surgery are not as well established. The risk of VTEs in patients undergoing minimally invasive surgery of intermediate complexity such as laparoscopic hysterectomy appears to be low based on retrospective analyses [19]. To date, there are no established guidelines that specifically provide a standard of care for patients undergoing minimally invasive gynecologic surgery for benign or malignant disease [20].

Pelvic surgery in general increases the risk of VTEs. The expositional risk after laparoscopic hysterectomy is considered to be intermediate and the dispositional risk of any patient is individual and needs to be addressed separately. Besides mechanical compression by graduated compression stockings the use of low molecular weight heparins (LMWH) is the standard postoperative pharmacologic prophylactic strategy based on multiple high-quality randomized trials [21–24].There is insufficient evidence to recommend graduated compression stockings alone in intermediate and high-risk surgical patients. According to a very recent evidence-based review the duration of prophylaxis should be extended to 28–35 days for patients undergoing abdominal/pelvic cancer surgery and higher doses of LMWH should be considered in obese patients [24]. In all studies the importance of early mobilization is emphasized.

Mobilization

Mobilization of patients at an early stage after surgery reduces postoperative complications and improves recovery and is one of the vital issues in the "fast-track surgery" concept [2]. For standard laparoscopic hysterectomy this can be within a few hours after surgery and even after extensive operative procedures mobilization on the day of surgery should be aspired.

Nutrition

In the past few years the dominating dogma of fasting periods after vaginal or laparoscopic hysterectomies was abandoned in favor of early food intake [25]. Even after major abdominal gynecologic surgery for either benign or malignant conditions early postoperative intake of fluids and food appeared to be safe without increased gastrointestinal morbidities or other postoperative complications according to a systematic Cochrane Database review. The benefits of this early postoperative feeding approach include faster recovery of bowel function, lower rates of infectious complications, shorter hospital stay, and higher satisfaction scores [26].

Daily Care, Monitoring and Diagnostics

The provision of a detailed nursing-care programme for each postoperative day is mandatory, and details about the care programme and the expected duration of hospital stay should be provided to patients (and relatives) upon indication for surgery and detailed planning of the surgical procedure for as well in-patients and out-patients [2, 4]. Intensive care observation is rarely necessary after laparoscopic hysterectomy and may be due to the patient's individual risk factors. Most clinics have standards for postoperative monitoring including recordings of pain, digestion, urination, vaginal bleeding and discomfort, daily ward rounds and if indicated physical examination. Any further diagnostic evaluation or examination should be symptom-driven and not be performed routinely. For instance, there is substantive evidence that routine hemoglobin level testing has little clinical benefit following elective laparoscopic hysterectomy and should be reserved for patients who develop signs or symptoms suggestive of acute anemia [27].

Very recent data suggest that e-health interventions providing personalized pre- and postoperative instructions on the resumption of daily activities, and tools to improve self-empowerment and to identify recovery problems result in a faster return to work, a higher quality of life and less pain during postoperative recovery after inter alia hysterectomy for benign conditions [28]. Thus, besides efficient nursing-care it is effective to inform patients in detail about the process of convalescence, instruct them and empower their responsibility.

Discharge and Recommendations to the Patient

After an uneventful postoperative recovery a general physical examination and conversation with the patient about the laparoscopic procedure, subsequent medical checkups, and instructions for the phase of convalescence are recommended and should be documented. There is no evidence to conduct a gynecologic examination or sonography prior to discharge without specific indication. It is important to make sure that the patient is mobile, urinating freely, has regular digestion and adequate pain control, and does not have excessive vaginal bleeding. Most clinics have checklists for the management of discharge and provide brochures with convalescence recommendations on daily activities (avoid heavy lifting, no sexual intercourse, no bath tub and swimming for up to 6 weeks, etc.). There is no scientific evidence to sustain these concrete recommendations, however. A Dutch interdisciplinary team defined convalescence recommendations rooted in expert-based knowledge for gynecological surgery. For laparoscopic hysterectomy his expert panel recommends the resumption of light, moderate and heavy activities after 1, 2 and 4 weeks respectively. These recommendations reflect an average functional recovery time for a healthy woman, but certainly the specialist in charge will take the presence of co-morbidities or potential complications into account for individual recommendations to a patient [29] (see also Table 53.1).

Table 53.1 Multidisciplinary convalescence recommendations

	Examples	Considered medically possible from (days/weeks after day of surgery)				
		Lapsc– Adn	LSH	TLH	VH	AH
Light activities	Lifting or carrying 5 kg	2 dy	1 wk	1 wk	2 wk	2 wk
	2 h sustained sitting					
	30 min sustained standing and walking					
Moderate activities	Lifting or carrying 10 kg	1 wk	2 wk	2 wk	3 wk	3–4 wk
	Pushing or pulling 15 kg					
	Riding a bicycle					
	Vacuum cleaning					
Heavy activities	Lifting or carrying 15 kg	2 wk	3 wk	3 wk	4 wk	6 wk
	Standing and walking during entire working day					
Resumption of (average) job	+/– 8 h a day	2 wk	3 wk	3–4 wk	4 wk	6 wk
	+/– 40 h a week

Ambulatory Care Setting

Recent data suggest that ambulant care appears to be safe and does not have higher rates of complications or readmissions even in advanced laparoscopic surgery such as laparoscopic hysterectomy [30–32].

In an ambulatory care setting, the patient is monitored for discomfort in the recovery room for a few hours postoperatively. The evaluation of vital signs every 30 min should provide sufficient safety. Preemptive analgesia, early mobilization and fluid and food intake at an early stage are recommended. The minimal duration of surveillance after general anesthesia is 2 and 4 h after application of opioids, respectively. After a final checkup by the anesthesiologist and gynecologic surgeon the patient can be discharged. Information about convalescence and practical instructions for daily activities should be provided to the patient prior to surgery and handing out brochures providing this information upon discharge are beneficial.

54 Extraperitoneal Hysterectomy-Total Pelvic Peritonectomy Combined with the Segmental Resection of the Rectosigmoid

Massaki Andou

The Extraperitoneal Hysterectomy

Theoretically, total removal of the pelvic peritoneum is the most beneficial tactic for disease restricted to the pelvis. With the total removal of the pelvic peritoneum in mind, we developed our laparoscopic extraperitoneal hysterectomy. The goals for this surgery are the complete eradication of tumor cells for stage II ovarian cancer and this surgery is also implemented as optimal cytoreductive surgery for selected stage III patients who have massive residual pelvic disease after previous surgery or neoadjuvant chemotherapy, where upper abdominal tumors have been completely controlled.

Ovarian cancer has the possibility to be extensive disease, with a traditionally invasive approach to treatment. Because ovarian cancer requires the most invasive surgery in gynecology, making this surgery patient friendly is a necessary theme. The feasibility and efficacy of laparoscopic staging and cytoreductive surgery in ovarian cancer is demonstrated in our series. Laparoscopic surgery for ovarian cancer is traditionally regarded as a contraindication. However, the standard laparotomy is a very invasive procedure which is sometimes difficult to perform with very poor performance status patients, and also potentially causes the delay of the main therapy; chemotherapy. In contrast, laparoscopic optimal cytoreduction allows quick recovery from surgery meaning a quick return to primary treatment. It also has the advantage of decreasing bowel morbidity, which also frequently causes delays in administration of chemotherapy.

Procedure

Four ports are used in this surgery- a 12 mm port in the umbilicus, another 12 mm port is placed in 4 cm median and 4 cms above the right iliac crest. One 5 mm port is placed at the same position on the opposite side. Another 5 mm port is placed directly between these two ports. The patient is placed in the lithotomy position with a slight Trendelenberg tilt. Standard laparoscopic instruments are used for most of the procedure. We also used a linear stapler and circular stapler for bowel reconstruction.

The extraperitoneal hysterectomy begins with a peritoneal incision starting from the pelvic sidewall triangle at the level of the pelvic brim (Fig. 54.1). The incision is extended anteriorly, curving along the upper edge of the public bone and finally arriving at the same point on the left side of the pelvis. The next step is the dissection of the bladder peritoneum from the bladder wall. The bladder peritoneum is dissected until the uterine cervix appears. The bladder is then dissected off from the cervix. After mobilization of the peritoneum of the bladder and pelvic

sidewall, the extraperitoneal transection of the parametria is started (Fig. 54.2).

After the ureter is detached from the posterior layer of the broad ligament, the ureter is dissected down until the entrance of the ureteral tunnel is reached. Then, the cardinal ligament is bipolar desiccated and transected (Fig. 54.3). The vagina is exposed and transected.

The second stage of this procedure is the removal of the rectosigmoid. As the peritoneum of this portion cannot be detached from the organ, the procedure requires the segmental resection of this segment. The rectosigmoid is mobilized starting from the dissection of the presacral space. This dissection continues until the pelvic diaphragm is reached. The mesosigmoid is divided using a harmonic scalpel. After full mobilization of the mesosigmoid, the upper portion of the segment is transected using a linear stapler (Fig. 54.4) and the caudal portion of this segment is also transected. After all of these procedures have been completed, the uterine body along with the rectosigmoid are put into a protection bag to stop the spilling of tumor cells in the abdominal cavity, and removed through the vagina (Fig. 54.5). Finally, the rectum is anastomosed to the sigma using a circular stapler (Fig. 54.6).

All cases underwent a hysterectomy, bilateral salpingo-oophorectomy, retroperitoneal lymph node dissection, sampling of ascitic fluid, multiple peritoneal biopsy, appendectomy and omentectomy. Some selected cases underwent cytoreductive procedures including elimination of peritoneal dissemination using an argon beam coagulator, removal of the pancreas tail and spleen because of metastatic tumors to the splenic hilus, resection of the total pelvic peritoneum including extraperitoneal hysterectomy, segmental resection of the rectosigmoid due to dissemination to the pelvic peritoneum and/or bowel wall

invasion (Fig. 54.7). Although the indications for this surgery are not broad, it is efficacious and safe for patients who require extensive pelvic resection or cytoreduction. Through this procedure, it has become possible to achieve complete tumor eradication if the tumor is located in the pelvis.

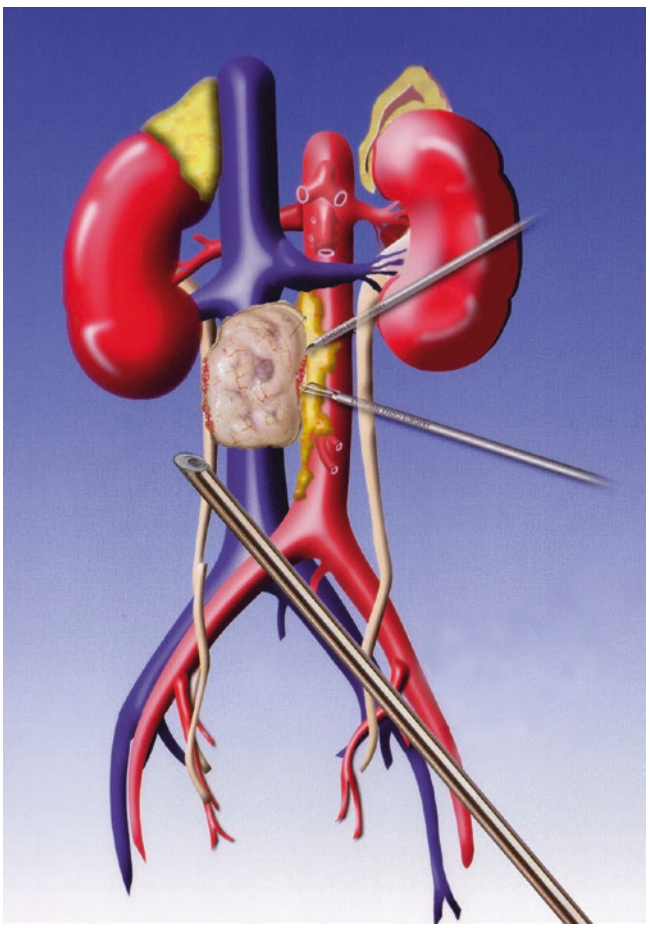

Fig. 54.7 Illustration showing the metastatic lymph node fixed to the inferior vena cava in debulking lymphadenectomy

Additional Cytoreductive Procedures

Because of the aggressive nature of ovarian cancer, many cases suffer from extensive tumor distribution or dissemination. For these cases it is necessary to find ways to manage the broad extension of the disease while considering the quality of life of the patient. We have introduced some additional procedures for laparoscopic cytoreductive surgery for advanced ovarian cancer such as a debulking lymphadenectomy, diaphragma stripping, omentectomy, and segmental resection of the small bowel or the rectosigmoid.

In the case of the debulking lymphadenectomy we use the paraortic dissection followed by the transperitoneal approach in the pelvis (Fig. 54.8). We use very fine bipolar forceps to grasp the base of the adhered metastatic lymph node and then simultaneously coagulate the connected area and slice off the lymph node in a sweeping motion (Fig. 54.9). The resected lymph nodes are retrieved from the port site after being placed in a retrieval bag to prevent the spillage of tumor cells.

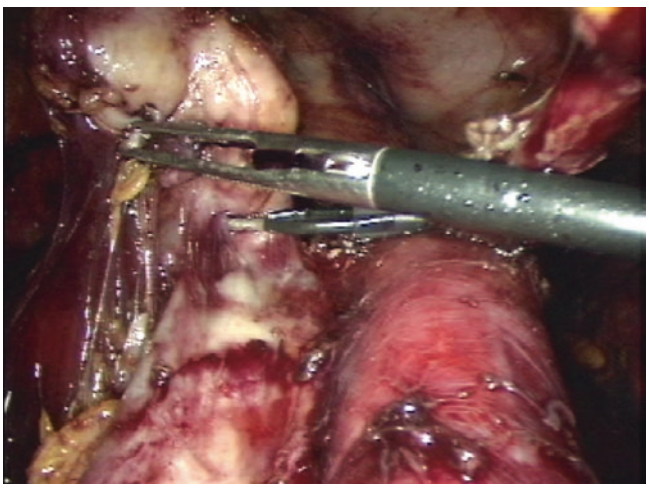

Fig. 54.8 Dissection of metastatic lymphnodes using bipolar forceps

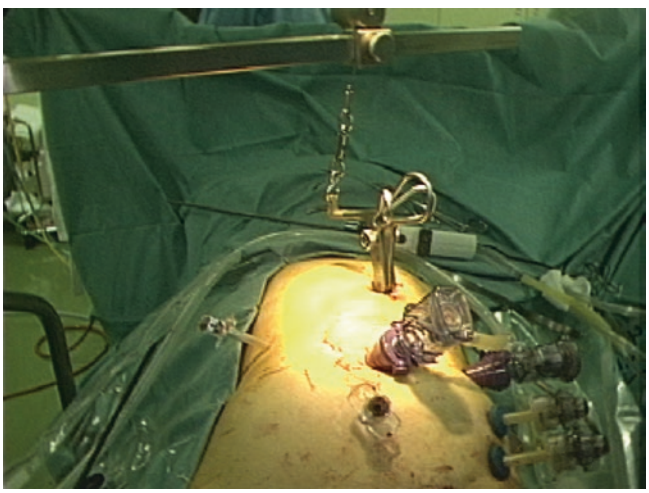

Fig. 54.9 Gasless technique for diaphragma-stripping

As for diaphragma stripping we use gasless laparoscopy at the very end of the entire procedure (Fig. 54.10). The reason for this is to prevent barotraumas like pneumothorax. We infiltrate diluted pitressin between the diaphragma fascia and the diaphragma muscle to create space (Fig. 54.11). Then we use a harmonic scalpel to remove the fascia layer. We do not use electrocautery to avoid the contraction of the diaphragma (Fig. 54.12a–d).

Fig. 54.10 Infiltration of diluted pitressin as aquadissection (diaphragma -stripping)

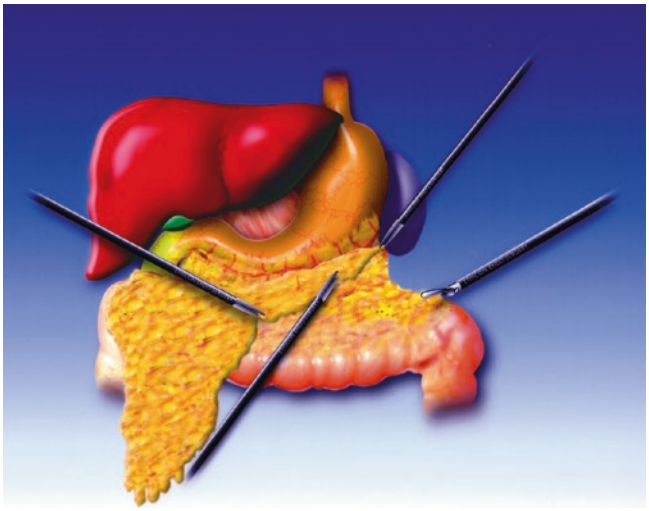

Fig. 54.12 Infragastric omentectomy- the omentum is removed below the gastroepiploic artery

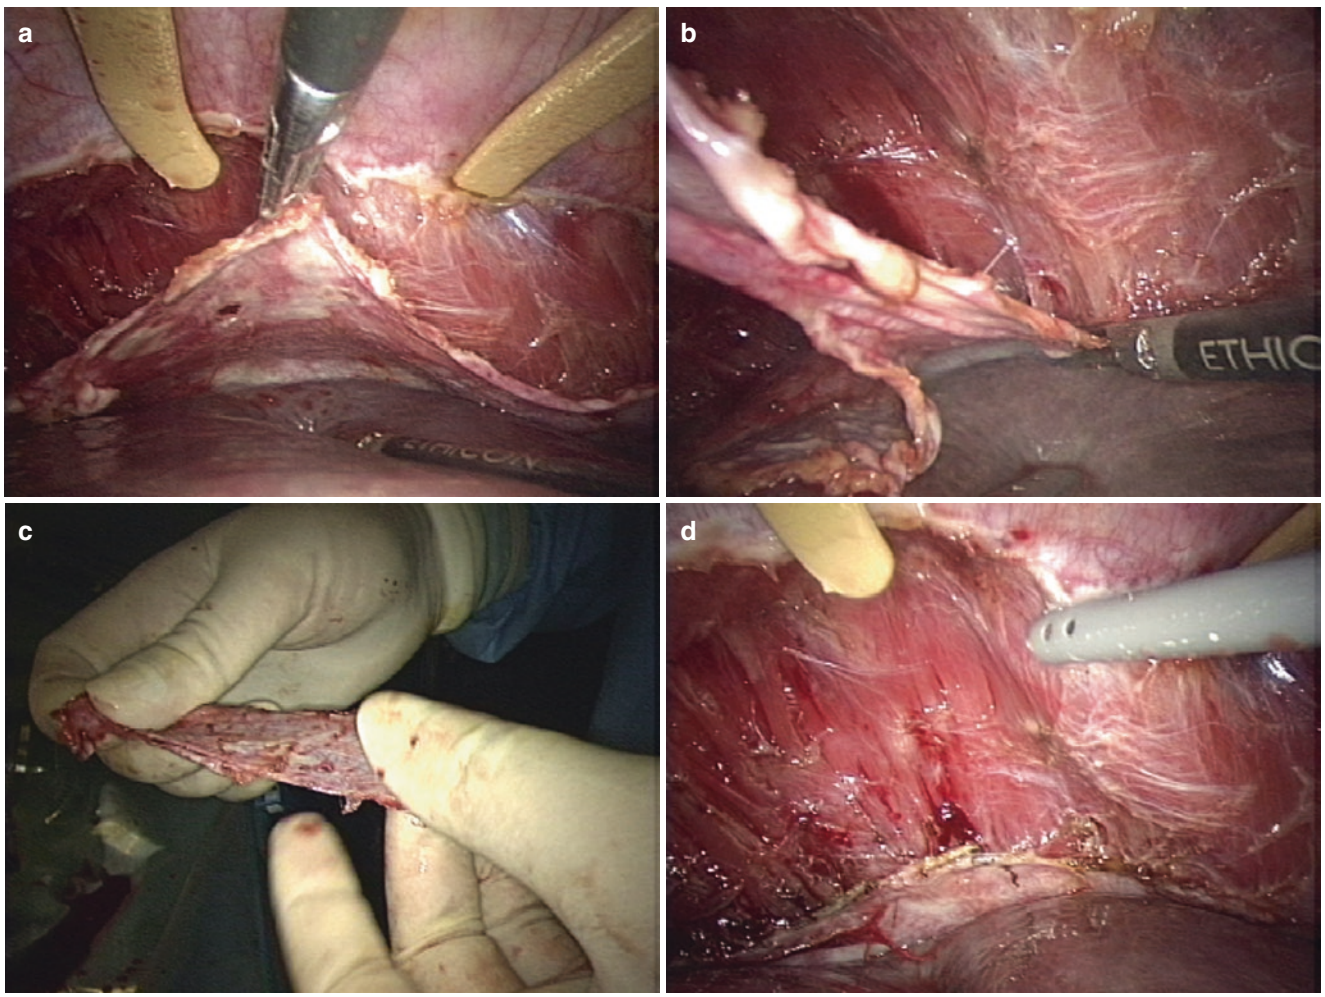

Fig. 54.11 (**a**) Dissection using harmonic scalpel (diaphragma-stripping). (**b**) Removal of dissected diaphragma (diaphragma-stripping). (**c**) Retrieved specimen after diaphragma-stripping. (**d**) Status after diaphragma-stripping

Fig. 54.13 Specimen after omentectomy

The omentectomy we perform is an infragastric omentectomy. The goal of this procedure is to remove as much of the tumor as possible. Initially, we cut the omentum from the transverse colon (Fig. 54.13) and dissect until the upper boundary, just under the gastroepiploic artery, with a harmonic scalpel (Fig. 54.14).

For resection of the bowel, we employ reconstructive techniques. Segmental resection of the bowel requires stapling, using both a linear and circular stapler. For the small bowel, functional end-to-end anastomosis using four linear staples produces the best result (Figs. 54.15 1–14, 54.16, 54.17, and 54.18). After transection of the segment of the small bowel using two 45 mm linear staples, anastomosis of the residual bowel stumps can proceed. The antimesenteric sidewall of both bowel stumps is approximated using a 3-0 stay suture. Each fork of a linear stapler is inserted into each of the orifices of the oral and anal stumps of the small bowel. Firing of the linear stapler results in side-to-side anastomosis. The open cut end of connected bowel stumps is stapled and closed using a 60 mm linear stapler.

For cases with extensive peritoneal implants, we eliminate peritoneal dissemination using an argon beam coagulator (Fig. 54.19). Some cases underwent resection of the pancreas tail and spleen because of metastatic tumors to the splenic hilus. We used a linear stapler to transect the pancreas tail. As a result of performing these additional procedures, we can offer optimal cytoreduction tailored to individual patients.

Results

From June 2000 to date, 21 patients have undergone pelvic peritonectomy with or with out rectal resection combined standard procedure. For some patients, the procedure had to be divided into two operative sessions due to the extensive nature of their disease. All patients underwent a hysterectomy and bilateral adnexectomy and retroperitoneal lymphadenectomy and omentectomy. Some patients also required an appendectomy. Six patients with one stage IIc, (clear cell carcinoma), five IIIc (serous papillary adenocarcinoma) and one IV (papillary adenocarcinoma) underwent he standard procedure plus a pelvic peritonectomy with LAR. Fourteen cases underwent the standard procedure plus a pelvic peritonectomy without LAR. These cases ranged from stage Ia to stage IV, diagnosed with granulose cell carcinoma, clear cell carcinoma, serous papillary adenocarcinoma, papillary adenocarcinoma and mucinous adenocarcinoma.

The average observation period is 87 months (range 16 months to 168 months). Of the patients who underwent rectal resection, two patients are alive with disease, five patients are alive with no evidence of disease. Of the 14 patients who did not undergo rectal resection seven patients are alive with no evidence of disease. Six of these patients have died from disease and we have no data on one patient. No major complications requiring reoperation occurred during the surgical procedures and the post-operative courses of all patients was uneventful and recovery was very quick.

Discussion

Although we cannot draw any definite conclusions for survival advantage in this retrospective analysis as we only have a limited number of cases over a relatively short period, the quality of life of patients who underwent this minimally invasive surgery is obviously better. There are some problems with this minimally invasive approach such as, the occurrence of port site metastasis and the difficulty in mastering the necessary surgical skills. Evaluating the treatment methods for patients with malignancy is difficult when considering the small number of patients with advanced ovarian cancer. We believe that the limit of traditional therapy may have already been reached. In order to achieve a new stage in management and to increase the quality of life of patients, it is necessary to break traditional patterns and attempt a new approach. This was our motivation in applying this technique to ovarian cancer cases.

Laparoscopic surgery, with its minimally invasive advantages, is vital for achieving a more patent friendly approach, even when dealing with diseases like advanced ovarian cancer. Through the kind of extensive debulking techniques described here, optimal cytoreduction can be achieved completely laparoscopically. Laparoscopy allows the possibility of expanding the radicality of surgery to match the needs of patients with advanced and recurrent gynecologic malignancy, without increasing the invasiveness of the surgery itself. Additionally, by also applying reconstructive techniques, it is possible to ensure full resection of all questionable tissue, a necessity for cases with malignant disease. Minimally invasive surgery benefits those who must undergo the most radical procedures and laparoscopy provides the necessary platform for reaching a new stage in malignancy management.

Part IX

Robotic-Assisted Laparoscopic Hysterectomy and Extended Procedures for Benign and Malignant Indications

Indications and Contraindications to Robotic-Assisted Hysterectomy

55

Melissa H. Lippitt, Edward J. Tanner III, and Amanda Nickles Fader

Introduction

Hysterectomy is one of the most common surgical procedures performed during a woman's lifetime. In 1998, there were approximately 540,000 hysterectomies performed in the U.S. This decreased to 430,000 by 2010 [1], due to introduction of more conservative approaches to management of uterine fibroids and abnormal uterine bleeding, the most common indications to hysterectomy. While the overall number of hysterectomies performed in the U.S. and Europe has declined substantially over the past decade, the use of minimally invasive techniques (MIS), including laparoscopic and robot-assisted approaches, has increased. Level I studies have shown the benefit of minimally invasive surgery compared with laparotomy, including improved perioperative outcomes, shorter hospital stays, improved quality of life and faster return to daily functions [2]. With regards to minimally invasive hysterectomy techniques, the first elective hysterectomy utilizing a vaginal approach was performed in Germany in 1801. Almost 200 years later, the first total laparoscopic hysterectomy was performed in 1988 [3], which was followed in 1999 with the first published case of robot-assisted gynecologic surgery [4]. After several iterations were developed by different U.S. companies, in 2005, the da Vinci Surgical System® (Intuitive Surgical, Sunnyvale, CA), was approved by the Food and Drug Administration for use in gynecologic surgery (Figs. 55.1 and 55.2).

Currently, robotic-assisted surgery is performed for both benign and oncologic gynecologic indications (Table 55.1) [5]. Gynecologists may perform a wide variety of robotic-assisted procedures, including hysterectomy, myomectomy, excision of endometriosis, tubal re-anastomosis to restore fertility, sacrocolpopexy, adnexal cyst removal, repair of vesicovaginal fistulas and staging of cervical and endometrial cancers [6–12]. The potential benefits of robotic surgery over conventional laparoscopy include improved depth perception with three dimensional stereoscopic vision, wristed instruments for improved dexterity, tremor canceling software to improve surgical precision, improved range of motion, optimization of ergonomics and autonomy, decreased learning curves and potentially decreased incisional pain [2, 13] (Table 55.2). The limitations of robotic surgery include the lack of haptic feedback, bulky platform, and increased cost compared with laparoscopic platforms and instrumentation.

Indications

Benign Indications

Robotic surgery for benign gynecologic disease is on the rise since the approval of the da Vinci Surgical System® in 2005. A recent study by Wright et al. examined the rate of hysterectomy for benign gynecologic disorders at 441 U.S. hospitals. During 2007 to 2010, robotically assisted hysterectomy rates increased from 0.5 % in 2007 to 9.5 % of all hysterectomies, while laparoscopic hysterectomy rates increased from 24.3 to 30.5 % [14]. Additionally, the authors found that the abdominal hysterectomy rates decreased among hospitals where robotic-assisted hysterectomy was both performed *and* not performed. A contemporary Cochrane review in 2014 concluded, "We are uncertain as to whether robotic assisted surgery (RAS) or conventional laparoscopic surgery (CLS) has lower intraoperative and postoperative complication rates because of the imprecision of the effect and inconsistency among studies when they are used for hys-

Tremor canceling software to improve surgical precision	Lack of direct access to the patient
Improved range of motion	Cost
Optimization of ergonomics and autonomy	
Decreased learning curves	
Decreased incision pain	

terectomy and sacrocolpopexy. Moderate-quality evidence suggests that these procedures take longer with RAS but may be associated with a shorter hospital stay following hysterectomy. Ongoing trials are likely to have an important impact on evidence related to the use of RAS in gynecology [15]." Currently, robotic surgery is used to treat a variety of benign gynecological diseases including large uteri, uterine leiomyomas, endometriosis, severe adhesive disease, cervical dysplasia, benign adnexal masses or cysts, management of pelvic organ prolapse and sacrocolpopexy.

Large Uteri and Leiomyomas

Payne et al. reported the feasibility of robotically assisted hysterectomy in women with large uteri in five community practices. The largest uteri removed in this study weighed 3020 g. The study showed that women with large uteri (uterine weights greater than 250 g) may successfully undergo robotically- assisted hysterectomy with low morbidity, low blood loss, and minimal risk of conversion to laparotomy [16]. A subsequent retrospective review compared outcomes of mini-laparotomy versus robot-assisted laparoscopy for uteri weighing at least 500 g. Unadjusted mean blood loss, rate of hemorrhage, and rate of blood transfusion were all higher with mini-laparotomy than with robot-assisted surgery, while the median postoperative stay was significantly shorter with robotic surgery [17]. Additionally, given the wristed instrumentation of the robotic platform, suturing and knot tying in the repair of myomectomy defects may be technically less challenging to perform with robotic-assistance than with conventional laparoscopy.

Endometriosis and/or Severe Adhesive Disease

In the hands of experienced surgeons, robot-assisted laparoscopic hysterectomy may facilitate hysterectomy for patients with endometriosis and/or severe adhesive disease who may otherwise not have been offered a minimally invasive approach. Advincula et al. published a feasibility study in 2005 and reported on the success of robot-assisted laparoscopic hysterectomy in patients with a scarred or obliterated anterior cul-de-sac [18]. More recently, a retrospective cohort study compared robotic versus laparoscopic approach of hysterectomy in patients with severe pelvic adhesions [19]. Robotic surgery was associated with a shortened operation time and reduced blood loss in patients with severe adhesions compared with laparoscopy. They also reported a lower postoperative pain score in the robotic group as compared to the laparoscopic group.

Pelvic Organ Prolapse – Sacrocolpopexy

The gold standard procedure for the surgical treatment of severe pelvic organ prolapse is open abdominal sacrocolpopexy. An alternative approach to laparotomy includes laparoscopic sacrocolpopexy and more recently robot-assisted laparoscopic sacrocolpopexy. A recent systematic review of conventional laparoscopic sacrocolpopexy versus robot-assisted laparoscopic sacrocolpopexy reported the clinic outcomes (estimated blood loss, intraoperative and postoperative complications) of prolapse surgery are similar, but robotic surgery is less efficient in terms of cost and time [20]. Laparoscopic sacrocolpopexy is technically more challenging because it requires the surgical skills to perform suturing with knot tying and the ability to accurately determine the correct planes for safe dissection of the vesicovaginal and rectovaginal spaces [21]. Robotic technology overcomes some of these limitations, allowing a surgeon who may be uncomfortable with laparoscopy to still be able to offer a minimally invasive approach.

Obese Patients

Obesity represents one of the most common causes of death in the Western hemisphere [22]. The robotic technique can optimize the surgical approach and recovery of obese patients with equally, if not better outcomes, compared to open and/or

laparoscopic techniques. Advantages of the robotic approach include minimal blood loss, low conversion to open rates, no need for drain use and quicker recovery period [23]. Robotic assisted hysterectomy is feasible in patients with all classes of obesity, including super obesity. A patient with a BMI of 98 successfully underwent a robotic-assisted hysterectomy [24].

Malignant Indications

In 2012, the Society for Gynecologic Oncology released their consensus statement on the use of robotic-assisted surgery in gynecologic oncology, stating "Robotic-assisted surgery has had a significant impact on the minimally invasive surgical approach to patients with gynecologic malignancies in the United States [25]." Currently, the robotics platform is used in the treatment of endometrial cancer, cervical cancer, and less commonly for ovarian cancer and resection of recurrent, oligometastatic disease.

Endometrial Cancer

Endometrial cancer is the most common gynecologic cancer in the United States and it has the most common use of the robotic platform [25]. Minimally invasive surgery approach is the accepted standard of care for endometrial cancer surgical staging. Eight randomized controlled trials, including the U.S. Gynecologic Oncology Group LAP2 study in 2009 demonstrated an improvement in surgical outcomes for patients undergoing laparoscopy for endometrial cancer staging when compared with those operated on by laparotomy [26–28]. While more data is needed to compare robotic surgery directly to laparoscopy, the adoption of the robotic platform has led to an increase in the total number of patients who were offered minimally invasive surgery [27, 29, 30].

In 2011 Paley et al. published a large, prospective, non-randomized study of 377 consecutive robotic surgical staging procedures for endometrial cancer compared with 121 staging procedures performed by laparotomy for the same indication. Overall, serious complications, such as wound dehiscence, bleeding, and urologic injury were found to be three times more likely in the laparotomy group. However, this study did not include a laparoscopy arm for direct comparison. Gaia et al. [28] published a systematic review of 1591 patients, from eight studies, undergoing robotic-assisted surgeries compared with traditional laparoscopic or laparotomy techniques for the treatment of endometrial cancer. The study found that the estimated blood loss was reduced in robotic hysterectomy compared with laparotomy ($P < 0.005$) and laparoscopy ($P=0.001$), length of stay was shorter for both robotic and laparoscopic cases compared with laparotomy ($P < 0.01$) and operative time for robotic hysterectomy was similar to laparoscopic cases but was greater than laparotomy ($P <0.005$). Conversion to laparotomy was more than double in the laparoscopy group (4.6 % vs. 9.9 %), but this was not statistically significant ($P = 0.06$). The mean number of lymph nodes and perioperative complication rates, which included gastrointestinal injury, urologic injury, and vaginal cuff dehiscence, were the same in the three study arms.

Sentinel lymph node mapping for endometrial cancer at that time of hysterectomy and staging results in reliable mapping of relevant lymph nodes that drain the uterus (Fig. 55.3). Advantages of SLN mapping including reduction of lymphedema and intraoperative complications and improved detection of positive lymph nodes with ultrastaging techniques. Sinno et al. published a study in 2014 comparing colorimetric versus flurometric sentinel lymph node mapping during robotic surgery for endometrial cancer, suggesting that fluorescence imaging with indocyanine green may be superior to colorimetric imaging with isosulfan blue in women undergoing sentinel node mapping for endometrial cancer. Currently, the robotic platform remains the most feasible method for performing accurate sentinel lymph node mapping [31–33].

Cervical Cancer

The standard of care for a patient with early cervical cancer (FIGO stage IA2 – IIA) is a radical hysterectomy, with 5-year overall survival rates of 62–90 % [34]. The intricacies of radical hysterectomy, which include a sophisticated

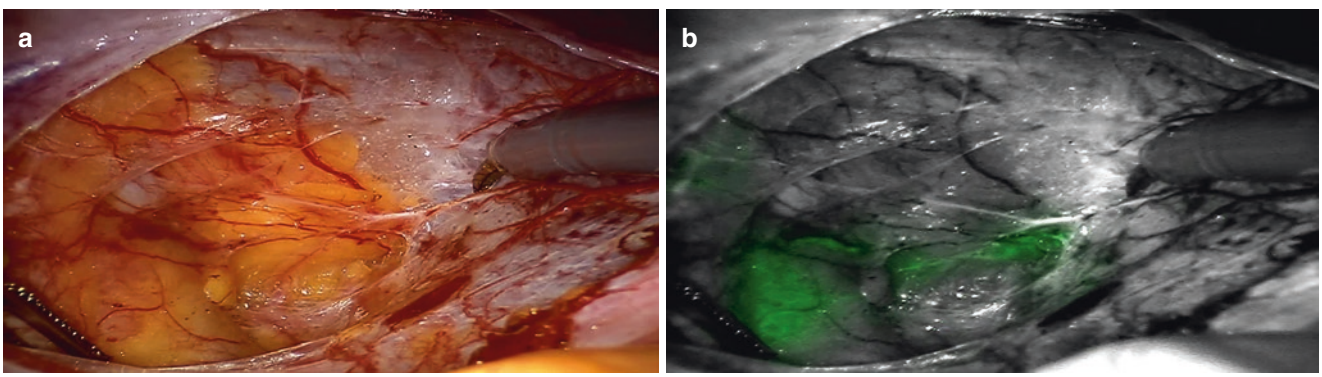

Fig. 55.3 Sentinel node mapping with indocyanine green: (**a**) without fluorescence, (**b**) addition of firefly fluorescence

dissection of the parametria, unroofing of the ureter from the ureteric canal within the cardinal ligament, and an en block resection of the uterus, cervix, parametria, and uterosacral ligaments, make it an ideal procedure to perform on the robotic platform, especially as only a small number of surgeons adopted the laparoscopic technique for this complex procedure [2]. Multiple studies have assessed the feasibility and safety of robotic-assisted radical hysterectomy (RRH) [35–38]. Boggess et al. [35] showed RRRH versus radical abdominal hysterectomy (RAH) to be associated with reduced operating room time, estimated blood loss, and length of surgery as compared to radical abdominal hysterectomy; Magrina et al. [38] showed improved outcomes for RRH vs total laparoscopic radical hysterectomy and RAH; Cantrell et al. [36] showed similar progression free survival and overall survival compared to RAH. One study, Soliman et al. [13] showed overall decreased intravenous opioid administration compared with the total laparoscopic radical hysterctomy (TLRH).

The robotic platform is also quite useful for radical trachelectomy in select patients with early-stage cervical cancer desiring fertility preservation [39]. Radical trachelectomy is a complex procedure, and the superior optics and wristed hand motions offered by the robotic platform compared with conventional laparoscopy are particularly attractive in this setting [2].

Ovarian Cancer

Comprehensive surgical staging in ovarian cancer requires exploration of the entire peritoneal cavity, from the diaphragm to the pelvic floor. The new fourth generation system allows multi-quadrant surgery without needing to undock and rotate patients. More research is needed to determine whether initial ovarian cancer debulking surgery will become a common use of robotic-assisted surgery in the future. Data suggests that robotic surgery is feasible for early stage ovarian cancer staging and select patients with recurrent ovarian cancer, in the absence of carcinomatosis, may be candidates for secondary surgical cytoreduction via a robotic approach [40, 41].

Contraindications

The only absolute contraindication to robotic hysterectomy is an anesthetic contraindication to pneumoperitoneum. Relative contraindications would include need for laparotomy to control bleeding, advanced malignancy and poor visualization or exposure, which may occur in a patient who has undergone multiple abdominal surgeries and has extensive adhesive disease. Additionally, in order to ensure a safe working environment, it is essential for the surgeon, bedside assistant and scrub technicians to be well versed and comfortable using the robotic surgical platform.

Additional Considerations

Single Site Robotic Assisted Hysterectomy

Laparoendoscopic single-site surgery may offer advantages versus conventional laparoscopy, including fewer operative complications related to trocar insertion, a cosmetically more pleasing incision, and a larger surface area for specimen retrieval in the post-power morcellator era [42, 43]. One of the first robotic assisted laparoendoscopic single-site surgeries was described by Escboar et al. in 2009, in which a hysterectomy was performed for a BRCA mutation carrier [44]. In this initial case report, a GelPort along with standard robotic trocars and standard robotic instruments were used. Today, Intuitive Surgical has developed a single-site apparatus that can be used with the Si da Vinci Surgical System. It utilizes novel robotic instruments with curved instrument cannulae and semi-rigid instruments, thereby optimizing the single site robotic-assisted hysterectomy (Fig. 55.4). Scheib et al. [45] presented one of the first series of robotic laparoendoscopic single-site surgery in 40 patients for the treatment of various gynecological conditions. A case report in 2015 reported the feasibility of sentinel lymph node biopsy and hysterectomy utilizing the single incision robotic surgery platform [46]. Further studies are needed to better define the ideal benign and malignant gynecological conditions for this new technology.

Cost Considerations

A controversy with robotic surgery remains the high cost associated with performance of the procedure. Proponents of robotic surgery have suggested that the technology can be made more cost-effective, especially as the learning curve improves and shorter operating times are optimized [2]. A large portion of the cost includes the initial purchase cost of

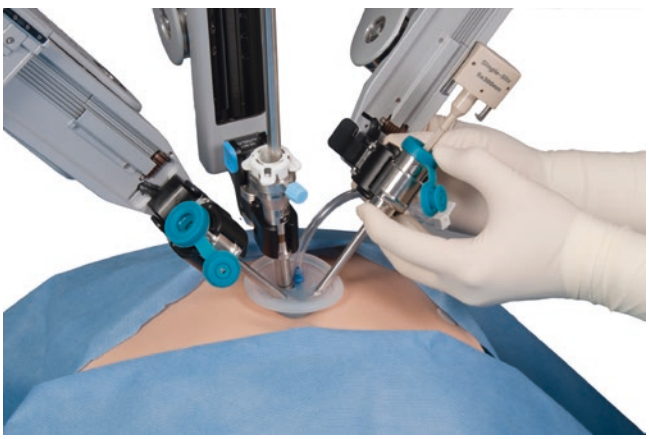

Fig. 55.4 da Vinci single-siteTM instrumentation for the da Vinci Si system (©2016 Intuitive Surgical, Inc Used with permission)

the robot as well as routine maintenance. In 2014, Wright et al. [47] performed an economic analysis to examine the influence of procedure volume, variation in hospital accounting methodology and use of various analytic methodologies on cost of robotically assisted hysterectomy for benign gynecologic disease and endometrial cancer. The authors concluded that the cost of robotic gynecologic surgery decreases with increasing procedure volume. However, in all of their scenarios, robotically assisted hysterectomy remained substantially higher in cost than laparoscopic hysterectomy. For surgeons who performed more than 50 procedures, robotic hysterectomy for benign indications cost $924 more than laparoscopic hysterectomy, and was $688 more for endometrial cancer. Compared to laparotomy, minimally invasive surgery has additional economic benefits including decreased complication rates leading to societal and indirect economic benefits of an earlier return to work [48]. While robotic surgery may remain more costly than laparoscopic surgery, the introduction of robotic surgery has led to an overall decline in the rate of open abdominal hysterectomy [14], and thereby decreasing the overall societal cost of hysterectomies. We expect to see the costs of robotic surgery continue to decrease as other technologies are introduced to the marketplace.

Conclusion

Minimally invasive surgery, including vaginal, laparoscopic and robotic approaches, should be the standard of care for hysterectomy when feasible. Many studies support the feasibility of robotic surgery for benign and malignant gynecologic indications. As robotic surgery continues to gain more popularity, we expect to see more studies exploring the benefits of the robot for benign and malignant gynecologic indications. Ideally, we will see a future with continued increases in the rates of minimally invasive surgery and therefore improved patient outcome.

Preparation of Robotic-Assisted Laparoscopic Hysterectomy

56

Martin Heubner

Planning robotic hysterectomy, special conditions and requirements have to be taken into account. The positioning of the patient is a crucial aspect regarding safety as steep Trendelenburg position, which is associated with special risks, is mandatory. The set-up of the robotic device, including draping and positioning of the patient cart again are issues concerning the technical functionality of the robotic system. Even more than other operative techniques, robotic surgery has to be regarded a team task in which communication and interaction between surgeons, nurses and anesthesiologists is mandatory to achieve good results.

History of the Patient

Noteworthy aspects of history taking involve precedent surgical procedures and preexisting comorbidities. It is important to recognize that patient positioning in robotic surgery is substantial for good results and is –in contrast to classic laparoscopy- not alterable during the operation.

Previous operations, especially abdominal operations should be recognized in order to estimate the extent and the location of adhesions, which is especially important considering the placement of the camera trocar. Open laparoscopy might be an option if extensive adhesions are suspected in the mid-abdomen. Heart, lung and cerebral diseases might be important considering the ability of steep Trendelenburg positioning of the patient.

Especially patients with obesity can benefit from the use of robotic surgery as it might avoid laparotomy with subsequent complications and intraoperative problems. There is no upper limit with respect to the patients' BMI. However, the prospects of anaesthesiological ventilation can be impaired to high ventilation pressure, especially in Trendelenburg position of the patient [1]. A useful indicator is whether the patient is able to sleep in a flat position without heightening of the upper part of the body. Special instrument, especially extra-long trocars should be held available for obese patients.

Important preexisting illnesses comprise heart diseases, especially higher grade heart valve failures or pulmonary hypertension, pulmonary illnesses such as chronic obstructive lung disease and vessel problems such as cerebral aneurysms. Orthopedic musculoskeletal problems are also important to recognize. All these and further yet unmentioned aspects may result in impaired options of patient positioning and require conference with the anaesthesiological team. Allergies are of importance as perioperative antibiotics are usually applied during surgery.

Informed Consent of the Patient

The preoperative information of the patient should cover all common complications and risks of other techniques of hysterectomy. Still, some special aspects should be considered. Steep Trendelenburg position requires special handling and can result in special complications such as ventilation problems, extremely rare ophthalmologic problems (corneal abrasion, ischemic optic neuropathy, visual loss) and postoperative orthopedic problems (e.g. shoulder problems or distension of the brachial plexus if shoulder pads are used). It is noteworthy that some authors report a higher rate of vaginal cuff dehiscence after robotic surgery; hence, this should be mentioned. As the size of the trocars regularly exceeds 7 mm, port-site hernias are also of importance.

Operative Set-Up

Patient positioning has to be carried out with great caution. Trendelenburg position of at least 30° is mandatory to assure adequate access to the pelvis. To prevent the patient from

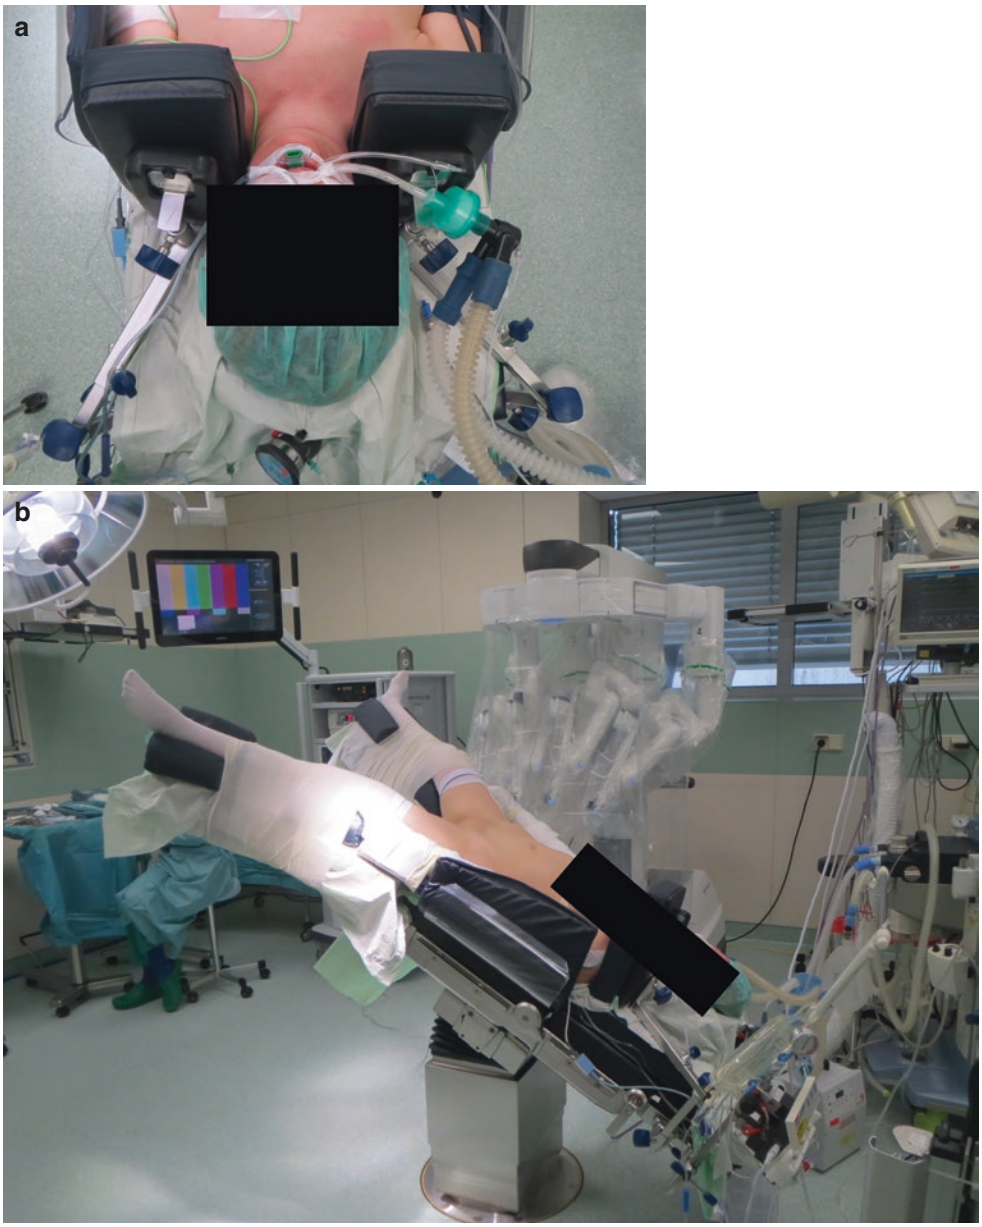

Fig. 56.1 Shoulder pads can be used to provide the patient from sliding (**a**), allowing steep Trendelenburg position (**b**)

sliding off the operating table, different technical options are available. Fixated shoulder pads, vacuum mattresses or boot-type leg holders are devices which might be useful, the preference is certainly individual (Fig. 56.1). The resulting forces acting upon the respective body parts in Trendelenburg position must not be underestimated. Positioning should be controlled before disinfection and during the operation and is a team task demanding involvement of surgeons, anesthesiologists and nurses. A skilled and experienced team is the major key to avoid complications and docking problems.

Docking should be carried out according to the manufacturers' instructions. The technique differs between different types of robotic systems. However, it is important to recognize that a professional docking is one of the most important aspects for a successful operation. Mistakes in the docking procedure occur frequently in the introduction phase of a robotic system and can grossly impair handling of the instruments during surgery. The position of the arms has to be considered not only in the start position but also extrapolated to future potential movements which again depend on the planned operating field. In this regard, it has to be ensured that moving robotic arms will not impair the patient, members of the OR-team or OR-equipment. This aspect appears self-evident. However, a surgeon beginning with robotic surgery technique faces a completely new situation: not being physically present at the operating table with no haptic or optical feedback apart from the direct operating field inside the abdomen. Thus, the permanent critical surveillance by assistants and immediate feedback to the console surgeon is crucial.

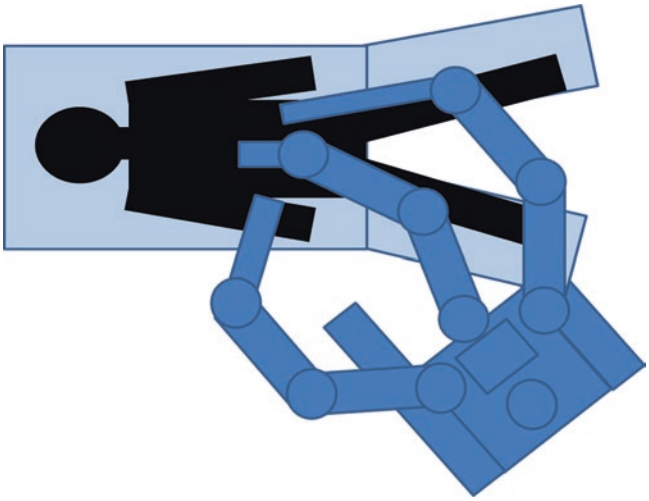

Fig. 56.2 Schematic sketch of side docking approaching over the right hip of the patient

There are different ways of approaching the patient with the patient cart. Placing the patient cart between the patients' legs usually makes the docking procedure easy as the resulting symmetrical geometry gives maximum space between the robotic arms. However, the prospects of vaginal manipulation are impaired by this method. **Side docking** in a 30° angle, usually approaching from caudally over the right hip of the patient, is a feasible method allowing access for vaginal manipulation and docking of the robotic arms without interference (this applies to the da Vinci® Si system or lower; see Fig. 56.2).

The type of docking also depends on the model of robotic device that is used. It is recommended that representatives of the accordant company and/or skilled physicians with experience on the respective device attend the first operations to give advice.

General Aspects: Introduction of Robotic Surgery as a Team Task

Introducing robotic surgery, it is certainly beneficial if the whole OR team including surgeons and anesthesiologists attend the first attempts of patient positioning, disinfection, draping and docking, as perspectives may differ within the team. E.g., potential movement dysfunctions of the robotic arms caused by wrong draping may be better foreseen by the surgeon while potential impairments of sterility aspects are often better estimated by the OR nurses. Patient positioning again has to offer good access to the surgical field for the surgeon and access to the patient for the anesthesiologist and has to ensure the patients' safety. In general, experience shows that it is helpful if the whole team is familiar with all aspects of the setup. This allows quick development of know-how and efficacy and helps to avoid demotivation throughout the whole staff.

Disinfection and draping should be carried out according to the standards of the surgical unit. It should be kept in mind that a switch to open surgery might become necessary and this should therefore be considered. Draping of the robot-arms and their handling under aspects of sterility is a complicated procedure requiring training and experience. It is important to consider the necessary free moving space of the robotic arm, tension should strictly be avoided. Wrong draping can result in functional errors of the robotic arms. The OR team should undergo several training sessions before conducting the first operation on a patient.

Although emergency transition to open surgery is very rare, draping should be conducted in a manner also allowing open access to the abdomen without necessity of additional draping/undraping or disinfection.

The perioperative application of a single-shot antibiotic prophylaxis should be carried out 30 min before surgery. A combination of ampicillin/sulbactam is feasible. Alternatively, e.g. in case of allergy to penicillin and its derivates, clindamycin can be administered. A prolonged treatment with antibiotics beyond the time of surgery cannot be recommended.

Instruments, Apparatuses and Uterine Manipulators for Hysterectomy with Special Focus on Robotic-Assisted Laparoscopic Hysterectomy

57

Mona E. Orady

Introduction

Hysterectomy is the surgical removal of the uterus. It may also involve removal of the cervix, ovaries, fallopian tubes and other surrounding structures [1]. Hysterectomy is the most common procedure performed for gynecological disorders. Overall hysterectomy rates vary from 1.2 to 4.8 per 1000 [2]. Removal of the uterus renders the patient unable to bear children (as does removal of the ovaries and fallopian tubes) and has surgical risks as well as long-term effects, hence surgery is only recommended when other treatment options are not available or have failed. It is expected that the frequency of hysterectomies for non-malignant indications will decrease as there are good alternatives in many cases [3]. However, hysterectomy will remain as the definitive treatment of uterine pathology. Uterine myomas are the most frequent indication for abdominal hysterectomy, accounting for 40 % of all hysterectomies, with other indications including endometriosis (12.8 %), malignancy (12.6 %), abnormal uterine bleeding (9.5 %), pelvic inflammatory disease (3.7 %) and uterine prolapse (3.0 %). Utero-vaginal prolapse is the indication for 44 % of all vaginal hysterectomies. In recent years, non – descent vaginal hysterectomy (NDVH) is being tried for most benign conditions and uteri of up to 12 weeks gestational size or more can be safely removed intact vaginally [2]. However, large leiomyomas, severe pelvic inflammatory disease, malignancy (invasive cervical cancer, endometrial carcinoma, ovarian and fallopian tube cancer, and gestational trophoblastic tumors) and most suspicious adnexal masses are still often approached via laparotomy [2].

The introduction and rapid advancement of laparoscopy has allowed for the development of alternative minimally invasive approaches to hysterectomy thus avoiding the morbidity associated with an abdominal hysterectomy when the vaginal approach is not feasible [4, 5]. Initially utilized in laparoscopic assisted vaginal hysterectomy, the laparoscope allowed the treatment of adnexal pathology or endometriosis and assistance in the release of the uterine structures and bladder flap from above, facilitating the vaginal approach in more complex cases. As tools and techniques advanced, a greater proportion of the hysterectomy procedure was undertaken using the laparoscopic approach leading to the first total laparoscopic hysterectomy successfully completed via laparoscopy in 1989 [4].

Following this, the development of tools that facilitated dissection, vessel sealing and suturing were developed in order to simplify and improve the procedure. The advantages of the minimally invasive approach for the patient included reduced pain, hospital stay, blood loss, and a much shorter recovery as compared to abdominal hysterectomy [5, 6]. This led to the desire to utilize this approach even in complex hysterectomy procedures, obese patients, and cancer surgeries. This motivated surgeons and the industry as whole to push the limits of the surgery, and to develop and explore other laparoscopic approaches such as single port surgery, mini-laparoscopy, natural orifice surgical procedures (NOTES) and combinations of the above, to see if the procedure could be accomplished with even less scarring, pain, and time required for recovery [7].

The most advanced and expensive tool used to date for the performance of minimally invasive hysterectomy procedure is the daVinci™ surgical robot (Fig. 57.1). After receiving FDA approval for use in gynecology in 2005, the frequency of daVinci robotic assisted total laparoscopic hysterectomy has exponentially increased [8, 9]. It offers all the benefits of the laparoscopic approach, but affords the surgeon improved vision utilizing a three dimensional magnified high definition camera and scope as well as superior control over articulating instruments with 7° of freedom. These features enable the surgeon to accomplish more difficult procedures by making it easier to work in areas deep within the pelvis or work around large fibroids which would otherwise restrict the

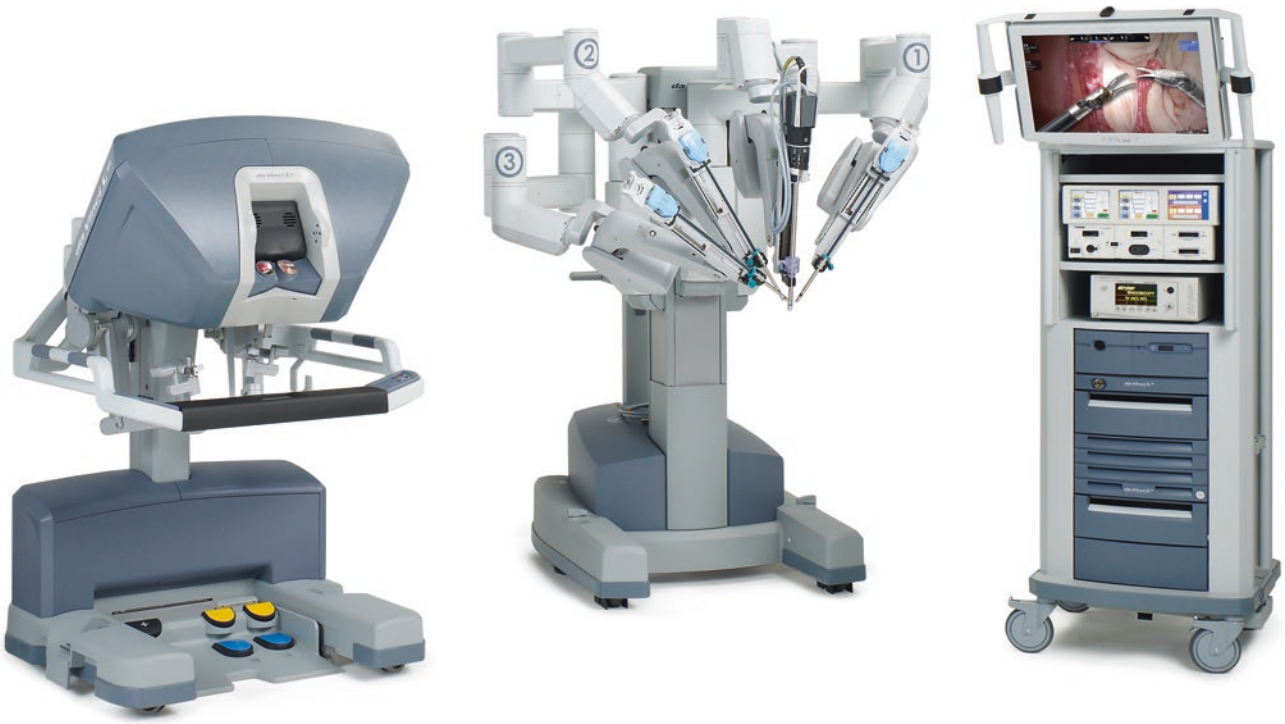

Fig. 57.1 The DaVinci surgical system TM is comprised of three components. The Vision Tower, Robotic Patient-side cart and the Surgeon Control Console. The tower contains light and energy sources as well as the vision monitor. The robot consists of the arms which attach to the robotic trochar cannulas, the robotic instruments, and the robotic camera, which pass through the robotic trocars, providing surgeon with direct intuitive control of the instruments, camera, and energy from the surgeon console. Some systems come with two consoles (Dual Console) which allow the surgeon to train a resident, fellow, or colleague giving the instructing surgeon the ability to take over control at any time, telestrate, or direct the learning real time during a case

Table 57.1 Comparison between traditional laparoscopy and robotic assisted laproscopy

	Traditional laparoscopy	Robotic assisted laparoscopy
Number of ports	3–5 ports	Tends to average one more than laparoscopy
Size of ports	Three 5 mm and one 10 mm on average	Three to Four 8 mm and one 5–12 mm on Average
Vision	2-D vision although some 3-D Scopes are becoming available	3-D HD 10 X vision Autofocus and Auto white balance available on newer models
Control of instruments	Camera and opposing instruments controlled by assistant but instruments easily interchangeable between ports	Camera and Opposing instruments controlled by surgeon but assistance must do all instrument exchanges and troubleshooting
Precision of movement	Straight instruments with fulcrum effect	Wristed instruments with 7° of movement
Ability to scale movements	Direct control	Console allows surgeon to allow scaling to 1:1, 3:1, or 5:1 ratio of hand movement to instrument movement to allow for fine motor control
Energy devices available	All ultrasonic and Advanced energy devices compatible with instrument ports	Only traditional monopolar and bipolar devices, as well as a single vessel sealing device and a PK dissector utilizing PK energy are available. Harmonic device lacks wristing
Tremor	Amplified by fulcrum effect	Filtered by console programming

movement and reach of conventional laparoscopic instruments [10, 11]. Table 57.1 provides a comparison of robotic assisted versus conventional laparoscopy for hysterectomy. This chapter will review the different tools that are utilized in hysterectomy procedures and the optimal tool selection methods appropriate for each individual procedure method.

Instruments for Access and Exposure

The most important aspects of surgery are access and exposure. Without access to and exposure of the relevant anatomy, the procedure cannot be performed. The three main approaches to hysterectomy require different vantage points

of access in order to achieve the appropriate exposure. More often than not, the perceived inability to achieve the required access and exposure of the anatomy in question via one approach is what leads a surgeon to selecting one modality over another.

Abdominal Hysterectomy

For abdominal hysterectomy, access is achieved directly through the abdominal wall, either through a transverse or vertical incision. The transverse Pfanennstiel incision is the most common in benign procedures while the midline vertical incision is more favored in oncologic procedures (Fig. 57.2). Vertical Incisions can be extended to accommodate larger or more complex pathology or allow access to para-aortic lymph nodes by extending it above the umbilicus. In turn, using a Maylard or Churney incision allows for increased exposure through a transverse incision, which is often preferred due to decreased pain, risk of hernia, and improved cosmesis [12].

Once the incision is made, the choice of retractor will aid in attaining the appropriate exposure. The most commonly used retractor in benign abdominal hysterectomy is the Balfour retractor which comes with wrenched side blades, an attachable bladder blade and an optional upper blade. For more complicated or larger pathology, the Bookwalter retractor allows attachment of multiple retractor blades of multiple sizes and configurations to a metal ring which is placed floating above the incision attached to a metal arm fastened to the operating table. More recently, disposable plastic double ring wound retractors such as the Alexis wound retractor can be useful in thicker abdominal walls providing retraction of skin, subcutaneous fat, muscle, fascia and peritoneum within a plastic sheath, thus providing maximal retraction and exposure with an even distribution of pressure. This can be useful for performance of a hysterectomy in obese patients, in whom obtaining exposure is often challenging [12] (Fig. 57.3).

Vaginal Hysterectomy

Vaginal exposure for vaginal hysterectomy yields its own challenges. Generally, the best candidates for vaginal hysterectomy are multiparous patients with some degree of uterine descensus and adequate room in the vagina to obtain exposure of the cervix. Most gynecologists will use vaginal sidewall retractors as well as a long posterior retractor in order to obtain exposure and protect the rectum such as a weighted Steiner retractor with a long lip that will reach the posterior vaginal cuff to retract it inferiorly. Anteriorly, either a long bladed Deaver or Right angle retractor can be used to protect and retract the bladder superiorly. Briesky or Jackson vaginal retractors can also be used to retract laterally as needed. The labia may be retracted using a suture or a Lonestar retractor

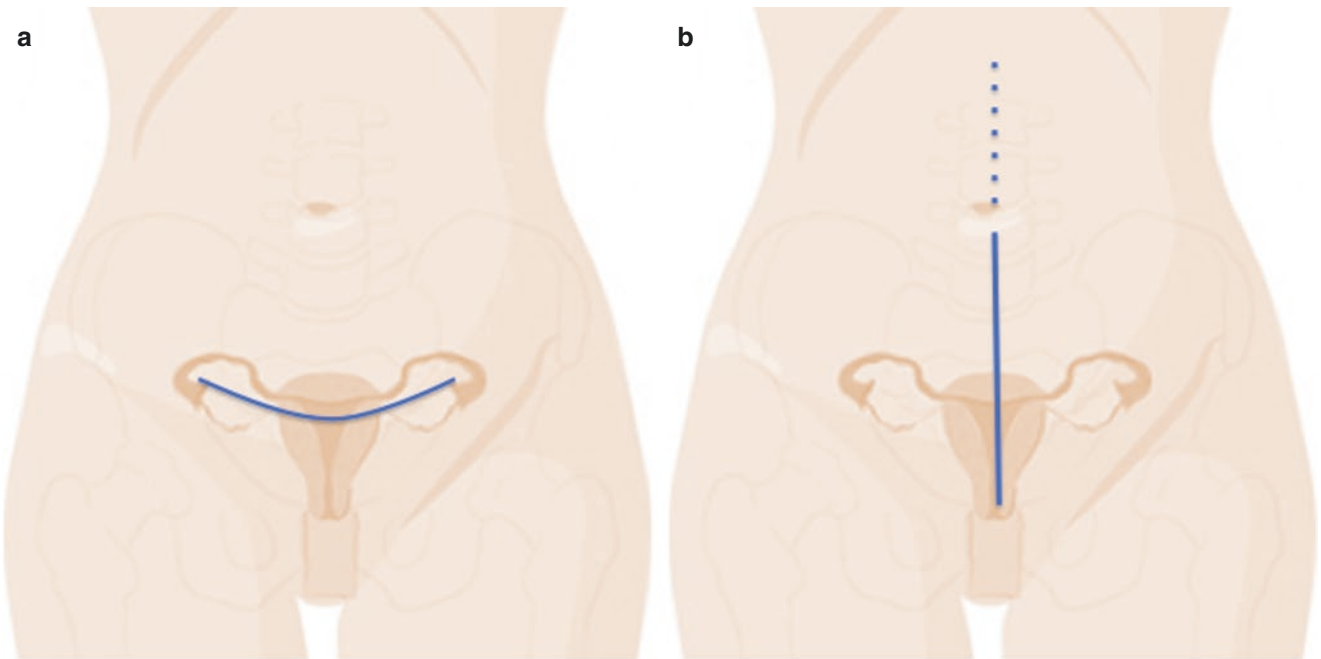

Fig. 57.2 Abdominal hysterectomy incisions: (**a**) Transverse Incision includes the options of a Pfanennstiel incision, Maylard Incision, or Cherney Incisions, depending on whether rectus muscles are separated, cut, or detached from insertion on the pubis. (**b**) Vertical incisions can remain below umbilicus or be extended above as needed and thus provide the opportunity to extend the incision in order to increase visualization, and are thus the most versatile. However, they cause more pain, worse cosmesis, and a greater risk for hernia than transverse incisions

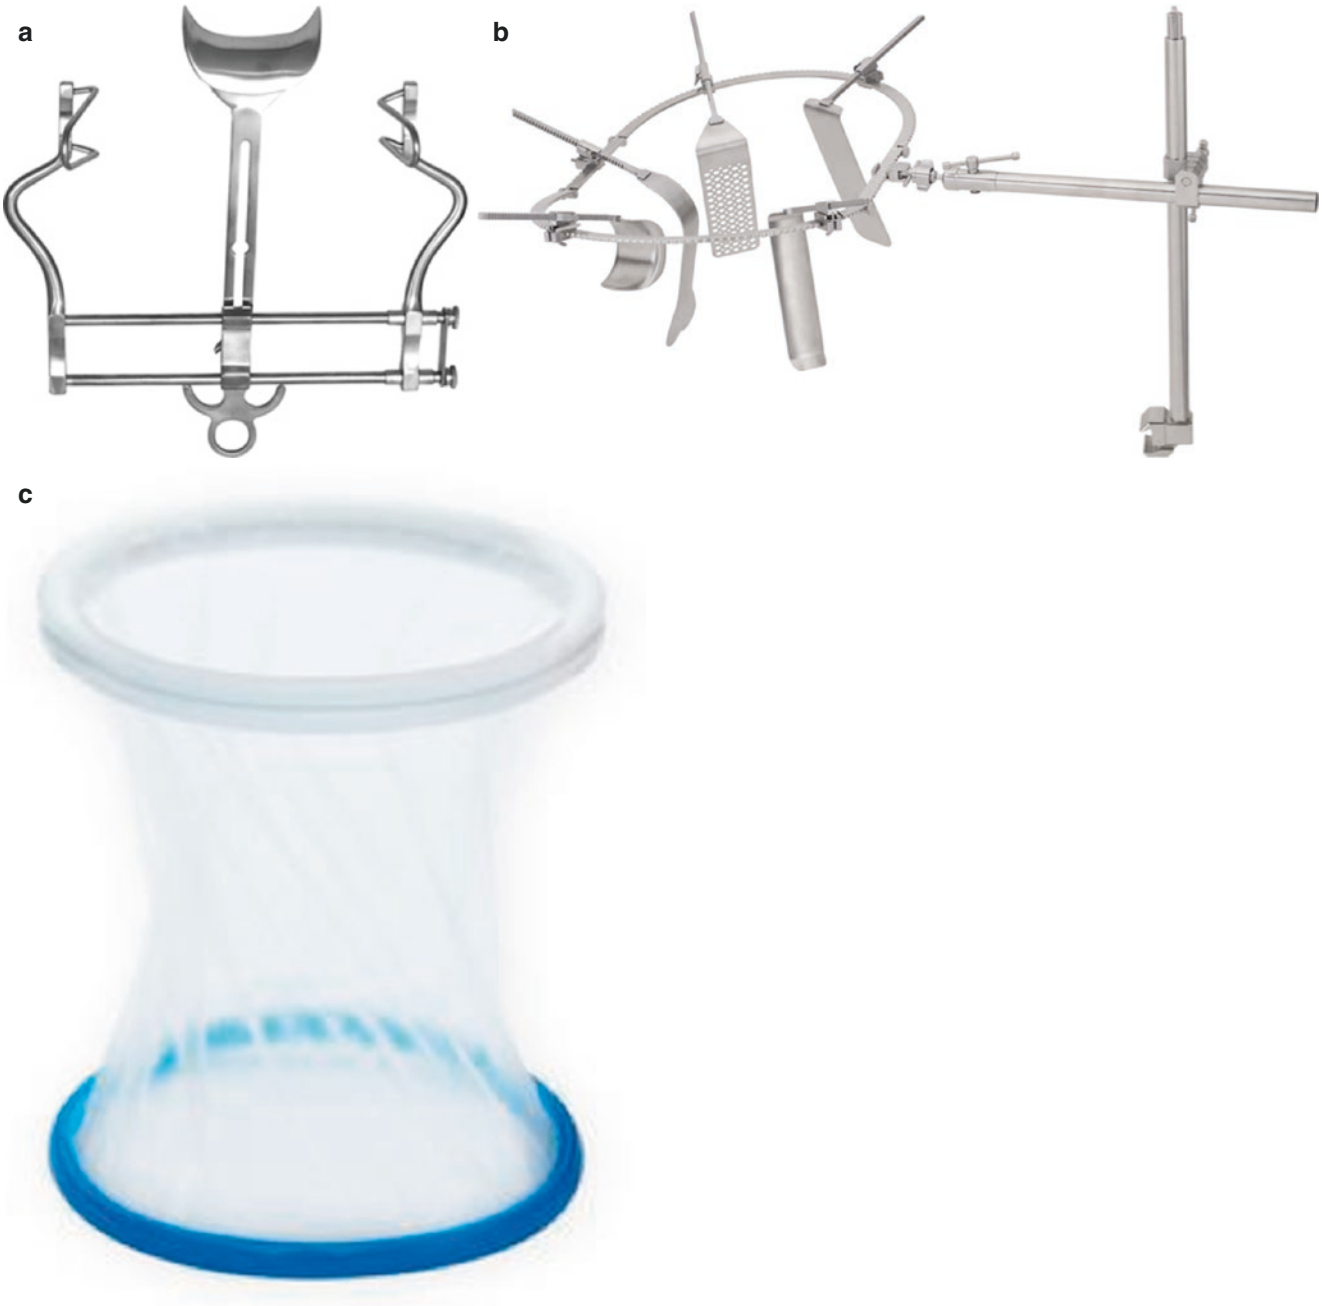

Fig. 57.3 Retractors for abdominal hysterectomy. (**a**) Balfour Retractor provides side wall retraction as well as a bladder blade for retraction of the bladder. (**b**) Bookwalter Retractor is the most versatile and can retract in all directions with many options for blades. It can thus be adjusted to the anatomy more easily. (**c**) Alexis Wound Retractor is useful for thick abdominal walls when limited visualization is needed or if an incision is meant to be kept small as in a mini-laparotomy. It provides 360° of retraction in all directions but is disposable and thus is just for single use

which consists of a plastic ring with hooks that grasp the labial folds or vaginal muciosa in order to obtain retraction at the introitus. A Bookwalter type of retractor (Bookwalter® Magrina II Retractor System) has also been developed for use in vaginal hysterectomy and is very useful to obtain stable, controlled retraction for efficient performance of a vaginal hysterectomy [13] (Fig. 57.4).

Laparoscopic Hysterectomy

For all the laparoscopic approaches to hysterectomy, including single port, mini-laparoscopy and robotic assisted laparoscopy, retraction is provided by insufflation of the peritoneal cavity, which creates space to work within the abdominal cavity without directly opening the abdominal wall. The Trendelenburg position then provides gravity

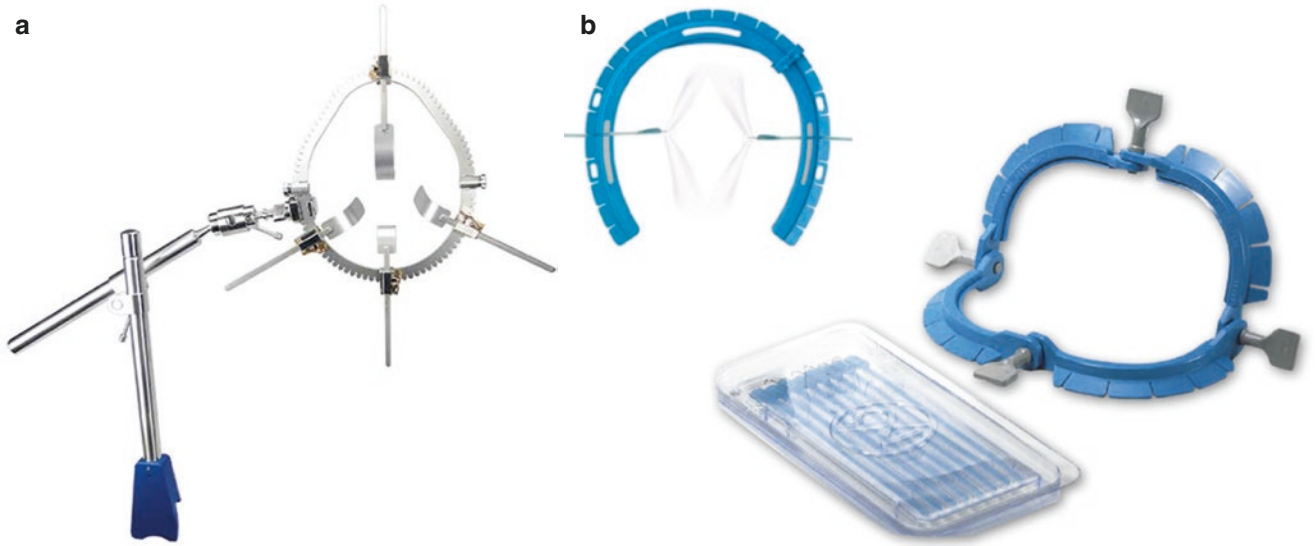

Fig. 57.4 Retractors for vaginal hysterectomy. (**a**) Bookwalter Magrina II Retractor System is similar to the abdominal bookwalter retractor but was developed specifically for vaginal hysterectomy providing adjustable blades in order to maximize visualization into the vagina. (**b**) Lonestar Vulvar Retractor is useful to enhance visualization during vaginal hysterectomy by using adjustable minimally traumatic hooks to retract away labia allowing easier access to the vagina

assisted retraction of the bowel while the uterine manipulator elevates the uterus allowing visualization and access to the uterus and surrounding structures for the performance of the hysterectomy. Passages through the abdominal wall then allow a camera to obtain visualization and instruments to be placed through the abdominal wall in order to perform the surgical procedure. Thus, the key is obtaining access to the intraperitoneal space, then placement of trochars through the abdominal wall, followed by utilizing an appropriate camera to provide visualization and an appropriate vaginal manipulator to provide manipulation and exposure of the vascular pedicles for the performance of the hysterectomy procedure [14].

None of the laparoscopic methods of hysterectomy differ on these two points but only differ on the size, number and location of the passages through the abdominal wall and the specific instruments used through these passages in order to perform the procedure. Thus, the advantages of each relate to the instruments used for the procedure since ultimately the end result of a hysterectomy is accomplished in a similar manner of isolating and sealing ovarian and uterine pedicles, transecting the uterus, removal of the specimen, and then closing the vaginal cuff if needed. All methods share the benefit of minimally access surgery for the patient including small scars and a fast recovery. The advantage of the robotic instrument relates to its precision, enhanced vision, and greater control, which allows more complex or difficult hysterectomies to be accomplished in a safe and efficient manner. Thus, patients who are morbidly obese, have extensive adhesions resulting from multiple prior surgeries or endometriosis, or have very large or obstructing fibroids may benefit from the surgeon choosing this instrument. For relatively straightforward hysterectomies in which the best cosmetic result is desired, either the vaginal, or mini-laparoscopic approach should be considered. If patients desire only a single incision then either single port laparoscopy or single port robotic assisted laparoscopic approach may be considered. Standard laparoscopy however remains the most utilized approach as all the other approaches are modifications of this approach and are highly dependent on the availability of specific instruments that facilitate the other approaches.

Initial Entry Techniques

Three forms of access or initial entry exist in Laparoscopy. Open (Hassan) technique, Veress Needle technique, and Direct entry. In the Open technique a disposable or re-usable trochar is placed directly into the peritoneal cavity after a small incision is made using retractors and a scalpel. The incision is then carried through the fascia and peritoneum. The Hassan cannula is then secured using sutures placed at the angles of the fascia and tied to the Hassan cannula. This technique can be useful if there is suspicion for severe adhesions or risk of adherence of bowel to the anterior abdominal wall. This method of entry is the method utilized in single port laparoscopy only a larger 1.5–3 cm incision is often needed. After this various single port access devices such as the Covidien SILSTM Port or the GELPORT by Applied Medical, and the Triport or Quadraport by Advanced Surgical Concepts are placed into the umbilical incision providing channels through which the instruments and the camera can then be introduced into the peritoneal cavity. Another option is to group small low profile laparoscopic trochars in a single incision made at the umbilicus [7] (Fig. 57.5).

Fig. 57.5 Port options for single port or single incision Hysterectomy. (**a**) Covidien SILS Port has instrument ports built in with an insufflation access point laterally and an additional vent available for smoke evacuation. (**b**) Storz Single port system also has three active port as well as an insufflation port. Its advantage is that it is re-usable and similar to the Covidian port does not require additional trochar because instruments can be passed directly through the ports (©2015 Photo Courtesy of KARL STORZ Endoscopy-America, Inc.) (**c**) ASC Triport and quadraport by advanced surgical concepts is another disposable multi-instrument access port for single incision laparoscopic surgery requiring a 2.5 cm incision that allows up to four instruments to be used simultaneously. (**d**) The GelPOINT Advanced Access Platform by Applied Medical allows low profile ports to be placed through a gel port seal which thus gives greater versatility for port placement but may thus sometimes requires a slightly larger incision for access. However, he integral Alexis wound protector/retractor offers atraumatic retraction and protection for specimen removal

Fig. 57.5 (continued)

For robotic single port surgery access is obtained in the same manner as for laparoscopic single port surgery, but currently a special port and cannulas are used that then attach to the robotic instrument (Fig. 57.6). Prior to these cannulas and ports being developed specifically for this platform surgeons would use the straight robotic cannulas placed through a GELPORT access port placed at the umbilicus. The 8 mm robotic camera and 8 mm robotic instruments would then be introduced through the approximately 2.5–3 cm umbilical entry point, occasionally with a hybrid 5 mm assistant port. This allowed the surgeon to have some wristed movements but there were still some issues with instrument clashing and difficulty in triangulation around relevant anatomy. The subsequently released single port robotic platform reduced the size of the umbilical incision down to 1.5–2 cm with a port similar to the SILS port and reduced the diameter of the cannulas down to 5 mm and added a curved shape in order to improve triangulation. However, reducing the diameter of the instruments and allowing them to bend to follow the curve of the cannula removed the wristing feature from the instruments and thus greatly decreased the range of motion of the instruments as compared to the straight 8 mm robotic instruments. Recently a needle driver with 4° of movement has been developed in order to allow some increased range of motion to facilitate suturing.

In the Veress technique a disposable or re-usable Veress needle (Fig. 57.7) is introduced into the peritoneal cavity via the umbilicus or left upper quadrant at Palmer's point in order to obtain insufflation of the peritoneal cavity with CO_2 gas prior to the introduction of initial cannula and trochar. The purpose of insufflation is to tense the abdominal wall and create a distance between it and the bowel and blood vessels with the intention of making an introduction of the blind trochar easier and safer. However, there is no concrete evidence that this technique reduces initial entry tochar injury. Initial trochar may then consist of a re-usable trochar with a sharp tip versus various configurations of re-usable trochars with bladed, blunt, or spreading tips. The advantage of spreading tips which are designed to spread rather than cut the muscle and fascia fibers is to reduce trauma to these fibers and reduce the size of the remaining defect once the cannula is removed. This may reduce pain at the trochar site and risk of hernia

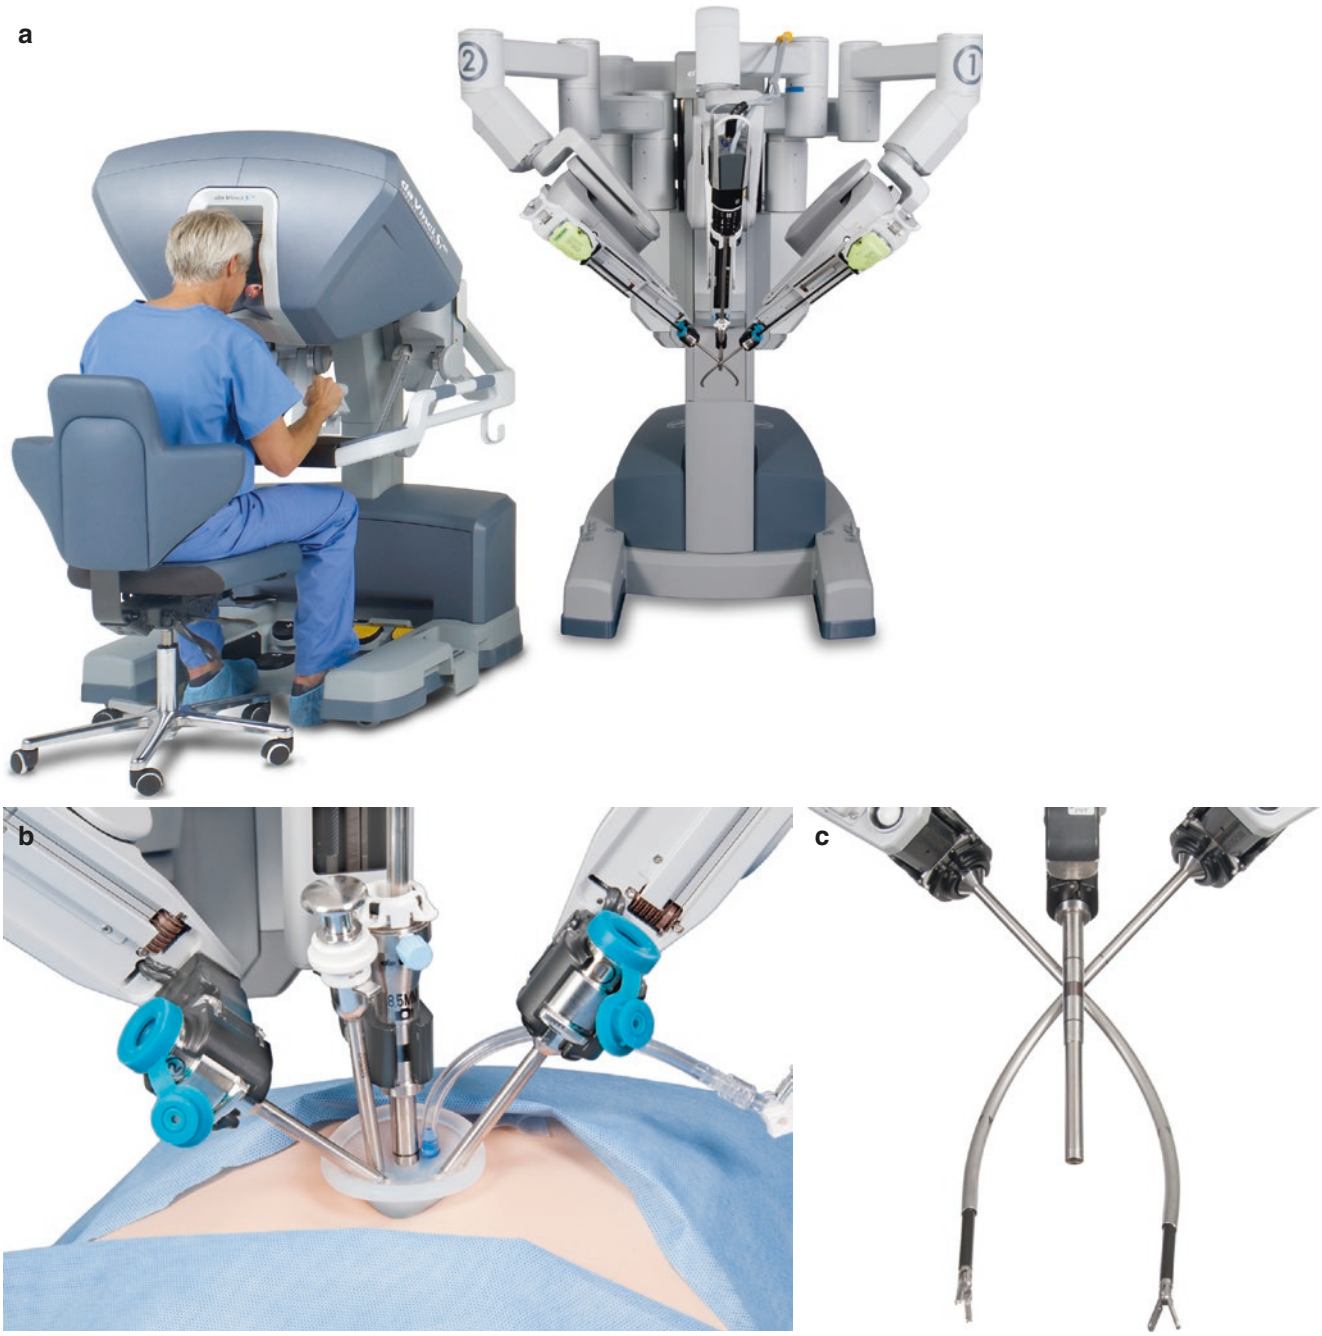

Fig. 57.6 Single port platform for DaVinci Robot. (**a**) The Si and Xi daVinci Systems have the possibility of use with a single port platform, which consists of a five-lumen SILS access port through which instruments and camera pass and cross. Remote center technology minimizes cannula collisions, arm interferences and port-site movement while the daVinci System software corrects for the crossing in order to intuitively coordinate the surgeon's hands with the instruments movements. (**b**) The five lumen port is placed through a 1.5–2 cm incision and provides access for two 5 mm curved instrument cannula, through which two semi-rigid 5 mm instruments pass, as well as the regular 8.5 mm 3D endoscope as well as a 5/10 mm accessory assistant port and the insufflation adaptor. (**c**) The curved architecture of the instrument cannulas allow the semi-rigid instruments to curve in order to optimize triangulation while minimizing external collision and crowding of instruments

formation. Some of the disposable trochars available include the possibility of visual entry via a camera channel within the trochar which allows the surgeon to visualize the layers of the abdominal wall as they are penetrated. The Versastep system includes a Veress needle with a sheath surrounding it, which may then be dilated using a blunt trochar allowing a completely blunt entry into the peritoneal cavity after access is secured with the needle at the site of needle placement. The only re-usable spreading visual entry trochar is the Ternamian trochar with a screw like blunt entry through the abdominal

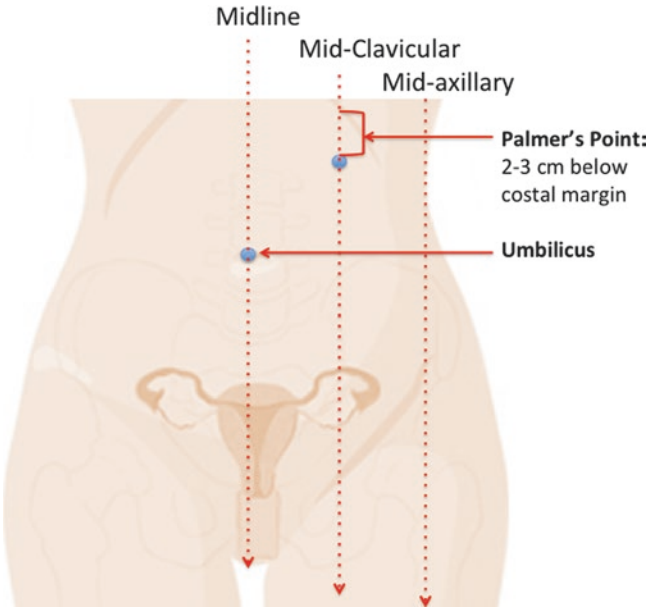

Fig. 57.7 Veress needle and points of entry. Palmer's point is 2–3 cm below left costal margin in Mid-clavicular line may be utilized if adhesions are suspected at umbilicus from prior surgeries. Contraindications to utilizing Palmer's point include right upper quadrant surgery such as prior gastrectomy or splenectomy

wall which allows the layers to be visualized as the trochar is screwed through them thus spreading the fibers [15].

The final method of entry into the peritoneal cavity is direct entry through the umbilicus without prior insufflation. In this method the abdominal wall is elevated via superior traction with the surgeons non-dominant hand or towel clip and the initial trochar is introduced directly into the peritoneal cavity either using a visual entry blunt-tipped or non-visual entry sharp disposable or re-usable trochar. Access is then confirmed via introduction of the camera, followed by insufflation through the port. In all methods, once access with initial trochar is obtained remaining trochars may then be introduced under direct visualization.

In robotic surgery, since the camera port can often be above the umbilicus, especially in the case of the large fibroid uterus extending above the level of the umbilicus, this needs to be taken into account when deciding on entry technique. Thus, open entry or the Hassan technique may not be optimal as it is more difficult to use the open technique above the umbilicus. Few surgeons are comfortable with direct entry above the umbilicus, and thus when a supra-umbilical camera port is desired most surgeon's will insufflate using a Veress needle, then either place the camera port first and then introduce remaining ports under direct vision. The author's preferred method is to place a 5 mm left upper quadrant visual entry port after insufflation and then use this port to survey the pelvis and decide on locations of both the robotic camera port and robotic re-usable ports dependent on the pathology. This is preferred as by optimizing camera and robotic ports according to pathology in difficult cases, one can obtain maximal vision and range of motion and prevent clashing of instrument arms or restriction of movement. As in other single-port procedures, single port robotic assisted procedures utilize open entry at the umbilicus and this location cannot be varied for the pathology, which is one of the limitations of single port surgery in general.

In mini-laparoscopy, small mini-laparoscopy ports measuring less than 3 mm in diameter are introduced laterally or in the suprapubic location after the initial camera port is placed at the umbilicus. Some mini-laparoscopy instruments measuring 2.5 mm in diameter do not require cannulas and are introduced directly through the skin into the peritoneal cavity. Generally, the initial port will consist of a 5 or 10 mm camera port placed at the umbilicus and mini-instruments are used laterally unless the small 3 mm mini-scope is available in which case this mini-scope is placed at the initial entry point.

As outlined above, the choice of type of entry and trochar type and tip is extremely surgeon specific. However, all surgeons should understand the different types of trochars that exist including advantages and disadvantages of each when selecting their preferred method of entry, torchar type and placement location [15]. After a preferred method is chosen, the surgeon should utilize this method as much as possible and only vary as needed for the case, as repetition prevents injury and several studies have shown that the highest rates of entry related complications occur immediately after changing a trochar type or entry method used by the surgeon. Figures 57.8 and 57.9 highlight the differences in access ports as well as port locations for the various approaches.

Visualization

Camera and scope technology are continuously evolving leading to the development of smaller, more maneuverable visualization tools that provide significantly improved vision while performing surgical procedures. Currently, laparoscopic scopes are available in the 10, 5, and 3 mm sizes (Fig. 57.9) and the 10 and 5 mm laparoscopes are available in either the 0 or 30° fields of view. The 30° increases the field of view in order to look around, above, or underneath structures and is most useful when operating deep in the pelvis with deep endometriosis or when performing hysterectomy for a very large uterus. The 3 mm camera by Storz is most useful in the performance of mini-laparoscopic hysterectomy, or for initial survey from the left upper quadrant in complex cases in which entry at palmer's point is preferred. Camera's with a flexible tip are (Fig. 57.9) available through Olympus are most useful for single port hysterectomy as they allow the camera tip to bend in order to obtain a better view for triangulation so that a surgeon's hand do not clash with the camera. It is also useful for NOTES procedures in which a Natural Orifice is used for introduction of the scope. Since one of the main advantages of robotic surgery includes the 3D HD

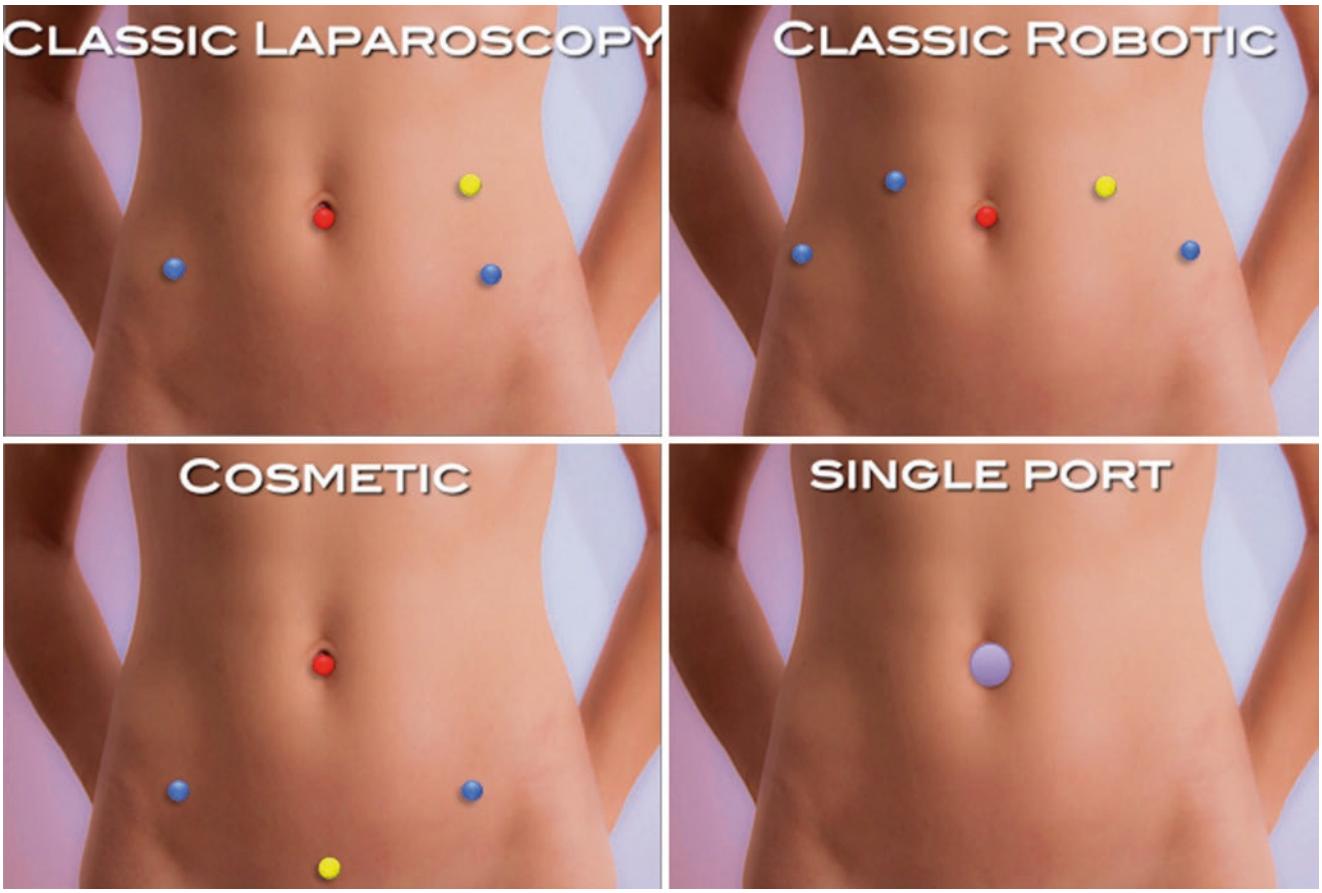

Fig. 57.8 Port placement in laparoscopic, robotic, single port, and mini-laparoscopy procedures. In Classic Laparoscopic hysterectomy four 5–10 mm ports are place as shown, although the accessory port (*yellow*) may vary in placement to opposite side or to the suprapubic area depending on surgeon preference. In classic robotic surgery port placement is usually in an M configuration or slight arc varied according to the pathology. Laparoscopic or robotic procedures can be made more cosmetic by lowering lateral ports or placing them more ultra laterally. However, the wristed instruments of the robotic platform make these more cosmetic port locations much easier to use with the wristed instruments of the robotic platform. Single port or single incision procedures always utilize the umbilicus. The incision incision is usually larger than laparoscopic ports measuring 2–3 cm and thus has a higher rate of herniation and wound complications. The advantage of mini-laparoscopy is that ports are only 2–3 mm and thus do not need closure and produce very minimal scars and have little to no risk of hernia formation

magnified vision for the surgeon, some companies such as Olympus have released a 3D laparoscopic scope and camera in order to provide a similar view for the laparoscopic surgeon. However, it does not duplicate the magnification and the complete immersion in the three dimensional environment provided by the surgeon console in robotic procedures.

Exposure and Uterine Manipulation

Uterine manipulators with a colpotomizer are a very important part of any of the laparoscopic approaches to hysterectomy, whether traditional laparoscopy, mini-laparoscopy, or robotic assisted laparoscopy. The uterine manipulator fulfills many functions (Table 57.2). However, the main purpose of the uterine manipulator is exposure. It assists in the elevation and movement of the uterus upwards and out of the pelvis to help provide exposure to the uterine vasculature and bladder flap while increasing the distance away from the ureters in order to avoid direct or indirect injury. This increases the safety of a laparoscopic hysterectomy. In addition, the colpotomy ring, cup, or blade can be used to push the ureters more laterally, and the uterine artery superiorly, while delineating the junction between the cervix and the vaginal fornices tenting them upwards. Tenting the vaginal fornices upwards will provide the necessary exposure aiding in the dissection of the bladder flap and cervicovaginal fasica as well as delineating the site for colpotomy incision at the apex of the vagina such that the incision will not shorten the vagina significants. This also provides the tissue tension required to swiftly make the colpotomy incision with minimal energy in order to avoid tissue necrosis and complications such as cuff cellulitis or dehiscence [16].

Many different uterine manipulators exist including some that are disposable, reusable, or have both re-usable and disposable components (Figs. 57.10 and 57.11). Some have straight handles and others are arched or curved. Arched manipulators allow the user to follow the arc of the sacrum

Fig. 57.9 Various cameras and scopes utilized in laparoscopic, robotic, single port, and mini-laparoscopy procedures. (**a**) Traditional laparoscopic Ports come in either 5 or 10 mm scopes providing a 0 or 30° scope angle. Bariatric 30° scopes assist with larger pathology or in single port procedures in order to move the camera away from other instruments to prevent clashing. ©2015 Photo Courtesy of KARL STORZ Endoscopy-America, Inc. (**b**) Mini-laparoscopy scopes are also now available measuring a mere 3.5 mm diameter, which is very useful in simpler or diagnostic procedures in which minimization of the port site may be desired. (**c**) Olympus has developed an articulating 5 mm scope as well as an articulating 5 mm 3-D scope designed for optimal visualization for singe port or notes procedures. (**d**) The scope providing the best visualization for precise intricate surgery is the scope and camera designed for the DaVinci Robotic instrument. This scope provides extremely detailed High definition vision utilizing both a right eye and a left eye in order to give the surgeon a 10X magnified 3D view inside the patient at the surgeon console. The camera is controlled by the surgeon from the surgeon console providing optimal control. With the newest Xi system the camera also has newer features of auto focus, auto white balance, and instant switch from 30° up to 30° down view. The camera can also now be placed at any position and be controlled by any of the robotic arms which greatly facilitates multi-quadrant surgery

and thus manipulate in a more anatomical fashion allowing for maximal elevation of the uterus out of the pelvis and away from the ureters. Straight manipulators, may be assisted by (articulation) in order to antevert or retrovert the uterus for exposure. Metal manipulators are sturdier and thus are less likely to bend or break with a larger uterus or severely deformed or deviated pathology such as in patients with large lower segment fibroids or severe endometriosis. [17].

In the United States the two most commonly used uterine manipulators for laparoscopic hysterectomy are V-care, which is entirely disposable, and Cooper Surgical's uterine manipulators including the Rumi, Rumi arch, Rumi II, and Advincula arch manipulators which work with a Koh ring and disposable tips. Recently the Koh ring has been incorporated into a backloading disposable piece which also incorporated the vaginal occluder balloon. One of the advantages of the Rumi and Arch

Table 57.2 Functions of the uterine manipulator

Functions of the uterine manipulator [11, 13]
Mobilizes the uterus including anteversion, retroversion, lateral and elevation movements
Clearly identifies and distends the vaginal fornices to enable a circular incision of the vaginal apex
Elevates and defines the cervico-vaginal junction to enable a safer dissection of the vesico-uterine fold and fascia
Enables the elevation of the uterus upwards in the abdomen, in order to obtain a good visualization of the uterine artery and its elevation above the ureter
Maintains pneumoperitoneum during colpotomy
Raises the uterus and brings it closer to the laparoscopic surgical instruments, facilitating the procedure
Manipulates the uterus, thus stretching and presenting the side being operated upon
Increases the distance between the uterus and the bladder, the ureters, and the rectum, thus reducing the chance of injury
Can be used pull the uterus out vaginally after its complete detachment
Facilitates the identification of the uterovesical peritoneum, the cul-de-sac, and the vaginal cuff just below the cervical attachment

Fig. 57.10 Examples of re-usable uterine manipulators. Many different re-usable uterine manipulators that consist of a manipulator portion and a colpotomizer system exist. Some examples include the Donnez, Clermont-Ferrand, Hohl and Mangeshikar uterine manipulators sold by Storz. Some of the features of these manipulators are reviewed in Table 57.4 (©2015 Photo Courtesy of KARL STORZ Endoscopy-America, Inc)

manipulators is that they are attachable to Copper Surgical's Uterine Positioning System (UPS) (Fig. 57.12). This device attaches to the operating room bed and holds the manipulator firmly in position using a hydraulic system which allows the manipulator to be moved in any direction and then holds the position without drifting. This precludes the need for a vaginal assistant to constantly hold and push up on the manipulator and affords the surgeon several advantages, especially in more complicated, difficult, or long cases. First, the surgeon can personally position the uterus as desired at any time, knowing that the position will not change. Second, it provides stability such that there is no drifting downwards as occurs when the assistant fatigues which often places the ureter at risk. Third by stabilizing and securing the anatomy, the surgeon can focus on dissection of the important anatomical structures without the position changing as the surgeon is working near or around the uterus [18].

Many other disposable manipulators exist including ones with a lighted ring in order to aid colpotomy. However, in Europe and other areas of the world re-usable manipulators predominate in an attempt to limit disposable instruments utilized in surgical procedures. Many re-usable manipulators

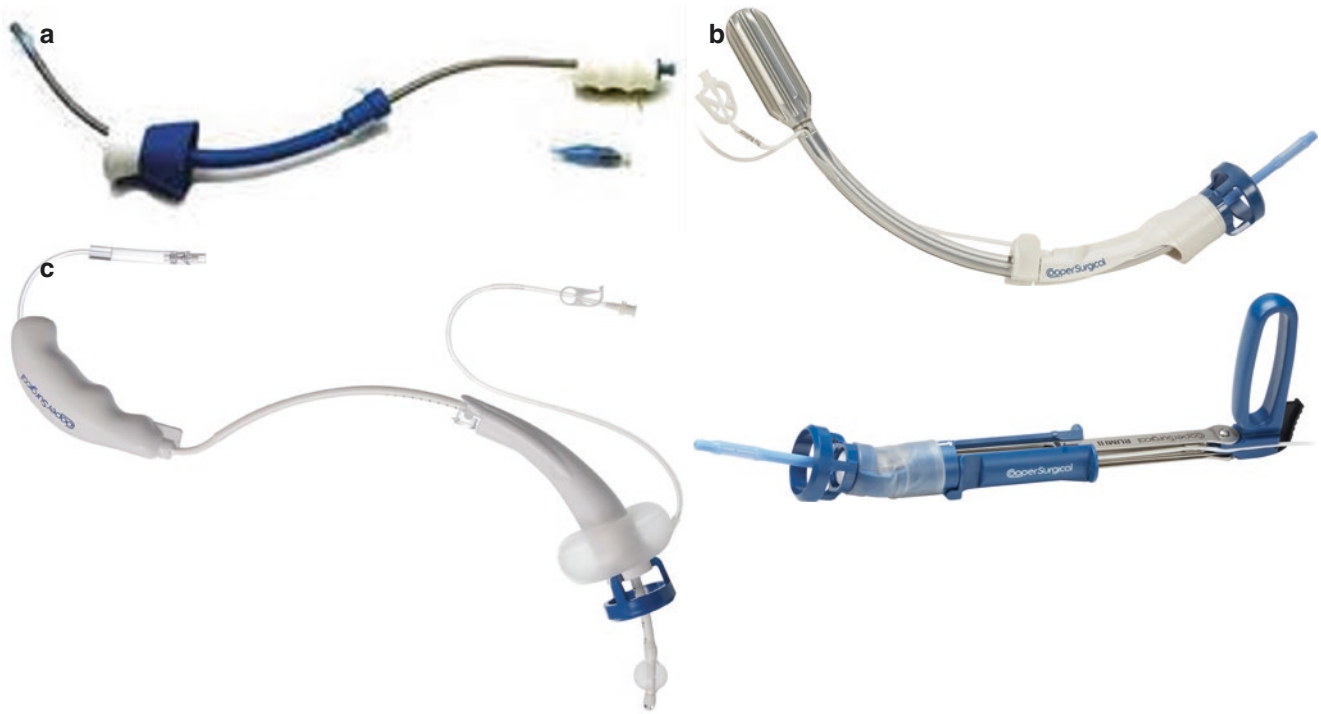

Fig. 57.11 Examples of disposable or partially disposable uterine manipulators. (**a**) V-Care uterine manipulator is fully disposable and has three cup sizes. It is shaped as an S shape for easier manipulation. (**b**) Copper surgical utilizes the Koh colpotomizer ring which is fenestrated and more cup shaped and thus provides clearer delineation of the colptomy site and lateralizes the ureter away from the uterine artery. The colpotomizer and occluder balloon section is disposable and comes in various sizes, as do the balloon tips which secure the uterus to the manipulator. Two manipulator bodies exist. One is a curved metal arc (Advincula Arch) which takes the curve of the vagina and is most useful for larger pathology. The other is the Rumi II system which allows anteversion and retroversion of the uterus via the handle. (**c**) Recently Cooper surgical has released a completely disposable version of the Advincula Arch which has the same advantaged of the KOH colpotomy ring and vaginal occluder balloon built in but has more of the S-shaped curve giving it easier handling for the user and less need for assembly. However, for larger pathology it may not be as sturdy as the metal arch

Fig. 57.12 Uterine positioning system. The uterine positioning system produced by Cooper surgical is compatible with either the Advincula arch or Rumi uterine manipulators. It is a device which attaches to the operating room table and holds the uterine manipulator with a hydraulic arm which remains fixed in place until the surgeon changes the position using a foot-pedal to release the hold. This allows the surgeon to position the uterine manipulator and uterus into any position and fixes it in place so that it does not drift or move. This thus takes the place of a vaginal assistant and allows the surgeon precise control of the uterus which greatly assists in difficult laparoscopic or robotic hysterectomy procedures

Table 57.3 Factors to consider in choosing a uterine manipulator

Factor for consideration	Ideal quality
Cost	Re-usable preferred
Ease of assembly	Minimal number of parts
Material	Metal or indestructible material
Range of motion	Pivoting head or arched shape
Placement into uterus	Easy placement with minimal cervical dilation required
Fixation into uterus	Method of fixation into uterus
Adjustability	Variable tip lengths and cup sizes to adjust for size of the uterus and cervix
Delineation of vaginal fornices	Circular cup or ring preferred over rotating valve
Vaginal occlusion	Method of occlusion to prevent loss of pneumoperitoneum

are present on the market. All share similar components of a method of fixation to the uterus, a cervical cup for delineation of fornices, and a method of vaginal occlusion. Most are straight rather than curved and several have the capability of anteversion and retroversion of the uterus. Table 57.3 lists some factors that should be taken into consideration when evaluating a uterine manipulator while Table 57.4 provides a comparison of some of the uterine manipulators available.

Table 57.4 Comparison of uterine manipulators

Manipulator	Re-usable	Number of parts	Pivoting head	Shape	Variable tip lengths	Method of fixation in uterus	Number fornix delineator sizes	Method of delineation of fornix
V-care	No	1	No	S-Shape	Yes	Balloon	4	Ridged cone
Rumi II	Partial	3	Yes	Straight	Yes	Balloon	4	Fenestrated cup
Advincula Arch	Partial	3	No	Arched	Yes	Balloon	4	Fenestrated cup
Donnez	Yes	3	No	Slight Curve	No	None	3	Cap
Clermont-Ferrand	Yes	6	Yes	Straight		Screw	3	Rod
Konninckx	Yes	4	Yes	Straight	No	Intrauterine clamp	1	Rotating cap
Hohl	Yes	4	No	Straight	Yes	Screw	3	Curved cap
Mangeshikar	Yes	6	No	Straight	Yes	Forceps	5	Cap
Minneli	Yes	4	No	Straight		Screw	3	Rotating valve

Ultimately cost and a surgeon's preferences determine which manipulator is used during a case [17].

Instruments for Dissection and Hemostasis

In general terms, a Hysterectomy has three components:

1. Isolation, sealing, and ligation of either the utero-ovarian or infundibulopelvic ligament depending on desire for ovarian preservation
2. Isolation, sealing, and ligation of uterine vasculature
3. Colpotomy or uterine amputation dependent on desire to preserve the cervix, followed by assurance of hemostasis and closure of openings including the vaginal cuff if needed.

All three components require dissection of the two vascular bundles, the bladder flap, and cervical vaginal fascia and transection with hemostasis of the two vascular bundles at the uterine isthmus and the adnexa [19].

Abdominal Hysterectomy

The standard instruments for surgeons are a clamp, scissors, and suture for ligation, and forceps and a needle driver for suturing. Thus, in abdominal hysterectomy, the clamp traditionally used is the Heaney clamp. However, the Seppelin clamp is more frequently used in oncologic procedures as the Z-configuration of clamp minimizes tissue slippage and need for a pedicle so that the cut can be made directly on the clamp with scissors or a scalpel. The neeldle driver tends to be a long handled but heavy needle driver in order to drive bites of suture through thicker ligaments such as the cardinal or uterosacral ligaments, and then used later for closure of the vaginal cuff which also consists of thick tissue and fascia. A monopolor current via bovie, is often used for dissection, cutting, and hemostasis while vasclular bundles are ligated generally using suture unless hand-held advanced bipolar instruments are used as an alternative. Vaginal hysterectomy is similarly performed but in the reverse order with dissection performed again with a scalpel, scissors, and bovie, while division of vascular pedicles is performed using a curved Heaney clamp to clamp, curved mayo scissors to cut, and a Heaney needle driver to suture the pedicles and for vaginal cuff closure.

Vaginal Hysterectomy

Since the advent of Laparoscopic surgery, many devices for dissection, hemostasis, and advanced vessel sealing have been developed and are even now slowly being incorporated into abdominal and vaginal procedures secondary to ease of use and speed of control of vascular pedicles. The main goal of energy devices is to seal vessels and attain hemostasis with or without cutting of the pedicle. Since exposure is usually adequate in abdominal surgery, there is little need to avoid the traditional clamp, cut, and tie rhythm. Thus, in abdominal hysterectomy, using these devices may add expense and save an insignificant amount of time. However, for difficult vaginal hysterectomies and in the vagina in general, where exposure is limited, a vessel sealing device can ease the procedure as it is often difficult to suture and tie pedicles in the tight vaginal space. Therefore, utilization of either a re-usable or disposable energy vessel sealing and cutting device may be advantageous. All are shaped similar to the curved Heaney clamp and thus may be applied in a similar manner to seal and divide the uterosacral or cardinal ligaments, followed by the uterine artery and broad ligaments, then either the infundibulopelvic or utero-ovarian ligaments in order to remove or preserve the ovaries. Re-usable devices include

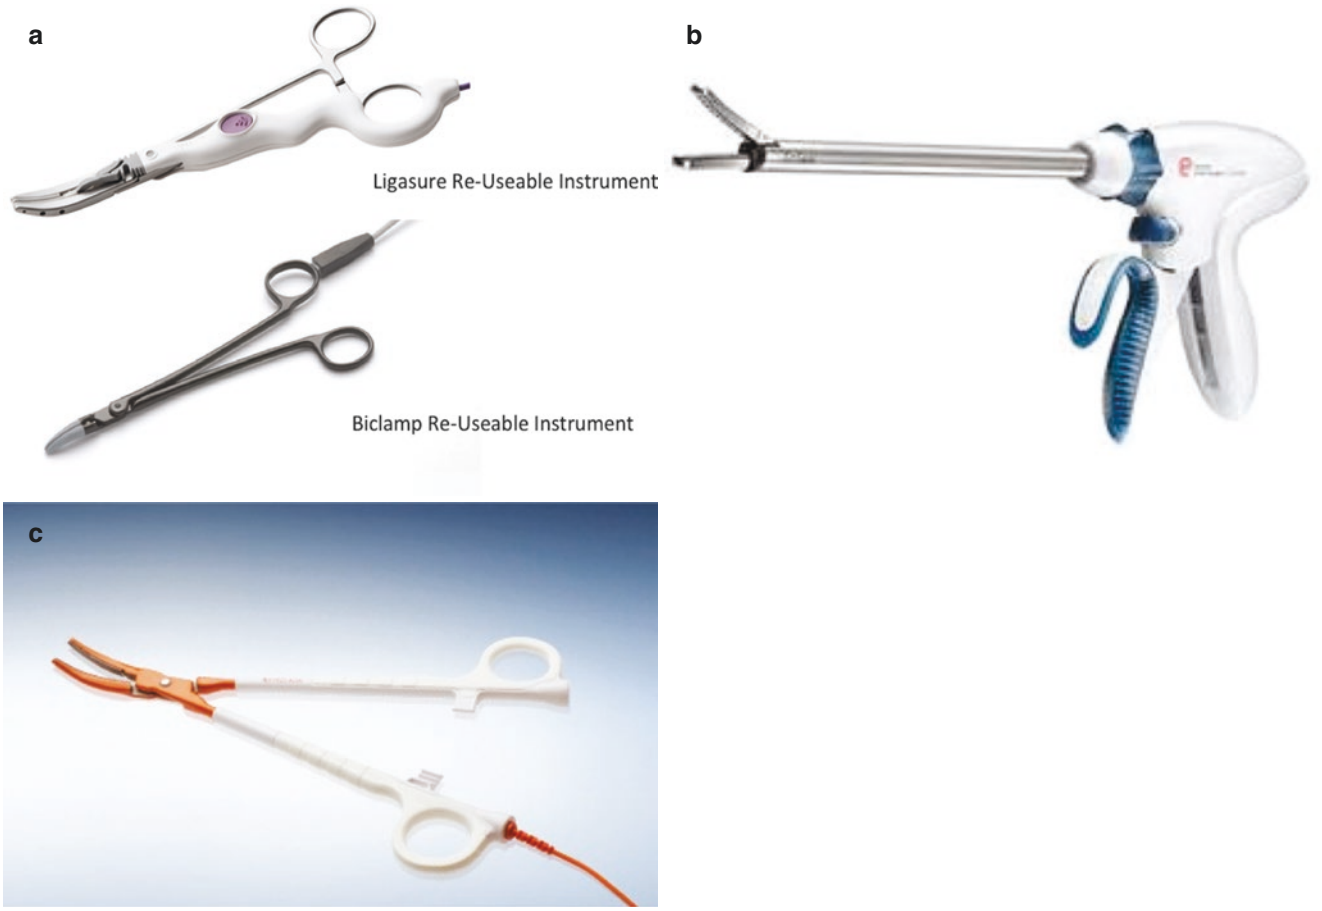

Fig. 57.13 Energy devices for vaginal hysterectomy. Bipolar instruments can be useful for expediting vaginal hysterectomy, used to seal vessels instead of suturing. (**a**) Re-usable instruments like the Ligasure or Biclamp are the most economic but only seal without seal and cut features. (**b**) Disposable instruments exist with the Enseal allowing sealing and cutting to occur simultaneously. (**c**) One of the first disposable instruments which was also used for vessel sealing in vaginal hysterectomy was the PKS Seal open forceps

the Biclamp or re-usable Ligasure devices, both of which have advance bipolar energy with Ligasure also utilizing additional pressure for vessel sealing. Disposable devices include the Gyrus SEAL, ENSEAL, and the Disposable Ligasure (Fig. 57.13). The Gyrus was the original advanced bipolar device using PK energy, followed by Ligasure and then the ENSEAL. Both Ligasure and Enseal utilize pressure, heat, and advanced bipolar energy to seal and cut the vessels. As the blade in Enseal applies pressure as it cuts, the pressure is more evenly distributed rather than decreasing near the tip as in Ligasure. However, Ligasure, like the Gyrus SEAL allows the surgeon to seal without cutting, thus providing the surgeon with more control [20]. Hysterectomy by using them to seal vascular pedicles instead of suture ligation. Re-usable instruments like the Ligasure or the Biclamp are overall the most economical but only seal without seal and cut features. The disposable Enseal allows sealing and cutting to occur simultaneously but this can be a disadvantage if the seal is not complete and does cost more per case. The PK seal open forceps was one of the first disposable instruments used for vessel sealing in vaginal hysterectomy but did not have the same cut feature as the PK used in laparoscopy. Thus, when choosing a device the advantages and disadvantages of each must be considered.

Laparoscopic Hysterectomy

Advanced Laparoscopic Surgeries such as total laparoscopic or supracervical hysterectomy have really been revolutionized by the advanced energy vessel sealing devices that have been developed for laparoscopy. The original energy utilized in Laparoscopy was monopolar energy, which is most useful for cutting (rather than sealing) such as in the use of monopolar scissors. Bipolar energy allowed passage of energy between the two blades of a grasper or forceps such as a Maryland and thus became utilized for coagulation of vessels in hysterectomy procedures. However, inadequate sealing of vessels secondary to charring and desiccation of tissue

surrounding the vessel which did not allow adequate passage of energy into the center of the vessel. This often resulted in inadequate sealing of the vessel and either immediate or delayed bleeding. In addition, other problems included lateral thermal spread to surrounding tissue, and sticking of the vessels and tissue to the clamp used to apply the energy with surface charring of the tissue. Thus, their use was limited especially when desiring to seal larger vessels. For this reason, early developers of the total laparoscopic hysterectomy procedure such as Harry Reich, would often suture uterine vessels rather than trying to seal them with energy [21]. Modern laparoscopic vessel sealing devices were later developed and have greatly facilitated the performance of laparoscopic hysterectomies. These devices may be categorized into advanced bipolar or ultrasonic energy devices or a combination of the two. All devices effectively seal vessels up to 7 mm in diameter and some have built in tissue transection capabilities. A comparison of these devices is provided in Table 57.5.

The first advanced bipolar energy system was the plasmakinetic pulsed bipolar system named the PK Gyrus (Olympus). It had an impedance dependent feedback-controlled method of delivery pulsed bipolar energy to the tissue causing vapor pulse coagulation induced sealing of vessels upto 7 mm in diameter. The intermittent and automatically adjusted pulses of bipolar energy produced by the plasma kinetic generator cause minimal lateral thermal spread and prevented sticking of tissue to the plasma kinetic forceps blades after coagulation. The Gyrus then offered a sharp blade for cutting the sealed pedicle with a hand control. The PK energy type could also be used with a dissecting forcep, spatula, needle-point, and hook in order to avoid the need for mono-polar energy during a case.

Other advanced bipolar devices include Ligasure, Bicision, and EnSeal. Advanced bipolar devices possess active feedback control over the power output, adjusting the energy according to the measured impedance of the tissue between the blades. Heat production is kept below 100 °C and the energy is pulsed to allow cooling [22]. However, there is no simultaneous tissue division and a cutting blade or mechanism is required for division or transection of the sealed vessel or tissue. Ultrasonic devices such as the ACE harmonic scalpel combine both the sealing and cutting steps into a single process and thus may increase dissection speed. However, the literature had reported that ultrasonic devices can create temperatures of up to 200 °C which can potentially put adjacent tissue at risk to lateral damage [21]. This concern has been partially addressed by adding a Teflon coating in newer ACE Harmonic devices which may decrease the peak temperature of the device.

Although many comparative studies have been performed, neither type of device has been proven superior. In general terms however, advanced bipolar devices ultimately produce less heat than ultrasonic devices. Both advanced bipolar and ultrasonic devices efficiently seal vessels ($\leq$7 and $\leq$5-mm diameter, respectively), and most also have built-in tissue transection capabilities. Bipolar devices are said to seal slightly larger vessels but do not seal and cut simultaneously or as efficiently as ultrasonic energy. Ultrasonic energy is best known for efficient dissection reflected by its ability to use the device in a cutting mode, and low lateral thermal spread to adjacent tissue. However, the device itself reaches higher temperatures and remains at this high temperature for an extended period resulting in initial concern of a higher rate of thermal injury to the ureter or bowel during hysterectomy procedures [23]. All Ultrasonic energy devices are disposable, as are most advanced bipolar energy devices, and thus add to the cost of the procedure. A reusable Biclamp using and Erbe generator is available and is frequently used in Europe for laparoscopic as well as vaginal hysterectomy as it is available in both a Maryland dissector and standard bipolar Forceps tips for use in laparoscopic hysterectomy. For vaginal hysterectomy it had a heavy ridged curved clamp similar to the Haney Clamp.

Only one device combines both bipolar and ultrasonic energy in order to try to combine the advantages of both types of energy [24]. The Thunderbeat (Olympus, Japan) is the first device to integrate both ultrasonically generated frictional heat energy and advanced bipolar energy in one instrument. This multifunctional device can interchangeably deliver the energies via two separate control buttons allowing the surgeon to favor advanced bipolar energy for sealing larger vessels and surface coagulation, while ultrasonic energy is preferred for quick cutting and sealing. The jaw is designed in a thin dissector design facilitating tissue dissection and increasing the multifunctional uses of the instrument.

Two publications involving animal models using this newer device compared the Thunderbeat with other commercially available energy devices in the market, namely, Harmonic Ace (Ethicon Endo-Surgery, USA), LigaSure (Covidien, USA), and EnSeal (Ethicon Endo-Surgery, USA) in the porcine model [24]. Compared with the other three devices, the Thunderbeat showed faster dissection speed, similar bursting pressure, and similarly acceptable thermal spread. The device was proven to be safe in cutting, coagulating, and tissue dissection. In another experiment led by Seehofer et al. [25] the Thunderbeat was compared to the Harmonic Ace and LigaSure in a pig model. Temperature profile, seal failures, maximum burst pressure, and cutting speed were measured. In this study, the Thunderbeat was faster than Harmonic Ace in terms of dissection while equaled the sealing efficacy of the LigaSure with a similar heat production.

Table 57.5 Comparison of advanced bipolar devices used in laparoscopy

Device	Energy type	Description	Positive features	Negative features
PK Gyrus (Olympus)	Plasma kinetic technology (Advanced bipolar)	Delivers a high current and very low voltage to the tissue. A series of rapid pulses allows a cooling phase decreasing lateral thermal spread	Holds onto the tissue being desiccated without slipping or sticking	Disposable
			A blade can be manually deployed through the forceps to transect tissue	Jaws can be traumatic
			Facilitates Dissection	Unreliable on vessels >7 mm
		The vessel is sealed by denaturing the protein within the vessel walls, forming a coagulum which occludes the lumen	Both a 5 and 10-mm version is available	Consistency somewhat dependent on user
			A Gyrus spatula is also available and can be used as both a cutting and coagulating instrument	
Ligasure (Covidien)	Advanced bipolar energy with pressure	Delivers high current, low voltage along with pressure from the jaws to tissue	Fast seal using combination of advanced bipolar energy and pressure	Disposable
			Compresses surrounding tissues to seal with the vessel	Hinders dissection secondary to bulky jaws and sealing of surrounding tissue
		The system monitors the energy expended while denaturing the collagen and elastin within the vessels walls. During the cooling phase of the cycle, cross-linking re-occurs creating a new seal	Both a 5 and 10 mm version is available	Unreliable on vessels >7 mm
				Pressure decreases near tip of the jaw
				Consistency less dependent on user
Enseal (Ethicon)	Advanced bipolar energy with pressure	Uses a bipolar electrode to concentrate energy on tissue within the plastic jaws of the instrument	Sealing using combination of advanced bipolar energy and pressure	Disposable
		Temperature sensitive matrix (nanopolar thermostats) within the jaws controls the energy delivered to the electrode-tissue interface	Easier to dissect with than Ligasure secondary to slim Jaws	Cutting may occur prior to adequate sealing as sealing is still occurring during cutting phase
			Has an articulating version which facilitates single port procedures and improves angles for vessel sealing	Unreliable on vessels >7 mm
		Pulsing of energy according to temperature allows cooling		Proper use requires a certain level of surgical skill thus is surgeon dependent
				Less efficient than some other devices
BiClamp (Erbe)	Advanced bipolar	A bipolar electrosurgical current produced by the ERBE VIO system ,with an optimally adjusted waveform, voltage and current density is applied and the tissue is coagulated and sealed	Tissue structures can be coagulated over larger areas and surgeon has greater control over width of area coagulated that seal and cut devices	Is a seal only device, therefore requires a separate instrument (usually laparoscopic scissors) for cutting once the vessel is sealed.
		The particular features of the ERBE BiClamp create a parchment-like coagulation seam during bipolar coagulation, thus sealing the vessel	Highly economical as the ERBE BiClamp is reusable	This may decrease efficiency of the procedure
			Auto stop and plug and play feature is user-friendly and adjusts automatically for different procedures	

(continued)

Table 57.5 (continued)

Device	Energy type	Description	Positive features	Negative features
Harmonic ACE (Ethicon)		High frequency ultrasonic transducer with active titanium blade vibrates at 55,000 cycles per second	Fast seal and cut	High external temperature
		Mechanical energy causes a breakdown of protein creating a coagulum. Vessel and tissue sealing is dependent on the power setting as well as the pressure exerted and the tissue tension	Low lateral thermal spread	Vessel sealing ideal <5 mm
			5 mm instrument	Poor reliability on vessels ≤7 mm
			Good for efficient dissection	
		A straight and curved blade is available	Lower working temperature causes less charring and sticking	Consistency is highly dependent on the user
			Variability of energy delivered can be adjusted by the surgeon ,depending on the need and tissue being transected	
			The active bade can also be used as a cutting knife useful for colpotomy	
Thunderbeat (Olympus)	Ultrasonic and advanced bipolar energy	Integrates both ultrasonically generated frictional heat energy and advanced bipolar energy in one instrument as a multifunctional device	Multifunctional device can interchangeably deliver the different energies	Disposable
			Allows the surgeon to simultaneously seal and cut vessels up to 7 mm in size with minimal thermal spread	Unreliable for vessels above 7 mm
			The jaw is designed to provide precise, controlled dissection and continuous bipolar support with grasping allowing for efficient dissection and hemostasis	Ease of use required practice and training of the surgeon

Specialized Laparoscopic Hysterectomy

For single port laparoscopic procedures, if an advanced energy device is desired for vessel ligation the surgeon must either try to present the vessels and tissue to the vessel sealer that they normally use for laparascopic hysterectomy or choose an articulating vessel sealing device. To date the only vessel sealer that is available with the ability to bend or articulate is the Enseal system by Covidien. The articulation of the instrument facilitates triangulation in single-port procedures.

In mini-laparoscopy, one of the main limitations to the performance of hysterectomy was the lack of bipolar energy devices. Thus, a 5 mm port was often utilized in a hybrid laparoscopic technique in either a "single port" or traditional laparoscopic orientation in order to seal the vascular pedicles. Storz has now released 3.5 mm ROBI Bipolar Graspers and Scissors providing energy application through a mini-laparoscopic port (Fig. 57.14). Other 2 or 2.5 mm instruments do not provide energy and thus mainly function as graspers, scissors, or dissectors but not as vessel sealers. As the energy devices advance in mini-laparoscopy instruments, it is likely that the performance of hysterectomies using "mini" ports will increase.

Fig. 57.14 ROBI bipolar graspers and scissors for mini-laparoscopy procedures. 3.5 mm instruments that allow bipolar energy application have been developed by KARL STORZ. These include graspers, dissectors and scissors. The ROBI bipolar grasper can be used to seal infundibulopelvic ligaments as well as uterine vasculature in laparoscopic hysterectomy procedures (©2015 Photo Courtesy of KARL STORZ Endoscopy-America, Inc)

Fig. 57.15 DaVinci surgical system. Robotic cart attaches to the trocars placed into the peritoneal cavity. Instruments are then placed into the peritoneal cavity through the trocars and attach to the robotic arms and intuitive full range of motion is given to the surgeon via the controls at the Surgeon Console. Assistants stand at the bedside and help with instrument exchanges, camera management and retraction. The surgeon controls the robotic instruments, energy, and camera from the surgeon console

The daVinci robotic surgical system (Fig. 57.15) is one of the most expensive and advanced tools available for the performance of hysterectomy, greatly extending the ability of a surgeon to push the limits of laparoscopy. However, one of the criticisms of the system is its extensive reliance on traditional bipolar and monopolar energy thus requiring the surgeon to understand the proper use of this type of energy and its effect on tissues in order to reduce risk of injury resulting from thermal spread. The disadvantages of traditional bipolar energy can be overcome using the concepts of adequate tissue dissection down to the vessel wall, made easier by the superior vision and articulating precisely

Fig. 57.16 Typical instruments used in DaVinci Hysterectomy. (**a**) Grasping instruments include the prograsp, long-tipped forceps, and robotic tenaculum. (**b**) Cutting devices include the mono-polar scissors, mono-polar hook, and mono-polar spatula. (**c**) Other useful instruments include the clip applier and suction irrigation device. The only other instruments required are some kind of bipolar vessel sealing or coagulation instruments reviewed in Fig. 57.17

controlled instruments. Bipolar energy can then be applied, applied directly to the vessel with intermittent manually pulsed application allowing heat and charring to dissipate so that the energy transmits further into the vessel. This thus mimics the pulsed bipolar energy of advanced devices but without the ability to adjust power for tissue impedance. Similarly, using appropriate tension and counter-tension techniques and principles of utilizing a larger surface area for coagulation and smaller surface area with a swift movement with tissue on tension for cutting using the mono-polar scissors reduces tissue damage and thermal spread (Fig. 57.16). These swift movements and precision in energy application is greatly facilitated by the wristed instruments that mimic the surgeons' hands exactly to a set scale (1:1, 1:3, 1:5 depending on the setting). Therefore, in experienced hands the energy can be used safely and effectively since the surgeon has much greater control over the movements and the precision of the dissection and energy application as compared to traditional laparoscopy. Thus, if the energy is utilized precisely and selectively only when needed, a safe and efficient dissection and hemostatic control of pedicles can be acheived with the added possibility of decreasing blood loss over laparoscopy.

As far as advanced bipolar energy use with the daVinci robotic surgical system, the S and Si Systems are compatible with a PK gyrus generator utilizing the PK dissector instrument for vessel sealing (Fig. 57.17). This instrument has the advantages of advanced bipolar energy and is optimally shaped for both dissection and vessel sealing, although it does not function well as a grasper and thus does not have the multi-purpose advantages of the fenestrated bipolar or bipolar Maryland instrument which utilize traditional bipolar energy. Thus, when choosing the instrument the surgeon must compromise one of two functions and compare that to the preference for type of energy. The PK dissector is slim and long and is optimal for careful dissection around vessels or in retroperitoneal space but does not grasp peritoneum or tissue well. However, its vessel sealing ability is superior secondary to the pulsed PK advanced energy. Thus, surgeons who utilize this instrument have a style of surgery focused on dissection and selective vessel sealing and use the blades of the PK dissector much like a Kelley instrument in abdominal

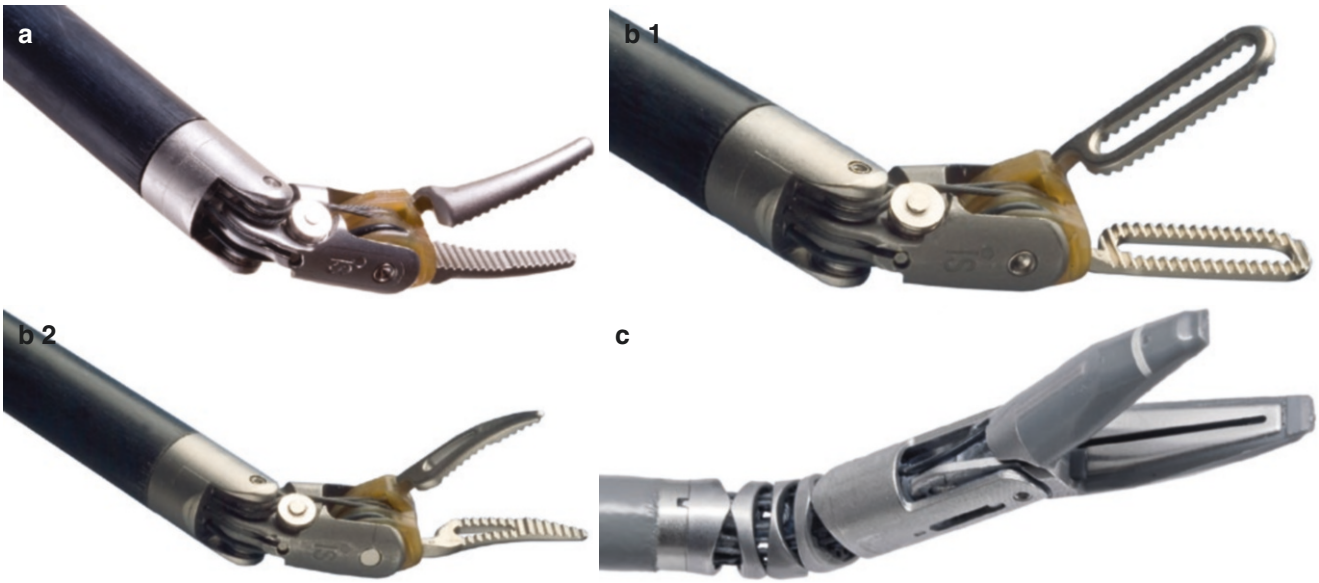

Fig. 57.17 Bipolar Instruments for use with DaVinci surgical System. (**a**) The PK dissector allows application of advanced bipolar energy for optimal vessel sealing. Its thin jawline also allows dissection of anatomy down to the vessel wall. (**b**) The fenestrated bipolar and bipolar Maryland apply traditional bipolar energy and thus require manual pulsing of the jaws in order to allow tissue to cool between pulses thus reducing sticking and charring and increasing efficiency during vessel sealing. (**c**) The newest instrument is a vessel sealer employing Ligasure-like technology to seal and cut vessels efficiently and rapidly. However the instrument is not multifunctional and thus functions poorly as a grasper or a dissector

surgery, utilizing the monopolar energy to cut tissue that is elevated between the blades. (Figure) Surgeons, who utilize the fenestrated bipolar or bipolar Maryland, tend to use more blunt dissection and traction of tissue and peritoneum to open spaces and will need to apply more energy in order to accomplish similar vessel sealing. Thus, the style of the surgeon also determines the instrument chosen for the task.

A newer vessel sealing and cutting instrument (Fig. 57.17) has also been released for the Si and Xi systems which has a similar seal and cut technology as the Ligasure device but its thickness and bulk make it function poorly as a dissector or a grasper. As such, it may not provide much advantage over the PK dissector for hysterectomies [26, 27]. Surgeons, that utilize this instrument prefer the combined sealing and cutting as compared to the seal and then cut seal and then cut with scissors or monopolar hook stating that this may save time by the combined sealing and cutting of pedicles. This is especially useful for colectomy, or other general surgery procedures. In hysterectomy, if a surgeon wishes to mimic the laparoscopic approach of sealing and cutting utero-ovarian or infundibulopelvic ligaments then sealing and cutting the broad ligament along the uterus until the uterine artery is reached then this instrument may accomplish this effectively. However, authors caution that if the broad ligament is not opened, allowing the ureter to fall ever further inferiorly or laterally, that this may decrease the distance between the ureter and vascular pedicles. This is especially important in cases of distorted anatomy such as in patients with a large fibroid uterus or severe endometriosis. In addition, as this instrument functions poorly as a dissector, the vascular pedicles may not be skeletonized as effectively potentially compromising vessel sealing especially if the vessel size is large such as in patients with large fibroids. It is thus extremely important that surgeons understand the instruments and energy that they are utilizing and watch different surgery styles using these instruments before selecting the method that will achieve both safety and efficiency in their hands.

Instruments for Tissue Extraction

Once a hysterectomy is performed the tissue needs to be removed from the abdominal cavity. In abdominal or vaginal hysterectomies, the pathology is removed via the incision used to obtain access, either abdominally or vaginally. When the laparoscopic approach is undertaken, removal of the specimen is dependent on the type of hysterectomy performed. If a total laparoscopic hysterectomy is performed, then extraction may occur vaginally through the colpotomy incision. Even if the uterus is enlarged, by placing vaginal retractors similar to those utilized in vaginal hysterectomy and using either long single, double, or triple toothed graspers on the uterus, the uterus can be extracted using wedge or strip cutting of the specimen until it is completely removed. If containment of the tissue is a concern, the specimen may be placed into a laparoscopic bag first then by pulling the opening of the bag out through the vagina and placing the

retractors within the bag, morcellation can be performed via the vaginal route in a contained fashion (Fig. 57.18).

If the specimen is too large to pull into the vagina, a small 2–4 cm suprapubic or umbilical incision can be made, placing a small Alexis wound retractor into the wound, grasping the tissue with towel clips or triple toothed graspers and similarly cutting the specimen in a systematic fashion in order to remove it. Again, if containment is desired, the specimen may be placed within a bag first then by pulling the bag up through the incision and placing the alexis retractor within, then morecellation can be performed in a contained environment. Newer bags with the retraction ring already built in have also been released and may be utilized for the same purpose (Fig. 57.19).

For supra-cervical hysterectomy, the cervix is spared and there is no colpotomy incsion. Therefore, the only options for extraction of the uterus with or without the adnexa are mini-lap morcellation or mechanical morcellation. Again consideration should be made for containment of the specimen if required. Mechanical morcellators are devices introduced into the peritoneum through a trochar site which is extended to 15–20 mm with a revolving blade that cuts the specimen into strips for extraction as a grasper pulls the tissue towards to blade pulling the strip out through the morcellator channel. Most mechanical morcellators are disposable and utilize a sharp blade for cutting. Although an energy based morcellator was available from Gyrus, lack of efficiency and excessive smoke production were limiting factors. The rotacut morcellator from Stortz is a re-usable mechanical morcellator in which only the blade is disposable. It is relatively strong and efficient but does require some assembly and does not have a retractable safety guard similar to disposable morcellators. There are several completely disposable morcellators available on the market that vary in their features but are limited by cost and durability. Table 57.6 compares the available morcellators. The Gynecare Morcellex was one of the

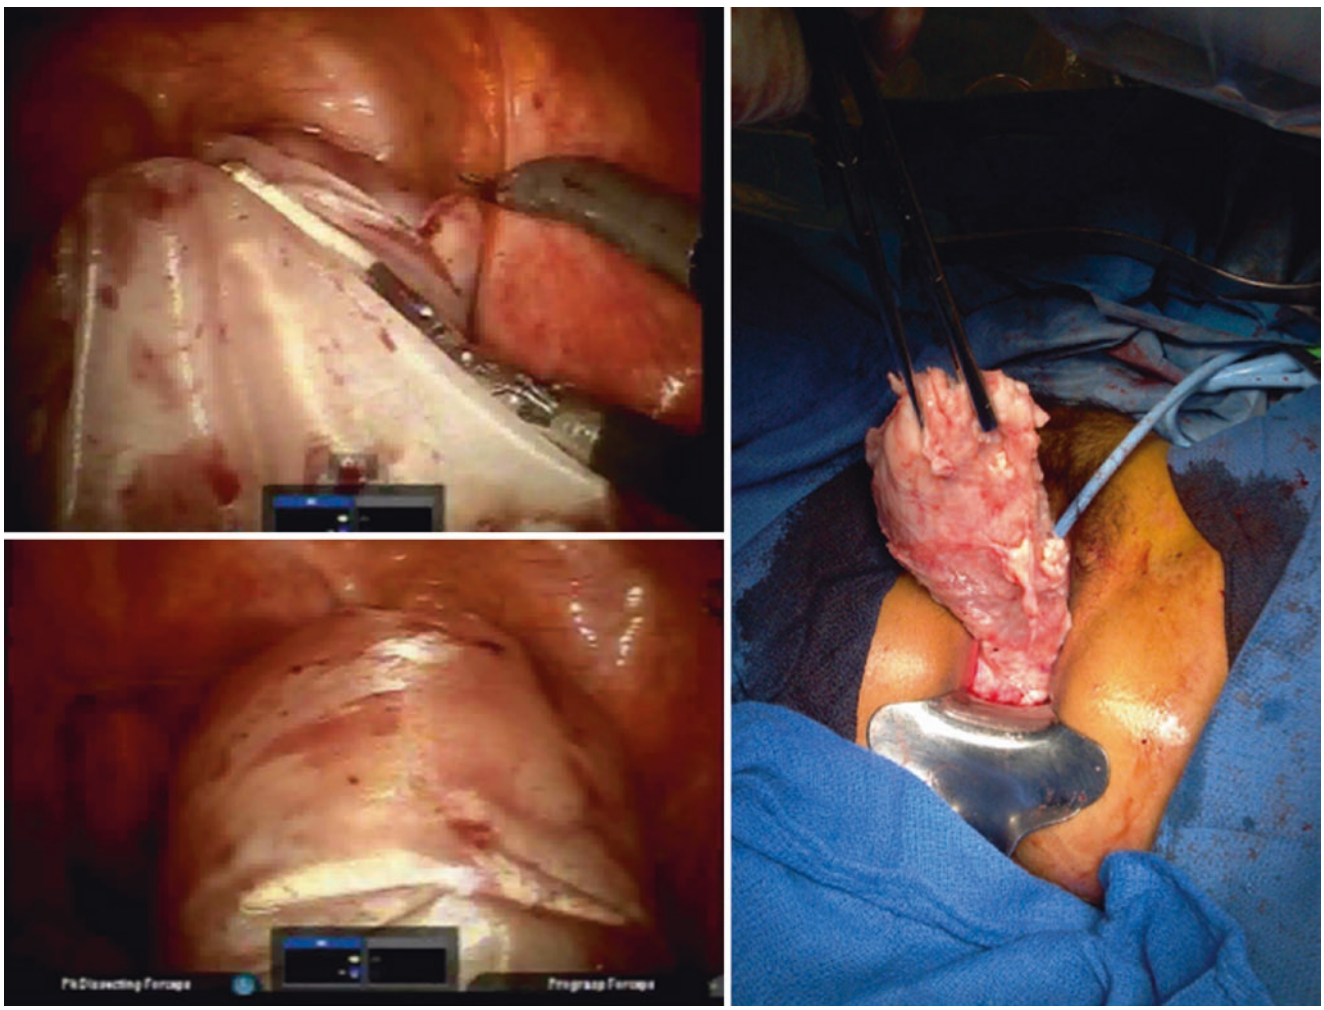

Fig. 57.18 Uterine specimen removed vaginally after placement within a specimen bag and hand scalpel morcellation within the bag. The bag is introduced through the vagina after the colpotomy is completed. The uterus can then be placed within the bag and the bag pulled out through the vagina. Vaginal retractors can then be placed and the uterus can be wedge resected or morcellated with the assistance of a scalpel until it is completely removed

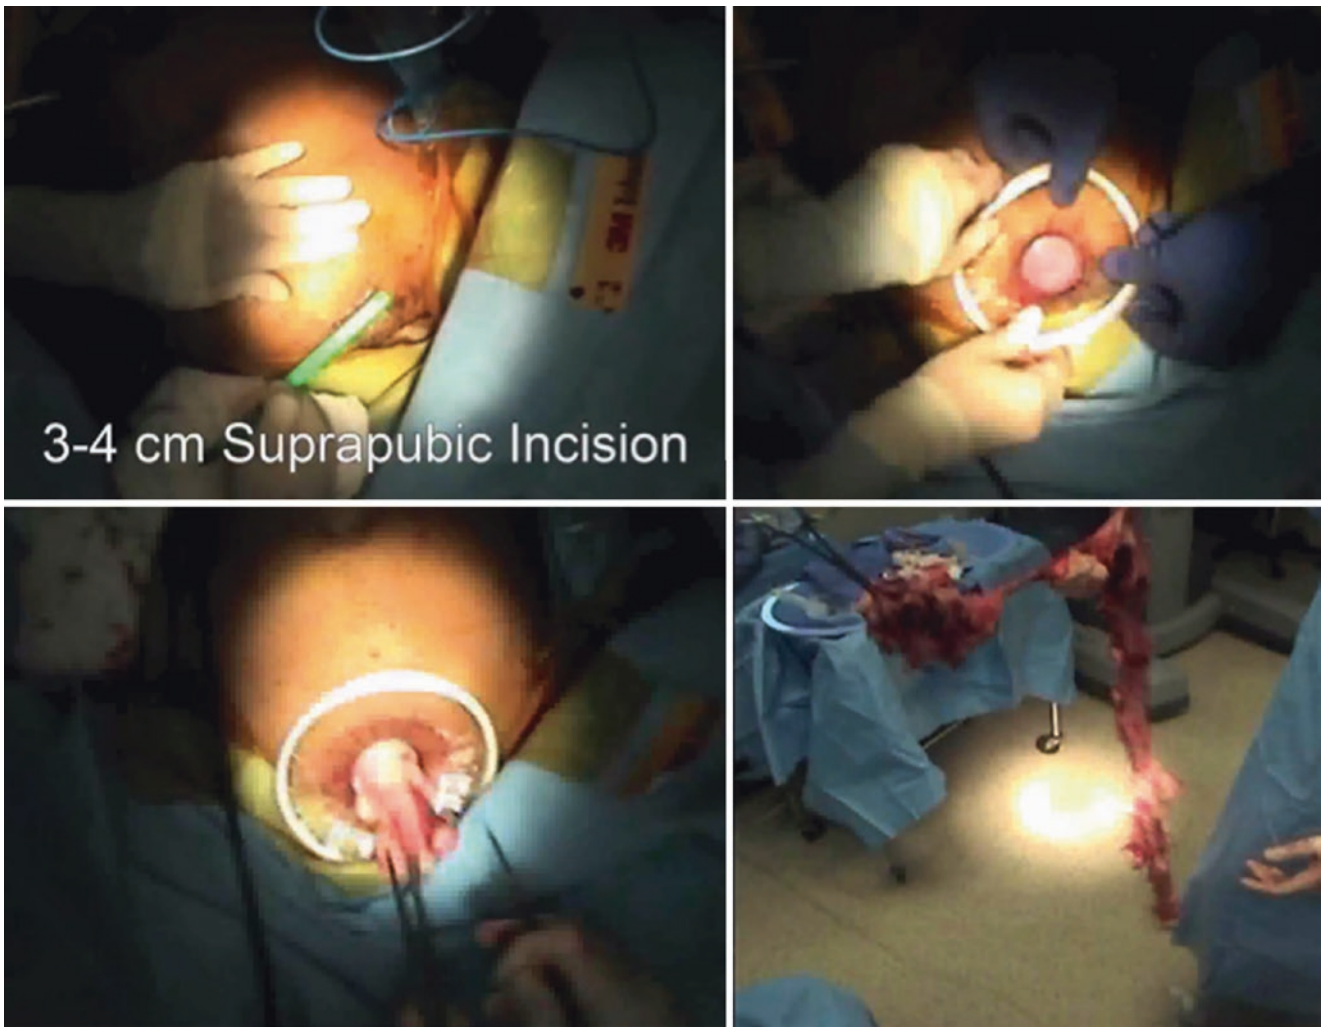

Fig. 57.19 Minilap Morcellation. Specimen is placed within a bag and pulled out through a suprapubic or umbilical incision measuring 2–3 cm. Wound protector/retractor is placed within the bag and scalpel is used to extract specimen using hand morcellation techniques

Table 57.6 Comparison of mechanical morcellators

Morcellator	Disposable	Cordless	Safety guard	Detachable from port	Sizes available	Criticisms
STORZ Rotocut Morcellator	No	No	Yes	No	15 mm	Bulky and heavy in size
	Disposable Blade		Cannula without safety also available for coring			Assembly required
LiNA Xcise	Yes	Yes	Yes	No	15 mm	Battery life is a limitation
		Battery operated				Hand control is only option
Blue Endo MOREsolution Tissue Morcellator	Yes	No	Yes	Yes	15 mm	As does disassemble some practice needed to keep morcellator from detaching from port
				Allows for extraction of tissue that may get stuck in the port	20 mm	
					Allows choice to increase size for larger specimen	
Gynecare Morcellex Tissue Morcellator	Yes	No	Yes	No	15	Inefficient blade
			First to be developed			Tissue fragmentation appears to be excessive
The PKS Plasma Sword Bipolar Morcellator	Yes	No	No	No	15 mm	Extremely inefficient compared to bladed systems
						Excessive smoke production
						Thermal injury is a concern

first disposable morcellators on the market and included the safety guard to protect the blade when not in use. It initially did lack some durability and when the blade dulled it tended to shred tissue leading the surgeon to have to use a second morcellator to complete the case. The Lina morcellator is completely cordless and functions off a battery pack. The Blue endo morcellator comes in both 15 and 20 mm sizes, allowing surgeons to extract larger pathology more easily. In addition, it detaches from its port so that if tissue gets caught within the channel it can be pulled out. Both of these also have a safety guard in their design. The use of morcellators in hysterectomy has been declining since the FDA warning was released in 2013 and many registries and studies are taking place to evaluate possible use of morcellation within containment systems to prevent spread of tissue within the peritoneal cavity during morcellation [28].

Instruments for Vaginal Cuff Closure

Closure of the vaginal cuff in both the Abdominal and Vaginal hysterectomy approaches is relatively simple as compared to Laparoscopic approaches. Although there were a few now abandoned attempts at staple devices used initially in an attempt to expedite abdominal hysterectomy, most surgeons close the vagina using either continuous or interrupted sutures incorporating the cardinal and uterosacral ligaments into the angles in order to provide support. Only a toothed forceps and long handled heavy needle driver are required. Similarly, in Vaginal hysterectomy a heavy Haney needle driver can make suturing the cuff at the apex of the vagina simpler. Again uterosacral ligaments are usually incorporated into the cuff closure in order to provide support and help prevent prolapse of the apex at a later time.

Although, with practice and persistence, laparoscopic suturing can be performed relatively efficiently utilizing either intracorporeal or extracorporeal knot tying utilizing a knot pusher, it is this area in which some devices have been developed in order to assist in vaginal cuff closure or laparoscopic suturing in general. These can be especially useful in single port hysterectomy procedures in which the lack of triangulation makes vaginal cuff suturing extremely challenging. Therefore, some surgeons may choose to either close the vaginal cuff using a vaginal approach or utilize a device to assist with suturing or knot placement. Two categories of such devices exist. The first are devices that assists in passing the needle through tissue and may also expedite knot tying, and another are devices that assists with knot tying by utilizing pre-loaded Roeder knots that are placed after the needle is passed through the tissue using standard laparoscopic suturing techniques. Although some of these devices are re-usable, all require purchasing of suture with needles specifically designed for each particular device and thus the cost of this suture should be accounted for in addition to the cost of the device.

Two examples of devices that assist with knot tying are the Pare Surgical Inc. Quik-Stitch re-usable knot tying device and the Ethicon Endo-Surgery Suture assistant. Quik-Stitch is re-usable, while Endo-surgery Suture assistant can only be reloaded 5 times. Both are 5 mm in diameter and function in a similar manner allowing the surgeon to pass the suture into the peritoneal cavity with a grasper at the end of the device, then after passing the needle through the tissue utilizing standard laparoscopic needle drivers the device is used to place and synch the knot in place.

There are several devices that assist with passing the suture through the cuff, as well as knot tying, by toggling a needle back and forth between tips of the grasping end of the device. Endo evolution Endo360° Reusable Stainless Steel Suturing Device is a 10 mm re-usable device with a curved tip and needle that may be used for vaginal cuff closure purposes as well as other applications. The suture with needle is specifically made for this device and thus must be purchased separately. Covidien has also developed a 10 mm single use device. Covidien Endo Stitch™ single use suturing device uses a straight needle that passes from one jaw to the next after grasping the tissue through which the needle needs to be passed. A similar articulating device, the SILS™ Stitch articulating suturing device performs a similar function but is designed specifically for single port surgery. Again, suture with needles need to be purchased separately. In addition to the expense, the disadvantages of these devices is that it is difficult to compensate for different tissue thickness or to adjust the size of the bites taken as well as with traditional suturing and thus there may be concern for inadeqate closure if not used properly.

Development of a needle driver with a small diameter for mini-laparoscopy that is strong enough to drive a needle through thick vaginal tissue did take some time and surgeon's performing hysterectomy by mini-laparoscopy often resorted to suturing vaginally, as did the surgeons' performing single port hysterectomy. Storz did develop an adequate needle driver which is re-enforced by a low-friction cannula that prevents the needle driver from bending when passing needles through tougher tissue. This now can allow surgeons to utilize a 3.0 mm port site in order to close the vaginal cuff. Both the trochar/cannula set and the needle driver are re-usable stainless steel instruments and thus are cost efficient.

For Hysterectomy, the robotic instrument has simplified vaginal cuff closure by greatly simplifying suturing and knot tying because of the ergonomic intuitive movements of robotic instrument arms completely mimicking open surgical technique allowing suturing in any angle. Although the single port platform still includes instruments that are not wristed, this will also soon change and will simplify single

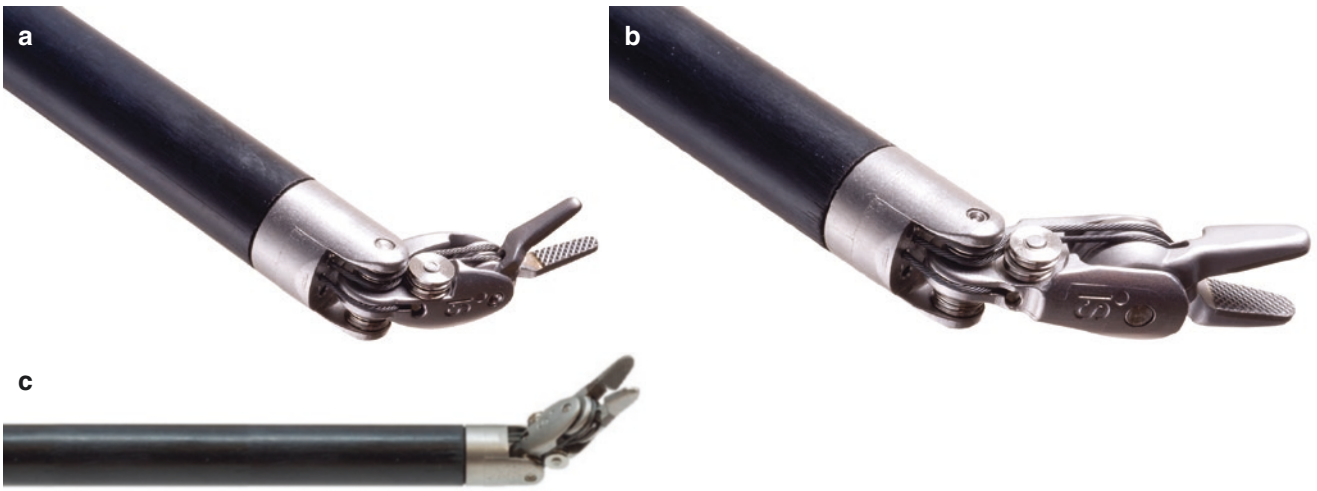

Fig. 57.20 DaVinci Suturing Instruments. For robotic hysterectomy there are two sizes of needle drivers that are available for use in vaginal cuff closure. The large needle driver (**a**) however is not as heavy or as sturdy as the mega needle driver (**b**) which is easier to use on thick vaginal tissue. Both also come as a suture-cut needle driver (**c**) which has a suture scissor in the shank thus allowing the surgeon to save time cutting suture. Initially 5 mm single port robotic needle drivers were not wristed and thus gave the surgeon more difficulty in suturing the cuff, but recently a wristed 5 mm single port needle driver was released greatly simplifying vaginal cuff suturing with the single-port platform

port robotic hysterectomy as well. Options for instrumentation for grasping the vaginal cuff include the Pro-grasp (often used for retraction with fourth arm during the case), the toothed cobra grasper, the long-tipped forcep, or the bipolar instrument utilized during the case such as the bipolar Marylyn or fenestrated bipolar instrument. As each robotic instrument utilized during the case costs money, most surgeons will try to use one of the instruments used earlier during the case for elevation and manipulation of the vaginal cuff rather than choosing a specific instrument solely for this purpose. For optimal suturing however, a needle driver should be used for driving the needle and trying to drive the needle with one of these other instruments may be cumbersome and cost time. In general, the heaviest option for needle driver should be chosen as the vaginal cuff tends to be relatively tuff tissue as compared to bowel or bladder for which a smaller (Large) needle drive is often used. One may choose either the option which incorporates scissors into the needle driver (Mega-Suture cut) or the needle driver on its own (Mega) needle driver and utilize their assistant for cutting the suture [26] (Fig. 57.20).

Conclusion

A well-informed surgeon should study and know the uses and limitation of the instruments available before selecting the appropriate instrument for the procedure and task at hand. Hysterectomies are one of the most commonly gynecologic procedures performed in women. The ultimate goal of a surgeon is to perform the procedure efficiently and safely while causing the least amount of trauma to the tissue and patient. Technology and devices is now allowing these procedures to be performed in most women utilizing minimally invasive surgical techniques, minimizing the need for laparotomy. Whether the vaginal, laparoscopic, mini-laparoscopic, single port, or robotic approach is undertaken, both patient selection and the choice of the appropriate instruments will determine the overall success of the procedure.

Diagnostic Laparoscopy via the Da Vinci Robot in General and Site Recognition

58

Agnieszka Oleszczuk-Cosse

Introduction

The robot assisted surgery is an innovative technique to perform laparoscopic procedures that is still evolving and is open for new operative possibilities. Robotic precision in tumor excision, easier intracorporal suturing and favorable ergonomics for the surgeon make the da Vinci robot particularly suitable for performing complex laparoscopic microinvasive surgical operations [1]. However, diagnostic laparoscopic procedure needs to be performed before every operation with the Da Vinci robot. Ongoing efforts to improve the morbidity and cosmesis have led to minimization of size and number of ports required for laparoscopic surgery. Single port laparoscopy or Laparo-Endoscopic Single Site surgery (LESS) represent the latest innovation in minimally invasive surgery. The advantages of the LESS via Da Vinci robot, with the use of only one port for a 3D camera and intuitive instruments together with the option to perform a tissue biopsy and a variety of therapeutic interventions through only one incision could be used also specifically for a diagnostic laparoscopy in a future.

The robotic surgery provides also the possibility of: performing an intraoperative ultrasound as well as through a Firefly™ Imaging System blood or lymph vessel or bile duct flow, now used in gynecologic oncology for real-time lymphangiography.

Thanks to better ergonomics of minimal invasive procedure, 3D stable visualization of enlarged operations field, and improvement of dexterity, as well as a use of a second console for assisted learning and also the intraoperative possibility of drawing lines on the screen showing the actual surgical site, the robot assisted surgery is the most effective way to teach and to learn pelvic anatomy and new surgical techniques due to a better site recognition. Through the extensive knowledge of the anatomy, the identification and the appropriate exposure of the surgical region with a safeguard of relevant structures like: ureter and depending on the operation also uterine artery and/ or pelvic nerves, almost every operation via the Da Vinci robot has a potential to be performed near to bloodless.

Diagnostic Laparoscopy via the Da Vinci Robot in General

Diagnostic laparoscopy via the Da Vinci robot is a minimally invasive method for identification of all relevant abdominal and pelvic structures and for the diagnosis of intra-abdominal diseases by direct inspection of intra-abdominal and intrapelvic organs with a possibility for a tissue biopsy, a culture acquisition, and a variety of therapeutic interventions.

Indication

The diagnostic laparoscopy is performed before every minimal-invasive operative procedure via the Da Vinci robot (Table 58.1). However, some surgeons preceding the previously planned robotic operation still prefer to perform the diagnostic laparoscopy by a gold standard method through a conventional laparoscopy [2].

The diagnostic laparoscopy via Da Vinci robot as a staging procedure of early cervical and endometrial cancer is useful for making a definitive clinical diagnosis whenever there is a diagnostic dilemma even after routine diagnostic workup. By enabling accurate staging, diagnostic laparoscopy permits patient selection for curative resection or a neoadjuvant chemotherapy while avoiding nontherapeutic laparotomy, which is associated with a delay in initiation of chemotherapy.

However, for other indications like: identifying the cause of infertility, acute or nonspecific abdominal pain, suspected intra-abdominal injuries or anatomical pathologies is the

Table 58.1 Indications for a diagnostic laparoscopy via the Da Vinci robot and via the conventional standard method with advantages and disadvantages of the Da Vinci robot in comparison to the conventional laparoscopy

Indications for a diagnostic laparoscopy	Via the Da Vinci robot	Via the conventional laparoscopy	Advantages of the da Vinci over the conventional laparoscopy	Limitations of the da Vinci in the shadow of the conventional laparoscopy
Laparoscopic operative probedure	Before every robotic operative probedure	Before every (robotic or conventional) laparoscopic operative probedure	Ergonomics Intuitive instruments 3D	Higher costs of the system An absence of a tactile feedback Additional time for docking Additional learning curve
Cervical or endometrial cancer	Before planned lymphadenectomy by an early cervical or endometrial cancer	Just to examine the abdomen and pelvis with or without planned lymphadenectomy		
Infertility	Only before a specific operative procedure	Just to examine the abdomen and pelvis with or without planned operative proceure		
Abdominal pain	Only characteristic pain before a specific operation for example on an endometiose	Acute and non-specific with or without planned operative proceure		
Suspected abdominal injuries	Only before a specific operation	With or without planned operative proceure		
Anatomical pathologies	Only before a specific operation	With or without planned operative proceure		

standard conventional laparoscopy the procedure of choice and the use of Da Vinci robot is until now still suboptimal. Although the robotic surgery is very advantageous through better ergonomics and intuitive instruments, for a short basic procedure as a diagnostic laparoscopy those advantages are not able to overwhelm still existing limitations of the robotics like much higher costs of the system maintenance and disposables per case as well as the absence of tactile feedback.

Procedure

Before the start of every robotic case, a patient is placed in low dorsal lithotomy position with arms padded and tucked at the sides of the patient after general anesthesia is administered. The bladder is drained with an indwelling urinary catheter, and if needed: a uterine manipulator, and alternatively an intrauterine catheter for chromopertubation is placed to assess tubal patency intraoperatively. Typically four trocars are used after pneumoperitoneum is obtained. A long 12-mm trocar is placed usually at the umbilicus or above it (depending on the size of the pelvic pathology or art of the planned operative surgery). This trocar serves the 3-dimensional robotic camera. Previously, it is possible to place an entry with a 3-mm micro-laparoscope in a left upper quadrant to help guide all other operative trocarplacements in patients with enlarged pelvic pathology or who may are at risk for intra-abdominal adhesions. Further, two 8-mm trocars are placed in the left and right lower quadrants, respectively. A fourth trocar as an accessory port can be placed between the camera port and the right lower quadrant port or also in the left upper quadrant. This trocar is typically 12 to

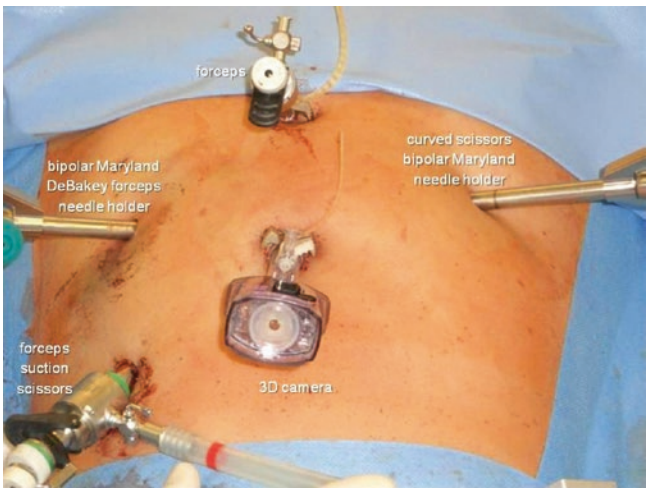

Fig. 58.1 Possible placement of trocars for a diagnostic and an operative laparoscopy via Da Vinci robot with an example of the instruments used in those trocars. A long 12-mm trocar at the umbilicus: is for 3-dimensional robotic camera; two 8-mm trocars are placed in the left and right lower quadrants are for: bipolar Maryland, DeBakey forceps, needle holder; and curved scissors, bipolar Maryland, needle holder, respectively; a left upper quadrant accessory entrance for: forceps, suction, scissors, or a special trocar a 3-mm microlaparoscope

15 mm to enable an introduction of other laparoscopic instruments for suction-irrigation, traction and countertraction or a possibility for introduction of a suture or probe for microbiologic examination. Additionally one 5-mm trocar above the symphysis can be placed for traction/ countertraction as needed.

Once all trocars are in place (Fig. 58.1), the patient can be placed in steep Trendelenburg position and the surgical cart with three robotic arms can be brought between the patient's legs and docked. Then, each trocar can be attached to the

assigned robotic arm with the exception of the accessory port(s) that are manipulated by the bedside surgical assistant(s). The robotic arms are docked to the assigned trocars: right and left operating robotic arms directly to the right and left lower quadrant trocars, respectively, whereas the robotic camera arm to either umbilical or supraumbilical trocar. Then the diagnostic laparoscopy can be performed while adhering to the basic principles of conventional diagnostic laparoscopic technique. A systematic examination of the abdominal and pelvic sites as well entire abdominal and pelvic viscera, including the peritoneum, omentum, liver, uterus, fallopian tubes, ovaries and bladder is performed to identify any pathology and its extension.

After the diagnostic procedure and depending on the diagnosed, abdominal and pelvic status, the planned operative procedure via Da Vinci robot can begin. If there is, however, an evidence of widespread or peritoneal-based disease, or for example bladder, rectum or depending on the operation lymph node metastasis diagnosed, or when there is a direct extension of the pathology to surrounding structures that preclude its respectability, the diagnostic laparoscopy procedure via Da Vinci robot may need to be terminated after taking confirmatory biopsy specimens.

To end the procedure, an adequate hemostasis and correct instrument and gauze and sponge counts is ensured. Ports are removed under direct visualization to prove that there is no visceral herniation or bleeding. A decompression of the abdominal cavity by expelling the pneumoperitoneum to reduce postoperative shoulder pain is performed. All port sites greater than 5–10 mm should be closed with an absorbable suture and skin is closed with either continuous or interrupted subcuticular sutures.

Possible complications typical for laparoscopy are the same for conventional as well as via Da Vinci robot and include fatal gas embolism, problems due to hypercarbia, postoperative crepitus, and pneumothorax, as well as procedure-specific complications for the diagnostic laparoscopy such as uterus, bladder, bowel, nerves and/or vessels injury.

Further Possibilities through Innovations

Ongoing advancements in surgical instruments, optics, and ports have allowed the development of new options for intraoperative procedures with the Da Vinci robot.

Single Port Surgery

LESS is surgical term used to describe various techniques that aim at performing laparoscopic surgery through a single, small skin incision concealed within the umbilicus. Single port techniques may help to reduce postoperative pain, promote earlier return to daily activities, and improve cosmesis and patient satisfaction. There is also a potential reduction in other complications associated with multiple incisions, such as port-site hernias and hemorrhage [3]. Recently published outcome data demonstrate feasibility, safety and reproducibility for LESS in gynecology in general but comparative data and prospective trials are required to determine the clinical impact of LESS in treatment under gynecologic conditions [4]. The Da Vinci robotic system with articulating instruments can also be integrated with LESS for many gynecologic surgical procedures. However, we are still far from the ideal robotic platform. Significant improvements are needed before this technique might reach widespread adoption beyond selected centers [5].

Advantages of the single-port robotic surgery over conventional multi-port laparoscopy include better cosmesis from a hidden umbilical scar, a possible decrease in morbidity that can result from visceral and vascular injury during trocar placement, a decrease in post-operative wound infections, hernia formation, an elimination of multiple trocar site closures, 3D visualization, and improvement of dexterity. Escobar et al. found, using robotic-assisted LESS for bilateral salpingo-oophorectomy and total hysterectomy, that the Da Vinci robotic LESS attempts to further enhance cosmetic benefits and reduce morbidity of minimally invasive surgery in gynecology, and the use of LESS improved patient recovery time and cosmesis [6].

Significant advances have been achieved in the field of robotic LESS since the first reported clinical series in 2009. The ideal robotic platform should have a low external profile, the possibility of being deployed through a single access site, and the possibility of restoring intra-abdominal triangulation while maintaining the maximum degree of freedom for precise maneuvers and strength for reliable traction [5]. A very promising new robotic development in form of instruments created for a combined use with one single port is da Vinci Sp Single Port Robotic Surgical System (Intuitive Surgical ®) that consists of three articulating endoscopic instruments and an articulating endoscopic camera inserted through a single robotic port (Fig. 58.2). The patient side cart uses the same basic cart as the da Vinci Surgical System, but the configuration of the surgical arms and manipulators are changed to manipulate the unique EndoWrist Sp instruments and a 3D high definition camera through a single port: a 25 mm cannula. This device is already available and approved by FDA up until now for special urologic procedures only. The robotic intuitive instruments available to be used by the system include flexible endoscopes, blunt and sharp endoscopic dissectors, scissors, forceps, needle holders, endoscopic retractors, electrocautery and accessories for manipulation of tissue, including grasping, cutting, blunt and sharp dissection, approximation, ligation, electrocautery and suturing. The instruments have also two more degrees of freedom than the da Vinci Single-Site instruments previously

Fig. 58.2 Da Vinci Sp Single Port Robotic Surgical System (Intuitive Surgical ®) that consists of three articulating endoscopic instruments and an articulating endoscopic camera inserted through a single robotic port

available allowing substantially more control for the surgeon. This da Vinci Sp Single Port Robotic System could further overwhelm the limitations of robotics and be very advantageous for cosmesis especially by performing as basic as a diagnostic procedure.

Laparoscopic Ultrasound

For a diagnostic purpose, to evaluate organs that are not amenable to inspection during an operative laparoscopic procedure via Da Vinci robot, also a laparoscopic ultrasound is possible to be performed by using a unique specialized ultrasound transducer for robotic-assisted surgery (BK Medical ProART™ 8826 Robotic "Drop-in" Transducer, Intuitive Surgical®) that fits through a standard robotic trocar.

Ultrasound during diagnostic laparoscopy via the Da Vinci robot, already used during urologic procedures, could be very useful especially proceeding oncologic procedures for example to see intraoperative high resolution real-time borders of a tumor on the same screen as an robotic operative field.

Fluorescent Robotic Lymphangiography

The ability to view intraoperative blood or lymph vessel, or bile duct flow provides a Firefly™ Fluorescence Imaging System, now used in gynecologic oncology for robotic real-time lymphangiography. The Firefly™ Imaging System is build inside the Da Vinci 3D camera and forms the Da Vinci Fluorescence Imaging Vision System for the Da Vinci Surgical System. During a sentinel lymphadenectomy operation for cervical or endometrial cancer, when indicated, this specifically built camera enables the performance of diagnostic real-time fluorescent lymphangiography, called also near-infrared (NIR) fluorescent robotic lymphangiography [7, 8].

Before the diagnostic lymphangiographic procedure an indocyanine green (ICG) fluorescent glowing dye is injected into the cervix. The ICG naturally binds to albumin that flows in lymph vessels. The da Vinci® Fluorescence Imaging Vision System is a special Da Vinci camera with excitatory light source for laser (Firefly™) built inside the scope. The Firefly Imaging System is intended to be used along with the usual white light as usual during an operation and, when indicated, the light source for laser (Firefly) can be activated and intraoperative real-time lymphangiography can be performed. For that, while operating, a surgeon turns on the Firefly through the console, then from the Firefly source in the scope the 803 nm wave length laser illuminates the surgical scene, the ICG dye is excited and glows green signal, showing the path of vessels to the Da Vinci camera and this into the vision cart. That enables surgeons to see the in real-time the green lymph vessels as the tissue without lymph flow appears gray. This provides the ability to view a real-time imaging of lymphatic tissue during lymphadenectomy.

Near-infrared (NIR) fluorescence imaging with intracervical ICG injection using the robotic platform has a high bilateral sentinel lymph node detection rate and appears more favorable than using blue dye alone and/or other modalities [8].

Site Recognition via the Da Vinci Robot

By operating via the Da Vinci robot it is important to recognize not only the surgical site where the 3-D camera is directed but also the structures that are in that region before and during a performed dissection.

Transperitoneal Site: Before any Dissection

During the diagnostic laparoscopy via the robot Da Vinci many additional key vascular structures can be identified transperitoneally before any dissection:

- The internal iliac artery runs parallel and just posterior to the ureter.
- The external iliac artery is several centimeters anterior to it on the psoas muscle.
- The external and internal iliac arteries can be followed superiorly to find the bifurcation of the common iliac arteries at the pelvic brim overlying the sacroiliac joint. This is an ideal place to identify the ureter transversing the point of bifurcation as it enters the pelvis.
- The right common iliac artery can be followed superiorly to the bifurcation of the aorta, above the presacral space at approximately the fourth lumbar vertebra.
- The left common iliac artery is difficult to identify because of the overlying mesentery of the sigmoid colon.

– The left common iliac vein is located just medial and inferior to the left common iliac artery in the presacral space. It may also cover the entire space between the both common iliac arteries [11].

Retroperitoneal Site: During Abdominal Dissection

The recognition of structures in an abdominal site and a presacral region are important for procedures like paraaortic lymphadenectomy or ovarian transposition. The structures, important to recognize for paraaortic lymphadenectomies are from right to left: the psoas muscle; ovarian vessels; the right ureter that runs medial at this point to the psoas muscle and lateral to the inferior vena cava (Fig. 58.3); vena cava that runs to the right lateral of the aorta; aorta and both common iliac arteries. Below the bifurcation of the aorta superficially in a presacral region is the superior hypogastric nerve plexus and the presacral nodes, and beneath them, the left common iliac vein crossing from the left to the right. On the left side of the aorta are further: the inferior mesenteric artery, the sigmoid colon, and its mesentery. Deeper medially, there are the lumbar veins and artery; laterally is the left ureter (Fig. 58.4) and on the far left is the psoas muscle.

Retroperitoneal Site: During Pelvic Dissection

The pelvic site is the main operating field in the gynecology. Therefore, through the knowledge of the anatomy and the identification of the three vascular pelvic regions: the pelvic brim, the pelvic sidewall and the base of the broad ligament, position of the ureter, as well as of the eight avascular spaces and through exposure and safeguard of the relevant anatomy, the operation via the Da Vinci robot can be performed near to bloodless. Therefore it is crucial to identify the structures and where is the ureter running within those regions.

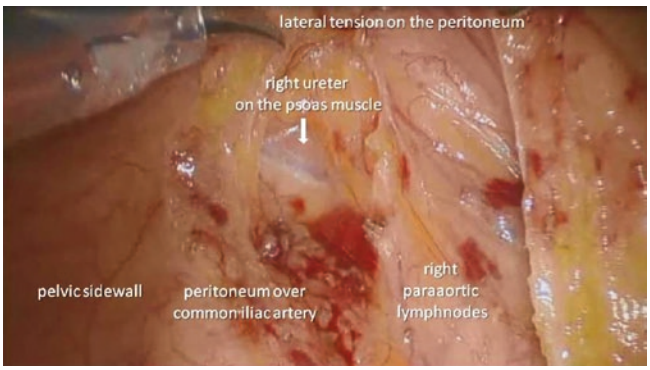

Fig. 58.3 Before the right paraaortic lymphadenectomy: identification of the right ureter. The right ureter runs medial to the psoas muscle

Vascular Regions

At the **pelvic brim** region we find vertically peritoneum, underneath that ovarian vessels in the infundibulopelvic ligament and medially is the ureter crossing over the bifurcation of the common iliac to internal and external artery (Fig. 58.5), underneath that is common iliac vein, further underneath is obturator nerve: exiting the psoas muscle medially to pass over the pelvic brim to the pelvic sidewall; and underneath that is the sacroiliac joint. The pudental nerve and the ureter comes into the pelvic brim in a vertical fashion, and then rotates in 90° to enter the pelvic sidewall.

In the **pelvic sidewall** region there are three surgical layers. The first pelvic sidewall layer is the ureter layer, where the ureter is enveloped in its own visceral sheet of visceral connective tissue [10]. There, an ureterolysis is performed posteriorly to the base of the broad ligament (Fig. 58.6). It leads inferiorly further to the pararectal space. The second pelvic sidewall layer is a vascular layer, which is also a safe zone for coagualtion and cutting that consists of the internal iliac vessels and their branches (Figs. 58.6 and 58.7). And last but not least, the third pelvic sidewall layer is a parietal

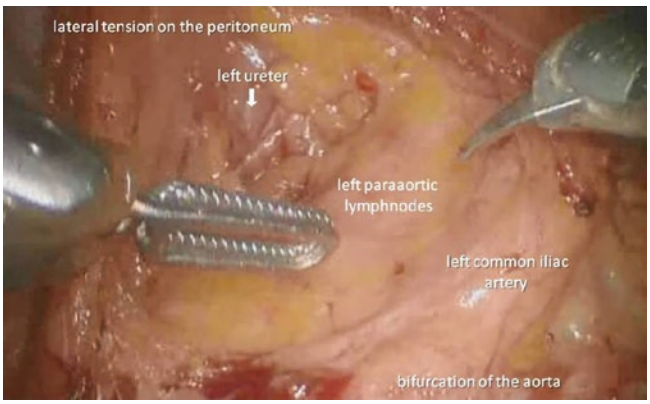

Fig. 58.4 Before the left paraaortic lymphadenectomy: identification of the left ureter. On the left side of the aorta laterally is the left ureter

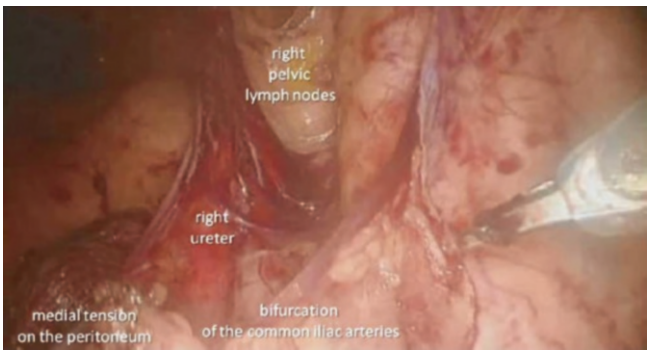

Fig. 58.5 Before the right pelvic lymphadenectomy identification of the right ureter in a peritoneal flap. At the pelvic brim region medially is the ureter crossing over the bifurcation of the common iliac to internal and external artery

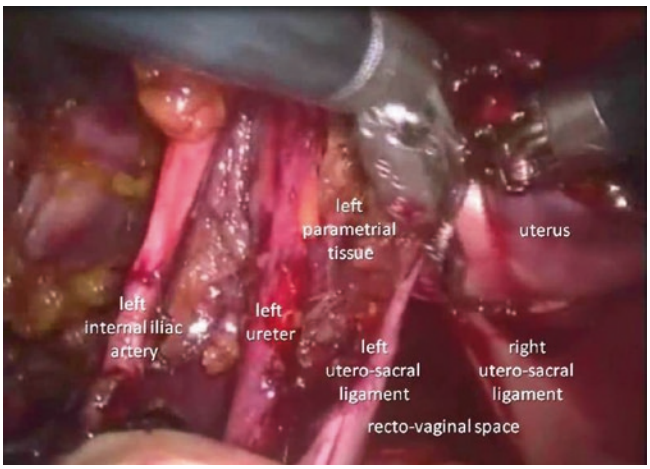

Fig. 58.6 After the ureterolysis and the dissection of uterine artery just before the arametrectomy on the left side by performing robotic radical hysterectomy. The rectovaginal space was previously entered vaginally. In the first pelvic sidewall layer is the ureter layer, where the ureter is enveloped in its own visceral sheet of visceral connective tissue. There is performed ureterolysis posteriorly to the base of the broad ligament

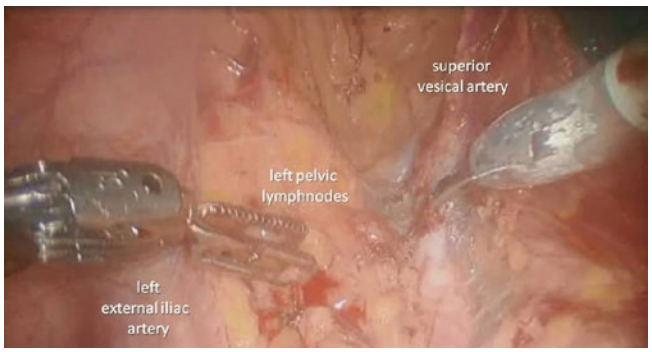

Fig. 58.7 Before the left pelvic lymphadenectomy: identification of the left superior vesical artery. The second pelvic sidewall layer is a vascular layer, which a safe zone that consists of the internal iliac vessels and their branches (here superior vesical artery)

layer that consists of the external iliac vessels on the medial board of the psoas muscle and obturator vessels and nerve on the anterior portion of the obturator internal muscle (Fig. 58.8). The base of the pelvic sidewall is a base of the broad ligament.

By every laparoscopic hysterectomy technique also performed by the robot Da Vinci the broad ligament is dissected. Anteriorly to the dissected ligament the bladder flap is developed in a vesico-vaginal space, posteriorly to the dissected ligament the posterior peritoneum of the uterus is dissected toward the base of the uterosacral ligaments where the uterosacral ligaments meet the cervix (Fig. 58.9). With the push-press dissection technique the uterine artery is identified and skeletonized laterally from there. Then the uterine artery is followed to find the ureter in the base of the broad ligament.

The **base of the broad ligament** region is a place to find where the ureter passes underneath the internal iliac artery (Fig. 58.10), 1–2 cm medial to the cervix but 2–3 cm medial

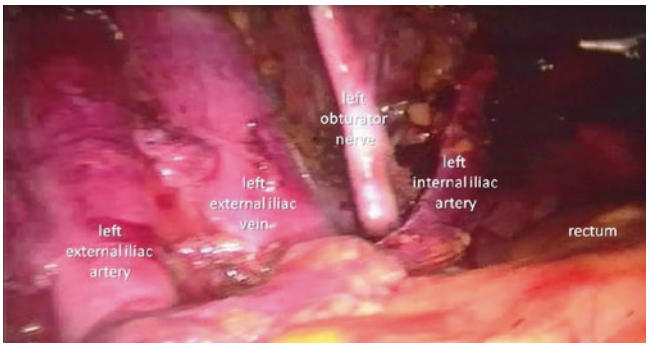

Fig. 58.8 Situs after the left pelvic lymphadenectomy. The third pelvic sidewall layer is a parietal layer that consists of the external iliac vessels and obturator nerve

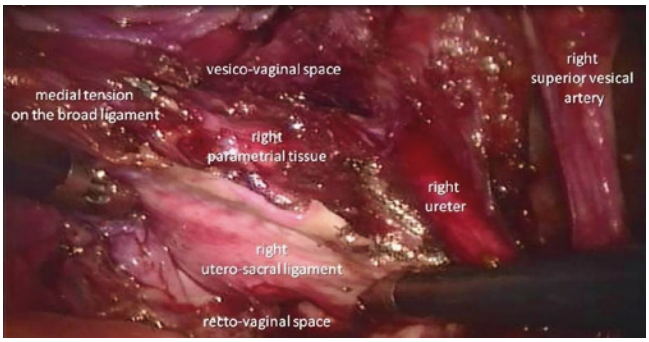

Fig. 58.9 After the ureterolysis, during the right parametrectomy by performing the robotic radical hysterectomy on the right side. The avascular vesico-vaginal and recto-vaginal spaces were previously entered vaginally. The dissection of the base of the broad ligament: anteriorly to the parametrial tissue is a vesico-vaginal space, posteriorly is the utero-sacral ligament. Here the rectovaginal space was previously entered vaginally

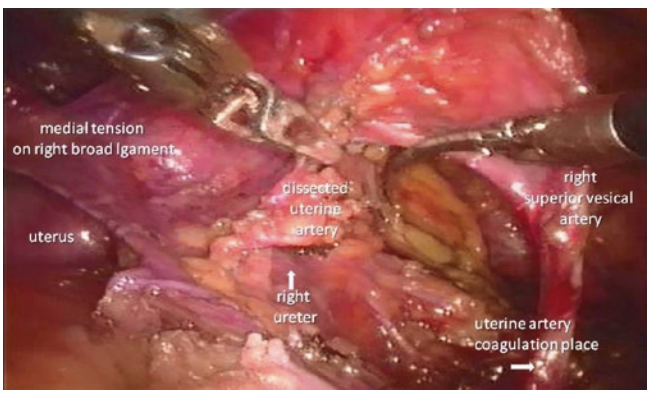

Fig. 58.10 After a dissection of the right uterine artery running over the right ureter, during robotic radical hysterectomy procedure. The ureter passes underneath the internal iliac artery at the base of the broad ligament region

and superior to the ischial spine. It is also the base of the cardinal ligament. The dissection allowed at the base of the broad ligament region is without cutting, only tenting, traction and counter-traction, push-press technique.

The further dissection anteriorly and inferiorly from the base of the broad ligament leads to the paravesical space which is simply also a paravaginal space and then more anterior and medial dissection leads into retropubic space of Retzius. The dissection posteriorly and inferiorly from the base of the broad ligament leads to the pararectal space.

Avascular Spaces

Three pairs of ligaments: uterosacral ligament (rectal pillars), cardinal ligament and vesicouterine ligament (bladder pillars) divide the pelvis into six potential avascular spaces with some vascular boarders: presacral, pararectal space, rectovaginal space, vesicovaginal space, paravesical/ paravaginal/ obturator space, prevesical (retropubic) space of Retzius [12].

The **presacral (retro-rectal or perlumbal) space**: is boarded laterally on the right side with the right ureter, on the left side with the left common iliac artery. It begins at the bifurcation of the aorta into the common iliac which boarder this space and lead into the pelvic brim. At the base of the mesosigma just inferior to the aortic bifurcation, the superior hypogastric plexus can be identified.

The **pararectal space**: is triangular, with the base of the cardinal ligament representing the anterior boarder. The medial boarder is the ureter and the rectal pillars (uterosacral ligament) with the rectum and the hypogastric nerve adhering medially to the mesorectum (Fig. 58.11) and the lateral border is the internal iliac artery and the iliococcygeus fascia and muscles. The hypogastric nerve is a continuation of the superior hypogastric plexus on either side. Inferiorly the hypogastric nerve, where the pelvic splanchnic nerves and the sacral splanchnic nerves join, form the inferior hypogastric plexus on the lateral surface of the uterosacral ligament (Fig. 58.12). On the floor is levator ani muscle and it leads to ischial spine and sacrospinous ligaments. The pararectal space is crossed by the vesical and rectal nerve plexuses. This space can be easily developed by bluntly dissecting

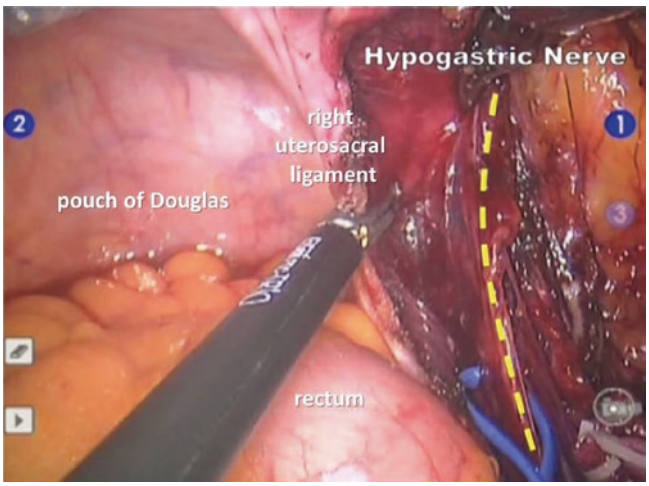

Fig. 58.11 Right pararectal space is triangular, the medial boarder is the right ureter and the right rectal pillars (uterosacral ligament) with the rectum and the right hypogastric nerve (right pelvic nerve) adhering medially to the mesorectum, to the lateral side of the right uterosacral ligament (rectal pillars). The right hypogastric nerve will be isolated till the cut end of the uterine vein and will be preserved by the devision of the right uterosacral ligament during nerve-sparing hysterectomy (Photo from educational video by Maggioni [9])

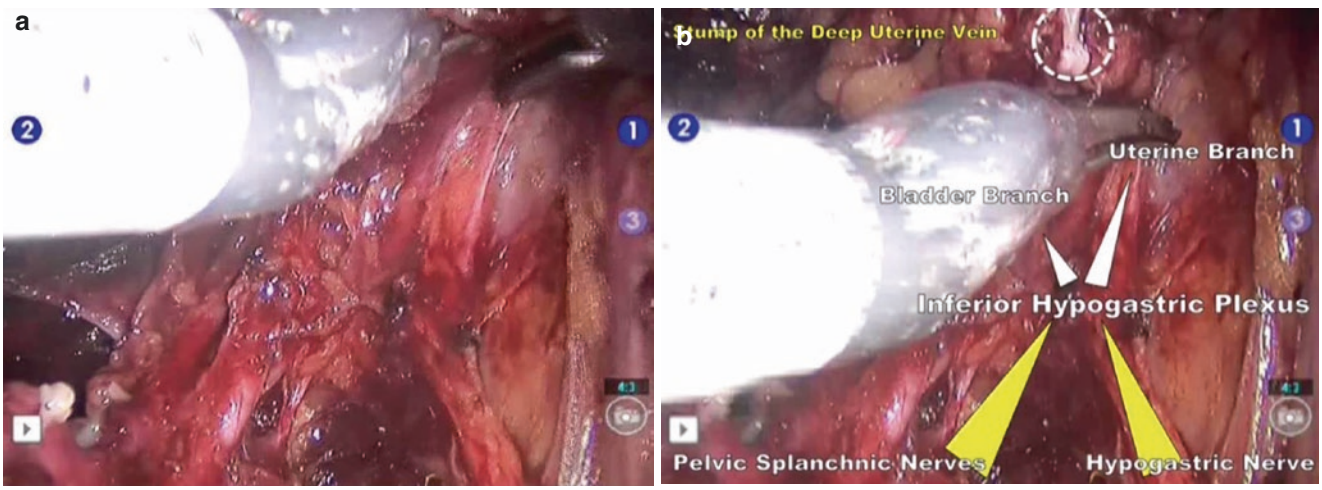

Fig. 58.12 Inferior hypogastric plexus (pelvic plexus) on the lateral surface of the uterosacral ligament. It is formed as a junction of splanchnic nerves and hypogastric nerve and has the bladder and the uterine branch. Only the uterine branch of the inferior hypogastric plexus is resected by the nerve-sparing radical hysterectomy. Left pararectal space after isolation and transsection of: the uterine artery, the superficial uterine vein and the deep uterine vein. The stump of the deep uterine vein is elevated up the level of hypogastric nerve (Photos from educational video by Maggioni [9])

posteriorly to the origin of the uterine artery and lateral to the ureter.

The **rectovaginal space**: is a safe avascular space, what is used for repair of the posterior vaginal wall defects or rectocel. It is framed by: superiorly with cul-de-sac peritoneum and utero-sacral ligaments; laterally: with iliococcygeus muscles; posteriorly: with rectum and its visceral fascial capsule with rectal fat; anteriorly: with vagina and its visceral fascial capsule; inferiorly: with perineum. It builds rectovaginal fascia/ septum. It is necessary to perform initially the ureterolysis on the both sides and then the dissection of the uterosacral ligaments to get to and dissect safely this rectovaginal space. To enter the space of the rectovaginal septum a transverse incision is made over the posterior cervix superiorly between the two uterosacral ligaments, also known as the medial-rectal-pillars. Then, the rectum is dissected inferiorly until the uterosacral ligaments are identified and transsected, thereafter, the rectovaginal space may be entered.

The **vesicovaginal space**: is a potential space between the bladder and the vagina (Fig. 58.13). Therefore, it has to be developed to mobilize the bladder of the lower uterine segment and the upper third of the vagina. Its lateral boarder is: the bladder pillars with ureters on the both sides. It is covered by the anterior peritoneal reflection and must be dissected for the completion of the hysterectomy to develop the bladder flap as a crucial part of that operation (Fig. 58.14). The dissection in this space is important to be performed medially and centrally, away from the bladder pillars in which are vascular vessels as well as the ureter. Once the dissection is done from both sides the bladder can be dissected of the cervix with cold scissors using push-(from below to the bladder)-cut-spread technique.

The **paravesical and paravaginal, and obturator space**: is anterior and inferior to the base of the broad ligament. Its boarders are: medial: the bladder and anterior vagina; lateral: obturator internus fascia with obturator nerve and vessels; floor: fascia endopelvina and the "white line": the arcus tendineus of the pelvis; posterior: internal iliac vessels and ischial spine; anterior: back of pubic bone. During dissection in the obturator space: in a straight line underneath the place where the obturator nerve enters the obturator foramen is the ischial spine with the pudental nerve behind the sacrospinal ligament. The obturator space and paravesical space are particularly important in pelvic lymphadenectomy, paravaginal space in nerve-sparing radical hysterectomy (Figs. 58.7 and 58.15).

The **prevesical (retropubic) space of Retzius** is the retropubic continuation of the paravesical space. It is located between the posterior part of the pubic bone and Cooper's ligament, which is its anterior boundary. Posteriorly is the anterior part of the bladder, lateral: the internal obturator

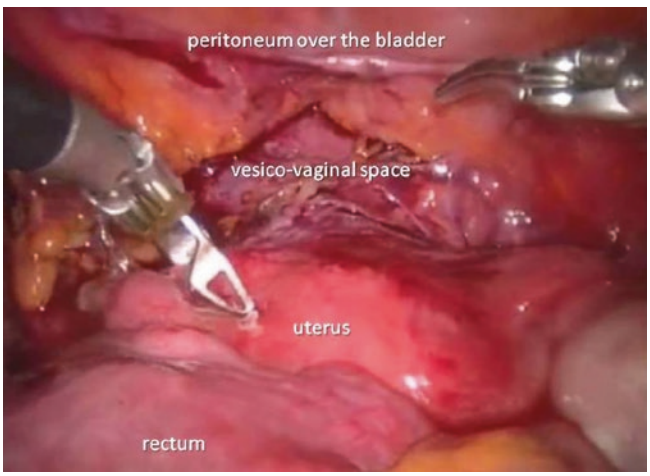

Fig. 58.13 After opening of the vesico-vaginal space before the robotic radical hysterectomy. The vesicovaginal space is a potential space between the bladder and the vagina

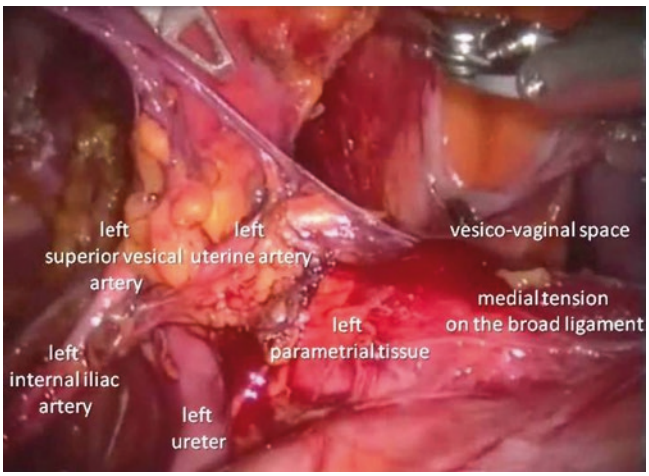

Fig. 58.14 After the ureterolysis, before the robotic radical hysterectomy on the left side. In the vesicovaginal space: the bladder flap was developed

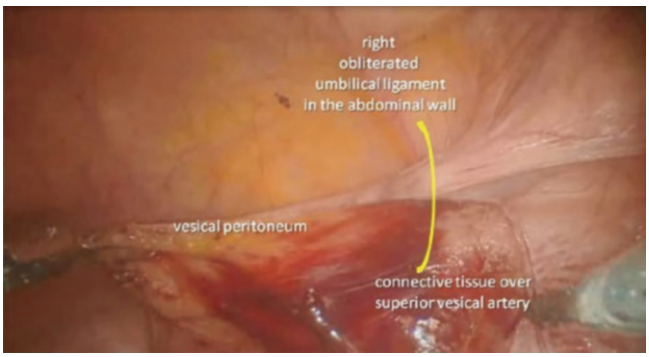

Fig. 58.15 An opening of the right paravesical space. By pulling up and down on the obliterated umbilical ligament the superior vesical artery can be easily identified and medial to that the paravesical space opened. After identification of the superior vesical artery and following it cranially the first medial branch of it is the begin of the uterine artery

muscle and it is continued posteriorly with the vesicovaginal space. The floor is the pubocervical (paravaginal) fascia, inserted into the tendinous arch in the internal obturator fascia. During the Retzius space development with blunt and sharp dissection of fibrofatty tissue a special care needs to be taken to avoid periurethral neurovascular injury.

Laparoscopic Identification of the Ureter, the Uterine Artery

For every gynecologic laparoscopic procedure via the Da Vinci robot, the previous anatomic surgical knowledge and the key gynecologic structures, especially where of the **ureter** is running in the abdominal and pelvic regions is essential for its intraoperative identification and to guarantee a safe gynecologic procedure. The lumbar ureter lies on the psoas muscle medial to the ovarian vessels (Fig. 58.3). It enters the pelvic cavity just superficial to the bifurcation of the common iliac artery and just deep to the ovarian vessels, which lie in the infundibulopelvic ligament at the pelvic brim. It lies in the anterior medial leaf of the broad ligament as it winds toward the bladder and can be recognized by its characteristic peristaltic motion. The ureter then passes just lateral to the uterosacral ligament, approximately 2 cm medial to the ischial spine through the upper part of the cardinal ligament at the base of the broad ligament. Here it lies just beneath the uterine artery, approximately 1.5–2 cm lateral to the side of the cervix. The ureter forms a "knee" turn under the uterine vessels and at from this point travels medially and anteriorly to pass on the anterolateral fornix of the vagina to enter the bladder at the junction of the upper and middle third of the vagina [11]. Therefore, special attention must be given after the hysterectomy by closing the vaginal cuff, where at the lateral angle of the vagina, as well as anterior and anterio-lateral in the upper third of the vagina is the ureter.

Before every operative procedure with the Da Vinci robot, in which the **uterine artery** needs to be ligated, in order to guarantee a hemostasis and a safe procedure, even before identification of the uterine artery, previously performed ureterolysis via the Da Vinci robot is of great importance. For the ureterolysis, the ureter can be found on the pelvic sidewall medial to the infundibulopelvic ligament as it crosses the external iliac. The peritoneum superior to the ureter is gently grasped and entered. The ureter is in the medial tenting sheet to the infundibulopelvic ligament. The peritoneal incision is extended: by tenting of the further peritoneum and cutting with millimeter by millimeter progression only of what can be seen or determined. The medial traction is placed on the medial edge of the peritoneal incision of the first pelvic sidewall layer to open retroperitoneal space, and the dissection is continued in a fat-nonfat interface (fat belongs to the rectum, the dissection is performed superior to the fat) until the ureter is identified medially in the opened space that further inferiorly leads to the pararectal space. There are two main structures after opening the peritoneum of the pelvic sidewall, that go down in the pelvis: first medial, that peristalses, that is the ureter; and the second lateral, that pulsates, that is the internal artery (Fig. 58.16) that branches medially to the uterine artery (Fig. 58.17). With further medial traction of the peritoneum, the ureterolysis is performed with push-spread-push-spread, traction-countertraction as well as millimeter snaps and millimeter wipes dissection technique continued to the level of the cardinal ligament.

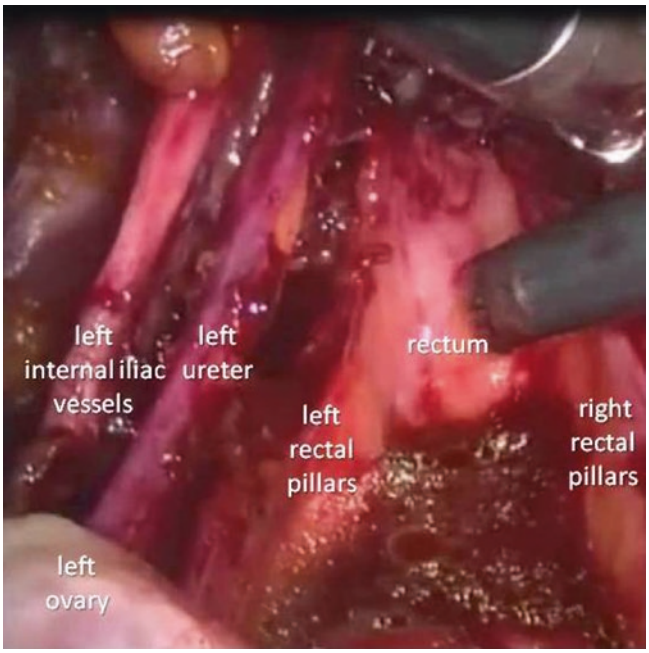

Fig. 58.16 Situs after a robotic radical hysterectomy without salpingectomy. There are two main structures that go from the pelvic sidewall down into the pelvis: first medial, that peristalses, that is the ureter; and the second lateral, that pulsates, that is the internal artery

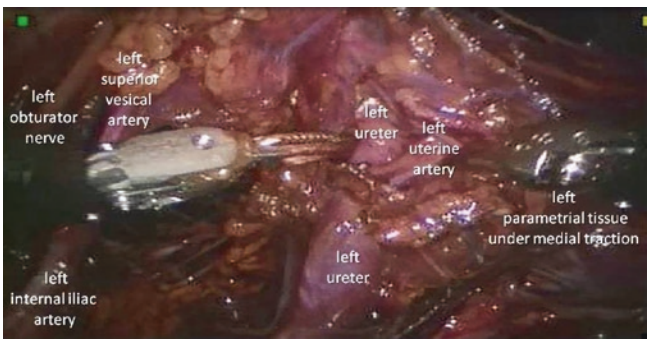

Fig. 58.17 After a pelvic lymphadenectomy and ureterolysis but before radical hysterectomy on the left side. The internal artery branches medially into the uterine artery that crosses from above the ureter in order to run into the uterus

In order to find the uterine artery, first, identification of the obliterated umbilical ligament can be helpful as a continuation of the superior vesical artery on the anterior abdominal wall (Fig. 58.15). Moving this ligament provokes a movement of the superior vesical artery, that lead straight further to the internal iliac artery (named also the hypogastric artery) coming from the bifurcation of the common iliac artery. The medial branch of the internal iliac artery is always the uterine artery (Fig. 58.14). Medial to the branching of the uterine artery from the internal iliac artery is the ureter, as the uterine artery crosses the ureter on its top aiming to the uterus. The ligation of the uterine artery is performed as lateral from the ureter as possible (at the uterus by total hysterectomy or at the internal iliac artery by radical hysterectomy procedure).

Laparoscopic Identification of the Hypogastric (Pelvic) Nerve, Splanchnic Nerves and Inferior Hypogastric (Pelvic) Plexus

Especially the Da Vinci robot with 3D stable and enlarged site view enable the surgeons to recognize the parts of the autonomic nerve system in the pelvis in order to preserve them during oncologic procedures and perform nerve-sparing operations. Those autonomic nerves that could be damaged during oncologic operations are: lumbar splanchnic nerves during periaortic lymph node dissection; superior hypogastric plexus during presacral lymph node dissection; hypogastric nerve during resection of the uterosacral ligaments (rectal pillars); proximal inferior hypogastric plexus during a division of the uterosacral ligaments and cardinal (transverse cervical) ligaments; and distal inferior hypogastric plexus during transection of the vesicouterine (pubocervical) ligaments.

The **hypogastric nerve (pelvic nerve)** can be identified in the pararectal space through an opening of the pararectal space between the internal iliac artery and the ureter, posteriorly to the uterine artery. There the hypogastric nerve runs parallel and approximately 2 cm inferior to the ureter (Fig. 58.18). The hypogastric nerve can be also found in the para\rectal space as adhering fibers to the lateral side of the uterosacral ligament (rectal pillars) (Fig. 58.11). The hypogastric nerve will be isolated until the cut end of the uterine vein to be preserved during the division of the uterosacral ligament by the nerve-sparing radical hysterectomy [9].

The hypogastric nerve inferiorly in a site where the pelvic splanchnic nerves and the sacral splanchnic nerves join, form **the inferior hypogastric (pelvic) plexus** with two branches (bladder and uterine branches) on the lateral surface of the uterosacral ligament (Fig. 58.12). In order to identify the hypogastric (pelvic) plexus: the ureter is separated from the posterior leaf of the VUL (vesico-uterine ligament) up to the loose tissue of the entrance of paravaginal space. The ureter is than shifted laterally. Then one can see: the posterior leaf of the left vesicouterine ligament that consists of left vesical veins that are draining into the deep uterine vein in the posterior layer of the vesicouterine ligament (VUL) (Fig. 58.19). The transsection of the vessical veins expose the bladder branch of the inferior hypogastric plexus (pelvic plexus) that runs posteriorly to the posterior part of the VUL. The exposure of the bladder branch (Fig. 58.12) is needed for its preservation during the nerve-sparing hysterectomy as only the anterior layer of the VUL is resected, where the uterine branch of the pelvic plexus runs.

In order to identify the **pelvic splanchnic nerves** the following structures need to be recognized: the uterine artery that is running just superior and parallel to the superficial uterine vein. Just inferior and parallel to the superficial uterine vein is the deep uterine vein (all those vessels are isolated and transected by the nerve-sparing radical hysterectomy) (Fig. 58.18). Just inferior and parallel to the deep uterine vein there are the pelvic splanchnic nerves localized. The pelvic splanchnic nerves are laterally to the hypogastric nerve that is running inferiorly to the ureter. If we follow the fibers of the hypogastric nerve further anteriorly, we can observe that they run just below the deep uterine vein (Fig. 58.18c).

Through a better site recognition, 3D stable view as well as magnification of the surgery area with better ergonomics, with the Da Vinci robot it is possible not only to learn and to teach the laparoscopic surgical anatomy but also to perform advanced laparoscopic operations that have been performed almost only by an abdominal approach before.

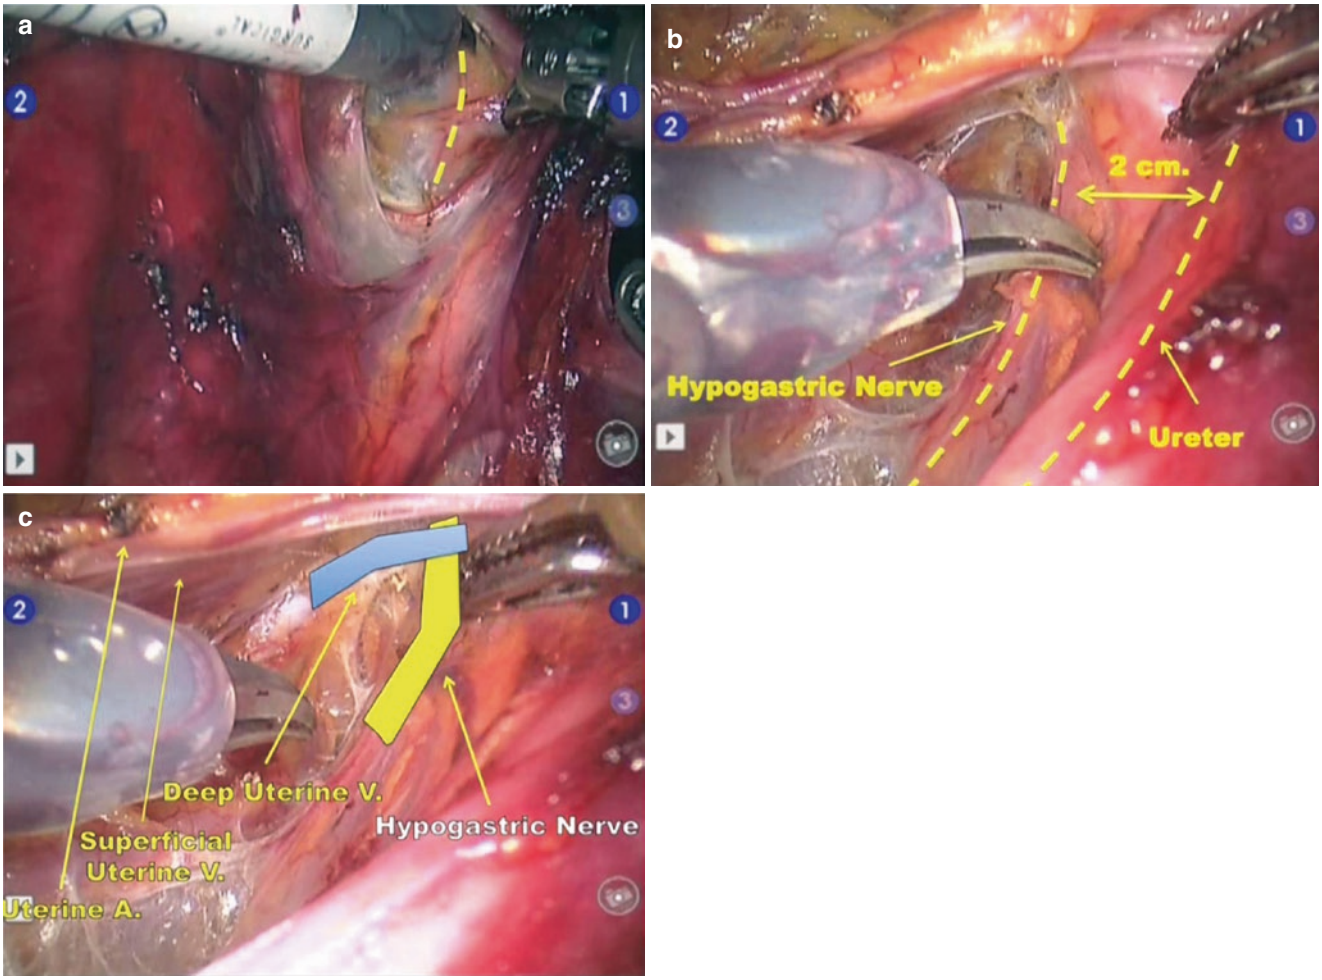

Fig. 58.18 Left pararectal space. The hypogastric nerve (pelvic nerve) can be identified in the pararectal space through an opening of the pararectal space between the internal iliac artery and the ureter, posteriorly to the uterine artery. There the hypogastric nerve runs parallel and approximately 2 cm inferior to the ureter. (**a**). An opening of the left pararectal space (between the left internal iliac artery and the left ureter, posteriorly to the left uterine artery) looking for the left hypogastric nerve (marked *yellow* here). (**b**). In the opened left pararectal space: the left hypogastric nerve is approximately 2 cm inferior to the left ureter. (**c**). The uterine artery is running just superior and parallel to the superficial uterine vein. Just inferior and parallel to the superficial uterine vein is the deep uterine vein (all will be isolated and transsected by the nerve-sparing radical hysterectomy) and just inferior and parallel to the deep uterine vein there are the pelvic splanchnic nerves localized. The pelvic splanchnic nerves are lateral to the hypogastric nerve, that is running inferior the ureter. If we follow the fibers of the left hypogastric nerve further anteriorly, we can observe that they run just below the left deep uterine vein (Photos from educational video by Maggioni [9])

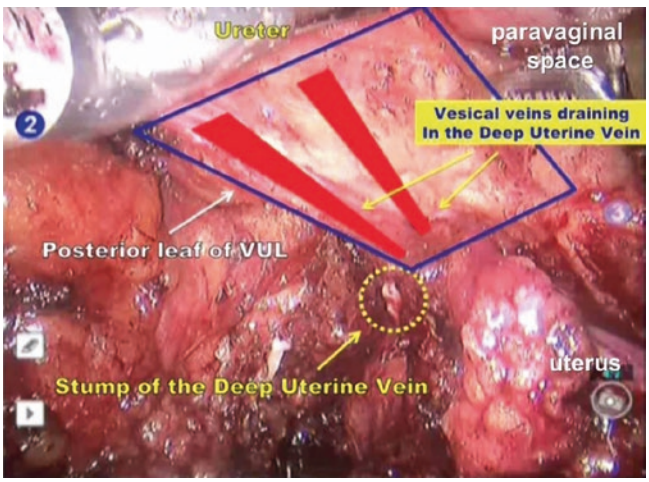

Fig. 58.19 Left vesicouterine ligament. The posterior leaf of the left vesicouterine ligament that consists of left vesical veins that are draining into the deep uterine vein in the posterior layer of the vesicouterine ligament (VUL) (Photo from educational video by Maggioni [9])

General Aspects and Their Handling: Adhesions

59

Alexander Di Liberto and Kubilay Ertan

Introduction

Peritoneal adhesions, this means mainly non congenital, abnormous fibrous connections between tissues, that are normally anatomically not conjoined, are an ubiquitous problem in abdominal surgery that could appear after every surgical intervention of each kind, including robot-assisted interventions and in this context robot-assisted hysterectomies, but with different likelihood.

Prior surgical interventions respectively post-inflammatory alterations in the upper abdomen (state after cholecystectomy, after pancreatitis and also after extensive surgical interventions via laparotomy) are mostly not relevant for the predominant proportion of laparoscopic interventions in the lesser pelvis respectively concerning the laparoscopic access points, but can cause problems and challenges just as the trocar positions would be shift to a more cranial localization, this means above the umbilicus (for example for the access to the paraaortic lymph node regions or to perform hysterectomy procedures in big uteri), especially in robot-assisted interventions, where generously a cranial shifting of the trocars have to be performed.

Basical problem is the preoperative estimation of the extent of adhesions, just after surgical interventions in the lower abdomen and lesser pelvis at the colon and small intestine or localised adhesions in the lesser abdomen and pelvis (e.g. after pelveoperitonitis due to adnexitis or severe endometriosis, but also after cesarean sections were unexpected large-area and firm adhesions between the anterior uterine wall and the abdominal wall can be found). In the state after peritonitis in particular generalised peritonitis respectively four-quadrant peritonitis extensive peritoneal adhesions have to be anticipated, so that the laparoscopic respectively robot-assisted methods of entrance to the peritoneal cavity have to be adapted correspondingly. The most commonly consequences of intraperitoneal adhesions are chronic pain syndroms in the lower abdomen, small intestine obstruction up to ileus, for the gynaecological patient cohort primary or secondary sterility and dyspareunia as well as the formation of pseudocysts in the lesser pelvis (with the partially difficult differential diagnosis to genuine cystic lesions and, for this reason, hindered decision-making for or against surgical clarification), and relating to subsequent operative interventions in the peritoneal cavity a higher risk of organ injury, especially bowel lesion (serosal defects, enterotomy, primary detected or unnoticed during surgery), major blood loss, and a increased rate of conversions to laparotomy (Table 59.1).

Adhesion-related complaints themselves frequently result in re-operations (the SCAR3 trial demonstrated an incidence of 10 % concerning adhesion-related hospital stays within 5 years postoperatively [1]) and are, in a great extent, both very questionable regarding the primary surgical outcome (i.e. elimination of the complaints), and concerning the long-term course, because the likelihood of recurrence of adhesion formation in identical or other localizations is very high, in spite of application of substances and materials for adhesion prophylaxis.

This leads to a significant long-term impairment of the quality of life on the one hand and a considerable charging of costs in the healthcare systems on the other hand.

Robot-assisted laparoscopic interventions are affected at least in an equal measure related to the complex of problems concerning peritoneal adhesions, both regarding preexisting adhesion (of any origin), and the induction of de novo adhesions, the last one perhaps in a higher degree, because just complex operative interventions are performed robot-assisted (notably complex hysterectomies, oncological therapy, surgical interventions in higher-degree endometriosis, complex myomectomies, etc.).

Table 59.1 Medical and surgical consequences of peritoneal adhesions

General medical and surgical aspects	Gynaecological aspects
Chronic pain syndroms (localised or generalised in the abdomen)	Primary/secondary sterility; increased rate of ectopic pregnancies
Small intestine obstruction up to ileus	Dyspareunia
Subsequent operative interventions (with higher risk of organ lesions, major blood loss and laparotomy)	Formation of pseudocysts in the lesser pelvis (diagnostic dilemma)
Socio-economic consequences	Increased complexity of gynaecological operations

Particularly in oncological interventions in cervical and endometrial cancer, which are exceedingly eligible for the robot-assisted technique, large-area accesses to the retroperitoneum have to be established, by what substantial peritoneal traumata occur.

In comparison to traditional laparoscopy the robot-assisted interventions are characterized by the utilization of a higher number of trocars and a larger trocar diameter leading primary to a greater surgical trauma in the area of the peritoneal entrances, but no data or reports are available on this topic, especially in comparison to traditional laparoscopy.

Surgical Principles of Prevention of Adhesions and of Adhesiolysis

In general, for robot-assisted laparoscopic interventions in gynecology the same surgical principles are valid for prevention of adhesions and of adhesiolysis.

For prevention of adhesiolysis, finally representing the most effective potential to avoid respectively to reduce adhesion-associated morbidity, the principles of "good surgical technique" are valid; this are beside the general awareness which pathophysiological mechanisms constitute for formation of adhesions the minimisation of direct and indirect surgical trauma at the parietal peritoneum and other serosal surfaces, provided that these are not related to the therapeutical target area. Therefore, this means gentle handling of tissues and organs, the reduction of HF surgical-caused heat effect at the peritoneum and other surfaces (i.e. sparing coagulation), the avoidance of ischemic change, this means especially the diminuation of bleeding not only by coagulation but by accurate and anatomical dissection and by conservation of smaller vessels, the avoidance of desiccation, which is particularly relevant in laparoscopic interventions concerning the capnoperitoneum, the reduction of application of external material and foreign bodies, the shortening of operation time, and, if necessary, the application of materials of adhesions prevention (see Chap. 6).

The basic principles of correct adhesiolysis are the careful and accurate dissection of adhesions, as possible without additional injury and trauma of the peritoneum and serosal surfaces, the economic use of electrocoagulation with concurrent avoidance of bleedings. Finally, the extent of adhesiolysis also depends on the mode of intervention and the dimensions of the required surgical field, and, eventually apparent complaints concerning adhesions.

Adhesions which do not impair the access to the surgical area or the surgical target area, and which do not cause anamnestic and/or clinical complaints, and are not a potential future menace, for example provoking intestinal/small bowel obstruction, should better be left and not to be touched.

However, even if they seem not to present a direct obstacle to the surgical activity, adhesions can constitute a risk factor for sticking with laparoscopic instruments and therefore causing delayed noticed bleedings or unnoticed blunt tissue trauma up to higher grade organ injury and complications.

For the traditional laparoscopy, which is characterized in comparison to open abdominal surgery by reduced formation of postoperative adhesions, there exist additional problems concerning the complex of problems of the capnoperitoneum, generally the gas pressure leading to microtrauma at the hole peritoneum, and the consecutive desiccation of the peritoneal surface – all of these constitue risk factors for the formation of adhesions, at least contribute to adhesions. However, these risk factors can be influenced by various methods and techniques: Adding of O_2 to the carbonic dioxide, limitation of gas pressure to a minimum limit (with the disadvantage of a potential diminished visualisation or an increase of bleeding in the surgical area), and a continuous humidification of the peritoneal cavity via the insufflation system or by an intermittend irrigation.

Robot-assisted laparoscopic operations allow a decreased gas pressure or a minimum of pressure of some mmHg because the abdominal wall is stretched tent-like by the anchorage of the trocars at the patient side cart, thus imitating a "gasless" laparoscopic intervention. In addition, the robotic technique provides the potential to perform adhesiolysis more precisely (better visualisation [higher image resolution and particularly spatial view], and the higher flexibility and dexteritiy of the robotic instruments and for this reason a pinpoint adhesiolysis, selective and punctual coagulation of small vessels in adhesion threads, respectively the avoidance of bleeding by increased visualisation. Robot-assisted adhesiolysis is carried out in close analogy to traditional laparoscopy by grasping the adhesion with a smooth grasping forces (e.g. of eligible EndoWrist™

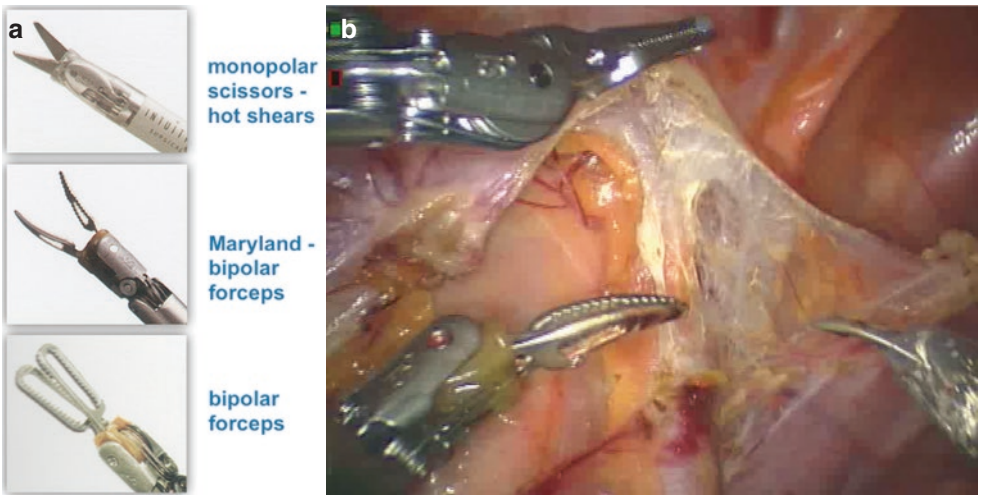

Fig. 59.1 (**a**) Eligible EndoWrist instruments for robot-assisted adhesiolysis (Source: Intuitive Surgical, Sunnyvale, California, with permission). (**b**) Arrangement of instruments in robot-assisted adhesiolysis (above: Grasping Forceps, bottom left: Maryland Bipolar Forceps; bottom right: Monopolar Curved Scissors, "Hot Shears")

instruments: Maryland Forceps or Bipolar Forceps, Fig. 59.1a), slight to moderate tension of the adhesion for delineation of the borders to normal peritoneum or other neighbouring organs (uterus, adnexa, bowel), as required selective and punctial coagulation of vessels in the adhesion and cutting the adhesion with monopolar scissors (e.g. of eligible EndoWrist™ instrument: Monopolar Curved scissors, Hot Shears, Fig. 59.1a), as necessary careful shifting and pushing of adjacent tissue structures respectively neighbouring organs under minimisation of bleedings, tissue trauma and especially serosal defects. Figure 59.1b shows a typical arrangement of instruments in robot-assisted adhesiolysis.

However, possible disadvantages of robot-assisted interventions are the generally higher number of inserted trocars leading to a larger peritoneal wound area (reduction of the peritoneal trauma by availability and application of a robot-assisted single port technique, which is already in use, but to date it is limited concerning complex minimal invasive procedures; for the future a flexible robotic single port technique is under way, which might overcome the current limitations of single port techniques), the absence of haptic and tactile feedback endangering a gentle handling of peritoneal and serosal surfaces, the increased view can compensate the latter only partially. There are no comparative and descriptive studies on this topic up to now.

Risk Factors for Adhesions/Planning of Operations in Expected Adhesions

Essentially, risk factors for existing peritoneal adhesions result from the patient's history, i.e. the indicated and presumed previous operations; the presumed previous operations are commonly only apparent by existing scarring at the abdominal wall because the patients oftenly do not remember operations which have been long ago, especially elderly patients.

Besides the medical history of an operation respectively the existence of an operation scar the antecedent of inflammatory disease (concerning the gynaecological sector these are adnexitis, resp. Pelveoperitonitis or simply chronic lower abdominal pain), and the history of endometriosis are relevant. Particularly in chronic inflammatory diseases of the bowel (Crohn's disease, ulcerative colitis) the presence of peritoneal adhesions with different extent must be anticipated.

This applies similarly both for robot-assisted and traditional laparoscopic interventions, and especially for hysterectomies.

Within the scope of the planning and preparation of operations the patient has to be informed about possible accesses to the peritoneal cavity (trocar placement), their situative variability (modification of the number of the trocars and their position), the higher risk of a conversion to laparotomy (including the information of and discussion about the particular incision line: Pfannenstiel incision versus longitudinal incision) and of an intraoperative neighbouring organ injury, particularly an enterotomy respectively an increased postoperative complication rate.

In addition, the constitution of the surgical team, if necessary the stand-by of a visceral surgeon has to be considered; furthermore, a longer operation time has to be taken into account (both concerning the medical resilience of the patient and the allocation of a sufficient logistic prearrangement [positioning, the patient warming, anaesthesiologic monitoring]). Finally, the essential items about this have to be documented in the informed consent.

In this connection there are no fundamental differences between robot-assisted laparascopic interventions and traditional laparoscopic operations, whereupon, in most cases, the primary more complex intervention would be accommodated.

Laparoscopic and Robot-Assisted Accesses in Presence of Adhesions

For robot-assisted intervention there are only a few differences concerning the accesses to the abdominal cavity compared to traditional laparoscopic procedures. Due to the major importance of the distance of the camera to the top of the uterus in robot-assisted operations (reduced flexibility of the daVinci™ camera, respectively the restrictation of fast camera movements), i.e. always a sufficient distance has to be given, this corresponds to a hand, in these interventions the trocar positions are in most cases more cranial as compared to traditional laparoscopic trocar positions (Fig. 59.2a–c). Just in operations of big uteri the camera trocar has frequently be placed above the umbilicus, so that especially in existing adhesions in the lower abdomen and in the pelvis the trocar positioning is primary outside of the hazardous zone. Insofar the Palmer's point can be utilized as access way as well as in traditional laparoscopy and later for replacement of the Veres needle with a daVinci™ working trocar. Here, plenty of surgeons apply previously of placing the daVinci™ camera a traditional endoscope to get a picture of the situation inside of the abdominal cavity. Likewise, an open sky technique can be applied in robot-assisted interventions; in this technique the abdominal cavity is opened under visual control both in the area of the lower umbilicus and supraumbilical, similarly to traditional laparoscopic open accesses, the so-called open sky access, whereas special open sky trocars for robotic-assisted surgery are not available.

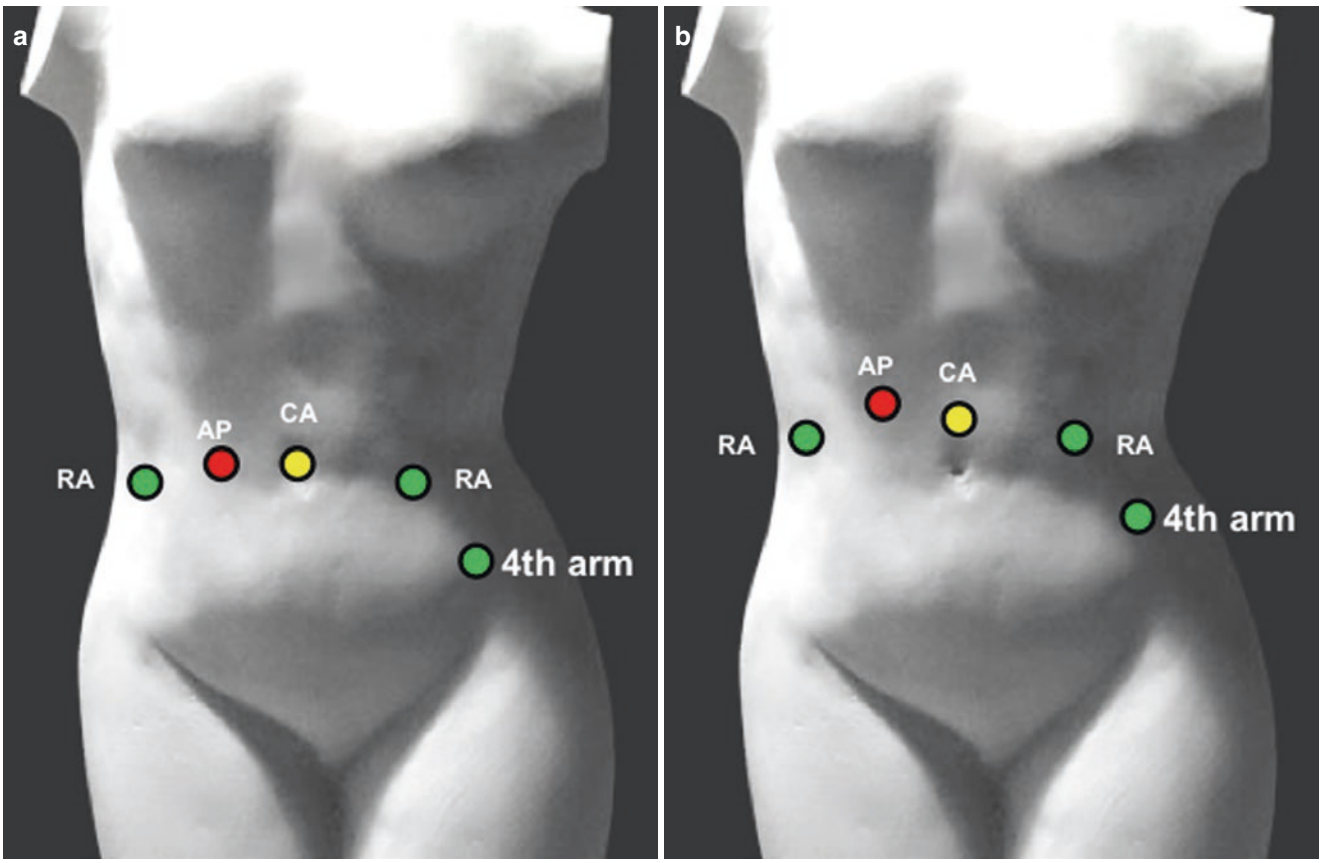

Fig. 59.2 (**a**) Suggestion for umbilical placement and arrangement of the camera and robotic trocars in case of adhesions in the lesser pelvis. (**b**) Suggestion for supraumbilical placement and arrangement of the camera and robotic trocars in case of adhesions in the lower abdomen and lesser pelvis and/or enlarged uterus. (**c**) Suggestion for subcostal placement and arrangement of camera and robotic trocars in case of upper abdominal adhesions and/or huge uterus

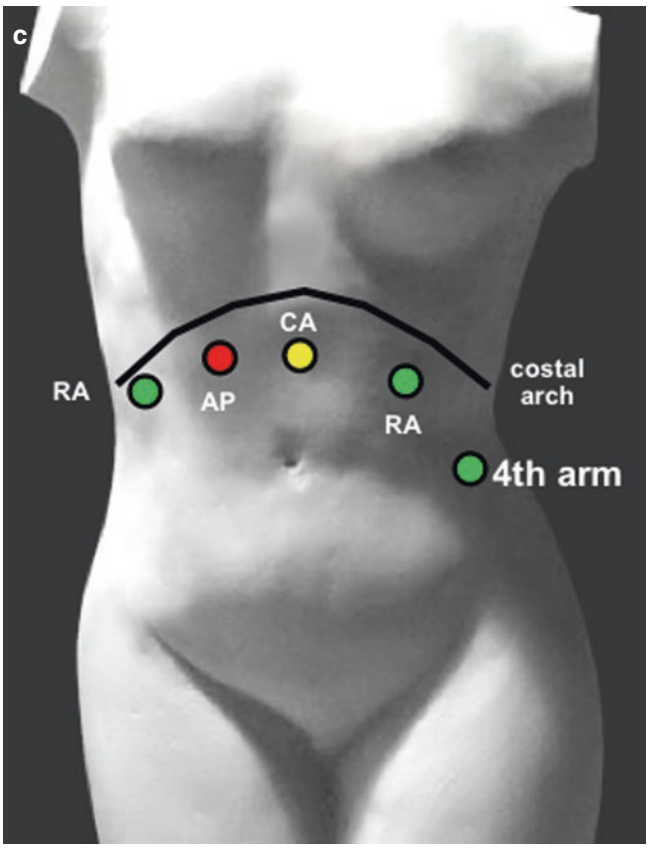

Fig. 59.2 (Continued)

Traditional Laparoscopic/Robot-Assisted Management of Adhesions (Before and After Docking of the Patient Side Cart)

In the case of existence of adhesions in the area of the trocar accesses the required flexibility of the robotic arms is limited in robot-assisted surgery. In this connection a traditional laparoscopic adhesiolysis is required until enough space, i.e. a sufficient surgical field for a sufficient mobility of the robotic arms is achieved in the proper surgical field in order to place all the needed daVinci™ trocars in the middle and lower abdomen.

Not till then, the patient side cart can be placed, the robotic arms can be docked and the operation can be continued from the surgeon's console.

In the event of adhesions in the lower abdomen and in the lesser pelvis adhesiolysis can be continued with the daVinci™ system after establishment of a sufficient surgical visual field, docking maneuver and taking over of the operation at the console.

Here, adhesiolysis can be performed much easier than in traditional laparoscopy due to the three-dimensional view, the superiority of instrument flexibility, and the higher number of freedom degrees of the EndoWrist™ instruments; for example, combined with the fixed camera position and the magnification of the daVinci™ optical system vessels can better be visualized in adhesional threads and can accurately be coagulated, and, thus, bleedings can be reduced at the best and thermal effects can be limited to a minimum.

In case of a required mobilisation of the intestinum for a better accessibility to the lesser pelvis (i.e. pelvic and paraaortic lymh node dissection) an adequate adhesiolysis has to be performed via traditional laparoscopy in the middle abdomen prior to the docking of the patient side cart so that the small intestine and the colon can be shifted to the middle and upper abdomen sufficiently by Trendelenburg positioning.

After docking of the patient side cart and installation of the camera the visual field is limited to the upper regions of the abdomen; this constitutes a relevant confinement of the robotic technique (the daVinci™ camera cannot pivoting more than 90° cranially; this limitation is largely eliminated in the daVinci™ 4th generation device, the daVinci™ Xi).

Application of Techniques for Prophylaxis of Adhesions.

All techniques of adhesion prevention and prophylaxis (e.g. oxidised regenerated cellulose [Interceed™], expanded polytetrafluoroethylene [Gore-Tex™], sodium hyaluronate and carboxymethylcellulose [Seprafilm™], icodextrin 4 % [Adept™], dextrane 32 %, carboxymethylcellulose and polyethylene oxide [Oxiplex™], polyethylene gylcol gels [Spraygel™], hyaluronic acid based gel [Hyalobarrier™], ferric hyaluronate gel 0.5 % [Intergel™], and others) are applicable in robot-assisted interventions as well as in traditional laparoscopic operations, at which the application of the particular medium and technique will be done after termination of the console phase and after undocking of the patient side cart at the end of the operation.

Available Data About Postoperative Adhesions After Robot-Assisted Operations

Regarding the influence of robot-assisted laparoscopic operations on the postoperative formation of adhesions there are no clinical or experimental trials from the gynecological sector available demonstrating a reduction or increase of adhesions on the one hand, and analyzing the performance of adhesiolysis in terms of effectivity and complication rate on the other hand, both in comparison to traditional laparoscopy and to open abdominal surgery.

There is only one experimental trial existing, from the urological sector [2], in which advantages of robot-assisted operations compared to open abdominal operations have been demonstrated in robot-assisted laparoscopic ileocystoplasty (RALI) on the basis of a porcine model.

The fact, that there is a higher amount of inserted trocars in robot-assisted surgery (at least 1 more trocar compared to

traditional laparoscopy), the larger incisions as well as the presumably stronger traction and shear forces at the abdominal wall by a quasi suspension of the abdominal wall at the patient side cart, and consequently a more intense trauma to the peritoneum, and the bias of a so-called negative selection, i.e. a case selection, which is primarily more complex due to the robotic case selection profile (both concerning anatomical alterations and surgical pretreatments) let at least suppose that the advantages of the more precise adhesiolysis and the operation technique of robotic surgery are revoked hereby.

Conclusions

Existing adhesions in the context of robot-assisted operations and especially robot-assisted laparoscopic hysterectomies are treated according to the basic principles as well as traditional laparoscopic operations. The establishment of an adequate field of action is carried out for the robot-assisted technique with the daVinci™ system with means of traditional laparoscopy. Adhesiolysis in the lesser pelvis can be performed effective and precise with the daVinci™ technique related to their advantages (3D view, flexibility and dexterity of the EndoWrist™ instruments, tremor free surgery, amount of magnification of the daVinci™ endoscope) (Fig. 59.3a–h).

To which extent de novo adhesions are fewer respectively the effectiveness of adhesiolysis in robot-assisted surgery is superior to traditional laparoscopic operations has to be investigated in further research.

General Aspects and Their Handling: Comorbidities

60

Celine Lönnerfors and Jan Persson

Medical and Surgical Comorbidities

In medicine, the term "comorbid" entails medical condition(s) existing simultaneously, but independently, with another condition.

Medical conditions known to increase the risk of surgery include bleeding disorders, diabetes mellitus, heart disease, obesity, liver disease, infectious disease, chronic respiratory disease, obstructive sleep apnoea, substance abuse and immunological disorders [1, 2], (Table 60.1).

In addition, the presence of extensive intraabdominal adhesions, advanced endometriosis and obesity are conditions associated with an increased surgical risk.

An understanding of the potential morbidity associated with surgery and different surgical approaches, as well as the impact of comorbidity, is important to offer the patient optimal treatment. For women with malignant disease, a higher surgical risk is acceptable than for women with benign disease and for women with significant comorbidities a thorough preoperative evaluation including patient information, optimizing patient status, and a comprehensive consideration of alternative, less invasive treatment options are key.

Minimally invasive hysterectomy is associated with less postoperative pain and a lower rate of morbidity, shorter hospital stay and convalescence [3–6]. An effort put into preserving the clinical benefits of laparoscopic surgery and facilitating the performance of more advanced surgery has led to the development of robotic surgery. The uptake of robot-assisted surgery was rapid. In 2008, only 3 years after the introduction, one in five hysterectomies for benign disease in the United States were performed robotically [7]. Three randomized, controlled trials comparing laparoscopic to robotic hysterectomy for benign disease have been published where the studies by Paraiso et al. and Sarlos et al. found a similar clinical outcome but an increased cost for robotics [8, 9]. In contrast, the randomized trial from our clinic showed that robotic hysterectomy for benign disease could be economically feasible if performed as excess capacity at a high volume center [10]. A recent Cochrane review on surgical approach to hysterectomy for benign disease concluded that when a vaginal hysterectomy is unfeasible, a laparoscopic hysterectomy is preferable to an abdominal approach. In addition, although the present evidence does not suggest that robotic hysterectomy is of benefit in this population, further evaluation is needed. The study further concluded that the benefits and hazards associated with different approaches is dependent on surgical expertise and that the approach to hysterectomy should be decided by the woman in discussion with her surgeon [11].

Patients with both substantial medical and surgical comorbidities are patients in whom surgery is particularly hazardous and where a minimally invasive approach might be particularly beneficial. Leonard et al. demonstrated that BMI, uterine size, leiomyoma size, and previous abdominopelvic surgery are all independent risk factors for intraoperative conversions from laparoscopy to laparotomy and Bonilla et al. showed that a large uterus increased the risk of a longer hospital stay, morbidity, and blood loss [12, 13]. These characteristics thereby provide a measure of the complexity and potential difficulty of a surgery and as such these high-risk surgeries have traditionally been performed by laparotomy [14]. Robotic surgery was introduced to overcome some of the limitations of traditional laparoscopy and to expand the patient population being offered minimal invasive surgery.

Robotic surgery is laparoscopic surgery utilizing an advanced tool. However, contrary to laparoscopic surgery, the requirement of a steep Trendelenburg position, large machinery impeding direct access to the patient, and an increased number of advanced, time consuming procedures all present additional management challenges for the surgical team [15], (Table 60.2).

Table 60.1 Medical conditions that increase the risk of surgery [1, 2]

Condition	Type and reason for increased risk
Bleeding or clotting disorder	Increased risk of bleeding or developing blood clots during and after surgery
Cardiovascular disease	Increased demands on the myocardium to maintain cardiac output due to surgical stress Increased susceptibility to surgical factors such as blood loss and volume shifts Enhanced myocardial oxygen demand caused by increased heart rate and blood pressure as a result of surgical stress
Chronic respiratory disease	Reduced ability to compensate for any alteration in the acid-base balance Increased risk of hypoventilation due to depressed respiratory function during anesthesia Changes in ventilation impair the diaphragm resulting in reduced volumes and lung capacities Increased risk of postoperative pulmonary complications due to risk of exacerbation of bronchial inflammation and increased risk of bronchospasm and postoperative pneumonia
Diabetes mellitus	Increased risk of infection and impaired wound healing due to altered glucose metabolism and associated impaired tissue perfusion Increased risk of lower limb ischemia and pressure sores Disruption and worsening of diabetes control Increased risk of postoperative acute myocardial infarction
Immunological disorders	Increased risk of impaired wound healing and infection
Chronic kidney disease	Impaired tubular excretory function of the kidney cause elevation in levels of creatinine and blood urea nitrogen Impaired synthetic function leads to a decrease in the production of erythropoietin (resulting in anemia) and active vitamin D-3 (causing hypocalcemia, secondary hyperparathyroidism, and hyperphosphatemia), accumulation of acid, potassium, sodium and water excretion (causing acidosis, hyperkalemia, hypertension, and edema), and platelet dysfunction (promotes bleeding) Drugs usually eliminated by the kidney including anesthetic drugs can accumulate to toxic levels Renal insufficiency is a risk factor for cardical complications in surgical patients
Liver disease	Decreased synthesis of plasma-binding proteins Impaired drug metabolism and elimination Impaired hormonal response to surgical stress Increases the risk of morbidity (bleeding, impaired wound healing, renal dysfunction, hepatic failure, infection) and mortality in the postoperative period
Nutritional status	Malnutrition further exacerbates the catabolic state induced by surgical stress Increased risk of postoperative infection and impaired wound healing for both obese and underweight women Obesity increases risk of having other comorbidities

Table 60.2 Anesthesiological challenges specific to robotic surgery [11]

Patient positioning	Steep Trendelenburg	Compromised hemodynamics and oxygenation. Restricted intraoperative airway access Increased risk of postoperative respiratory stress, nerve injury, occult blood loss, corneal abrasion
Pneumoperitoneum		Increased peak inspiratory and plateau airway pressures and end-tidal CO_2 tension while decrease in lung compliance and vital capacity leading to ventilation-perfusion mismatch, atelectasis, subcutaneous emphysema and gas embolism
Restricted access		Might impact patient care in emergency situations

Communication and teamwork are vital to create a safe, effective and efficient environment to minimize complications and optimize the perioperative period for the patient. Proper training and experience with the procedure in low-risk patients is important prior to undertaking surgery in high-risk patients.

To perform robotic gynecologic surgery optimal exposure of the pelvis is necessary and this is possible through a steep Trendelenburg position [16]. Without proper exposure, the procedure is prolonged and there is an increased risk of intraoperative complications [17]. The dorsal lithotomy position can have significant physiological consequences. Most susceptible to the head-down extreme position are the cardiac, respiratory, and central nervous systems and patients with underlying disease might be especially vulnerable [18]. The cranial movement of the diaphragm by pneumoperitoneum and abdominal contents, can decrease pulmonary compliance and functional residual capacity, cause pulmonary edema, and exacerbate ventilation/perfusion mismatch, which can be particularly perilous in the morbidly obese or in patients with underlying chronic lung disease [19–21] The establishment of pneumoperitoneum can result in increased postoperative

complications in patients with underlying lung disease. Patients with chronic obstructive pulmonary disease are less efficient in eliminating excessive CO_2, which can lead to postoperative respiratory hypercarbia and acidosis [22, 23]. In addition, the development of subcutaneous emphysema contributes significantly to the total amount of CO_2 absorbed [15]. Obese women have less efficient ventilation during pneumoperitoneum and are at higher risk of coronary artery disease, pulmonary dysfunction, and diabetes [24, 25]. The combination of the steep Trendelenburg position with pneumoperitoneum influences cardiopulmonary physiology; increased left ventricular filling pressure and systemic vascular resistance and decreased cardiac output [26–28]. Prolonged surgery places the patient's cardiorespiratory capacity under pressure for longer [29].

The president of the American Congress of Obstetricians and Gynecologists released the following statement in 2013: *Patients should be advised that robotic hysterectomy for benign disease is best used for unusual and complex clinical conditions in which improved outcomes over standard minimally invasive approaches have been demonstrated* [30]. No randomized studies on the optimal hysterectomy approach for women with significant medical or surgical comorbidities or for complex cases such as severe adhesions, extensive endometriosis or difficult anatomical conditions are available, i.e. cases where robotic surgery has been suggested to be most beneficial.

Retrospective and prospective studies on the impact of surgical comorbidities are available and several studies have indicated robotic surgery to be feasible and safe in women with complex benign disease. Boggess et al. found robotic hysterectomy in 152 consecutive cases with complex benign disease (obese patients, patients with one or more prior pelvic or abdominal surgeries, patients with moderate to severe endometriosis or leiomyomas, and patients with large uteri) to be associated with short hospital stay, minimal blood loss and no conversion to laparotomy. They concluded that robotics allows for a safe and efficient surgery in patients with complex pathology [14]. Several study groups have reported on the feasibility of complex endometriosis surgery using robotics and several studies have indicated that robotic surgery is feasible and safe in women with other complex benign disorders such as large uteri, pelvic fistula or in case of previous intraabdominal surgery [18, 24, 31–42]. In addition, several publications indicate that robotic surgery is utilized to an increased extent in women with comorbidities [24, 33, 34, 43, 44]. Patzkowsky et al. compared the perioperative outcome of 288 robotic and 257 laparoscopic hysterectomies for benign disease and found that even though more complex cases were being performed robotically the surgical outcome was similar in both groups [45]. This selection case bias where more difficult cases are chosen for a robotic approach, is increasingly evident at our clinic where the referrals specifically indicating a wish for robotic surgery has increased substantially.

The impact of obesity has been most extensively studied, particularly in women undergoing hysterectomy for endometrial cancer. Obese patients are more likely to have additional comorbidities that may increase the risk of surgical and anesthetic morbidity and mortality when compared with women of normal weight [46–48].

Due to the increasing prevalence of obesity, it is important to develop surgical techniques to manage these patients appropriately. Three large randomized controlled trials found laparoscopic surgery to be a valid alternative to laparotomy for surgical treatment of endometrial cancer [5, 49–51]. The complexity of advanced traditional laparoscopic procedures in obese women has hindered a general adoption of laparoscopic surgery for this group of patients.

For morbidly obese patients (BMI $\geq$40 kg/m^2) laparoscopic surgery is particularly challenging but also more advantageous compared to open surgery [52–54]. A recent study evaluating the impact of obesity on the outcomes of surgical treatment of endometrial cancer by either laparoscopy or laparotomy found laparoscopy to be associated with a better clinical outcome [55]. However, the conversion rate increased and the lymph node yield decreased in women with BMI exceeding 40, the latter was true even for women operated by laparotomy. In the Lap2 study, the overall conversion rate was 25.8 %, although for women with BMI $\geq$40, the rate was 56 % [5]. Wound related complications are the most common complications for obese women undergoing laparotomy. Decreasing the rate of laparotomy while retaining an acceptable oncological outcome is highly important in obese women.

Extreme obesity has traditionally been considered a relative contraindication to laparoscopic surgery; thicker panniculus reducing the range of instrument motion, the effect of steep Trendelenburg position on the respiratory system and the redundancy of bowel interfering with optimal exposure of the pelvis [56].

Robotic surgery for gynecological disease has been found to be feasible in obese women [44, 57–62]. Concerns about whether or not robotic surgery is safe in obese patients has been raised, particularly due to the need for a very steep Trendelenburg position during the procedure. Several recent publications have concluded that robotic surgery is safe in this group of patients. Wysham et al. found a low incidence of pulmonary complications and overall complications in 1032 obese women following robotic surgery for gynecological disease and Corrado et al. reported a perioperative complication rate of 10 % and no conversions to laparotomy in their study on 70 morbidly obese patients [60, 63]. A large cohort study by Zakhari et al. showed that although women undergoing robotic surgery were more likely to have a much higher burden of comorbidities as well as significantly more

often being obese or morbidly obese, a greater rate of lymph node dissection, a decreased length of hospital stay as well as comparable postoperative morbidity and mortality was seen when compared to laparoscopy [44]. This trend towards a higher utilization of robotics in higher BMI categories has also been demonstrated in urology [64].

The intraoperative management of extensive intraabdominal adhesions is a surgical challenge. Adhesiolysis is associated with a prolonged operative time and an increased risk of intraoperative and postoperative complications, especially inadvertent bowel injury [65–67]. Unlike other postoperative complications, the consequences of adhesion formation comprise a lifelong risk of various clinical entities [65, 68–72]. The presence of adhesions increases the risk of small bowel obstruction, the need for emergency surgery with adhesiolysis as well as decreased pregnancy rates, increased need for fertility treatments, and chronic abdominal pain [65, 66, 72–77].

Data about the incidence of adhesions differ considerably, although most studies report an incidence of between 20 and 93 % [78–82]. These significant variations may be explained by diverse procedures and entry techniques as well as by varying underlying disease [83]. Pediatric and lower gastrointestinal surgery is associated with a majority of adhesion-related problems whereas the rate is lower following urological and gynecological procedures [77]. The presence of adhesions is more probable in patients with a history of laparotomy or extended surgery. Laparoscopy reduces, but does not prevent, the occurrence of adhesion-related complications [79, 84].

For laparoscopic and robotic surgery, the presence of adhesions in the umbilical area must be considered as the insertion of a trocar can lead to bowel injury. In their study on 814 patients, Audebert and Gomel found the rate of umbilical adhesions to be 0.68 % of patients with no previous abdominal surgery, 1.6 % following laparoscopic surgery, 19.8 % following a previous horizontal suprapubic incision, and 51.7 % after a midline incision [85]. In addition, the study demonstrated that the presence of severe adhesions involving the bowel was low in women with no previous surgery, after laparoscopic surgery or after a horizontal incision (0.42–6.87 %), but 31.46 % in women with a previous midline incision [85]. Sepilian et al. found the incidence of umbilical adhesions and bowel adhesions to be 21.2 and 2.6 % in patients with a history of laparoscopy through an umbilical incision [86]. Consequently, in patients with a history of laparoscopy or laparotomy, an alternative access to the abdominal cavity such as the Palmer's point should be considered to minimize the risk of inadvertent organ perforation during trocar entry. The occurrence of adhesions at the Palmer's point after previous operations is unlikely because most abdominopelvic operations are conducted farther from this anatomical region [83]. Since 2012, direct access at Palmers point using the 12 mm semi blunt assistant trocar has been the preferred method for gaining access to the abdominal cavity for robotic procedures at our clinic. During the last 3 years performing approximately 900 procedures, one complication (bleeding from mesenteric vessels in a women with low BMI) has occurred following direct entry at Palmers point. The overall complication rate during port placement at our institution is low (0.3 %) and known or suspected adhesions are considered an indication rather than a contraindication for robotic surgery [87].

Lysis of adhesions is associated with a prolonged operative time and an increased risk of intraoperative and postoperative complications [65, 66, 77]. Adhesions precluding acceptable exposure are, in addition to unanticipated carcinomatosis, the most commonly stated reasons for conversion to laparotomy in robotic surgery.

The conversion rate during robotic hysterectomy for benign disease is low. Most studies report rates of less than 1 % [8–10] and even in women with complex benign disease the rates are in the range of 0–1.7 %. [14, 45]. For robotic hysterectomy for malignant disease most report rates <4 %, although in a recent publication by Jones et al. the rate was 8.7 % [62, 87–91]. The latter publication evaluated the risk factors for conversions from robotic surgery to laparotomy in 459 patients and found bowel injury, increasing BMI and non-White race but not prior surgery, medical comorbidities or malignant disease to be associated with conversion to open surgery [91]. The Lap2 study, a randomized study comparing staging for endometrial cancer by laparoscopy and laparotomy found increasing BMI, age and metastatic disease to be associated with an increased risk of conversion [5].

The conversion rate in the first 1000 robotic procedures performed at our institution for malignant or benign disease was 3.7 %; 41 % of the conversions were due to intraabdominal adhesions and 3 % due to an intraoperative complication [87]. Overall, 36 % of the women had at least one previous laparotomy and 24 % had intraabdominal adhesions necessitating adhesiolysis. An intraoperative complication occurred in 3.3 %. A urinary injury (ureter or bladder) occurred in 1.7 %, a bowel injury in 0.8 %, a vessel injury in 0.6 % and a neural injury in 0.2 % of the patients. Sixty-five per cent of patients with an intraoperative complication had major intraabdominal adhesions. The conversion rate and the rate of intraoperative complications in patients with adhesions was 5.8 % and 5.4 % respectively [86].

In a later study on our first 949 hysterectomies for malignant and benign disease, the overall conversion rate was 2.4 %; 46 % was due to intraabdominal adhesions. In 70 % of the conversions, the decision was made prior to docking the robot and the conversion rate among women in whom the robot was docked was 0.8 %. The conversion rate in the 240 women undergoing hysterectomy for benign disease was 0.4 % [87]. In 2013/2014, one (1.2 %) conversion and no

intraoperative complications occurred during a hysterectomy for benign disease even though 66 % had at least one complicating factor (ASA ≥3, severe endometriosis, > one previous midline incision, BMI >40 kg/m^{2,} uterine size >200 g). The conversion was due to extensive intraabdominal adhesions in a woman with several previous midline incisions.

The presence of adhesions is associated with a somewhat higher risk of conversion and intraoperative complications. The latter can, in a majority of cases, be managed robotically and adhesions should not dissuade from performing a robotic procedure if other factors favor this approach.

Dry-lab studies have shown that the robot is more advantageous compared to traditional laparoscopy when the procedure becomes technically more challenging regardless of the level of the surgeons experience [92]. Even though no randomized controlled trials comparing laparoscopy and robotics for patients with significant comorbidities within this patient group are available, several studies indicate that even with an experienced and skilled surgeon, obese patients, patients with prior abdominal surgeries, or patients requiring lengthy and high-risk surgeries are likely to benefit from robotic surgery. In addition to a thorough preoperative evaluation, intraoperative monitoring, teamwork, good communication and a heightened awareness of the possible problems that might arise are important to achieve a successful surgery and an uncomplicated postoperative period. Training, experience and refinement of practice has, at our institution lead to a decrease in the overall rate of intraoperative-, postoperative-, and ≥ grade 3 complications according to the Clavien-Dindo scale by 46 %, 44 % and 76 % respectively. This decrease has occurred over a seven-year period and illustrates that the effort and time needed to implement a successful robotic program should not be underestimated.

Robotic surgery for benign disease has been suggested to be beneficial primarily in complex cases or in high-risk patients. The development a standardized, reproducible method of hysterectomy for all benign cases called **safe, simple hysterectomy** is in our opinion key to minimize the risk of complications for all patients. This method mimics surgery for malignant disease where the pelvic sidewalls are opened and the ureters identified, dissected and visualized during the entire surgery and the vascular pedicels are skeletonized and secured. Proper training and experience with this method in non-complex cases is important prior to undertaking the more challenging procedures. In high-risk surgeries aberrant anatomy due to endometriosis or adhesions, decreased visibility due to obesity, enlarged uteri or suboptimal pneumoperiotoneum or Trendeleburg's positioning due to anaesthesiological issues are challenges that must be overcome to successfully complete the case. The predictability of this method for the console surgeon, the bedside assistant and the operating room nurse optimizes the chances of the surgery being uneventful. This allows for swift damage control when necessary, and thereby decreases the risk of intraoperative complications, intraoperative bleeding, and conversion to laparotomy as well as the risk of reoperation, which is particularly important for this high-risk population.

Safe, Simple Hhysterectomy: Surgical Technique

All models of the da Vinci robots can be used. Ports should be placed as for standard pelvic surgery. Central docking or side docking at surgeon's discretion for the Si robot whereas the Xi robot is usually docked 90 ° from the side. Suitable robot instruments are: monopolar scissors, a bipolar forceps, and a prograsp. The latter can, in most cases, be used for closing the vaginal cuff. For the assistant, a 10–12 mm trocar is used for suction/irrigation, insertion of sponges, clips, and needles.

For identification of the vaginal fornices, a vaginal tube is placed at onset of surgery.

Initial entry into the abdomen is usually achieved through direct entry at Palmers point in the upper left quadrant with the assistant trocar or with Verress needle or open entry at the midline. A midline entry is avoided in case of previous extensive intraabdominal surgery.

Triangulation and tensioning of the tissue is created using the fourth arm with the infindibulopelvic (IP) ligament, the round ligament and the pelvic sidewall as the parameters (Fig. 60.1) and the peritoneum is opened approximately 1 cm lateral to the IP ligament (Figs. 60.2 and 60.3). The areolar, avascular space is identified and, when possible, dissection is performed in this space to minimize bleeding. The ureter is identified (Fig. 60.4), the pararectal space is developed (Figs. 60.5 and 60.6) and the uterine artery is identified (Fig. 60.7), skeletonized (Fig. 60.8) and sealed with a hemostatic clip

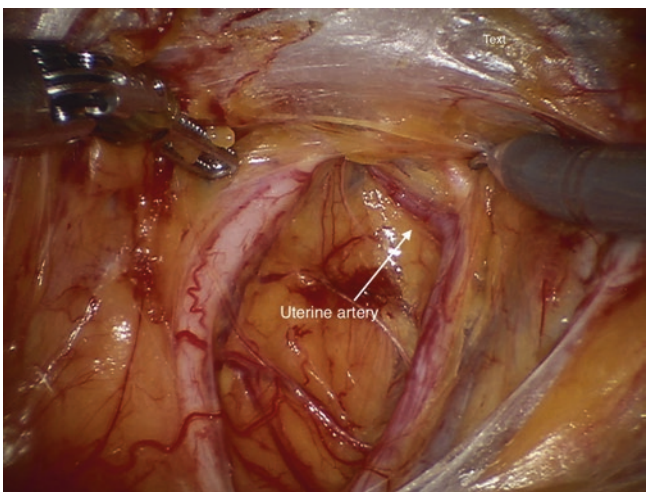

Fig. 60.7 Identifying the uterine artery

(Figs. 60.9 and 60.10). The ureters are dissected off the posterior peritoneum, carefully lateralized to maintain blood supply (Fig. 60.11). The previous steps are performed on the contralateral side. In case of ovarian preservation, the fallopian tubes are removed (Fig. 60.12). The medial broad ligament is opened (Figs. 60.13 and 60.14), the IP ligament is skeletonized, and in case of a bilateral salpingoophorectomy, a hemostatic clip is placed (Figs. 60.15 and 60.16). When preserving the ovaries careful coagulation of the ovarian ligament including the parametrial veins is performed (Fig. 60.17). The Okabayashis space is developed (Figs. 60.18 and 60.19) and the rectovaginal space is opened (Figs. 60.20, 60.21 and 60.22). The round ligaments are divided, (Figs. 60.23 and 60.24) the anterior peritoneum opened (Figs. 60.25 and 60.26), the vesicouterine peritoneal fold is identified and, using the vaginal tube as a guide, the bladder is mobilized off the lower uterine segment (Figs. 60.27 and 60.28). The vaginal tube facilitates identification of the vaginal fornices as well as moving the ureters laterally. Desiccate and divide the uterine vessels at the level of the lower isthmus

Key Points

- Identify patients with significant comorbidities
- Proper indications for surgery
- Adequate patient information, informed consent
- Optimize the patient prior to surgery
- Be aware of the increased risks of performing surgery in patients with comorbidities
- Training and experience in non complex cases before undertaking complex cases
- Use a standardized, reproducible, safe surgical approach
- Be prepared for all possible medical or surgical complications during surgery
- Teamwork and communication

General Aspects and Their Handling: General Surgery Conditions and Techniques for Robotic Hysterectomy

61

Jan-Hendrik Egberts

During the last 30 years, minimal invasive surgery has revolutionized many general and especially oncological surgical techniques. After a controversial debate about the safety and efficacy of this new surgical approach, it is now widely accepted. For colorectal cancer, several prospective and multicenter studies have demonstrated the potential advantages of minimal invasive techniques [1, 2]. However, even today the rate of minimal invasive resections for colorectal cancer is still limited due to technical limitations, the long learning curve and other reasons.

The application of robotic assistance in minimal invasive surgery has been a logical development over the last years. Today, robotic assisted surgery is gaining acceptance in all surgical fields, such as thoracic surgery, upper GI surgery, HPB surgery and transplantation surgery, with encouraging results [3].

Especially in anatomical regions like the pelvic or the thorax with limited access, the advantages are obvious. The first use in colorectal surgery was for a segmental colonic resection for a benign disease in 2002 [4] and for a low anterior rectal resection in 2006 [5]. In 2012 a prospective multicenter study was initiated, investigating the safety and efficacy of robotic-assisted vs. laparoscopic low anterior rectum resection (ROLARR-study) [6]. The recruitment was recently completed.

Besides the technical improvements in surgery, another milestone in rectal cancer surgery was the description of the "holy plane" by Heald [7]. Based on the embryology of the rectum with the development of the complex anatomy of the pelvic floor, the distribution of lymphatic nodes and vessels and nerval structures becomes more systematic. The surgeon should follow the embryological fasciae (i.e. perirectal fascia and the pelvic fascia which is called the "holy plane") in order to achieve the best optimal oncological specimen by preserving the autonomic pelvic nerves that comprise the superior hypogastric plexus, the right and left hypogastric nerves and the right and left inferior hypogastric plexuses. The precise preparation in this plane, developing the whole rectum with perirectal tissue, is called "total mesorectal excision (TME)" [8].

Knowledge of embryology might be of special interest for the oncological resection of other compartments in the pelvic region, such as urological and gynecological cancers. Especially in tumors infiltrating the rectum, for example ovarian cancers or in cases of deep endometriosis, the gynecological surgeon might be in a position to dissect this tissue.

In the following section, the set-up and technique for a low anterior resection, as an example of a pelvic surgical procedure, is described.

Setup

Patient Positioning

Due to the current limitation in the movement of the patient table, the patient positioning gains even more importance before the docking maneuver since the procedure sometimes requires an extreme positioning of the patient. Also, several surgical procedures require a dual docking, in which the robot arms are disconnected and re-docked after the repositioning of the patient. Future developments will synchronize the robot arms with the table in order to move the patient during the robot procedure similar to the conventional laparoscopic technique.

For procedures in the pelvic region, such as low anterior resections, the patient is placed supine in a modified lithotomy position. The legs are abducted with flexed knees and the arms alongside the body. It is important to standardize the set-up for different procedures in order to maximize the safety and efficacy.

OR Set-Up

A 12 mmHg pneumoperitoneum is achieved by a mini-laparotomy and the ports are introduced as follows:

- Two 12 mm conventional laparoscopic trocars (camera and assistant trocar)
- Three 8 mm robotic trocars

Once the camera trocar is inserted, an assessment of the entire abdomen is performed and the trocars are placed at their optimal sites.

Elements of the Procedure

The major elements of a low anterior resection (LAR) for rectal cancer are:

- central ligation of the inferior mesenteric artery (IMA) and inferior mesenteric vein (IMV)
- mobilization of the left colon/ splenic flexure
- rectal resection with total mesenteric excision (TME)
- specimen removal and anastomosis

The operation for LAR starts with a visual inspection of the abdomen (especially the liver for metastases) and a central ligation of the IMA and IMV. A so-called "medial to lateral approach" begins with the incision of the peritoneum after lifting the sigmoid colon and upper rectum. The incision starts at the level of sacral promontory. The superior rectal artery will be seen and followed to its origin of the IMA after identification of the left colonic artery and sigmoidal artery. These structures should be free of other tissue in order to avoid an injury of the ureter. The ligation of the artery can be taken by the surgeon's preferred method as shown in Fig. 61.1.

The dissection in this plane will be continued in the layer of the anteriorly localized IMV and colonic mesentery and the posteriorly localized retroperitoneum (Fig. 61.2). In this layer the retroperitoneal structures, such as the pancreas, ureter and vessels, can be detected and saved by blunt dissection. The surgeon dissects the tissue laterally to the left colonic flexure and cranially the pancreas tail (Fig. 61.3). During this dissection the IMV is ligated near the ligament of Treitz. The final mobilization of the left colon and splenic flexure is then performed from a lateral approach.

The removal of the rectum and mesorectum (total mesorectal excision –TME) is carried out according to Heald's principles [7]. By staying in the avascular plane between the endopelvic visceral fascia and the endopelvic parietal fascia, an avascular space is developed. In this plane the hypogastric nerve plexus becomes visible and can be preserved. Also, the sacral venous plexus, located deep in the parietal layer, will be untouched. During this preparation it is essential to use the robot arms to provide upward traction and counter traction by cautious and frequent repositioning in order to avoid damage to the TME specimen. The dissection in this plane is completed posteriorly to the level of the pelvic floor. The lateral stalks are then dis-

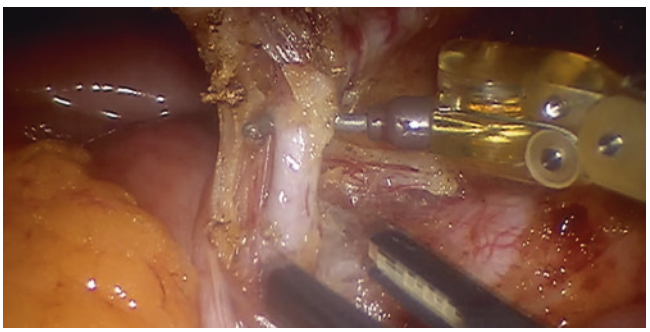

Fig. 61.1 Inferior mesenteric artery prior to central ligation

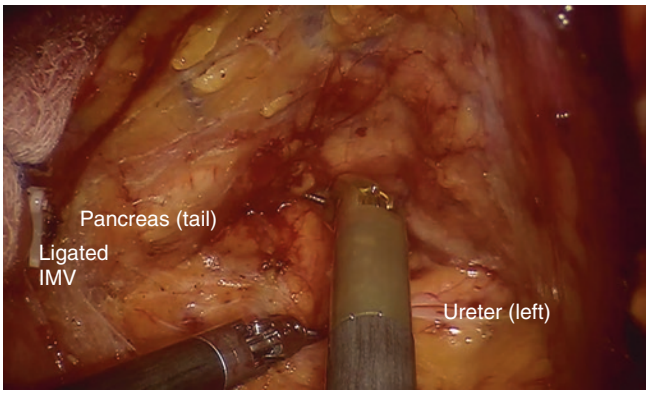

Fig. 61.3 Medial to lateral view after left flexure mobilization

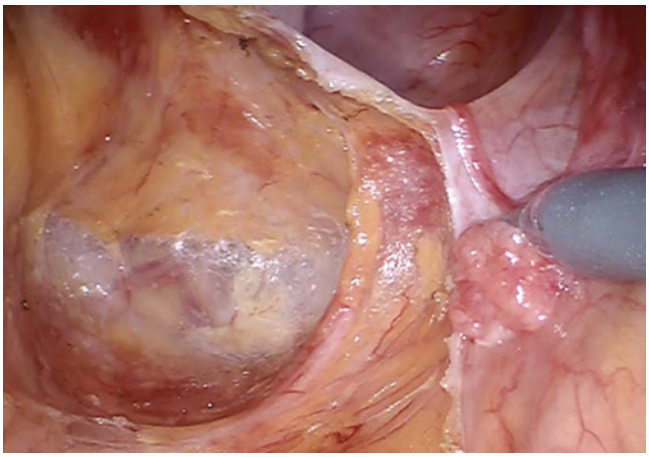

Fig. 61.4 View in the pelvic after dorsal mobilization of the rectum

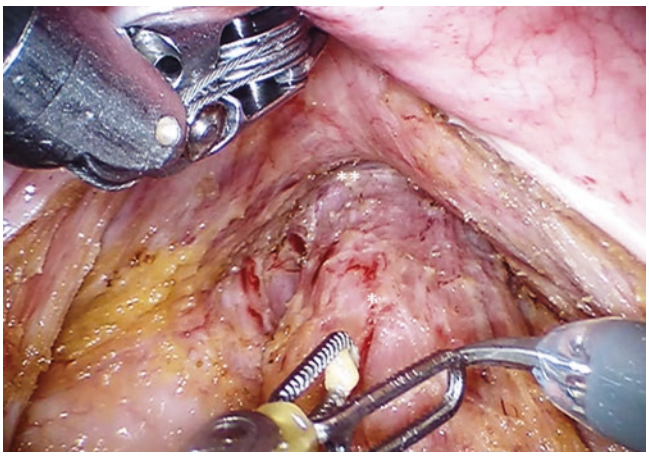

Fig. 61.6 View in the pelvic after complete ventral mobilization of the rectum

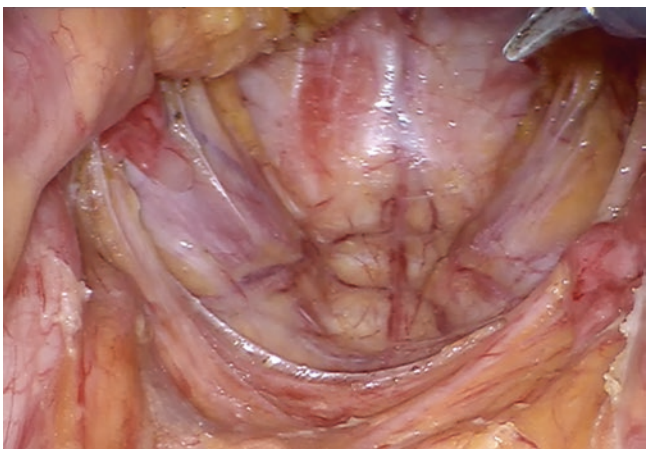

Fig. 61.5 View in the pelvic after complete dorsal mobilization of the rectum

sected. Here the vagina or the seminal vesicals and prostate are dissected free and protected (Figs. 61.4, 61.5 and 61.6). The autonomic nerves are localized laterally on the pelvic wall and should be protected during these dissecting steps.

The dissection is continued until the pelvic floor is reached (bare rectum area) and finally divided with a stapler device. The removal of the specimen is now possible and performed by an incision.

The anastomosis and reconstruction is usually performed by a circular stapler device with a side-to-end anastomosis. If adequate colonic length is present, a colonic J pouch is performed.

Up until now, the anastomosis and reconstruction is performed in a standard laparoscopic approach since no robotic instruments are available so far.

Conclusions

The robotic approach for surgery for rectal cancers appears promising. It creates new opportunities and allows a perfect view and mobility in the limited area of the pelvic region.

In general and thoracic surgery, the number of robotic-assisted procedures is increasing. There is a wide range of indications for procedures that can be performed with robotic assistance, extending the limitations of the minimal invasive approach.

Robotic Assisted Supracervical Hysterectomy

62

Noam Smorgick

Introduction

Supracervical (subtotal) hysterectomy refers to the removal of the uterine corpus with preservation of the uterine cervix. This subtype of hysterectomy is technically simpler compared with total hysterectomy because it does not require an extensive dissection of the cardinal ligaments and the vesico-uterine fold, nor suturing of the vaginal cuff. Thus, with the advent of laparoscopic and robotic hysterectomy, the rates of supracervical hysterectomy from all hysterectomies increased considerably. More recently, robotic assisted supracervical hysterectomy combined with sacral colpopexy has been found to be an excellent treatment for apical (level I) prolapse, further increasing the use of this procedure. Nevertheless, because supracervical hysterectomy requires some type of morcellation for specimen extraction, recent concerns regarding dissemination of leiomyosarcoma during power morcellation may limit the use of this procedure. Similar to total hysterectomy, the debate regarding the benefits and challenges of the robotic platform for supracervical hysterectomy continues. This debates centers on the relative advantage of converting an open hysterectomy to a minimally invasive hysterectomy by using the robotic platform when taking into account its higher cost.

Indications for Robotic Supracervical Hysterectomy

The main indications for this procedure are:

1. Hysterectomy for benign indication in women without cervical pathology. Robotic supracervical hysterectomy is an acceptable alternative to total hysterectomy in women requiring removal of the uterus for benign indications such as uterine fibroids, abnormal uterine bleeding and pelvic pain. As for total hysterectomy, the robotic platform may enable performing a minimally invasive hysterectomy in women with high surgical complexity (such as large fibroids or extensive pelvic adhesive disease from prior abdominal surgeries or pelvic inflammatory disease) who may not have been candidates for laparoscopic hysterectomy. Of note, supracervical hysterectomy is contraindicated in cases of cervical dysplasia for obvious reasons. Supracervical hysterectomy is less recommended for women with advanced endometriosis and pelvic pain because of higher rates of persistent postoperative pelvic pain [1].
2. Removal of the uterine corpus combined with sacral colpopexy in cases of pelvic organ prolapse. Sacral colpopexy for repair of level I pelvic floor defect (i.e., apical prolapse) is considered an excellent treatment for this pathology, and has been found to be superior to vaginal repair in a recent Cochrane review [2]. This procedure is often combined with total or supracervical hysterectomy. Sacral-colpopexy requires extensive suturing for placement of the mesh on the cervix and the anterior and posterior vaginal walls, which may be simplified with the use of the robotic platform. Moreover, supracervical rather than total hysterectomy has the advantage of lower risk of mesh erosion [3].
3. Patient desire and request. Some women may elect to preserve the cervix when it is unrelated to the uterine pathology (i.e., in case of uterine corpus leiomyoma) because of personal preference. The surgeon should provide appropriate counseling regarding advantages and disadvantages of supracervical hysterectomy (see below) in order to allow for patient's informed decision and consent.

Advantages of Robotic Assisted Supracervical Hysterectomy

To date, no studies have directly compared robotic assisted total and supracervical hysterectomy. However, related trials have been performed comparing abdominal total and supracervical hysterectomy. Most of these studies have not found a significant difference between the two surgeries in long term outcomes. A highly quoted 2002 randomized controlled trial by Thakar et al. found similar outcomes regarding bladder, bowel, and sexual function at 12 months [4]. In addition, the rate of pelvic organ prolapse was similar between the two groups. Nevertheless, short term outcomes such as postoperative hospital length of stay and rates of postoperative fever and wound hematoma were lower in the supracervical hysterectomy group [4]. On longer follow up of 14 years using a mailed questionnaire, no differences were found in rates of urinary incontinence, pelvic organ prolapse, pelvic pain, sexual function and quality of life [5].

Despite similar long term outcomes when compared to total hysterectomy, supracervical hysterectomy remains popular because it is considered technically "simpler" compared with total hysterectomy. Supracervical hysterectomy requires less dissection of the cardinal ligaments and the vesicouterine fold (i.e., bladder flap), and more importantly does not require suturing for closure of the vaginal cuff. This advantage is very important for the laparoscopic approach, since laparoscopic suturing is a relatively advanced surgical skill. Furthermore, the main surgical complication associated with vaginal cuff closure, vaginal cuff dehiscence, which is more common in laparoscopic and robotic assisted hysterectomy compared with abdominal and vaginal hysterectomy, is practically non-existent in supracervical robotic and laparoscopic hysterectomy [6]. Accordingly, supracervical hysterectomy constitutes up to 80 % of laparoscopic hysterectomies in Germany [7], as well as a large share of robotic assisted hysterectomies.

Disadvantages of Subtotal Hysterectomy

The risk of cervical cancer in the remaining cervix has been considered a disadvantage of subtotal hysterectomy. However, recent high quality studies have concluded this risk to be less than 0.1 % when appropriate pre-operative patient selection is performed [8]. Cyclic vaginal bleeding caused by remnants of endometrial tissue in the cervical stump occurs in up to 15 % of women [9].

Tissue extraction remains the main disadvantage of subtotal hysterectomy. In the absence of vaginal vault opening, the only means of extraction of the uterine corpus are power morcellation (using commercially available morcellators) or "cold knife" hand morcellation through incisions in the abdominal wall or the pouch of Douglas. As discussed below, recent concerns regarding the dissemination of malignant fibroids by use of power morcellation are currently a major limitation of this technique.

Morcellation

Until recently, the usual method for specimen extraction in supracervical hysterectomy was the use of laparoscopic power morcellators through a 12–15 mm port. The unquestionable disadvantage of this method is intraperitoneal spread of uterine and fibroid fragments. It was assumed that those fragments may cause dissemination of malignant fibroids (leiomyosarcoma) or stromal sarcoma, but these events were considered extremely rare, in the range of 1/1000 [10]. However, following claims that dissemination of leiomyosarcoma may be more common than previously thought, the US Food and Drug Administration (FDA) issued a statement in 2014 warning against the use of power morcellators in the majority of women undergoing hysterectomy [11].

Setting aside the FDA warning and its impact on medical practice, the actual rate of inadvertent leiomyosarcoma morcellation in a patient undergoing supracervical hysterectomy for fibroids presumed benign is debatable. The FDA concluded that the risk of unsuspected uterine sarcomas and leiomyosarcomas in patients undergoing hysterectomy for presumed benign fibroids is 1 in 352 and 1 in 458, respectively. However, this report was based on retrospective studies originating from referral centers with high risk patients with possible selection bias [11]. Furthermore, due to the lack of high quality studies, the impact of unsuspected sarcoma dissemination by power morcellation on the patient's ultimate survival is also unknown. More recent studies have attempted to investigate the risk of a sarcoma being inadvertently morcellated. A large Norwegian study which included 4791 women undergoing various gynecologic procedures concluded that the incidence of leiomyosarcoma among women suspected of having benign fibroids was 0.5 % (1 in 183 women), while the risk of unintended morcellation of a leiomyosarcoma was much lower, 0.02 % (1 in 4791 women) [12].

In view of the medical and medico-legal issues that are currently associated with the use of power morcellators [13], other methods for specimen removal which may be used for supracervical hysterectomy have been suggested. These include cold knife hand morcellation through the abdominal wall (after the specimen is placed in a retrieval bag) and contained power morcellation, i.e. power morcellation of the specimen within a closed bag. The former technique is straightforward to perform, but may require an extension of the port incision (especially when the specimen removed is large) and longer operative time. The latter technique is more cumbersome, and has mostly been described in vitro [14]. However, future development of contained power morcellating devices may once again make this technique both safe and easy to use.

Prophylactic Removal of the Adnexa or Fallopian Tubes

Removal of the adnexa or the fallopian tubes may be performed in conjunction with supracervical hysterectomy for benign conditions. Removal of the fallopian tubes with ovarian preservation carries minimal surgical risks and presumably low risk of premature ovarian failure, but may provide some protection from ovarian carcinoma in the future [15]. Furthermore, prophylactic bilateral salpingectomy prevents the benign post-hysterectomy complication of hydrosalpings (which may appear on ultrasound as ovarian cysts and may lead to unnecessary future surgery) [16]. Thus, we favor prophylactic salpingectomy in all patients undergoing hysterectomy.

The decision to perform prophylactic oophorectomy is more complex and depends on the patient's age, menopausal status, and their personal or familial history of breast and ovarian cancer. Prophylactic oophorectomy in pre-menopausal women would cause early surgical menopause, associated with increased risks for coronary artery disease, osteoporosis, and possibly dementia [17–19]. These risks may be partially overset by replacement estrogen therapy. On the other hand, the overall risk of ovarian cancer in those women without family history of breast/ovarian cancer whose ovaries were preserved during benign hysterectomy is low, ranging from 0.03 to 1.96 % [17]. Thus, the risks and benefits of this procedure should be considered and appropriate patient's consultation should be provided. The current recommendations of the American College of Obstetrics and Gynecology [20] and the Society of Gynecologic Oncologists [21] are to favor ovarian preservation in pre-menopausal women with average risk for ovarian cancer. The recommendations for ovarian preservation versus removal in menopausal women with average risk for ovarian cancer are inconclusive due to lack of sufficient studies. In women with higher risk for ovarian cancer due to family history or BRCA1/BRCA2 mutation, the risk-reducing bilateral oophorectomy is recommended in pre-menopausal women when childbearing is complete, factoring in the age at onset of cancer in affected family members.

The Step-by-Step Use of the Robotic Platform for Subtotal Hysterectomy

Patient's Positioning and Preparation

As for laparoscopic and robotic total hysterectomy, patient's positioning and operating room organization is of the utmost importance for the successful completion of this surgery. Following general anesthesia and endotracheal intubation, the patient is placed in a dorsal lithotomy position, with the buttocks slightly protruding outside the operating table. The arms are padded and tucked to the patient's sides. The legs are placed in stirrups, preferably padded "boot" stirrups which allow placing most of the patients' weight on their heels as well as easy upward and downward movement of the legs during surgery, if required (Fig. 62.1). Use of pneumatic compression device is recommended. Robotic hysterectomy, especially when combined with sacral-colpopexy, requires positioning in steep Trendelenburg position, often for several hours. As a result, patients' positioning on the operating table must be secure in order to avoid cephalad slippage during the surgery. This may be accomplished by using shoulder braces, vacuum positioning systems, or specially designed mattresses such as the "egg-crate" mattress. A grounding electrode is placed on the patient's thigh.

Following patient's positioning, the vagina and the abdomen are prepped and draped. A Foley catheter is routinely placed. A uterine manipulator, although not always deemed necessary for removal of a small uterus, is often very helpful for performing subtotal hysterectomy. Uterine manipulators containing a cervical ring, which helps delineate the vaginal margins when performing the colpotomy incision during total hysterectomy, are also useful for subtotal hysterectomy by elevating the uterine vessels further away from the ureters and possibly decreasing the risk of thermal injury during the coagulation of these vessels. These manipulators are manufactured in reusable and non-reusable forms. The choice of specific uterine manipulator is usually guided by surgeon's preference. Our own preference is to use easy to handle manipulators containing colpotomy rings such as the VCare (Conmed, Utica, New York, USA) or the RUMI (Cooper Surgical, Trumbull, Connecticut, USA) (Fig. 62.2).

Fig. 62.1 "Boot" stirrups allowing for comfortable positioning of patients in a lithotomy position during long surgeries, as well as easy movement of the legs from low to high lithotomy position

Fig. 62.2 Operative vaginal table prepared for robotic supracervical hysterectomy and sacral colpopexy. A plastic uterine manipulator containing a cervical ring (in this figure, the VCare) and an end-to-end anastomosis sizer are shown

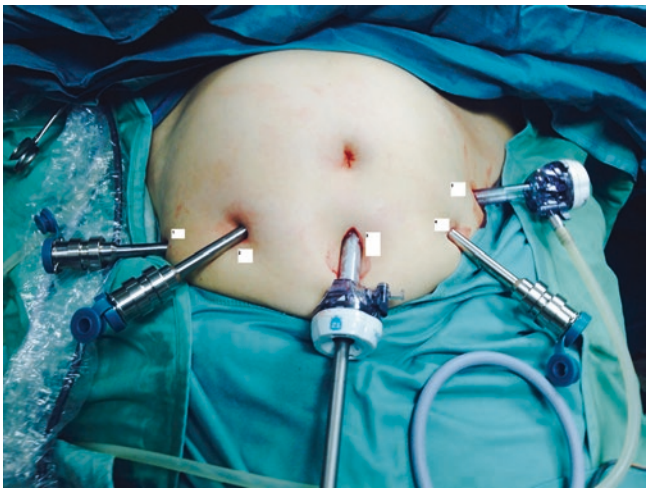

Fig. 62.3 Port configuration for robotic supracervical hysterectomy and sacral colpopexy. The camera port is located about 3 cm above the umbilicus. One robotic port is placed on the right side and two other robotic ports are placed on the left side. The bed-side assistant port is placed on the right side

Setup of the Robotic Platform

The basic setup includes the surgeon operating from the robotic console and controlling the robotic camera and 2 or 3 robotic arms, a bedside assistant using a laparoscopic port and standing on the right or left side of the patient (according to the port configuration – see below), and a second assistant sitting between the patient's legs and handling the uterine manipulator. The scrubbed surgical technician is often positioned in front of the first surgical assistant, on the other side of the patient. This positioning allows for easy reach to each of the robotic arms, required for instrument replacement and troubleshooting. A "vaginal" table is placed within arm's reach of the second surgical assistant. On this table are placed surgical instruments required for the insertion of the uterine manipulator (i.e., speculum, uterine sound and cervical dilators) and other vaginal instruments which may be required for sacral-colpopexy (i.e., sizers and spatula retractors). It is extremely important to place monitors in the room to allow for comfortable viewing of the surgery by the two surgical assistants and the surgical technicians. The robot may be docked in a direct line over the lower part of the patient's body, or on the left side or right side of the patient (i.e., side docking). The side docking technique allows for more comfortable seating for the second surgical assistant, which often translates into easier manipulation of the uterine manipulator.

Initiation of Pneumoperitoneum

According to surgeon's preference, pneumoperitoneum may be initiated with the closed technique (using a Veress needle), the open technique (i.e., the Hasson method) or the direct entry technique. The latter was recently modified with the introduction of optical trocars, which allow "under vision" direct entry.

Port Configuration for Robotic Subtotal Hysterectomy

Similar to other types of robotic hysterectomy, the usual port configuration for robotic subtotal hysterectomy will include -

1. *The robotic camera port (either 8 or 12 mm)*: this port should be placed at least a handbreadth (i.e., 10 cm) above the uterine fundus. For normal size uteri to mildly enlarged uteri (up to ~12 gestational weeks size), the typical placement is the umbilicus. For enlarged uteri, this port is moved cephalad. In cases of combined subtotal hysterectomy and sacral-colpopexy, although most often a normal sized uterus is removed, it is helpful to place the camera port a few centimeters above the umbilicus to allow for optimal visualization of the sacral promontory area (Fig. 62.3).
2. *Two lateral ports for robotic instruments*: the typical placement is a right sided 8 mm port for the monopolar shears and a left sided 8 mm port for the bipolar forceps (or similar electrosurgical instruments such as the Plasma Kinetic forceps). These two ports may be used later on to introduce needle drivers, in case a suture is placed on the cervical stump or on the vaginal walls for sacral-colpopexy.
3. *A third robotic arm*: this arm may be placed when an additional grasping instrument is required, most often in

cases of large uteri, peritoneal adhesive disease, or when a concomitant sacral-colpopexy is performed. The robotic instruments often used for these purposes are the pro-grasp or the tenaculum. The third robotic arm is usually placed between the camera port and the lateral robotic port, either on the right side or on the left side. When a concomitant sacral-colpopexy is performed, it is convenient to place the third robotic arm of the left side to allow for retraction of the sigmoid colon and easier exposure of the sacral promontory area. When the procedure includes only the subtotal hysterectomy without sacral-colpopexy, it is more convenient to place the third robotic arm on the right side of the patient in order to allow the surgeon a control of robotic grasping instruments on both side of the pelvis.

4. *Laparoscopic port for bedside surgical assistant*: this port is usually placed on the opposite side of the third robotic arm. In cases only two robotic arms are used, this port is usually placed on the left side of the patient. This port is used for introduction of laparoscopic graspers, suction irrigator and sutures as required. The size of the port can range from 5 mm (in case only graspers and suction/irrigation are used) to 12 mm (in case multiple sutures are used, i.e. in a sacral-colpopexy procedure).

Surgical Steps for Robotic Assisted Supracervical Hysterectomy

The surgical steps are similar to laparoscopic and open supracervical hysterectomy. The pelvis and the abdomen are surveyed, and any adhesions which may hinder the hysterectomy steps are taken down with sharp or blunt dissection. The course of the ureters from the pelvic brim downward is identified. When a concomitant sacro-colpopexy is planned, the sacral promontorium is identified. In cases of a large fibroid uterus, the uterus is moved with the manipulator and the robotic/laparoscopic instruments in order to evaluate the access of the vascular pedicles and the visibility of the colpotomy ring.

1. *Separation of the adnexa from the uterus*: The hysterectomy itself may begin with coagulation and division of the utero-ovarian ligaments and the fallopian tubes, even in those cases when removal of the adnexa is planned (Fig. 62.4). This step allows a good visualization of the posterior leaf of the broad ligament and the posterior side of the uterus. The adnexa may be removed later on separately when indicated.
2. *Division of the round ligament and anterior leaf of the broad ligament*: The round ligaments are coagulated and divided, and the incision is carried anteriorly to the vesico-uterine pouch (Fig. 62.5). The upper margin of the colpotomy ring may serve as a guide to the location of this incision, with the manipulator pushed cephalad.
3. *Dissection of the vesico-uterine pouch (i.e., the bladder flap)*: The vesico-uterine pouch is developed by using blunt and sharp dissection of the areolar tissue separating the urinary bladder from the cervix and the upper part of the vagina (Fig. 62.6). In most cases, this is easily accomplished with a downward pressure using the blunt side of the monopolar shears while the bladder is held with a grasping instrument to provide counter-traction, combined with the cephalad traction by the manipulator. In women with prior cesarean section or endometriosis, this step of the surgery is often more complicated because of dense adhesions. In those cases, the surgical plane may be identified laterally rather than medially. In addition, retrograde filling of the bladder with 200–300 cc may help identify its margins. Of note, the

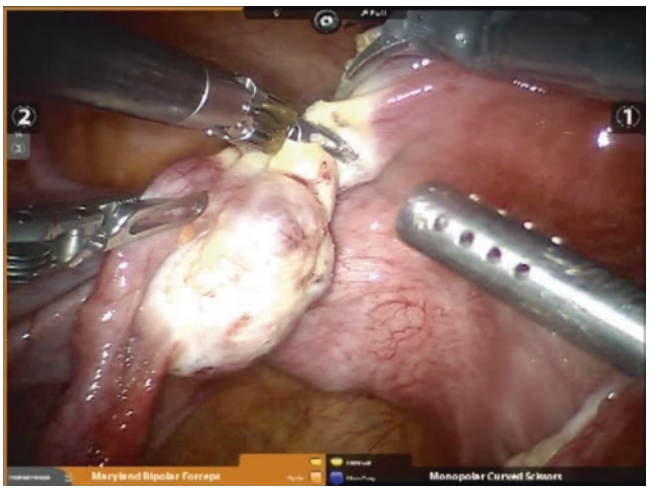

Fig. 62.4 Coagulation of the utero-ovarian ligaments

Fig. 62.5 Division of the round ligament

Fig. 62.6 Development of the bladder flap. The bladder flap is developed by holding the bladder upwards with a grasping instrument and applying sharp and blunt traction with the blunt end of the monopolar shears on the vesico-uterine fold

Fig. 62.7 Coagulation of the uterine arteries. After skeletonization of the uterine arteries, the vessel is grasped and coagulated with a bipolar instrument (in this figure, with robotic bipolar forceps)

Fig. 62.8 Amputation of the uterine corpus. Once the uterine vessels are secured, the corpus is amputated at its isthmus with monopolar shears. The movement of the uterine manipulator as well as the use of grasping robotic and laparoscopic instruments for upwards traction of the uterus is helpful in maintaining the uterus in a safe distance from the bowel and the bladder, minimizing the risk of thermal injury through the extensive use of electro-surgery during this step of the surgery

dissection of the vesico-uterine pouch required for supracervical hysterectomy (unless combined with sacral colpopexy) is less extensive than for total hysterectomy. In the former, this dissection should allow for safe margins when coagulating the uterine vessels and resecting the uterine corpus.

4. *Division of the posterior leaf of the broad ligament*: The incision of the round ligament is then carried posteriorly to the level of the colpotomy ring, just above the insertion of the sacro-uterine ligaments to the uterus. During this step, the serosa is separated from the underlying uterine vessels. This step may be performed using the bipolar Maryland forceps or PK forceps as a dissecting instrument.
5. *Skeletonization of the uterine vessels*: The areolar tissue surrounding the uterine vessels is taken down with sharp and blunt dissection in order to create a distinct vascular pedicle. This will allow to coagulate those vessels with less electro-surgery, resulting with decreased thermal spread (Fig. 62.7).
6. *Division of the uterine vessels*: During this step, the cephalad traction of manipulator increases the distance from the ureters. The uterine vessels are coagulated with bipolar or PK forceps, while ensuring that the coagulating instrument is placed at a 90° angle to the vessel. Before the vessels are divided, it is important to ensure that the distal portion of the pedicle is well coagulated. In addition, the proximal portion of the pedicle is also coagulated in order to decrease the "backflow" bleeding from the uterus.
7. *Division of the cardinal ligaments*: This step is minimal for supracervical hysterectomy. The cardinal ligaments are coagulated by placing the bipolar instrument at a 90 degree angle to the colpotomy ring. It is important to avoid excessive electro-surgery during this step due to the risk of thermal spread and thermal injury to the ureters. As before, cephalad traction on the manipulator will decrease this risk.
8. *Amputation of the uterine corpus*: The uterus is separated from the cervix by cutting it at its isthmus, above the insertion of the utero-ovarian ligaments to the uterus, using the monopolar shears (Fig. 62.8). The usual direction of the incision is from one side to the other. Due to extensive use of electro-surgery during this step, the

adjacent organs (i.e., bowel, bladder, etc.) must be clearly visualized at all times. Movement of the manipulator in the appropriate direction may facilitate this step, which may be difficult when removing a large and bulky uterus. Monopolar loops are usually unnecessary for robotic supracervical hysterectomy. If the uterine manipulator is left in place during this step, its stem is encountered along the process, marking the midline of the isthmic incision. Most manipulators stems are manufactured from plastic or other non-conductive materials so that thermal injury through the monopolar shears is minimized. However, judicious use of monopolar energy and complete visualization of pelvic structure during this step is essential since inadvertent thermal injury to adjacent pelvic structure (i.e., bowel, bladder) may occur.

9. *Coagulation of the internal cervical os*: once the uterus is removed, the cervical canal may be coagulated with the bipolar forceps. This step may decrease the long term sequel of cyclic cervical bleeding originating from residual endometrial tissue within the cervical canal. Another option is to perform a "reverse cervical conization", where a cone-shaped cervical tissue is removed with monopolar shears. This technique may also decrease the rates of cyclic bleeding. The uterine manipulator may be removed vaginally once the uterine corpus has been amputated, and replaced by vaginal retractors such as a malleable retractor or rectal sizers (Fig. 62.2). Alternatively, some manipulators (such as the VCare) allow to retract the uterine stem, leaving in place the cervical ring which allows for some cervical manipulation vaginally.
10. *Adnexectomy or salpingectomy*: As explained above, prophylactic removal of the adnexa or the fallopian tubes should be discussed with the patient before surgery. Prior to coagulation of the ovarian vessels, the course of the ureters is again visualized. The ovarian vessels are coagulated with bipolar forceps, taking care to ensure adequate coagulated margins before the vessel are divided. The adnexa or the fallopian tubes may be removed through a 12 mm assistant laparoscopic port or with the use of a bag.
11. *Hemostasis*: the surgical pedicles are irrigated in a stepwise fashion and any bleeding is identified and coagulated. Further hemostasis control may be performed with a "low pressure check", whereby the intra-abdominal pressure is lowered to 4–5 mmHg.
12. *Specimen removal*: National guidelines should guide whether or not power morcellation is performed for specimen removal. Other options for specimen removal include cold knife morcellation through the largest abdominal port. For this technique, the uterus is placed in a specimen retrieval bag and brought with a grasper to the abdominal wall. For normal size uteri, a 12 mm incision may be sufficient. However, larger uteri containing fibroid may necessitate an enlargement of the abdominal incision to 2–3 cm.
13. *Routine cystoscopy*: Although routine cystoscopy has not been found to be cost-effective in all hysterectomy cases [22, 23], it may be performed with low surgical risks associated with the procedure and relatively quickly. Due to the higher rates of urethral injury in prolapse or incontinence surgery, routine cystoscopy may be justified in those cases.
14. *Port closure*: Fascial closure is often performed for laparoscopic ports larger than 10–12 mm. This may be performed with a laparoscopic needle. Smaller ports do not require fascial closure, and the skin may be closed with a continuous intradermal suture or with interrupted mattress sutures.

Surgical Steps for Concomitant Sacral Colpopexy

This procedure includes dissection of the anterior and posterior vaginal walls, followed by exposure of the longitudinal ligaments at the sacral promontory area, and placement of Y shaped mesh. Finally, the mesh may be covered by a peritoneal layer. The procedure begins with assessment of the pelvic anatomy, ease of visualizing the anterior and posterior vaginal walls, and the sacral promontory area.

1. Dissection of the anterior vaginal wall: similar to the technique described above for dissection of the bladder flap for hysterectomy, the bladder is taken down further using traction on the bladder with a grasping instrument (i.e., the robotic prograsp, or a laparoscopic grasper held by the bedside assistant) and combined sharp and blunt dissection with the monopolar shears (Fig. 62.9). In the correct surgical dissection plane, minimal bleeding is encountered. This dissection is aided by use of a wide curved vaginal obturator such as the end-to-end rectal anastomosis sizer (Fig. 62.2). The extent of the dissection is guided by the degree of prolapse of the anterior vaginal wall on pre-operative exam.
2. Dissection of the rectovaginal space: after the vaginal manipulator is placed in the posterior fornix, the loose peritoneal covering of the pouch of Douglas, in between the sacro-uterine ligaments, is grasped and a shallow incision is made in order to enter the rectovaginal space. This space usually contains loose areolar tissue which may be easily separated downward to the level of the rectum medially and the levator ani muscles laterally, while exposing the rectovaginal septum (also called Denonvilliers' fascia) (Fig. 62.10). As before, in the cor-

Fig. 62.9 Further exposure of the arterial vaginal wall. In this figure, the end-to-end anastomosis sizer is placed in the anterior fornix of the vagina, providing excellent demarcation of surgical plane between the vagina and the bladder

Fig. 62.10 Dissection of the rectovaginal space and exposure of the rectovaginal septum

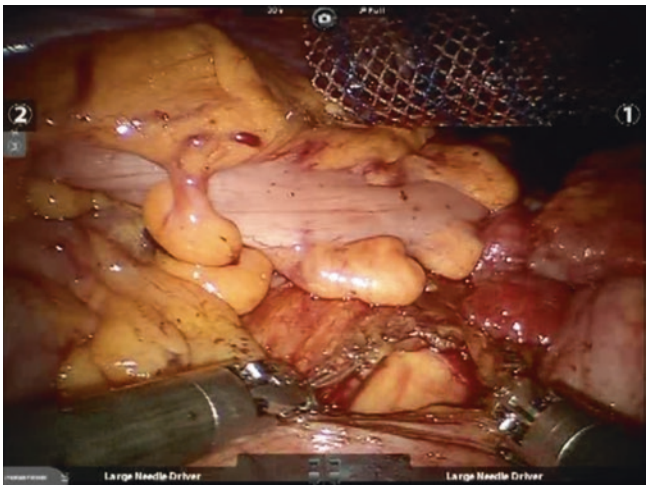

Fig. 62.11 Exposure of the anterior longitudinal ligament at the presacral area

rect surgical plane the bleeding is minimal during most of the dissection. However, in cases of extensive dissection (which may be required for advanced prolapse) some blood vessels are often encountered close to the rectum. We have found that use of the 30° optics pointed upwards aids in the visualization of the rectovaginal space. Likewise, a rectal probe may aid in recognizing the borders of the rectum. As for the dissection of the anterior vaginal wall, the extent of dissection of the rectovaginal space is guided by the degree of prolapse.

3. Dissection of the presacral area: this area is best visualized with a 30° optics pointed downwards, and after the sigmoid colon is retracted to the left with a grasping instrument (usually the prograsp) placed in the left robotic arm. In cases of a relatively mobile sigmoid colon the retraction of the sigmoid colon with grasping instruments may be insufficient for optimal visualization. In those cases, the sigmoid colon may be fixed to the left middle anterior abdominal wall by passing a suture on a straight long needle through the abdominal wall, to the sigmoid epiploica in 2–3 spots and back through the abdominal wall, close to the entry point. The suture is then tied and left in place for the duration of the surgery. Next, the bifurcation of the aorta, the course of the right common iliac artery and the course of the right ureter crossing over the pelvic brim are noted. The peritoneum above the dissection area in the sacral promontory is grasped and incised. The loose areolar tissue bellow is gently separated until the white anterior longitudinal ligament is seen. A dissection area of several centimeters is sufficient (Fig. 62.11). The major intraoperative complication during this step of the procedure is bleeding, which may originate from the middle sacral artery and vein or from smaller vessels. Thus, meticulous coagulation with bipolar forceps or the PK forceps combined with careful dissection is key. In addition, vascular clips or hemostatic agents should be available in the operating room in case they are required for hemostasis.
4. Dissection of the lateral peritoneum: the peritoneal incision on the presacral area is continued towards the Douglas pouch, medial to the right ureter and lateral to the rectum. This incision will be used to cover the mesh at the conclusion of the procedure. Alternatively, blunt dissection of this space while undermining the peritoneum with monopolar shears but without the peritoneal incision would allow to pass the mesh from the pelvic to the presacral area below the lateral peritoneum. This technique

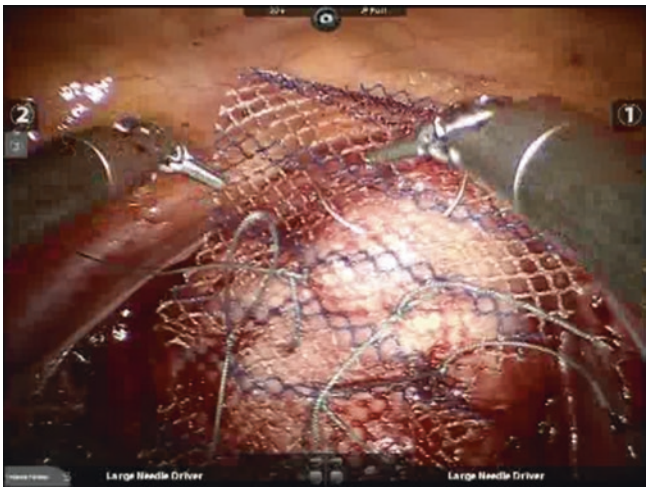

Fig. 62.12 Interrupted sutures anchoring the mesh to the cervical stump using a 2-0 non-absorbable suture and intracorporeal knots

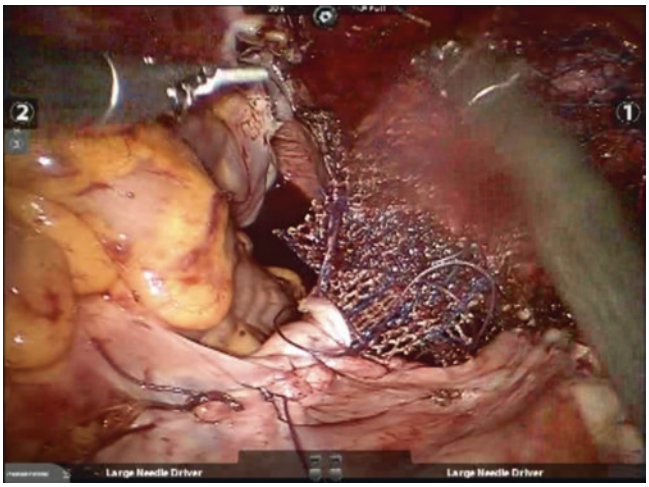

Fig. 62.13 The peritoneum is closed over the mesh using a running 2-0 or 1-0 absorbable suture

may shorten surgical time because peritoneal closure over the mesh with a continuous suture is unnecessary.

5. Tailoring of the mesh: the macroporous, polypropylene mesh, required for sacral colpopexy has a Y shape and include two rectangular pelvic arms (for the anterior and posterior vaginal walls) and one rectangular sacral arm. This mesh may be fashioned individually from a large 15*15 cm mesh square or purchased as a "ready to use" Y mesh. The commercially available Y meshes may also need some tailoring prior to their introduction into the abdominal cavity because their arms are too long for most patients.
6. Suturing of the Y mesh: the robotic monopolar shears and bipolar forceps are switched to needle drivers. The triangle of the Y mesh is placed on the cervical stump and 1–2 sutures are used to anchor it in place (Fig. 62.12). Subsequently, the mesh is anchored to the anterior vaginal wall, followed by the posterior vaginal wall, by a series of interrupted sutures using a small diameter suture (such as 2-0) and intracorporeal knotting. Use of the vaginal obturator to move the cervical stump according to the suturing area is very helpful. The choice of suture material is debatable: a non-absorbable polyester braided suture such as Ethibond (Ethicon, Somerville, New Jersey, USA) or a comparable absorbable suture (such a polyglactin suture). The former is easy to handle and knot, but should it protrude to the vaginal side of the vaginal wall, postoperative removal may be required. For the sake of efficiency, a relatively long suture (~35–40 cm) may be introduced into the abdominal cavity and used for several interrupted sutures.
7. Anchoring the mesh to the anterior longitudinal ligament: The sacral arm of the mesh is pulled cephalad, carrying the cervical stump upwards and correcting the prolapse. The position of the cervical stump is adjusted to ensure it is "tension free". At the chosen location, the sacral mesh arm is anchored to the anterior longitudinal ligament at the S1 region with a tacking instrument or with a couple of non-absorbable sutures. The tacking instrument is easy and quick to use, however, concerns have been raised regarding its possible role in the development of lumbosacral osteomyelitis and spondylodiscitis, a rare but severe complication of sacral colpopexy. Those concerns stem from the presumed deeper penetration of the bone tack compared to sutures. Nevertheless, since lumbosacral osteomyelitis has been reported with use of both tacking instruments and sutures, it is unclear whether one technique is safer than the other, and many surgeon continue to use tacking instruments until further evidence is available [24, 25]. If use of the tacking instrument is preferred, the best approach to operate it in terms of proximity to the presacral area and angle is offered by the right robotic port. This would require temporary undocking of the right robotic arm.
8. Peritoneal closure: any excess mesh is excised, and after hemostasis of the presacral area and the pelvic has been checked, the peritoneum is reapproximated over the entire length of the mesh with a running 2-0 absorbable suture (Fig. 62.13).

Surgical Outcomes and Complications of Robotic Sacral Colpopexy

Abdominal sacro colpopexy, whether by open, laparoscopic or robotic approach is considered superior in treatment of apical prolapse compared to the vaginal approach in terms of prolapse recurrence, residual prolapse [2]. However, the

robotic approach is not necessarily superior to the conventional laparoscopic sacral colpopexy. In a randomized controlled trial by Paraiso et al. [26], 78 patients were randomized to the laparoscopic or robotic sacral colpopexy. There were no differences in vaginal support and functional outcomes at 1 year follow up, but the robotic surgery was significantly longer and more expensive than the laparoscopic one. Nevertheless, since laparoscopic sacral colpopexy is a technically demanding procedure requiring advanced suturing skills and a long learning curve, the robotic platform may allow additional surgeons to perform it.

A recent systematic review on the outcomes and complications of robotic sacral colpopexy included 1488 cases from 27 studies, published from 2006 to 2013 [27]. Intraoperative complication occurred in 3 % (including mostly vaginotomies, urinary tract injuries, and bowel injuries). Postoperative complications occurred in 11 % of cases overall, but only 2 % were graded as severe (such as bowel obstructions, port site hernia, port site nerve entrapment, and peritonitis due to bowel injury). Mesh erosion at the vaginal area was reported in 2 % of patients, and appeared to be related to the execution of total hysterectomy as opposed to supracervical hysterectomy, and to the use of a standard weight polypropylene mesh as opposed to a lightweight polypropylene mesh (the latter being a protective factor).

Finally, spondylodiscitis of the L5-S1 disc or vertebral osteomyelitis is rare complication of the procedure, with less than 30 cases reported in the literature for all sacral colpopexy surgical approaches [24]. This severe complication (which may or may not involve mesh erosion at the presacral area) is often preceded by a urinary tract or vaginal cuff infection. Patients present with back pain several weeks after the procedure and often require additional surgeries for drainage, debridement and mesh removal in addition to broad spectrum intravenous antibiotic treatment.

Cervical Stump Extirpation with Regard to Robotic-Assisted Laparoscopic Hysterectomy

63

Hung-Cheng Lai and Yu-Chi Wang

Introduction

Over the past decades, minimally invasive surgery MIS) has become a trend in the field of surgery. The laparoscopic surgery boomed in the late 1980s and continued to gain popularity into the 1990s and this MIS have been successfully applied to the gynecological benign and malignant tumors. For many years, MIS appeared to represent an alternative approach in the gynecological surgery compared to the traditional exploratory laparotomy. Another novel MIS technology called "robotic surgery" which composed of patient-side cart, computer stand-interface and surgeon console is introduced in the 2000s and provide advantages for the surgeons. It is particular useful in obese patients, long-time surgeries and the operation required extensive suturing. This newly technology is similar to or better than previous laparoscopic surgery in shortened hospital stay, less blood loss, less surgical pain, a faster recovery and less scarring.

Since the approval by the US Food and Drug Administration (FDA) in 2005, robotic surgeries have been widely used in gynecologic field including benign and malignant disorders [1]. The first case of hysterectomy by robotic surgery was reported in 2002 [2]. By 2011, 37 % of hysterectomies in United State were performed by laparoscopy and 27 % were by robot. (Intuitive surgical Inc., Sunnyvale, CA, USA).

Although minimally invasive surgery provide many advantages, the extirpation of uterine cervix remains a challenge since the vicinity of cervix contains structures such as bladder, ureter and rectum which may subject to injuries (Fig. 63.1). The key of success include the identification of uterine artery, ureter and the plans of uterine-vesicle fold and recto-vaginal space. Here, we described the details of these procedures in this chapter.

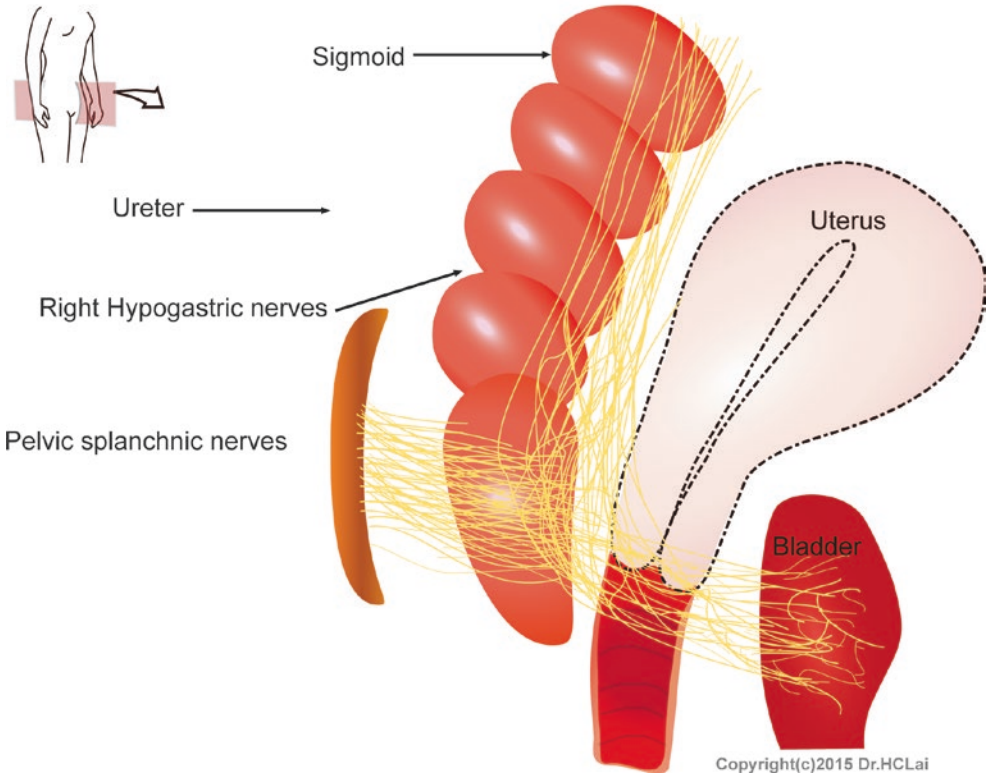

Fig. 63.1 The anatomy of the pelvic structures including bladder, uterus, cervix, bowel, ureter and pelvic nerve. The ureter comes across uterine cervix at about 2–3 cm lateral to the isthmus. Nerve innervation spread along and below ureter to the bladder

Hysterectomy

The uterus is elevated using manipulator (Fig. 63.2). Carefully checking the whole pelvis and avoid to trauma and tear the bowel, bladder and vessels. First, the round ligament and fallopian tubes are grasped and coagulated by a bipolar forceps and then cut using monopolar spatula or scissors at right side (Fig. 63.3). Then, the anterior leaf of broad ligament is subsequently separated down to the bladder peritoneum to the uterus. After opening the retroperitoneum, the ureter can be identified on the posterior leaf of the broad ligament The grasper can hold the peritoneum and the ureter can be dissected carefully using a blunt dissector or spatula. The uterine artery is then identified and clamped (Figs. 63.4 and 63.5). The ureter, then, can be bluntly pushed a little bit laterally to have more space when doing colpotomy. The bladder is pushed downward to expose the vaginal colpus. Then the anterior colpotomy can be made using the unipolar spetula or forceps, and, circumscribe the cervix (Fig. 63.6). The uterine manipulator can be pushed forward to get a little tension of tissues for better cutting. Then the cervix is clamped by a tenaculum forceps and retrieved it through vagina. If the specimen is large, the uterus can be removed piece by piece

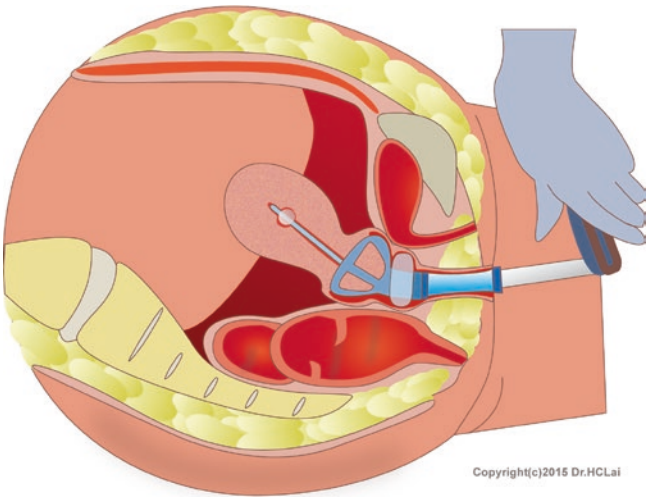

Fig. 63.2 The uterine manipulator is used to displace the uterus away from the bladder, ureter and rectum

by vaginal or transumbilical morcellation. The sponge in a glove or a baby nose suction bulb is placed into the vagina to prevent the loss of pneumoperitoneum (Figs. 63.7 and 63.8). Finally, the edge of the vaginal cuff is sutured (Fig. 63.9).

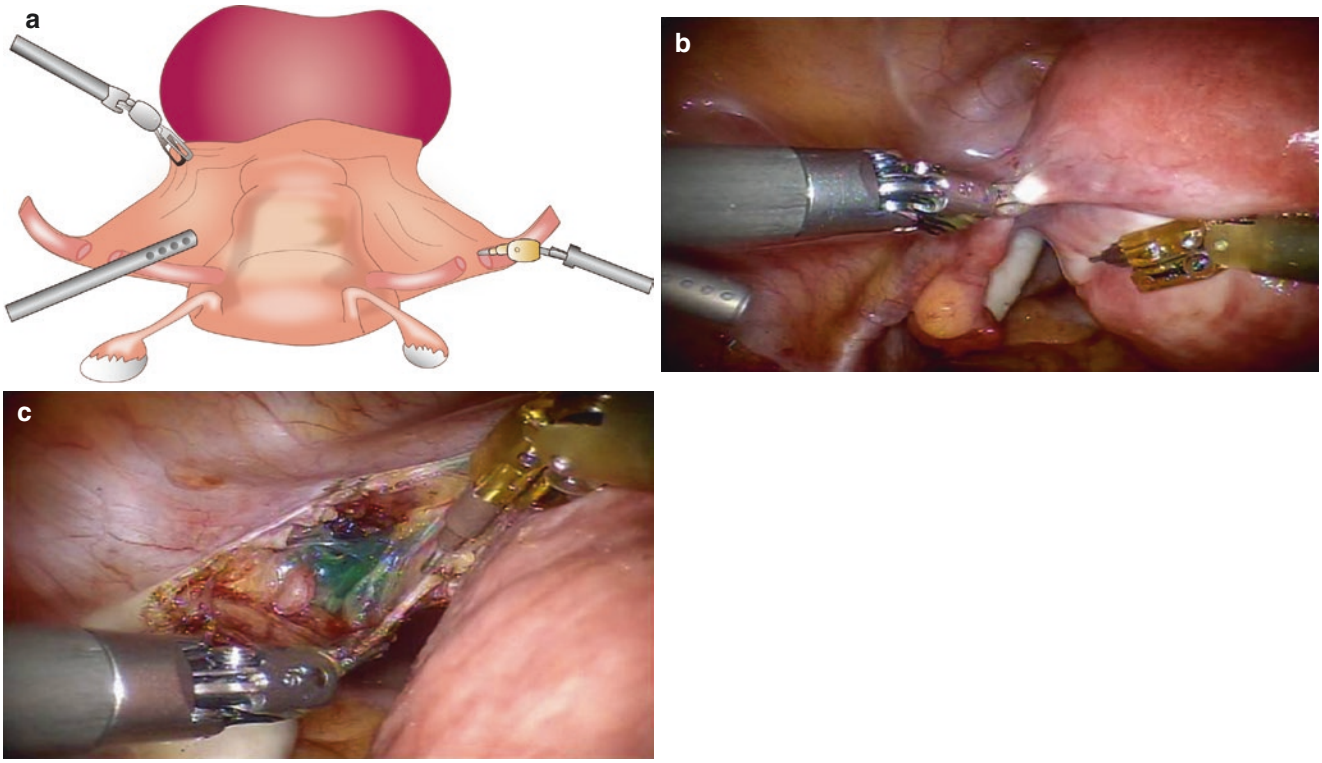

Fig. 63.3 (**a**) Illustration of round ligaments and the leaves of the broad ligament. (**b**) The round ligament and fallopian tubes are coagulated and then cut. (**c**) The anterior leaf of broad ligament is subsequently separated down to the bladder peritoneum to the uterus

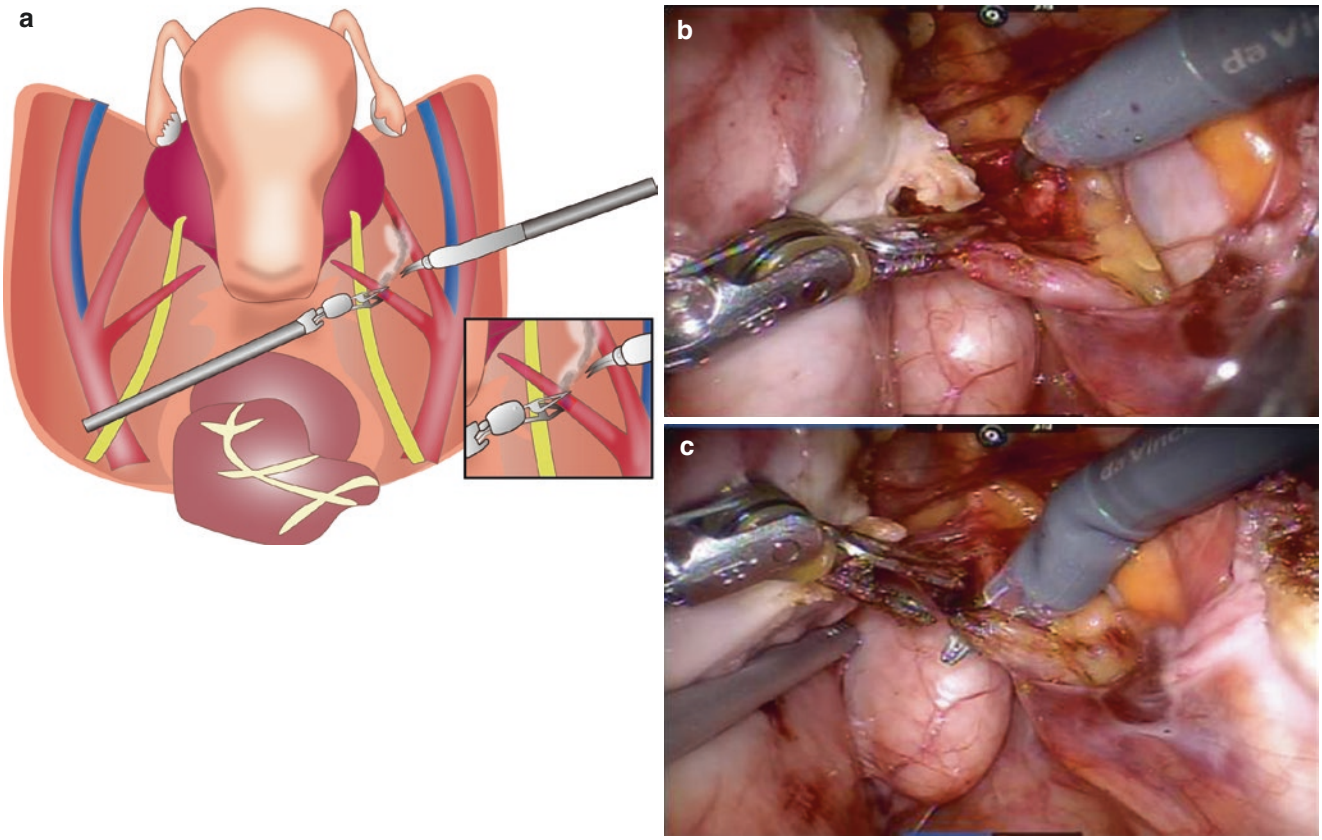

Fig. 63.4 (**a**) Illustration of uterine artery and ureter at the level of "bridge over trouble water". (**b**)The ureter can be identified at the level of pelvic brim and be bluntly dissected by scissor from its peritoneal attachment down to the parametrial level. (**c**) The uterine artery is then skeletonized as "the bridge over trouble water" and then coagulated using bipolar forceps

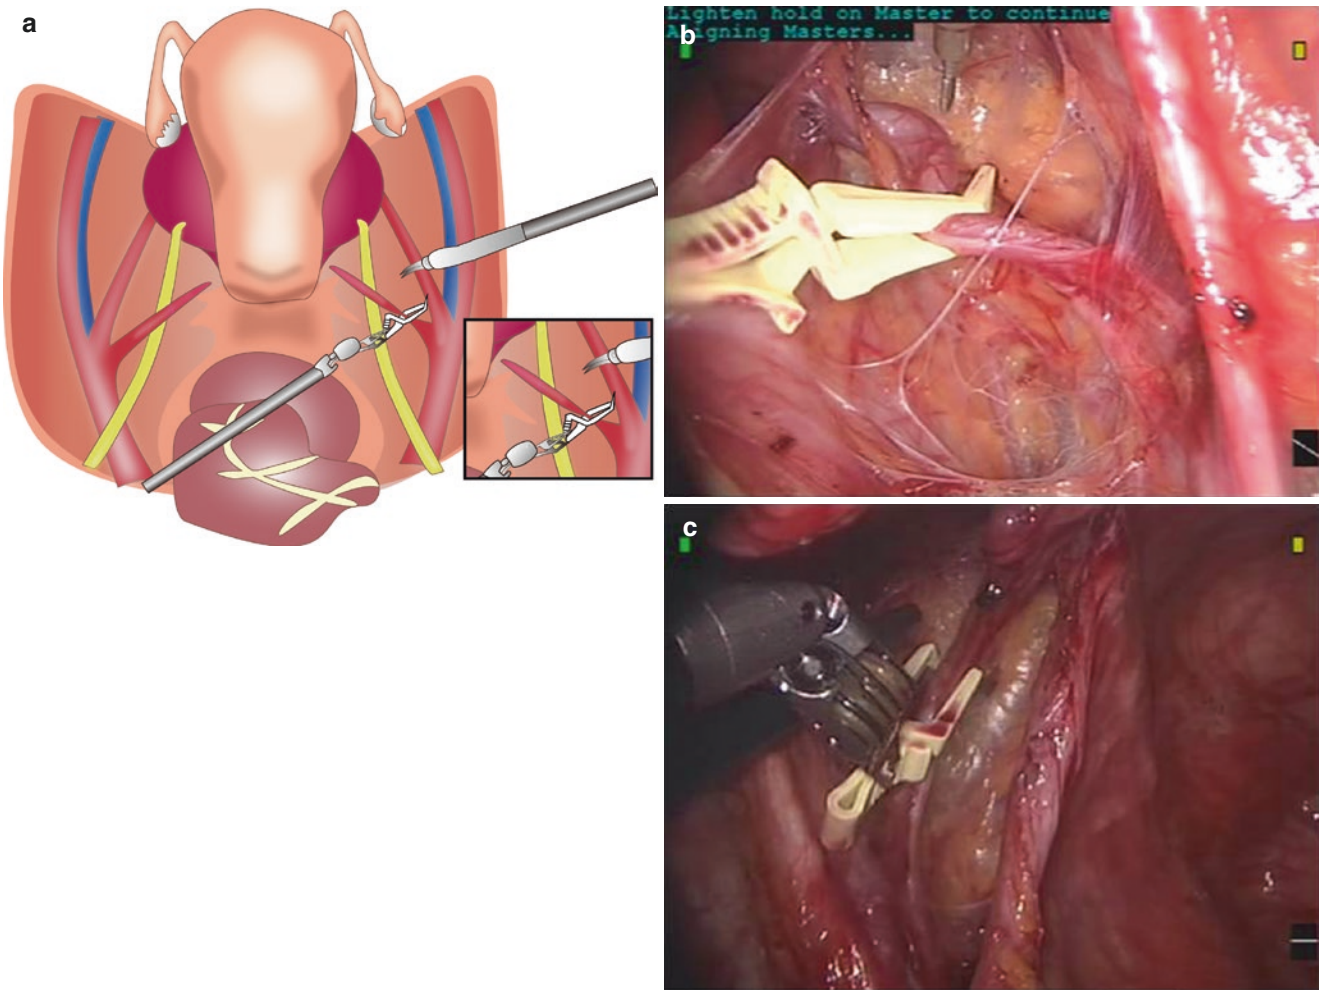

Fig. 63.5 (**a**) Illustration of clamping uterine artery at its origin from internal iliac artery. (**b**) The right ureter was bluntly dissected using a scissor dissector or spatula. The origin of uterine artery from internal iliac artery can be identified parallel to the ureter at this level. A bulldog clamp can be introduced using fenestrated forceps and temporarily clip the uterine artery until the uterine incision was sutured. The bulldog is removed after a complete homeostasis of the uterine body. (**c**) The clipped uterine artery and ureter, left

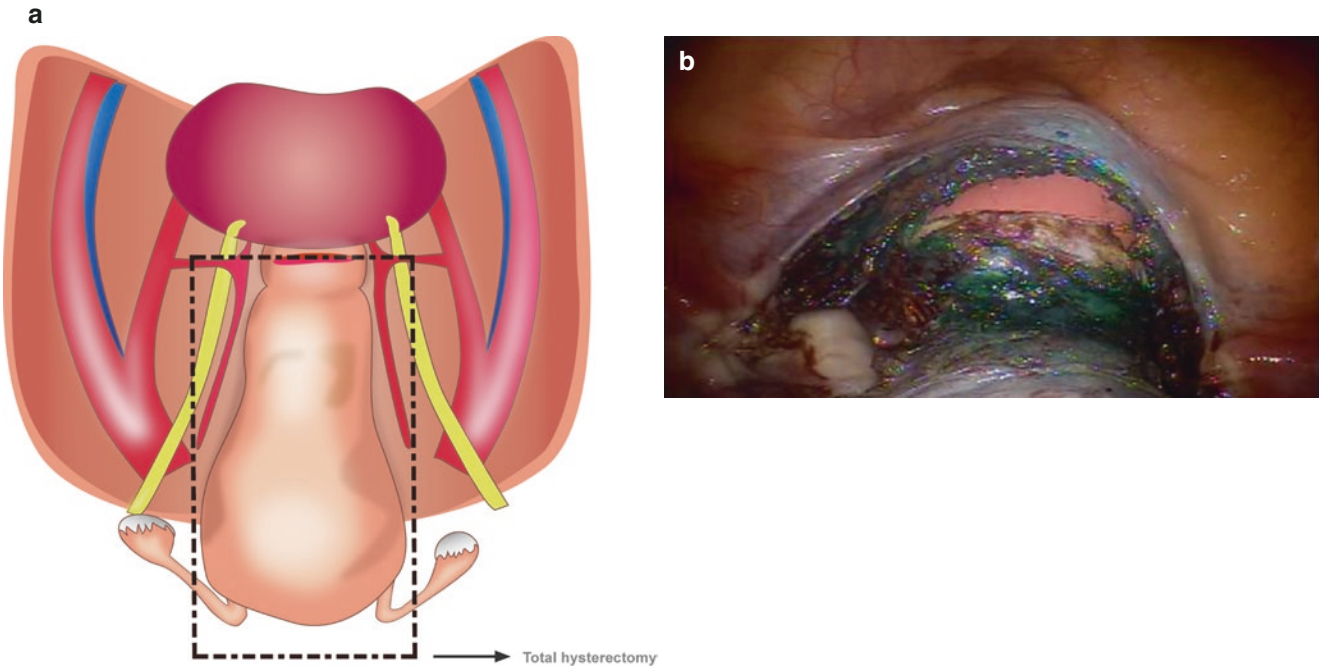

Fig. 63.6 (**a**) Illustration of the robotic view of total hysterectomy. (**b**) The placement of a baby nose sucker in vagina provides a good support for colpotomy. After the placement of a suction ball to the apex of the fornix, the bladder is released from the cervix by using scissors. Then the vagina is incised and opened by monopolar scissors

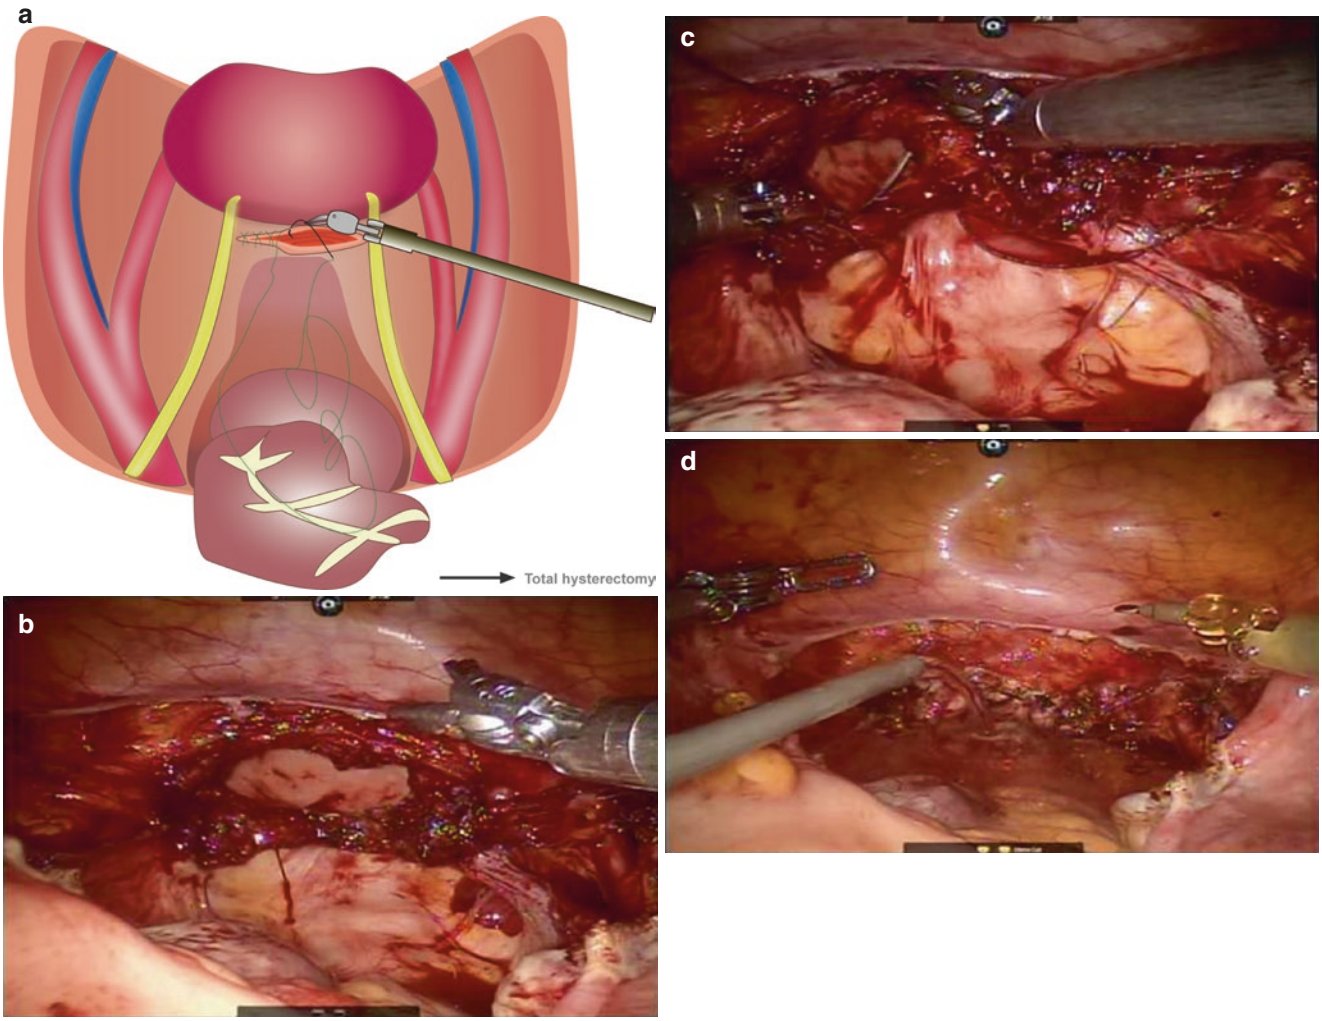

Fig. 63.9 (**a**) Illustration of the vaginal cuff closure. (**b**) The vaginal cuff after colpotomy and removal of uterus. (**c**) Closure of the first layer of vaginal cuff using V-lock suture. (**d**) Completion of double layered suture of vaginal cuff

Subtotal Hysterectomy

After the dissection of round ligament and ovarian ligament, the ureter can be identified at the posterior leaf of peritoneum. The peritoneum can be graped by bipolar grasper. Then, a gentle scratching using spatula or scissor on the medical aspect of peritoneum from the level around internal iliac artery may lead to the white peristalsing ureter covered by whirling vessels. Parallel to the ureter along the pelvic wall, the uterine artery can be identified by pulsation. The uterine artery can be skeletonized and dissected down to the cross above ureter (Figs. 63.4 and 63.5). Care should be taken to avoid tearing veins below. The uterine artery can be cauterized by bipolar forceps at any level of the course. For a large uterine mass, the origin of uterine artery can only be identified below the level around pelvic brim. Usually, using robot, the "bridge over trouble water" can be reached posteriorly. After uterine artery is cauterized, the ureter can be gently pushed laterally to release more space between cervix and ureter (Figs. 63.10 and 63.11). Then, the fundus is elevated by manipulator or tracted by tenaculum forceps or grasp. An incision is made anteriorly or posteriorly at the isthmus level above uterine artery. Ascending branches of uterine arteries and veins can be cauterized by bipolar forceps. After hemi-transection of the cervix, the manipulator can be removed.

The dragging of uterus due to deep Trendelenburg position exposes the cervical cannel. The cervix can be cut using unipolar spatula or scissor. The uterus can be removed by morcellator. Alternatively, a tenaculum forceps can be used to grasp the uterus to avoid wandering uterus in the abdominal cavity. Then, the robot can be detached. The uterus can be removed through a 2.5 cm umbilical incision with wound retractor.

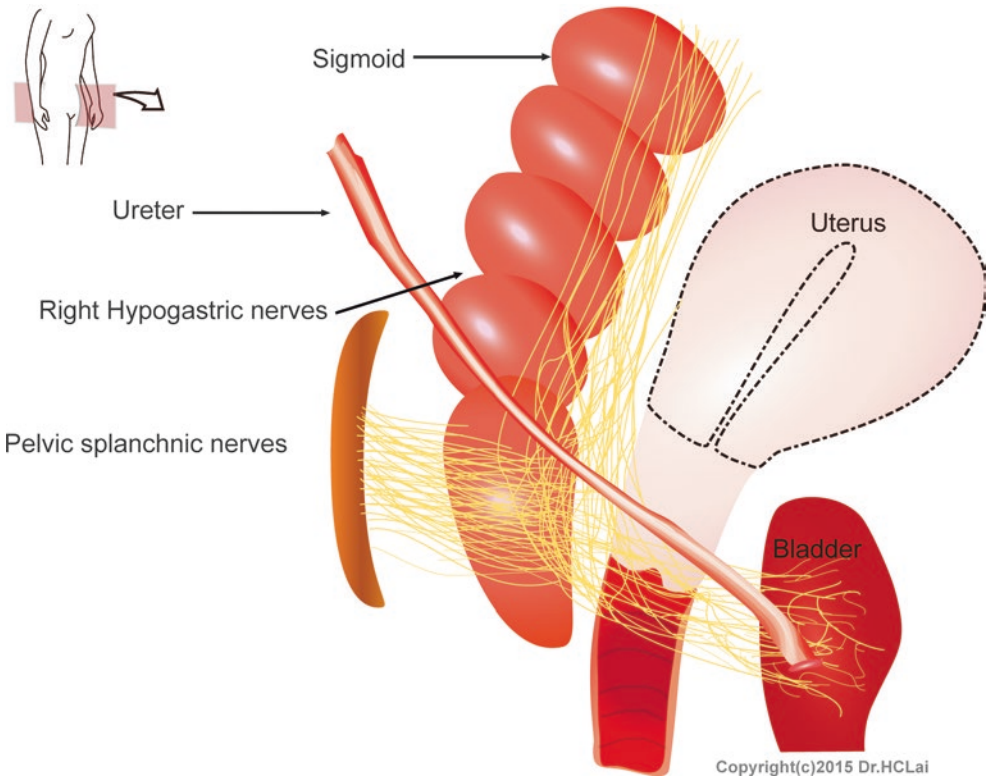

Fig. 63.10 Subtotal hysterectomy: After the uterine artery is clamped or ligated, the uterus is retracted by a grasper or a manipulator. The uterus and cervix is separated by the monopolar scissors at the isthmus where uterine artery enters uterus

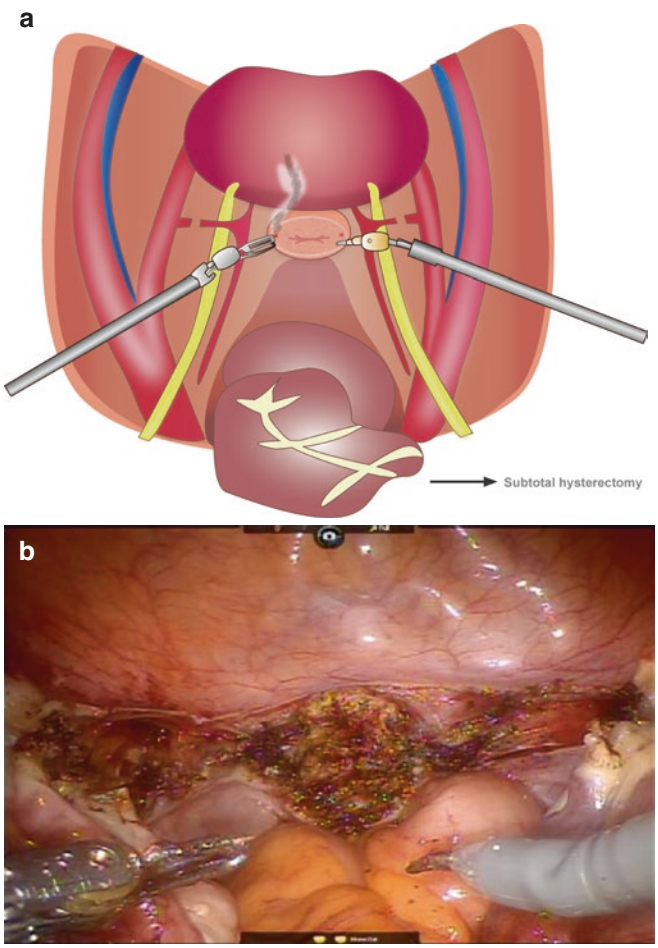

Fig. 63.11 (**a**) Illustration of cervical stump after supracervical hysterectomy. (**b**) Cervical stump after supracervical hysterectomy. Hemostasis is easier if the uterine arteries are ligated before the transection of uterine cervix

Radical Hysterectomy

The paravesical spaces are bounded by the external vessels laterally and the bladder medially (Fig. 63.12). The pararectal spaces are bounded by the rectum medially and the hypogastric artery laterally (Fig. 63.13). Then they are opened with gentle dissection using the monopolar spatula or scissors down to the pelvic wall. Furthermore, the uterine artery can be identified at the origin of hypogastric artery (Fig. 63.14). It is coagulated using bipolar forceps and cut. Then the uterine artery is elevated using grasper and the ureter can be identified below along the medial leaf of peritoneum. The ureter is pushed laterally along the tunnels and anterior leaf is exposed. The hypogastric nerve can be identified along the lateral aspect of rectal peritoneum (Fig. 63.15). The nerve fibers heading to the uterus is cut using monopolar scissor or spatula along the posterior leaf of tunnel. Then the recto-vaginal space is dissected and exposed at the middle, extended laterally to bilateral uterosacral ligament (Fig. 63.16). The uterosacral ligament are transected using the bipolar forceps ad scissors later. Finally, the bladder is pushed downward to expose the vaginal colpus. A circle colpotomy is made (Fig. 63.17). The uterus is dissected, extirpated through vagina (Fig. 63.18). The vaginal cuff is sutured (Fig. 63.19).

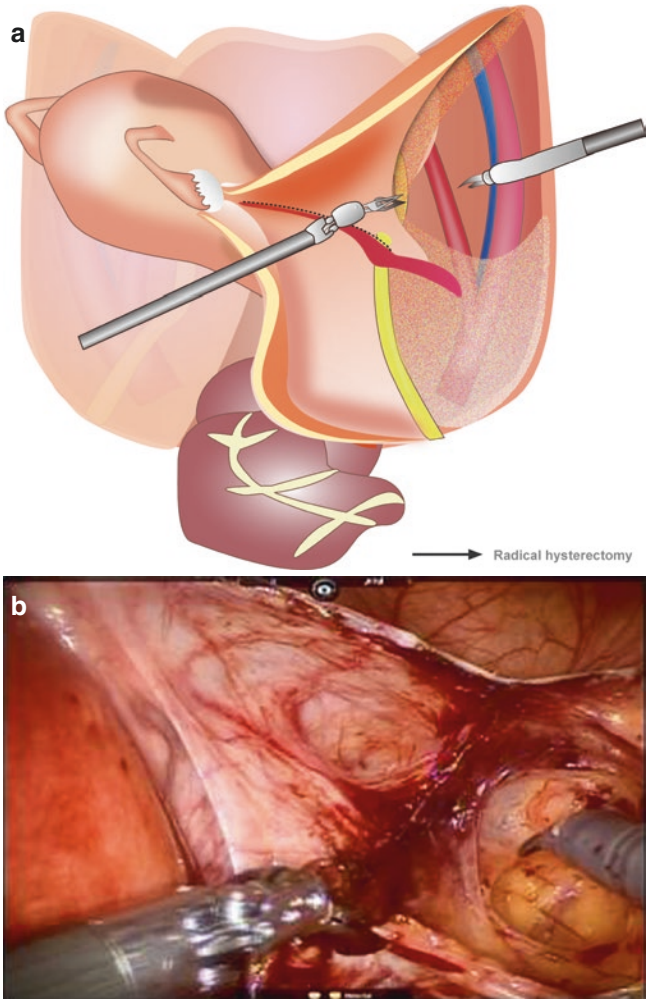

Fig. 63.12 (**a**) Illustration of paravesicle space. (**b**) The paravesical space is developed by a gentle dissection of bladder away from pelvic wall laterally. The umbilical artery can be identified and pushed laterally

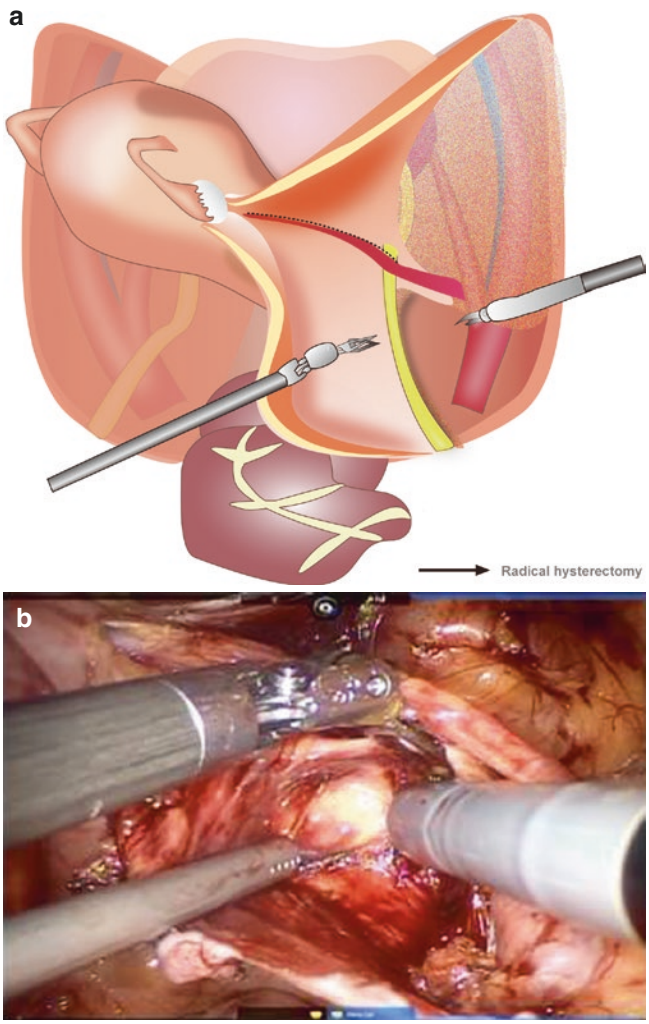

Fig. 63.13 (**a**) Illustration of pararectal space. (**b**) The pararectal space is developed by dissection down along the medial aspect of peritoneum. The ureter can be identified at the peritoneum medially and the internal iliac artery is the boundary laterally. The space can be developed down to the pelvic floor

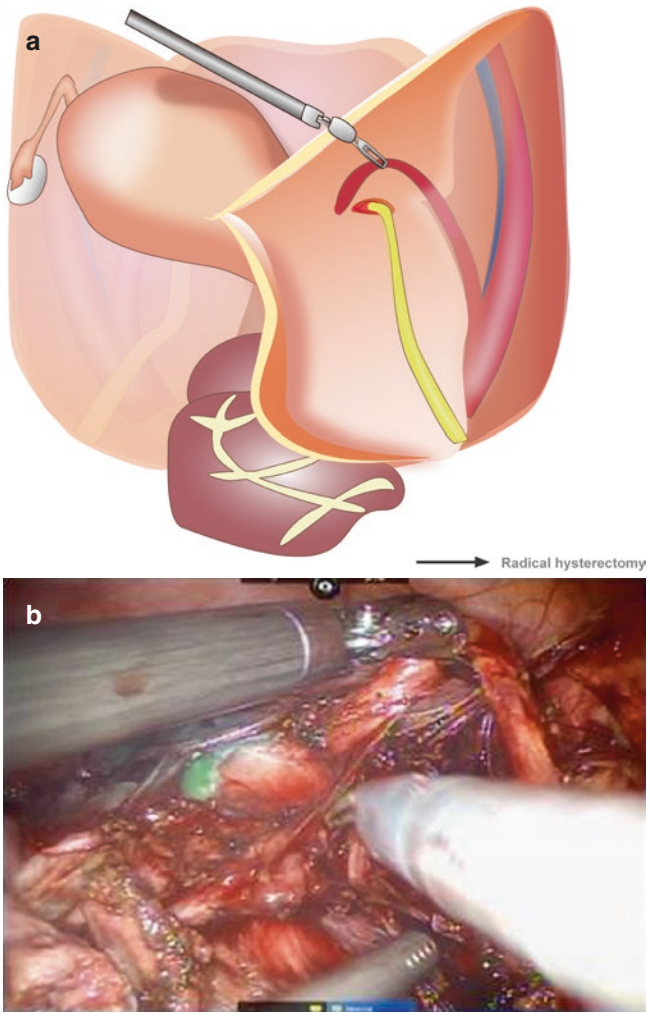

Fig. 63.14 (**a**) Development of anterior leaf of tunnel. (**b**) The ureter tunnel is identified by lifting the uterine artery and pushing downward the ureter until the complete separation of ureter and uterine artery. The anterior leaf is identified by the tissues covering ureter between bladder and uterus

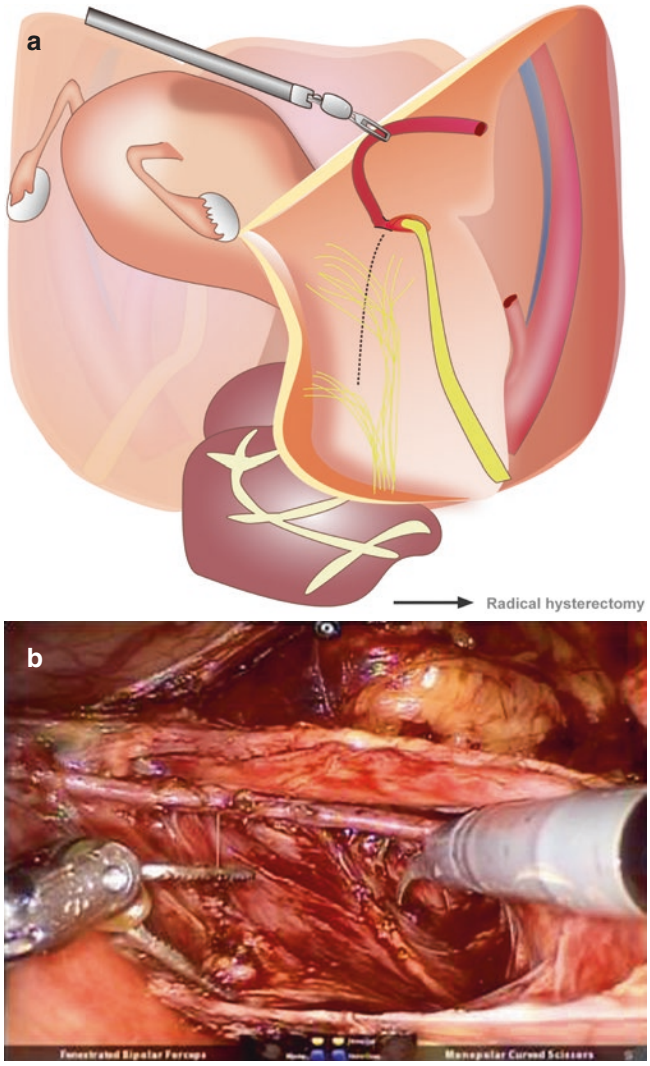

Fig. 63.15 (**a**) Illustration of posterior leaf of tunnel and hyogastric nerve. (**b**) The ureter run from pelvic wall to the uterus along (along with a preserved uterine vein). The posterior leaf of tunnel can be identified at below the ureter. Nerve fibers spreading around the peritoneum, the hypogastric nerve, are identified along the medial aspect of peritoneum down to the posterior leaf. An incision perpendicular to ureter can be made from the pararectal peritoneum along the posterior leaf. Nerve fibers toward uterus are dissected whilst fibers toward bladder can be preserved

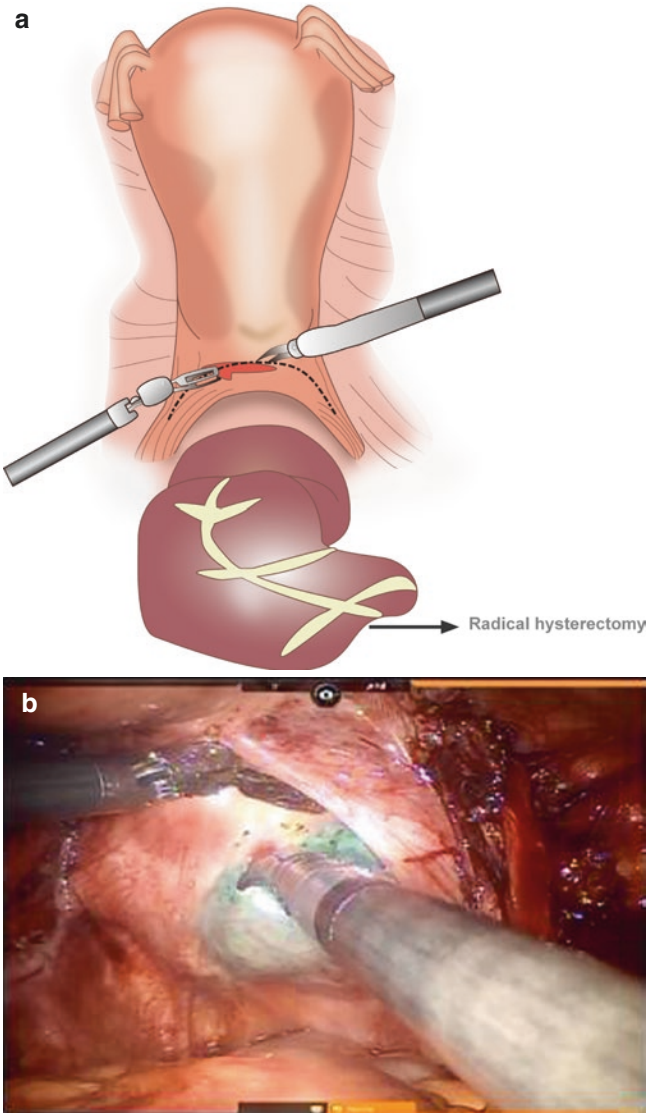

Fig. 63.16 (**a**) Illustration of posterior colpotomy. (**b**) The bulging of posterior fornex by pushing the nose sucker in vagina can be identified. An incision is made at the level of uterosacral ligaments and the recto-vaginal space can be developed downward. The space can be expanded laterally toward uterosacral ligaments. Then, uterosacral ligaments are transected, followed by the paracolpos below

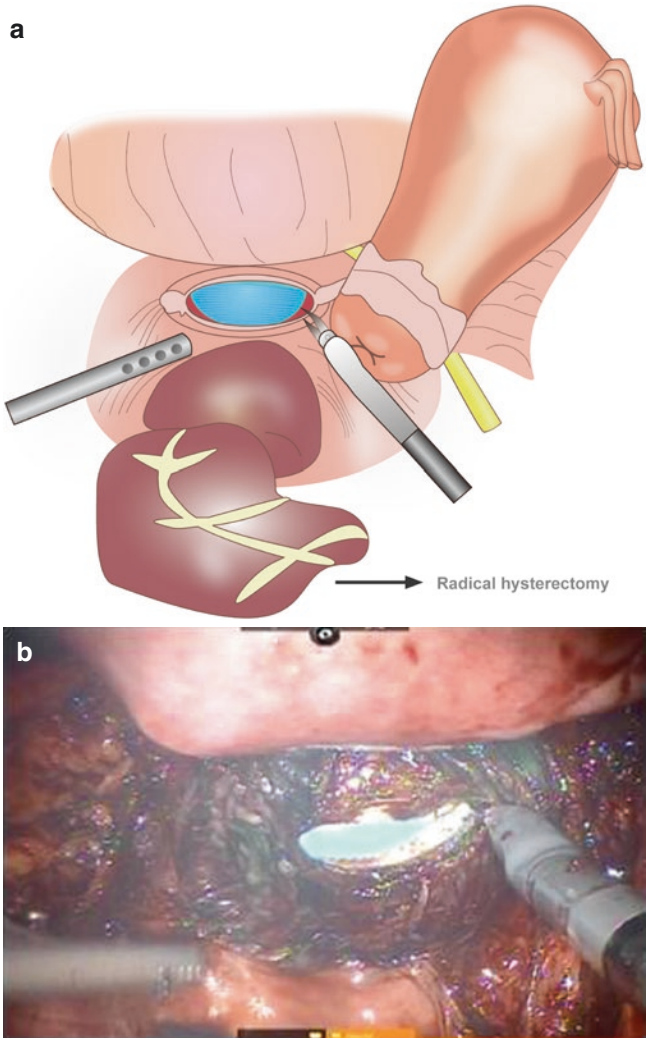

Fig. 63.17 (**a**) Illustration of colpotomy. (**b**) The colpotomy is made using monopolar scissors at posteriorly and anteriorly. The dissection is completed by circumscribing the vagina on the sucker bulb

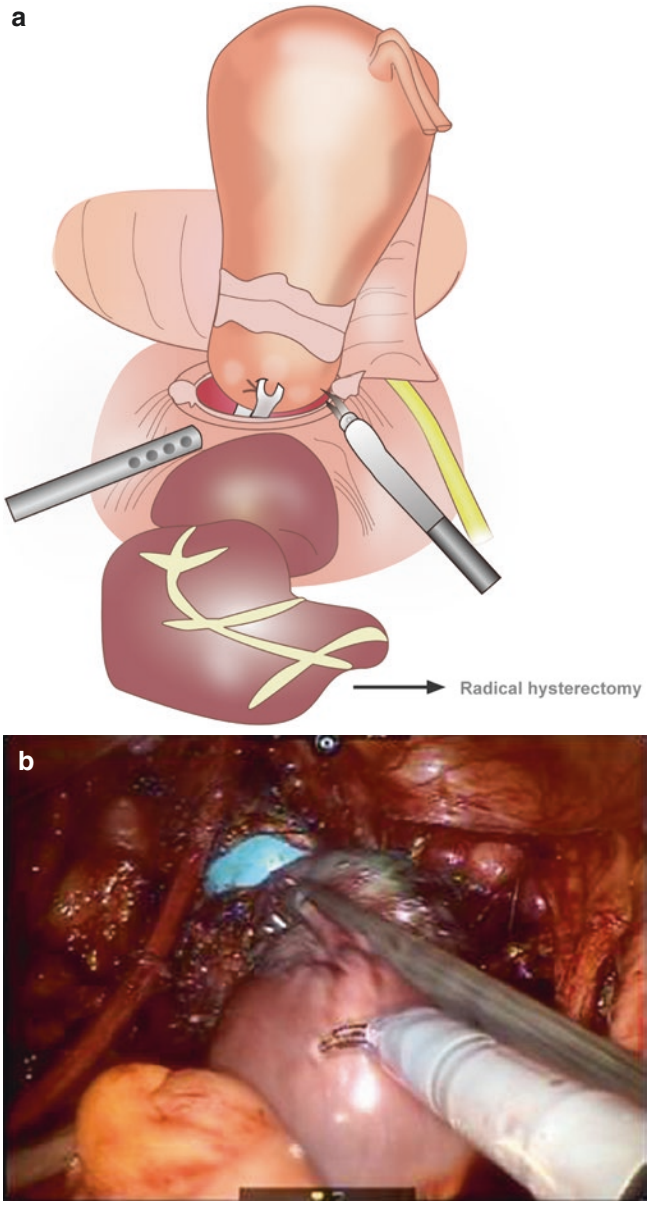

Fig. 63.18 (**a**) Illustration of removal of uterus. (**b**) The uterus is extirpated from the vagina using the Allis clamp or tenaculum forceps

Robotic-Assisted Total Hysterectomy: Hysterectomy Techniques in the Normal-Sized and Small Uterus

64

Megan N. Wasson and Javier F. Magrina

Introduction

The introduction of robotic technology has dramatically altered the surgical approach to hysterectomy. Following introduction of the robotic surgical system, there has been a dramatic decrease in the proportion of hysterectomies being performed via laparotomy. Furthermore, a continually growing number of hysterectomies are being performed via laparoscopy both with and without the assistance of robotic technology [1].

Patient Positioning

The combination of Trendelenburg and dorsal lithotomy positioning and can result in neurologic injury if not performed correctly. Correct preparation of the operating room table prior to the patient entering the operating room is essential (Figs. 64.1, 64.2, 64.3 and 64.4). Following administration of anesthetic, methodical positioning of the patient in the dorsal lithotomy position is performed (Figs. 64.5, 64.6, 64.7, 64.8, 64.9, 64.10, 64.11 and 64.12).If the patient is obese, the arms may be supported on arm boards placed alongside the operating table.

Fig. 64.1 The operating table is prepared for the patient by placing a draw sheet across the table. This will later be used to assist in securing the patient's arms at her side

Fig. 64.2 A piece of egg crate foam is placed on top of the draw sheet and operating table padding

Fig. 64.11 Care is taken to ensure there are no areas of pressure or potential nerve compression

Fig. 64.12 Correct positioning ensures that there are no areas or pressure or potential nerve compression

Trocar Placement

When completing a hysterectomy for a normal-sized or small uterus, four trocars are typically required (Fig. 64.13). One serves as the optical trocar, one serves as the assistant port, and two are used for the robotic arms. Use of the third robotic arm is not routinely necessary in these cases.

Correct placement of the trocars is essential to prevent robotic arm collision during the procedure. A common configuration consists first of the optical trocar placed through the deepest aspect of the umbilicus. Two robotic trocars are placed at the level of the umbilicus, 12 cm to the right and left, respectively. A 5 or 10 mm assistant trocar is positioned equidistant and 3 cm cranial between the umbilicus and the left robotic trocar.

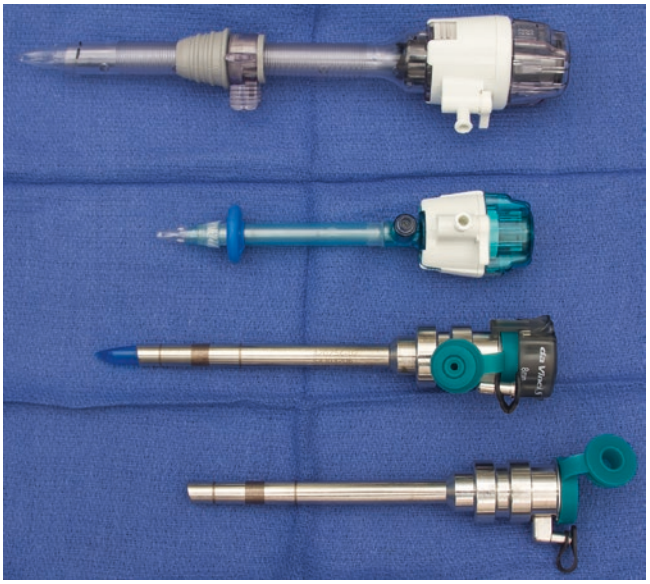

Fig. 64.13 Four trocars are typically required for completing a robotic hysterectomy

Fig. 64.14 The robotic column is maintained away from the operating table until the surgeon is ready for docking

Robotic Column Location

At the initiation of the hysterectomy, the robotic column is stored away from the surgical field (Fig. 64.14). When docking is performed, the robotic column can be placed in the midline or to the right or left of the patient. Midline placement is not ideal, as this impedes access to the vagina and thereby limits the ability for specimen removal or uterine manipulation (Fig. 64.15). Utilization of a template can assist in obtaining an optimal docking location (Figs. 64.16 and 64.17).

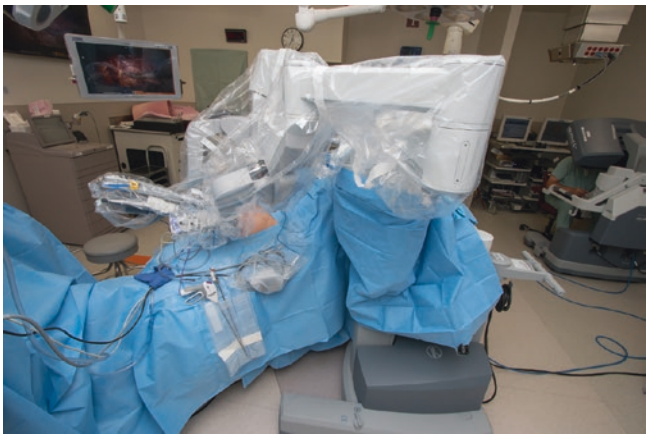

Fig. 64.15 Placing the robotic column to the left or right of the patient's legs eliminates the restriction faced with midline placement

Fig. 64.16 The Mayo Clinic robotic template is placed in the area of desired robotic column location

Fig. 64.17 Utilization of the Mayo Clinic robotic template facilitates accurate, efficient, and reproducible placement of the robotic column for all pelvic surgeries

Fig. 64.18 The robotic laparoscope is 12 mm in diameter and is introduced through the optical trocar at the umbilicus

Robotic Instrumentation

Following docking of the robotic system, the robotic instruments are introduced through the robotic trocars. The first instrument introduced is the laparoscope as this allows for direct visualization of all subsequent manipulation of the robotic instruments (Fig. 64.18).

Utilization of a bipolar instrument, monopolar instrument, and needle driver are essential to completing a robotic hysterectomy (Fig. 64.19).Use of the monopolar scissors or spatula is dependent on the surgeon's preference.

Typical placement of the robotic instruments for a right-handed surgeon consists of the monopolar instrument in the right hand and the bipolar instrument in the left hand (Fig. 64.20).

Monopolar energy is ideal for opening thin tissue layers overlying larger structures, such as the vesicouterine peritoneum. Monopolar energy can also be utilized to achieve and maintain hemostasis when addressing small or superficial blood vessels.

Bipolar energy is ideal when larger vessels are encountered and able to be isolated from surrounding structures. Coagulation of the infundibulopelvic ligament or uterine arteries can be achieved with either bipolar energy or a vessel sealing device. If bipolar energy is utilized to coagulate large blood vessels, monopolar energy must be employed for vessel transection.

When the time comes for suturing, the monopolar instrument is exchanged for the meganeedle holder.

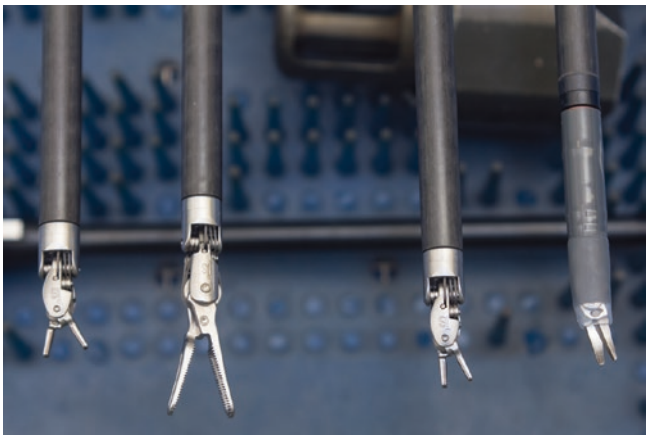

Fig. 64.19 For completion of a hysterectomy for a normal-sized or small uterus, the most commonly used instruments are the bipolar PK dissecting forceps, monopolar scissors or spatula, and meganeedle holder. When permitted, it is preferred that the meganeedle holder have the incorporated suture-cutting scissors

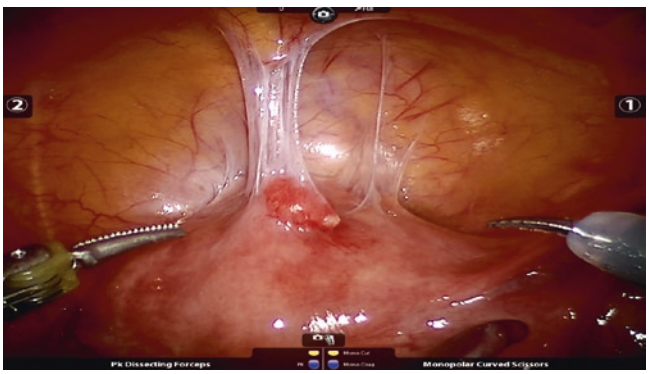

Fig. 64.20 The monopolar instrument is used with the right arm and a bipolar PK dissecting forceps is used with the left arm for right-handed surgeons

Fig. 64.21 Various laparoscopic instruments are utilized by the assistant

Use of Assistants

The efficiency and economy of the hysterectomy is improved by the use of a trained, knowledgeable assistant. The assistant provides assistance with vessel-sealing, suction and irrigation, tissue retraction, specimen retrieval, introduction and removal of suture and needles, and correcting malfunctions of the robotic instruments or arms (Fig. 64.21).

Hysterectomy Procedure for a Normal or Small-Sized Uterus

To begin a robotic hysterectomy, first expose the pelvic side wall by placing traction on the round ligament. Enter the retroperitoneal space by incising the peritoneum adjacent to the infundibulopelvic ligament (Fig. 64.22). Further open the retroperitoneal space to identify the ureter (Fig. 64.23). Following identification of the ureter, the infundibulopelvic ligament can be easily isolated and divided if a salpingo-oophorectomy is desired (Figs. 64.24 and 64.25). The peritoneum is then opened further separating the uterus from the pelvic side wall (Fig. 64.26). The round ligament is then divided (Fig. 64.27). The vesicouterine peritoneum is then opened to develop the bladder flap (Fig. 64.28). Continue to open the broad ligament and skeletonize the uterine vessels (Fig. 64.29).Follow the ureter starting at the pelvic brim where it is most easily identified. The distance between the cervix, uterine vessels, and the ureter should be noted to estimate the risk of ureteral injury when dividing the cardinal ligament.

If the ureter appears coursing towards the cervix, divide the uterine artery over the ureter and displace the ureter laterally. Utilize the vessel sealing device to seal and divide the lower cardinal ligaments adjacent to the cervix bilaterally (Fig. 64.30).

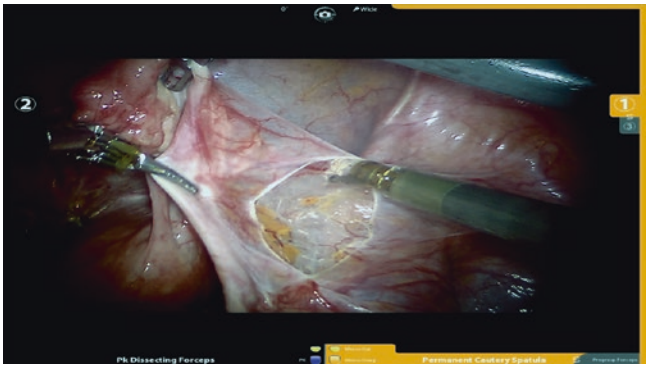

Fig. 64.22 Grasp the uterus by one of the round ligaments and pull it towards the patient's contralateral side. Make a peritoneal incision lateral and parallel to the infundibulopelvic ligament using monopolar energy

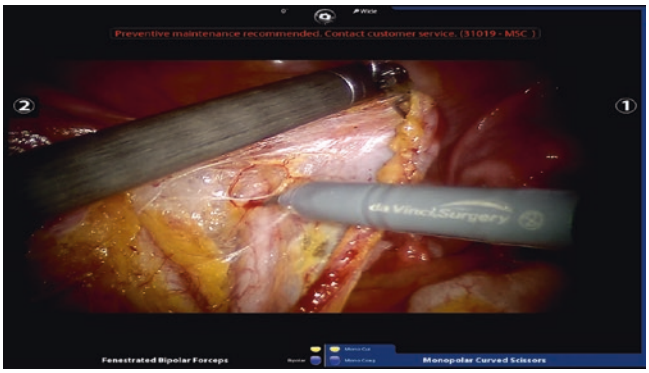

Fig. 64.23 Open the retroperitoneal space lateral to the infundibulopelvic ligament using monopolar energy and identify the ureter. Short bursts of monopolar energy followed by blunt dissection allows hemostasis to be maintained, while decreasing risk of injury to surrounding structures

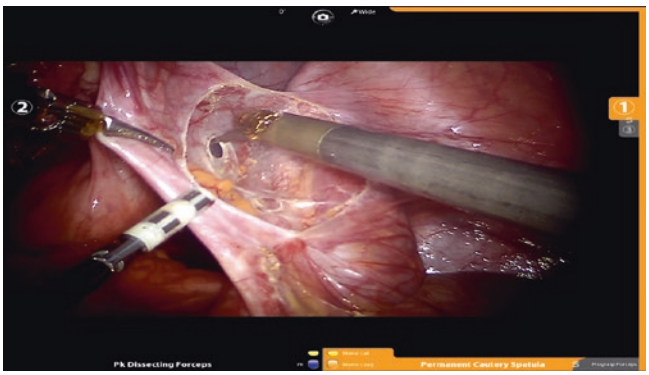

Fig. 64.24 Create a window in the medial leaf of the broad ligament above the ureter and below the infundibulopelvic ligament using monopolar energy

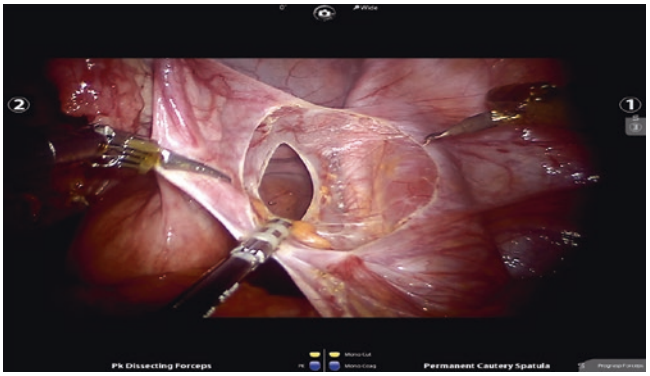

Fig. 64.25 Grasp and divide the infundibulopelvic ligament using a vessel sealing device

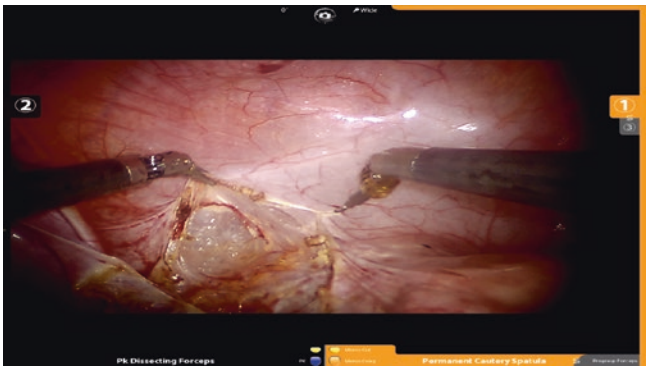

Fig. 64.28 Using monopolar energy from the scissors or the spatula incise the anterior leaf of the broad ligament towards the vesicouterine peritoneal reflection

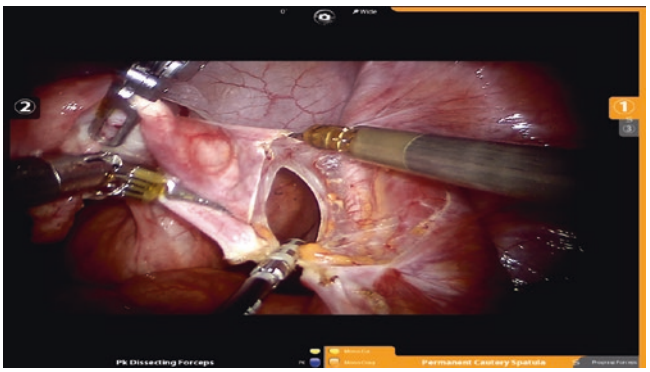

Fig. 64.26 Using monopolar energy, incise the peritoneum overlying the external iliac vessels towards the lateral aspect of the round ligament

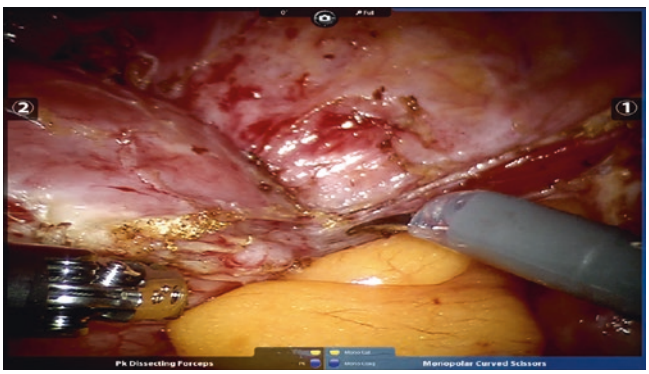

Fig. 64.29 Dissect the retroperitoneal areolar tissue in the broad ligament using monopolar energy until the uterine vessels are clearly visible along the lateral wall of the uterus

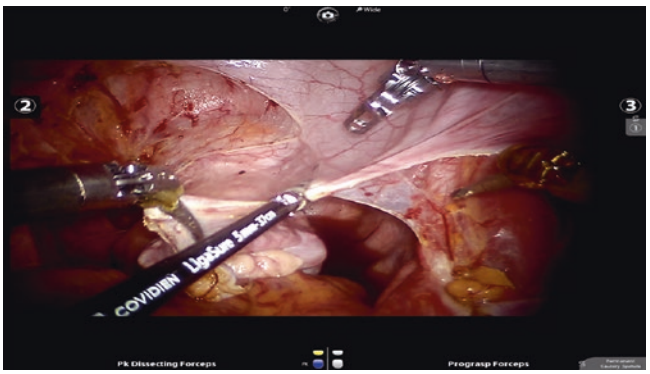

Fig. 64.27 Transect the round ligament at its lateral aspect using the bipolar PK dissecting forceps and monopolar energy or a vessel sealing device

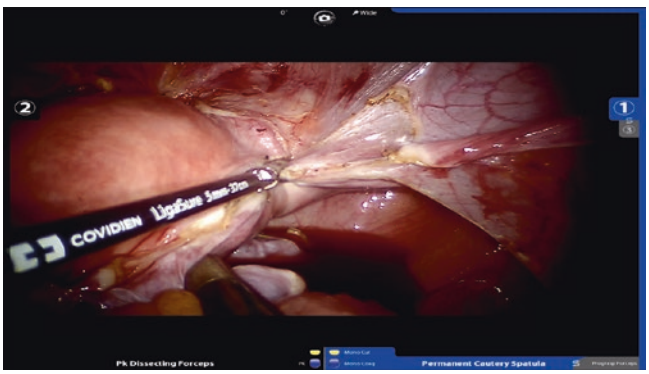

Fig. 64.30 Utilize a vessel sealing device to divide the upper cardinal ligament adjacent to the lateral cervical wall

All steps are then repeated on the opposite side.

Utilize a vaginal probe to assist with further development of the bladder flap (Figs. 64.31 and 64.32).

When performing a hysterectomy on a patient with history of cesarean delivery, adhesions between the bladder and uterus are likely to be encountered. Care must be employed to safely separate the bladder from the uterus (Figs. 64.33 and 64.34).

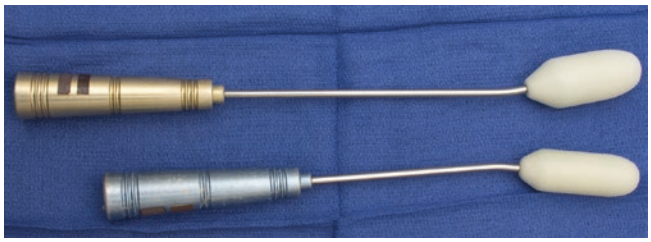

Fig. 64.31 To assist with bladder dissection, the surgical technician introduces a reusable vaginal probe or cervical cup. This helps to facilitate bladder dissection and identification of the cervicovaginal junction. A uterine manipulator is not required with this technique

Fig. 64.32 The bladder is dissected from the anterior cervix and upper vagina at a distance of 1–2 cm from the cervicovaginal junction by separating the areolar tissue between the cervix and bladder using monopolar energy. The dissection is carried out first in the midline and then to the right and left

Fig. 64.33 Patients with a history of cesarean delivery can develop scar tissue between the bladder and uterus

The vaginal probe is also essential for identifying the cervicovaginal junction (Fig. 64.35). Monopolar energy is then utilized for perform a circumferential colpotomy (Figs. 64.36, 64.37, 64.38 and 64.39). When making the colpotomy, maintenance of pneumoperitoneum is achieved by

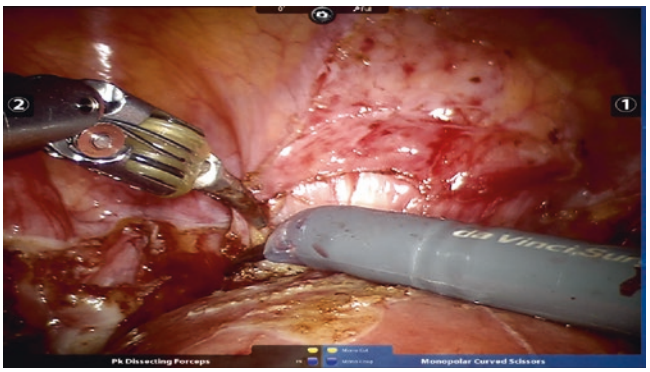

Fig. 64.34 In patients with a history of cesarean section, the dissection is carried out first on the right or left of the uterine scar and then in the midline

Fig. 64.35 The cervicovaginal junction is identified and marked with monopolar energy

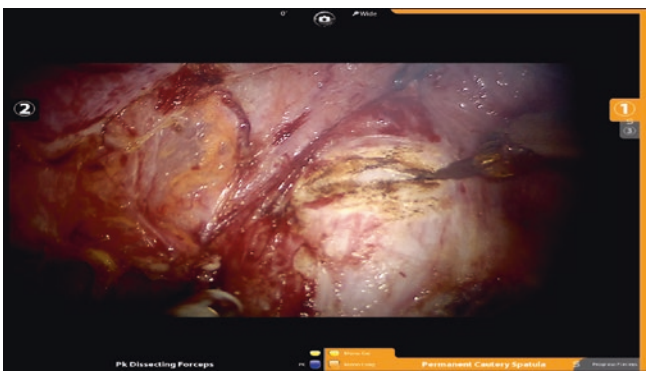

Fig. 64.36 Perform a colpotomy utilizing monopolar energy starting at the 12 o'clock position at the previously identified site on the cervicovaginal junction. It is preferred that this is completed on the "cut" monopolar energy setting

approximating the labia majora in the midline over a laparotomy sponge.

Following completion of the colpotomy, the uterus is delivered through the vagina (Fig. 64.40). Pneumoperitoneum is then maintained utilizing a vaginal occluder (Fig. 64.41).

The vaginal cuff is then closed with barbed suture in a continuous fashion, with a continuous suture using 2-0 PDS, or with interrupted figure-of-eight sutures (Figs. 64.41, 64.42, 64.43, 64.44, 64.45, 64.46, 64.47, 64.48, 64.49, 64.50, 64.51, 64.52, 64.53, 64.54, 64.55, 64.56, 64.57 and 64.58).

Assess for hemostasis including lowering the intraabdominal CO_2 pressure, allowing visualization of any venous bleeding. Any areas of bleeding should be identified. Small,

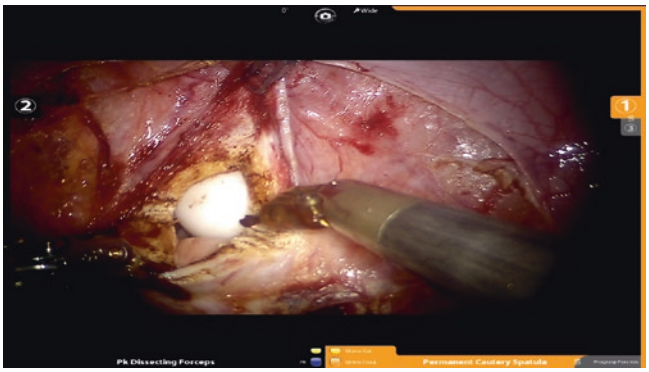

Fig. 64.37 Extend the colpotomy towards the right vaginal fornix

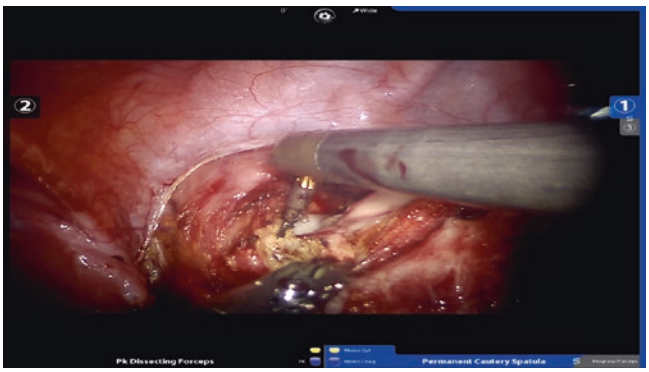

Fig. 64.38 Continue the colpotomy circumferentially along the cervico-vaginal junction

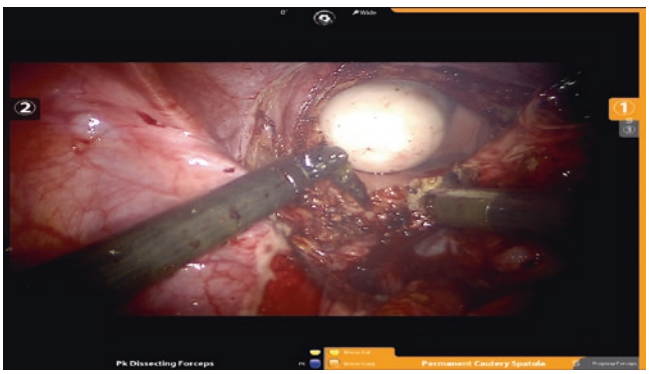

Fig. 64.39 Continue the colpotomy posteriorly until the previous site of transection is met on the opposite side

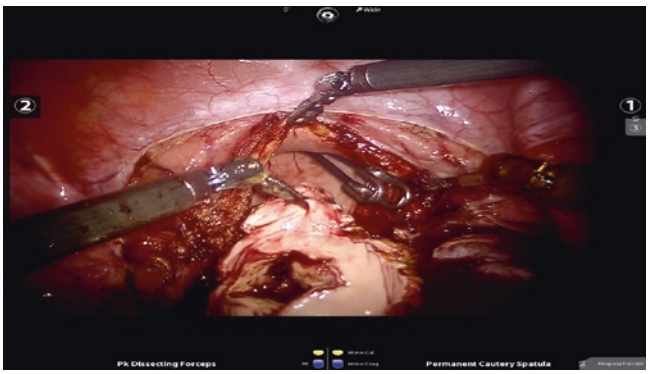

Fig. 64.40 Once the colpotomy is complete, a double-toothed tenaculum is introduced through the vagina, while maintaining approximation of the labia majora. The cervix is then grasped and the uterus is removed through the vagina

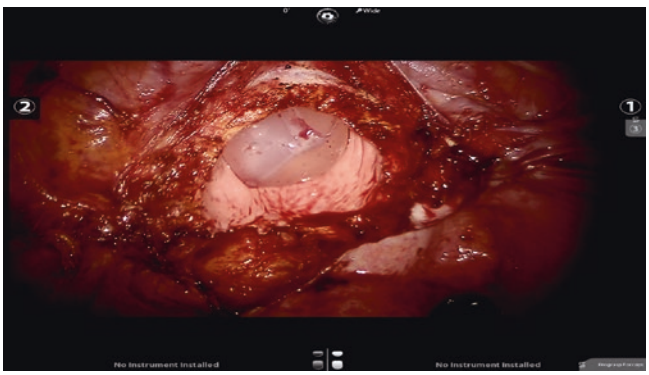

Fig. 64.41 Following specimen removal, a plastic balloon is placed in the vagina and filled with 60 mL of water. This allows pneumoperitoneum to be maintained throughout colpotomy closure

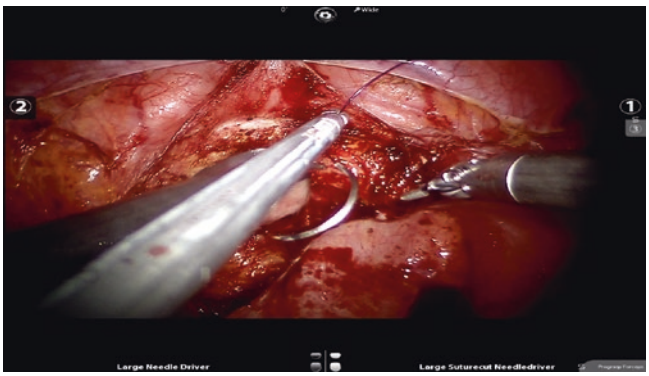

Fig. 64.42 The assistant then exchanges the monopolar device for the meganeedle holder and introduces the needle and suture for the vaginal cuff closure

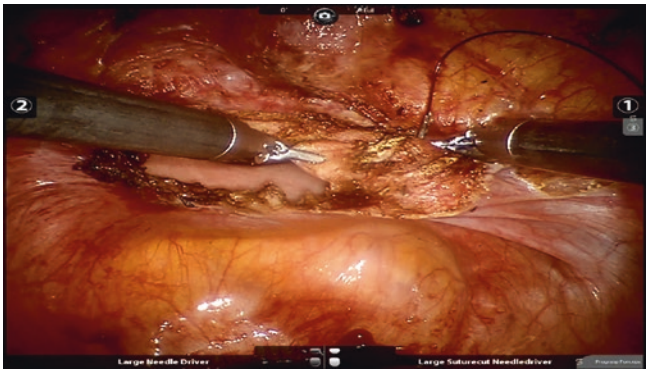

Fig. 64.43 To close the cuff with figure-of-eight sutures, the vaginal angle is first everted and the vaginal mucosa is exposed using the non-dominant hand. The needle is then placed laterally to the vaginal angle. Care is taken to avoid entrapment of the ureter

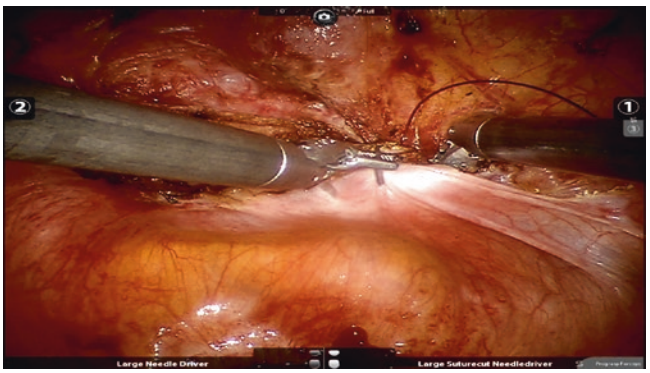

Fig. 64.44 The non-dominant hand then grasps the needle as it exits the uterosacral ligament and overlying peritoneum

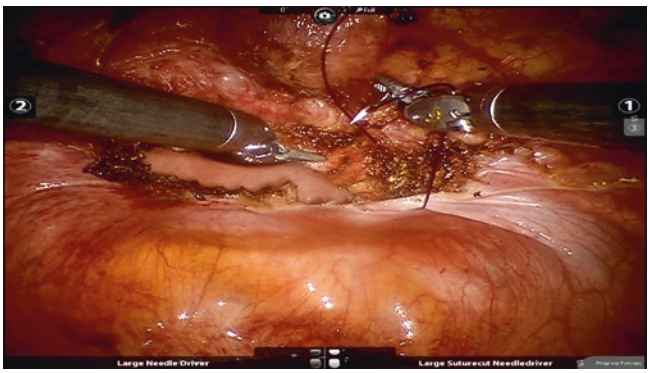

Fig. 64.45 The needle is transferred back to the dominant hand. The anterior portion of the vaginal cuff is then grasped and everted with the non-dominant hand. The needle is placed through the vaginal cuff using the dominant hand

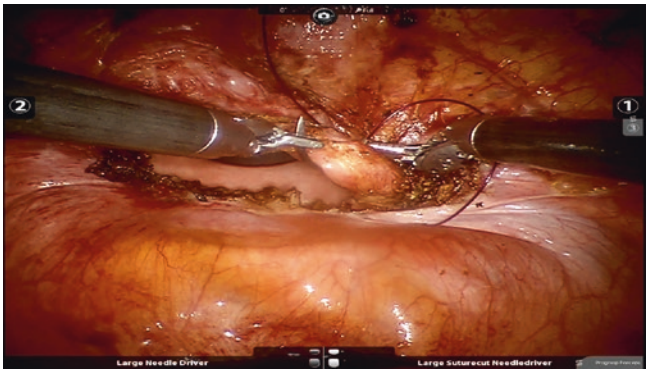

Fig. 64.46 The non-dominant hand then grasps the needle as it exits the vaginal mucosa

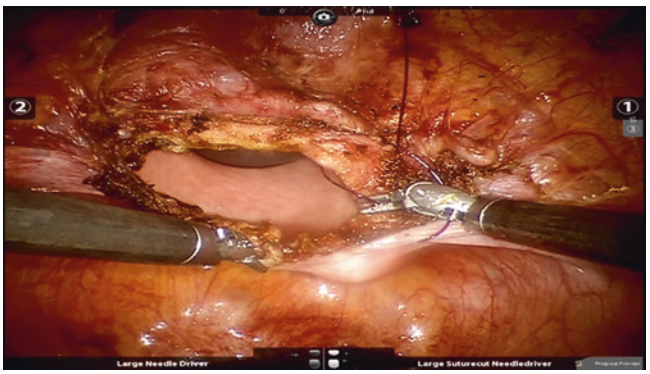

Fig. 64.47 The needle is transferred back to the dominant hand. The posterior portion of the vaginal cuff is then grasped and everted with the non-dominant hand. The needle is placed through the vaginal cuff using the dominant hand

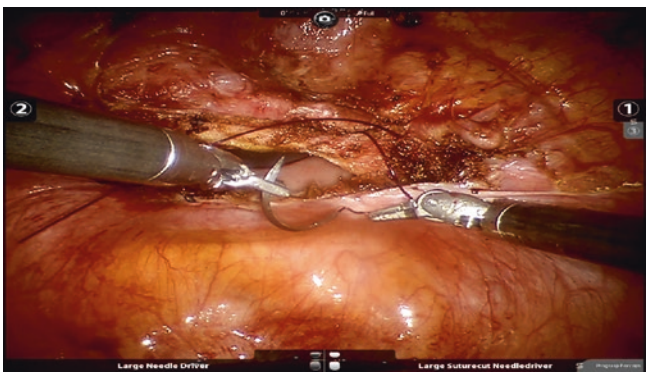

Fig. 64.48 This technique creates a figure-of-eight stitch

superficial vessels can be coagulated using monopolar energy. Larger vessels, such as the uterine artery, can be coagulated using bipolar energy or a vessel sealing device.

When assured of excellent hemostasis, undock the robotic arms from the trocars. The robotic column is then moved away from the patient to its initial parking location. The surgeon returns to the operating table to assist with closure.

During vaginal cuff closure, 5 mL of indigo carmine is injected intravascularly. Depending on the trained personnel available, cystoscopy is performed before, during, or after trocar closure to ensure bladder integrity and bilateral ureteral outflow.

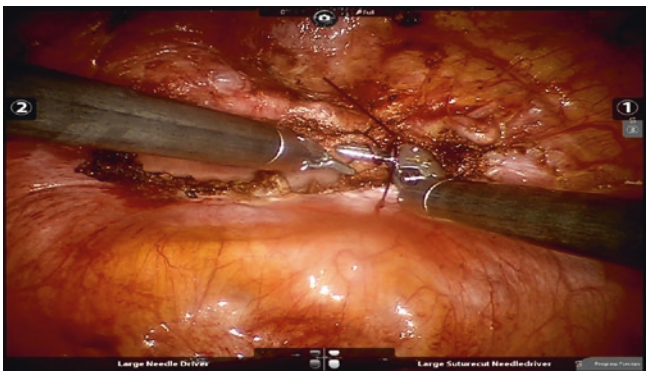

Fig. 64.49 The dominant hand is then placed along the suture line. The non-dominant hand is used to wrap the suture counter-clockwise around the dominant hand for two complete circles. This creates a surgeon's knot

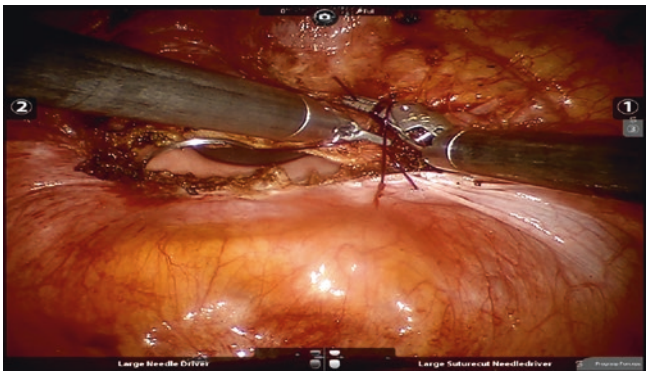

Fig. 64.50 The dominant hand then grasps the free end of the suture

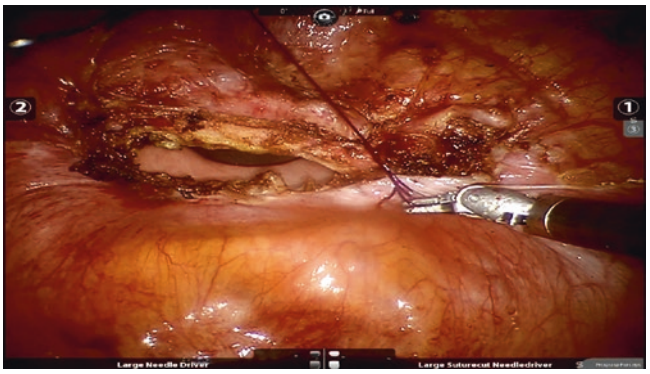

Fig. 64.51 The dominant and non-dominant hands are then pulled apart. The knot is laid flat

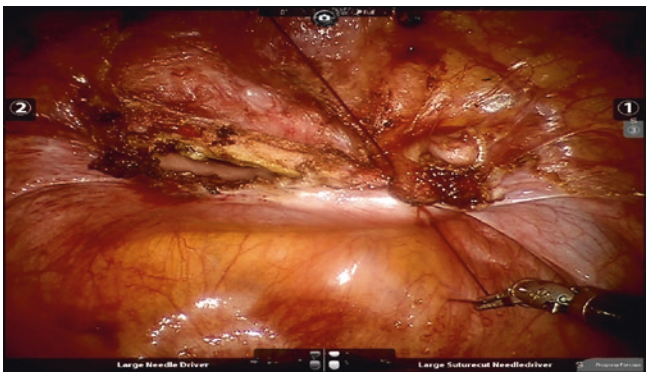

Fig. 64.52 Tension is applied to ensure tight approximation of the cuff edges

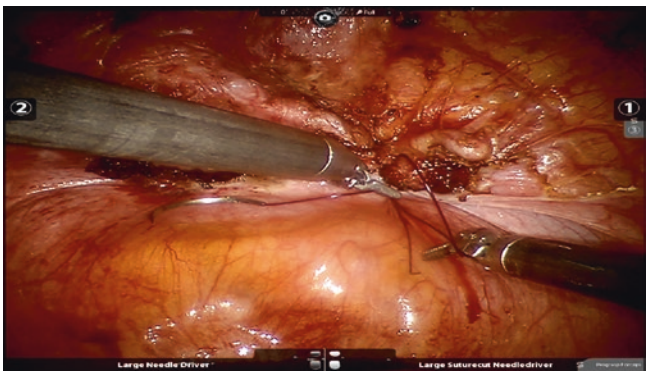

Fig. 64.53 The non-dominant hand is used to wrap the suture clockwise around the dominant hand. The dominant hand then grasps the free end of the suture

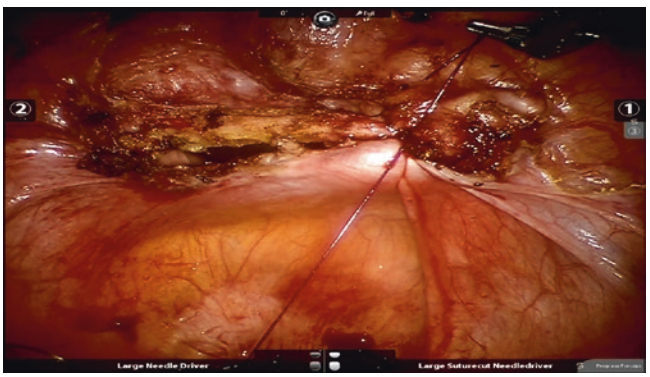

Fig. 64.54 The dominant and non-dominant hands are then pulled apart, creating a square knot. This is repeated for an additional two throws. The suture is then cut and the steps repeated along the entire length of the vaginal cuff

While performing cystoscopy, pneumoperitoneum is evacuated to decrease the intraabdominal pressure. Following cystoscopy reestablish pneumoperitoneum and evaluate for hemostasis.

Close the fascia on all laparoscopic ports greater than or equal to 10 mm using a delayed absorbable suture, such as 0-0 vicryl. A fascial closure device can be used to provide assistance.

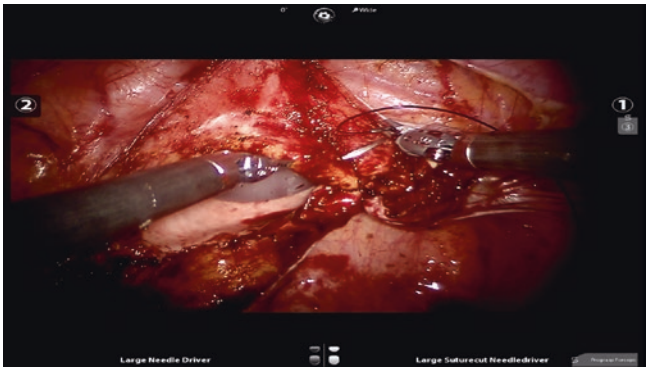

Fig. 64.55 Regardless of the technique, the needle is placed 5 mm from the outer (not mucosal) vaginal margin, which is easily identifiable by the cautery marking. The needle bites are placed at 5 mm intervals

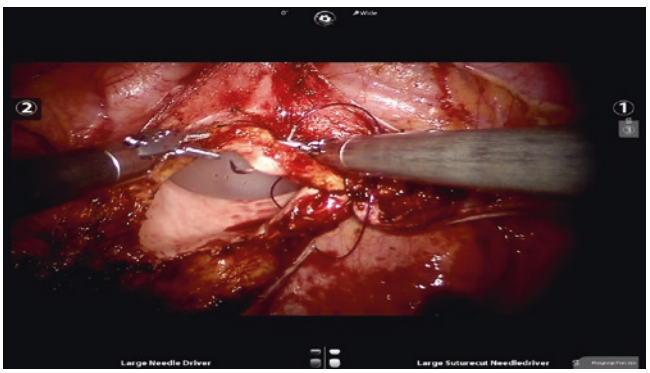

Fig. 64.56 Eversion of the vaginal mucosa confirms adequate distance from the vaginal margin

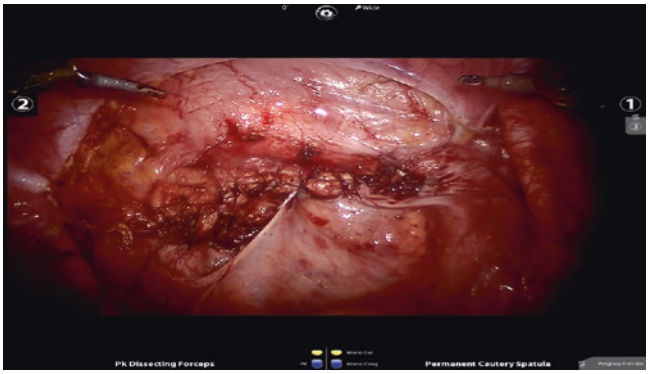

Fig. 64.57 Care is taken to incorporate the uterosacral ligaments at each vaginal angle

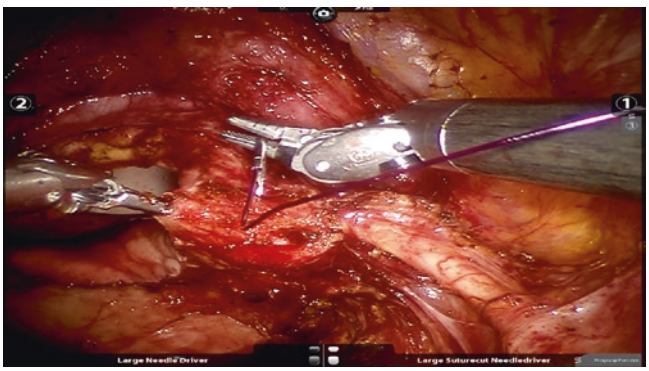

Fig. 64.58 Ensure adequate distance between the cuff closure and the ureters

Robotic-Assisted Total Hysterectomy: Hysterectomy Techniques for the Large Uterus

65

Dan-Arin Silasi

Introduction

Uterine leiomyomata are common benign tumors in women of reproductive age. They can reach significant sizes and cause debilitating symptoms such as abnormal uterine bleeding, dysmenorrhea, pelvic pain, dyspareunia, or urinary and intestinal symptoms.

Hysterectomy is the definitive treatment for leiomyomata, and in the United States leiomyoma represents the leading indication for this operation [1, 2]. Published studies recognize laparoscopy as a surgical approach with better outcomes when compared with laparotomy [3].

However, the ability to perform a laparoscopic hysterectomy decreases as the uterine size increases [4–7]. Other deterrents for a laparoscopic approach are a history of abdominal or pelvic surgeries and morbid obesity [8].

In our practice, we believe that the robotic surgical system has significantly impacted patients who present with a surgical indication for very large uteri [9].

In our experience, a large uterine size does not constitute a contraindication for robotic surgery and none of our surgeries for uteri larger than 1000 grams have required laparotomy [10–13]. This chapter addresses the challenges in robotic surgery when treating patients with a very large myomatous uterus.

Preoperative Evaluation

Our routine preoperative evaluation includes taking a complete history and performing a physical examination. Aspects to consider are the size and mobility of the uterus and the vaginal caliber.

Uterine Mobility

Very large uteri are commonly wedged into the pelvis but in most cases, on examination, the uterus can be mobilized cephalad, sometimes by just a few millimeters. When uterine mobility is present, even when it is severely limited, access can be gained to the uterine vessels and to the ureters. A frozen pelvis should be addressed with caution. The most common cause of lack of mobility is the expansion of the leiomyomata deep into the retroperitoneum. In these cases, extensive retroperitoneal dissection will be necessary to free the uterus and gain access to the vascular pedicles and ureters (Fig. 65.1).

Vaginal Caliber

With the exception of a few patients who present with a very wide vaginal caliber or extensive uterine adenomyosis rendering the uterus soft and pliable, the uterus will be too large to be delivered transvaginally intact. In most cases, the uterus will be morcellated in the vagina. Morcellation via minilaparotomy should be reserved for patients with unfavorable vaginal anatomy.

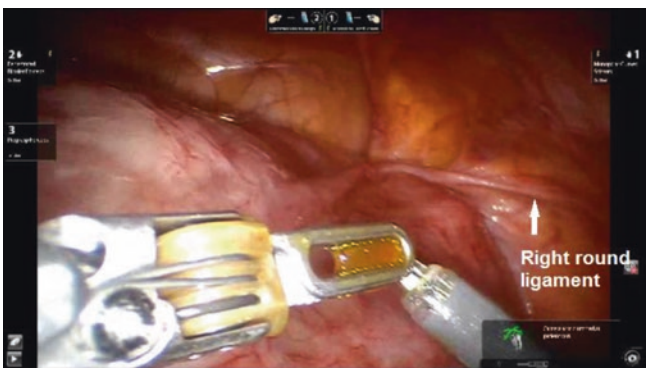

Fig. 65.1 The uterus is too large to fit into the operator's view. It is wedged into the pelvis. Extensive retroperitoneal dissection is necessary to free the uterus and gain access to the ureters and vessels

Uterine Size

Imaging studies for evaluation of the pelvic anatomy and uterine size are not routinely ordered in our practice unless very large pelvic masses are identified preoperatively [14]. Large masses are not a contraindication to robotic surgery if they have a cystic component. This will allow the mass to be contained in a laparoscopic bag; the mouth of the bag will then be everted at the vaginal introitus and the mass will be partially drained without any spillage or contamination of the peritoneal cavity. The limiting factor is the diameter of the laparoscopic bags available to the surgeon from the supply room. The largest laparoscopic bag available at our institution is the 20 cm wide LapSac® Surgical Tissue Pouch by Cook Medical (Bloomington, IN) (Fig. 65.2).

GnRH Analogues

We do not routinely administer gonadotropin release hormone (GnRH) analogues. In most cases, they will decrease the uterine size and may improve the preoperative anemia. However, the uterine sizes addressed in this chapter are too large for GnRH analogues to make a meaningful impact at the time of surgery.

Preoperative Diagnosis of Cancer

Patients who present with abnormal uterine bleeding require endometrial sampling prior to hysterectomy. The tests available to diagnose uterine sarcomata preoperatively are unreliable.

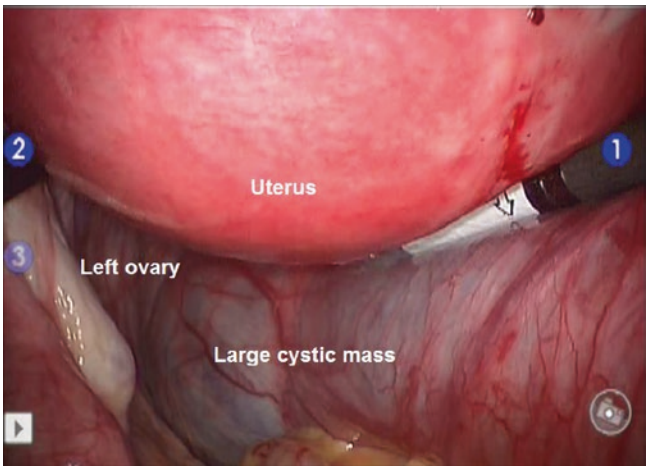

Fig. 65.2 Large myomatous uterus and large cystic mass. The cyst was densely adherent to the cul-de-sac peritoneum and rectum serosa

Bowel Preparation

Preoperative mechanical bowel preparation is common in the clinical practice of laparoscopic pelvic surgeons. Current clinical data, mostly obtained from colorectal surgery practice, offers no evidence to support the claim that preoperative colon cleansing reduces the risk of anastomotic leaks or infectious complications. On the contrary, doing so may increase the rate of anastomotic complications. For laparoscopic gynecologic procedures, randomized controlled trials have shown no improved exposure during the procedure [15]. Preoperatively, our patients are given instructions for a clear liquid diet the day before the procedure.

However, certain aspects related to the lack of exposure in these patients need to be mentioned. In obese patients, the mesentery and epiploica are heavily laden with fat and so the volume that the intestines occupy in the peritoneal cavity is much larger. This impairs the manipulation of the bowel and its storage in the upper abdomen during pelvic surgery. Also, the hypertrophic omentum also takes up more space in the upper abdomen, thus displacing the bowel towards the pelvis. In addition, the severely hypertrophic uterus takes up the entire pelvis and a good portion of the abdomen. For these reasons, in some cases, preoperative bowel preparation may be of value by decreasing the amount of intraluminal chime, hopefully allowing better exposure and visualization. In these cases, where the operator struggles to obtain visualization, considerations other than the preoperative patients' discomfort should be prioritized, such as intraoperative safety and reduced operative time.

Patient Positioning

We use two positioning methods:

- The patients are positioned on a gel pad over a bean bag (Vac-Pac® Olympic Medical, Seattle, WA) and then placed in a dorsal low lithotomy position using Yellofin® stirrups (Allen Medical Systems, Acton, MA). The disadvantage of using the bean bag is that a laparotomy retractor such as the Bookwalter retractor cannot be attached to the operating table's siderails in case of conversion to laparotomy (Fig. 65.3)
- Alternatively, a foam pad and padded shoulder braces can achieve the same stabilization of the patient (Figs. 65.4, 65.5 and 65.6)

Fig. 65.3 The patient is stabilized on a bean bag with the help of a sling made from hospital sheets

Fig. 65.4 The patient is placed on Devon™ Trendelenburg Positioning Kit (Medtronic, Minneapolis, MN)

Fig. 65.5 The hands are protected and the arms are tucked

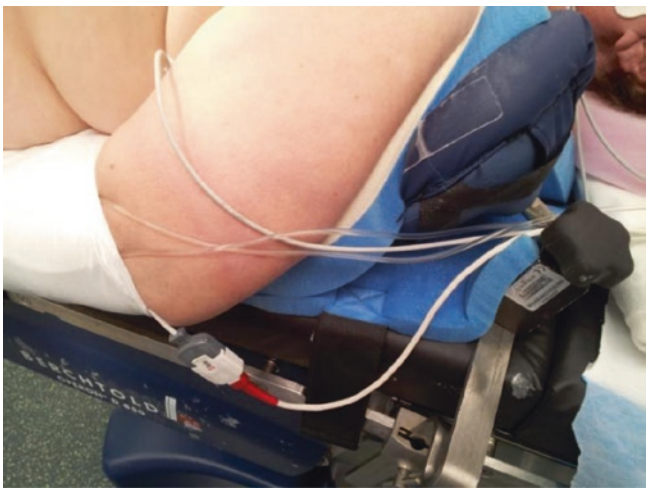

Fig. 65.6 Shoulder supports prevent the patient from sliding on the table. The pressure is on the infraspinous fossa, not on the acromion

Port Placement

Commonly we place the ports symmetrically, in an arch centered by the camera port ("sunrise or half-moon distribution"). The camera port is inserted at a level that is higher than the uterine fundus. If the uterine fundus extends to the xyphoid, the initial port can be placed in the left upper quadrant or left flank to achieve pneumoperitoneum and visualization.

These port configurations work well for all 3 robotic systems: S, Si, and Xi (Figs. 65.7, 65.8 and 65.9).

Sunrise placement of ports: Variations of the sunrise configuration can be used, depending on the particular anatomy of the patient (Figs. 65.10, 65.11, 65.12, 65.13, 65.14, 65.15 and 65.16).

The surgeon can oversee the entire operative field when performing hysterectomies for moderately sized uteri. This is not possible in most cases described in this chapter. The lack of access and visualization and particularities of each case dictate the strategy in each operation. The same operative routine will not be applicable in different patients. Instead, the surgeon must visualize in his/her mind the

Fig. 65.7 The most common port placement (sunrise): the camera port located above the umbilicus, one robotic port and the assistant port on each side of the umbilicus and two robotic ports below the umbilicus. This is the Xi system; from right to left: arm 1 (Prograsp), arm 2 (fenestrated bipolar), arm 3 (camera port), 12 mm assistant port, arm 4 (monopolar scissors)

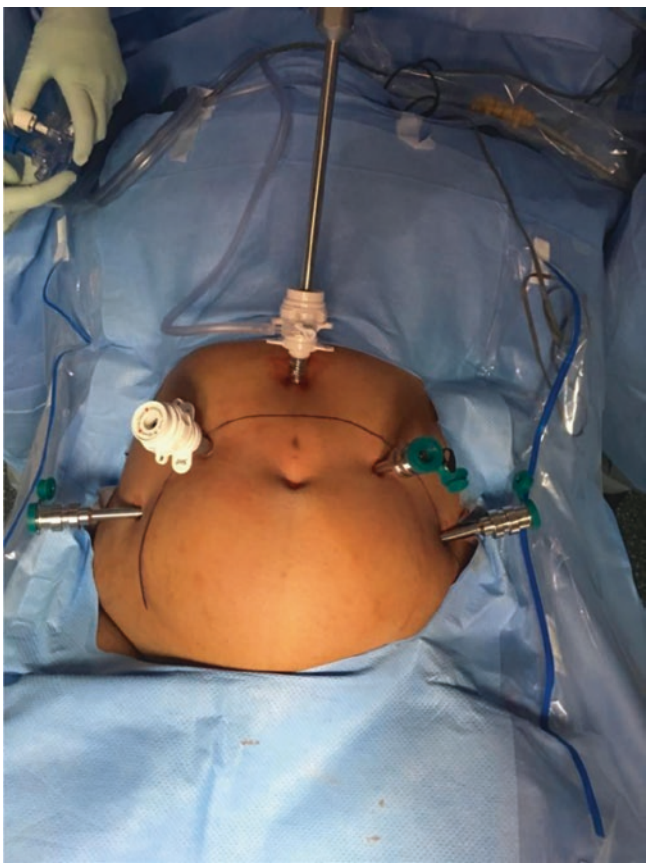

Fig. 65.8 The sunrise placement for the S and Si systems. From right to left: arm 3 (Prograsp), arm 2 (fenestrated bipolar), camera arm and port, 12 mm assistant port, arm 1 (monopolar scissors). The contour of the uterus is outlined on the abdominal wall for illustration purposes

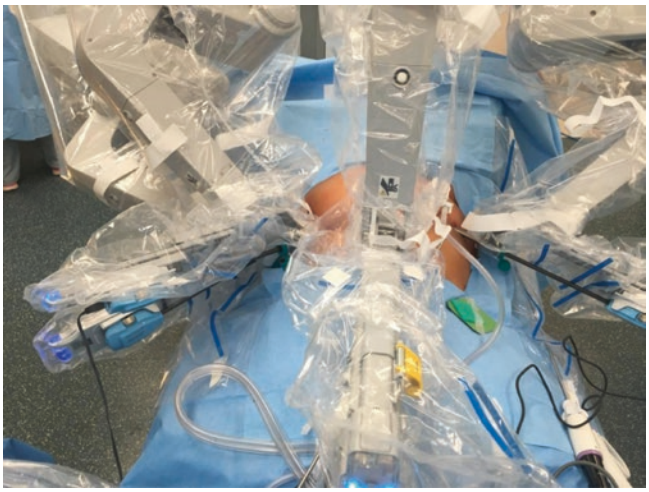

Fig. 65.9 The Si system after docking.

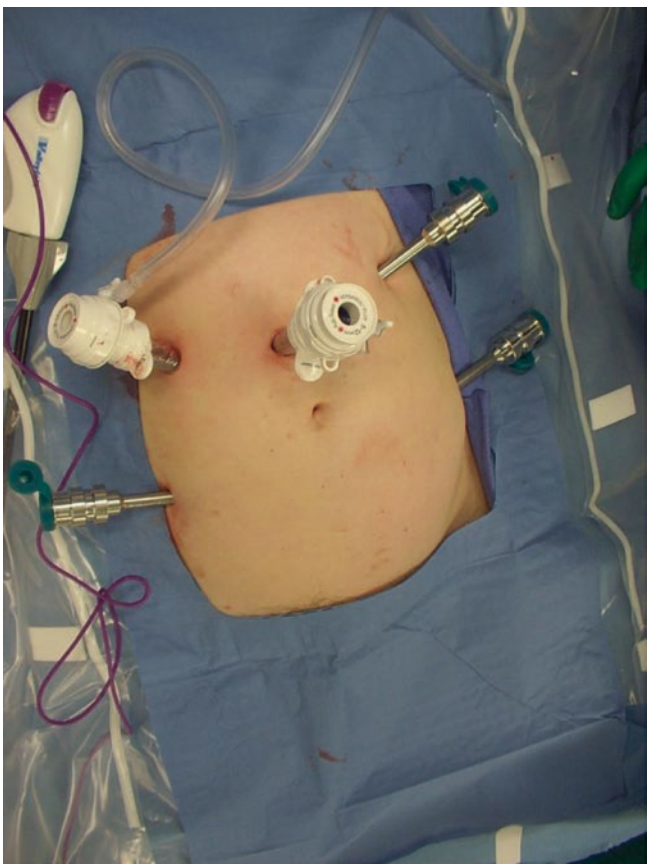

Fig. 65.10 The camera port is midline and above the umbilicus. The abdomen of this patient is long and narrow. For this patient, this port configuration is more favorable than the usual sunrise placement since the ports are closer to each other. This configuration prevents the arms clashing during the procedure

Fig. 65.11 Tips and tricks: Telescoping. Freehand laparoscopy and camera placement through several ports (for lysis of adhesions, etc.) may be needed prior to docking. The camera of the Xi system is 8 mm in diameter and fits through all ports. However, this is not the case for the S and Si systems. The figure shows the repurposing of a regular port into a robotic port. A port-in-a-port placement works well, without undue tension on the fascia

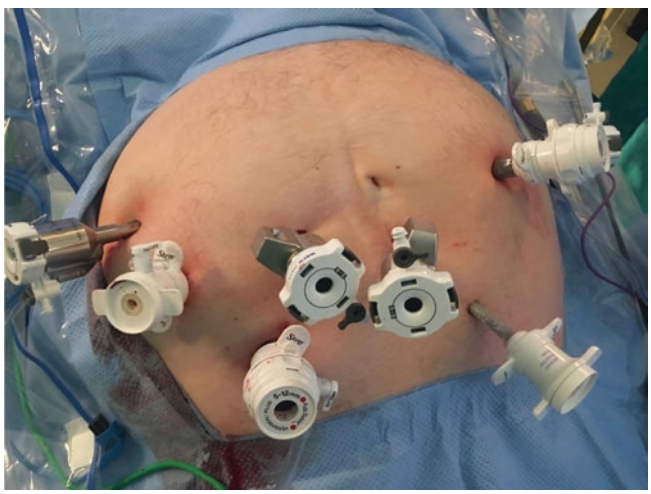

Fig. 65.12 Severe adhesions in the entire abdomen required placement of more ports. Additional laparoscopic incisions will have no detrimental impact on the patient's recovery

necessary to complete the procedure and the remaining surgical steps and bring everything together in the end.

Sometimes simple adjustments like switching a 0º degree to a 30º camera provide significant payback. The figures show how the visual field changes dramatically when switching cameras. One has to remember that the angle of the camera to the patient's body changes for different angles of the lens. The 30º camera is much closer to the patient's face and padding of the face and endotracheal tube is prudent (Fig. 65.17).

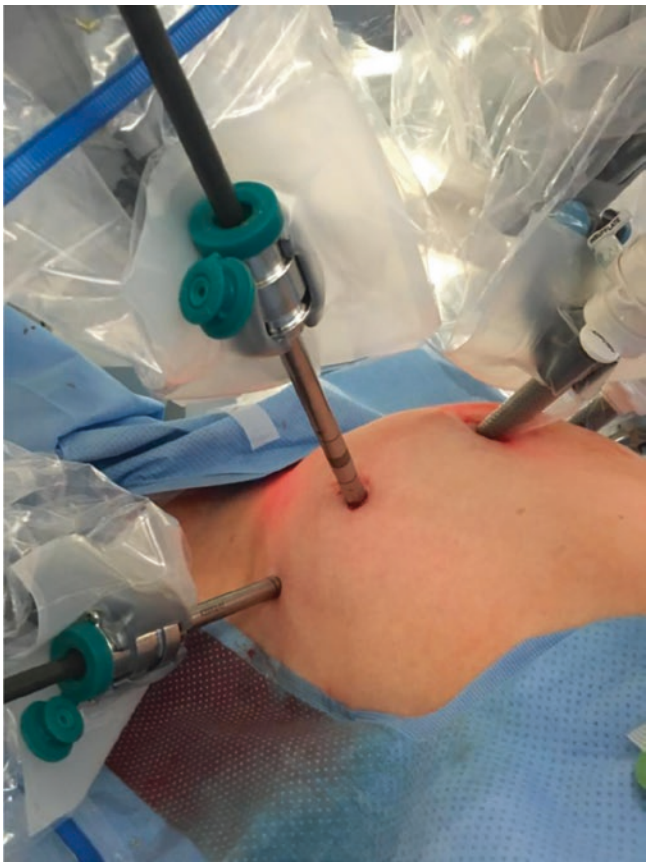

Fig. 65.13 Tips and tricks. S and Si systems: The best use of the obesity trocar is in very thin patients. In a patient with a narrow abdomen the ports will be very close to each other. The figure shows the camera port (right), the obesity trocar for arm 2 (middle) and a regular robotic port for arm 3 (left). This "stacking" will prevent clashing of the robotic arms during the procedure

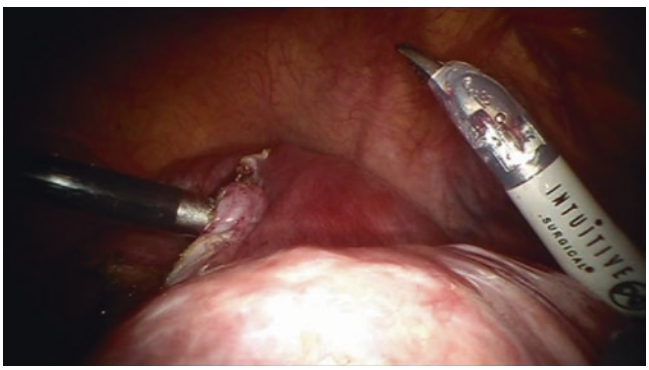

Fig.65.14 A large myoma causes ballooning of the lower uterine segment. In cases like this, changing the 0 ° to a 30 ° camera helps visualization when developing the bladder flap

Sometimes, additional ports may need to be inserted during difficult cases, mostly to assist with bowel retraction and exposure or when instruments cannot reach from one side of

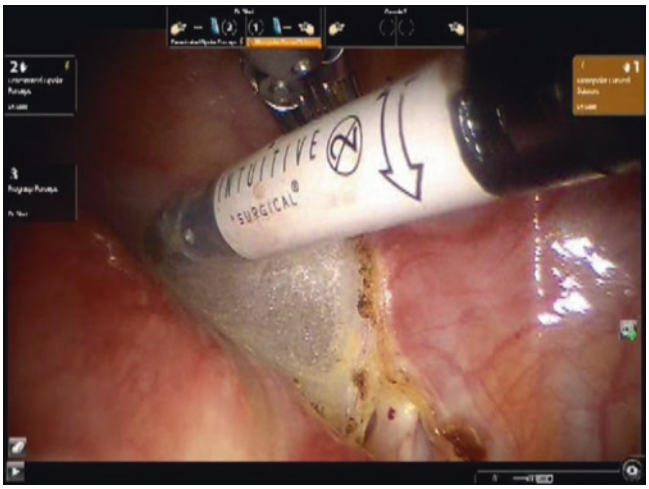

Fig. 65.15 This is an example of how visualization improves when changing the 0º degree to a 30 ° camera. Figure 65.15 shows the maximum achievable visualization with the 0 ° camera

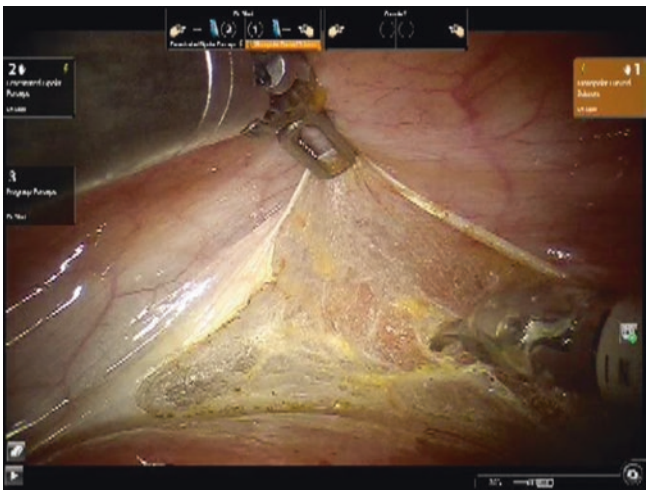

Fig. 65.16 It is easier to complete the bladder serosa incision by switching to the 30 ° down camera

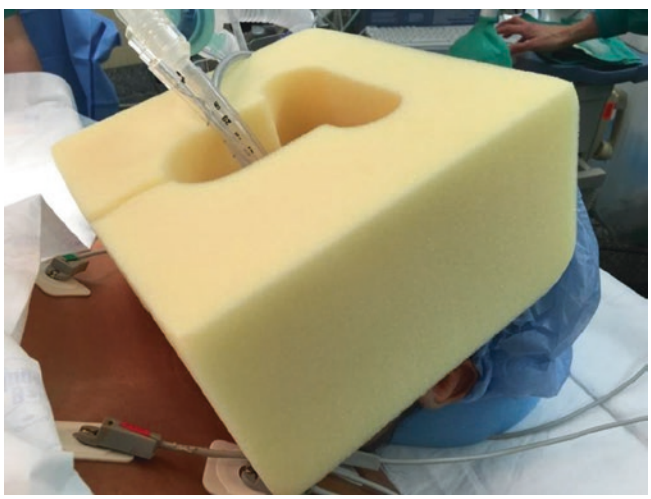

Fig. 65.17 Protection for the patient's face

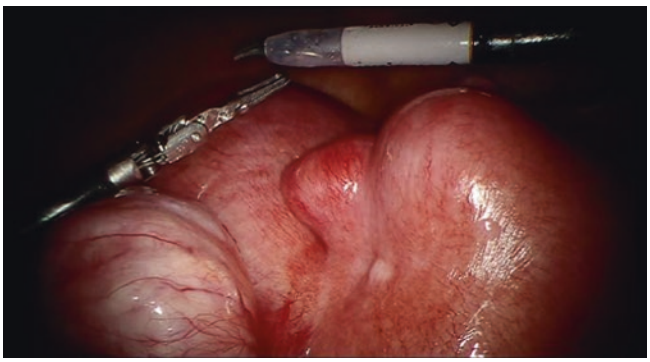

Fig. 65.18 The instruments' reach to the opposite side of the pelvis is severely impaired by the large uterine corpus

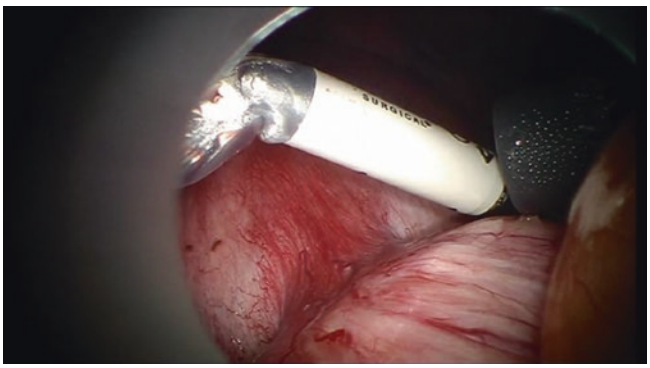

Fig. 65.19 Visualization and maneuvering can be severely impaired. The fat in the right lower corner is from high placement of the port into the falciform ligament

the abdomen over the massive uterus to the other side. In some cases, the uterine size precludes the access of the dissecting instrument used by the dominant hand all the way to the contralateral side across the uterine bulk. Switching the instruments and operating with the nondominant hand while grasping with the dominant hand can overcome this situation (Figs. 65.18 and 65.19).

In patients with previous scars from abdominoplasty, cholecystectomy, or other surgeries, we have inserted the ports through the existing scars, if feasible.

However, these are only guidelines and, depending on the torso length or overall width of the patient, as well as the goals to be achieved during the surgical procedure, the ports should be logically placed so as to maximize maneuverability and visualization.

The assistant port should measure 11 or 12 mm in diameter. This will facilitate insertion of sponges in the peritoneal cavity when needed. The 8 mm robotic ports or a 5 mm assistant port will make this task unfeasible.

The assistant trocar is used for insufflation, and one of the robotic ports is used to attach a smoke evacuator.

For patients with very large uteri, we recommend performing the operations using all four arms of the robotic surgical system. Also, we recommend positioning the robot between the patients' legs (S and Si models) since side-docking severely

limits the reach of arm 3 into the upper abdomen. For this setting, the robotic system will be undocked for transvaginal delivery of the uterus. The boom of the Xi model allows side-docking with no impact on the arms' maneuverability.

Robotic Instruments

The main robotic instruments (Intuitive Surgical, Sunnyvale, CA, USA) used are Hot Shears (monopolar curved scissors) with a tip cover accessory and power setting of 50 W for arm 1, fenestrated bipolar forceps with a power setting of 50 W for arm 2, and Cadiere or ProGrasp (Intuitive Surgical, Sunnyvale, CA, USA) forceps for arm 3. The arm numbers are different for the Xi model. Vascular pedicles were coagulated and transected by the scrubbed assistant with a LigaSure sealer/divider (Valleylab, Boulder, CO, USA).

Grasping and traction and counter-traction should be generally avoided. The specimen is too heavy and the tissue will tear and bleed. Instead, manipulation by pushing the uterine corpus is effective in achieving exposure (Figs. 65.20, 65.21, 65.22 and 65.23).

Uterine Manipulator

The uterine manipulator is less useful for manipulation since the uterus is so large. However, when coupled with a cervical cup, it is an excellent tool for delineating the vaginal fornices prior to colpotomy. This is especially useful when the uterocervical junction is extremely bulky or when abundant adiposity completely obscures the anatomical landmarks. I prefer the Koh Colpotomizer™ System (CooperSurgical, Trumbull, CT) in conjunction with a RUMI® Uterine Manipulator (CooperSurgical, Trumbull, CT) and a Colpopneumo Occluder™ balloon. These are inserted prior to port placement. When the manipulator is pushed by the assistant, the distance between the uterine vessels and ureters will increase by up to 1 cm. This additional maneuver helps to protect the ureters from thermal injury. Generally, in heavy patients, the distance between the cervix and ureters is slightly less than in thin patients, but this difference is clinically insignificant. Also, in many cases, as an added difficulty to the lack of visualization and exposure, the distances between the ureters and cervix are not the same on the right and left [18, 19].

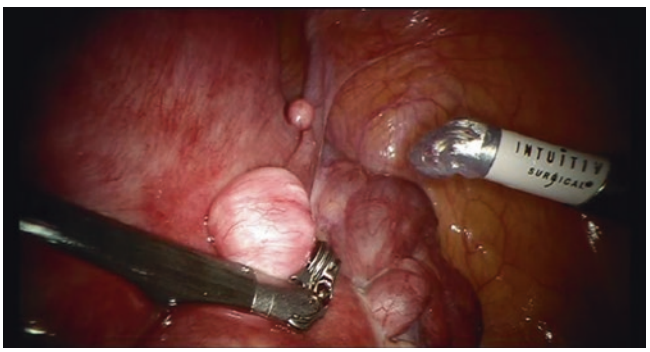

Fig. 65.20 Irregularities in the uterine contour are very helpful for providing grasp and manipulation

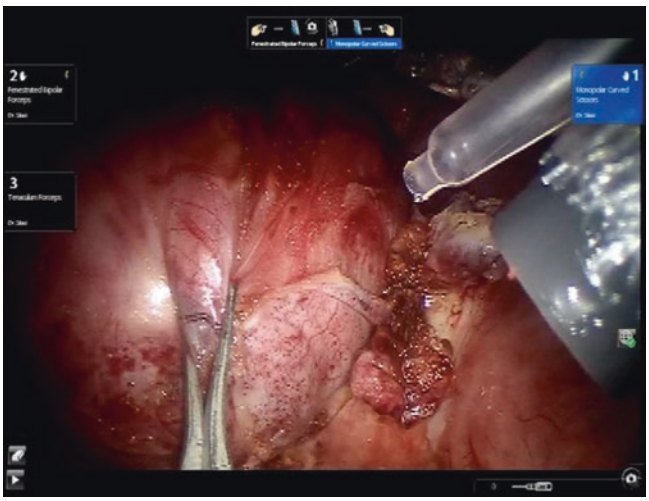

Fig. 65.21 The robotic tenaculum can be used when no other means of manipulation are available. This is frequently the case when lower uterine segments are ballooned out. The insertion site should be carefully chosen. A trial and error approach will result in profuse bleeding from every puncture site

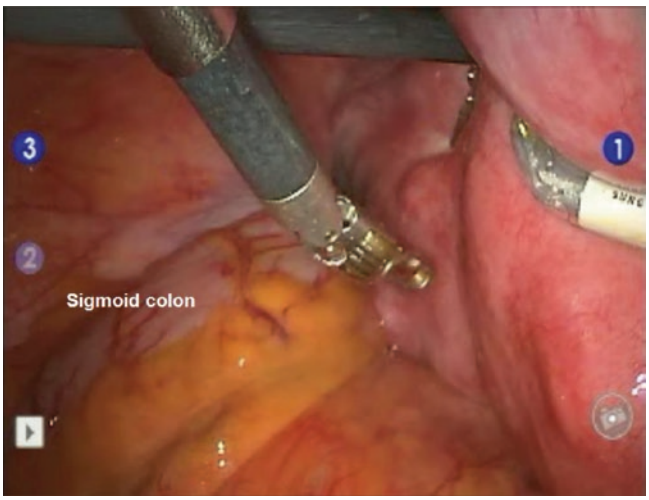

Fig. 65.22 The left ovary is engulfed by expanding leiomyomata. Pushing is a more effective strategy than grasping

Energy Instruments

The cost of the operating instruments is an important consideration for any surgical procedure. The use of the robotic bipolar cautery is effective and inexpensive. However, for the resection of very large uteri I recommend the use of an

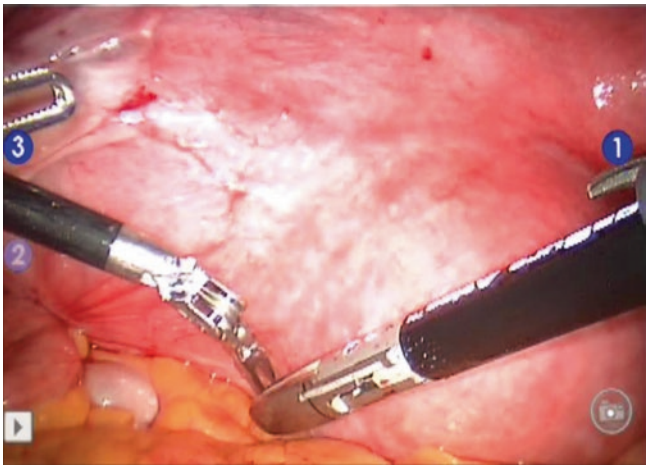

Fig. 65.23 The assistant can help with lifting and manipulation when the uterus is too heavy for the robotic instruments

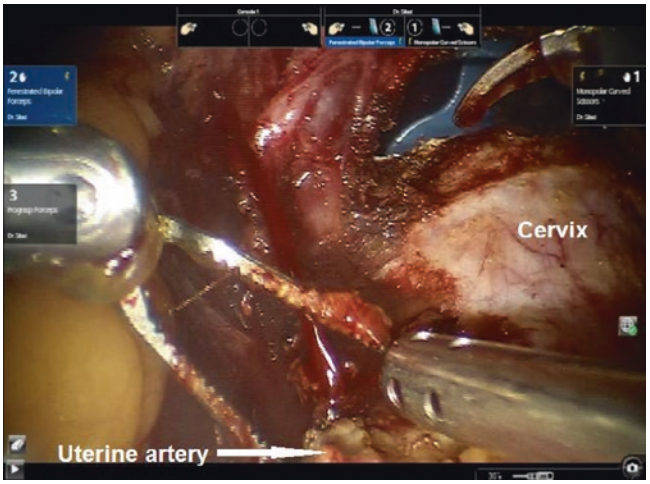

Fig. 65.24 The distal segment of the transected left uterine artery is actively bleeding after sealing was unsuccessful. The fenestrated bipolar cautery will grasp the bleeding vessel

advanced energy device in addition to the traditional bipolar cautery. A wristed vessel sealer is also available for the robotic system. The maneuverability of this device is outstanding but the tradeoff is poor grasping and dissection capabilities.

I prefer a free-hand 5 mm advanced vessel sealer, which will allow freehand laparoscopy when needed. Sometimes these complex procedures require a combination of freehand and robotic laparoscopy. The sealing capacity of the 5 mm instrument is close to that of the wider device with the advantage that this vessel sealer can be inserted through the 8 mm robotic port.

Frequently, one or several of the vessels' diameters will exceed the manufacturer's recommendations for the safe use of any sealing device. In addition, when pelvic edema is present, the vessel walls have a higher than normal water content as well. The efficacy of the sealing devices can be impaired in these circumstances. The vessel wall edema can be anticipated when the dissected retroperitoneal tissues are edematous and fluid is leaking from the open retroperitoneal spaces. Excessive amounts of steam will be released when sealing the vessels: because of the crowded space, the camera is very close to the operative site and the lens will fog. The edema and tissue weeping will resolve once the hysterectomy is completed, sometimes even before the vaginal apex is sutured.

For prevention of catastrophic hemorrhage of very large vessels, I grasp the pedicle with the bipolar cautery while the assistant applies the sealing device on the pedicle. Both ultrasonic and bipolar electrosurgical instruments employ tissue sensing technology and can seal blood vessels with supra-physiologic burst pressure equal to or higher than that of surgical clips or ligatures. The thermal impact to surrounding tissue is minimal [16, 17].

If the sealing is not complete and the vessel is still open after transection, the bipolar cautery will keep the vessels from retracting and can accomplish the following maneuvers:

- Coagulate the vessels held within the jaws of the instrument and achieve hemostasis. Desiccation of the tissues in bipolar diathermy is accomplished when the bubbling stops. The disadvantage of this approach is that when it fails the surgeon is left with the charred end of a (still) bleeding vessel (Fig. 65.24)
- Hold the vessels and apply Weck® Hem-o-lok® polymer clips on the pedicle. The titanium clips available for the robotic system are too small for this task. Alternatively, if the surgeon estimates that successful sealing of the vessels is improbable, the pedicle or individual vessels can be skeletonized and then transected after polymer clips have been applied, without any use of thermal energy (Fig. 65.25)
- One of the advantages of the wristed robotic instruments is the ease of suturing and knot-tying. However, for patients with very large uteri, this advantage is almost always lost because of the very limited space available to perform these maneuvers

Vessels

The most important aspect of hysterectomy for very large uteri is securing the vascular pedicles. Failure to achieve hemostasis in operations where the uterus is massive and extends into the abdominal cavity often leads to abandoning the laparoscopic approach and performing a laparotomy to control the bleeding. It is imperative that meticulous hemostasis is maintained throughout the entire case.

An important reminder is that the anatomy of the pelvic structures can be severely altered. The bladder location and

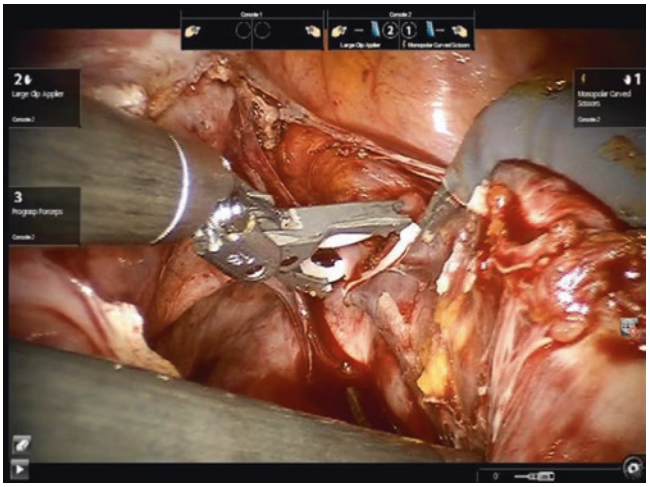

Fig. 65.25 Application of the Weck® Hem-o-lok® polymer clips using the specialized robotic instrument

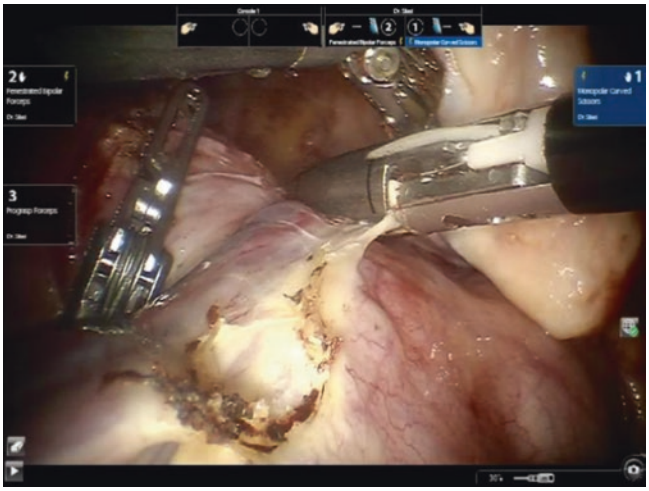

Fig. 65.26 The sealing instrument is applied on the hypertrophic utero-ovarian vascular arcade. The ProGrasp™ instrument is wrapped around the utero-cervical junction: it is very effective in moving the uterus out of the pelvis. I call it the 'choking maneuver'

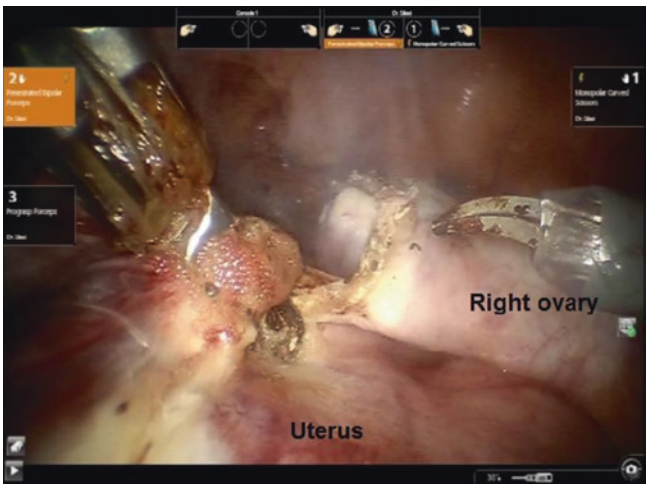

Fig. 65.27 Sealing was incomplete. The severed vessel retracts into the body of the uterus. A lengthy application of bipolar diathermy is necessary to control the bleeding. Ongoing bubbling means that complete desiccation has not occurred yet

contour, the trajectory of the ureters and sometimes even the course of the external iliac or hypogastric vessels can be different than expected. Meticulous dissection is the key to identify these structures and restore the normal anatomy. When the retroperitoneal tissues achieve the foamy appearance caused by pneumodissection, the vessels, ureters, and bladder are easier to identify. However, even a small hemorrhage will saturate the retroperitoneum with blood and obscure the surgical landmarks. Irrigation will also saturate the avascular planes, albeit with a clear and transparent fluid, and it should be avoided if possible. The best approach to improve visualization once the actively bleeding vessels have been secured and the blood is suctioned, is to insert a sponge through the assistant port and dab the bloody site.

Despite limited visualization from above because of the uterine bulk, the location of the four uterine pedicles is quite predictable.

Ovarian Vessels

Even if they are not visible initially, the ovarian vessels are easy to find by pushing the uterus forward.

The anatomy of these pedicles is the most consistent and the infundibulo-pelvic ligaments retain their usual location. They are the easiest to secure, whether the hysterectomy includes adnexectomy or it is performed with the intent of ovarian preservation. The diameter of these vessels is larger than normal. For ovarian preservation, the utero-ovarian arcade can be more difficult to secure if the ovaries are engulfed by the expanding uterus. In this case, care must be taken to seal the vessels thoroughly before transection. When transected without achieving complete hemostasis, the vessels will retract inside the uterine mass and will be out of reach for repeat thermal applications. This will cause profuse bleeding that is very difficult to contain. If there is enough room for maneuvering, it may be prudent to apply the energy device at adjacent spots on any pedicle and increase the probability of sealing. Redundant thermal sealing will increase the operative time but achieving complete hemostasis is very important since these complex procedures leave very little room for error (Figs. 65.26 and 65.27).

It is easier in these procedures, when compared to hysterectomy for normal-size uteri, to avoid thermal injury to the ureters at the pelvic brim while securing the infundibulo-pelvic ligaments. The ovarian vessels are elongated and stretched away from the ureters by the large uterus (Fig. 65.28).

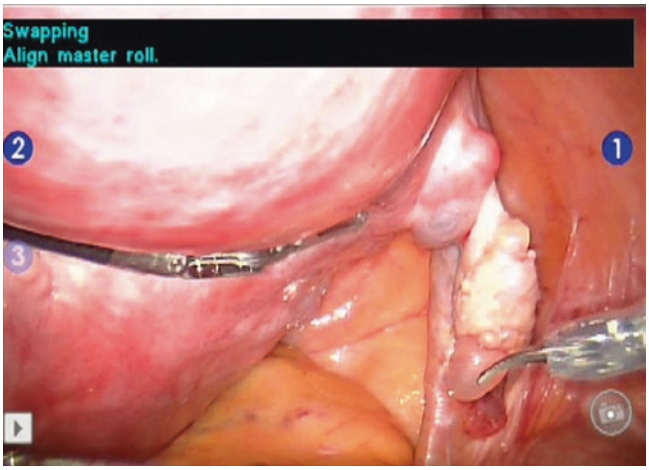

Fig. 65.28 The infundibulo-pelvic ligaments are exposed by lifting the uterus. Routinely they are elongated and stretched away from the ureters

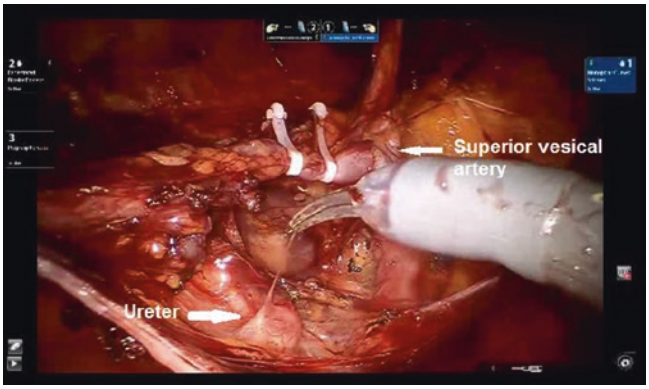

Fig. 65.29 The vessels can be secured at or close to their emergence

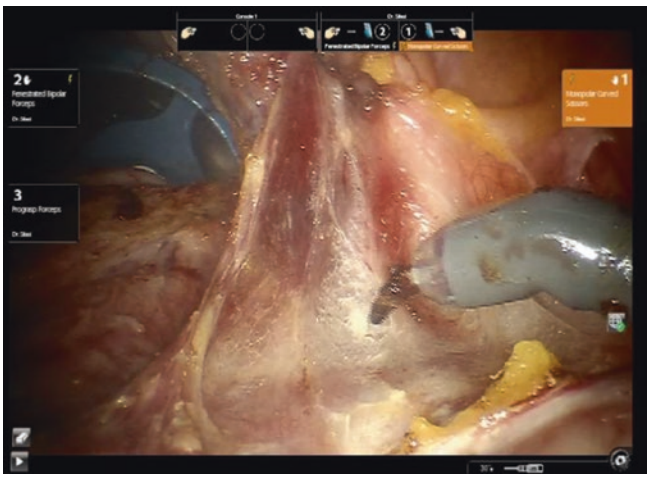

Fig. 65.30 The edema of the retroperitoneal tissues is pronounced as evidenced by the glistening and weeping areolar spaces

Uterine Vascular Supply Below the Pelvic Brim

Unless the anatomical presentation dictates otherwise, I recommend securing the left-sided uterine vessels first, followed by the right-sided ones. The reason is that once three out of four uterine pedicles have been sealed, the fourth will swell up, sometimes markedly so. The absence of the sigmoid colon on the right side of the pelvis allows for better exposure and increased room for maneuvering, which may be necessary to achieve hemostasis.

Arteries

The arteries are hypertrophic because of the increased blood supply and the surgeon will frequently encounter unusual branching. Even the ascending cervical artery, an insignificant vessel in normal circumstances, can flood the pelvis when transected without effective sealing.

Frequently, the uterine bulk completely obscures the utero-cervical junction. A simple strategy to find the uterine vessels is to follow the lateral uterine contour down into the pelvis after dissection of the avascular space of Graves. For better visualization of the vessels, the 0 ° camera may need to be changed to a 30 ° down camera. The camera will sneak in between the massively enlarged uterus and pelvic sidewall and may need to be rotated clockwise on the right and counterclockwise on the left to achieve visualization.

If the uterine vessels cannot be secured at the utero-cervical junction, the alternative is to coagulate them at the emergence from the superior vesical artery. At this proximal level, the arterial wall is less edematous and the success of thermal sealing with one application is higher. The ureter should be identified and mobilized if necessary. The para-vesical and para-rectal spaces should be developed in the same manner as in a radical hysterectomy and the skeletonized vessels can be sealed safely (Fig. 65.29).

Excessive blood loss can occur when the sealing device cannot achieve complete hemostasis of the uterine vessels, especially when the vessel diameter exceeds the recommended 7 mm size. In addition, the retroperitoneal tissues and the vessel walls can be quite edematous from impaired venous return, and although collagen denaturation will occur, tissue desiccation can be suboptimal after firing the sealing device (Fig. 65.30).

When the diameter of the vessels, especially of the veins, is too large, we recommend skeletonizing the components of the pedicle and sealing the vessels individually (Fig. 65.31).

For smaller vessels, if hemostasis is not complete, titanium clips can correct the problem when applied by the assistant or by the robotic arm while the operator holds and exposes the bleeding vessel. Despite the fact that placement of suture ligatures are facilitated by the articulated wrist, this is usually not possible because of the limited space.

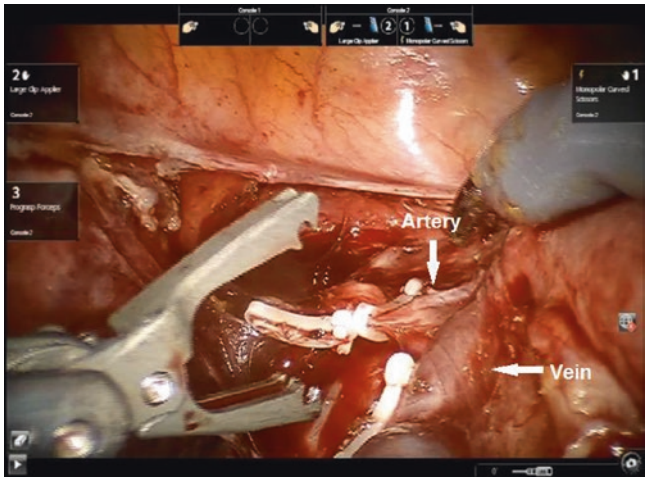

Fig. 65.31 The dilated uterine vein is secured first, followed by the artery

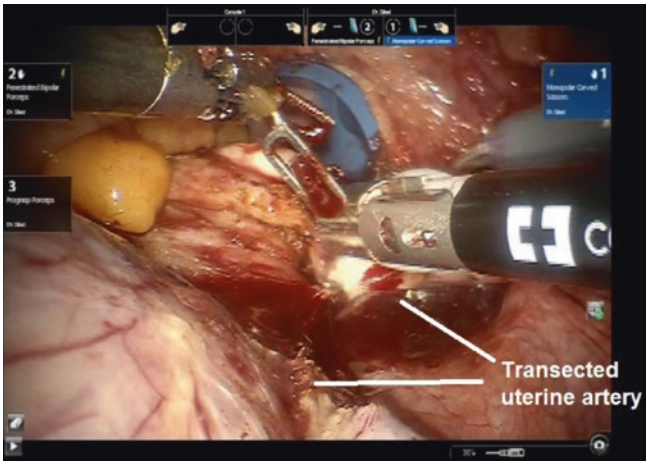

Fig. 65.33 The sealing was unsuccessful

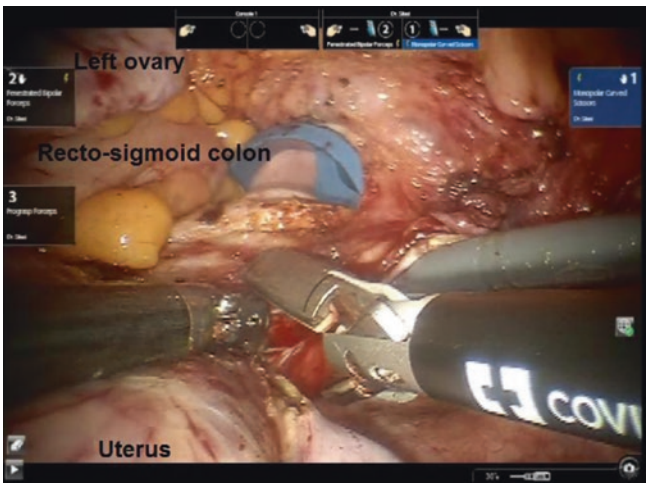

Fig. 65.32 The sealer divider is applied on the right uterine pedicle

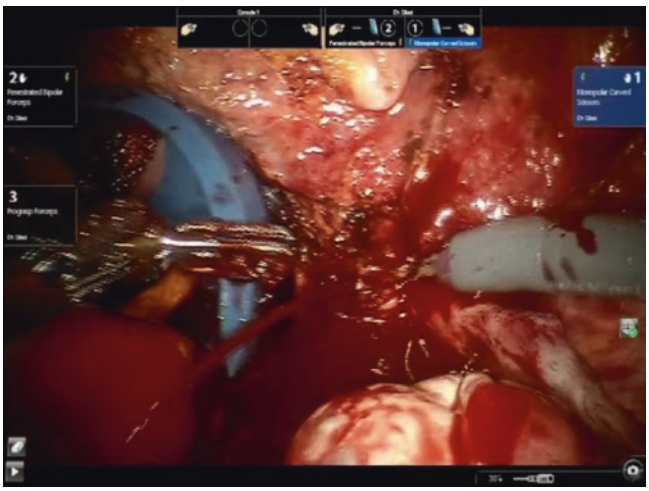

Fig. 65.34 Active bleeding from the uterine artery

In very difficult cases, when the surgeon is confronted with a lower uterine segment too large to allow access to both uterine arteries with the sealing device from the assistant port, the placement of a sixth port in a convenient location can provide the required access (Figs. 65.32, 65.33, 65.34 and 65.35). In morbidly obese patients this additional port can be used for a bowel retractor to improve exposure. Alternatively, the wristed vessel sealer of the robotic system can be used with any arm, for a multitude of angles.

Veins

The enlarged vein diameter is caused by the increased blood supply, but it is also compounded by the impaired venous return produced by the mechanical compression of the hypertrophic uterus resting on the great vessels in the pelvis. Special consideration needs to be given to the venous plexus

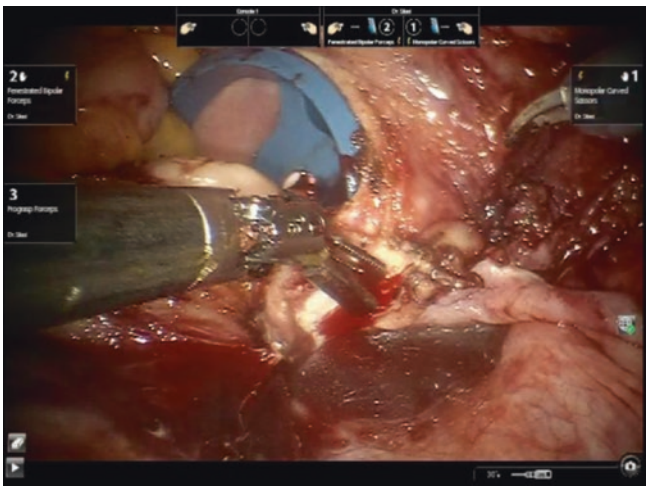

Fig. 65.35 The artery retracts, floods the pelvis and can be difficult to secure. Prior lateral mobilization of the ureter is essential to avoiding thermal injury when exposure is severely limited

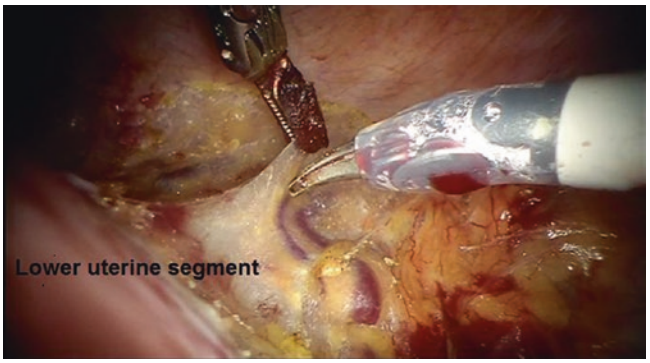

Fig. 65.36 The anatomy of the venous plexus of the bladder is unpredictable and meticulous dissection is required

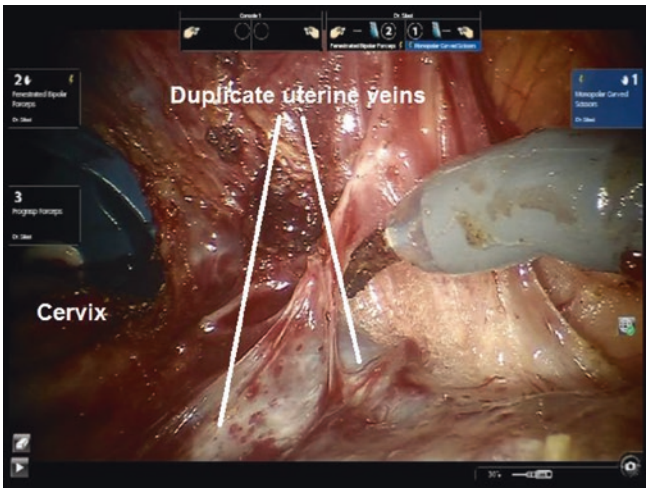

Fig. 65.37 The diameter of the very wide double veins can be estimated intraoperatively by comparing it to the known size of one of the instruments

of the bladder when leiomyomata are ballooning out the lower uterine segment. These vessels have highly irregular locations, are very tortuous, and tend to be severely engorged and prone to easy bleeding. Once injured, they will flood the pelvis and will be very difficult to secure (Fig. 65.36).

Indiscriminate suction to evacuate the blood will collapse the pneumoperitoneum and the intestines will slide from the upper abdomen over the sacral promontory and pile up on top of the pelvic organs. The trocars are fixed to the robotic arms and the collapse of the anterior abdominal wall may cause the loss of one or more ports at a time when complete access and visualization are critical (Fig. 65.37).

Special emphasis has to be placed on neovascularization when the uterine leiomyomata extend into the retroperitoneum, as is frequently the case. Vessels of various origins and calibers will feed and drain the leiomyomata that grow into the virtual spaces of the retroperitoneum. Most commonly, the location of these uterine extensions are deep within the broad ligaments and in the pararectal spaces. Involvement of the paravesical spaces or Waldeyer's space is less common. A thorough knowledge of the retroperitoneum is required if the uterine bulk extends into the retroperitoneal virtual spaces and distorts the normal anatomy.

Bleeding

Blood loss is inherent to surgery and while all surgeons strive for bloodless procedures and dry operative fields, heavy bleeding will happen occasionally, irrespective of the level of skill or experience. However, the level of skill and experience will determine how fast the hemorrhage will be stopped.

Prevention is key and one of the steps that should always be be accomplished is mobilization of the bladder and ureters laterally at enough distance to prevent thermal injury to these structures in case repeat application of heat is required. The classic teaching is to seal (or clamp) the uterine vessels intimately close to the cervix, and the residents are thought to bounce the instrument off the cervix while closing the jaws. This technique leaves no room for error if the vessels bleed after transection. They will inevitably retract and make re-grasping and sealing very difficult. Instead, the sealer/divider should be applied slightly more lateral to the cervix and this will compensate for vessel retraction in the event of non-sealing. However, this approach requires intraoperative knowledge of the ureter trajectory.

Other prevention methods that can be used:

- The surgeon develops the para vesical and para-rectal spaces similar to a radical hysterectomy and the uterine vessels are secured at this level. The linear segment of uterine artery as it crosses over the ureter is one of the most stable characteristics of this otherwise tortuous vessel (Figs. 65.38 and 65.39)
- An X-ray detectable sponge inserted into the peritoneal cavity prior to attempting to seal the vessels can be an useful adjunct in case the bleeding vessel is not easily discernible. It has a much greater surface than the robotic/laparoscopic instruments and can be used to tamponade the bleeding area. The robotic system provides the surgeon with the advantage of locking in place the arm with the sponge without getting tired. This time can be gainfully used to suction the pool of blood, dissect around the area with the other two arms, and have the circulator nurse bring needed supplies into the room (Fig. 65.40)

Arterial blood can squirt on the camera lens and completely obscure the view. This is unusual for venous hemorrhage.

If only one lens of the binocular camera is affected, there is no need to waste valuable time to clean the camera and the surgeon can continue to operate using only one eye until the hemorrhage is contained. If the loss of visualization is

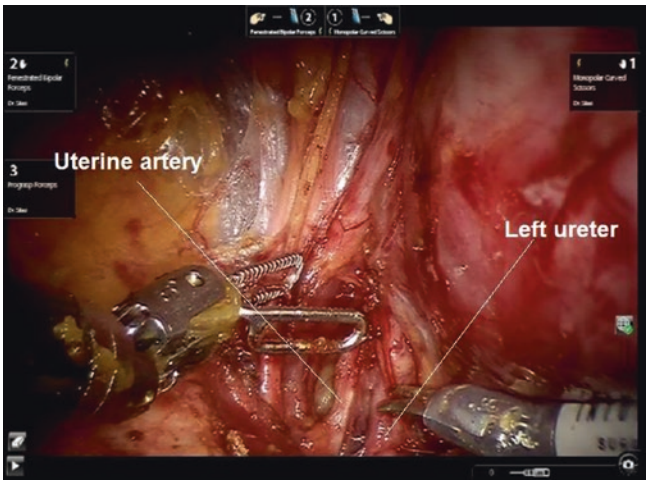

Fig. 65.38 Dissection of the retroperitoneum with emphasis on the ureter and uterine artery

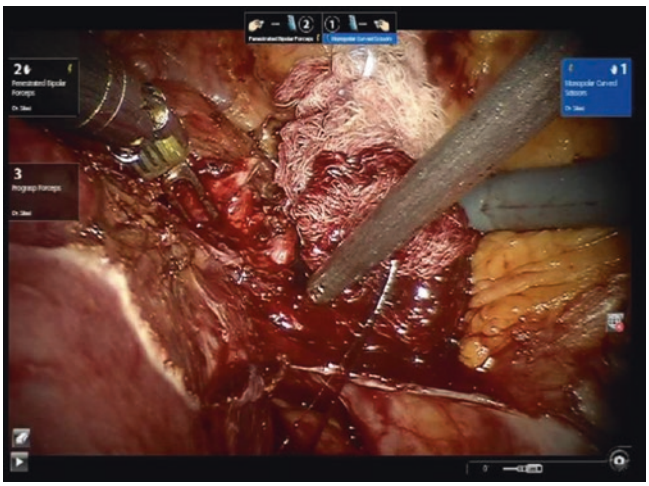

Fig. 65.40 The sponge is held in place with arm 1. Arm 2 with the bipolar cautery is holding one end of the bleeding vessel while the assistant uses the suction to clean the operative field

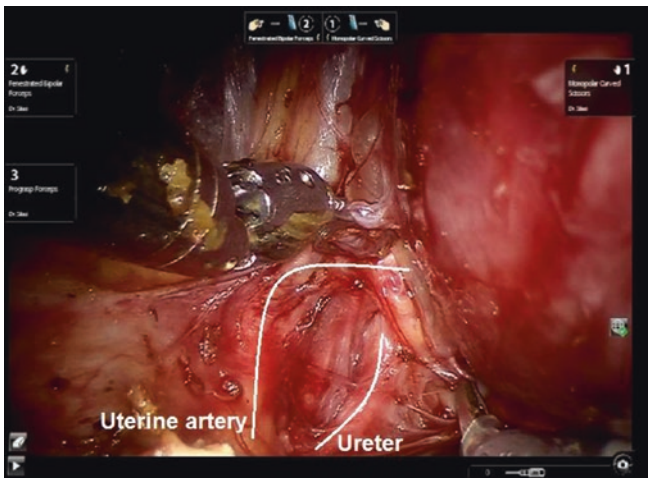

Fig. 65.39 Once dissection is completed, the uterine artery is easily elevated away from the ureter. The uterus is too large for the sealing device to reach from across the abdomen but the bipolar cautery in arm 2 will be used to desiccate the vessel

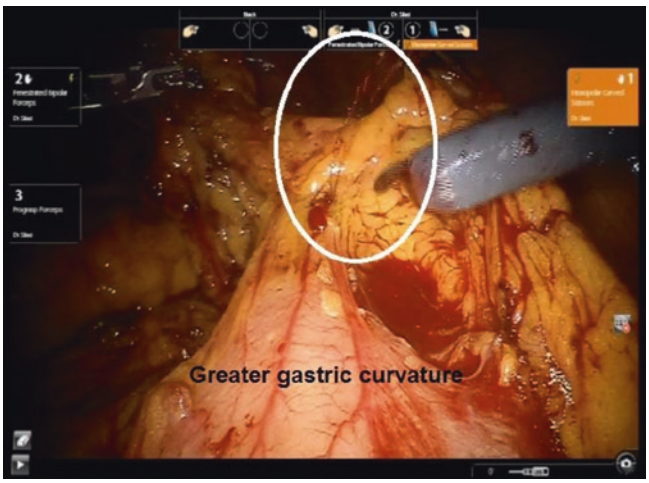

Fig. 65.41 No hysterectomy images were available for blood squirting onto the lens. However, the problem is the same regardless of the procedure. Blood from one of the short gastric vessels shoots towards the lens during omentectomy

complete, the surgeon will move the camera back and point it straight down. This simple move that changes the angle of the camera to the patient's axis will greatly facilitate the ability of the assistant to remove the camera and clean it at a time when seconds matter (Figs. 65.41 and 65.42).

In the rare event when the previously described intra-abdominal sponge was not damp or soaked, I have used it to clean the lens with the robotic arm, with inconsistent results.

If bleeding is uncontrollable, do not hesitate to undock the robot and perform a laparotomy. In most but the life-threatening cases, a Pfannenstiel or Maylard incision will be adequate to access the uterine vessels proper. The risk of bladder injury is minimal since the bladder was already mobilized caudad. There is no need to access the mid- and upper abdomen to reach the ovarian pedicles; they were already secured. Once the bleeding vessels are secured and the colpotomy completed, the specimen can be easily delivered through the new incision.

Lymphatics

Occasionally, the surgeon encounters massively distended lymphatic vessels with serpiginous channels of 1–2 cm diameter accompanying, wrapping around, and obscuring the blood vessels. Lymphatic drainage, even more so than venous drainage, can be severely impaired by the mechanical obstruction caused by the large and irregular uterus. There is

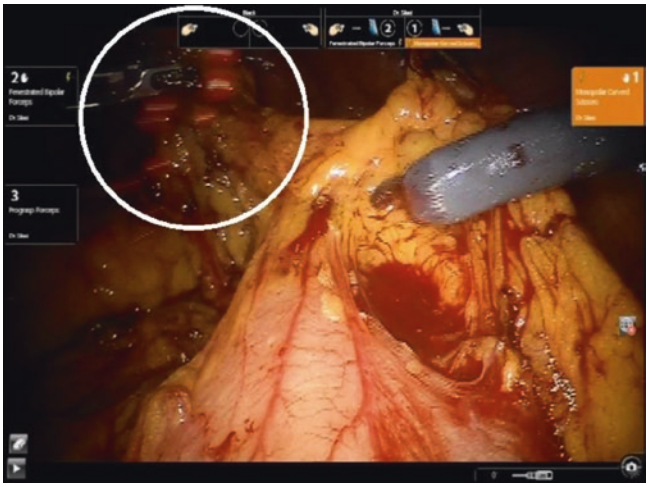

Fig. 65.42 The recording shows the blood drops immediately before they splash into the camera

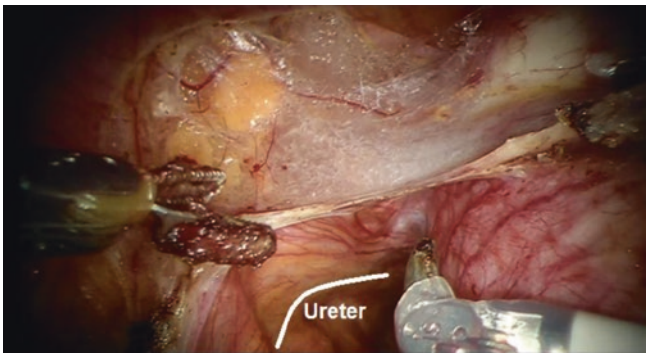

Fig. 65.43 Favorable situations like this one are rare: there is no edema or neovascularization, and the ureter can be easily identified

no corresponding lymphedema of the lower extremities, but cystic spaces of up to several centimeters in size surround the uterine vessels and are filled with clear straw-colored fluid. Their presence can surprise the operating physician. A sudden gush of this clear fluid can be misinterpreted as injury to urinary structures but is of no consequence.

Complications

The following retroperitoneal structures need to be identified and dissected with caution: the external iliac and hypogastric vessels and the ureters.

Injuries to the Ureter

The identification of the ureter trajectory is imperative before applying an energy source to seal any uterine vessels (Figs. 65.43 and 65.44).

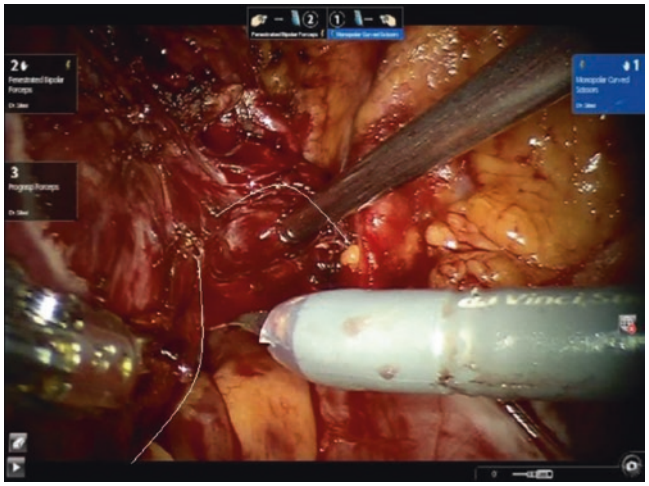

Fig. 65.44 This is an example of an unfavorable situation. There is bleeding, fibrosis, and poorly defined surgical planes. The trajectories of the ureter and uterine artery are more a guess than a certainty. In such cases, patience and meticulous dissection are required

The uterine vessels are pushed laterally by the expanding lower uterine segment and are in closer proximity than usual to the ureters. In addition, the anatomy can be significantly distorted and the ureters pushed cephalad by the uterus as it grows out of the pelvis. It is not unusual for the ureters to be at the same or higher level than the superior vesical artery. For this reason, sometimes it is easier to seal the uterine vessels at their origin from the anterior division of the hypogastric artery. The ureters are easiest to identify at the bifurcation of the common iliac arteries, as they dive into the pelvis. From there, their trajectory can be followed to the level of the uterine vessels and into the ureter tunnel. Another good landmark for ureter identification is where it crosses under the uterine artery.

Precise identification of the ureter course into the retroperitoneum has important practical implications. Incomplete sealing of the vessels requires re-application of thermal energy in a crowded pelvis, while the visualization is impaired from the accumulating blood. Knowledge of the ureters' trajectories will afford the opportunity to use energy more liberally.

Transperitoneal observation of ureteral peristalsis at the pelvic brim provides no assurance that thermal injury or transection below the pelvic brim has been avoided. While complete ureterolysis is not necessary in all cases, the surgeon should be proficient in this procedure and perform it when necessary (Figs. 65.45 and 65.46).

When extensive ureterolysis has been performed and the ureter is readily visible, injuries can easily be averted. However, comprehensive visualization of the ureter is not always possible. Ureter injury prevention relies heavily on mobilizing the ureter laterally, away from the vessels where thermal energy will be applied. Adequate mobilization of the

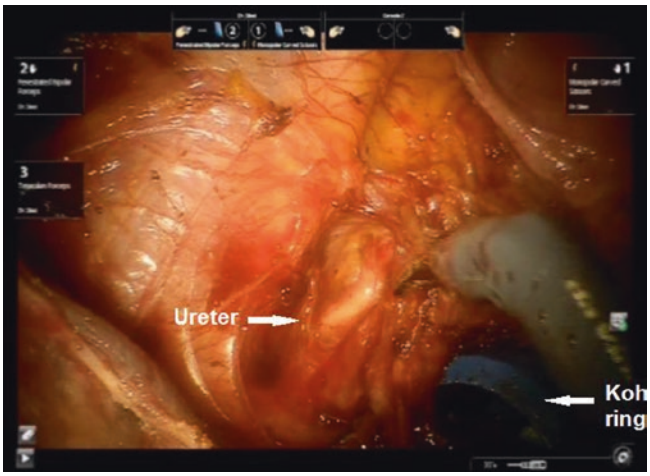

Fig. 65.45 The left ureter is very close to the colpotomy incision despite pushing the colpotomy ring from below

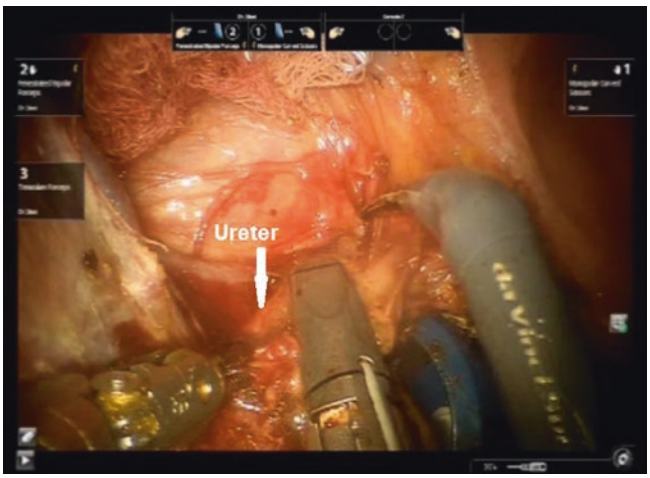

Fig. 65.46 The ureter is immediately adjacent to the vessels. An overzealous assistant attempts to apply the sealer divider on the vessels and ureter. Previous dissection of the left ureter allowed timely identification and prevention of thermal injury

bladder flap will move the ureters laterllay. Also, pushing the uterine manipulator cephalad will add up to 1 cm to the distance between the point of sealing the uterine vessels and the trajectory of the ureters, thus adding an additional maneuver of protecting the ureters from thermal injury [18].

A study performed at Ben-Gurion University in Israel evaluated this extremely important aspect in hysterectomy: the anatomical proximity between the cervix and the ureters. The distance between the ureters and the cervix was measured in 499 computerized tomography (CT) studies at the most dorsal reflection of the ureters. At least one ureter was within 0.5 cm of the cervix in 3.6 % of patients with normal CT scans and in 10.3 % of patients with cervical pathology. Overall, the right ureter was significantly closer to the cervix than the left (2.0 ± −0.8 cm vs. 2.2 ± 1.0 cm, $p < 0.05$). In cases were the pathology was limited to the cervix, the right ureter was more distant than the left (2.0 ± 0.6 cm vs. 1.7 ± 0.6 cm, $p < 0.05$). The distance between the ureters and the cervix was inversely correlated with the lateral diameter of the cervix ($r = 0.18$, $p < 0.001$) and its anterior-posterior diameter ($r = 0.11$, $p < 0.001$) [19].

A study from the University of Indianapolis in the United States was aimed at determining the distance of the ureter from the cervix and the influence of age and weight on this distance. In 52 patients, at the most dorsal reflection of the ureter, the average distance from ureter to cervical margin was 2.3 ± 0.8 cm (range, 0.1–5.3 cm). There was no relationship to age, but there was a linear relationship between this distance and body mass index (R2 = 0.075; P = .049); thus the ureter was slightly more proximal to the cervical margin in heavier women. They concluded that in women with apparently normal pelvic anatomy, the average distance between the ureter and cervix is >2 cm but this distance is <0.5 cm in 12 % of the patients studied [20].

We have not used the preoperative placement of regular or lighted ureteral stents to facilitate intraoperative ureter identification and we recommend against the practice of universal cystoscopy during major gynecologic cases.

Injuries to the Vessels

The prevention of injuries to the aorta or vena cava at the beginning of the procedure require full attention of the surgeon. Trivial aspects and sounds common to the start of any procedure such as the scrub technician setting up the instrumens, with the accompanying noise, the beeping of the monitors, and everybody talking at once, can distract the operator. However, no other surgical inadvertent situation can change the fate of the entire procedure within seconds and put the patient's life at risk.

My preference for insufflation is the Verres needle with the gas on high flow and as it penetrates the abdominal wall into the peritoneal cavity, the gas pressure readings provide the surgeon with useful information and decrease the 'blindness' of the blind insertion. Insertion injuries of the solid organs like liver, kidney, pancreas, are exceedingly rare and a clean needle stick does not need to be addressed. The only life-threatening injury that demands immediate attention is to the greater vessels. For obese patients, the point of entry into the abdomen in relationship to the retroperitoneal greater vessels is higher than for thin patients and for patients with very high BMI the needle is not long enough to reach the vessels. However, the surgeon should keep in mind the possibility of vessel injury and retroperitoneal hemorrhage. A retroperitoneal hematoma needs to be observed for expansion with the intra-abdominal pressure decreased to a minimum. If it appears stable, the surgeon can continue with

the procedure. Re-insufflation of the peritoneal cavity for the duration of the procedure will add to the hemostatic effect. Retroperitoneal exploration is usually counterproductive in small injuries of the great vessels and should be reserved for large iatrogenic defects.

Other penetrating injuries of the great vessels are immediately evident. The uterine bulk severely limits exposure and maneuvering space and these injuries can be life-threatening. If feasible, one of the robotic graspers can hold and approximate the vessel defect tight while titanium clips are applied by the assistant or the robotic specialized instrument. Vessel suturing can be accomplished much easier with the robotic system than with conventional laparoscopic instruments.

In patients with very large uteri, the trajectory of the external iliac vessels is less affected than that of the ureters. The hypogastric vessels have the most stable presentation, with the exception of the anterior division.

When the uterus expands into the retroperitoneum, neovascularization is present and unpredictable. Meticulous and gentle dissection will avoid tears, especially of the veins. A previously inserted sponge is much more effective in applying pressure and containing the bleeding than the instrument alone.

The surgeon should notify the anesthesiology team immediately if a major injury occurs. Do not hesitate to perform an emergent laparotomy if the hemorrhage cannot be contained laparoscopically.

In patients with uteri up to 16–18 weeks' size, the organ can be visualized in its entirety at all times throughout the procedure. For very large uteri, 24–30 weeks' size and above, the organ is too large and extends beyond the visual field of the surgeon. For this reason, I strongly recommend periodic surveillance of the already sealed pedicles. While the operator is focused on the lower uterine segment, the pressure and traction applied on the corpus for manipulation and visualization purposes can force the previously sealed utero-ovarian vessels to re-open. The surgeon will not notice this extensive hemorrhage since the blood will be pooling into the upper abdomen because of the Trendelenburg position. This complication is unique to these procedures.

Injuries to the Bladder

The use of the 30° down laparoscope is helpful when developing the bladder flap.

If injured, the bladder can be easily repaired once the uterus is removed. The defect should be closed in several layers. The wristed instruments facilitate suturing greatly. Imbricating the tissues is aided by the redundancy of a bladder that was extensively stretched by the enlarged uterus (Figs. 65.47 and 65.48).

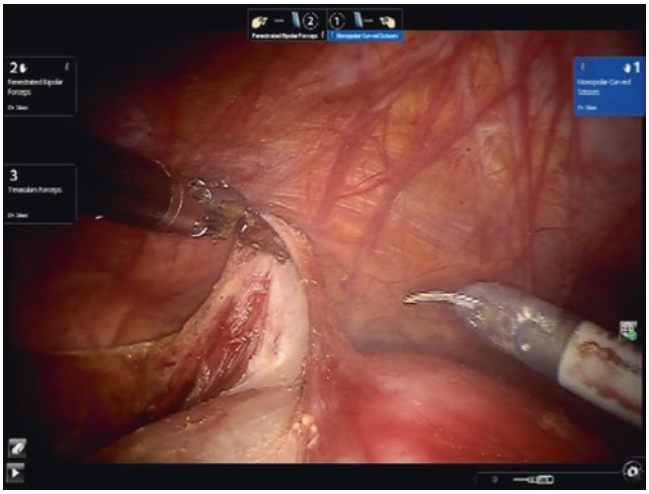

Fig. 65.47 A large anterior myoma has stretched the bladder and the bladder serosa reflection is almost at the level of the umbilicus

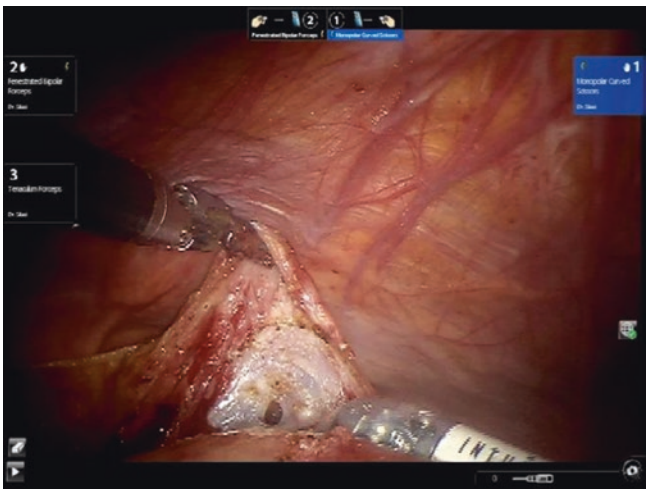

Fig. 65.48 The bladder wall is very thin at this level and a more careful dissection would have avoided the cystotomy

Delivery of the Specimen

The tests available to diagnose uterine sarcomas preoperatively are unreliable. The incidence of uterine sarcomas in patients with leiomyomata is the subject of significant controversy and the use of power morcellators has been the focus of the Federal Drug Administration [20].

The surgical presentations addressed in this chapter are not cases where the uterus can be delivered intact transvaginally. If cancer is diagnosed or suspected preoperatively, the hysterectomy should be accomplished by laparotomy. Techniques where the uterus with endometrial cancer is cored or spirally sliced to fit in the vagina and is delivered without intraperitoneal spillage have been described [21, 22].

However, these techniques are not applicable to uteri of this size when cancer is suspected or diagnosed.

The technique of power morcellation in a bag has been described but no commercially available bags exist for specimens this large.

After complete devascularization and separation of the uterus, the large specimens are removed by two methods: (1) piecemeal delivery of the uterus through the vagina or (2) piecemeal delivery of the uterus through mini-laparotomy.

Specimen removal, especially the transvaginal approach, accounts for a considerable part of the operative time. Delivery is facilitated when extensive adenomyosis is present, making the uterus soft. Also, multiple small leiomyomata can be individually shelled from their pseudocapsule and this will also aid delivery. The least desirable situation for delivery is the presence of a single very large and very firm leiomyoma.

Transvaginal Delivery

If the robotic system is docked between the patient's legs, undocking provides a much greater range of motion for the operator and assistant and allows the return of the patient to a horizontal or minimal Trendelenburg position for the duration of the specimen removal. The uterus is grasped and gradually brought into the vagina and cut piecemeal with scissors and/or a scalpel while Breisky-Navratil vaginal retractors provide exposure and protection of the vaginal walls. All cutting occurs in the vagina without contamination of the peritoneal cavity. Inevitably, blood and other fluids will run off from the uterus while it is being cut into pieces. Removing the patient from the Trendelenburg position will prevent contamination of the peritoneal cavity with these fluids. Any type of morcellation can be used: bisection, coring, "paper-roll" technique, or wedge morcellation [23–25].

Special consideration should be given to old and infarcted leiomyomata that are completely calcified and larger than the vaginal caliber. When sharp instruments are unable to cut through this tissue, monopolar cautery on high power can penetrate the tissue. Delivery of these specimens is very tedious.

Transabdominal Delivery

Some patients will present with a narrow and/or long vagina. In these cases, enlarging one of the port sites or performing a suprapubic mini-laparotomy allows piecemeal delivery of the uterus. However, this approach will contaminate the peritoneal cavity and abdominal wall with uterine debris.

Conclusion

Resection of very large uteri using the robotic system is a feasible alternative to laparotomy, regardless of the patients' body habitus. However, it requires sophisticated surgical skills and is a more time-consuming approach. Without doubt, the benefits of this approach to the patients surpass the longer operative times and the higher costs associated with the amortization of the robotic system.

Robotic-Assisted Total Hysterectomy: Hysterectomy Techniques in Prolapse Situations

66

Emad Matanes, Roy Lauterbach, and Lior Lowenstein

Introduction

Pelvic organ prolapse (POP) is a protrusion of pelvic organs and their associating vaginal segments descend from their normal positions into the vagina [1]. This condition is common, being symptomatic in approximately 30 % of women 50–89 years of age and requiring a corrective procedure in 11 % of women by 80 years of age. In the next 30 years, the demand for treatment of POP will increase 45 % on the background of the increase of old women population [2]. Other associated risk factors for development of POP include: vaginal delivery, history of hysterectomy, obesity, race and history of previous operations [3].

Definitions

Cystocele: Herniation of the anterior vaginal wall. (Fig. 66.1)
Rectocele: Herniation of the posterior vaginal wall. (Fig. 66.1)
Enterocele: Protrusion of the small intestines and peritoneum into the vaginal canal. (Fig. 66.2)
Uterine prolapse: Downward protrusion of the cervix and uterus toward the introitus. (Fig. 66.3)

Pathophysiology

POP results from weakening of the supportive structures which is caused either by stretching and tearing of the supportive system or by neuromuscular dysfunction. The structures that support the vagina and the uterus are divided into three levels which correspond to differing areas of support [4]:

Level I: The upper part of the vagina and the cervix are suspended from above. The suspension referred to the **cardinal and uterosacral ligaments**.

Level II: The midline position of the vagina is maintained by the paravaginal attachments of the lateral vagina and the **endopelvic fascia** to **arcus tendineus**.

Level III: The distal vagina is supported by muscles and connective tissue which surround it. It is fused laterally to the levator muscle and posteriorly to the perineal body while anteriorly it blends with the urethra.

Anatomy

The pelvic organs are arranged in three compartments:

Anterior compartment: Contains the urinary bladder, the Urethra and the anterior wall of the vagina.
Posterior compartment: Includes the rectum and the vaginal posterior wall. It is supported by the pelvic floor musculature and connective tissue posteriorly and the pararectal fascia and its attachments to the lateral pelvic floor musculature and its fascia.
Apical compartment: Contains the uterus, cervix and the apical part of the vagina.

Treatment

The treatment for POP is based on both, surgical and nonsurgical approaches.

Nonsurgical Treatment

It is recommended in cases of:

- Mild to moderate POP.
- Patients who are still interested in having future pregnancies.
- Patients who are not interested in surgical approach.

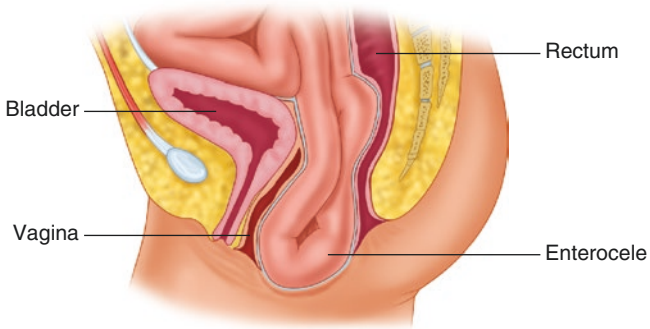

Fig. 66.2 Protrusion of the small intestines into the vagina

Options for treatment are:

1. Life style intervention:
   - Pelvic floor muscle training PFMT
   - Weight loss
2. Mechanical devices (Pessary)

Surgical management

The main purpose of surgical treatment is symptomatic relief by restoration of the vaginal anatomy. Three main surgical approaches for treatment of POP: vaginal, abdominal and laparoscopic (both conventional and robotic). The use of vaginal meshes was very common until October 2008, when the FDA published its` first warning regarding possible complications following the use of mesh in vaginal surgeries. Since then, many surgeons around the world converted their surgical approach from vaginal to abdominal and returned to use the traditional gold standard approach for POP repair thus sacrocolpopexy [5].

Sacrocolpopexy can be performed by abdominal approach, conventional laparoscopy or robotic laparoscopy.

The principle of the procedure is to lay a Y shaped mesh over the prolapsed organ, whether it is the vaginal wall, the cervix (in cases in which Supra cervical hysterectomy is performed) or the uterus (in cases in which the uterus is not excised). The upper arms of the Y shaped mesh embrace the prolapsed organ and the remaining part of the mesh is fixated to the anterior longitudinal ligament of the sacrum.

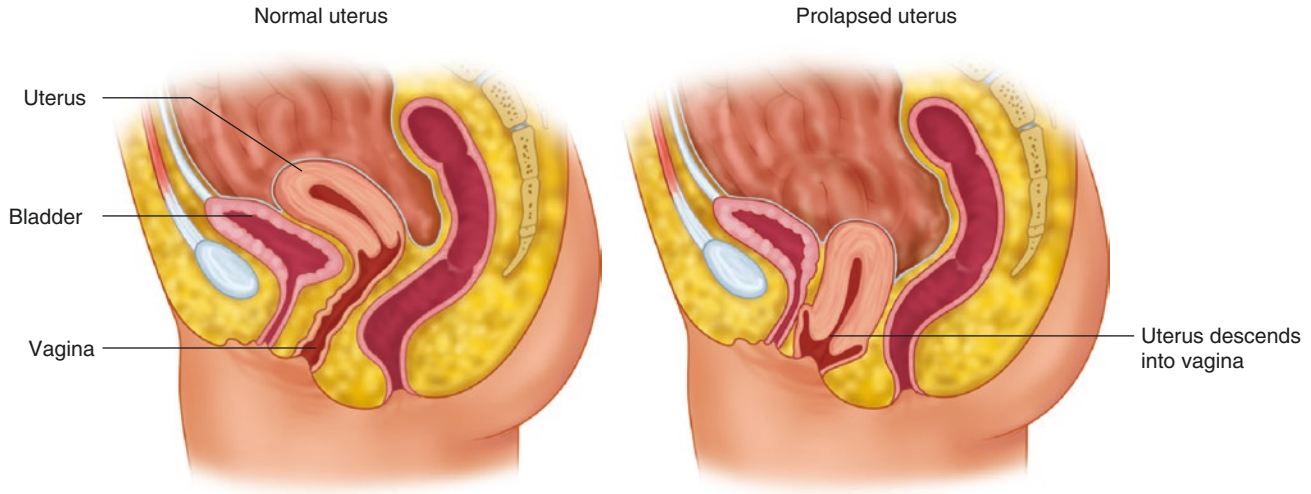

Fig. 66.3 Weakened cardinal and utero-sacral ligaments may lead to uterine prolapse

In the past two decades, the open approach has been replaced by the laparoscopic one due to its` proven advantages, and recently, there has been another shift from conventional laparoscopy to robotic laparoscopy [6] .

The Robot Evolution

- 1985: The first robotic surgical operation was presented, Kwoh and his associates reported performing a brain biopsy with a robotic arm PUMA560 successfully [1]
- 1993: Robodec was the first robot to be granted FDA approval for a hip replacement surgery.
- 2001: The first Telerobotic cholecystectomy was performed successfully with the ZEUS robot.
- 2005: The FDA approved robotic technology for gynecologic surgery.
- 12/2011: The FDA accepted the specific Single-Site equipment for use with the Da Vinci Surgical System (Fig. 66.4).

Fig. 66.4 The Da Vinci Robot is the most utilized robot today in the surgical world. The arms marked "1", "2", "3" are the operating arms, and the 4th arm is the camera holder. During single port surgery the arm marked "3" is not in use during surgery. ©2016 Intuitive Surgical, Inc.

Robotic Sacrocolpopexy and Supracervical Hysterectomy–Multiport

Insertion of the veress needle and creation of pneumoperitoneum. Before inserting the veress needle in, it is necessary to identify the possible insertion points based on the patient's medical and surgical history. The common approach is by making a small medial incision approximately 2 centimeters above the umbilicus. In patients with a history of previous abdominal surgery, it may be wise to consider approaching the abdomen with an incision at palmer's point, located at the left mid-clavicular line, approximately 2–3 centimeters under the rib cage.

During the insertion of trocars at the site of the first incision, RUQ, RLQ and LLQ (Fig. 66.5), it is imperative to

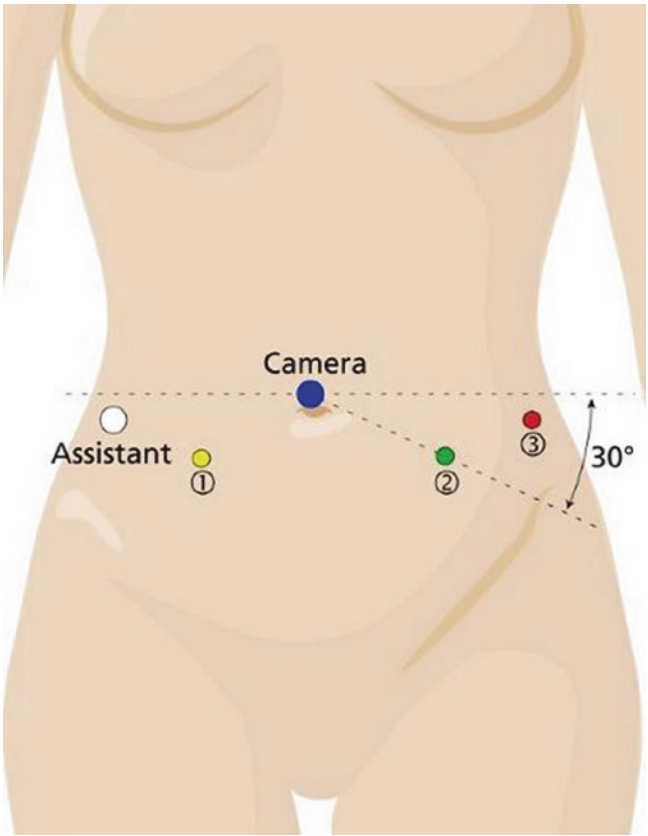

Fig. 66.5 During multi-port surgery 5 incisions are made in the abdomen, in the shape of a "W", 4 incisions are designated for the insertion of the robot arms, and the 5th incision is designated as the assistant port, allowing the insertion and extraction of surgical tools (needles/mesh/instruments) that otherwise assist the surgeon during surgery. Single port surgery utilizes a single supra-umbilical incision, thus making the other incisions redundant. ©2016 Intuitive Surgical, Inc.

avoid perforating 2 significant arteries that pass through the abdominal wall:

(a) Inferior Epigastric vessels that originate from the External Iliac arteries run superiorly and enter the rectus sheath deep to the rectus abdominis, while supplying the rectus abdominis muscle, and the deep abdominal wall of the pubic and inferior umbilical regions.
(b) Superficial Epigastric arteries that originate from the Femoral artery run in the subcutaneous tissue toward the umbilicus, while supplying the superficial abdominal wall of the pubic and inferior umbilical regions (Fig. 66.6).

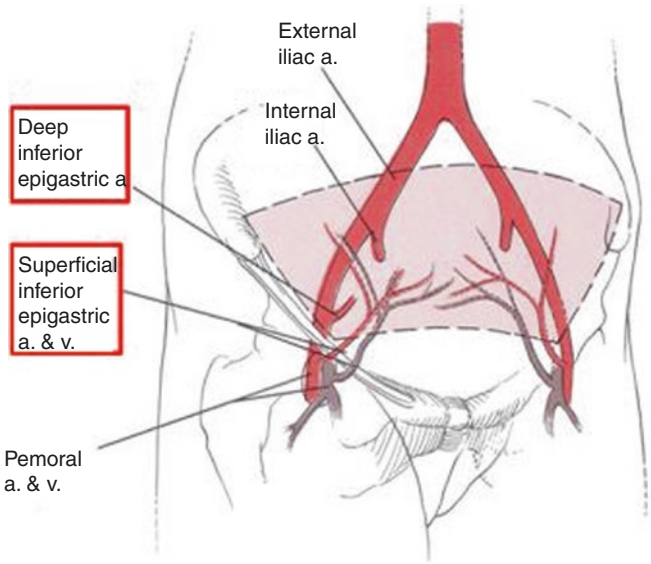

Fig. 66.6 Make an effort to avoid making incisions on the course of the DEEP INFERIOR EPIGASTRIC ARTERY AND SUPERFICIAL INFERIOR EPIGASTRIC VESSELS- that run down the abdominal wall

Fig. 66.7 Two robot instruments are inserted through the single port on top of a camera, an assistant trocar and the gas tube attached to the port, thus making the extra 4 incisions made in multi-port surgery redundant. ©2016 Intuitive Surgical, Inc.

Single-Port Surgery

The next generation of robotic assisted laparoscopy is the single port access, in which the surgeon operates almost exclusively through a single entry point, typically the patient's navel, leaving only a single small scar (Figs. 66.7, 66.8 and 66.9). Benefits of single-port robotic assisted sacrocolpopexy surgery may include:

- Faster recovery.
- Shorter hospitalization.
- Minimal post op pain.

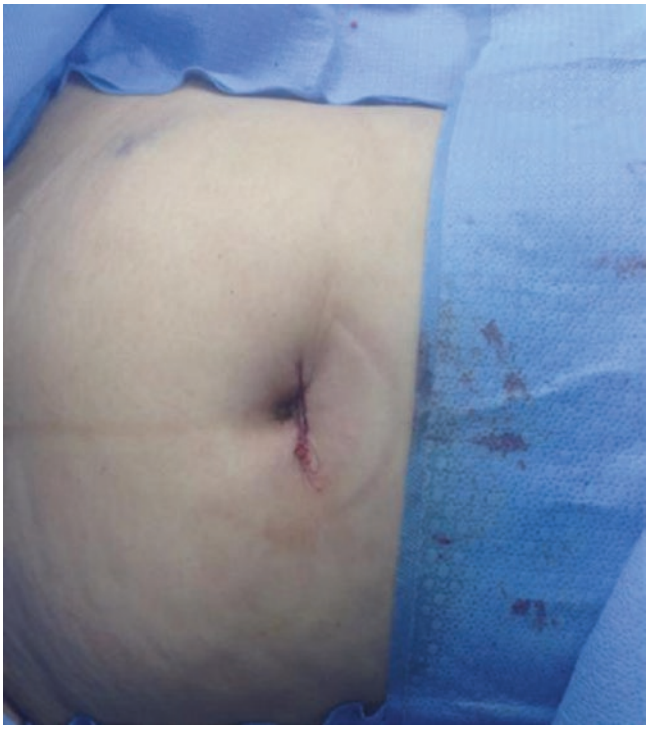

Fig. 66.8 The post-surgical minimal scar after single port surgery

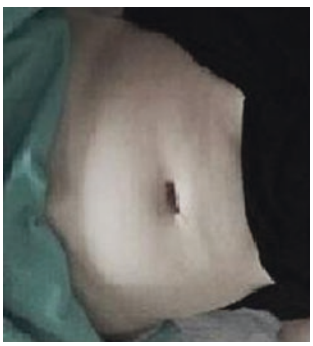

Fig. 66.9 Three weeks post-surgery, the scar is embedded into the umbilicus and is barely recognizable

- Virtually Scar free results.
- Minimal blood loss.

Four instruments are inserted via the single port in addition to the CO2 tube creating the pneumoperitoneum.

During Surgery

On visualization of the pelvic cavity it is crucial to keep in mind the course of the ureters. The ureters descend subperitoneally into the pelvis, passing inferior of the uterine artery. They then penetrate the bladder wall obliquely from its` posterio-inferior angle. The pelvic portion of each ureter is served by the vaginal artery and the internal iliac veins.

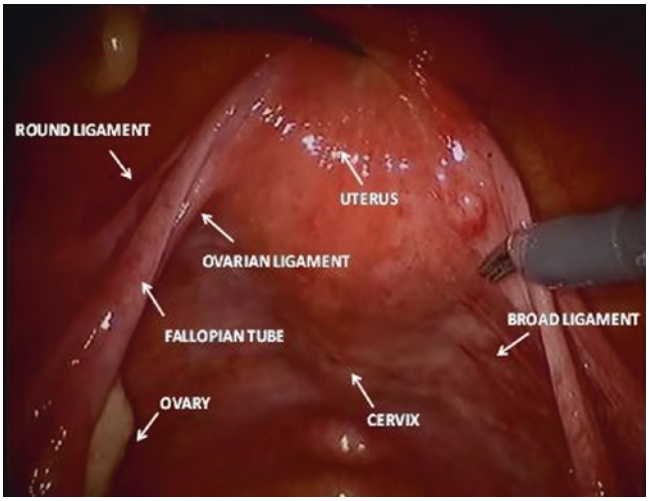

Fig. 66.10 Anatomical orientation: The posterior plane of the uterus, attached on both sides to the ovarian ligaments (connecting the uterus and the ovaries); the round ligament lies anterior to the fallopian tubes that are connect at the superior-lateral aspects of the uterus on their medial part and run laterally to the ovaries, which can be recognized on the left side as an oval, white structure. The broad ligament is the peritoneal sheet that covers the uterus anteriorly and posteriorly and contains several important structures including uterine blood vessels, ovarian blood vessels, ligaments and fallopian tubes

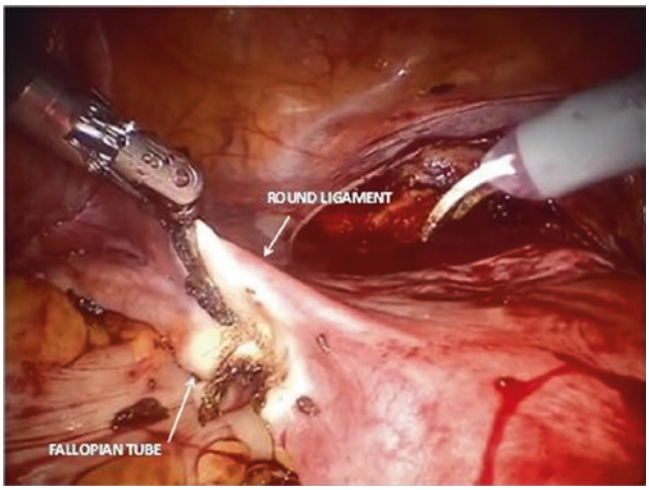

Fig. 66.11 Bipolar (searing) in the right arm, and scissors (cutting) in the left arm utilized to detach the round ligament, a preliminary step during Hysterectomy

Upon entering the peritoneal cavity, it is very important to orientate anatomically (Fig. 66.10):

Surgery Steps

1. Sealing and cutting of the round ligament and the fallopian tube (Fig. 66.11).

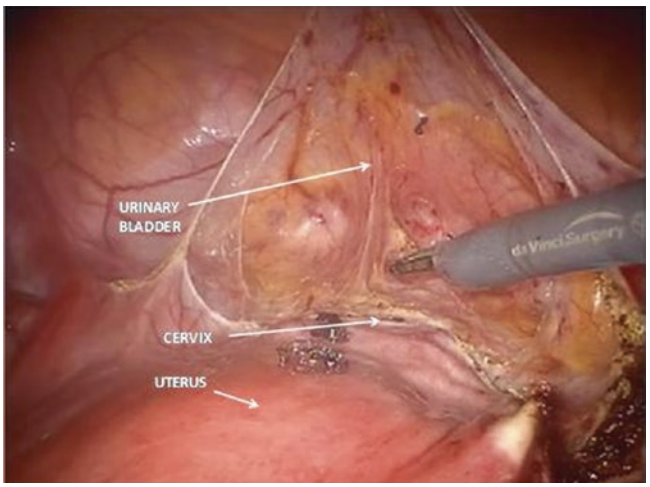

Fig. 66.12 Peeling of the bladder off the cervix

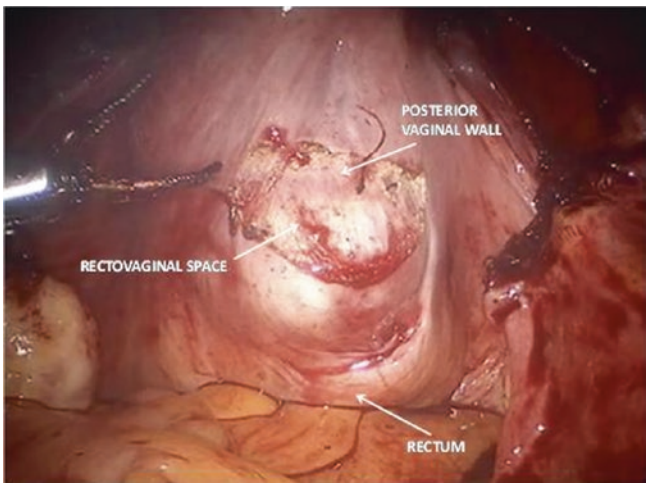

Fig. 66.14 Preparation of the posterior vaginal wall for the fixation of the posterior portion of the mesh

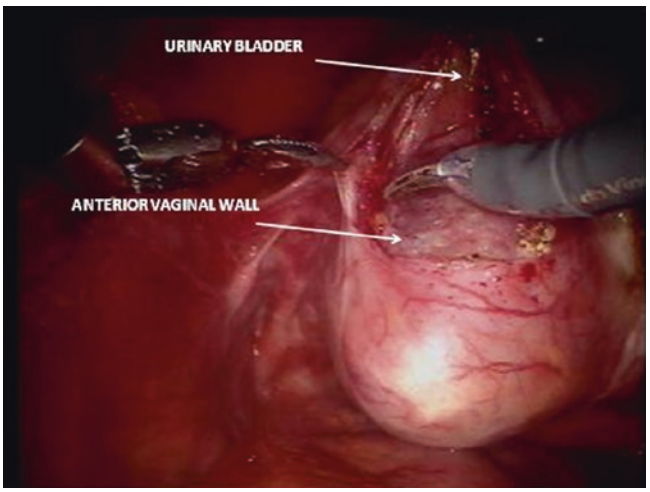

Fig. 66.13 Preparation for the fixation of the anterior portion of the mesh, an important step during surgery that serves a double purpose: avoiding damage to the bladder, and optimal fixation of the mesh, thus allowing better prolapse fixation results

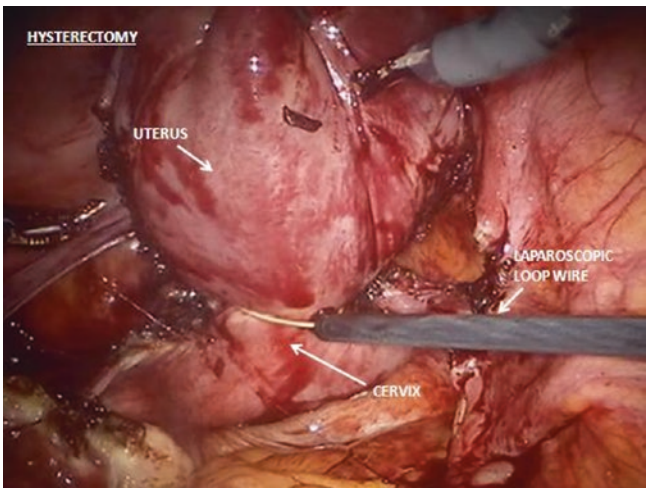

Fig. 66.15 Hysterectomy: usually performed supra-cervically. After detaching the uterus from its` supplying blood vessels, a loop wire is manipulated around the uterus, until reaching the upper part of the cervix, where uterine detachment is facilitated

2. Opening of the broad ligament and the posterior sheet.
3. The same actions need to be repeated on the other side of the uterus.
4. Opening of the bladder fold and pushing it over the anterior vaginal wall and the bladder's neck (Figs. 66.12 and 66.13).
5. Sealing and cutting the uterine arteries.
6. Developing the posterior rectovaginal space- opening the peritoneum on the posterior vaginal wall. (Fig. 66.14)
7. Total removal of the uterus using a loop wire while leaving the cervix intact (Figs. 66.15 and 66.16).
8. The anterior longitudinal ligament is exposed. The middle sacral vessels should be visualized to avoid inadvertent injury (Figs. 66.17 and 66.18).
9. Open the peritoneum from the sacral promontory downward toward the cul-de-sac and the posterior vaginal wall in order to cover the mesh with peritoneum.
10. Sewing the surgical mash to the posterior vaginal wall, the cervical stump and the anterior vaginal wall.

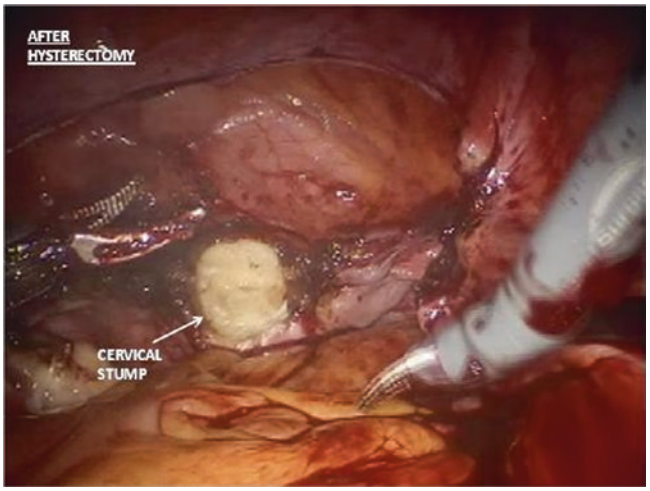

Fig. 66.16 The cervical stump is utilized later in surgery as an anchor for mesh fixation

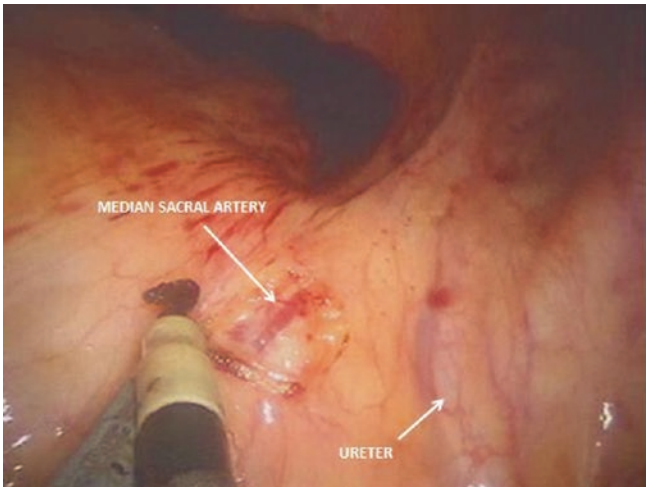

Fig. 66.18 Avoid damage to the median sacral vessels

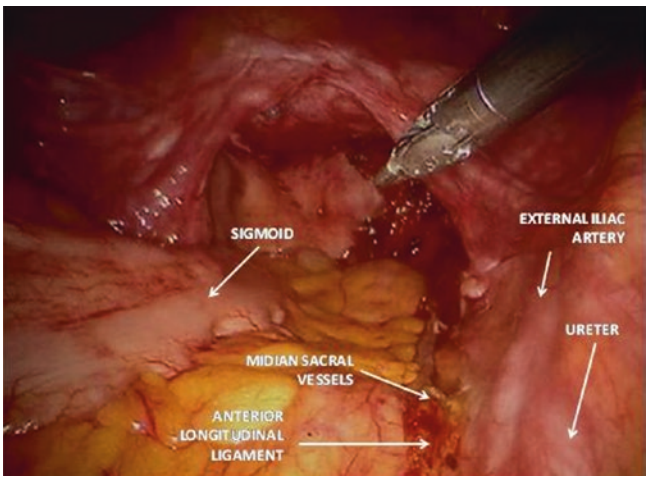

Fig. 66.17 Preparation of the promontorium for mesh fixation-anatomical landmarks that the surgeon must identify in order to avoid complications-ureter on the right side of the picture (usually identified by it's peristalsis; the common iliac artery in its` bifurcation to internal and external iliac arteries. Peeling the peritoneum off the promontorium to identify the longitudinal ligament

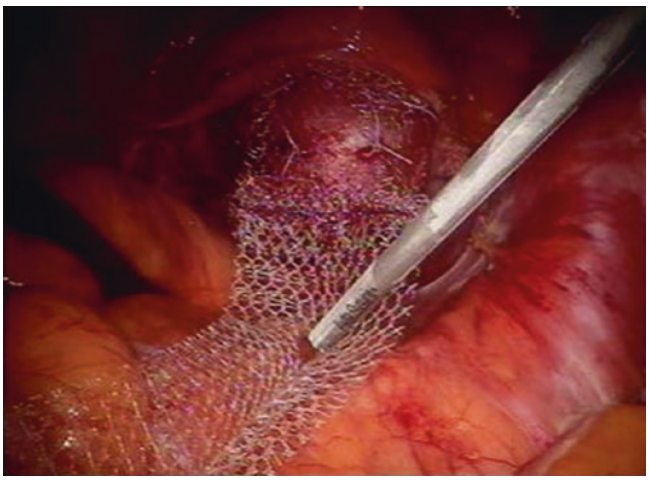

Fig. 66.19 Fixation of the inferior portion of the "Y" shaped mesh to the longitudinal ligament with tacks

11. Fixation of the surgical mesh to the promontory of the sacrum with tacks (Fig. 66.19).
12. Peritoneal closure: Fixation of the mesh to the sacral promontory, followed by re approximation of the peritoneal edges, and concealment of the mesh retroperitoneally.

Covering the mesh with peritoneum is in debate, while some consider this as a preventive measure for bowel adhesions to the mesh, this was not proven to be evidence based.

Opening the peritoneum along the promentriom toward posterior vaginal wall can result in bleeding and rarely to damage the sigmoid colon or the ureter. Closure the peritoneum over the mesh needs to be learned. Injury to adjacent vessels or the ureter can also occur during the procedure (Figs. 66.20 and 66.21).

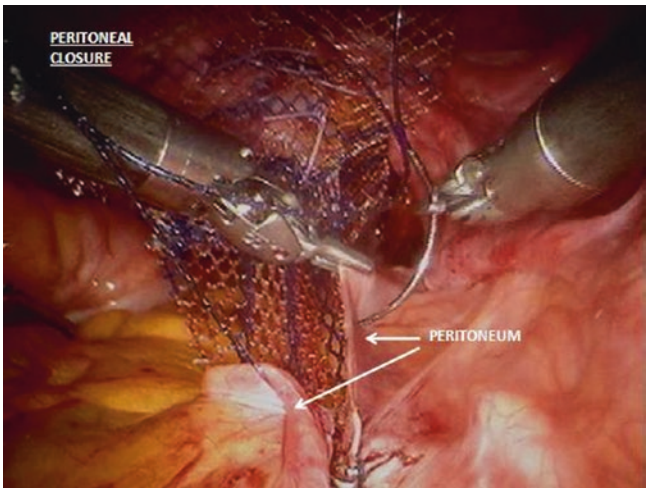

Fig. 66.20 After peeling the peritoneum and fixating the mesh to the promontorium, the mesh is "buried" under the peritoneum by suturing both ends of the peritoneum with a v-lock suture

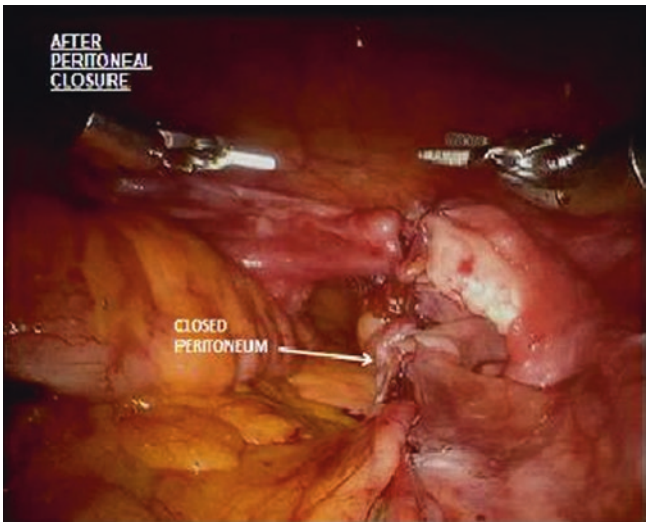

Fig. 66.21 The sutured peritoneum after peritonization (the mesh is buried under the peritoneum)

Robotic-Assisted Radical Hysterectomy

67

Emma L. Barber and John F. Boggess

Indications for Robotic Radical Hysterectomy

Piver, Rutledge and Smith originally described five types of hysterectomy for treatment of cervical cancer in 1974 [1]. A type I hysterectomy is an extrafascial or simple hysterectomy and is appropriate for the treatment of stage IA1 carcinoma of the cervix without lymph-vascular space invasion. In a type II hysterectomy, the uterine artery is ligated at its junction with the ureter and the para-cervical tissue medial to this is removed. This allows for preservation of the blood supply to the ureter and a decreased risk for ureteral vaginal fistula formation. A type II radical hysterectomy along with pelvic lymphadenectomy is appropriate treatment for IA2 carcinoma of the cervix, with or without lymph-vascular space invasion. A type III radical hysterectomy mandates removal of the parametria medial to the origin of the uterine artery as it branches off the internal iliac artery, removal of the uterosacral ligaments at their origin and an upper vaginectomy. A type III radical hysterectomy along with pelvic lymphadenectomy is the standard treatment for IB1 cervical cancer and may also be used for select IB2 as well as IIA lesions. Radical hysterectomy, either type II or type III can also be used to treat cases of uterine cancer with gross cervical involvement (Table 67.1).

Soon after the introduction of the robotic platform in 2005, Sert and Abeler published the first case report of robotic assisted type III radical hysterectomy [2]. The technique was later described in a series of 51 patients where robotic hysterectomy was found to decrease complications, specifically blood loss, and to shorten hospital stay when compared to open radical hysterectomy [3]. In addition, retrospective studies have shown that robotic assisted radical hysterectomy has equivalent survival to open radical hysterectomy [4–6]. The oncologic indications for robotic type III radical hysterectomy are the same as those for the open procedure. Laparoscopy and the robotic platform also require appropriate patient selection. Insufflation and steep Trendelenberg positioning promote physiologic cardiopulmonary changes that can result in increased hypercarbia, decreased cardiac output, and decreased pulmonary compliance. Thus, patients with significant pulmonary or cardiac conditions may not be able to tolerate the required positioning for the duration of the operation. This patient positioning also increases both the intraocular pressure and intracranial pressure. Thus, any intracranial pathology associated with intracranial hypertension or disruption of the blood-brain barrier are contraindications (Table 67.2). Additionally, among patients with glaucoma, preoperative tonometry should ensure that intraocular pressure is not increased, as robotic surgery in addition to an already elevated intraocular pressure can result in permanent ocular damage (Fig. 67.1).

Uterine size is another contraindication to a minimally invasive approach. A large bulky uterus can limit visualization and given that morcellation should be avoided in the case of cervical carcinoma, the uterine specimen must be able to be delivered through the vagina at the conclusion of the surgery. Previously described contraindications include increased patient BMI and extensive prior surgical history. While it is true that patients with a high BMI can provide a challenge in terms of increased weight on the diaphragm and the resulting decreased pulmonary compliance, we have found that many morbidly obese patients without significant cardiopulmonary co-morbidities are able to tolerate required positioning and do not experience an increased risk of perioperative pulmonary complications based on the degree of obesity [7]. Additionally, the surgical benefits of wristed instruments within the abdomen and pelvis as well as a camera that is able to descend into the pelvis actually offers increased visualization and dexterity in the obese patient over open surgery. Extensive prior surgical history has also been noted as a contraindication to minimally invasive surgery, however, we do not consider this a contraindication.

Table 67.1 Types of radical hysterectomy

	Indications	Location of uterine artery ligation	Uterosacral ligaments	Vaginal margin
Type I (extrafascial)	IA1 cervical carcinoma without LVSI	Insertion into the cervix	Insertion into cervix	At cervico-vaginal junction
Type II (modified radical)	IA2 cervical carcinoma, uterine cancer with cervical involvement	Junction with the ureter	Midpoint between cervix and sacral attachments	1–2 cm of vaginal margin
Type III (radical)	IB1 cervical carcinoma and select IB2 and IIA lesions, uterine cancer with cervical involvement	Origin at the internal iliac artery	At sacral attachment	2–3 cm of vaginal margin

Table 67.2 Contraindications to a robotic approach

	Degree of contraindication	Rationale
Uterine size	Absolute	Morcellation should not be performed. Therefore, the specimen must be able to be delivered vaginally at the conclusion of the procedure
Conditions with increased ICP	Absolute	Required positioning will exacerbate intracranial hypertension ad can result in disruption of blood-brain barrier
Glaucoma with increased IOP	Absolute	Required positioning increases the intraocular pressure and can result in permanent vision loss and even blindness
Morbid obesity without cardiopulmonary compromise	None	These patients are generally able to be ventilated and the benefits of minimally invasive surgery and the wristed instruments of the robotic platform are even more pronounced in the morbidly obese
Cardiopulmonary compromise	Relative	Depending on the degree of compromise, patients may not be able to tolerate the required positioning, however, this is difficult to predict preoperatively and thus patients should have a trial of positioning before deeming this a contraindication
Extensive surgical history	None	Robotic platform allows for increased dexterity and visualization allowing the surgeon to perform lysis of adhesions

Fig. 67.1 Securing patient for steep Trendelenberg positioning. The patient's chest is padded and she is secured to the bed using thick cloth tape. The tape is passed around the patient and the bed 3–5 times depending on the patient's weight

Robotic Versus Laparoscopic Versus Abdominal Radical Hysterectomy

Minimally invasive radical hysterectomy, including both robotic and laparoscopic radical hysterectomy, offers advantages over abdominal radical hysterectomy. Minimally invasive radical hysterectomy has been associated with decreased blood loss, lower rates of transfusion, decreased length of hospital stay, equal or lower rates of postoperative complication, and an equal or increased number of lymph nodes sampled when compared with an open procedure [8–11].

Studies examining robotics versus traditional laparoscopy have found that traditional laparoscopy is associated with similar postoperative outcomes, but longer operative times. In addition, most laparoscopic radical hysterectomy series are limited to patients with a BMI under 30 whereas robotic papers include obese and morbid obese patients in their cohorts. Traditional laparoscopy is also associated with a longer learning curve and does not offer the same ergonomic benefits as robotic surgery. In contrast with other surgical procedures such as benign hysterectomy, robotic radical hysterectomy is not associated with increased cost compared with traditional laparoscopy [11]. In the only study to examine the cost of robotic, abdominal and laparoscopic radical hysterectomy for the treatment of cervical cancer using a large national database, the authors found that laparoscopic radical hysterectomy was associated with median costs of $11,774 whereas robotic radical hysterectomy actually had a statistically significant lower median cost of $10,176 [11].

Data on oncologic outcomes are similarly reassuring. One study showed no difference in 3-year overall and recurrence free survival for patients undergoing robotic versus abdominal radical hysterectomy [4]. A multicenter retrospective study examined 517 patients and demonstrated no difference in recurrence or survival between patients undergoing open or robotic radical hysterectomy with a median follow up of 34 months [12]. The same is true for laparoscopic versus open radical hysterectomy with both having similar risk of recurrence and mortality [6].

Surgical Procedure

Clinic Evaluation and Patient Counseling

History and physical examination are essential to identify patients who are good candidates for robotic radical hysterectomy. Evidence of parametrial spread on examination or imaging that reveals metastatic disease necessitates primary treatment with pelvic chemoradiation or systemic chemotherapy. Preoperative assessment should also screen for the previously mentioned contraindications to robotic surgery. Standard preoperative assessment with indicated laboratory work including a type and screen should be performed. Bowel preparation is not necessary.

As with any surgical procedure, patients should have an informed consent discussion regarding the risks and benefits of robotic radical hysterectomy. Standard risks such as bleeding, infection and injury to blood vessels, nerves, bladder, ureter, and bowels should be discussed. Additionally, for robotic radical hysterectomy, the risk of conversion to a laparotomy, risk of fistula formation and risk of both short-term and long-term bladder dysfunction should all be discussed. Patients should also be informed of the possibility of postoperative radiation depending on the final surgical pathology.

Preoperative Positioning

The patient is brought to the operating room and placed under general anesthesia. Prior to induction, sequential compression devices are placed on the lower extremities. She is then positioned in the low dorsolithotomy position using Allen stirrups to allow for adequate space to bring the robot to the bedside. Examination under anesthesia is performed prior to beginning the surgery to reorient the surgeon to the patient's anatomy and to confirm the absence of parametrial or pelvic sidewall disease, which would preclude a surgical approach. After the patient is positioned in the dorsolithotomy position, she is secured to the table to allow for steep Trendelenberg positioning. This can be done using shoulder blocks, chest padding with taping or a beanbag device which molds to the patient. Given the risk of brachial plexus injuries relying only on shoulder blocks and the cost of bean bag devices, we prefer to use chest padding and taping to secure the patient to the bed. Although uterine manipulation is standard in robotic hysterectomy, for a robotic radical hysterectomy, we prefer to avoid disruption of the tumor and instead place a large rectal dilator (EEA sizer) in the vagina prior to draping for use at the time of colpotomy. A pneumo-occluder balloon is also placed in the vagina to prevent loss of pneumoperitoneum during the colopotomy. A foley catheter is also placed to decompress with bladder and decrease the risk of bladder injury. Prophylactic antibiotics are administered prior to skin incision (Fig. 67.2).

Abdominal Entry

We routinely enter the abdomen in the left upper quadrant at Palmer's point (left upper quadrant 2 cm below the costal margin in the mid-clavicular line) after an orogastric tube has been placed to suction. This allows us to avoid adhesions from prior surgery and will be the site for our assistant port [13]. We inject the skin with local anesthetic prior to incision and enter the abdomen with a 2 mm miniport. Once the abdomen is insufflated, a 2 mm camera is inserted into the abdomen and an abdominal survey is performed focusing on the anterior abdominal wall and presence of any adhesive disease. An alternative technique is to insufflate at this site with a veress needle and place a 5 mm visiport under direct visualization.

Port Placement

Five total trocars are used. Two traditional laparoscopic trocars are used for the camera and assistant port and three robotic trocars are used for the robotic arms. A 12 mm trocar is placed in the umbilicus and functions as the camera port. The robotic camera is introduced through this port and a complete abdominopelvic survey is completed to identify any evidence of metastatic disease or adhesive disease that

Fig. 67.2 EEA sizer and vaginal balloon. A rectal end-to-end anastomosis (EEA) sizer is placed into the vagina to allow for uterine manipulation and to assist in identification of the cervico-vaginal junction. A pneumo-occluder balloon is placed around the handle and inflated to prevent the loss of pneumoperitoneum during colpotomy

will prevent port placement. Any abnormalities encountered in the abdomen or pelvis that are suspicious for metastatic disease should be biopsied and sent for frozen section. Confirmation of metastatic disease should prompt the surgeon to consider aborting the surgery in favor of radiation therapy depending on the clinical scenario. Any encountered adhesive disease, which prevents port placement or will not be accessible with the robot is taken down laparoscopically. Additional robotic trocars are placed as follows: arm 1 is placed 8–10 cm lateral to the camera port in the right upper abdomen, arm 2 is placed in the left upper abdomen again, 8-10 cm lateral to the camera port, mirroring arm 1, and arm 3 is placed in the left lower quadrant just superior to the anterior iliac spine and at least 8 cm in distance from arm 2. A 10/12 mm assistant port is placed in the left upper quadrant at the site of laparoscopic entry. All trocars are placed under direct visualization and all ports are advanced to the thick black line on the trocar cannula to allow for optimal range of motion for the robotic arms. The patient is then placed in steep Trendelenberg. If tolerated, we use 30 ° of Trendelenberg. The robot is moved into position either between the patient's legs or over the left leg in a side docking position. The camera arm is docked first. The robotic arm clutch button is pressed and the angle of the camera arm is aligned with the angle of the trocar. The trocar is stabilized with one hand and the other hand is used to press the robotic arm clutch button and deliver the arm to the trocar, clipping both wings to secure the robotic arm to the trocar. The remaining three robot arms are docked to their respective trocars in the same fashion (Fig. 67.3).

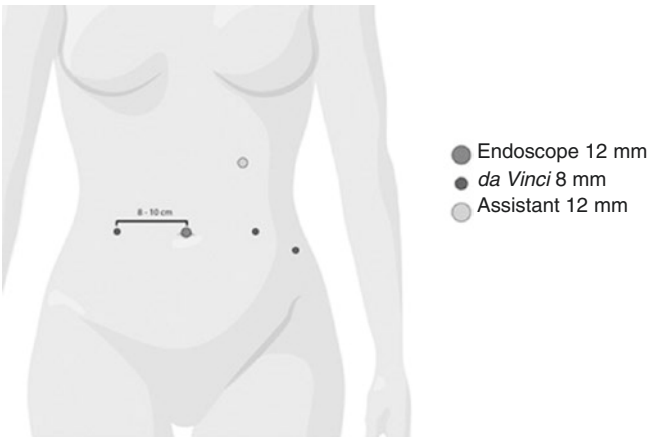

Fig. 67.3 Port placement. A 12 mm trocar is placed in the umbilicus and functions as the camera port. Arm 1 is placed 8–10 cm lateral to the camera port in the right upper abdomen and arm 2 is placed in the left upper abdomen mirroring arm 1. Arm 3 is placed in the left lower quadrant just superior to the anterior iliac spine and at least 8 cm in distance from arm 2. A 10/12 mm assistant port is placed in the left upper quadrant at the site of laparoscopic entry (With kind permission from John F. Boggess, MD 2007)

Robotic Instruments

Once the robot arms have been docked, the robotic camera is introduced through the camera port. We use a 0-degree camera throughout the surgery. The robotic instruments are then introduced. The monopolar scissors are used in the right hand and the fenestrated bipolar in the left hand. A blunt grasper, such as a prograsp or a cadiere, is used in arm 3. All instruments are introduced into the abdomen under direct visualization.

Opening the Retroperitoneum and Avascular Spaces of the Pelvis

The uterus is manipulated with the fourth robotic arm. The right uterine cornua is grasped and moved to the patient's left. The right round ligament is transected using monopolar cautery as far laterally as possible and this peritoneal incision is extended cephalad parallel to the infundibulopelvic ligament. The medial umbilical ligament is placed on tension medially and caudad to allow for identification of the superior vesical artery. The peritoneum just lateral to the artery is incised cephalad to its origin. The monopolar scissors and fenestrated bipolar graspers are then used to spread perpendicular to the pelvic sidewall to bluntly open the paravesicle space down to the level of the levator muscles. The pararectal space is opened in a similar fashion by spreading in a perpendicular manner in between the ureter and internal iliac artery and vein. After the paravesical and pararectal spaces have been opened, the parametria to be resected can be easily identified as the remaining tissue between the two spaces. At this time, any extension of tumor into the parametrial tissues is evaluated and as evidence of extension indicates the need for postoperative radiation and the surgeon evaluates whether or not to proceed depending on the clinical scenario (Fig. 67.4).

Pelvic Lymphadenectomy

A bilateral pelvic lymphadenectomy is then performed. The fourth robotic arm is used to reflect the superior vesical artery medially and open the paravesical space. The operative assistant using a laparoscopic grasper retracts the proximal peritoneum at the pelvic brim to expose the entire area of nodal dissection. The nodal tissue just inferior to the bifurcation of the common iliac artery is grasped and elevated with the fenestrated bipolar forceps. The monopolar scissors are used to make an incision overlying the psoas muscle just lateral to the artery and the genitofemoral nerve is mobilized laterally. Once the sur-

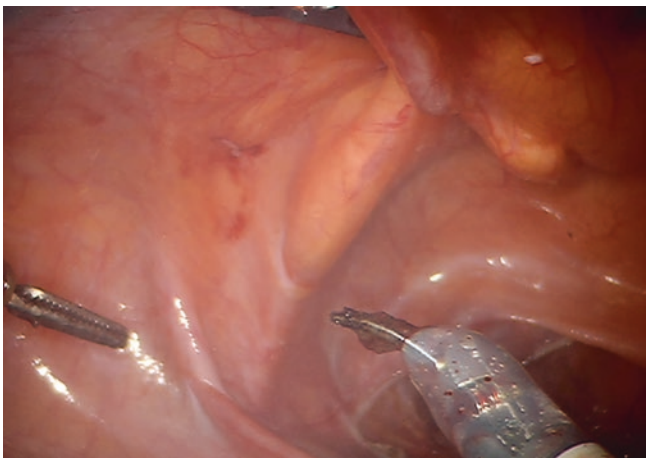

Fig. 67.4 Identification of the superior vesical artery. The median umbilical ligament is identified on the anterior abdominal wall. It is placed on tension medially and caudad which in turn pulls the superior vesical artery medially and away from the pelvic sidewall to allow for easy identification

face of the external iliac artery is identified, the nodal tissue is dissected free from the artery caudally using a combination of blunt dissection and cautery, as appropriate, until the deep circumflex iliac vein is encountered. The nodal bundle is reflected medially and gentle dissection is used to identify the surface of the external iliac vein and the nodal tissue is freed from its attachments to the vein cephalad to the bifurcation. The nodal bundle is grasped at the midpoint between the bifurcation of the common iliac artery and the crossing of the deep circumflex iliac vein. The vein is pushed laterally in order to enter the space between the nodal bundle and the pelvic sidewall. The obturator nerve is identified and the caudad portion of the nodal bundle in the obturator space is grasped with the fenestrated bipolar forceps and reflected medially and cephalad. The surface of the vein is pushed laterally and the obturator nerve is pushed inferiorly to free the nodal bundle from the obturator space. This process is continued cephalad until the bifurcation is reached and the specimen is freed. It is placed in a specimen bag in the upper abdomen for subsequent removal. The same is done on the left side (Figs. 67.5 and 67.6).

Ureteral Dissection

The ureter is identified along the medial leaf of the broad ligament. It is dissected free from its medial attachments and mobilized laterally to the level of the uterine artery and cardinal ligament in order to allow adequate visualization for the origin of the uterine artery. Care is taken to preserve the blood supply, adventitia and muscularis of the ureter to decrease the risk of fistula (Fig. 67.7).

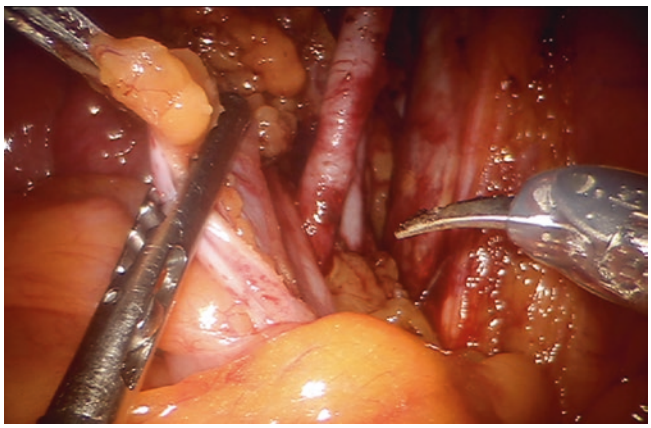

Fig. 67.5 Peritoneal retraction. The assistant retracts the peritoneum at the pelvic brim medially to allow for exposure to perform the nodal dissection

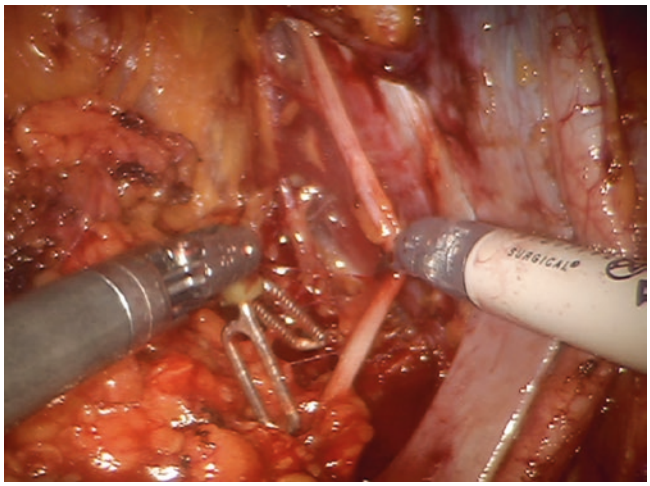

Fig. 67.6 Obturator nerve. The obturator nerve is identified and the nodal bundle is dissected free by grasping the nodal bundle, moving it cephalad and medially, and pushing the nerve laterally and inferiorly

Bladder Flap, Uterine Artery Transection and Parametrial Dissection

The vesico-uterine fold is incised with monopolar cautery and extended laterally to create the bladder flap. The vesico-uterine peritoneum is elevated and the vesico-uterine space is entered using a combination of blunt and sharp dissection with use of cautery as appropriate. This space is further dissected caudally until the bladder has been taken down sufficiently off the anterior vaginal wall to achieve an adequate margin. The uterine artery is identified at its origin from the internal iliac artery. The origin is isolated by dissecting away the surrounding tissue with blunt dissection with the fenestrated bipolar forceps. The artery and vein are then cauterized with bipolar cautery and transected. The artery is then freed from its attachments to the ureter and the ureter is

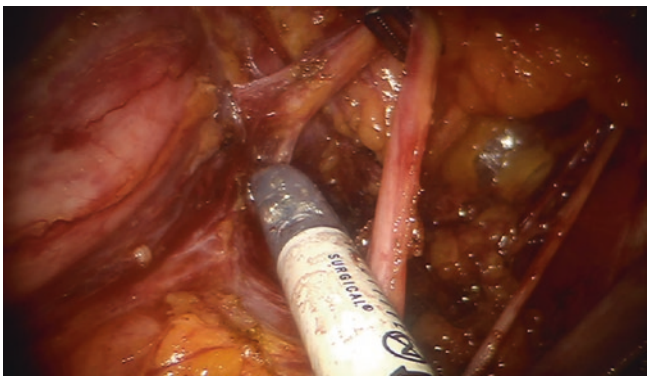

Fig. 67.7 Ureteral dissection. The ureter is reflected laterally and dissected free from its medial attachments

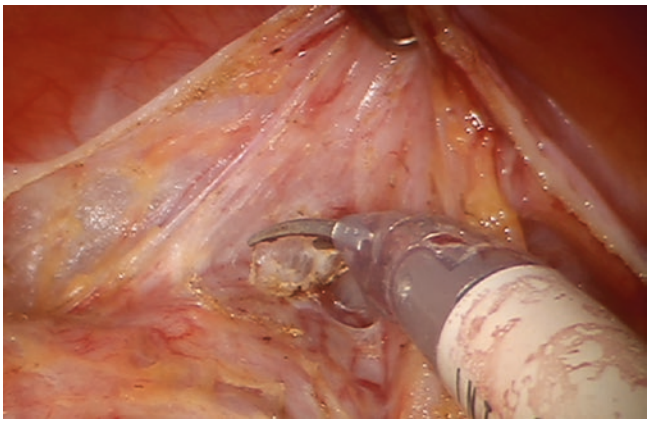

Fig. 67.8 Bladder flap. The vesico-uterine peritoneum is elevated and the bladder is dissected off the cervix and vagina

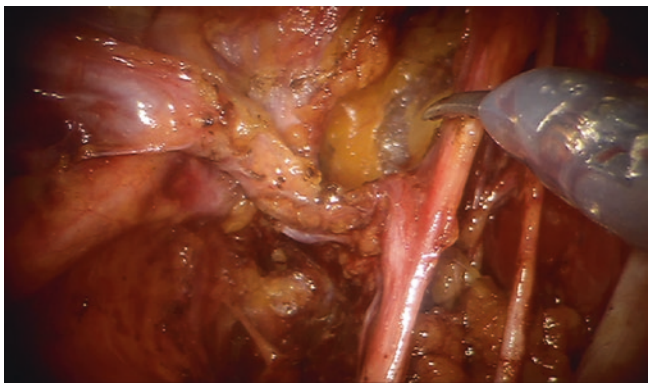

Fig. 67.9 Uterine artery isolation. The uterine artery is isolated at its origin

further mobilized laterally. The parametrial tissue is dissected off the ureter and mobilized medially. This allows for exposure of the ureteral tunnel of Wertheim and the ureter is unroofed to its insertion into the bladder by bipolar coagulating the anterior vesico-uterine ligament (Figs. 67.8, 67.9 and 67.10).

Transect the Utero-Ovarian Ligament or Infundibulopelvic Ligament

At this time, either the infudibulopelvic ligament or the utero-ovarian ligament is transected depending on the patient's age and the clinical circumstance. If the ovary is preserved, salpingectomy should be considered in order to reduce the future risk of ovarian cancer [14]. The paravesical space has been previously opened and the ureter is again identified. A window is made in the broad ligament below the infundibulopelvic ligament and above the ureter using the monopolar scissors. Blunt traction is used to extend this incision along the length of the infundibulopelvic ligament. Bipolar cautery followed by transection with the monopolar scissors is used to transect either the infundibulopelvic ligament at its origin or the utero-ovarian ligament (Fig. 67.11).

Transect Uterosacral Ligaments While Preserving the Sacral Nerve Plexus

The uterus is retracted anteriorly using the third robotic arm. The incision along the posterior broad ligament is continued medially towards the uterosacral ligament. As this is performed, the endopelvic fascia containing the hypogastric nerve plexus is dissected laterally. The peritoneum overlying the rectovaginal space between the two uterosacral ligaments is incised and the rectovaginal space is developed with blunt dissection. The uterosacral ligaments are cauterized with bipolar cautery at their insertion into the posterior vaginal wall and the remainder of the cardinal ligament is resected to the pelvic sidewall (Figs. 67.12, 67.13 and 67.14).

Colpotomy with Upper Vaginectomy

The EEA sizer which was previously placed in the vagina is advanced to identify the cervicovaginal margin. An incision is made along the anterior vaginal wall 2–3 cm inferior to the cervicovaginal junction to allow for an adequate margin. This incision is made with the monopolar cautery and continued around circumferentially, freeing the specimen. The specimen is removed through the vagina as are the specimen bags with the previously dissected pelvic lymph node specimens (Fig. 67.15).

Vaginal Cuff Closure

A mega suture cut needle driver is introduced into the right hand and a 0-vicryl suture on a CT-1 needle cut to 25 cm is passed through the assistant port. The vaginal cuff is closed in a running unlocked fashion from right to left. It is important

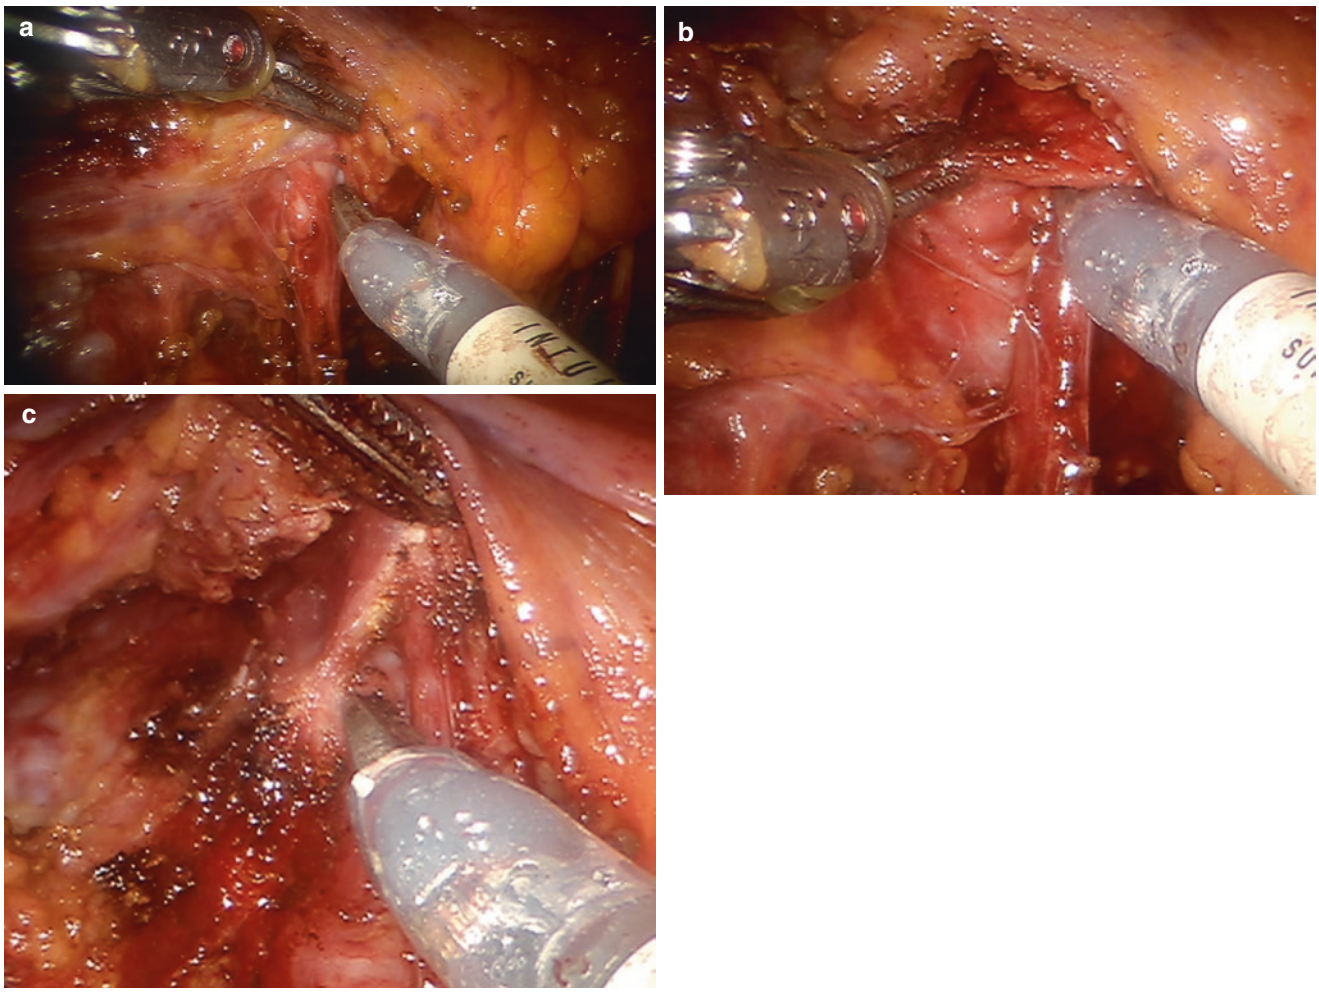

Fig. 67.10 Anterior vesicouterine ligament and tunnel of Wertheim. The ureter is unroofed through the tunnel of Wertheim (**a**). The anterior vesicouterine ligament is coagulated (**b**) and transected (**c**) exposing the insertion of the ureter into the bladder

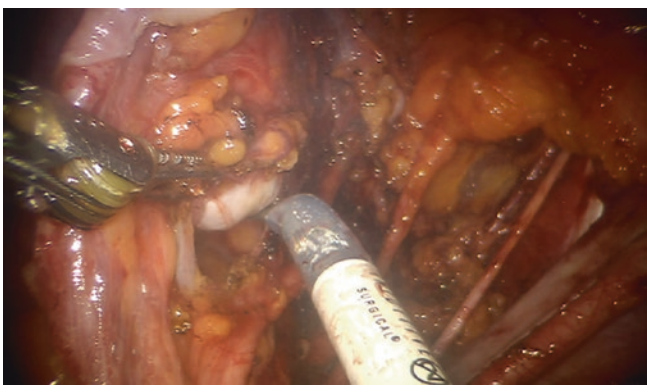

Fig. 67.11 Infundibulopelvic ligament. A window is made in the broad ligament and the infundibulopelvic ligament is cauterized and transected

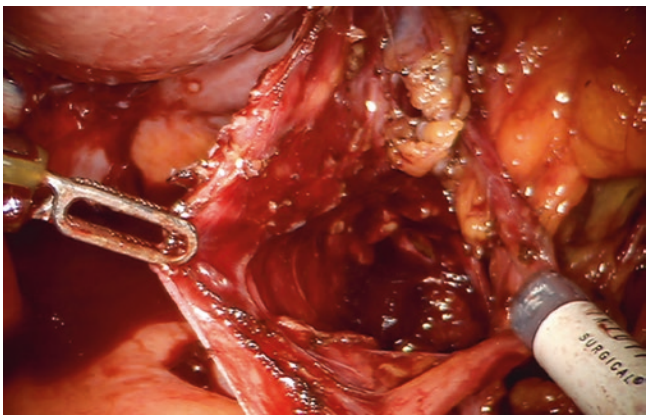

Fig. 67.12 Preserve the hypogastric plexus. The peritoneum is grasped and the endopelvic fascia containing the hypogastric nerve plexus is dissected off the peritoneum by sweeping laterally

to incorporate approximately 1 cm of vagina in each suture bite, to include the fascia and to keep the running closure on tension throughout by having the surgical assist "follow" with a laparoscopic needle driver holding the suture. The suture cut needle driver is used to cut the suture and the needle is

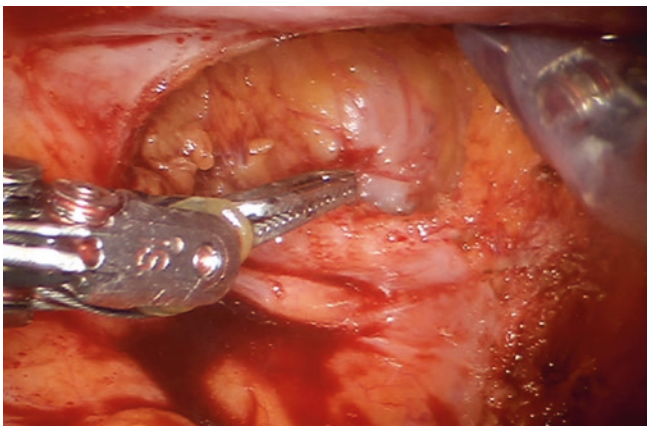

Fig. 67.13 Open rectovaginal space. The rectovaginal space is developed using blunt dissection

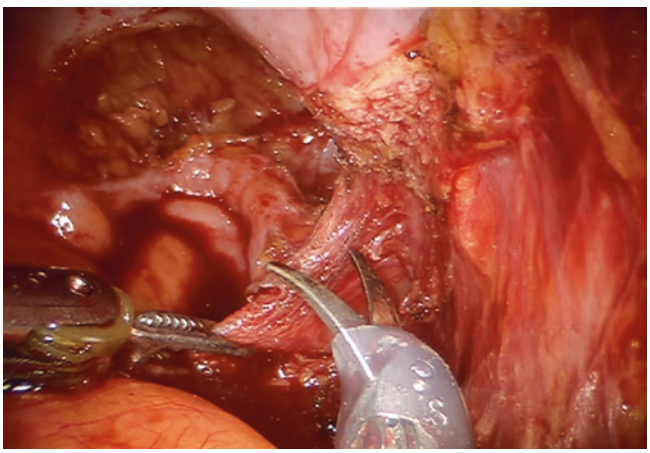

Fig. 67.14 Uterosacral transection. The uterosacral ligaments are transected at their sacral insertion after the hypogastric nerve plexus has been dissected laterally

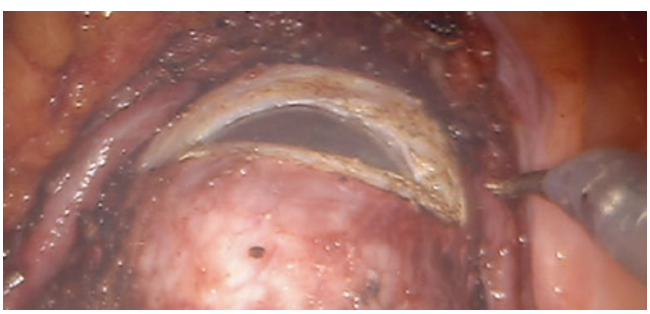

Fig. 67.15 Colpotomy. An incision is made along the vaginal wall 2-3 cm inferior to the cervico-vaginal junction. The EEA sizer is used to provide anatomic orientation

passed out of the assistant port. The abdomen and pelvis are irrigated and all operative sites are assessed for hemostasis (Fig. 67.16).

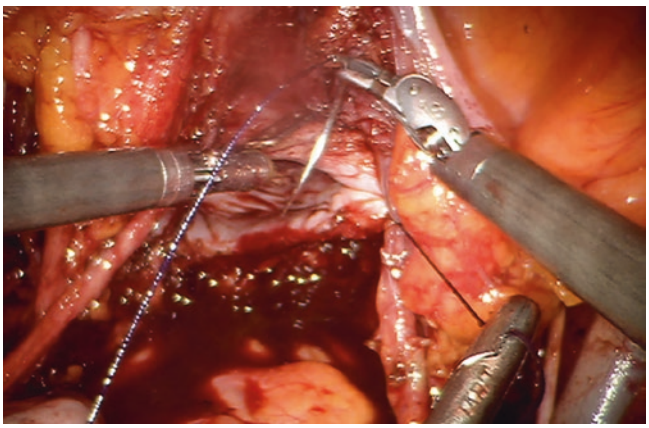

Fig. 67.16 Vaginal cuff closure. The assistant follows the surgeon using a laparoscopic needle driver to ensure continuous tension is maintained

Oophoropexy

If the ovaries are left in situ, oophoropexy may be performed to protect ovarian function in the event that adjuvant radiation is required. The peritoneum surrounding the infundibulopelvic ligament is further skeletonized using the monopolar scissors to allow increased mobility. The adnexa is mobilized above the pelvic brim. A 0-vicryl suture is passed through the assistant port and the ovary is sutured and tied to the pelvic peritoneum above the pelvic brim using a figure of eight stich. If desired, the ovaries can be marked with surgical clips for identification in radiation planning. The needle is removed via the assistant port.

Closing

After the abdomen and pelvis are irrigated and hemostasis is achieved, all robotic instruments are removed from the patient's abdomen. The robotic arms are undocked from the trocars and the robot is moved from the bedside. The abdomen is desufflated and manual breaths are given by the anesthesiologist to decrease residual intra-abdominal gas. The fascia at the 12 mm ports is closed with 0-vicryl to prevent hernia formation. The skin is closed in a subcuticular fashion with 4–0 vicryl or using dermabond (Fig. 67.17).

Postoperative Care

The postoperative management and recovery after a robotic radical hysterectomy mirrors that of other minimally invasive surgery. Patients are given a general diet on postoperative day zero and in our experience, all patients are able to tolerate oral pain medications and do not require any intravenous narcotics.

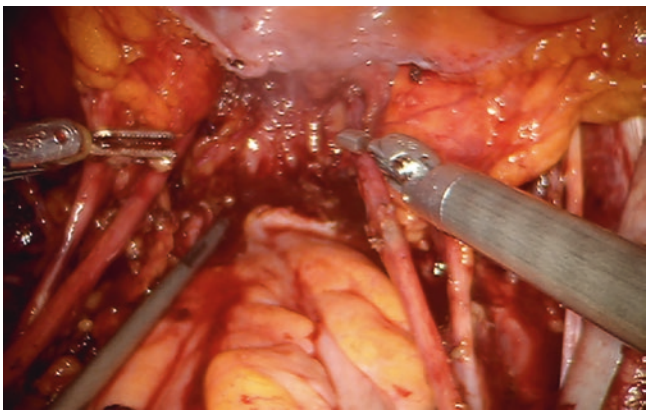

Fig. 67.17 Irrigation and hemostasis. At the conclusion of the procedure, irrigation is performed and hemostasis is assured

Patients do not require intravenous fluids by early postoperative day one. The vast majority of patients are able to go home on postoperative day one. Given the extensive bladder dissection and resulting parasympathetic and sympathetic denervation required for type III radical hysterectomy, all patients are sent home with a foley catheter and present to clinic four to seven days postoperatively for a voiding trial to ensure adequate bladder function prior to catheter removal.

Robotic-Assisted Radical Hysterectomy (RRH) as Nerve-Sparing Procedure

68

Gun Oh Chong and Yoon S. Lee

Radical hysterectomy is a well-accepted treatment modality of early-stage cervical cancer. Radical hysterectomy is defined as the en bloc removal of the uterus and cervix with the surrounding parametrial tissue, upper vagina. The term radical hysterectomy has been used to refer to a wide range of procedures that act with different degrees of radicality. In 1974, Piver and Rutledge describe five different types of extended abdominal radical hysterectomy [1].

A new classification has recently been proposed by Querleu and Morrow in 2008 (Table 68.1) [2].

Because conventional radical hysterectomy (CRH) involves dividing and disrupting the cardinal and utersacral ligament, which contain the autonomic nerves, urinary, anorectal, and sexaul dysfunction can be developed. One thrid of patients report bladder dysfunction after radical hysterectomy such as difficulty emptying the bladder, incomplete emptying and urgency [3]. Furthermore, anorectal dysfuction, including constipation, have been reported in 5–10 % of patients after CRH [4]. Considerable sexual dysfunction, including decrease in sexual interest and organism, and vaginal dryness, are also noticed after CRH, which compromise sexual activity and result in subtantial distress [5].

Japanese surgeons first introduced the nerve-sparing radical hysterectomy (NSRH) procedure to preserve pelvic autonomic nerves, with desire to prevent disabling long-term adverse effect [6]. Subsequently, most international investigators who described their experiences using NSRH reported favorable outcomes, including earlier return of bladder function [7, 8], better vaginal blood flow [9], and fewer symptoms related to anorectal function [10]. A recent meta-analysis also showed that NSRH may decrease intraoperative complications, and urinary and anorectal dysfunction [11, 12]. Howerver, NSRH has been suggested to decrease the resection scope of radical hysterectomy, so that the narrowed resection scope may compromise therapeutic effect [13]. Possover et al. and Höckel et al. provided type III NSRH including meticulous cleansing of the neural part of the cardinal ligament from all fatty and lymphoid tissue [7, 14]. Whether leaving neural part of the cardinal ligament poses an increased risk for recurrence or lowers chances of survival remains a matter debate in the literature [15–17]. A recent meta-analysis demonstrated that NSRH may have similar clinical safety and extent of resection compared with CRH and not affect prognosis [11, 12]. However, Basaran et al. provided that the evidence adressing the oncological safety of NSRH over that of CRH is neither adequate nor statistically relevant in their systemic review [18]. A properly disigned, prospective randomized noninferiority trial is needed to assess the oncological outcomes of NSRH.

Since the introduction of the conventional laparoscopy, improvements in gynecologic surgery have been notable. However, laparoscopic radical hysterectomy is not a popular choice among gynecologic oncologist because of the increased operative time and the steep learning curve required for competency [18]. Moreover, laparoscopic NSRH has a higher urological complication rate, longer operating times, and much blood loss than does CRH, especilly during the initial learning perioid [8]. Robotic technology has recently come into wide-spread use to overcome the limitations of laparoscopic surgery. Robotic surgery gives more surgical options, such as nerve-sparing technique, due to its superior visualization (3-dimensional imaging of the operative field), mechanical improvement (seven degree of instrument mobility inside the body) and stabilization/tremor filtration of the instrument within the surgical field which lead to easier identification and preservation of anatomical structures. Marchal et al. [19] performed the robotic radical hysterectomy (RRH) in 2005, and more recently Magrina et al. [20] described techniques of robotic NSRH. It has been reported that RRH is a feasible and safe surgical modality compared with the existing radical abdominal hysterectomy and laparoscopic radical hysterectomy for the treatment of early-stage cer-

vical cancer. [21–24]. Chong et al. reported that mean blood loss and intraoperative complication rate in the robotic group were significantly lower than those of laparoscopic group during initial phase of NSRH (Tables 68.2 and 68.3) [25]. Furthermore, no differences in cervical cancer recurrences occured in patients who undergone robotic, conventional laparoscopic, or abdominal radical hysterectomy in long-term follow-up data [22, 26].

If we focus on the advantages of robotic NSRH, esay differentiation between the fine sacral afferent fibers and the deep uterine veins due to articulating movement of the robotic arms ; stable traction and conter-traction of robotic arms, which enable us to expose the surgical plane consistently and precisely ; and an excellent 3-dimensional viwe of the robotic system within the narrow space. Furthermore, these technical advantages have given us improved dissection of the posterior vesicouterine ligament. The vesical branch of the inferiror hypogastric plexus can be preserved after dissecting several fragile veins step-by-step.

Anatomy of Pelvic Autonomic Nerves

1. Superior hypogatric plexus

Superior hypogatric plexus (SHP) is an unpaired structure situated anterior to the fifth lumbar vertebra and the sacral promontory, between the two common iliac arteries, and is formed by the union of numerous filaments, which descend on either side from the aortic plexus, and from the lumbar ganglia [27]. The SHP divides into right and left branch at or below the sacral promontory.

2. Pelvic splanchnic nerves

Pelvic splanchnic nerves (PSN) are parasympathetic nerve fibers arising near the sacral foramina from the ventral rami of the sacral nerve S2-S4. They are variable number and not always found arising from S2-S4 [28]. The S3 and S4 branches are the main contributors to the inferior hypogastric plexus (IHP) [29], the S3 branch being the largest one [28].

3. Sacral splanchnic nerves

The sacral splanchnic nerves are orginated from S2 sympathetic ganglion and contributes to the IHP [29]. Their primary function is to provide sympathetic component to the sacral plexus nerves for vasomotor, pilomotor, and sudomotor innervation of the lower extremity.

4. Inferior hypogastric plexus

IHP is composed of three different component : SHP via the hypogastric nerve, the sympathetic trunk via sacral splanchnic nerves, and the parasympathetic nerves via pelvic splanchnic nerves. IHP contains sympathetic and parasympathetic innervation. Symphathetic innervation from the SHP projects to the two IHPs via the bilateral fiber bundles of the hypogastric nerves. The sacral splanchinc nerve is originated from S2 symphathetic ganglion and contributes to the IHP. The hypogastric nerve fuses with parasympathetic splanchnic nerves originating from S2-S4 to the inferior hypogastric plexus (IHP). In the horizontal plane the IHP is located at about the level of S4 and S5. In the sagittal plane, the IHP is observed more commonly in the uterosacral ligament (57 %) and less commonly at the level of the parametrium (30 %), or between the lateral vaginal wall and the bladder (11 %) or at the rectal wall (2 %) [29]. The IHP continues inferior the vagina and bladder along with posterior vesicouterine ligament and the lateral wall of the vagina [30, 31].

Functions of Pelvic Autonomic Nerves

The pelvic autonomic nerves are essential for a normal physiologic function of the pelvic organs. For urinary function, parasymphathetic nerve disruption causes a hypocontractile of acontractile bladder with decreased sensation. Symphathetic nerve disruption results in a bladder with decreased compliance and high storage pressures. Moreover, sympathetic denervation may cause bladder neck incompetence and incontinenec. Disruption of the autonomic nerve supply to the rectum results in colorectal motility disorder [32, 33]. Autonomic nerve disruption results in altered vascular function during sexual arousal, and possibly disordered orgasm [34]. The exact role of SHP still remains unclear. However, Virtanen et al. reported an increase in the frequency of constipation and defecation problems after sacrocoloplexy [35]. Moreover, damage to the SHP could lead to urinary incontinence, especially due to incompetence and leakage at the internal urethral sphincter [36]. Hence, we should make an effort to preserve SHP during para-aortic lymphadenectomy.

Procedures of Robtoic NSRH: Step-by-Step

Patient Preparation, Docking and Instrumentation

The patients were placed in the a 20–30° Trendelenburg position. Proper initial positioning is essential because the robot must be disengaged before any change in position of the oprating table can be made. A 5-puncture technique was used with 4 robotic arms. A 12-mm primary trocar for 30 degree telescope was directly placed though the umbilicus. For lower para-aortic lymphadenectomy, a 12-mm primary trocar was placed 1–3 cm above the umbilicus. Two 8-mm lateral trocars were placed 7–8 cm lateral to the primary trocar for the 2 robotic arms. A fourth robotic tracar was placed 7–8 cm lateral and caudal to the right robotic trocar. An accessory 12-mm trocar was placed in the left upper quardrant for assistance, such as suctioning, irrigation, retraction, or grasping (Fig. 68.1). An EndoWrist monopolar scissors (Intuituve Inc., Sunnyvale, CA) was used in the right hand, and EndoWrist fenestrated bipolar forceps (Intuituve Inc., Sunnyvale, CA) in the left hand. An EndoWrist Prograsper (Intuituve Inc., Sunnyvale, CA) was placed in the fourth robotic arm. For vaginal cuff closure, the monopolar scissor was replaced by an EndoWrist needle holder (Intuituve Inc., Sunnyvale, CA).

The assistant, sitting to the left of the patient, at shoulder level, performed important tasks using an accessory torcar, such as sealing and division vascular structure using a Ligasure system (Covidien, Valleylab, Boulder, CO) or an Enseal device (SurgRx Inc., Redwood City, CA), suction and irrigation, removal of biopsy specimens, tissue retraction and grasping, and introduction and retrieval of sutures for vagianl cuff closure. The second assistant was situated between the patients' legs and moved the uterine manipulator. The robotic column was positioned between the legs of the patient, behind the second assistant.

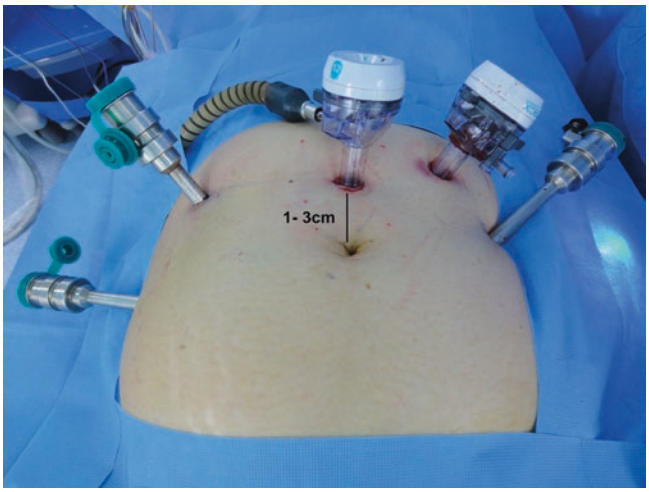

Fig. 68.1 Positioning of trocars for robotic nerve-sparing radical hysterectomy.

Identification of Superior Hypogsatric Plexus (SHP)

After left upward traction of rectosigmoid mesentery using EndoWrist Prograsper, a peritoneal incision is made at below inferior mesenteric artery. The SHP is found overlying the aorta and sacral promontory, medial to both ureters (Fig. 68.2). Rectosigmoid is mobilized, and then the avascular space of the lateral rectal portion is found by using the upward traction of rectosigmoid mesentery. The SHP is isolated by vessel loop. The SHP divides into right and left branches at or below the sacral promontory. A continuous downward dissection is then made uint the hypogastric nerve is identified. Using this approach, communication between the SHP and hypogatric nerve could be found.

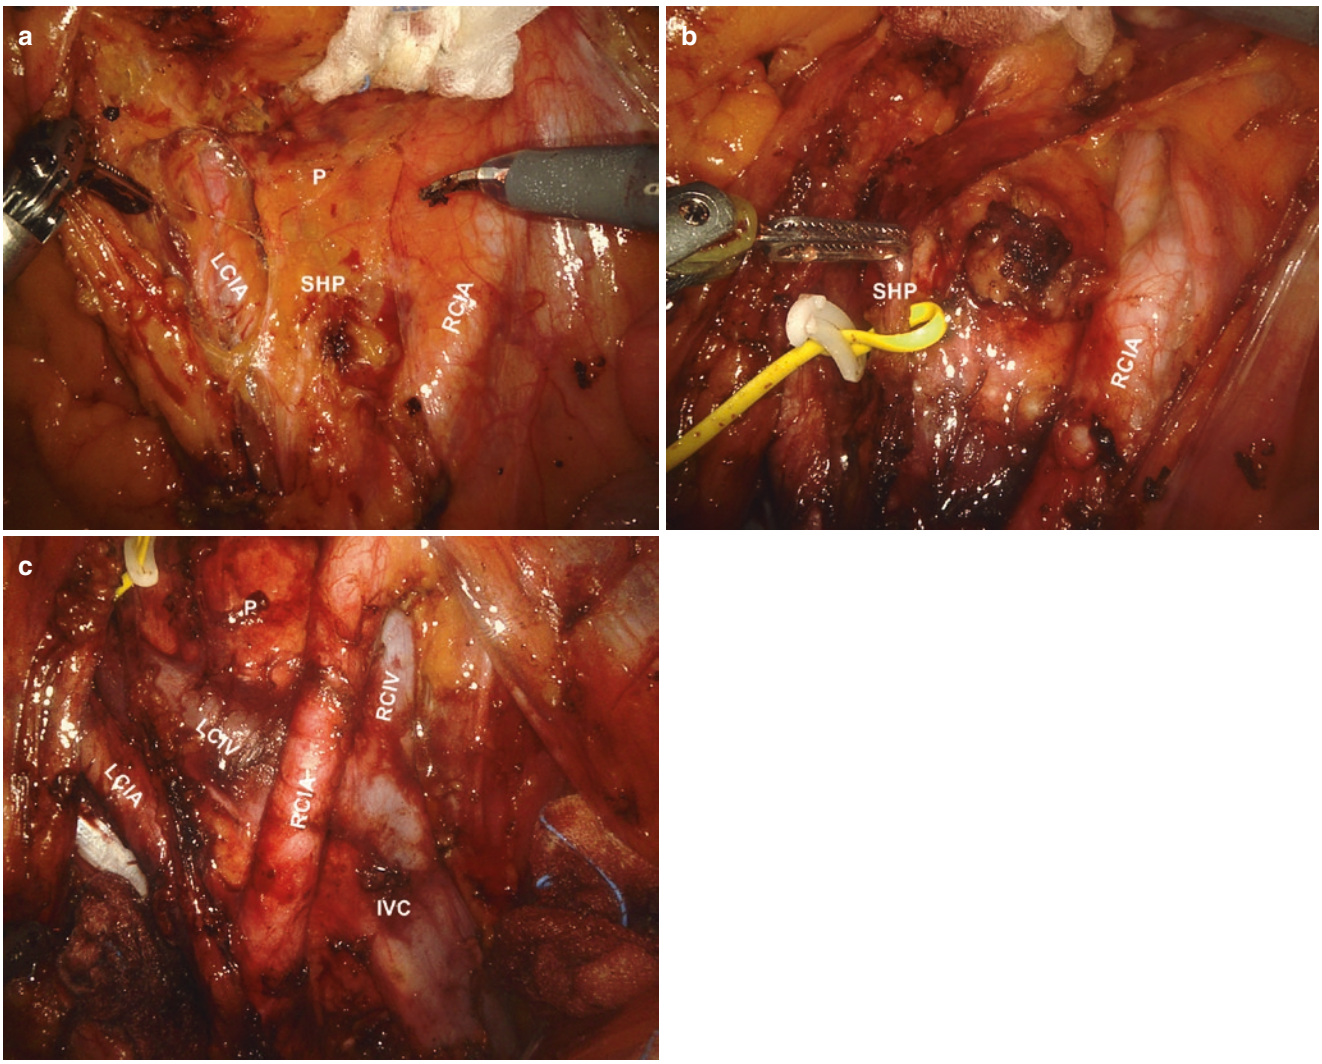

Fig. 68.2 Identification of Superior hypogastric plexus. (**a**) After traction of rectosigmoid, peritoneal incision is made and we can identify the common iliac artery, superior hypogastric plexus, and promontory. (**b**) Superior hypogastric plexus is isolated by vessel loop. (**c**) Final view of lower para-aortic lymphadenectomy and the superior hypogastric plexus (isolated by vessel loop). *IVC* inferior vena cava, *LCIA* left common iliac artery, *LCIV* left common iliac vein, *P* promontory, *RCIA* right common iliac artery, *RCIV* right common iliac vein, *SHP* superior hypogastric plexus

Identification of Pelvic Splanchnic Nerve (PSN), Inferior Hypogastric Plexus (IHP) and Hypogastric Nerve

Between the paravesical and pararectal spaces, the cardinal ligament was sperated by a scissor dissector. The uterine artery is dissected at the level of the hypogatric artery and several deep uterine veins are coagulated with bipolar graspers and transected. After careful seperation of deep uterine vessels to the base of the cardinal ligament, PSNs that communicated with the IHP and hypogastric nerve are observed. PSNs are variable in number 3–4. Sometimes PSN are indistinguishable to fibrotic connective structure. Then, the hypogastic nerve appears as a thickened band and is identified approximately 2–5 cm below the ureter (Fig. 68.3).

Identification of the Hypogastric Nerve and IHP During the Dissection of the Uterosacal and Rectovaginal Ligaments

After well dissection of the rectovaginal space, both uterosacral ligaments clearly identified. The hypogastric nerve is located in the lateral portion of the uterosacral ligament. The hypogastric nerve is mobilized laterally from the the lateral aspect of the uterosacral ligament. A space between medial part of uterosacral ligament and hypogastric nerve is developed. Only the medial fibrous component of the uterosacral ligament is divided, and the lateral nervous compartment is perserved (Fig. 68.4).

Identification of Vesical Branch of the IHP from Posterior Vesicouterine Ligament

This step is the most critical step in the nerve-sparing procedure. After unroofing the ureter with dissection of the anterior vesicouterine ligament, the ureter is mobilized laterally to identify and isolate the posterior vesicouterine ligament. Posterior vesicouterine ligament is exposed by anterior and lateral retraction of the ureter. And then, several vesical veins (lateral, middle, medial, inferior) in the posterior vesicouterine ligament are identified and these veins are carefully separated and skeletonized step-by-step. The vesical branches of the IHP may be easily damaged during extensive removal of paravaginal tissue. To spare the vesical branches of the IHP completely, only the uterovaginal branches of the IHP should be resected. After the cut edge of the inferior vesical vein is pulled medially with upward traction, the vesical branches of the IHP are exposed, which divided into medial and lateral branches [37]. In advanced cases, the medial branches of the IHP could be sacrificed to obtain an adequate cancer-free margin [37]. After these procedures, the vesical branches of the IHP are preserved (Fig. 68.5). After nerve-sparing RRH, the entire course of pelvic autonomic nerves could be examined cleary incluing SHP, hypogatric nerve communicating with parasympathetic nerves, and vesical branch of the IHP (Fig. 68.5e).

Extended Lymphadenectomy

The areas of extended lymphadenectomy are the superior and inferior gluteal, presacral (subaortic), common iliac, and lower paraaortic nodes. Extended lymphadenectomy is started without injury to the SHP and hypogastric nerve. Right paraaortic lymph nodes are dissected at the level of the inferior mesenteric artery. The inferior mesenteric artery and SHP are then identified, and a space is created between the inferior mesenteric artery and SHP that enable the ureter to be displaced laterally and the left paraaortic node to be displaced medially. Inframesenteric nodes are removed without injury to the ureter and the left common iliac nodes are easily removed due to the upward traction of the rectosigmoid. Through the left upward traction of the SHP, the right side of presacral nodes on the promontory is removed without injury to the presacral vein. By using the right upward traction of the SHP, the left side of the presacral nodes and left common iliac nodes are removed. After further dissection of the hypogastric vessels, we can identify the posterior branches of the hypogastric artery, the superior gluteal artery which locates between lumboscaral plexus and S1, and inferior gluteal artery which locates between S2 and S3. After extended lymphadenectomy, the pelvic anatomy could be examined more clearly including the SHP, promontory, lower part of aorta, common iliac vessels, hypogastric vessels, hypogastric nerve communicating with parasympathetic nerves, and vesical branches of the IHP (Fig. 68.6).

Extended lymphadenectomy may contribute to the prevention of locoregional relapse [38]. Recent study showed the the prevalence of internal iliac vein anomalies was 26.7 % in the presacral area [39]. To prevent life-threatening the internal iliac vein injury, the anatomical variations of the internal iliac vein should be known exactly during lymphadenectomy at presacral area.

Table 68.4 Systemic review of robotic radical hysterectomy versus abdominal radical hysterectomy and robotic radical hysterectomy versus laparoscopic radical hysterectomy

Variables	RRH vs. ARH	RRH vs. LRH
Estimated blood loss	RRH – Pro ARH – Con	RRH – Pro LRH - Con
Operative time	Equivalent	Equivalent
Lymph nodes count	Equivalent	Equivalent
Intraoperative complications	Equivalent	Equivalent
Hospital stay	RRH – Pro ARH – Con	Equivalent

RRH robotic radical hysterectomy, *ARH* abdominal radical hysterectomy, *LRH* laparoscopic radical hysterectomy

Robotic NSRH

Recent systemic review and meta-analysis shows that RRH may be superior to abdominal radical hysterectomy (ARH) with lower estimatated blood loss, shorter hospital stay, less febrile morbidity and wound-related complications [38]. Although RRH was associated with less estimated blood loss than laparosocpic radical hysterectomy (LRH), mean differnenc was of borderline significance. There was no significant differece in operative time or intraoperative complications. RRH and LRH appear equivalent in intraoperative and short-term postoperative outcomes (Table 68.4) [40].

Robotic NSRH is a feasible and safe modality for the treatment of early cervical cancer without compromising radicality. Excellent 3-dimensional image amplification facilitates visualization and the teaching of the pelvic autonomic nerves. Moreover, articulating movement of the robotic arms, lack of tremor, stable traction and counter-traction of robotic arms provide us to expose the surgical plane consistently and precisely.

Robotic-Assisted Radical Hysterectomy as Compartmental Resection According to rTMMR and rPMMR

69

Rainer Kimmig

Introduction

On the basis of ontogenetic compartmental development the findings about compartmental border control in malignant tumour progression led to the concept of "compartmental resection" in solid malignant tumors [1–4]. Since loco-regional recurrence usually occurs in compartment remnants or in the associated lymph compartments total "compartments of risk" have to be removed completely, whereas neighbouring compartments may left entirely untouched. The first tumour resected following this concept was rectal cancer by total mesorectal excision (TME) resulting in dramatically reduced loco-regional recurrence [5]. At present this procedure has become standard in rectal cancer surgery [6]. For cervical cancer M. Höckel has convincingly shown by his monocentric data that the corresponding method named total mesometrial resection (TMMR) also reduces efficiently locoregional recurrences compared to standard treatment – without any additional radiation therapy even in risk situations [7, 8]. The Method is described for open surgery in a separate chapter. Together with M. Höckel total mesometrial resection (rTMMR) has been translated to robotic surgery [9]. On parallel, the modification of compartmental resection for endometrial cancer as peritoneal mesometrial resection (PMMR) according to the different lymph drainage has also been adopted to robotic surgery as rPMMR [10]. Although, the two methods have to be applied together with therapeutic pelvic or pelvic and paraaortic lymphadenectomy to control not only for local but also for regional disease, in this chapter the technique of radical hysterectomy only is described; however technique of therapeutic lymphonodectomy has already been published elsewhere, and will be described step by step in the following chapter 70.

Anatomical Basis of Müllerian Compartment and Local Lymph Drainage

For uterine cancer removal of the Müllerian compartment and its draining lymphatic compartments has to be performed completely. Embryological development, compartment borders and type of resection in uterine cancer is perfectly described by M. Höckel [4, 7]. As shown in Fig. 69.1, the uterus has to be removed together with the vascular mesometrium (corresponding to the uterine vessel system including vesicouterine anastomoses) and the ligamentous mesometrium (corresponding to the rectovaginal and sacrouterine ligament). However, there is no longer any modification with respect to the tumor size, as the concept requires always complete resection. There is only one part of the Müllerian compartment left in situ for functional reasons – the vagina. The vaginal resection margin is the only intracompartmental resection has directly to be controlled for clear margins (>10 mm recommended) in compartment confined tumors [4]. According to the different lymph drainage of the upper and lower Müllerian compartment in cervical cancer vascular and ligamentous mesometria have to be resected. In endometrial cancer without cervical involvement there is no drainage along the ligamentous mesometria; on the other hand there is drainage along the mesonephric pathway on parallel to the ovarian vessel system. Thus, ligamentous mesometria may be preserved, but infundibulopelvic ligaments have to be resected completely in corporal uterine disease as can be seen from Fig. 69.1 a–d.

Due to the lymphatic network which develops embryologically by sprouting from embryonal veins [11], compartment visualization can be achieved by fluorescent agents. Isocyanine-green (ICG) may be injected into the uterine cervix or corpus according to the tumour site and fluorescence will be detectable in the lymphatic system from minutes to many hours from application during surgery [12]. In short, 0.3 ml of a solution of 1.25 mg/ml ICG had injected ´0.5–1 cm deep either into cervical stroma at 3, 6, 9 and 12 o'clock in cervical cancer or at 3 and 9 o'clock twice at the fundal and midcorporal part in endometrial cancer. Lymphatic drainage is

(**c**) Reprinted from Gynecologic Oncology, vol. 107, supplement 1, Höckel M, Do we need a new classification for radical hysterectomy? Insights in surgical anatomy and local tumor spread from human embryology, S106–S112, Copyright 2007, with permission from Elsevier. (**d**) (Modified from Hepp et al. [14], with permission)

directed from midline to lateral and drains primarily either to the iliac nodes along the vascular and ligamentous mesometria or to the paraaortic nodes along the mesonephric ovarian vessel system, or both. Up to now we never observed a drainage into the vesical or rectal compartment, neither via the vesicouterine nor the rectovaginal ligament. For better understanding of compartmental resection visualization by fluorescence will be added to the anatomical illustrations of the technique.

Technique of Total Mesometrial Resection and Peritoneal Mesometrial Resection [9, 10]

Principles of TMMR are described already in detail by Michael Höckel. The compartmental resection of the Müllerian compartment with respect to cervical and endometrial cancer does not differ in principle but only with respect to sub-compartments and their route of lymph drainage. Therefore, the technique of TMMR and PMMR adapted to robotic surgery will be described "Step by Step" for both procedures together. Steps only valid for cervical cancer or endometrial cancer will be indicated, common steps will be highlighted. As already mentioned, intention of compartmental surgery in uterine cancer is invariably to remove the local and regional compartment of risk entirely. Thus, the therapeutic lymphadenectomy is intrinsically tied to the radical hysterectomy, although not described in this chapter. The radical hysterectomy will usually be preceded by the therapeutic pelvic and – if indicated – paraaortic lymphadenectomy (technique [13]). Dependent on the sub-compartmental origin of the tumor either TMMR or PMMR or a combination of the two is performed. Differences and common steps are summarized in Table 69.1.

Surgical steps for TMMR are described in Steps 6 and 8–20, for PMMR in Steps 1–7 and 12–20, whereas all common steps are high-lighted in the text.

General Remarks and Trocar Placement

Robotic surgery usually starts cranially and proceeds caudally for technical reasons due to the steep Trendelenburg positioning to guarantee a clear visual field throughout the surgery. Four robotic arms (camera and three instruments) are used and one 10 mm trocar for assistance. The incision for the camera has to be made about 8–10 cm cranially to the upper limit of surgery, if possible. A typical setting of Incisions is shown in Fig. 69.2 for TMMR and pelvic lymphadenectomy for the da Vinci SI system. In the da Vinci Xi System this is no longer necessary since surgery can be performed in the entire abdomen without any change in docking.

Steps one to seven are dedicated to the therapeutic resection of the mesonephric sub-compartment of infundibulopelvic ligaments, therapeutic pelvic and paraaortic lymphadenectomy and peritoneal incision strategy. Except for lymphadenectomy these steps refer exclusively on PMMR for endometrial cancer.

Lymphatic drainage of uterine corpus may be visualized by intracorporal injection of Indocyanine green (ICG) solution made visible by near infrared excitation during surgery. As demonstrated in Fig. 69.3 lymphatic drainage from uterine corpus via infundibulopelvic ligaments runs along the mesosalpinx and mesovarian lymphatic network (A/B) and consists of two main lymphatic truncs accompanying the ovarian artery and vein (C/D) with variable intercalated nodes. They drain to the preaortic nodes inferior to the right ovarian artery and the precaval nodes medially of the ovarian vein on the right and to the left "renal angle" on the left (not shown).

Step 1

Incision of the peritoneum lateral to the right infundibulopelvic ligament superior to the crossing of right common iliac artery and division of peritoneum along the border to the right mesocolic fat tissue (Fig. 69.4) to expose the anterior aspect of the caval vein, the right ureter, the right infundibulopelvic ligament and the right colon mesentery (Fig. 69.5).

Step 2

The border between the mesonephric compartment of the ovarian vessel system and the compartment of right colon is identified; anastomosing vessels of the ovarian and right colonic vessels – which always are present - have to be identified and dissected (Fig. 69.6).

Step 3

The infundibulopelvic ligament is elevated and mobilized from laterally to medially keeping the connections to the paraaortic lymphatic system intact and separating it dorsolaterally from the right ureter and mesureter. Ureteral supplying vessels should kept intact (Fig. 69.7).

Table 69.1 Common and different steps in TMMR and PMMR

	Uterus	Vascular mesometrium	Ligamentous mesometrium	Fallopian tubes	Ovaries	IP ligaments
TMMR and therapeutic LNE	Yes	Yes	Yes	Yes	No[a]	No
PMMR and therapeutic LNE	Yes	Yes	No[a]	Yes	Yes	Yes

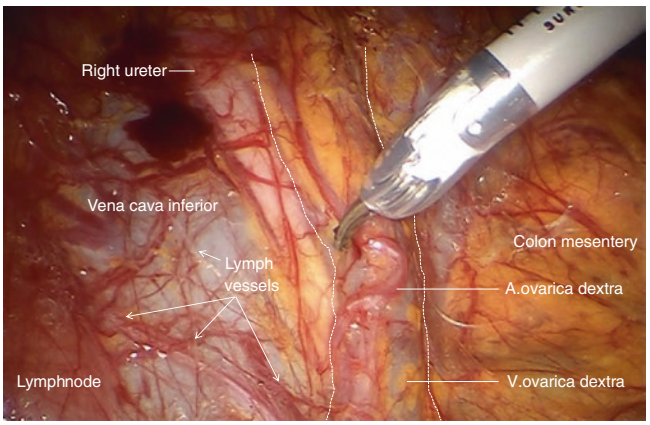

Fig. 69.5 Identification of right infundibulopelvic ligament, ureter and right colon mesentery

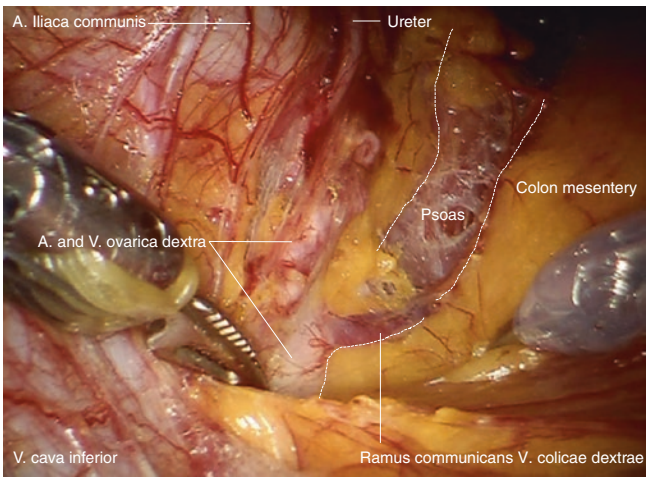

Fig. 69.6 Separation of right infundibulopelvic ligament from right colon mesentery

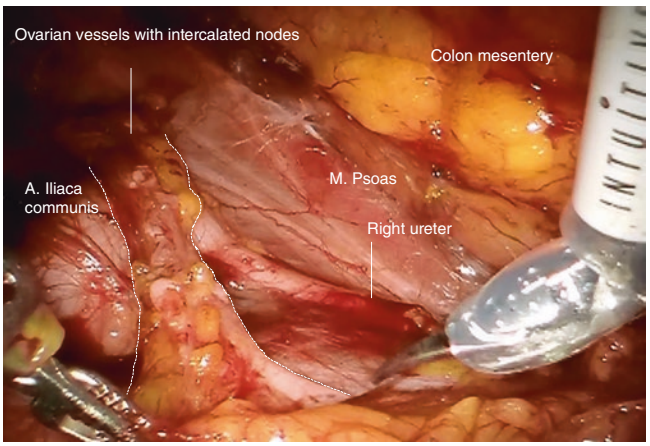

Fig. 69.7 Separation of ovarian vessel system from mesocolon, psoas muscle, ureter and caval vein

Step 4

Resection of the right infundibulopelvic ligament following the dissection of ovarian vessels at their origin together (Fig. 69.8) with periaortic lymphadenectomy which has to be performed completely up to the renal vessels. The right infundibulopelvic mesonephric compartment is completely mobilized together with adherent compartment of right periaortic nodes (Fig. 69.9).

Step 5

On the left side preparation of the infudibulopelvic ligament will start cranially. Following mobilization and dissection of the left paraaortic lymph compartment the left ovarian vein and artery (Fig. 69.8 c, d) are resected at their origin and mobilized from laterally to medially; again vessel anastomoses to the left colon mesentery have to be resected and the left ureter has to be prepared identically to the right (Fig. 69.10). The ligament is developed to the left pelvis dorsally of the mesosigma and pulled though the so-called "sigmoid tunnel". Since there are no lymphatic connections to the infundibulopelvic ligament below the left common iliac vessels the further moblization to the uterus now may be done as usual.

Step 6

Completion of therapeutic pelvic and paraaortic lymphadenectomy as previously described for endometrial cancer and/or cervical cancer [13].

Step 7

Incision of the peritoneum covering the round ligament, the ovarian vessels, the utero-ovarian junctions and the vascular mesometrium. This maneuver assures a complete resection of Müllerian compartment together with the connecting structures to the mesonephric compartment containing the lymphatic network together with the ovaries and the infundibulopelvic ligaments (Fig. 69.11).

Step 8

Radical hysterectomy with complete resection of the vascular mesometrium will now be performed as described

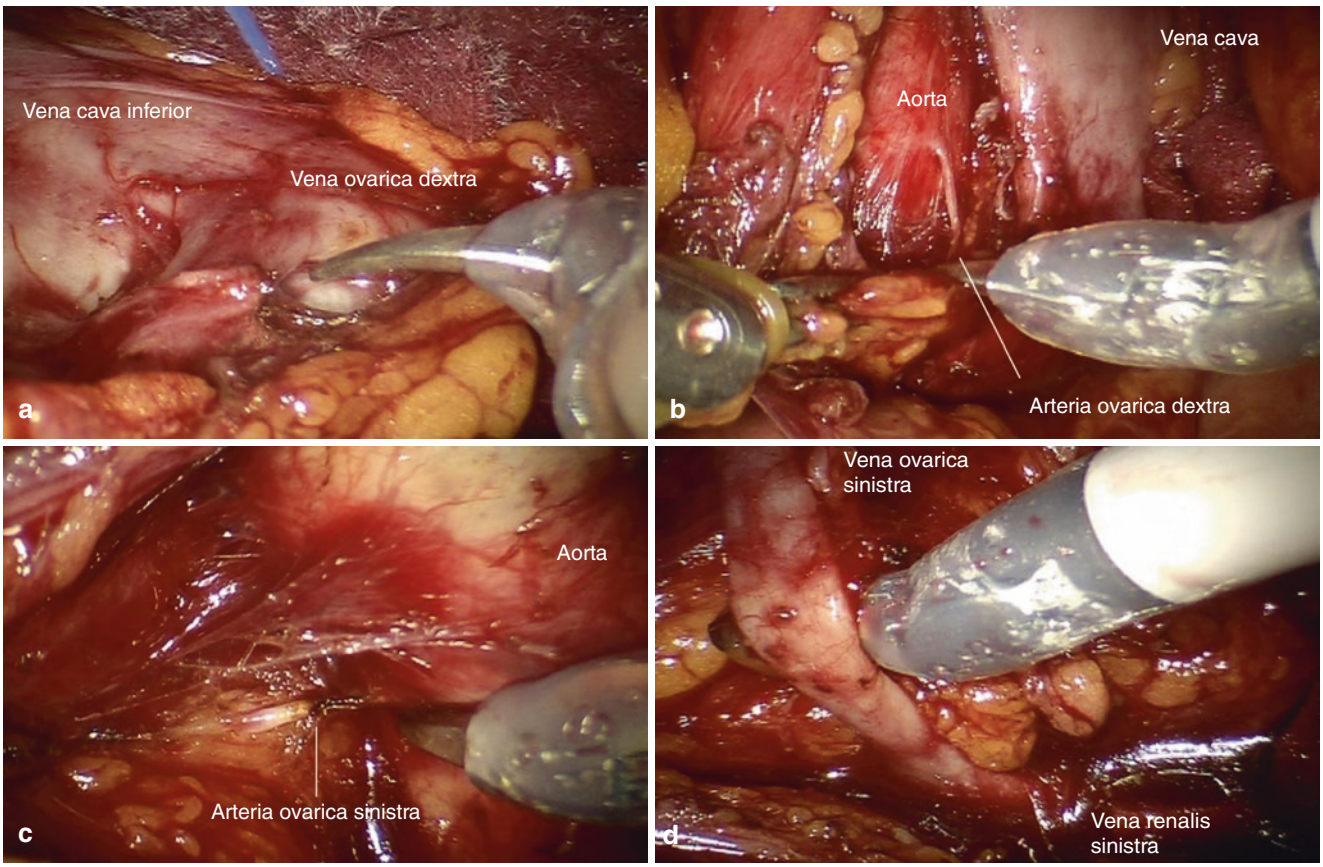

Fig. 69.8 (**a**–**d**) Dissection of ovarian veins and arteries from caval and renal veins and aorta

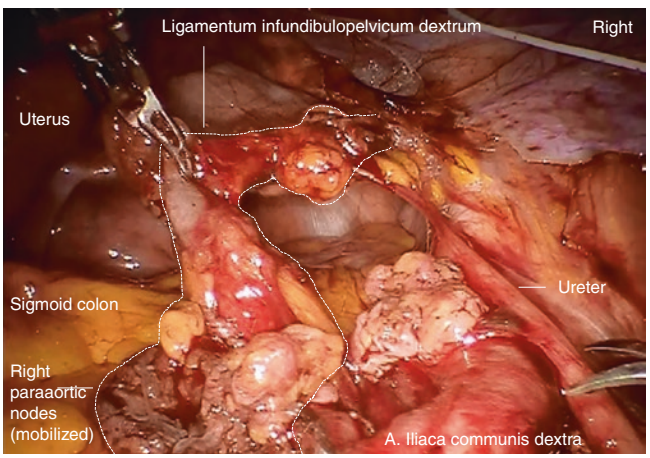

Fig. 69.9 Completely mobilized right ovarian vessel system with right paraaortic nodes

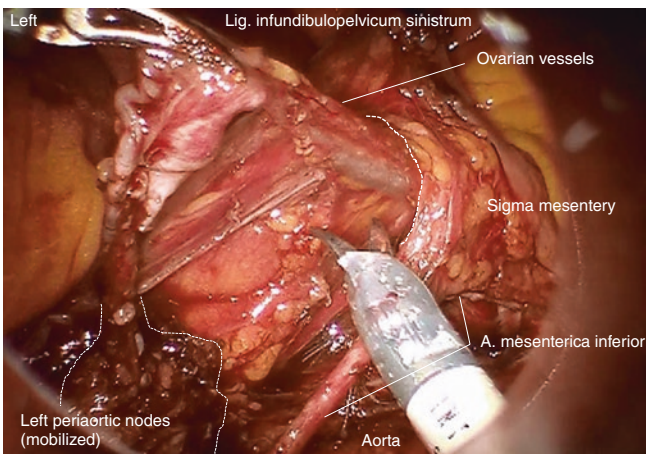

Fig. 69.10 Mobilized left ovarian vessel system entering the "sigmoid tunnel"

in detail for rTMMR [9]. If ovaries should be preserved in cervical cancer, fallopian tubes will be dissected along the mesosalpinx and ligg. Ovarii propria will be dissected.

Step 9

Preferably preparation starts posteriorly. Peritoneum will be incised in the pouch of Douglas and the rectum is mobilized medially from the vaginal wall. Preparation should free the

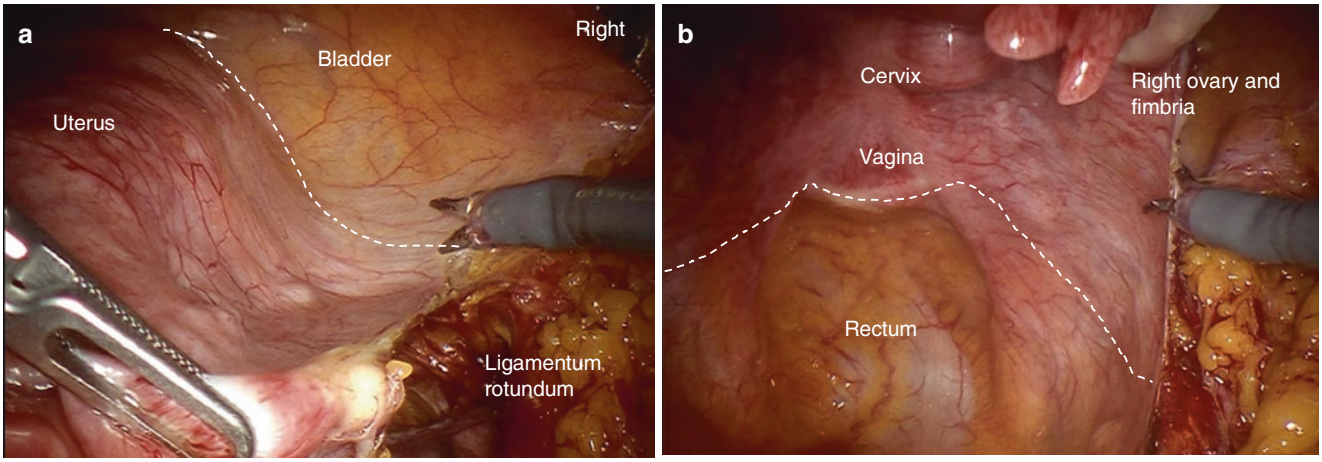

Fig. 69.11 Ventral (**a**) and dorsal (**b**) peritoneal incision in PMMR covering the utero-ovarian vessels

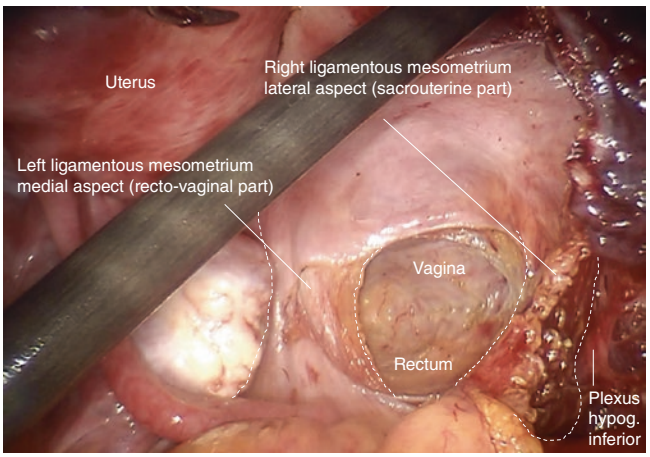

Fig. 69.12 Incision of peritoneum of Douglas pouch and separation of vagina and rectum and preparation of ligamentous mesometria

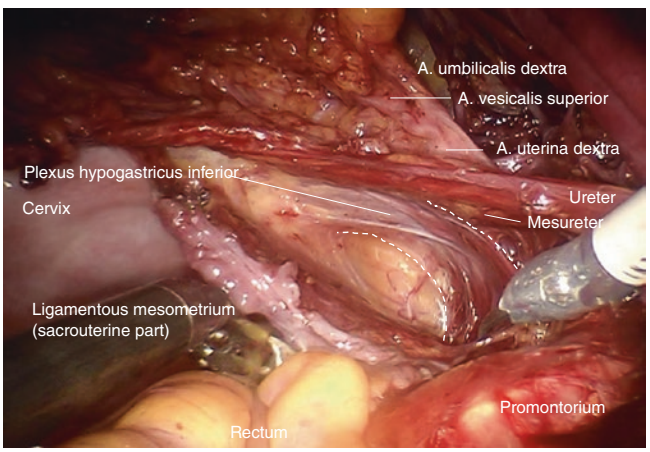

Fig. 69.13 Detaching of right ureter, mesureter and plexus hypogastricus inferior from right ligamentous mesometrium

vaginal wall at least 1 cm more caudally as intended resection line. The ligamentous mesometria (Fig. 69.12) which correspond medially to rectovaginal and rectouterine ligament are lateralized until their insertion to the perirectal tissue is reached usually ventrally to the descendent branch of the rectal artery.

Step 10

Starting on the right side the ureter is identified at its attachment to the pararectal peritoneum and detached together with the mesureter and the adherent inferior hypogastric plexus and nerve without separating these structures from each other. Thus, the avascular plain between the lateral part of the ligamentous mesometrium (anatomically corresponding to the sacrouterine ligament) may easily be opened and the nerve plain can be dissociated laterally from the ligamentous mesometrium (Fig. 69.13). The lymphatic drainage from uterine cervix is demonstrated by ICG fluorescence and is limited to the ligamentous mesometrium and postponed lymph compartment not draining to the rectal compartment, the ureteral or nerve plains (Fig. 69.14).

Step 11

The medial and lateral part of the ligamentous mesometrium may now be completely exposed (left, Fig. 69.15) and resected first laterally, pararectally along the pelvic side wall (sacrouterine part, along the mm. coccygeus and iliococcygeus and the endopelvic fascia); second, prerectally along the descending branch of the rectal artery (rectouterine/vaginal part).

Step 12

To detach the vesico-uterine attachment, the anterior surface of the uterus has to be exposed and put under tension to facilitate incision of the peritoneum at the vesico-uterine fold. The

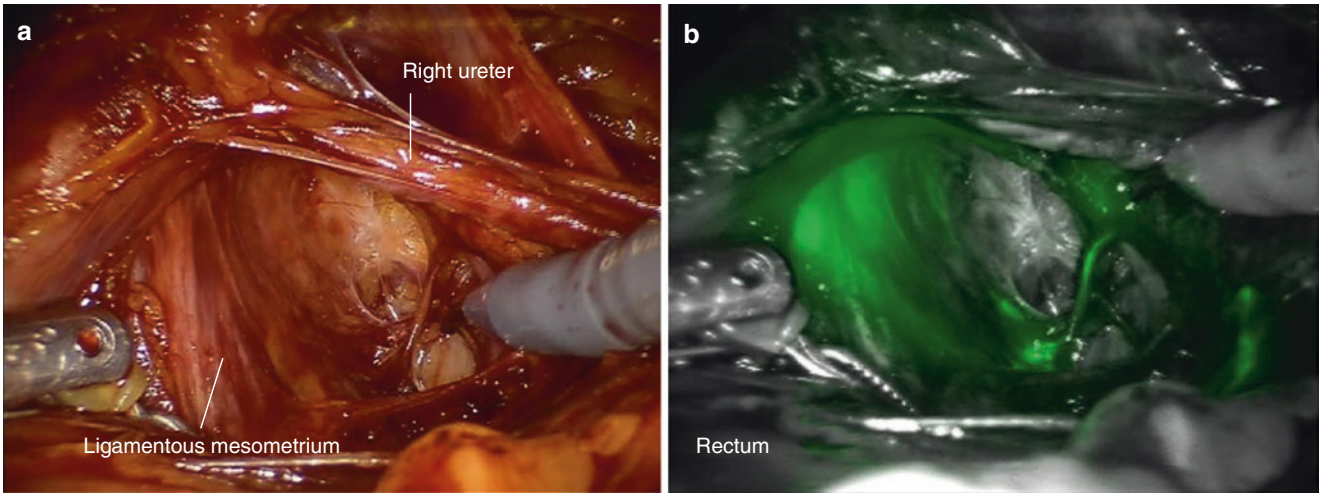

Fig. 69.14 Lateral (sacrouterine) part of right ligamentous mesometrium in cervical cancer and its connections to deep paravisceral lymph node compartments ((**a**) normal light, (**b**) ICG Fluorescence in near infrared light)

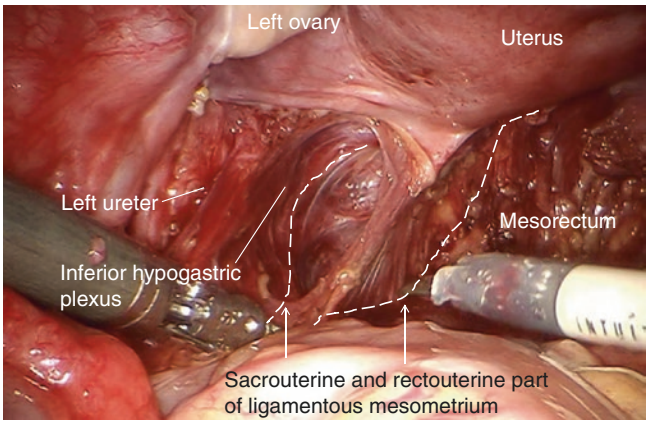

Fig. 69.15 Ligamentous mesometrium on the left side. Overview and resection lines of ligamentous mesometrium in cervical cancer

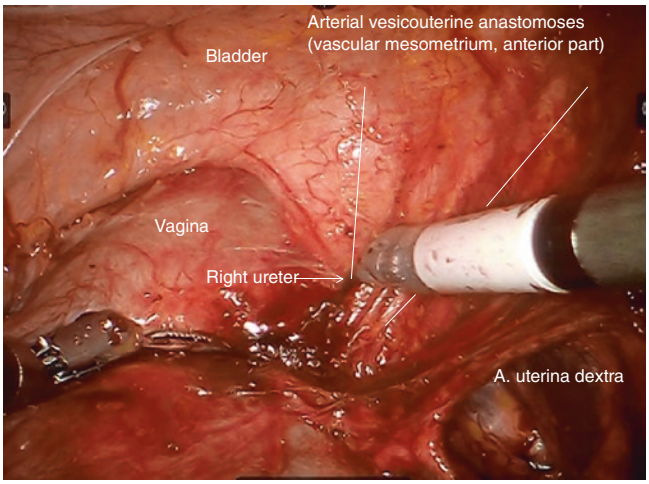

Fig. 69.16 Dissection of the vesicouterine and vesicovaginal tissue plain and preparation of vesicoureteral junctions

peritoneum has to be incised in direction to the lateral part of the round ligaments to divide these at the entrance to the inguinal channel. The loose connective tissue of the vesicouterine and vesicovaginal tissue plain is dissected caudally until the ureters are identified entering the vesical wall (Fig. 69.16). The preparation is extended then laterally and the border of the vesical and Müllerian compartments is identified.

Step 13

The right umbilical artery is identified and completely exposed to its origin from the internal iliac artery. Thus, branching of uterine artery and one or more superior vesical arteries can easily be identified (Fig. 69.17). Now, the ventral border of the vascular mesometrium may be prepared between the uterine and superior vesical vessels, the dorsal border between the uterine artery and the hypogastric plexus, laterally to the ureter.

As it has been shown already for the ligamentous mesometrium in Fig. 69.17, the vascular mesometrium will also be identified by ICG transporting lymph vessels from uterine cervix (Fig. 69.18). There is sharp delineation and no lymphatic drainage to the bladder compartment or along the superior vesical artery.

Step 14

The vascular mesometrium can now be exposed, first by developing the avascular space between its anterior surface and the bladder mesentery containing the superior vesical artery (Fig. 69.17); secondly, by developing the avascular space between the posterior surface and the plain of the ureter, mesureter and inferior hypogastric plexus (Fig. 69.19). The caudal border of the vascular mesometrium is marked by

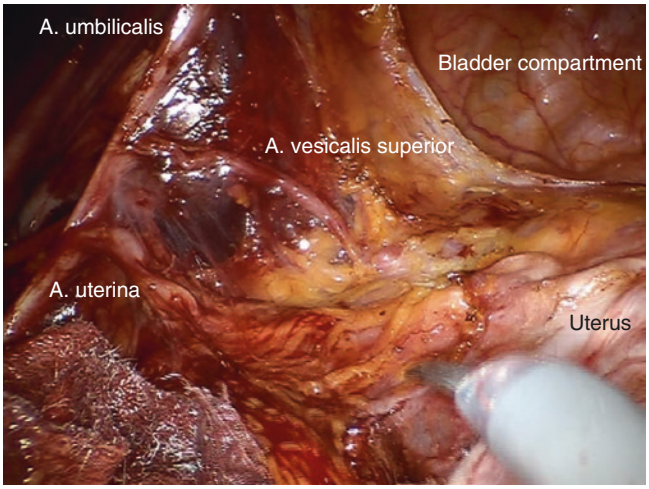

Fig. 69.17 Ventral aspect of vascular mesometrium separated from the bladder compartment

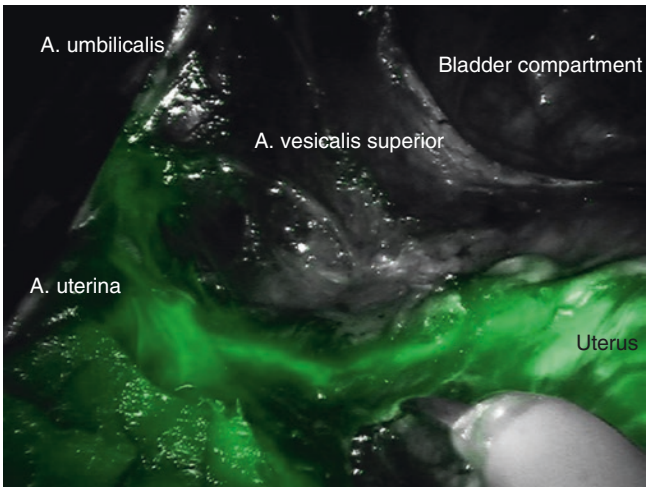

Fig. 69.18 Corresponding ICG lymphography of left vascular mesometrium (Fig. 69.17)

the deep uterine vein, which should also be resected in cervical cancer, but may be left in endometrial cancer (Fig. 69.20). The deep uterine vein often is branching from a common trunc with superior vesical vein. It should be prepared and coagulated before dissection to avoid bleeding. Splanchnic nerves always cross below the vein, thus never will be damaged, if the level of deep uterine vein is taken as the caudal border of resection – with or without resection of the vein.

Step 15

The complete resection of the vascular mesometrium including all paracervical/mesometrial intercalated nodes starts with the coagulation and division of the uterine artery and superficial uterine veins at their origin from the iliacal vessels. This step should be carried out without separating

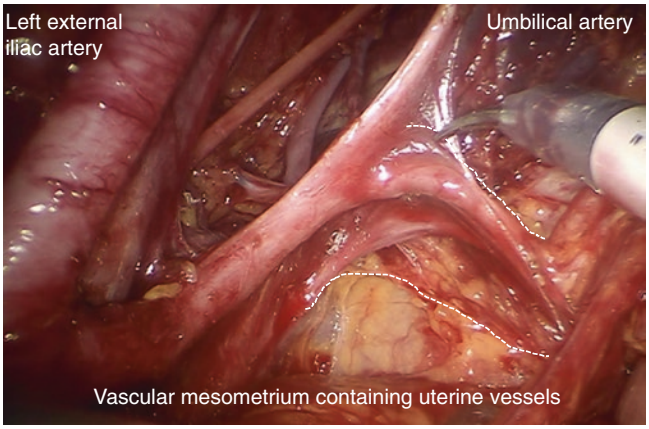

Fig. 69.19 Left vascular mesometrium (lateral part, dorsal aspect)

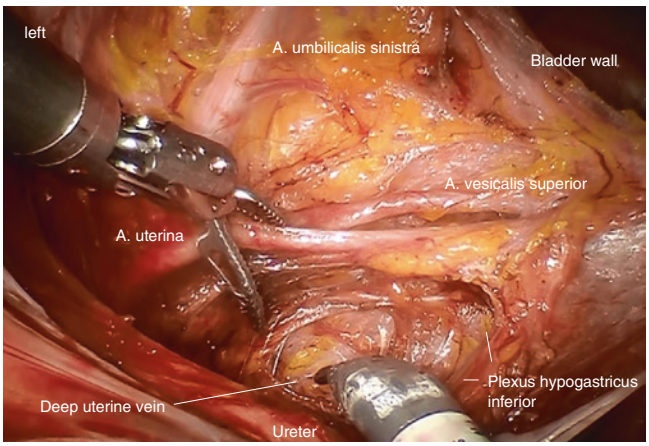

Fig. 69.20 Resection of left vascular mesometrium

the vessels in order to remove all perivascular lymphatic tissue "en bloc" (Fig. 69.20). The deep uterine vein is identified and coagulated separately.

Step 16

Dissection of the ureteral branch of the uterine artery (and vein) following elevation of the uterine bundle is necessary to mobilize the ureter in its "tunnel" (Fig. 69.21). Coagulation and dissection of vesicouterine/vaginal arterial anastomoses in the anterior part of vesicouterine ligament will separate the Müllerian from the vesical compartment ventrally, carefully preserving the ureteral branches of the bladder mesentery (Fig. 69.22).

Step 17

Dissection of the uterine nerve fibers of the hypogastric nerve at the lateral posterior aspect of the cervix will enable to preserve the bladder branches of the hypogastric nerve.

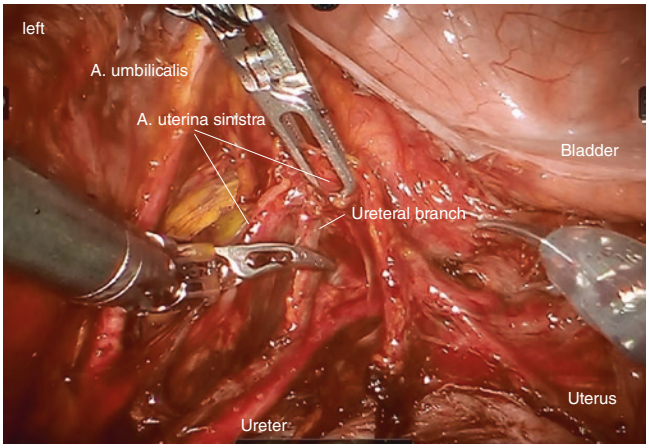

Fig. 69.21 Disection of ureteral branch of uterine artery, left vascular mesometrium

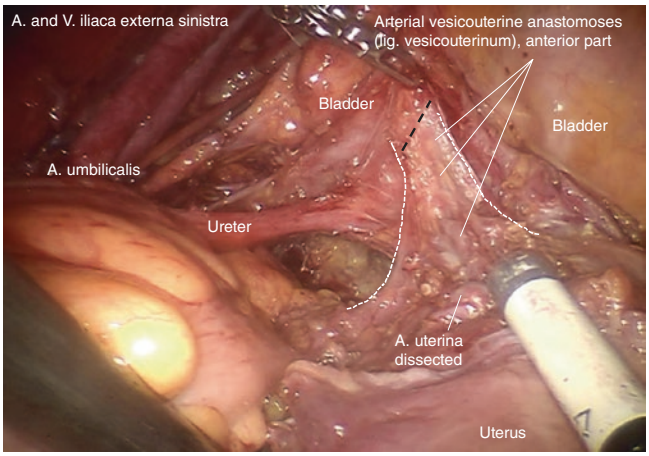

Fig. 69.22 Preparation of anterior part of left vascular mesometrium corresponding to vesico-uterine ligament

They will be lateralized and pushed caudally together with the ureter (Fig. 69.23).

Step 18

Dissection of the "ladder-like" arranged vesicovaginal venous anastomoses (Fig. 69.24), if not already done during separation of the ventral aspect of vascular mesometrium from the bladder mesentery (so called "posterior leaf of vesicouterine ligament").

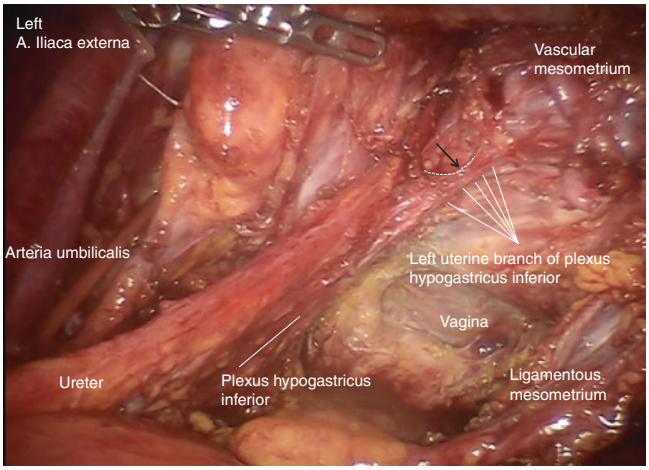

Fig. 69.23 Dissection of left uterine branching nerves to lateralize inferior hypogastric nerve

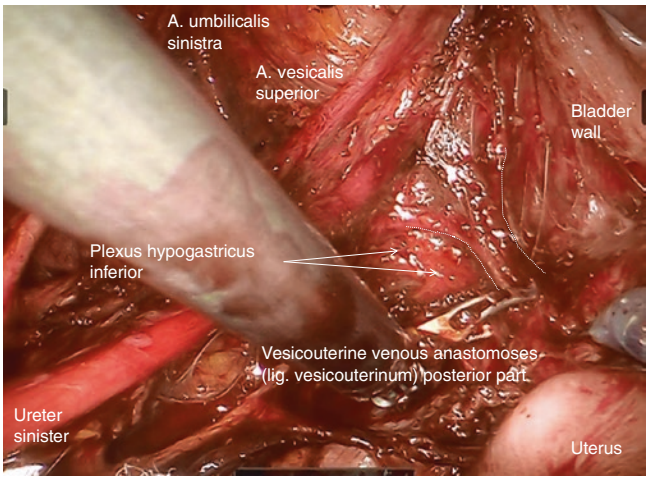

Fig. 69.24 Dissection of venous vesico-uterine anastomoses of vascular mesometrium on the left

Step 19

Definition of the vaginal resection plane and dissection of the mesocolpium if necessary. Opening the vagina from dorsally and resection of vaginal cuff with sufficiently clear margins confirmed by frozen section (Fig. 69.25).

Step 20

Removal of resected tissue, bags and sponges vaginally, and confirmation of clear margins. The vagina is closed by running suture.

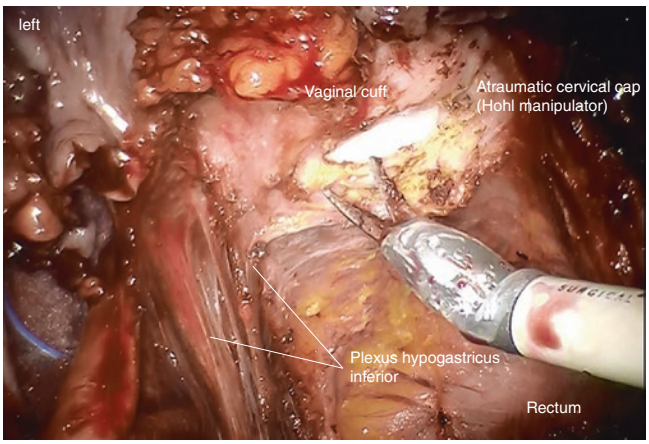

Fig. 69.25 Definition of length of vaginal cuff and colpotomy

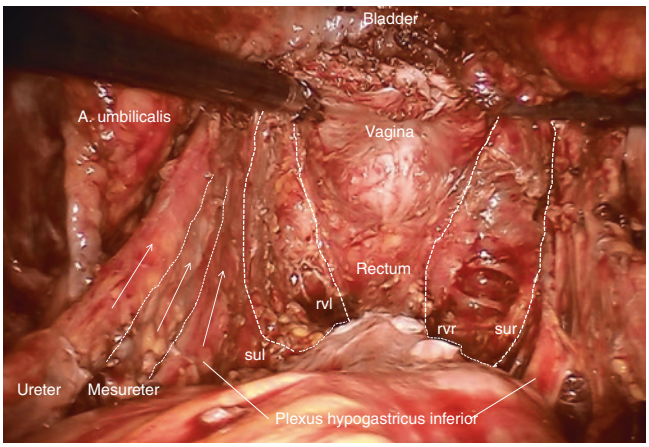

Fig. 69.26 Final situation following TMMR: resection lines ligamentous mesometria su (sacrouterine), rv (recto-vaginal), l/r

Finally, all tissue of Müllerian compartment has been removed completely - except for the vaginal part for functional reasons - but adjacent structures of neighbouring compartments such as ureter, mesureter, hypogastric plexus, rectal and vesical mesentery are entirely preserved whereas the vascular and ligamentous mesometria are entirely removed (Fig. 69.26). Thus, this procedure may be performed identically for all compartment defined cervical and endometrial cancers ensuring maximum radicalness with respect to tumor resection without increasing morbidity by extending surgery to neighboring structures. Adaption of surgery to compartments instead of tumor size and extent may enhance loco-regional tumor control, whereas unnecessary morbidity is prevented.

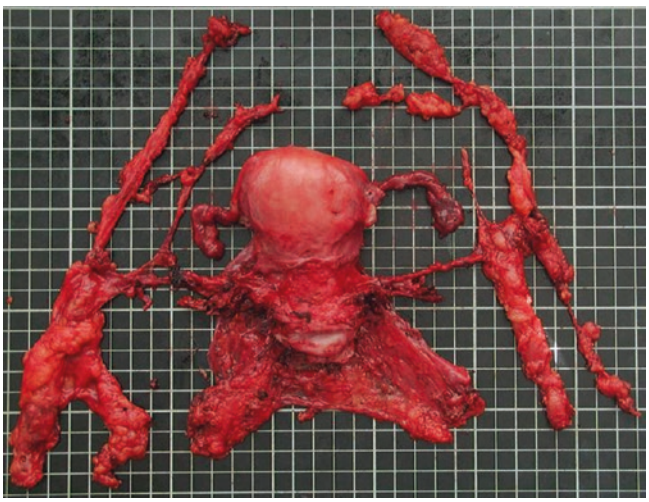

Fig. 69.27 Typical specimen following TMMR in cervical cancer with vascular and ligamentous mesometria and pelvic lymph node compartments

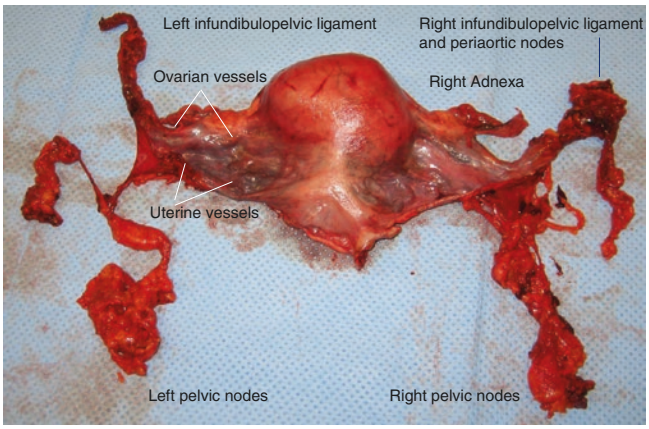

Fig. 69.28 Typical specimen following PMMR in endometrial cancer with vascular mesometria, uteroovarian vessel network and mesonephric compartment of infundibulopelvic ligaments

Finally, typical specimens following TMMR (Fig. 69.27) and PMMR (Fig. 69.28) are shown. Figure 69.29 demonstrates that ICG labeling of the Müllerian compartment reliably persists over hours during cancer surgery for intraoperative orientation and postoperative control.

To compare clinical results of surgical techniques in practice and even more in studies the procedure has to be named and exactly standardized. Thus, in this chapter the technique of TMMR and PMMR performed by robotically assisted laparoscopic surgery has been defined and described step by step.

Robotically Assisted Therapeutic Pelvic and Paraaortic Lymphadenectomy in Uterine Cancer

70

Rainer Kimmig

Introduction

There are several strategies in lymphadenectomy and even more techniques all named "pelvic lymphadenectomy" or "paraaortic lymphadenectomy."

Thus, first it has to be defined what will be the intention of lymphadenectomy – diagnostic or therapeutic? In case of diagnostic intent sentinel node biopsy may be an adequate approach for reduction of morbidity, other forms of staging lymphadenectomy may be too but are more or less undefined. To confirm a "sufficient" lymphadenectomy indication of numbers of nodes retrieved has been proposed. However, on the contrary, in case of therapeutic intention it makes no sense to define any number of nodes to be taken out, but to define not to leave any node in with respect to the compartment of risk.

In conjunction with compartmental resection of "organ compartments at risk" which have to be resected entirely, only resection of the entire "node compartments at risk" may considered adequate for maximum potential therapeutic effect.

Just to remember the basis of compartmental resection from Chapter 69: On the basis of ontogenetic compartmental development the findings about compartmental border control in malignant tumour progression led to the concept of "compartmental resection" in solid malignant tumors [1–4]. Since loco-regional recurrence usually occurs in compartment remnants or in the associated lymph compartments total "compartments of risk" have to be removed completely, whereas neighbouring compartments may left entirely untouched. The first tumour resected following this concept was rectal cancer by total mesorectal excision (TME) resulting in dramatically reduced loco-regional recurrence [5]. At present this procedure has become standard in rectal cancer surgery [6]. For cervical cancer M. Höckel has convincingly shown by his monocentric data that the corresponding method named total mesometrial resection (TMMR) also reduces efficiently locoregional recurrences compared to standard treatment – without any additional radiation therapy even in risk situations [7, 8]. The Method is described for open surgery in a separate chapter. Together with M. Höckel total mesometrial resection (rTMMR) has been translated to robotic surgery [9]. On parallel, the modification of compartmental resection for endometrial cancer as peritoneal mesometrial resection (PMMR) according to the different lymph drainage has also been adopted to robotic surgery as rPMMR [10]. Although, the two methods have to be applied together with therapeutic pelvic or pelvic and paraaortic lymphadenectomy to control not only for local but also for regional disease, in this chapter the technique of therapeutic lymphonodectomy (tLNE) only is described; however technique of TMMR and PMMR has already been described step by step in Chapter 69.

Anatomical Basis of Müllerian Compartment and Local Lymph Drainage

For uterine cancer removal of the Müllerian compartment and its draining lymphatic compartments has to be performed completely. Embryological development, compartment borders and type of resection in uterine cancer is perfectly described by M. Höckel [4, 7]. As shown in Fig. 70.1 the uterus has to be removed together with the vascular mesometrium (corresponding to the uterine vessel system including vesicouterine anastomoses) and the ligamentous mesometrium (c+orresponding to the rectovaginal and sacrouterine ligament). However, there is not any longer any modification with respect to the tumor size, as the concept requires always complete resection. There is only one part of the Müllerian

compartment left in situ for functional reasons – the vagina. The vaginal resection margin is the only intracompartmental resection has directly to be controlled for clear margins (>10 mm recommended) in compartment confined tumors [4]. According to the different lymph drainage of the upper and lower Müllerian compartment in cervical cancer vascular and ligamentous mesometria have to be resected. In endometrial cancer without cervical involvement there is no drainage along the ligamentous mesometria; on the other hand there is drainage along the mesonephric pathway on parallel to the ovarian vessel system. Thus, ligamentous mesometria may be preserved, but infundibulopelvic ligaments have to be resected completely in corporal uterine disease as can be seen from Fig. 70.1 a–d.

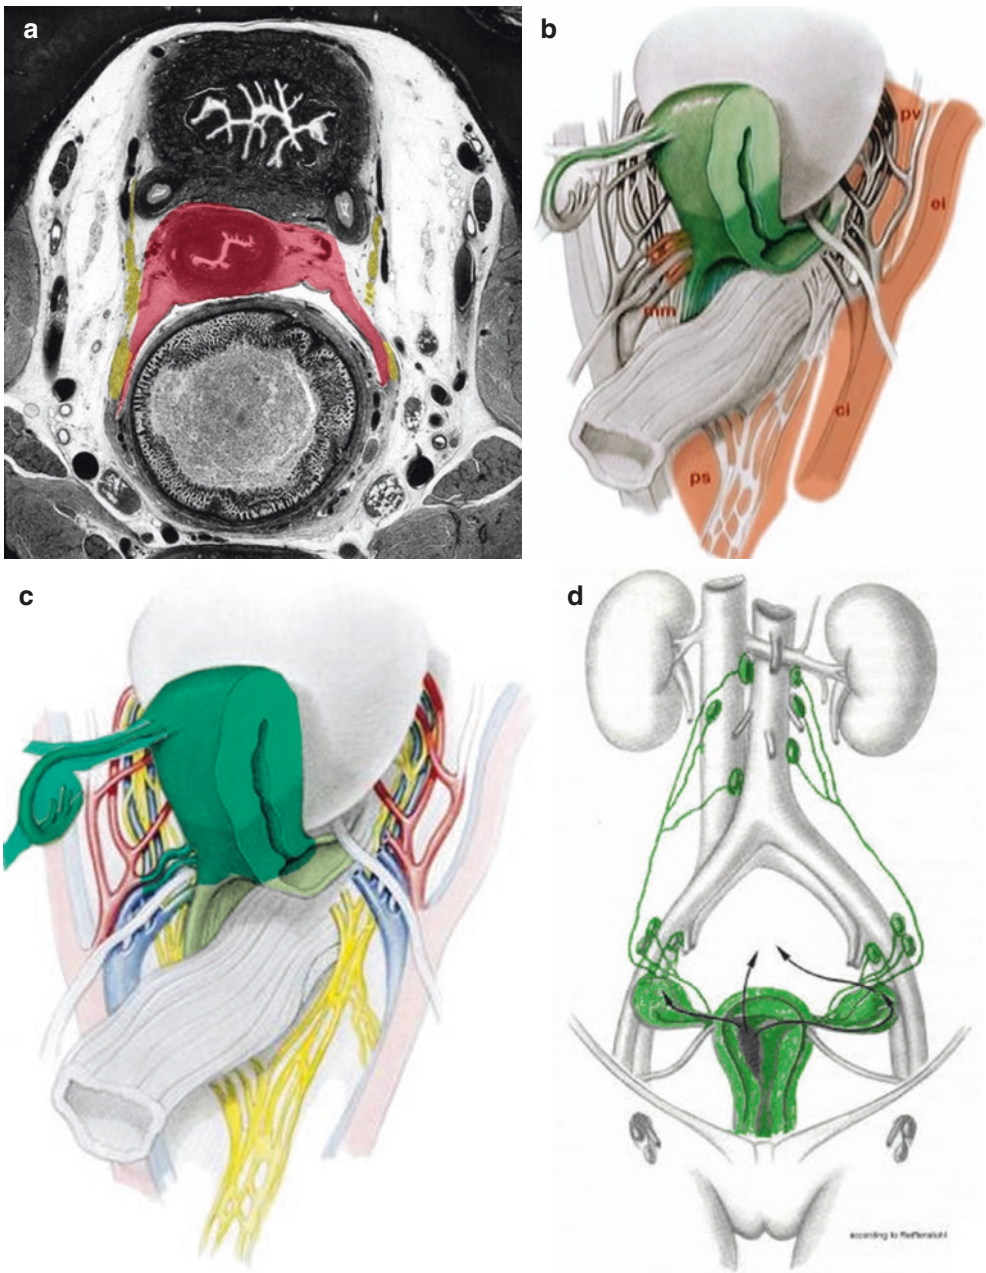

Fig. 70.1 (**a**) Embryologic development of Müllerian compartment (*red*); (**b**) Müllerian compartment in the adult (*green*); (**c**) Involvement of Müllerian compartment in endometrial cancer (*green*); (**d**) Additional lymphatic drainage in endometrial cancer (*green*)

Therapeutic Lymphadenectomy

In this chapter this type of "therapeutic lymphadenectomy" as described by M. Höckel will be demonstrated using robotically-assisted laparoscopy exclusively for the different pelvic and paraaortic lymph compartments. This has already been published in [9–17].

As outlined in Chapter 69 the lymphatic network of the Müllerian system derives from embryonal veins [18] and thus covers the whole compartment and may visualized by fluorescence lymphography intraoperatively. In mammals, embryologic development is suggested as a stepwise process starting from the embryonic veins, where lymphatic endothelial cells (LEC) are initially specified [19]. The lymphatic system develops by budding from "cardinal veins" and thus, necessarily parallels the venous system, although no open connection remains between the two systems except for the iugular lymph sacs to the subclavian veins which enable lymph drainage back to the blood circulation. There is some evidence that the origin of the very first draining lymphatic capillaries may arise not only by sprouting but also by scattered local mesenchymal cells expressing lymphoendothelial markers [19]. Very important is the fact, that collecting lymph vessels and also main transporting lymph vessels develop lymphatic valves which guarantee a directed "downstream" lymph flow [19]. This is also true for the connecting lymph vessels from the organ compartment to the lymph compartments (basins of first or subsequent order). Thus, visualization of the lymphatic vessel network of a distinct organ should be able to mark the organ compartment and the compartments of specific lymphatic drainage "downstream" from a defined localization resembling functional aspects. This should have dramatic clinical impact on surgical oncology with respect on individual radical compartmental surgery in cancer due to the compartmental order of tumor progression [20] and the tremendous impact of the lymphatic system on local, regional and distant tumor progression.

Uterine Cervix and upper vagina is drained via two different pathways: first, along the uterine and vaginal arteries and veins to the pelvic side wall, using mainly the lymph vessels running along of the uterine artery. They drain primarily into the paravisceral and external iliac lymph basin which are the lymph compartments of first order for these organ (sub) compartments and contain the respective site information. The second pathway runs along the posterior ligamentous mesometrium and mesocolpium (corresponding to the sacrouterine and rectovaginal ligaments) and drains primarily to the deep paravisceral nodes ventrally to the ischiadic spine and the nerve roots of the ischiadic nerve. There are collecting lymph channels transporting the lymph fluid to the common iliac lymph basin, ventrally and dorsally of the common iliac vessels and again connecting this compartment of second order to the inferior paracaval and paraaortic lymph node compartment (third order) connected again to the infrarenal lymph paraaortic and paracaval nodes (forth order) which may also serve as first order lymph compartment for the mesonephric and colonic system, for example.

We have to keep in mind, that the draining lymph channels of the lower Müllerian compartment (Cervix, Vagina) run caudally and dorsally, thus involving rather the posterior nodes along the vessels; Anatomically the paraaortic and paracaval nodes are separated in two subcompartments on each side: the anterior (mesenteric) and the posterior (lumbar) part. Although, lymphatic spread is found in cervical and vaginal cancer predominantly in the lumbar subcompartment there are a lot of anastomoses between the lymphatic systems, which can be shown anatomically and by ICG fluorescence, that ther may be also metastatic spread to the mesenteric subcompartment.

In endometrial cancer lymphatic spread is different. From the upper part of Müllerian compartment lymphatic drainage runs cranially of the uterine artery and predominantly ventrally to the main vessels. In addition, there is a mesonephric pathway along the ovarian vessels directly to the paraaortic lymph compartment. Consequently, tumor spread is predominantly found in the ventral, mesenteric subcompartments; same is true for ovarian cancer where more or less the same lymphatic pathways are used.

If we respect that in a functional intact lymphatic system the lymphatic flow is unidirectional due to valves consequent and complete removal of the lymph compartments at risk should be able to control for locoregional disease. This may no longer be true in macroscopically bulky disease since in that situation due to tumor barriers in the downstream system may lead to upstream dissemination by valve insufficiency.

For systematic reasons it makes sense to define pelvic and paraaortic lymphadenectomy as different entities. However, with respect to the compartmental order of lymph basins in ontogenetic development it seems to be more appropriate to define pelvic and paraaortic lymph compartments draining the respective organ (sub) compartments of the tumor origin.

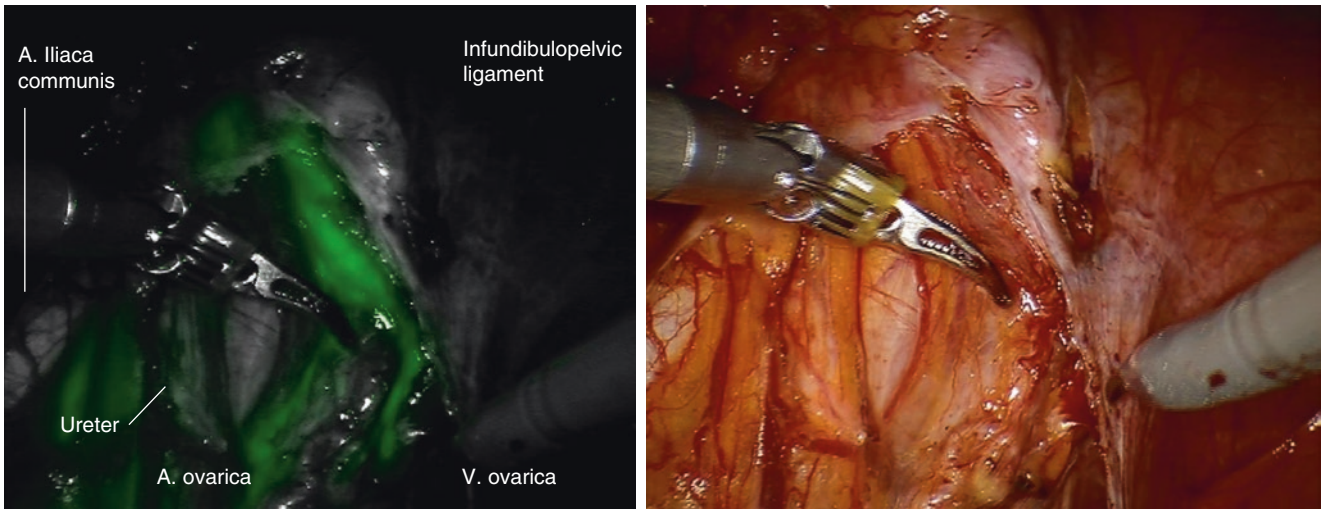

Fig. 70.2 Lymph drainage right infundibulopelvic ligament (ICG and real light comparison)

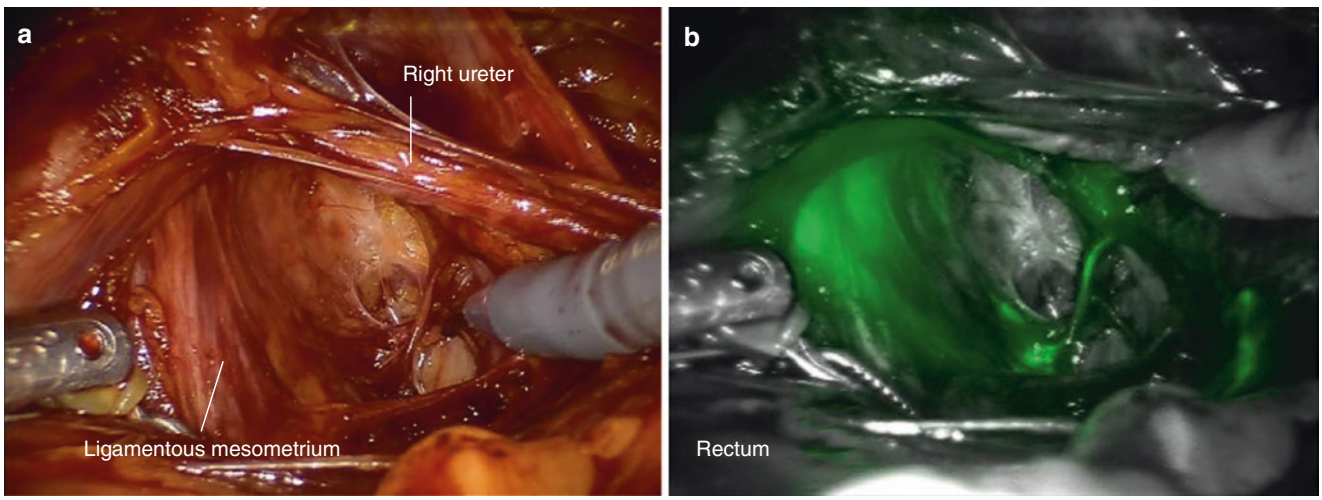

Fig. 70.3 Lateral (sacrouterine) part of right ligamentous mesometrium in cervical cancer and its connections to deep paravisceral lymph node compartments (*A* normal light, *B* ICG Fluorescence in near infrared light)

Lymph Compartments at Risk for Endometrial and Cervical Cancer

Due to the embryological development of lymphatic drainage of the Müllerian compartment there are three main pathways to reach the pelvic and paraaortic basins. First, Müllerian pathway along the vascular mesometrium to the paravisceral and external iliac basin, second along the ligamentous mesometrium to the paravisceral basin, predominantly along obturator and gluteal vessels to posterior part of internal iliac vessels. Third, the mesonephric pathway along the infudibulopelvic ligaments. Wheras cervical subcompartment drains to the lower vascular and ligamentous mesometrium, the corporal subcompartment drains to the upper vascular mesometrium and the infundibulopelvic ligament. Typical situations of intraoperative visualization using ICG in cervical and endometrial cancer are shown in Figs. 70.2, 70.3, 70.4, and 70.5.

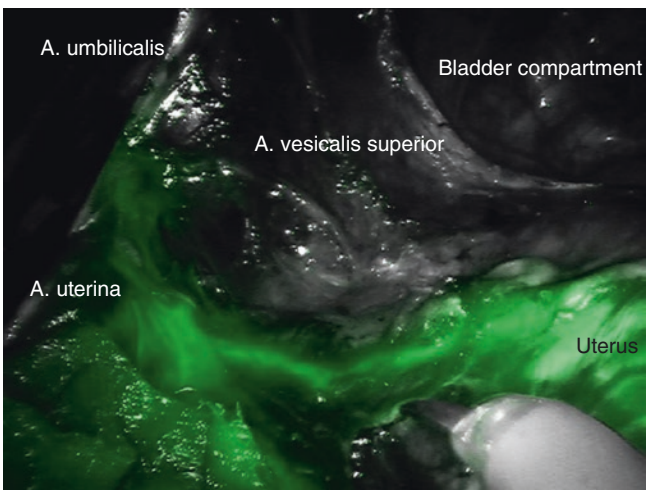

Fig. 70.4 Ventral aspect of vascular mesometrium separated from the bladder compartment

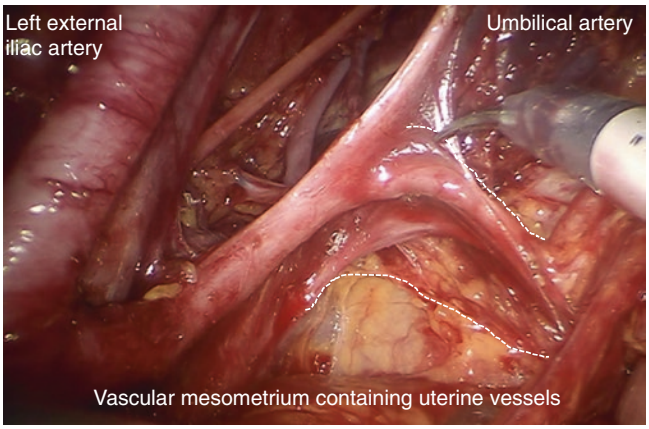

Fig. 70.5 Corresponding ICG lymphography of left vascular mesometrium (Fig. 70.4)

Therapeutic Pelvic Lymphadenectomy: Step by Step

The pelvic lymph basins draining the uterine compartment are: External iliac basin, paravisceral basin including preischiadic and prespinal region, common iliac basin including subaortic nodes (Fig. 70.1).

Thus, the lymph compartment of first order is represented by the paravisceral and external iliac lymph basin and of highest risk, postponed (second order) are the common iliac basins including subaortic nodes getting at risk following involvement of first order lymph basins.

Surgical Strategy and Technique

Step 1

Usually, pelvic lymphadenectomy starts at the level of the right common iliac artery. Following opening of the peritoneum laterally to the artery but medial to the ureter the complete retroperitoneal lymph basins are exposed from the aortic bifurcation to the bifurcation of the common iliac vessels down to S2 (Fig. 70.6, before dissection). Following peritoneal incision the superior hypogastric plexus will be elevated ventrally together with the mesosigma, forming the so-called sigmoid tunnel and the intact retroperitoneal lymphatic compartments are exposed (Fig. 70.7).

Step 2

Lateral borders of the dissection dorsally are defined by the psoas muscle, the ureter, the genitofemoral nerve and if preserved, ventrally the infundibulopelvic ligament (Fig. 70.8). All structures have to be separated from the lymphatic compartment.

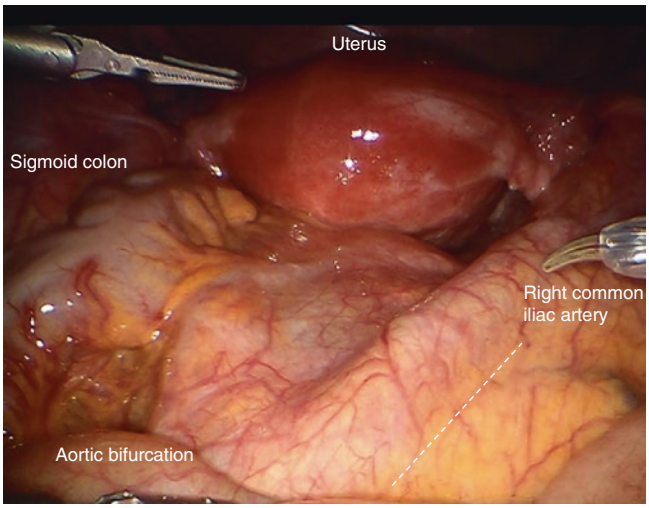

Fig. 70.6 Exposition prior to peritoneal incision at the level of right common ilac artery

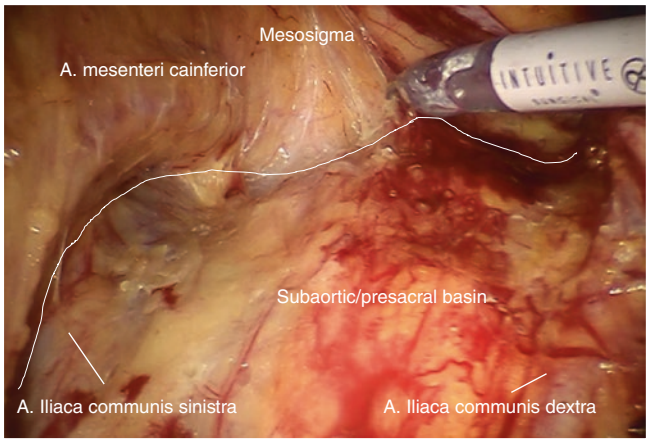

Fig. 70.7 Subaortic and caudal mesenteric paraaortic lymph compartment exposed

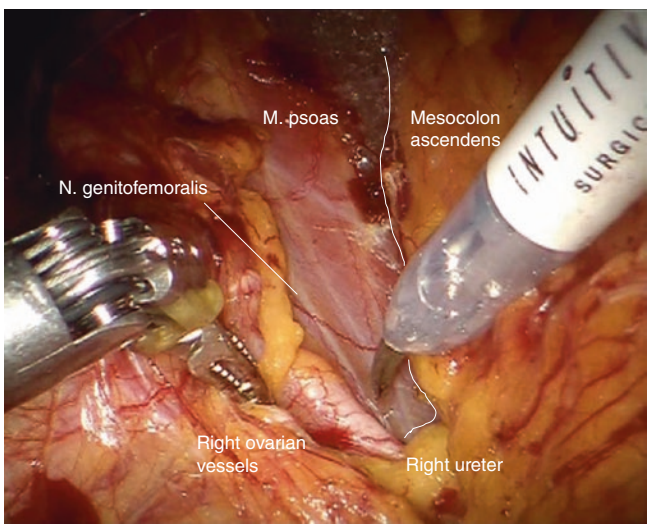

Fig. 70.8 Right lateral border of common iliac lymph basin

Step 3

Common iliac lymph basins will be resected "en bloc" from right to left, starting at the level of aortic bifurcation. Following structures should be exposed and detached from right to left: ureter, left sympathetic chain, n. genitofemoralis, n. obturatorius, truncus lumbosacralis, a. and v. iliaca communis, promontorium, A. sacralis media and same to the left (Figs. 70.8, 70.9, 70.10, 70.11, and 70.12). The connection to the inferior lumbar and mesenteric aortic basins can be taken as upper border for the dissection (Fig. 70.13). The lower border of dissection will be the ureter crossing at the common iliac bifurcation; medially, however, internal iliac nodes should be resected already down to the level of S2 (Fig. 70.14); lower crossing splanchnic nerves will thus be preserved.

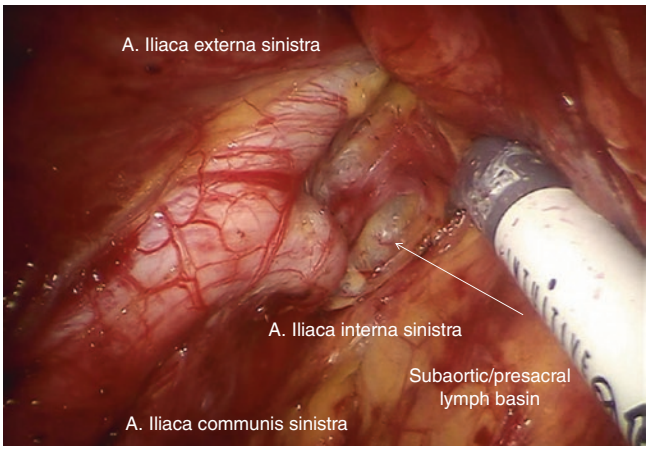

Fig. 70.11 Subaortic (left medial common iliac) and upper paravisceral lymph compartment to S2

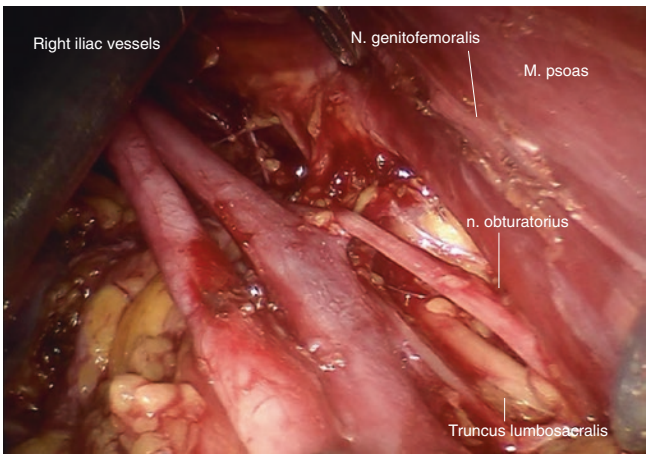

Fig. 70.9 Lateral common iliac lymph basin partially dissected on the right

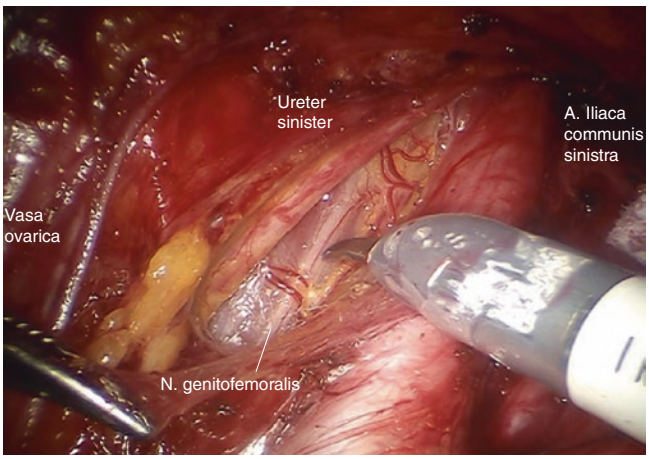

Fig. 70.12 Left lateral border of common iliac lymph basin

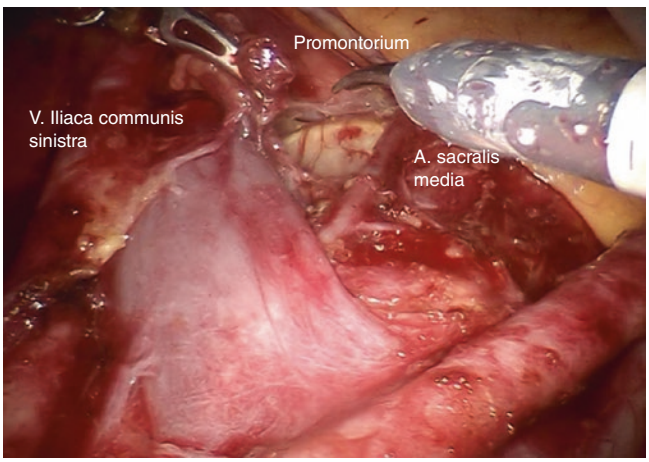

Fig. 70.10 Subaortic (medial common iliac) lymph basin partially dissected

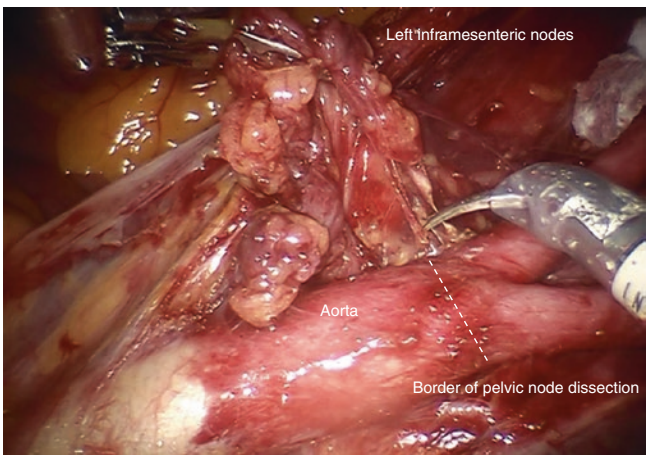

Fig. 70.13 Cranial border of common iliac lymph basin

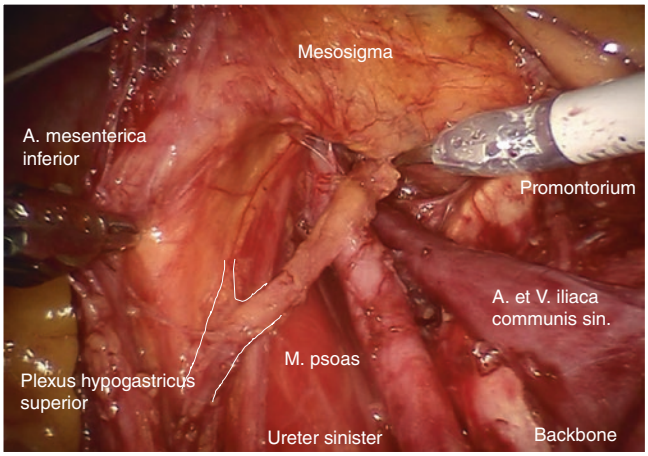

Fig. 70.14 Left caudal border of common iliac lymph basin

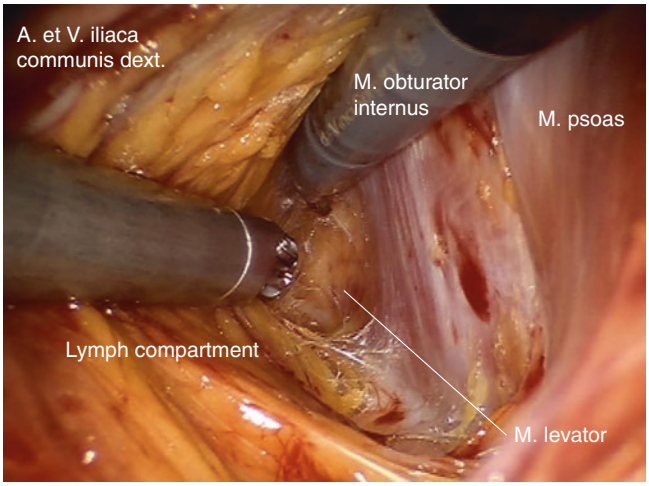

Fig. 70.15 Lateral border of right pelvic paravisceral lymph compartment

Step 4

Lateral exposition of external and paravisceral lymph basin on the right. Lateral border again is represented by the genitofemoral nerve and the psoas fascia. These structures will be separated from the lymph compartment. Next, the lymph compartment will be detached from the pelvic side wall by following the psoas muscle to the internal obturator muscle, passing the arcus tendineus to the levator muscle and the endopelvic fascia. This can easily be achieved lateral to the external iliac vessels, inferior to the gluteal vessels and the ischiadic nerve since this region is more or less avascular (Fig. 70.15).

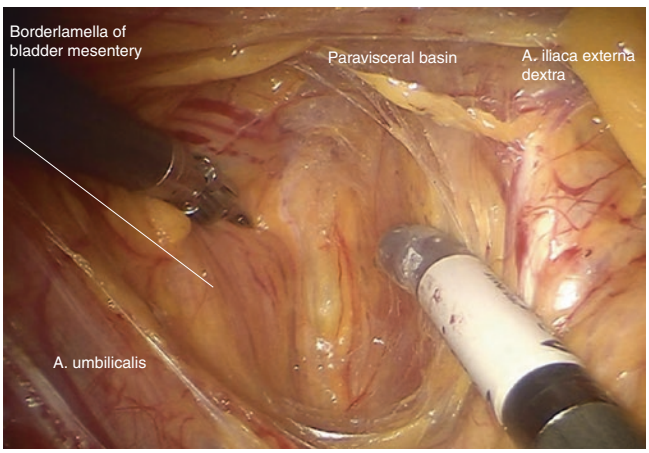

Fig. 70.16 Medial border of right pelvic paravisceral lymph compartment

Step 5

Medial exposition of external and paravisceral lymph basin on the right. Medial border is represented by the bladder mesentery containing the umbilical artery. The avascular space beween the border lamella and the lymphatic compartment will be opened again down to the endopelvic fascia (Fig. 70.16). Now the caudal resection of external iliac nodes is defined and the compartment border is detached in the avascular space separating it from the parainguinal fat tissue ventrally to the iliac vessels. At this level the inferior epigastric and the circumflex iliac vessels can be visualized (Fig. 70.17). The connecting lymph vessels of the medial femoral channel will be dissected and the connecting vein from external iliac to obturator vein can easily be followed to the obturator nerve and vessels.

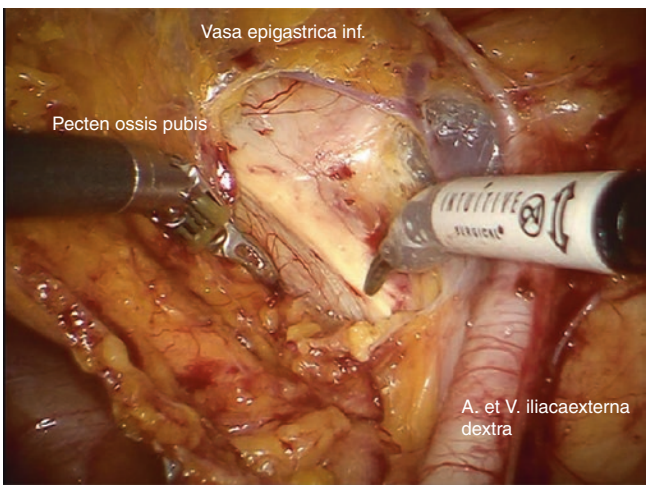

Fig. 70.17 Caudal border of right pelvic external iliac lymph compartment

Step 6

Resection of external and paravisceral lymph basin "en bloc".

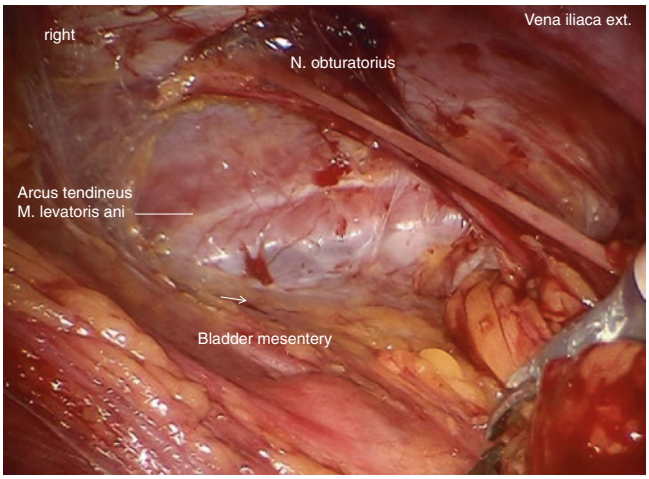

Fig. 70.18 Caudal part of right paravisceral lymph compartment removed

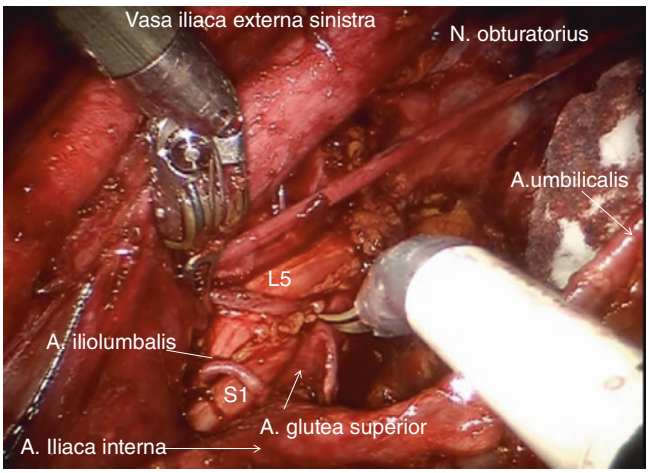

Fig. 70.19 Cranial part of left paravisceral lymph compartment removed (**a**)

To unwrap the external iliac vessels lymphatic tissue of the medial and lateral part is divided best along external iliac artery. Pulling the nodal tissue medially it may be detached from the iliac vein and the obturator bundle is exposed. Due to the prior lateral detachment, the whole tissue can now be detached completely from the obturator bundle and the obturator fossa from caudally to cranially reaching the posterior internal iliac region laterally and the anterior branches ventrally. At this level, all the lymphatic tissue up to the dissection border of common iliac nodes can now be retrieved from medially (Fig. 70.18).

Step 7

Resection of upper posterior paravisceral lymph basin preischiadically.

Whereas the prespinal nodes are already resected with the obturator nodes it is more challenging to remove all the preischiadic nodes between the gluteal and pudendal vessels. If necessary veins can be dissected but arteries normally can be preserved. The tissue has to be removed and the sacral roots and main stem of ischiadic nerve are cleaned (Figs. 70.19 and 70.20, shown on the left).

Steps 8–11 on the Left Side Are as Described for Step 4–7 on the Right

The surgical steps on the left side will be identically performed as desrcibed for the right.

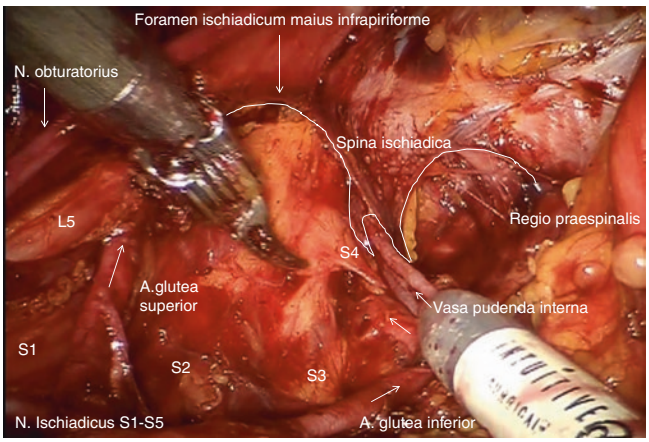

Fig. 70.20 Cranial part of left paravisceral lymph compartment removed (**b**)

Therapeutic Paraaortic Lymphadenectomy: Step by Step

There are two different types of paraaortic lymphadenectomy; with or without mesonephric lymph system along the ovarian vessels; this has to be removed additionally in endometrial and ovarian cancer, whereas in cervical cancer it will be not necessary.

Trocar Placement

With respect to trocar placement it is important to define preoperatively to define at which level nodes have to be removed, predominantly using a “da Vinci Si″ system. The

camera trocar has to be placed about 8–10 cm more cranially as the most cranial point of planned dissection and the instrument trocars have to be placed more cranially but in the same configuration as in demonstrated in Fig. 70.21. If this is not possible, trocars have to be placed around the umbilicus (mostly a little bit lower) and the patient cart has to be re-docked to reach the higher abdominal regions. Using the "da Vinci Xi" system this is no longer mandatory; placing the trocars at the level of the umbilicus in one straight line the whole abdomen is accessible without re-docking, facilitating the procedure in the cranial part and allowing easily to extent the surgery to the upper abdomen, if necessary.

Differences of Paraaortic Lymphatic Drainage in Cervical and Endometrial Cancer

Again to keep in mind: In endometrial cancer lymph drainage primary lymph basins are pelvic and paraaortic and have to be removed entirely since lymphatic drainage follows the vascular mesometrium and the infundibulopelvic ligament. Thus, whereas in cervical cancer, paraaortic lymph basins are of third or higher order postponed to pelvic basins and may be spared in case of negative pelvic nodes, in endometrial cancer paraaortic nodes are of first order. That means the compartment at high risk for nodal metastases comparable to the pelvic lymph compartments.

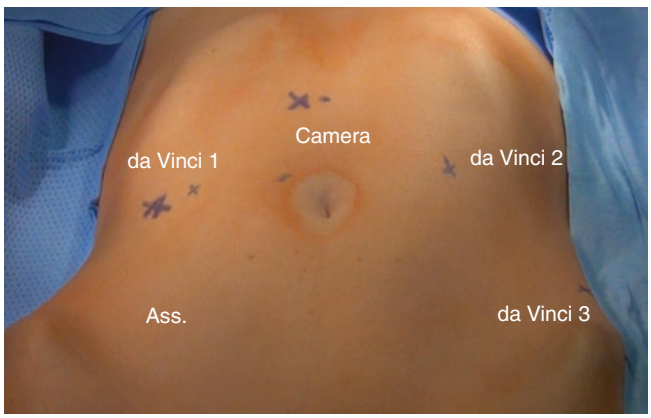

Fig. 70.21 Trocar postitioning for robotic TMMR and therapeutic pelvic LNE

Consequently, in the therapeutic approach – analogous to cervical cancer – in endometrial cancer together with the vascular mesometrium also the network for vascular and lymphatic anastomoses between uterus and adnexa has to be removed, at best covered by the peritoneal leaves of the broad ligament (PMMR). The vascular and lymphatic drainage system along the ovarian vessels has also to be removed in analogy to the vascular mesometrium up to its connection to the periaortic and pericaval lymph basins. Whereas the vascular anastomoses to the mesenteric vessel system (right and left colon) are dissected the connections to the periaortic lymph basins are preserved and removed together "en bloc." Since there is no drainage from uterine corpus to the ligamentous mesometrium the deep gluteal, pudendal, and rectal nodes may be preserved. As already outlined lymphatic tumor spread in endometrial cancer will take place predominantly in the ventral part of lymph compartment such as the mesenteric paraaortic and paracaval nodes, due to embryologically derived anatomy.

Table 70.1 illustrates lymph compartments to be removed in cervical and endometrial cancer.

Step 12

In case of cervical cancer inframesenteric periaortic lymphadenectomy may be performed following elevation of the superior hypogastric plexus (Fig. 70.22), the inferior mesenteric artery, and the sigmoid colon ventrally, thus continuing lymphadenectomy from common iliac vessels (Figs. 70.13 and 70.23). It has to be ascertained to remove the interaortocaval nodes (Fig. 70.24) and the lumbar chains dorsolaterally of vena cava (Fig. 70.25) and aorta; the connecting branches from right sympathetic chain to the superior hypogastric plexus may be maintained (Fig. 70.26).

Step 13

For infrarenal lymphadenectomy dissection has to be extended cranially to the renal vessels. In principle, retroperitoneal compartments will be exposed by defining right lateral border (ureter and psoas muscle), cranial border (renal veins, detaching duodenum). The ventral border by elevating

the plexus mesentericus inferior and hypogastricus superior together with inferior mesenteric artery and vein. Usually, connecting nerve branches to the right sympathetic chain (Fig. 70.26) have now to be dissected to allow ventral elevation of the plexus. Finally, left lateral border will be defined by the ovarian vein, ureter and psoas muscle; now interaortocaval infrarenal nodes and left infrarenal nodes can be removed; connecting nerve fibres to the left sympathetic chain may be preserved (Fig. 70.27).

Step 14

Complete resection of paraaortic infrarenal lumbar and mesenteric lymph compartments from right to left is now completed (Fig. 70.28) in cervical cancer without the need of resecting the mesonephric ovarian vessel system.

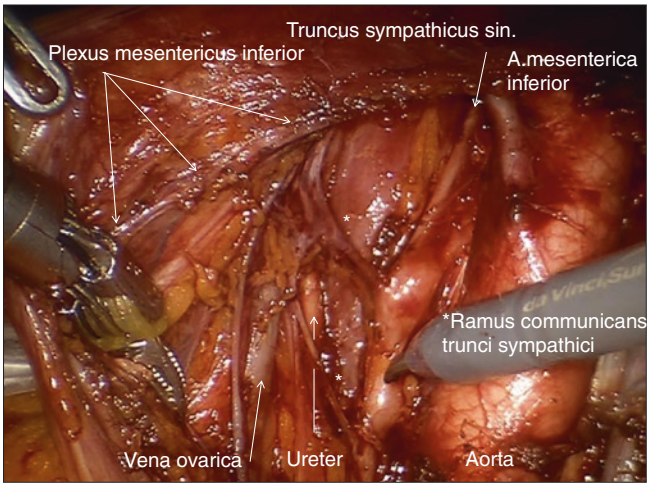

Fig. 70.27 Removal of left infrarenal paraaortic lumbar lymph compartment

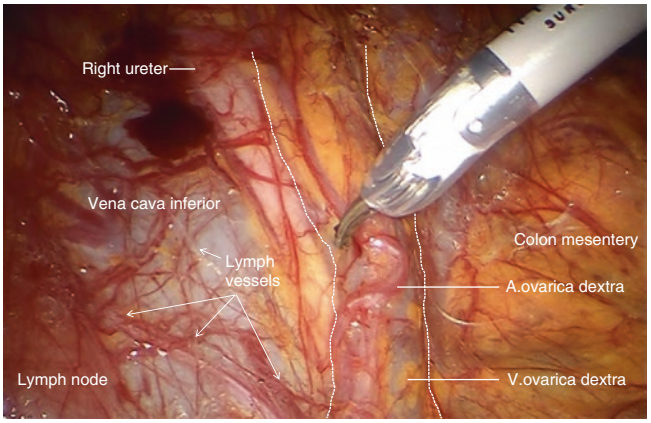

Fig. 70.29 Identification of right infundibulopelvic ligament, ureter and right colon mesentery

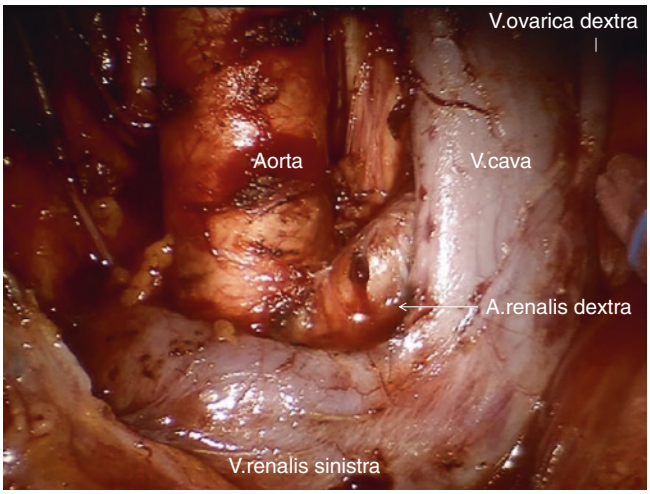

Fig. 70.28 Removal of left infrarenal mesenteric and lumbar lymph compartment (renal angle)

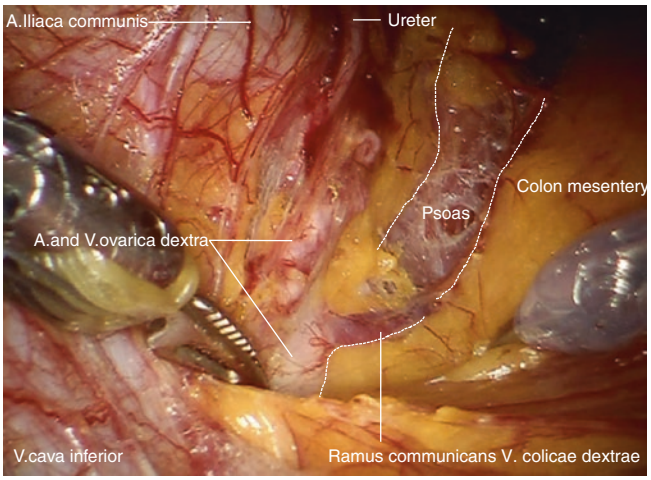

Fig. 70.30 Separation of right infundibulopelvic ligament from right colon mesentery

Step 15 in Endometrial and Ovarian Cancer (Instead of Steps 12–14)

In case of endometrial or ovarian cancer the infundibulopelvic ligaments have to be resected first; aorta, vena cava, the right ureter, and the right infundibulopelvic ligament are identified (Fig. 70.29). Mobilization of the right colic mesentery allows to identify vessel anastomoses to the ovarian vessel system and can be divided (Fig. 70.30). Following the ovarian vein the lateral border of the ovarian lymphovascular drainage bundle can be mobilized until the caval vein is reached (Fig. 70.31). Thus all anastomoses to the periaortic lymph basin will be kept intact. The duodenum usually is loosely attached to the preaortic region and has to be mobilized.

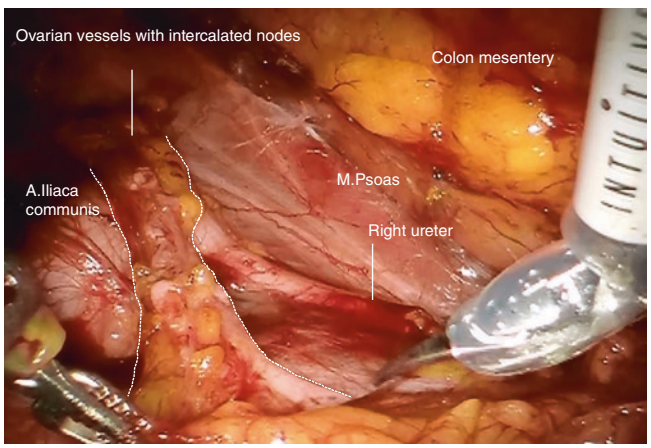

Fig. 70.31 Separation of ovarian vessel system from mesocolon, psoas muscle, ureter and caval vein

Step 16

The right ovarian vein is dissected at the level of caval vein and dissected (Fig. 70.32a). The lymphatic downstream channels may be dissected cranially along the right renal vein and dorsally to the right paracaval region to expose the back bone. The mobilized right lymphatic paraaortic compartment may now be pulled to the left, and the interaortocaval region will be exposed. The vertebral vessels will identified and and detached from lymphatic tissue as it is the case with the caval vein. Care has to be taken to remove the lumbar lymph node chain running dorsolaterally draining from deep right pelvis, which is not directly connected to the ventral chain of the mesenteric compartment. The right ovarian artery will be exposed, coagulated and divided (Fig. 70.32b). The left renal vein will be followed from its caval angle to lateral, and again the lymph channels will be dissected along the left renal vein until the left ovarian vein can be identified. The nerve fibres of the inferior mesenteric plexus are crossing ventrally, should be elevated and preserved (Fig. 70.33). The left ovarian vein is coagulated, and cut ((Fig. 70.32c). Now moving downward using the ovarian vein as lateral border and the aorta as medial border for mobilization and resection of left periaortic lymphatic basin left ovarian artery will be identified approximately at the level of right ovarian artery, coagulated, and cut (Fig. 70.32d). As described in the Chapter PMMR, the mesonephric vessel system will be removed together with the adjacent paraaortic lymph nodes.

Most important, in therapeutic lymphadenectomy, is to keep the surgical field dry to be able to safely remove the entire compartment. Although, there are plenty of vessels, which may be injured, normally it is no problem to perform surgery in a way that the vessels are kept intact or coagulated before dissected. To prevent problems prophylactically, sponges should be used instead of suction/irrigation since those are not at risk to cause additional injury and keep the field try; in addition, in venous bleeding compression with a sponge for some minutes may be very effective in controlling bleeding from smaller vessels; in larger venous lesions the application of a hemostatic patch such as Tachosil® instead of a suture is most efficient in our hands. In arterial lesions, however, a suture using 4-0 to 5-0 monofilamental unresorbable material is usually the best way to control the bleeding following clamping the proximal and distal part of the vessel transiently for endoscopic suture. Most bleedings may be managed endoscopically; prevention of any bleeding, however, is the safest way, to avoid further complications. Specifically for robotic surgery: don't risk bleeding

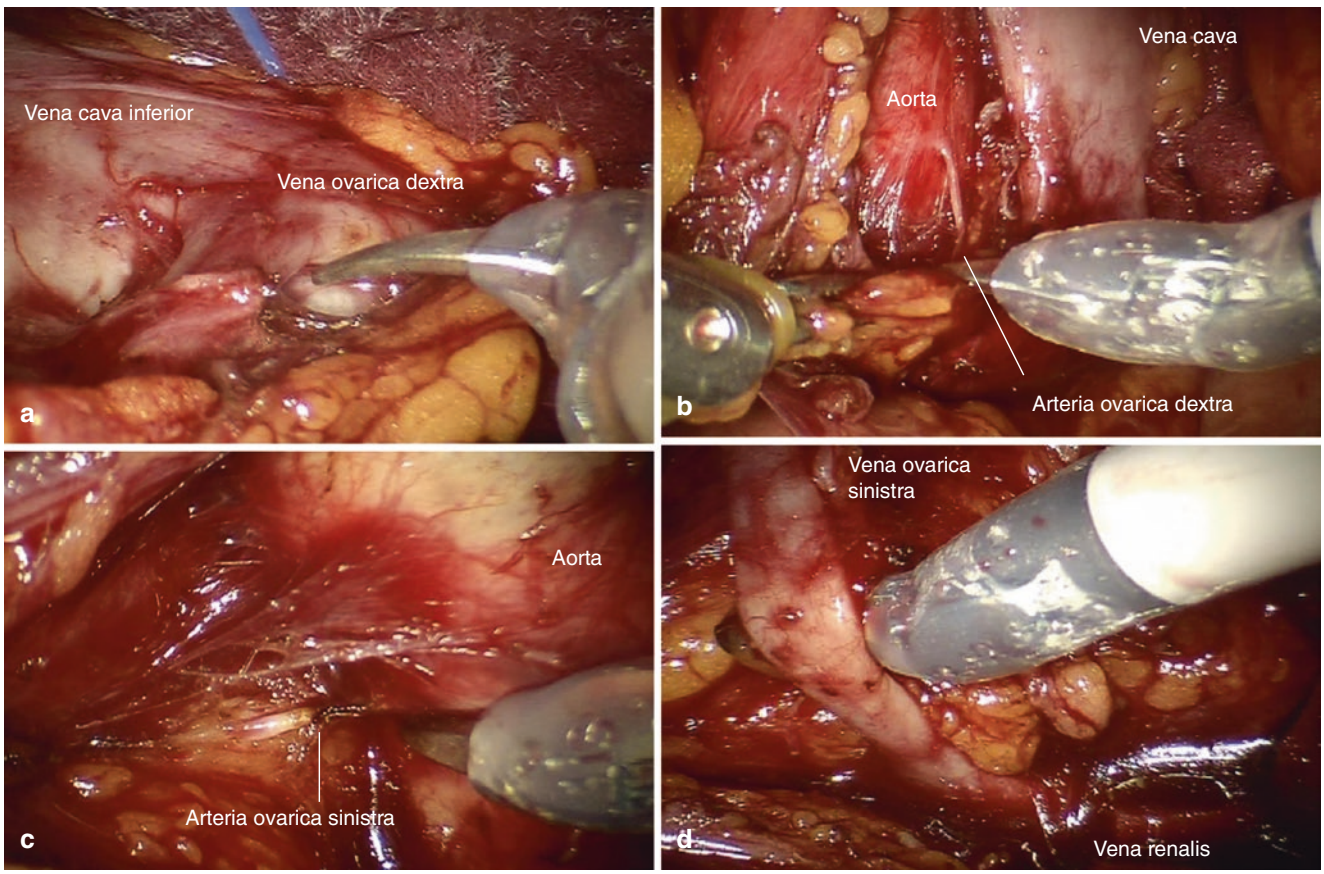

Fig. 70.32 Dissection of ovarian veins and arteries from caval and renal veins and aorta

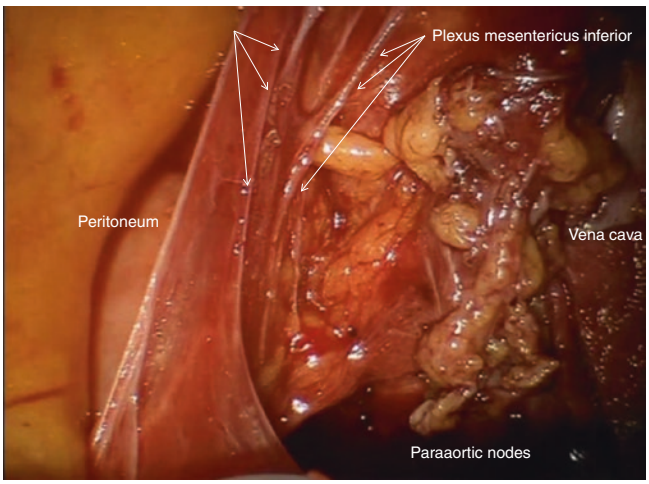

Fig. 70.33 Inferior mesenteric plexus in preparation at the infrarenal level

when you are close to the border of range of motion with your instruments! This will primarily be true using the "da Vinci SI" instead of the "da Vinci Xi".

In summary, therapeutic lymphadenectomy in cervical cancer consists of: external iliac, paravisceral, common iliac and subaortic lymph compartments. In case of positive nodes additionally the inframesenteric lumbar and mesenteric lymph compartments and if also involved the infrarenal lumbar and mesenteric lymph compartments. In endometrial and ovarian cancer all the compartments correspond to primary sites but the preischiadic and prespinal nodes of the paravisceral compartment may be spared since they will not be involved in the drainage of these subcompartments as long as lymphatic valves are intact. However, additionally, the mesonephric ovarian vascular and lymph vessel system has to be removed.

Robot Assisted Laparoscopic Fertility Sparing Radical Trachelectomy

71

Jan Persson

Introduction

In 1994 Daniel Dargent described vaginal radical trachelectomy in conjunction with laparoscopic pelvic lymphadenectomy to preserve fertility in women with early stage cervical cancer [1]. A trachelectomy can also be performed abdominally either as an open procedure or by laparoscopy. The latter approach has not gained any popularity, probably due to its complexity [2–5]. Robot assisted laparoscopic trachelectomy was first described in 2008 and may help overcome some of the surgical difficulties associated with traditional laparoscopy [6]. More than 900 cases of fertility sparing trachelectomy have been published, of those 760 with the laparoscopic/vaginal approach [7]. The procedure is considered as safe as a radical hysterectomy, with a recurrence rate of less than 5 % and a mortality of less than 3 % given strict selection criteria [7–13].

As a rule, only well informed women with a wish for preserved fertility and no previous history of infertility are candidates for fertility sparing trachelectomy. Selection criteria include cervical squamous or adenosquamous epithelial cancers from stage IAI (with lymphovascular space invasion) to stage 1B1 ≤2 cm. A more restrictive policy is advocated in case of adenocarcinomas and in particular in case of rare high risk histologies such as clear cell or neuroendocrine cancers. The tumor should be possible to resect with sufficient margins still leaving an adequate length of the remaining cervix which may disqualify women with previous large cone biopsies from being candidates for trachelectomy. If applying the aforementioned criteria, around 45 % of women younger than 40 years and with operable cervical cancer are estimated as potential candidates for fertility sparing surgery [8]. As age at first childbirth is increasing in many countries the proportion of women being candidates for trachelectomy will most likely increase further over time.

J. Persson
Genecological and Robotic Surgery, Department of Genecology and Obstetrics, Skåne University Hospital, Lund, Sweden
e-mail: Jan.persson@med.lu.se

Surprisingly, and despite the use of recommended fecundity criteria as above, Ramirez et al. report that only 43 % of women attempt to get pregnant following a trachelectomy. A 70 % pregnancy rate is reported among those with an active wish to conceive [7, 8, 14–17].

There are no studies evaluating the risk of premature birth related to the remaining cervical length but it is generally believed that the remaining cervix should be at least 10 mm to avoid a too high prematurity rate. The use of a permanent cervical cerclage may compensate for a short cervical length but may cause problems in case of a late spontaneous abortion. A cerclage placed to distally may erode to the vaginal and cause a foreign body reaction usually necessitating removal in particular if multifilament materials are used for the cerclage. The association between cervical stenosis and cervical cerclage is however unclear.

Due to the importance of radical resection and still an adequate remaining cervix, it is cruzial that the surgical approach is reproducible, allows an exact resection level and an optimal placement of the cervical cerclage.

So far, the da manufacturer of the da Vinci robot (da Vinci ® Surgical System, Intuitive Surgical Inc, CA, USA) has so far launched four different robot systems (DaVinci standard, S, Si and Xi systems) all four providing instruments with a wrist function at the tip, movement downgrading, tremor elimination, a stable 3-dimension view of the operative field and an ergonomic working position. These features may help the surgeon overcome some of the limitations associated with traditional laparoscopic surgery. As most women candidates for radical trachelectomy are nulliparous vaginal access may be restricted. Therefore a radical vaginal trachelectomy may be difficult to perform in a standardized manner and times between procedures may be long making surgical training for this particular approach insufficient. In a setting where robot assisted surgery is frequently used for other advanced gyneoncological procedures a robot assisted laparoscopic abdominal approach for the trachelectomy seems reproducible and accurate and experience from other advanced procedures helpful [18–21].

Patient Selection and Preoperative Assessment

A careful selection is mandatory to achieve the desired oncological and fertility outcome and includes women with a desire to preserve fertility and with beneficial tumor characteristics. It is important that the woman and her partner are well informed about preoperative examinations, situations in which a planned trachelectomy concept may have to be abandoned (i.e. metastatic lymph nodes or inadequate surgical margins) as well as alternative treatment in such situations. It is also important to discuss the risk of premature delivery. The cervical cancer should have diameter less than two cm (FIGO stage IAI with LVSI, IA2, IBI), preferably squamous cell cancers. IBI cancers requires a beneficial localization in the distal part of the cervix and with tumor invasion less than half the cervical stroma. A more restrictive attitude should be advocated in case of adenocarcinomas. Patients with clear cell and neuroendocrine cancers should not primarily be candidates for fertility sparing surgery. Therefore a review by an expert gynecological pathologist with focus on the histological subtype, lymphovascular space invasion, depth of invasion and in case of a cone biopsy the proximal and distal tumor margins is important. To evaluate the tumor diameter, the degree of stromal invasion against outer cervical margins and to evaluate the possibility to achieve adequate negative surgical margins a MRI is recommended. A CT scan of the thorax and abdomen should be performed to rule out disseminated disease. It is also strongly recommended that the surgeon him/herself estimates the length of the whole cervix with the use of high resolution vaginal ultrasonography to ensure both the possibility of adequate surgical margins and ideally 10 mm remaining cervix after a completed trachelectomy. A preoperative evaluation of the cervix is particularly important after a previous cone biopsy. A colposcopy is recommended to rule out cancer spread or severe dysplasia in the vagina.

Intraoperative Assessment

A radical trachelectomy may be performed in two separate sessions, an initial lymphadenectomy, and if lymph nodes are free from metastases at final histology, the trachelectomy in a second session. From a logistic and patients' perspective this approach is not ideal. Given appropriate selection, women planned for fertility sparing trachelectomy have a low risk for lymph node metastases. The sentinel lymph node concept allows an intraoperative detection of the nodes with the highest risk for metastases and a reversal of the fertility sparing approach if nodes are found metastatic at frozen section. It is still under debate whether it is safe to remove the sentinel nodes only but if used in tumors less than two cm the sentinel node technique has shown a high sensitivity and low false negative detection rate [22].

The transsection level of the cervix is cruzial. On one hand, the remaining cervix should be at least 10 mm to minimize premature childbirth and on the other hand, the tumor should be removed with adequate proximal (and distal) surgical margins to ensure safe oncological outcome without need for adjuvant treatment. The importance of the preoperative workout and surgeons' experience cannot be overestimated. It is recommended that the trachelectomy specimen and in some cases also a separate proximal disc of the remaining cervix are evaluated as frozen section as well as a being subject for an elaborate final histological workout. Finally, during surgery it is important also to investigate for and describe the presence and extent of possible factors that may impair fertility, i.e endometriosis, tubal pathology and pelvic adhesions, for proper postoperative fertility guidance and to avoid a delayed instigation of necessary assisted reproduction measures.

Surgical Technique

All models of the da Vinci robots can be used but we recommend a da Vinci Si or Xi system adapted for the near infrared fluorescent technique with the use of Indocyanine green as detecting dye. Ports should be placed for standard pelvic surgery as recommended for the respective systems. The Si robot may be docked centrally or side docked at surgeons' discretion whereas the Xi robot usually is docked 90° from the side. Suitable robot instruments are; a monopolar scissors, a bipolar forceps, a grasper and a needle holder. For the assistant one 10–12 mm trocar is needed for suction/ irrigation, insertion of sponges and loops and for retrieval of lymph nodes. We recommend to always use a nodal retrieval bag. For identification of the vaginal fornices a vaginal tube or another type of fornix presenter without an intracervical part is placed at onset of surgery.

The operation may be divided into three steps; the pelvic lymphadenectomy with detection of sentinel lymph nodes, the radical trachelectomy including dissection and lateralization of the ureters pelvic hypogastric nerve fibres and the reconstructive part including readaptation of the vagina to the remaining cervix and placement of a permanent cerclage. To avoid time loss during waiting for frozen section, it is important to perform the different steps in a correct order depending on local logistics for frozen section.

For detection of sentinel lymph nodes we inject a total of one mL Indocyanine green (diluted to 2.5 mg/mL in sterile water) slowly submucosally at 2-4-8-10 o'clock in the cervix immediately before docking the robot.

The identification of nodes starts with a careful development of the pararectal and paravesical spaces during which

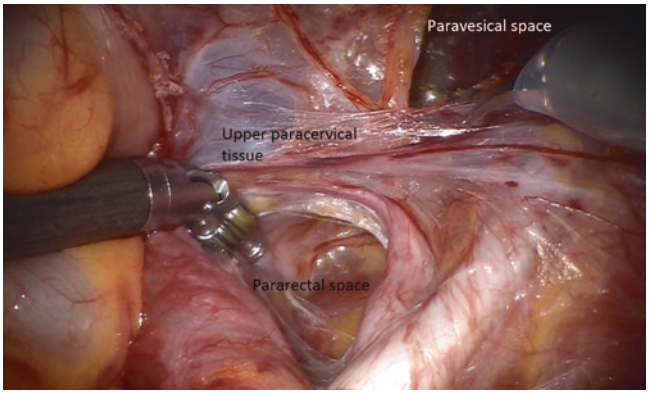

Fig. 71.1 The upper paracervical tissue is kept intact by opening the avascular paravesical and pararectal spaces

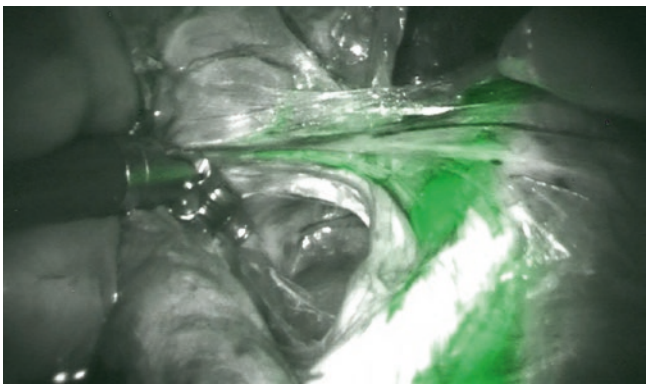

Fig. 71.2 Lymphatic vessels and a sentinel lymph node appears green with the use of the near infrared fluorescent technique and indocyanine green injected into the cervix

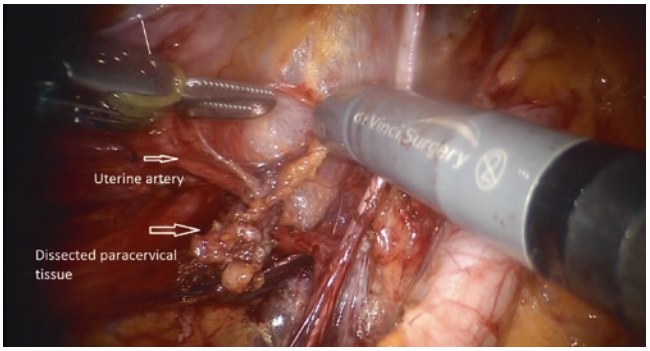

Fig. 71.3 The upper paracervical tissue is removed separately sparing the uterine artery

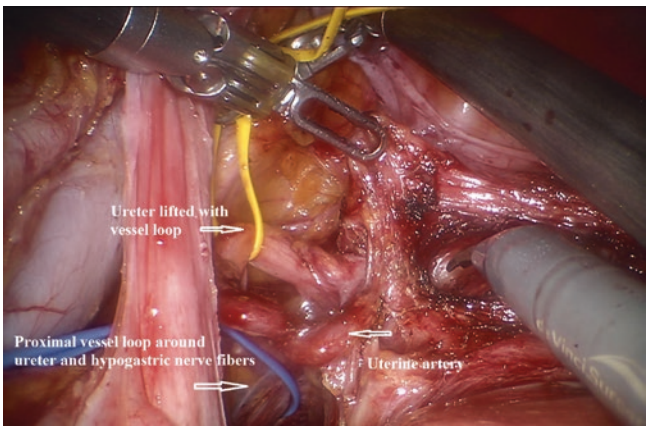

Fig. 71.4 Vessel loop placed around the ureter distal of the uterine artery

it is important to leave the upper paracervical tissue and lymph vessels intact to avoid spillage of dye and to enable a detection of individual lymph vessels (Fig. 71.1). The sentinel nodes are removed separately and sent for frozen section along with any clinically suspect nodes (Fig. 71.2). In case of a no uptake of Indocyanine green a full pelvic lymphadenectoomy has to be performed at the respective pelvic side wall and in this situation it is particularly important to look for macroscopically suspicious nodes for analyse during surgery. Awaiting frozen section results, the common iliac nodes are removed bilaterally. This is most easily done by opening the peritoneum along the medial part of the right common iliac artery to the level of the aortic bifurcation and on the left side by lifting the sigmoid colon together with the ureter and infundibulopelvic ligament with the fourth robot arm to get full access to the nodes. Local treatment protocol and the histology and size of the cervical cancer decide whether removal of the sentinel nodes only should be considered safe or if the frozen section results should be used only for tailoring of the further lymphadenecomy and abortion of the trachelectomy concept if sentinel lymph nodes are metastatic. After the remaining pelvic lymphadenectomy (if so required) the uterine arteries are identified together with the upper paracervical tissue. The ureters are then dissected and visualized also at the ventral and distal side of the uterine arteries to enable a careful removal of the upper paracervical tissue sparing the uterine arteries and visualizing the descending uterine artery (Fig. 71.3). Vessel loops are placed around the ureter distal of the uterine artery to facilitate later dissection of the lower paracervical tissue and bladder pillar (Fig. 71.4).

The posterior dissection starts with a further dissection of the pararectal space to identify the hypogastric nerves. The medial broad ligament is then opened and by developing the Okabayashi space the lateral nervous part of the sacrouterine ligament is separated from the medial fibrous part (Fig. 71.5). Vessel loops are then placed around the ureter and the nervous part of the ligament for retraction and to help identification of the hypogastric nerve fibers during further dissection (Fig. 71.6). The rectovaginal space is then opened to facilitate division of the fibrous parts of the sacrouterine ligaments at the desired level. Then the anterior peritoneum is opened (leaving the round ligaments intact) and a strict

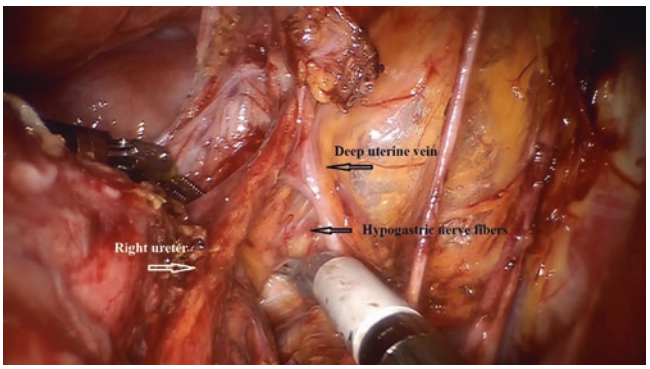

Fig. 71.5 The Okabayashi space is opened to separate the medial fibrous and lateral nervous parts of the sacrouterine ligament followed by lateralization of the ureter and nerves with a vessel loop (Jan Persson 2012)

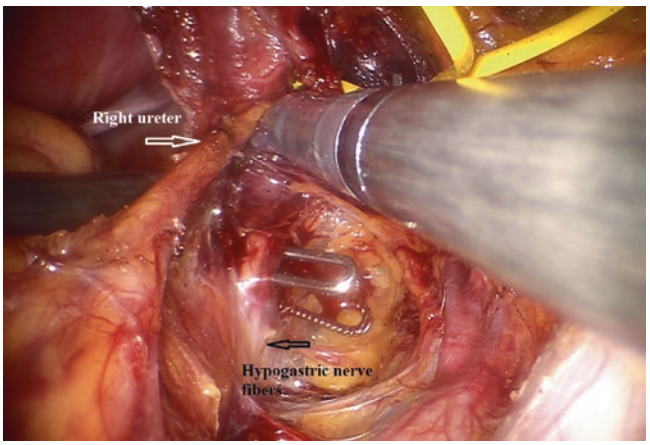

Fig. 71.6 Identification and dissection of the lower paracervical tissue and bladder pillar (left side)

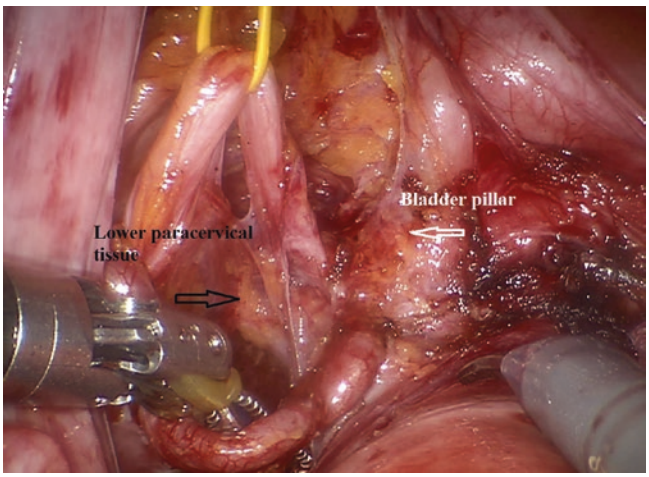

Fig. 71.7 The vaginal tube helps identification of the vaginal fornices and estimation of an appropriate length of the vagina

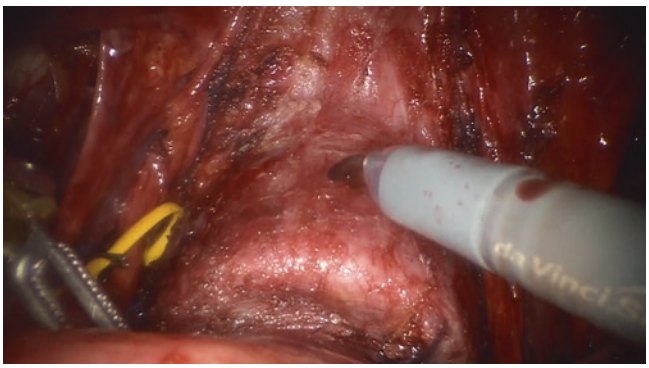

Fig. 71.8 The level of cervical transsection is dediced with help of the uterine contour after the vagina is opened

midline dissection of the bladder is performed to separate the bladder pillars for later division. Before the final lateral dissection the descending uterine arteries are identified and ligated twice on each side allowing to allow cutting in between them without blood loss. The further lateral dissection (lower paracervical tissue) and dissection of the bladder pillar is facilitated by the aid of the previously placed second vessel loop around the ureter distal of the intact uterine artery (Fig. 71.7). By the use of separate vessel loops around the hypogastric nerves and the distal ureters the bladder branches of the nerves may be identified and saved along their course in the lower paracervical tissue. Finally, the vagina is dissected distally approximately 1.5 cm further than the desired vaginal cuff specimen length to mobilize enough vaginal tissue for a sufficient reaattachment to the cervix (Fig. 71.8). With the preoperative vaginal ultrasonography and tumor localization in mind a careful planning of the cervical transsection level is important. The outer contour of the uterus as well as the level of the approaching main uterine branches is a good help for defining the level of the proximal uterine isthmus (Fig. 71.9). The vagina is opened at the desired level to facilitate the transsection of the cervix by visualization from the vaginal and abdominal side. The whole trachelectomy specimen is sent for frozen section to ensure negative margins. It is recommended to dye the proximal and distal edges of the specimen to simplify its orientation for the pathologist. Awaiting the final frozen section results the vagina is reattached to the remaining cervix with resorbable mattress sutures in order to cover most of the cut cervix but still leaving the new external orifice free. The suturing should start at the lateral corners of the vagina to ensure an even distribution of the opened larger vaginal circumference around the smaller cervix (Fig. 71.10). Finally, a permanent monofilament non resorbable cerclage (i.e 0 Prolene) is placed at the level of the inner os. The cerclage is placed medial of the uterine arteries. The tension of the cerclage suture is decided visually with the aid of a posterior sliding locking knot gradually tightened to achieve a slight induration of the tissue (Fig. 71.11). No intracervical device is

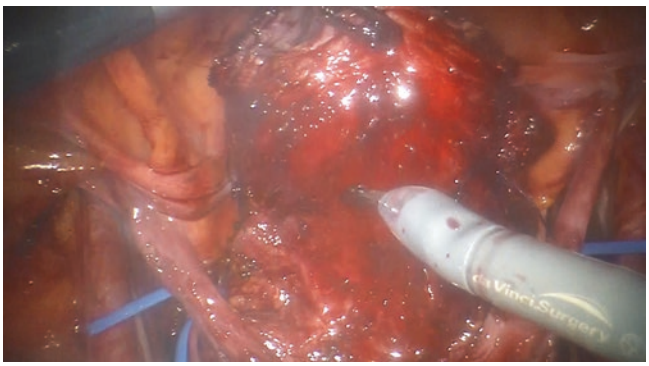

Fig. 71.9 The vagina is sutured to the remaning cervix starting at the lateral corners to ensure an even distribution of vagina anteriorly and posteriorly

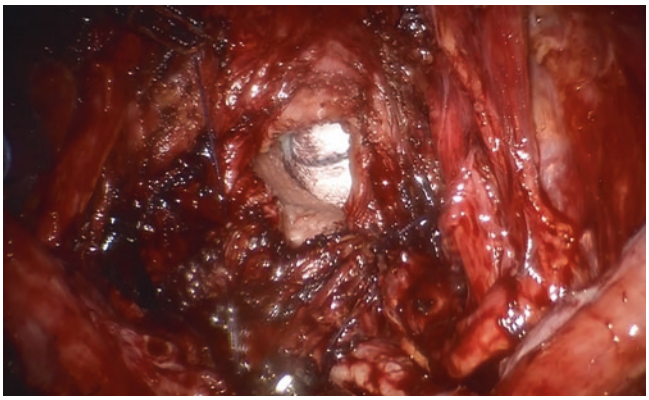

Fig. 71.10 A permanent monofilament suture is placed medial of the vessels at the level of the upper uterine isthmus

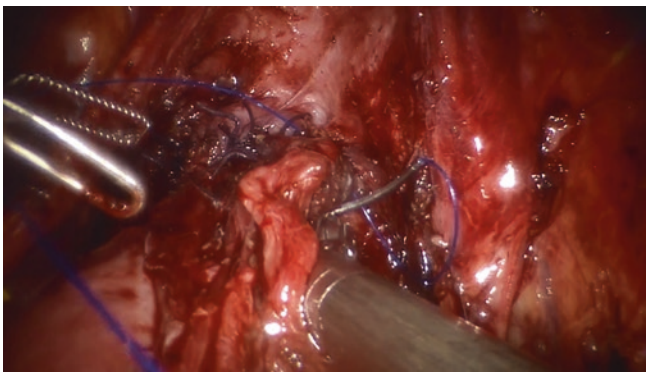

Fig. 71.11 Laparoscopic view three weeks after a robotic radical trachelectomy

necessary to secure patency of the cervical canal. A final check of the readapted uterus should be done.

If proximal margins are insufficient it may in selected cases be place for removal of an extra part of the cervix. If the margins are tumor involved a conversion to a radical hysterectomy is recommended, simply by releasing the vaginal/cervical sutures and cutting the round ligaments and by releasing the ovaries. The ovaries can then be tunnelled retroperitoneally and transpositioned in the paracolic gutters at desired level. Figure 71.11 shows a laparoscopic view of the pelvis three weeks after a robotic trachelectomy.

Postoperative Care and Follow Up

Postoperative surgical morbidity is low frequent after a vaginal or laparoscopic trachelectomy. Most side effects are due to the lymphadenectomy. An early onset moderate abdominal swelling or a proximal lymphedema of the vulvar area, labiae and inner thighs may be scaring for the patient but are usually self limiting. Postoperative urinary retention is rarely a problem but should be controlled. Bleeding from the cut cervix may occur similar to after a large cone biopsy. Fertility sparing trachelectomy is associated with cervical stenosis and rejection/exteriorization of the cervical cerclage. A cervical stenosis is associated with subsequent infertility and may hinder retrieval of intracervical cells for Pap-smear during follow up. Rejection of parts of the suture used for cervical cerclage is likely associated with a too distal placement of the suture. One study indicates that robotic trachelectomy, compared with vaginal trachelectomy, results in a cerclage placement closer to the inner cervical os, theoretically beneficial for reducing both the rate of cerclage erosion and the rate of preterm delivery [19].

No commonly used criteria for timing of pregnancy after surgery exist. It may be advisable to await a negative Pap-smear at first follow up 3 months after surgery. It is unclear whether antibiotic prophylaxis and general advise during pregnancy reduces the risk for prematurity. Some centers advocate the use of oral Metronidazol from gestational week 16 to 22, no sexual intercourse and in case of a strenuous work sick leave from week 22 + 0 and throughout the pregnancy.

All patients should be planned for a Cesarean delivery and informed to seek immediate help in case of premature uterine contractions. A particular problem with the permanent cervical cerclage is late first trimester or second trimester miscarriages necessitating a removal/ division of the cerclage to enable a complete transvaginal evacuation of the fetus and placenta without the need for a Sectio Parva. Cutting of the cerclage can be performed via a posterior culdotomy or laparoscopy and the cerclage may later be replaced laparoscopically. In general we discourage from the use of IUD as contraceptive due to a potentially increased risk for ascending infections.

Protocols for follow up usually advocate controls every 3–4 months the first 2 years, then every 6 months until 5 years after which the patient may be subject to routine controls or on an individual basis. It is important to harvest intracervical cells for Pap-smear. It should be indicated that the patient has

been subject to a trachelectomy as the cytological evaluation may be more difficult to interpret. A HPV test may add further information. A colposcopy and guided biopsies or cervical curettage should be performed in case of aberrant bleeding and a pathological Pap-smear. It is however common with aberrant vaginal bleedings in particular the first 6–12 months due to exteriorization of intracervical mucosa. As quality control, a vaginal ultrasonography can be performed to evaluate the length of the remaining cervix, the placement of the cerclage and to rule out retention of menstrual blood in the uterus as a sign of a cervical stenosis. MRI or PET-CT investigations should be performed if clinically indicated.

Some patients ask for a post trachelectomy hysterectomy after finalizing childbirth. This may be performed after proper counselling as a second operation will further shorten the vagina. As a post-trachelectomy hysterectomy, preferably by a second robot assisted laparoscopic approach, may be complex the operation should be performed by an experienced gynecological oncologist and include a thorough inspection of the whole pelvis.

Robotic-Assisted Radical Hysterectomy with Anterior and Posterior Exenteration-Urological Perspectives

72

Saad Hatahet, Ahmad Shabsigh, Dimitrios Moschonas, and Petros Sountoulides

Introduction

Pelvic exenteration (PE) describes a radical surgery involving the en bloc resection of the pelvic organs, including the internal reproductive organs, the urinary bladder and the rectosigmoid. Indications include advanced primary or recurrent pelvic malignancies, most commonly local or locally advanced cervical and bladder carcinomas.

From an urological point of view, PE has been utilized for the treatment of localized or locally advanced bladder cancer. Bladder cancer is one of the most common urologic malignancies in the world. In the USA, about 74,000 new cases are expected to be diagnosed in 2015, with an estimated 16,000 deaths related to them [1]. At initial diagnosis, more than 70 % of patients have Non-Muscle-Invasive Bladder Cancer (NMIBC). These less aggressive neoplasms are generally treated with transurethral resection of bladder (TURB) with or without intravesical immuno or chemotherapy [2]. Radical cystectomy (RC) with bilateral pelvic lymphadenectomy is still the gold standard treatment for the local control of non-metastatic muscle invasive bladder cancer (pT2-T4aN0M0) [3]. Radical cystectomy is one of the most morbid surgeries in urologic oncology. It is associated with high post-operative complication rates (27–64 %) [4], high risk of readmission, and re-operation. Over the last few decades, numerous modifications of the surgery were developed to reduce the post-operative morbidity and the long-term impact of this major operation. Minimally invasive techniques, continent urinary diversions, and better perioperative management all aim to achieve these goals. In the following few pages we review the history, surgical steps and outcomes of robotic assisted radical cystectomy in the setting of total pelvic exenteration.

History of Laparoscopy and Robotic Surgery in Bladder Cancer Management

The first laparoscopic simple cystectomy was reported by Para in 1992 [5]. A year later, de Badajoz performed the first laparoscopic radical cystectomy for bladder cancer with an ileal conduit urinary diversion [6]. By the year 2000, experienced minimally invasive surgeons took advantage of better laparoscopic instruments, and performed the first two cases of laparoscopic radical cystoprostatectomy with intracorporeal ileal conduit [7].

Shortly after the Da Vinci surgical system was approved by the Food and Drug Administration (FDA) in 2000, the Vattikuti Urology Institute in Henry Ford Hospital reported the nerve-sparing robot-assisted radical cystectomy (RRC) for in 17 bladder cancer patients (14 men and 3 women) [8]. In 2003, Beecken and his colleagues performed the first robotic radical cystectomy and completely intra-abdominal formation of an orthotopic neobladder [9].

Over the last decade, the use of the Da Vinci system became more prevalent. By 2012, more than 400,000 robotic surgeries were done in the USA, triple the number just four years earlier. In 2013 almost 1,400 U.S. hospitals (nearly 1 out of 4) had at least one Da Vinci system. By June 30, 2015, there were 3,398 units worldwide, 2,295 of them in the United States (Intuitive LLC).

The early reports of RRC were promising. Not surprisingly, the operation took more time than open radical cystectomy. More importantly, RRC was associated with lower post-operative morbidity. As expected, there was a rapid adaptation of technology. Data from 279 hospitals across the United States revealed an increase in RRC rates from 0.6 % in 2004 to 12.8 % in 2010 [10]. Currently, most, if not all, large oncology centers in the USA utilize robotic assisted radical cystectomy.

Laparoscopic Radical Cystectomy (LAR): Benefits and Difficulties

Since its inception, laparoscopic radical cystectomy remained a technically challenging procedure. The inherent constraints of laparoscopic instruments and the challenging nature of minimally invasive pelvic surgery prevented the wide adaptation of this technique. Even with these difficulties, most published studies have shown LAR to be feasible with less morbidity and mortality, and comparable oncologic outcomes compared to open surgery.

Recently, a meta-analysis of sixteen eligible case series reports comparing LRC vs ORC was performed. The study confirmed the safety and feasibility of LRC. It was clear that while the average operative time for LRC was longer, laparoscopic radical cystectomy was associated with significantly fewer overall complications, less blood loss, shorter length of hospital stay, less need of blood transfusion, shorter time to ambulation, shorter time to regular diet, and less narcotic requirement [20]. Surprisingly, there were fewer positive surgical margins, positive lymph node, lower distant metastasis rate, and lower mortality with LRC. These findings are more likely to be related to patients' selection than true better oncologic outcome with laparoscopic surgery [11].

Robotic Radical Cystectomy Benefits

The robotic systems provided reliable solutions for most of the difficulties encountered during laparoscopic surgery. Surgeons can benefit from the magnified 3D high-definition vision system and special wristed instruments that bend and rotate far greater than the human wrist, allowing the surgeon to perform difficult dissections and suturing. A surgeon's hands tremors or sudden strong moves are not transmitted to the robotic arms, protecting patients from accidental errors and enhancing their safety. Despite the surgeon's loss of real tactile sensation of the tissue with the Da Vinci system, surgeons were able to use the visual clues to perform safe and efficient surgeries. More importantly, there was a significantly shorter learning curve compared to laparoscopy, increasing the benefit of minimally invasive surgery for patients with bladder cancer.

Pelvic Lymph Node Dissection (PLND) in Radical Cystectomy

General Aspects

Bilateral pelvic lymph node dissection is an essential part of surgical therapy for bladder, prostate and gynecologic malignancies [3, 12, 13]. To develop the needed skills to perform adequate lymph node dissection, surgeons need to commit significant time and effort to learn the subtleties of systematic and efficient dissection. In most cases, skilled surgeons spend more time performing pelvic lymph node dissection than the time required to complete the exenteration. Unless cystectomy alone is considered, it is recommended that PLND is done first. This sets the surgical fossa for a fast and easy radical cystectomy, helps define the vascular pedicels of the bladder and the prostate, and gets the pelvis ready for urinary diversion.

Technically, there is no reason that the same lymph node dissection done in open surgery is not duplicated robotically. With appropriate port placement and exposure, robotic pelvic lymph node dissection achieves comparable results to open surgery [14].

How Many Lymph Nodes Should Be Dissected?

The number of lymph nodes identified after surgery depends on multiple factors, including the limits of the dissection and its thoroughness, the pathologic processing, and how meticulous the pathological examination is. In practice, wider and more systematic resection leads to an increase in the likelihood of identifying positive LNs. Furthermore, extended LNs dissection not only provides the most accurate staging but may also offer the patient the best chance of survival [15–17].

With increased experience, the number of lymph nodes dissected during RC increased substantially between 1988 and 2010 (≥10 nodes removed as an adequate number). However, a minority of patients still do not receive LND, and removing >14 lymph nodes has been shown to improve progression-free survival [18].

Limited (Standard) Pelvic Lymph Node Dissection

Standard PLND was described by "Stewart's Operative Urology" and includes the pelvic sidewall between the genitofemoral and obturator nerves, and bifurcation of the iliac vessels to the circumflex iliac vein [19], including all lymphatic tissues around the common iliac, intercommon iliac, and internal iliac groups, and the obturator group bilaterally [20, 21] (Fig. 72.1).

Up to one-third of all positive lymph nodes are located around the common iliac artery. About 80 % of all positive nodes could be cleared completely by standard PLND, including all lymphatic tissues along the common, external, and internal iliac regions [14, 16, 22]. Some experts recommend doing frozen section on the true pelvis LNs; if the frozen section examination revealed no positive LNs, LN dissection does not need to be carried out further. If, however, the frozen section examination is not performed, or if it identifies positive nodes, an extended PLND is done [21].

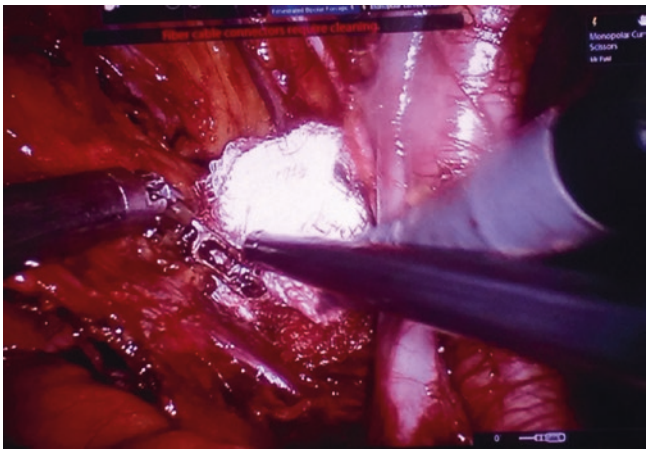

Fig. 72.1 Taking care of minor bleeding during robot-assisted lymph node dissection at the time of radical cystectomy

Extended PLND Limits and Benefits

Extending the dissection up to the aortic bifurcation or the inferior mesenteric artery increased the detection of positive nodes by 13–16 % [16, 20].

A recent lymphatic bladder mapping study suggests that the template for an appropriate PLND at cystectomy should include the external iliac (including the fossa of Marcille), obturator and internal iliac region (lateral and medial to the internal iliac vessels), as well as the common iliac vessels up to at least the uretero-iliac junction bilaterally [17].

Standard PLND is associated with suboptimal staging, and a higher rate of local progression. In contrast, extended PLND provides better 5-year recurrence-free survival for patients with lymph node positive disease. Even patients with pT2N0 or pT3N0 bladder cancer have better prognosis after RC and extended pelvic lymph node dissection [16, 17, 23].

The possible benefits of higher resection must be weighed against the potential increased demands in both time and extent of surgical field, the increased risk of complications, and injury to the autonomic sympathetic nerves, threatening both sexual function and continence in patients who are candidates for orthotopic bladder substitution [17].

Robotic Radical Cystectomy: Surgical Technique

Patient Preparation

Bowel preparation before radical cystectomy and urinary diversion does not provide any advantage. It does not seem to impact the rates of perioperative infectious, wound, and bowel complications [24, 25]. Omitting bowel preparation before ileal urinary diversion is safe, and not associated with bacterial overgrowth or added complications [24]. To the contrary, avoidance of preoperative bowel preparation led to early restoration of intestinal function and shorter hospital stay [25, 26].

Improving performance status prior to surgery is essential. Proper nutrition, ambulation, and relieving ureteral obstruction with ureteral stent or nephrostomy tube are all good measures that should be considered if possible. Post radical cystectomy venous thrombus events are common [4, 27]. Thus, wearing compression socks, using sequential compression devices, and perioperative anticoagulation are indicated for these patients [28].

Positioning

Lithotomy position with legs in Allen Yellowfins stirrups (Allen Medical Systems, Acton, Massachusetts) is the standard position during RRC. This allows the Robot cart to be moved between the patient's legs. All pressure points should be padded for safety and the patient should be secured to the table. The patient should then be put in a steep Trendelenburg position, which helps in mobilization of the small bowel for better access to the pelvis. The assistant can stand on either side of the patient. After prepping and draping the patient, a 20–22 Fr Foley catheter should be inserted in the bladder. In female patients a sponge on stick can be placed in the vagina to help in identification of vaginal cuff. We personally like to use EEA reusable stainless steel sizer and vaginal pneumo-occluder.

Port Placement in Four-Arm Robotic Approach

To facilitate proximal lymph node and ureteral dissection, the port placement is considerably more cephalad in comparison with robotic assisted radical prostatectomy. The camera 12-mm port is placed 3–8 cm above the umbilicus while the three working 8 mm robotic ports are placed 2–5 cm above the level of the umbilicus in an arch line. If the patient had prior surgeries, the first port is usually placed under direct vision away from the scars. The abdomen is then inspected, and any adhesions are taken down.

A 12 or 15-mm assistant port is placed slightly more caudal and lateral; this positioning allows for improved angulation during stapling of the bowel reconstruction. The 15-mm port is used to pass the 15-mm Endocatch bag as well. In females, if possible, the specimen is extracted via the vagina. Additional 12 mm assistant port could be used and placed laterally in the level of robotic ports on the side of the assistant [29].

Bladder Removal and Extended PLND

Right Ureter Dissection

The posterior peritoneum is incised around the cecum. The incision is extended laterally at the white line of Told and medially anterior to the right common iliac artery. The right ureter is identified over the common iliac artery. The ureter is dissected off the common iliac artery. A vessel loop is used to to mobilize the ureter by the assistant. The ureter is dissected distally all the way to the superior vesical artery. It is very important to preserve as much of the peri-ureteral tissue as possible to avoid ureteral ischemic injury. The ureter can be clipped distally with two clips and cut between them at this time, or just prior to taking the bladder pedicels. Distal ureteral margin can be sent for frozen section. It is recommended to use Hem-o-lock to clip the ureter and take a suture at the corner of the distal ureter end; this will help in handling the ureter and reduce traumatic injury to the ureter [30].

Extended PLND

The first important role of a thorough and efficient pelvic lymph node dissection is exposure and setting up the field. After isolation of the right ureter, the hypogastric artery is dissected to the obliterated medial umbilical ligament. This is usually retracted medially, to expose the medial side of the external iliac and obturator lymph nodes. The dissection is carried on both sides of hypogastric vessels to the perirectal fat. This will isolate the obturator fossa from the hypogastric lymph node packet. Attention is then paid to the lateral limits of the dissection. The femoro-genital nerve is identified and isolated. The external iliac lymph nodes are pushed medially. We recommend that the lateral limit of the dissection is developed at this point by dissecting the right external iliac and obturator lymph nodes medially of the pelvic side wall. Small vessels and lymphatics should be cauterized. Splitting the lymphatic tissue over the entire extent of the right common iliac artery and right external iliac artery is recommended. The tissue is dissected on both sides of the right external iliac artery and vein. The distal side of the external iliac packets should be clipped to reduce the formation of symptomatic lymphocele. Next the right obturator nerve and vessels are identified. The obturator lymph node packet is then dissected off the posterior edge of the external iliac vein all the way from the bifurcation of the iliac arteries to the lymph node of cloquet. The lymph nodes are then dissected off the anterior side of the obturator nerve. It is strongly recommended that the proximal end of the packet is dissected first. This will prevent the obturator lymph nodes from dropping and making the dissection of the proximal end more difficult. The distal side of the packet is then clipped. The lateral hypogastric lymph nodes are then dissected. The right common iliac lymph nodes are dissected all the way to the lateral edge of the right common iliac vein and IVC. Followed by the dissection of the right fossa of Marcille, this is done by retracting the right common iliac vein medially. Attention to the proximal end of the obturator nerve is important. The tissue is then dissected in a medial direction exposing the left common iliac vein and anterior surface of the sacrum. The lymph nodes of the left common iliac vein are then removed. Use of bipolar is recommended to control the small vessels at the inferior side of the left common iliac vein toward the sacrum. The lymph nodes anterior to the sacrum and at the medial side of the hypogastric lymph nodes are removed. The right and left common iliac node packets are clipped and divided at the anterior side of the bifurcation of the aorta and also starts the left pelvic lymph node dissection by exposing the medial aspect of the left common iliac artery which will serve as a landmark after the leftcolon is reflected. This will help in developing the mesenteric window that is used to pass the left ureter to the right side of the pelvis. After completion of the medial dissection, the lymphatic packet is mobilized laterally.

Additionally, this approach allows improved exposure of the internal iliac vein. The lymph nodes should be placed in a 10 mm specimen retrieval bag and can be removed in appropriate packets through the 12 or 15 mm port. In order to limit cost, a reusable 10 mm bag can be used for all lymph node packets [30].

Left Ureter Dissection

The sigmoid colon is mobilized at the white line of Told, then it is mobilized medially with the forth arm (Prograsp forceps). This usually exposes the left ureter anterior to the left common iliac artery. The ureter is dissected all the way to the superior vesical artery. At this point we usually develop the mesenteric window caudal to the inferior mesenteric artery. Caution should be taken to avoid injury to the colon blood supply. The left pelvic lymph node dissection is then performed.

The Posterior Dissection in Women

Unless fertility preservation is a consideration, the surgeon should remove the uterus, ovaries, and Fallopian tubes with or without anterior vaginectomy. This depends on the location of the bladder cancer and the stage of the disease. Examination under anesthesia and pre-operative imaging are essential in this decision. If the female genital organs are spared, the peritoneum is incised at the posterior bladder wall between the bladder and the uterus. The plane is developed inferiorly and laterally to reach the lower ureters which should be dissected. The rest of the surgery is similar to the full pelvic exenteration.

Since cystectomy is much more common in elderly patients, sparing the female genitalia is rare and full pelvic exenteration is usually done. In this case the gonadal vessels

are clipped at the time of ureteral dissection. Attention should be to the infindibulopelvic (IP) ligaments, which should be clipped and cut. By continuing dissection inferiorly, the uterine artery should be identified and clipped. The sponge stick or the vaginal sizer is pushed anteriorly in the posterior fornix. If the anterior vaginal wall is removed with hysterectomy, the vaginal sizer is pushed and the vaginal cuff is incised posterior to the cervix. The vascular pedicles of the bladder are defined, dissected, clipped and cut bilaterally. Then the vesico-vaginal space is dissected inferiorly, all the way to the urethra, and if vagina is persevered then performing a supra-cervical hysterectomy. After the anterior dissection (discussed in a following section), the vagina is closed with figure of eight absorbable sutures.

Bladder Pedicles and Neurovascular Bundles Dissection Nerve-Sparing Technique

The anterior peritoneum is incised lateral to the medial umblilical ligaments and the urachus. The bladder should not be dropped at this point, as it would increase the difficulty of bladder pedicle dissection and control.

The right and left ureters are double clipped with Hem-o-loc clips and incised as close as possible to the bladder. The endopelvic fascia is incised and opened to the prostato-urethral junction. At this point the vascular pedicles of the bladder are defined, clipped or stapled with an Endo-GIA or bipolar device like the Ligasure.

Unless nerve sparing is contraindicated, the neurovascular bundles should be identified close to the tips of the seminal vesicles. The dissection starts immediately next to the walls of the seminal vesicle, between the vesicle and the posterior layer of Denonvillier's fascia; high anterior dissection is preferred. A combination of antegrade and retrograde dissection of the neurovascular bundle is done similar to robotic radical prostatectomy. Use of electrocautery during dissection of the pedicles is controversial. Some surgeons recommend avoiding any thermal injury, while others advocate the safety of bipolar devices [8, 31–33]. Finally, nerve sparing should be carried down to the genitourinary diaphragm to prevent injury during the apical and urethral dissection.

Anterior Bladder Wall Dissection

The urachus is incised; attention to the small vessels at the proximal end is important. The bladder is dropped from the anterior abdominal wall all the way to the space of Retzius towards the bladder neck.

If neobladder urinary diversion is planned, the puboure-thral suspensory ligaments should be spared to avoid extensive dissection of the urethra for better preservation of the urethral sphincter complex and its nerve supply.

Urethral Dissection and Removal of the Bladder Specimen

When reaching the anterior wall of the bladder neck, the Dorsal Vein complex should be identified and ligated with 0 polysorb suture or stapled with EndoGIA. In females, flexible cystoscopy helps to identify the proximal limit of the urethra and the relationship to the tumor. This facilitates excellent preservation of the urethra and improves the recovery of continence after neobladder diversion. Preservation of the neurovascular bundles lateral to the urethral is achieved by blunt and gentle dissection. Similarly, for male patients, the apex of the prostate is dissected superiorly to obtain adequate urethral stump. Avoidance of spillage is achieved by leaving a catheter balloon inflated, grabbing the catheter with Prograsp forceps and cutting distally. The catheter can then be used to lift the specimen until it is placed in an Endobag. Alternatively, the catheter can be removed and the bladder neck can be closed with a figure of eight suture. If neobladder urinary diversion is planned, urethral margin sample should be sent for frozen section. This can be taken from the bladder neck.

Urinary Diversion

One of the main questions when performing a urinary diversion after a robot-assisted cystectomy, is whether to create the urinary diversion intra- or extracorporeally? The standard types of urinary diversion that are used in a classical open radical cystectomy could be performed in RRC. The first extracorporeal ileal conduit was described by Menon et al. [8]. In this approach, a periumbilical extraction incision is usually sufficient. We would recommend that the ureters are tagged with full length 2-0 suture robotically prior to opening the abdomen. This will help in bringing the ureters to the extraction incision for anastomosis. An Alexis retractor can be used to facilitate the extracorporeal construction of the ileal conduit. It is recommended that a continent cutaneous urinary diversion should be done in an extracorporeal fashion as well.

Intracorporeal Ileal Conduit Formation

Isolate the Bowel Segment

To isolate the bowel segment, the ileocecal valve is identified first. Using a marked umbilical tape, the distal end of the bowel segment is defined approximately 15–20 cm from the ileocecal valve. Some surgeons prefer Intraoperative fluorescence imaging to evaluate the segment's blood supply [34]. Double 3-0 silk sutures are placed on both the proximal and distal end of the ileal conduit for retraction. The bowel segment is then isolated and stapled using a 60 mm Endo-GIA stapler with bowel staples.

The bowel continuity is restored by a standard side-to-side anastomosis using a 60 mm Endo-GIA stapler through the assistant 12 mm assistant port. Three 3–0 silk sutures are placed spaced 2 cm apart on the anti-mesenteric sides to re-approximate the segments of bowel and to aid in completing the side-to-side anastomosis. The stapler should be applied at the anti-mesenteric ileum border. Finally the mesenteric window is closed with interrupted 3-0 silk sutures.

Uretero-Intestinal Anastomosis

The anastomosis between the ureters and the bowel segment could be performed by either Wallace technique or Bricker techniques [7, 30].

Wallace Technique

A stay suture is placed to hold the two ureters ends together. The ureters are spatulated 2 cm long. The posterior walls of the ureters are sutured side-to-side using a 4-0 polyglactin suture. Two single-J, 90-cm ureteric stents or 8 Fr pediatric feeding tubes are introduced over a guide wire. Double J stents can also be used. Using the Prograsp forceps, the stents are pulled through the afferent limb and pushed up into the ureters on each side. The uretero-ileal anastomosis between the Wallace plate and the pouch is performed according to a modified van Velthoven et al. technique. A suture is placed close to the distal end of the conduit to help with maturation of the stoma. Finally, the stoma is performed in the standard method after de-inflating the abdomen [30]

Bricker Anastomosis

Two small incisions are made in the ileal conduit near its proximal edge. The ureters are spatulated as mentioned before. We prefer to place a 5-0 silk suture as a sty suture between the peri-ureteral tissue and the ileal conduit. This can facilitate the anastomosis. The uretero-enteric anastomosis is done by placing one 4–0 polyglactin sutures at each sides of the anastomosis, and then continue the anastomosis with some interrupted sutures. Stents are placed and the anastomosis is completed (Fig. 72.2).

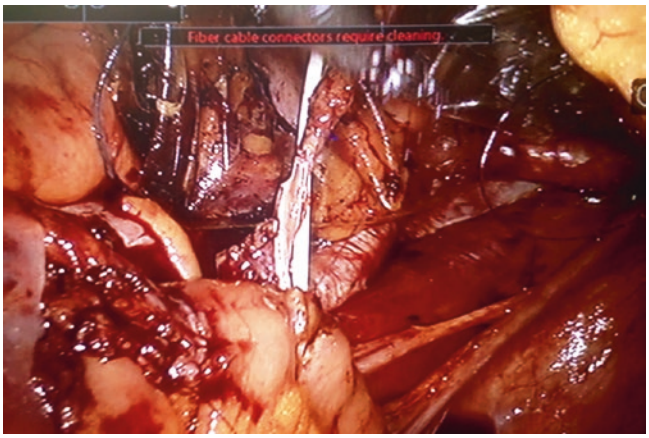

Fig. 72.2 Uretero-iliac anastomosis during a Bricker urinary diversion. The stented ureter is ready to be anastomosed to the isolated ileal segment

Intracorporeal Neobladder Formation

Robotic intracorporeal neobladder reconstruction is more challenging. Initial perioperative results seem to be comparable to open series [35]. Some researcher reported that it can be performed in a safeand reproducible fashion, even during the early learning curve [36].

There are general concepts that are used in all types of intracorporeal neobladders. The first general step is returning the patient's position from the Trendelenburg position to the supine position. This allows the bowels to move back to the lower abdomen cavity, reducing the tension off the urethro-enteric anastomosis. Second, isolating the bowel segment is done in the same fashion as described earlier. The length of the bowel segment depends on the type of the neobladder that is planned. Third, we recommend that a 3-0 silk suture is placed at the most depended part of the segment to advance the pouch into the pelvis for the anastomosis. Finally, the uretero-enteric anastomoses are performed in a similar fashion as the anastomoses performed during a robot-assisted ileal conduit.

U-shaped Pouch

A 60 cm segment is isolated. The distal 45 cm of the bowel segment is detubularized in the standard fashion for a Studer neobladder [34]. The proximal limb of 15 cm of ileum is left intact for the chimney and the eventual site for the ureteral anastomoses. The posterior plate of the bowel is then sutured together with a barbed suture in a running fashion to achieve a watertight closure [37]. The inferior side of the anterior plate should also be closed prior to the urethro-enteric anastomosis. A 2 cm incision at the most depended part of the pouch is made. Using the midpoint silk suture, the pouch is advanced into the pelvis using the Prograsp forceps.

A figure of eight 2-0 polysorb or barbed suture is then tied down from the posterior side of the most dependent portion of the pouch to posterior plate to Denonvillier's fascia just adjacent to the rectrourethralis muscle. This releases the tension from the urethro-eneteric anastomosis [38]. The urethro-enteric anastomosis is performed by placing a double armed 3-0 barbed sutures (or double armed 3-0 Monocryl) on a small tapered needle. The closure is usually started at a 4–5 o'clock position of the right side of the pouch's neck. In a running counterclockwise fashion, the posterior closure is completed. The assistant should facilitate the closure with the tip of a Foley catheter. The right arm of the suture is then used to close the anterior part of the anastomosis.

Modified Ileum Studer Neobladder

In a modified Studer neobladder the anastomosis between the urethra and bowel is performed at the beginning, before detubularisation of the bowel segment. This will stabilize the bowel loop and enhance forming the neobladder. First, the most dependent part of the bowel segment is identified, this is usually more than 35 cm proximal to the ileocecal valve. This part is brought down to the urethra and a small incision at the contra-mesenteric side is made to perform the urethral anastomosis according to the Van Velthoven technique with a two-times 2-0 suture. First, the suture is placed at the 5:30-o'clock position by passing the needle from the outside to the inside of the bowel's opening, and from inside to outside in urethral lumen. Then, the other suture is put at the 6:30- o'clock position by the other needle. The rest of the anastomosis is done in standard fashion. A 22 Fr Foley catheter is passed through the anastomosis and the balloon is inflated to 5 ml. Then an ileal segment of 20–25 cm from the ileocecal valve and 15 cm from the urethral–enteric anastomosis is selected and isolated as before. For the afferent reservoir loop, a distance of about 40 cm from the urethral–enteric anastomosis is selected and cut with a stapler in the same way. The rest of the procedure is similar to the standard Studer pouch [35, 36, 39].

Robotic Radical Cystectomy Versus Open Radical Cystectomy Outcomes

Retrospective Cohort Studies

Over the last few years, multiple reports of case cohorts were published, as is common for a new surgical technique. These focused on defining the perioperative benefits, morbidity, and mortality of RRC compared to gold standard ORC. Most of these studies were small in numbers and represented single center experiences. Recently, a good systematic literature review was conducted. The study focused on reports published within the last 5 years [40]. In summary, the review showed that robotic radical cystectomy consistently had less estimated blood loss, faster time to bowel activity, and reduced hospital stay; however, these improvements come with increased operative time and cost [40].

Retrospective comparative studies showed statistically significant reduction in operative **Estimated Blood Loss** (EBL) in RRC (<300 ml) [41, 42]. As a consequence, the rate of perioperative blood transfusion was lower [42–45]. Most studies indicated a longer **Operation Time** in RRC [40, 46, 47]. The average operation time was between 349–393 min in ORC compared to 415–455 min in RRC [47, 48].

Regarding post-operative morbidity and mortality, results were mixed. Some researchers reported favorable rates of low grade complications after RRC. However, these favorable trends did not translate to a decrease in major complications [46, 49, 50]. Others reported lower risk of mortality and minor and major complications after RRC [43, 44].

Patients who underwent RRC have quicker **bowel function recovery**, and shorter time to passing flatus [46, 51]. They used less **analgesics** [40, 52]. Finally, most studies reported a shorter **hospital stay** after RRC [43, 49].

Short term oncological outcomes of RRC were similar to ORC [41, 50]. Due to the short follow up in these studies, their focus was on pathologic stage, number of nodes harvested, and positive surgical margin rates [22, 52, 53]. Short term survival rates were also similar in both approaches. The Kaplan-Meier estimate for 2-year recurrence-free, disease-specific, and overall survival were 67 %, 75 %, and 68 % for robotic radical cystectomy, and 58 %, 63 % , and 63 % for open radical cystectomy [49]. In one small study, the long-term oncologic outcome of 14 RRC patients who were followed for more than 5 years was comparable to these for ORC (overall survival of 64 %, disease-specific survival of 75 %, and disease-free survival of 50 %) [48].

Health-related quality-of-life measures were not significantly different between ORC and RRC. Aboumohamed et al. used validated instruments (cancer body image scale (BIS) and the bladder cancer index (BCI)) to evaluate urinary, bowel, sexual function, and body image after RRC and ORC. Prospectively collected data from 182 patients from multiple institutions showed no difference between the two groups [51].

Prospective Randomized Control Trials

Up till now, only three randomized trials were performed to compare RRC and ORC. All of these trials agree on the benefits of RRC in lowering the EBL and in cost of longer operating time. None of the randomized trials showed statically significant benefits for RRC over ORC in reducing complications rate or improving the oncological outcomes.

The first trial was published in **2009 by Nix J** in University of North Carolina [45]. 41 patients were randomly assigned to one of the two techniques. The study showed that RRC was associated with lower EBL (258cc vc 575cc), significantly longer operation time (4.20 h vs 3.51 h), and less need for inpatient narcotic requirements. Other variables including complication rates were almost similar between the two procedural groups [45].

The second randomized surgical trial was published in 2012 by Parekh DJ et al, at The University of Texas Health Sciences Center at San Antonio. Again, this was a small trial of 40 patients. There was decreased estimated blood loss with RRC (400cc vs. 800) and decreased hospital stay with no significant differences in surrogates of oncologic efficacy [54].

The last and largest randomized trial was published in 2014 by Bochner et al. from Memorial Sloan Kettering

Cancer Center, New York. The study was a superiority trial of 118 patients. Although there was a trend for lower low grade complications after RRC, the authors concluded that the RRC is associated with lower mean intraoperative blood loss and significantly longer operative time. But it is similar in 90-d complication rates, hospital stay, pathologic outcomes, and 3- and 6-mo health-related quality-of-life outcomes between the two surgical techniques. Of note, the trial was designed to prove a 20 % improvement of post-operative morbidity after RRC. Thus the trial failed to identify a large advantage for RRC over ORC [54].

Finally a multi-institutional, randomized, non-inferiority NCI sponsored Trial (RAZOR) finished accrual of 350 patients in 2014. Fifteen institutions used standardized measures to evaluate cancer outcomes, surgical complications and HRQL of ORC vs. RRC with a primary endpoint of 2-year progression free survival. Full data from the RAZOR trial is not expected until 2016–2017 [55].

Costs

Few studies evaluated the financial burden of robotic surgeries. A recent systematic study compared the cost effectiveness of robotic surgeries (not only RRC) to open surgeries. The authors found that robotic surgeries' costs were consistently higher than open and laparoscopic surgery [56].

Smith and his colleagues looked specifically at the economics of RRC as part of the first randomized surgical trial in 2010. RRC was associated with an overall higher financial cost (+$1,640) than the ORC in the perioperative setting. (Robotic $16,248 vs open $14,608) [57]. A larger study that compared the cost of 1444 ORCs to 224 RRCs have also shown that the robotic approach is significantly more costly [58]. This increase of expenses in the robotic surgery itself were related to the high purchase and maintenance cost of the robotic platform[58], longer operating time, and the higher costs of robotic supplies [49, 59]. In a well done analysis, Martin et al. found that RRC was 16 % more expensive than ORC when only comparing direct operative costs[60].

The two main drivers of higher cost after radical cystectomy cited in the published data were hospital length of stay and operative durations [59, 60]. Although RRC was consistently associated with shorter length of stay, the cost deference was insufficient to offset the increased cost of robotic surgery [59]. Interestingly, there was a 38 % cost advantage found favoring RRC in the actual total patient costs in the Martin AD study [60].

It is possible that cost of robotic surgery will drop with the increased competition between manufacturers and wider dissemination of the technology [61]. When that happens, it is expected that the impact of indirect costs of post-operative complications and the longer hospital stay of ORC may deem RRC to be a more cost efficient treatment for invasive bladder cancer [43, 58].

The Future of RRC

The use of the robot in urologic surgery continues to increase. With the facilities that this technology provide for surgeons and the comparable outcomes between RRC and ORC that have shown by the available studies, RRC continues to be more popular and favorable. The improvement of surgeons' experience was quick and obvious with the decrease in operative time [61] and the performance of more complicated procedures, such as intra corporeal urinary diversion, robotically and successfully. The short learning curve of RRC compared with laparoscopic radical cystectomy as minimally invasive approaches helps new physicians and residents to perform radical cystectomy more efficiently [62]. All these factors and many others make the RRC a promising surgery either in regards to the quality of health care, or in surgeon's preference. And who knows – if RRC shows more significant clinical and statistical outcomes, it could become the gold standard approach in management of muscle invasive bladder cancer!

Comments

Because it includes many different surgical steps and techniques, radical cystectomy is a comparatively unique surgery in urology. The high morbidity and mortality rates make this procedure more challenging. Now, 12 years after the initial RRC was performed, urologists have formed a more inclusive understanding of the advantages and disadvantages of RRC. It is clear that the technical advantages, lower EBL, and faster recovery after RRC comes at the price of increased operative time and financial burden. However, it is promising that the perioperative and oncological outcomes of RRC were similar or better but not worse when compared with the gold standard ORC.

The results of a valuable multi-institutional, non-inferiority, randomized surgical trial (**RAZOR**) designed to compare RRC with ORC is expected in the near future. This trial is promising because of its statistical design and large cohort. It remains to be seen if it will support the RRC as an acceptable minimally invasive alternative to the classical ORC.

Urological Complications of Radical Hysterectomy and P.E

Injuries to the Bladder and Ureters

Ureteral injuries as well as bladder injuries may happen during any type of hysterectomy, particularly during the

learning curve, and are estimated to occur with a frequency of 1.2% (range 0–6%) for ureteral injuries and 2 % (range 0.6–4%) for bladder injuries [63, 64]. Ureter injuries are in 70% of cases detected after surgery, often resulting in an unintended emergency laparotomy or second laparoscopy [65].

The ureters are always at risk during any type of radical pelvic surgery as they lie close to the rectum and the female reproductive organs. During laparoscopic hysterectomy, in particular, the distal ureters may be injured during ligation of the uterine arteries, or at the time of dissection and division of the cardinal ligaments below the uterine vessels [66]. However it is the cases with abnormal anatomy that pose the highest risk for ureteral injury. Special caution should be exercised in patients with severe prolapse where the pelvic anatomy is distorted and the ureter may lie just 0.5 cm lateral to the cervix. Cystoscopic evaluation with administration of i.v Indigo carmine dye may be helpful in these cases in order to confirm bilateral ureteral integrity.

Steps to be taken in order to avoid ureteral injury include (a) staying in the midline when incorporating the perivesical fascia as sutures placed too lateral may cause ureteral injury, (b) placing the clamps close to the uterus, (c) removing the uterus intact with surgical margins in close proximity to the uterus, thereby avoiding ureteral injury.

Ureteral injuries are much less likely to be recognized intraoperatively, and in some cases can be missed despite the use of intraoperative cystoscopy. The surgical treatment for ureteral injuries follows established operative principles, which include resecting devitalized injured ureteral tissue, establishing tensionless mucosal apposition over a stented ureter, isolating the anastomotic repair with omentum or fat, and placing of a drain in close proximity to the repair. The operative technique is dependent upon the location of the ureteral injury. Distal ureteral injuries, which are usually the case in R.E, can be managed with direct uretero-utereral anastomosis, ureteroneocystostomy with psoas hitch or Boari flap.

Lately, minimally invasive surgery using the robot is leading to a paradigm shift in the management of urinary tract injuries, which has been traditionally approached with open surgery. There are reported cases of robotic total hysterectomy and concomitant repair of incidental ureteral injury via ureteroureterostomy using standard end-to-end anastomosis technique and intracorporeal retrograde double J stent placement [67–69].

Bladder injuries may occur during attempt to enter the vesicouterine peritoneal space and are more frequent in women with history of cesarean section and scarring in this area. In transvaginal procedures, injuries to the bladder most commonly occur when perforating into the retropubic space. In general the risk of cystotomy can be reduced when one makes sure that the bladder is empty prior to perforation. Usually these cystotomies are at the base of the bladder and generally above the trigone. When repairing bladder injuries, care must be taken to close the cystotomy in two layers using absorbable sutures and test for watertightness using methylene blue dye instilled through the catheter. A bladder catheter is such cases should be kept for 7–10 days postoperatively [70].

In patients with a history of pelvic irradiation, an omental flap of labial fat pad interposition should be considered in order to prevent fistula formation [71]. If a bladder injury however is not detected intraoperatively, a trial of conservative management with an indwelling Foley catheter can be attempted. It is important to remember that early identification of bladder, or ureteral injury is crucial, considering that the best time for repair is at the time of injury when the tissues are in their best condition and all options for repair are still available.

Delayed Complications-Ureteral Stricture

Ureteral strictures are the usual long-term complications of iatrogenic injuries to the ureters. Upper urinary tract obstruction from a stricture may encounter months to years after hysterectomy. The treatment options include either an immediate percutaneous nephrostomy in case of a severely obstructed urinary tract or efforts to dilate the ureter and pass a retrograde stent over a guidewire in cases of mild dilatation and short stricture length [72, 73].

According to some, delayed recognition of a ureteral injury should be best managed by percutaneous drainage and definitive surgical repair should be postponed until after several months, depending again on the location and length of the strictured area. Percutaneous ureteral dilatation followed by antegrade stent placement has been reported with good success rates especially in strictures that are short in length [74].

Finally in challenging cases when other options are not available, a short segment of the ileum can be used for the creation of an ileal ureter. Ileal-ureter substitution is a valuable option in selected patient with complex ureteral defects that are not amenable to or have failed endourological approaches. Avoiding the complexity of tailored and tunnelled anastomoses may reduce the potential morbidity and re-intervention rate in patients with challenging surgical fields [75, 76].

Robotic-Assisted Radical Hysterectomy with Anterior and Posterior Exenteration: Surgical Perspective

73

Sanghoon Lee, Seok Ho Kang, Seon Hahn Kim, and Jae Yun Song

Introduction

Cervical cancer is the fourth most common cancer in women, with an estimated 528,000 new cases/yr. worldwide. In 2012, it was also the fourth most common cause of cancer deaths in women worldwide. More than 70 % of all cervical cancers occur in underdeveloped areas [1]. Human papillomavirus (HPV) infection is regarded as the major cause of cervical intraepithelial neoplasia (CIN) and cervical cancer. Genital HPV infection is common in sexually active young women and persistent infection with carcinogenic HPV causes almost all cervical cancers. A minority of women with precancerous lesions develop invasive cancer [2–4]. The establishment of causal links between HPV and cervical cancer has helped to guide age-appropriate interventions for preventing cervical cancer [5].

The rates of incidence and death of cervical cancer have decreased gradually over the last decade due to early detection and treatment in most developed countries [6]. In the past, open radical hysterectomy (RH) through a midline incision, was the standard operative management for early stage cervical cancer. However, minimally invasive surgery for RH has recently become widespread as the result of advances in laparoscopic instrumentation and surgical techniques [7–10]. Many studies have demonstrated the safety, feasibility, and benefits of laparoscopic RH. The advantages of laparoscopic surgery include decreased blood loss, shorter recovery time, shorter hospital stay, earlier return of bowel and bladder function, and higher quality of life [9, 11, 12]. An increasing number of studies comparing the feasibility and advantages of robot-assisted surgery for early stage cervical cancer with conventional laparoscopy or laparotomy have appeared during recent years [13–16].

Here, we reviewed published articles to assess the current role of robotic surgery including RH and pelvic exenteration in women with cervical cancer.

Robotic Radical Hysterectomy

RH is one of the most complex surgeries in gynecologic oncology and is the standard surgical treatment for early stage cervical cancer. More than a century ago, the first abdominal RH was reported by Wertheim. The technique was then modified by Meigs in the 1950s [44]. Later, vaginal RH was described by Schauta in 1901. Laparoscopic RH with pelvic and paraaortic lymphadenectomy was introduced by Canis et al. in 1989. In the early 1990s, and over the last two decades, numerous studies have indicated that total laparoscopic RH is feasible.

Traditionally, RH has been associated with higher complication rates due to the numerous dissections required for the bladder, ureter, parametrium, and rectum. In the past two decades, gynecologic oncologic surgeons have utilized minimally invasive techniques to decrease morbidity while maintaining surgical and oncological outcomes. Many studies have demonstrated the safety and feasibility of laparoscopic RH as the treatment for early-stage cervical cancer. Although the laparoscopic approach provides long-term outcomes comparable to those of open radical hysterectomy, this approach was not widely adopted in surgical practice, due to disadvantages such as: long learning curve, two dimensional view, poor ergonomic position for surgeons, and limited movements of instruments. These conditions negatively influenced the surgical performance, resulting in tremor, fatigue, and less accuracy [37]. Laparoscopic RH also poses difficulties in ureteral and parametrial dissection similar to conventional laparoscopy [17]. Dissection is technically easier with robotic approaches [18]. The concept of robotic assisted surgery started in 1994 [45]. Initially developed for

battlefield medicine, robot-assisted surgery was approved by the U.S. Food and Drug Administration in 1999 for urologic and cardiac procedures [43]. Robotic surgery has several advantages over laparoscopy: three dimensional vision, wristed instrumentation, less tremor, and ergonomic positioning for the surgeon while performing the surgical procedures [19]. Such benefits enhance dexterity and decrease skill-based error. Since 2005, the role of robots in gynecological surgery has increased, with robot assistance being used in many traditional procedures, including hysterectomy, prolapse surgery, myomectomy, tubal surgery, endometriotic and adnexal surgery, pelvic and paraaortic lymph node dissection, and sacrocolpopexy [26]. In procedures such as RH, that are technically challenging by laparoscopy [37, 38], the enhanced visualization provided by the robotic technique gives surgeons improved ability to identify tissue planes, blood vessels, and nerves during surgery [20]. Therefore, robotic surgery is reported to be associated with decreased blood loss in comparative studies.

The female pelvis is a confined space for surgeons to perform procedures. Standard laparoscopic instruments have more limited degrees of freedom than human hands, and they may hamper surgeons' procedures. Standard laparoscopic instruments have limited degree of positioning for the surgeon during intracorporeal knot tying. On the other hand, wristed robotic instrumentation, like human hands, provides greater dexterity with seven degrees of movement. Three degrees are provided by the robotic arms attached to the abdominal wall trocars (insertion, pitch, yaw) and 4 ° result from the "wristed" instruments (pitch, yaw, roll and grip). The degrees provided by the robotic arms attached to the abdominal wall trocars around the robotic instruments coordinate system origin and the center of mass. Pitch is the rotation around the lateral or transverse axis; yaw is the rotation around the vertical axis; and roll is the rotation around the longitudinal axis. The resultant improved dexterity allows finer, more delicate and tremor-free manipulation, dissection, removal, or resection of tissue. In addition, fatigue and physical discomfort can limit any surgical procedure. During laparoscopy, surgeons have to pose uncomfortably to successfully complete the surgical procedure because they need to reach over the patient. With robotic surgery, surgeons may sit comfortably at the surgical console from the vantage point of standing at the patient's head, and manipulate the hand controls and foot pedals in an ergonomic position. This may reduce fatigue and discomfort during complex surgical procedures.

The major disadvantages of robotic surgery include the cost, large volume of robots and consoles, limited availability within some health systems, and the need to train the residents, attending surgeons, and operating room personnel in the use of such technology. Another limitation of robotic surgery is the lack of haptic or tactile feedback. This has been noted to be a limitation for novice robotic surgeons, but they most quickly adapt and obtain heightened visual feedback from the magnified, three-dimensional vision system. If there are particular structures that surgeons desire to palpate, such as the cervicovaginal colpotomy ring during hysterectomy or sacral promontory during sacrocolpopexy, they can do so by laparoscopy before docking robots, or by asking the bedside assistant to palpate and confirm the location.

The first robotic assisted RH for cervical cancer was reported by Sert and Abeler in 2006 [21]. Since then, there have been several case series focusing on cervical cancer management. Kim et al. examined 10 patients with cervical cancer, and Fanning et al. included 20 patients in their analysis. These patients underwent robotic laparoscopic RH with only a few intraoperative complications; one patient had a cystectomy, which was repaired. They also had only a few postoperative issues; one patient had an uterovaginal fistula and one patient developed pneumonia, with operating time 355–390 min, and mean blood loss 207 and 300 ml, respectively. Recent systematic reviews and meta-analyses suggest that robotic RH may be superior to abdominal RH with less estimated blood loss, shorter hospital stays, less febrile morbidities, and wound-related complications. The percentage of robotic-assisted hysterectomies is increasing; while 0.5 % of total hysterectomies were performed robotically in 2007, 9.5 % utilized robotic techniques in 2010 [42].

Robotic RH and laparoscopic RH appear to have equivalent intraoperative and short-term postoperative outcomes [22]. Longer operative time and learning curve are among the reasons why the robotic technique has not yet been adopted worldwide in gynecologic oncology practice. In robotic surgery, total operation time consists of docking and console time. Docking time is the time needed to assemble instruments, attach patient to the robot, advance column to the operating table, fasten the robotic arms to the inserted trocars, and introduce the laparoscope. Console time is defined as the surgical time needed to perform the entire operation at the console. Operative time is defined by the anesthesiologists as the time between the insertion of the Foley catheter and the closing of the last trocar site. Sert and Eraker described 25 patients with early stage cervical cancer who had undergone robot-assisted RH and pelvic lymph node dissection, showing a total mean time of 219 min, with a mean console time of 170 min. Estape et al. compared 32 RH by robotic approach with 17 by laparoscopy and 14 by open surgery; the mean console time in the robotic, laparoscopic, and laparotomy groups was 2.4 h, 2.2 h, and 1.9 h, respectively [16]. Magrina et al. compared 27 patients who underwent robotic or modified RH with patients who underwent RH via laparoscopic and laparotomic approach. They found similar operative time from skin incision to skin closure between robotic (189.6 min) and laparotomic RH, but it was significantly shorter than the time required for the laparoscopic approach [20]. From a multi-institutional experience, Lowe and Chamberlain et al. found the median

operative time of robotic-assisted RH to be 215 min. From a prospective study of seven patients who underwent robot-assisted RH, Lowe and Hoekstra et al. found no statistically significant difference in operative times; 260 min in robot-assisted RH and 264 min in traditional RH [45]. Overall, surgical experience and personal learning curve may influence the operative time. Several studies demonstrated that the robotic docking time decreases significantly as surgeons and assistants gain experience, with the reported mean docking time being 10 min at the beginning and 2–3 min at the end of the learning curve [20, 38].

There is a general agreement on the significant decrease in intraoperative bleeding in minimally invasive surgery. An article reported similar levels of blood loss between robotic with laparoscopic RH; which were, importantly, different from those of open surgery. In patients who underwent robotic or laparoscopic RH, the overall rate of blood transfusion was very low. Sert and Abeler compared 35 patients who underwent hysterectomy via robotic radical (RRH), laparoscopic (TLRH) and laparotomic (ORH) approaches. The mean estimated blood loss was significantly reduced in the group of patients who received robot-assisted surgeries compared with those who received laparoscopic and laparotomy surgeries [41]. Blood transfusion rates for symptomatic postoperative anemia after robotic RH vary from 5 to 35 % [16, 39]. Magrina et al. reported that in the robotic group, one patient with an operative blood loss of 180 ml had an unexplained drop of Hb to 6.6 g on her first postoperative day. The patient was transfused and discharged the following day. In the laparotomy group, all three patients were transfused postoperatively, while one of them had preoperative anemia (Hgb 9.0 g/ml) secondary to postmenopausal bleeding [20]. Gortchev et al. compared 294 T1b1 cervical cancer patients; robot assisted RH was performed in 73 patients, laparoscopic-assisted vaginal RH in 46 patients, and abdominal RH in 175 patients. No significant differences between the three operative methods were found in the values of the postoperative hematocrit ($p = 0.153$), and between the pre- and postoperative hematocrit ($p = 0.253$). In a systematic literature review and meta-analysis by Geetha et al., 21 studies (1339 patients) of laparoscopic RH, 14 open RH (1552 patients) and 12 robotic RH (327 patients) were compared. Mean blood loss was significantly higher in open RH than in both laparoscopic and robotic RH (ANOVA $F(2.44) = 21.6$; $P<0.001$). The difference in blood loss between laparoscopic and robotic RH was not statically significant. Both laparoscopic and robotic RH had a significantly lower proportion of patients with blood transfusion compared with the open method (ANOVA $F(2.24) = 20.5$; $P<0.001$). Although the robotic RH appears to require less blood transfusion, the difference in transfusion percentage between laparoscopic and robotic RH was not statistically significant [46]. Moreover, Estape at al. compared 32 cases of RH by robotic approach with 17 by laparoscopy and 14 by open surgery. The results showed that the incidence of blood transfusion was highest (35.7 %) in the cases of laparotomy, with one patient given a blood transfusion pre-operatively due to anemia [16].

Lower rates of intraoperative complications occur in minimally invasive surgery compared with the open approach, due to more accurate tissue manipulation and better anatomic visualization [37]. The complication rates in radical robotic surgery vary in a wide range-from 7.8 to 59 %. Different criteria for defining minor complications and different periods of follow-up are the main reasons for the variations observed. Definitions of early and late postoperative complications also vary. Magrina et al. define early complications as those that occur in the first 6 weeks after the operation, while Maggioni et al. define them as those that occur in the first month after the operation [38]. Urinary injury, which may happen during ureterolysis and bladder isolation steps, is frequently reported in RH. Sert and Eraker described three cases of bladder perforation among 25 cases of robotic RH, which were successfully repaired robotically. A recent review comparing robotic versus total laparoscopic RH for early stage cervical cancer found similar overall rates (~6 %) of major intraoperative complications, with lower rates of vascular and bladder injury during robotic RH [37]. Estape et al. reported one cystotomy in the robotic group in a patient with three cesarean sections, and two cystotomies in the laparoscopic group. Another recent review article described a significant difference in the number of major postoperative complications between RRH (9.6 %) and TLRH (5.5 %). The RRH group included 11 cases of vaginal dehiscence, 10 cases of vaginal cuff abscess, and 5 cases of port site hernia [39]. On the contrary, no significant differences in the frequency of the complications were established in publications that compared the robotic with the open and/or laparoscopic surgery [16, 41].

An increased relative risk of vaginal cuff complication has been observed for minimally invasive hysterectomy techniques when compared with vaginal or abdominal ones. The study that observed this risk is controversial, due to the lack of a standardized method of classification and registration of postoperative injuries. A recent review showed a higher rate of vaginal dehiscence in the RRH group than in the laparoscopic group, which may be associated with the extensive use of monopolar and bipolar electrosurgery, which may increase thermal damage and devascularization of the cuff site. Other studies disagree with the above review and describe a similar incidence of vaginal cuff separation in laparoscopic and robotic hysterectomies [39]. Other organs are also under the risk of thermal injury. Thermal injury to bowel may be more difficult to diagnose intraoperatively [47]. Person et al. reported the leaking of lymphatic fluid through the vagina and/or vaginal cuff dehiscence in 10 out of 80 women (12 %) who underwent robotic RH with pelvic lymphadenectomy. The frequency of this complication was significantly different between three surgeons who performed robotic RH [37].

Magrina et al. reported that intraoperative injuries were noted in the laparoscopy group and laparotomy group only. One patient from the laparoscopy group had rectotomy during the resection of an invasive endometriotic lesion of the anterior rectal wall, and was included as complication, but was the only readmission. Another patient had an umbilical trocar site infection. In the laparotomy group, one patient developed pneumonia, one had sterile wound seroma, and one had ileus. Minor early complications (<6 weeks) in the robotic group consisted of one case of urinary retention and two of urinary tract infection. In the laparoscopic group, one patient had a corneal abrasion, one experienced urinary retention and one had passage of lymphatic fluid through the vagina on the fifth postoperative day through an intact vaginal cuff. In the laparotomy group, one patient had urinary retention, and two had vomiting [20]. Sert and Abeler et al. reported that three robot-assisted RH patients and one laparoscopic patient had accidental cystotomy, which was repaired peri-operatively. No readmission was required, and no bowel or ureter injuries happened [41].

Geetha et al. reported the mean percentage of patients with infectious morbidity for the three types of RH studies. Post-operative infectious morbidity was significantly higher among patients who underwent open RH compared with those who underwent RH via other methods (ANOVA F (2.36) = 6.24; P = 0.005). The difference in infectious morbidity between laparoscopy and robotic RH was well within the range for chance fluctuations. The mean percentage of patients with non-infectious morbidity for the three types of RH was similar (ANOVA F (2.37) = 1.80; P = 0.179). No cases of bowel injury were reported among patients who underwent robotic RH. The mean number of patients with ureteric injury after all three types of RH was similar (ANOFA F (2.39) = 1.21; P = 0.309). Ureteric injury was reported in 7/13 (53.9 %), 6/19 (31.6 %) and 2/10 (20 %) of ARH, LRH, and RRH studies, respectively [46].

Shorter hospital stay is one of the most important advantages of minimally invasive surgery. The length of hospital stay reflects the difference in the postoperative outcomes of the patients with different operative procedures. Factors that determine the hospital stay are: the ability of the patient to ambulate independently, recovery of the functions of the gastrointestinal tract and the ability to use oral drugs. Recovery of urinary bladder function (residual urine <50 ml) is not a determinant. All comparative studies of robotic RH reported a mean length of hospital stay of 1–2 days, which was similar in the laparoscopic RH group, but significantly shorter than in the open RH group [16, 37–40, 42]. Table 73.1 summarizes reports on robot assisted laparoscopic radical hysterectomy for early stage cervical cancer.

Increased maneuverability of the instruments with a robotic platform is most likely the reason for increased lymph node yield in the robotic group when compared with both laparoscopic and laparotomy groups [41]. Oncological outcomes after RH for early stage cervical cancer are determined by the number of lymph nodes retrieved and the recurrence rate. Results concerning the number of lymph nodes retrieved by the different surgical approaches are controversial. Several comparative studies found no significant differences in the number of lymph nodes retrieved between robotic, laparoscopic, and open techniques. A case control study which compared robotic to open type III RH found a better node retrieval outcome in the robotic approach. On the contrary, Maggioni et al. showed a reduced number of lymph nodes in the RRH group compared with the ORH group [37]. More recently, Estape et al. reported a case-matched comparative analysis between laparoscopic, robotic, and abdominal RH with lymphadenectomy, and reported a significantly higher number of nodes retrieved in the robotic approach and equivalent rates of positive surgical margins [37]. The increased lymph node yield may be explained by the agility of the robotic instruments that allows more comprehensive and accurate node dissection. The number of lymph nodes obtained may increase further following a learning curve [42].

Data about the follow-up period and recurrence rates in patients with cervical cancer who underwent robotic RH have been reported in a few articles [48, 51, 47, 49] Estape et al. reported that mean patient follow up was shortest for the robotic group (242.2 days) followed by the laparoscopic (941.6 days) and laparotomy groups (1382 days) [16]. Gortchev et al. reported that the mean follow-up period was significantly shorter in the robotic group (316 days), followed by the laparotomy (808 days) and laparoscopy groups (1531 days) [38]. All patients were followed according to the routine study protocol, including clinical examination, vaginal ultrasound, smear from the vaginal cuff, routine blood tests, and chest x-ray. The follow up examination was performed every 3 months during the first 3 years, every 6 months until 5 years and once a year thereafter. In some cases, MR scans of the pelvis, additional PET-CTs or CT scans were required [41].

Although robotic assisted-technology is theoretically an enhancement of conventional laparoscopy, several studies have reported the conversion of the robotic approach to laparotomy, not laparoscopy. There were six cases of conversion from robot-assisted laparoscopy to laparotomy in two studies due to: dense adhesions (n = 1), tumor erosion into the rectosigmoid colon (n = 2), non-life threatening bleeding from the vena cava (n = 2), and uterine myomas and obliterated cul-de-sac to avoid morcellation (n = 1). Some physicians are comfortable using the robot, while those who are not, continue the procedure using the traditional laparoscopic technique. This is of concern because the advantages of laparoscopy and robotic technology are comparable, whereas laparotomy leads to greater complications, such as more blood loss and longer hospital stay. Robotic assisted laparoscopy and traditional laparoscopy have differences.

Abbreviations: *RALRH* robot-assisted laparoscopic radical hysterectomy, *Lap* laparoscopy, *Op time* operation time, *EBL* estimated blood loss, *LOS* length of hospital stay, *NM* not mentioned

Because of the bulkiness and limitations unique to the robot, certain procedures, such as achieving hemostasis of uncontrolled bleeding and performing dissection and resection of bulky tissue (e.g., bowel resection and large tumors), are easier with traditional laparoscopy than with the robot. The robotic surgical approach may have negative effects on the training of surgical fellows, because some institutions rarely choose the traditional laparoscopic approach and, instead, choose the robotic approach when considering minimally invasive surgery. Future surgeons should be trained in both laparoscopy and robotic technology to take advantage of both techniques [42].

Surgical Procedure for Radical Hysterectomy

The round ligaments are clamped and divided, and a bladder flap is developed on either side. The top of the broad ligament is incised in a cranial direction. The infundibulopelvic ligament is clamped, transected, and doubly suture-ligated. At this point, the peritoneum on the lateral aspect of the broad ligament is dissected further laterally to expose the psoas major muscle. During the course of the dissection, the ureter is identified and dissected free at the point where it crosses the common iliac artery, which is then identified and cleared of fat, as is the external iliac vein. During the course of the dissection, the ureter is located posterior to the ovarian vascular complex. As the external iliac node dissection proceeds towards the iliac bifurcation, the internal iliac artery is identified and cleared of fat. Elevation of the external iliac vein exposes the obturator fossa, which is filled with fat and lymph nodes. The fat is dissected out of the fossa, and the obturator nerve and artery are cleaned of fat and lymph tissue. The dissection is carried laterally until the fascia of the obturator internus muscle is reached. Great care must be taken not to tear or otherwise injure the tributaries of the internal iliac veins because they bleed profusely and are very difficult to secure. When the obturator dissection is completed, the operator turns their attention to the common iliac node dissection. Again, great care must be taken not to injure the left common iliac vein. Next, the ureter is dissected inferiorly, removing the encompassing fibrofatty tissue, and reflecting it medially to be removed with the uterus. The uterine arteries and veins are clamped far laterally, just distal to their origin from the anterior division of the hypogastric artery. If the hypogastric artery is to be clamped, this should be performed distal to the origin of the superior and inferior gluteal arteries. At this point, the ureter is entering its tunnel through the cardinal ligament just cephalad to where it enters the wall of the bladder. The ureter is now free of the parametria. Next, the bladder pillars are identified, cut, and secured. The vesicouterine space is dissected downward well below the uterine cervix. The peritoneum between the uterosacral ligaments is divided, and the rectouterine space is developed and dissected downward below the cervix. The uterosacral ligaments are cut and suture-ligated. The lower cardinal ligament, deep parametrial fat, and fascia are clamped and cut medial to the

Fig. 73.1 Robotic radical hysterectomy. (**a**) Opening of the paravesical and pararectal spaces and dissection of the ureter (yellow rubber band ligation) and vessels. Resection of pelvic lymph nodes and the right lateral parametrium. (**b**) Dissection of the urinary bladder and vaginal wall. Removal of the specimen and closure of the vaginal cuff

ureter. The vagina is clamped approximately 4 cm below the cervix, and the specimen is removed. The peritoneum is drained with catheter and the abdominal incision closed [48] (Fig. 73.1).

Robotic Pelvic Exenteration

Pelvic exenteration (PE) has been used for 60 years to treat cancers of the lower and middle female genital tract in

radiated pelvis [27]. PE is a radical surgery involving the en bloc resection of the pelvic organs, including the internal reproductive organs, bladder, and rectosigmoid. The indications for PE include advanced primary or recurrent pelvic malignancies, among which centrally recurrent cervical carcinomas are most common; while other gynecologic, urologic, and rectal cancers are also included [28]. The following are contra-indications for PE: patients with major medical, psychiatric, or emotional co-morbidity, and incapacity; lower extremity lymphedema indicating unresectable disease; extrapelvic disease associated with poor prognosis; immobile tumors fixed to the pelvic sidewall (relative if bone can be resected); invasion of the proximal (S1 or higher) lumbosacral spine or lumbosacral plexus/sciatic nerves; and encasement of the external or common iliac vessels by the tumor [31]. Distant metastasis has also traditionally been a contraindication for PE with curative intent [28].

In 1948, Brunshwing introduced PE as the treatment for persistent or recurrent gynecological cancer [27]. The first study of this technique reported that among 22 patients studied, 5 died from the operation itself [30]. In the following 50 years, the criteria for selecting patients that would benefit the most from this extensive surgery were defined. Improvements in surgical techniques and peri-operative care, and implementation of reconstructive procedures reduced the operative mortality to 0–5.3 % [29]. PE is now considered a safe and feasible procedure that can help selected patients with no other options for cure, although the reported morbidity rates remain high (38–65 %) [32]. PE is associated with a significant complication rate, with ~40–50 % major complications and ~80 % minor complications [28]. The most common morbidity is infection (19–86 %), which includes wound infection, urinary tract infection, sepsis, and abscess. The most common late morbidities are intestinal obstruction and fistula (5–10 %) [30]. Mortality rate is 1–16 %, with disparate causes including sepsis, thromboembolic disease, and cardiopulmonary failure. Death in the perioperative period occurs in less than 5 % of patients, while women over the age of 65 have the highest risk [28]. Relative contra-indications are: ureteral obstruction, poor candidate for surgery because of medical comorbidities, or poor candidate for surgery because of inability to care for stomas or senility. Advanced age has previously been considered a relative contraindication to exenterative surgery, probably because older patients are more likely to have pre-existing medical conditions, such as heart disease, obstructive pulmonary disease, decreased renal function, and altered immunologic response [49].

The 5 year survival rate of patients who underwent PE for recurrent or persistent cervical cancer following surgery and radiotherapy or radiation therapy alone was 52 % [28, 29]. This result confirms that cervical cancer patients are appropriate candidates for PE. Even though vaginal, vulvar, and endometrial cancer patients can benefit from the operation, it is still debatable whether they are good candidates for such an aggressive surgery, given that their usual bad prognosis maybe due to the different biology and pathways of diffusion of their cancers.

The recent development of laparoscopic pelvic surgery and robotically assisted laparoscopic pelvic surgery, particularly in uro-oncology and colorectal cancer, has created new possibilities. Minimally invasive therapy can offer operative and early postoperative advantages, although the long-term oncological and palliative outcomes still have to be evaluated. Blood loss and transfusion rate are significantly reduced, and the time needed to recover oral intake and bowel function are reduced. The patients generally return to normal activity more quickly, although complication rates are more or less equivalent [31]. Careful selection of patients is vital for robotic-assisted PE to be successful. The tumor should be removed according to strict oncologic criteria (en-bloc removal of cancer, obtaining free margins, avoiding dissemination of tumor by manipulation of cancer mass) and correct surgical technique should be used in order to achieve urinary and fecal diversion [32]. Table 73.2 summarizes reports on robot assisted pelvic exenteration for cervical cancer.

Surgical Procedures for Pelvic Exenteration

PE is classified as anterior (APE), posterior (PPE), and total (PE). APE is the removal of the reproductive tract and bladder; PPE is the removal of the reproductive tract along with the rectosigmoid colon; and TPE is the removal of the reproductive tract, bladder, and rectosigmoid colon [29]. Here, we describe the surgical techniques for all three procedures.

Pelvic exenteration consists of three important and distinct components: determination of resectability, resection, and reconstruction. The procedure begins with the patient in a low lithotomy position to allow for abdominal and perineal portions of the surgery. Combined epidural and general anesthesia may be considered for additional postoperative pain control. PE is traditionally performed as an open abdominal procedure, but recent developments in laparoscopy and robotics have allowed for the minimally-invasive adaptation of the technique. First, the abdomen and pelvis are thoroughly examined for evidence of metastatic disease. Washings may be sent for cytology. Any suspicious lesion is biopsied and sent for frozen section to exclude the possibility of distant metastatic disease that would preclude complete resection or alter the surgical plan. For recurrent cervical cancer, low para-aortic and pelvic lymph node dissection may be performed again to preclude metastatic spread beyond the pelvis. Lateral involvement of disease to the pelvic sidewall should be assessed at this time [27, 28, 50]. The round ligaments are divided, and the paravesicular and pararectal spaces are

Table 73.2 Summary of reports on robotic pelvic exenteration for cervical cancer

Study	Publication type	Histologic type	Type of operation	Procedure duration, (min)	Blood loss, (ml)	Complications	Postoperative stay (days)
Lambaudie et al. [25]	Case report	Squamous cell carcinoma	Anterior pelvic exenteration	480	200	Perineal abscess, Miami pouch fistula, ureteral stenosis	53
Akhil et al. [30]	Case report	Squamous cell carcinoma	Total pelvic exenteration	240	300	NM	11
Davis et al. [36]	Case report	Squamous cell carcinoma	Anterior pelvic exenteration	540	550	NM	8
Lim et al. [24]	Case report	Squamous cel carcinoma	Total pelvic exenteration	375	375	None	10
Lavazzo et al. [33]	Cases	Squamous cervical cancer	Anterior pelvic exenteration	375–600	200–550	Postoperative complications-perineal abscess, ureteral stenosis	3–53

NM not mentioned

developed. At this time, the pelvic sidewalls may again be examined. At this point, the extent of PE must be determined. Total PE includes removal of the bladder and distal uterus, portions of rectum and sigmoid colon, internal reproductive organs, and vagina.

En bloc resection Removal of the specimen begins with the ligation and division of the fibrovascular pedicle containing the uterine vessels, cardinal ligament, and ureter bilaterally. The uterine artery is ligated at its origin from the hypogastric artery, lateral to the ureter. The infundibulopelvic ligaments are ligated above the level of the common iliac vessels. The sigmoid is then mobilized and transected with a gastrointestinal anastomotic stapler, and the sigmoid vessels are identified and ligated. Care must be taken to preserve blood flow to the remaining colon-usually the sigmoid and the sacrum are developed to the level of the levator ani muscles. The avascular plane between the sigmoid and the sacrum is developed to the level of the levator ani muscles. The prevesicular space is extended bluntly. At this point, the specimen should be freely mobile in the pelvis. The perineal portion of the procedure is then performed. An incision is marked to include the urethra, vaginal opening, anus, and possibly the vulva. The muscles of the pelvic floor are transected circumferentially. The pubococcygeal and anococcygeal ligaments are identified and divided. Upon completion of the dissection, the entire specimen is free to be removed.

Anterior pelvic exenteration Anterior PE involves the removal of the bladder and internal reproductive organs but spares the gastrointestinal tract. The rectosigmoid, anus, and lower portion of the posterior vagina are left intact. Bimanual palpation, in which the pelvic hand inserts one finger into the vagina and another into the rectum, while the abdominal hand palpates the posterior cul-de-sac and retracts the rectum posteriorly, will confirm the initial impression that an anterior resection is advisable. If the space posterior to the cervix feels free, then an incision can be made in the cul-de-sac to allow the rectum to drop away from the upper vagina, leaving at least 4 cm margin on the vagina. The potential space between the rectum and posterior vagina is developed abdominally, and adequacy of the margin is confirmed by direct vision vaginally. The posterior vaginal incision is made from below, with the cancer in view, to ensure adequate margin. Biopsies of the vagina, which will be left intact over the rectum, are sent for frozen section. The perineal incision is made, removing the urethra and surrounding soft tissue, but preserving the clitoris and labia (Fig. 73.2).

Posterior pelvic exenteration Posterior exenterations are rarely performed, except for primary stage IVA cancers of the cervix invading the rectum. Posterior PE removes the internal reproductive organs and rectosigmoid, but spares the anterior vagina, urinary bladder, and uterus. After dividing the round ligaments and developing the perivesicular and perirectal spaces, the peritoneum between the bladder and uterus is incised, and the bladder is reflected as inferiorly as possible with sharp dissection. The uterus is then mobilized and dissected free of soft tissue attachments, similar to the technique for RH. The uterine arteries are divided at their origin and reflected medially, trying to preserve other branches of the internal iliac arteries. The cardinal ligaments are then divided laterally, the ureteral dissection is completed to the bladder, and the anterior vagina is entered. The rectosigmoid is freed posteriorly, the parametrium is mobilized medially, and the dissection is carried down to the levator muscles, identical to the posterior dissection in a total exenteration. The perineal incision will involve only the posterior aspect of the vulva and anus. An omental flap and small pack

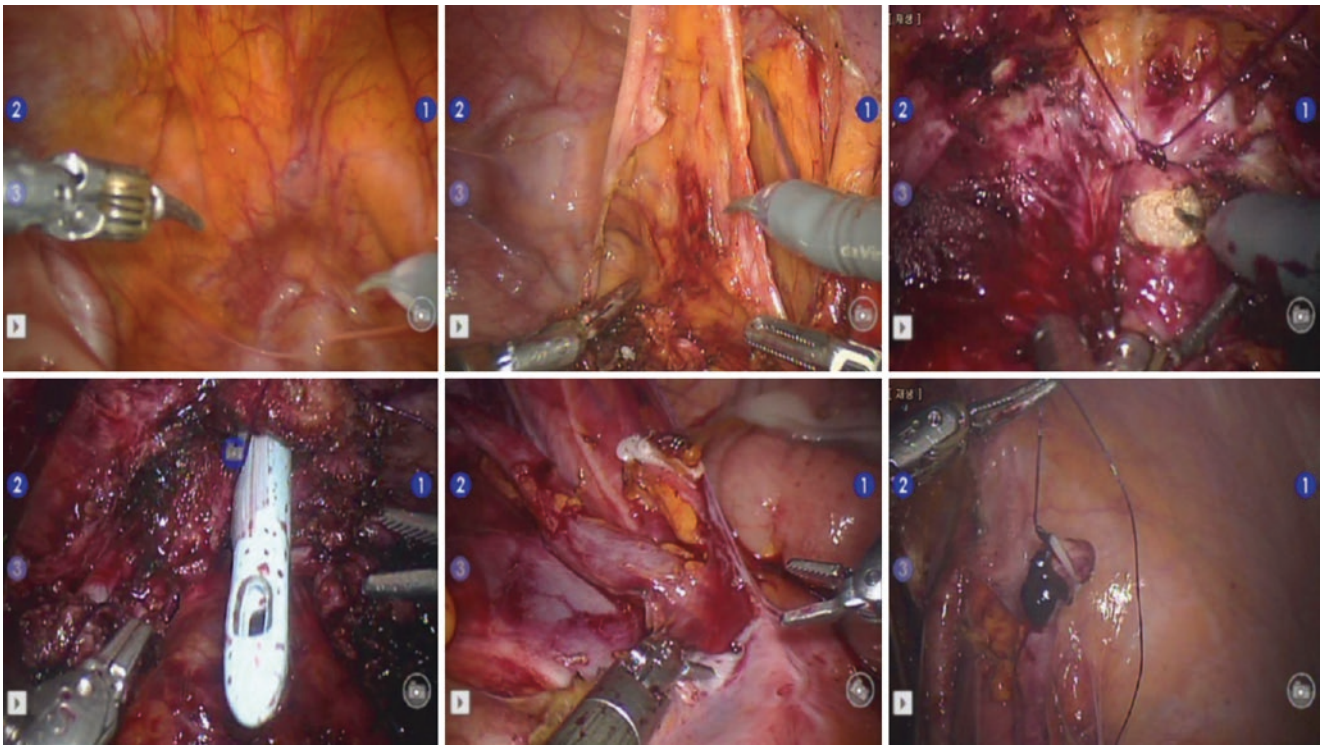

Fig. 73.2 Robot-assisted pelvic exenteration-Anterior PE. Dissection of the lateral pelvic wall and urinary bladder. Resection of the urinary bladder and mobilization of the ureter. Preparing of the urinary diversion to the lower abdominal wall

can be used to complete the management of the defect, and colostomy is performed (Fig. 73.3).

Supralevator pelvic exenteration Women with disease extending posteriorly from the cervix onto the vaginal epithelium or into the rectal wall are candidates for this procedure, provided the cancer does not extend to the lower third of the vagina posteriorly. After the bladder, urethra, and anterior vagina are mobilized, as previously described, the posterior vaginal wall incision is made 4 cm below the tumor. The vaginal epithelium is mobilized for 1–2 cm away from the rectal muscularis. The hand then encircles the mobilized rectum and pulls it cephalad. The specimen side is clamped to reduce spillage of feces and divided, leaving an anal and rectal stump. The length of the anal rectal stump from the anal sphincter is ideally 6 cm or greater. If less than 6 cm in length, the risk of fistula and incontinence is greater. After mobilization of this lower specimen, the sigmoid colon is divided along with the sigmoidal arteries and the superior rectal artery. Ample mobilization for reanastomosis is accomplished by incising the lateral attachments of the sigmoid and descending colon, mobilizing it and, if necessary, sacrificing some of the sigmoidal vessels. The major blood supply is from the inferior mesenteric artery, which has significant anastomoses between it and the middle colic artery. After the sigmoid and left colon are mobilized, the colon should be observed for adequacy of blood supply and viability while the urinary diversion is done, and the flaps for neovaginal construction are harvested. The anastomosis is accomplished using 28–31 mm-diameter circular staplers. Following anastomosis, the omentum is mobilized and brought into the pelvis as an omental graft. It is used to wrap the low rectal anastomosis and to fill the presacral space.

Reconstruction

Urinary Diversion The standard urinary diversion for several decades was the urinary conduit using a segment of the ileum to which the ureters would be anastomosed, and a stoma created in the right lower abdomen. Currently, the preferred method of urinary diversion is a continent pouch, created from the distal ileum, ascending colon, and a portion of the transverse colon. The ileum is divided 10–12 cm proximal to the ileocecal valve, and the transverse colon is divided just distal to the middle colic artery (Miami pouch). An ileotransverse colon enterostomy is performed to restore continuity to the gastrointestinal tract. The isolated segment of bowel is opened with cautery along the tenia. The bowel is then folded on itself in a U-shape conduit and the edges closed with a stapling device. This formation of the colon creates a reservoir and interrupts the ability of the bowel to peristalsis and increase the pouch pressure.

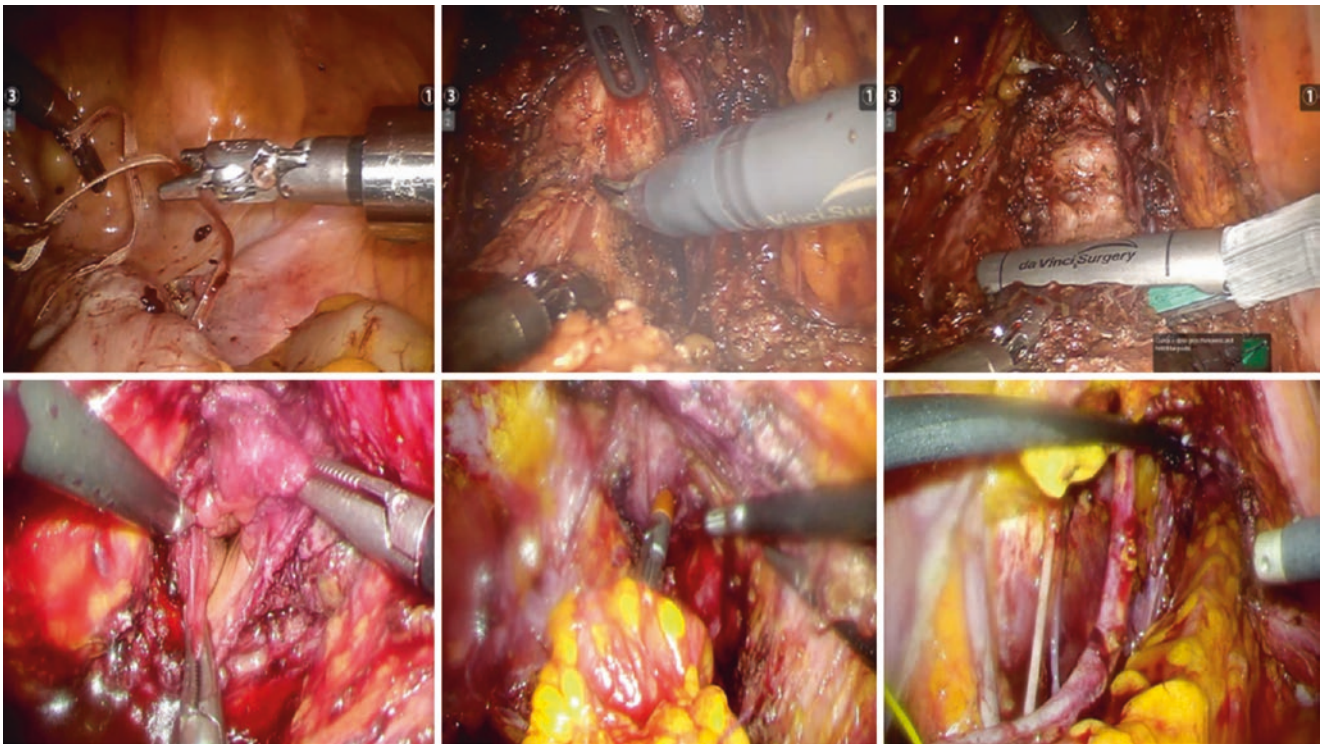

Fig. 73.3 Robot-assisted pelvic exenteration-Posterior PE. Developing of the perirectal spaces and dissection of the rectosigmoid colon. Resection of the rectosigmoid colon above the levator muscles. Reconstruction of the proximal sigmoid colon to the rectal stump

The ureters brought through stab wounds into the bowel reservoir, and the spatulated ends are anastomosed mucosa to mucosa. The left ureter is brought through the sigmoid mesentery to reach the reservoir. A 14 French catheter is placed into the ileum and passed through into the reservoir. Excess ileum is excised from the antimesenteric edge with a stapling device, and three purse string sutures are placed at the ileocecal valve to tighten the ileum. The tapered end of the ilium is brought out as a stoma. The ureters are stented and, with a Malecot catheter, are brought out through the anterior wall of the reservoir and through a separate opening in the abdominal wall. Stents and catheter are removed 2 weeks postoperatively.

Fecal diversion For patients whose disease requires infralevator dissection posteriorly, permanent end colostomy will be required because the anal sphincter is compromised or excised. If the sphincter and enough rectum may be spared without compromising the chance at complete disease resection, low rectal anastomosis with circular staplers is a reasonable option, if enough healthy tissue remains. To improve the frequency of stooling by improving the reservoir of the rectum, a colonic J-pouch may be used, particularly in patients with very little rectum remaining (less than 5 cm) [27, 28, 50, 51].

Robotic systems maintain the advantages of conventional laparoscopy while enabling the surgeon to dissect down and into the narrow pelvic floor. 3D stereoscopic vision (facilitated by the use of binocular optical systems), tremor filtration, and reduced operators' fatigue are the obvious advantages of robotic technology. The articulated instruments permit a wide range of motions while increasing the ability of the operator to work efficiently within the confines of the pelvic floor. All of these advantages can help procedures to preserve anatomic structures of the pelvis and make both destruction and reconstruction phases of PE easier [31, 32]. Moreover, the harmonic scalpel enables control of the pelvic sidewall vessels and transaction of the ligamentous attachments around the extirpated pelvic structures. Intestinal anastomosis after colorectal cancer resection can be performed by an experienced surgeon, in accordance with current oncologic guidelines. In addition, the 360° motion of a robotic wrist permits fine suturing that is necessary for performing ureteral iliostomy and ideal loop urinary diversion [34]. Robotic assisted laparoscopic surgery is associated with significantly less blood loss, less pain, shorter recovery time, shorter hospital stay, and better aesthetic results. Furthermore, shorter hospital stays and quicker return to normal activity may mean that postoperative chemotherapy or radiation can begin earlier, and complications related to bowel adhesions caused by radiation can be reduced [28, 32].

The cases of robotic-assisted laparoscopic PE with urinary diversion performed extracorporeally (ileal conduit diversion + orthotopic neobladder) were first described by Pruthi et al. [23] in 12 women with localized bladder cancer. Lim [24] reported the first case of robotic assisted total PE with ileal loop urinary diversion and end colostomy for the treatment of recurrent cervical cancer. Lavazzo et al. reported eight patients between 43 and 67 years of age treated with robotic-assisted PE for IB2 to IVA squamous cell carcinoma of the cervix. In 7 out of the 8 patients, anterior PE was performed; the other woman underwent total PE, with the duration ranging from 375 to 600 min, and blood loss from 200 to 550 ml. Postoperative complications occurred in two patients and included perineal abscess, Miami pouch fistula, and ureteral stenosis. Postoperative hospital stay ranged from 3 to 53 days, while postoperative follow-up ranged from 2 to 31 months [32].

Lawande et al. reported a 35 year old female with advanced cervical cancer who presented with vesicovaginal and rectovaginal fistula. They performed total robotic PE with colo-anal anastomosis and uretero-sigmoidostomy. The total operation time was 240 min and the console time was 120 min. The estimated blood loss was 300 ml and the intensive care unit stay was 2 days. Post-operatively, the patient had good fecal and urinary continence and high quality of life [26].

Davis et al. reported two women, 50 and 58 years old respectively, who required anterior PE for recurrent cervical cancer (squamous cervical cancer-IVB). Mean operation time was 9 h, mean blood loss was 550 ml, and postoperative hospital stay was 8 days. Postoperative complications were not mentioned. The authors reported that the robotic system is promising in patients needing surgery for recurrent cervical cancer. It provides improved visualization of the deep pelvis, enhanced manipulation of radiated fibrotic tissue, and reduced blood loss [36]. Subsequently, Lambaudie et al. reported a case series of three patients who underwent robot-assisted total PE [25]. Interestingly, the urinary diversion was made extracorporeal by transrectal laparotomy. The authors reported that with regard to hospital stay, there was no benefit compared with laparotomy, essentially due to urinary diversion management (catheterization) and self-catheterization to preserve the nerve.

Given the radical and prolonged nature of this procedure, patients and providers must be prepared for a long and potentially complicated hospital course. Many patients, after operation, need to stay in the intensive care unit immediately for close monitoring, particularly for dramatic fluid shifts. Blood loss may be high with transfusion required in most patients. Special attention to prophylaxis for thromboembolism, respiratory care, and nutrition is required. Some patients will require total parenteral nutrition due to prolonged inability to eat postoperatively to prevent relatively common ileus [43].

All series show that about 25–40 % of well selected patients with no metastatic disease survive for a minimum of 5 years. Patients who had palliative exenteration may still benefit from surgery in terms of quality of life and life expectancy of 18–24 months. The organ and histological subtypes often have significant influence on long-term prognosis. As a rule, exenteration for colonic and rectal adenocarcinomas results in better survival. This may be partly due to better responsiveness to chemotherapy and new small molecule-targeting agents. Cervical cancer also shows reasonably good survival due to its response to radiation therapy [31].

Considering the novelty of this minimally invasive procedure, several principles and standards must be rigorously evaluated and maintained. First, it remains paramount to observe and maintain the oncologic principles of such procedure without surgical modifications. That is, pathologic endpoints and consequent oncologic outcomes must never be compromised with such new techniques. Second, such procedures should have appropriate perioperative outcomes including operation time, blood loss, and length of hospital stay. Such measures may reflect and influence morbidity, recovery, and operative difficulty (i.e., the learning curve) of surgeons. For example, in robotic prostatectomy procedures, operation time has been used as an indirect measure of surgical difficulty and progress in overcoming the learning curve [35].

Conclusions

In summary, laparoscopy and robotics are preferable to laparotomy for patients requiring RH, with some advantages noted for robotics over laparoscopy. Current evidence demonstrates the safety and feasibility of robotic-assisted RH for early stage cervical cancer. Robotic approach provides clear benefits of minimally invasive surgery, such as lower morbidity, reduced blood loss, and faster recovery than open surgery. Further studies are necessary to evaluate long term survival and to analyze morbidity after surgery and adjuvant therapies.

Despite the apparent encouraging early results suggesting the advantage of minimally invasive surgery for PE, questions remain about the surgical effectiveness of this approach. Further studies on minimally invasive techniques for PE are needed prior to widespread clinical application of these techniques. Furthermore, research should also focus on the postoperative quality of life and other benefits for the patient.

Robotic-Assisted Laparoscopic Hysterectomy and Endometriosis

74

Camran Nezhat, Erika Balassiano, Ceana H. Nezhat, and Azadeh Nezhat

Introduction of Robotic Surgery in the Field of Gynecology

Leonardo da Vinci sketched the first prototype of a robot in 1464 when he was 12 years old (Fig. 74.1). His life-sized armored robot knight was not realized until 1495 when it was built for the entertainment of his patron, the Duke of Sforza, at a celebration in the Court of Milan [1]. Five hundred years later, the field of robotics is not limited to entertainment, but has improved many aspects of everyday life. In medicine, for example, robotics has brought advancements to minimally invasive surgery.

The da Vinci robot was developed by the Medical Technology Laboratory (MTL) team, at the Stanford Research Institute (SRI), under the direction of Dr. Ajit Shah in early 1990s [2]. In collaboration with the Department of Defense and the National Aeronautics and Space Administration, the initial objective was to allow military surgeons to perform surgery from a remote location on wounded soldiers in mobile medical facilities close to the battlefield [3]. As the technology further developed with improved visual systems, articulating instrument manipulators, and better ergonomics, new uses for the robotic telepresence technology evolved and the robotic system was adapted to civilian surgical use as a new minimally invasive surgical technology.

The da Vinci® Robotic Surgical System (Intuitive Surgical® Inc., Sunnyvale, CA) pioneered as the first integrated three-dimensional viewing systems for minimally invasive surgery. The first successful telesurgery with the da Vinci® was a cholecystectomy performed in 1997 by Jacques Himpens and Guy Cardier in Brussels, Belgium [4]. A few years later in 2000, the U.S. Food and Drug Administration approved the da Vinci® Surgical Robotic device for laparoscopy, and in 2005, it was specifically approved for laparoscopic hysterectomy. Its current breadth of medical applications includes minimally invasive cardiothoracic surgery, urology, colorectal, general surgery, otolaryngology, and gynecology.

In the field of gynecology, the da Vinci® surgical system assists with a number of procedures including hysterectomy, myomectomy, complex resections of endometriotic lesions, tubal reversal, sacral colpopexy, and oncology surgery [5]. Since its introduction in 2000 to the U.S. market, the number

Fig. 74.1 A recreation of da Vinci's robot, fashioned in German-Italian medieval armor, was able to make several human-like movements. This model is on display in Berlin

of surgeon users has exponentially increased. Its widespread acceptance and application to gynecologic surgery can be attributed to its ease of use over conventional laparoscopy which subjects surgeons to counterintuitive hand movements, 2-dimensional video images, limited degrees of instrument motion, in addition to ergonomic challenges and tremor amplification [5]. Currently, there are over 3000 da Vinci® Systems installed worldwide and more than 2000 in the U.S. alone. The number of da Vinci® procedures performed in 2009 was 180,000 and within 1 year the number of procedures increased by 35 % to 278,000 in 2010 [6].

Advantages

The most obvious advantages of minimally invasive surgery are smaller incisions, less pain, shorter hospital stays, faster postoperative recovery, and improved patient satisfaction. Specific features of the da Vinci® Robotic System that enhance laparoscopic surgery are the immersive, high definition, 3-dimensional visual imaging which allows the surgeon to have better depth of perception and ability to magnify (x2 to x10). The computer can translate the surgeon's hand movements into the same movements of the robotic instruments. The robotic wrist can roll (twisting motion), pitch (up/down), yaw (side-to-side), and grip, allowing the surgeon 7° of freedom for each hand. Dexterity is further enhanced through computer motion scaling which allows the surgeon to make large macroscopic movements that the computer translates into microscopic movements of the instrument tips in the surgical field. In addition, the computer filters out high frequency hand motion and decreases operator tremor. The surgeon console decreases operator fatigue by allowing the surgeon to sit and comfortably perform the procedure.

Disadvantages

Certainly, there are some drawbacks to robotic surgery. The initial cost for the hospital system is high. A da Vinci® Robotic Surgical System costs slightly under $two million with an annual maintenance average cost of $140,000 per year. The cost-per-case for drapes and instruments is approximately $1000 [6]. The three component robotic system is bulky and requires large operating room space to comfortably accommodate and maneuver the system components. The unwieldy robotic arms have large excursion arcs that lead to frequent collisions and limitations on the placement of ports on the patient's torso. Furthermore, the bedside surgical assistant has to maneuver around the large robot and manage the uterine manipulation. Technical disadvantages are lack of tactile feedback to the surgeon operating from the console, and the inability to regulate the force applied to the tissue. Another drawback is that neither the patient nor the surgical table can be moved or repositioned once the robot is docked.

Preoperative Preparation, Patient Selection, and Anesthesia Considerations

Preoperative preparation can help assess the patient's ability to successfully undergo a robotic-assisted laparoscopic surgical procedure. Cardiovascular and pulmonary comorbidities should be thoroughly evaluated with appropriate preoperative testing. Although there is no data to support the use of preoperative mechanical bowel preparation, we believe that it helps to decompress the bowel for better visualization, decreases the risk of contamination due an unintended bowel injury, and allows for primary repair of the bowel, if needed. Specifically in cases of severe and deep infiltrating endometriosis involving the posterior cul-de-sac and the recto-sigmoid colon, adhesion formation and anatomy distortion can be very prominent, making bowel preparation extremely helpful.

In order to provide safe patient care, surgeons and anesthesiologists must understand the physiologic derangements that robotic-assisted laparoscopic surgery can have on anesthetic management. Several important issues specifically related to robotic surgeries include patient medical comorbidities, especially cardiovascular and pulmonary diseases, patient positioning, duration of the procedure, development of hypothermia, hemodynamic and respiratory effects of the pneumoperitoneum, and blood loss.

Intraoperative anesthesia considerations during robotic surgery are similar to traditional laparoscopy. Gynecologic procedures such as hysterectomy are performed in lithotomy with steep Trendelenburg position to take advantage of gravity that allows the bowel to drop down and out of the surgical field. It also helps to run the bowel in order to search for endometriotic lesions. Several hemodynamic changes occur with insufflation of the abdomen and the steep Trendelenburg position. The compressive effects of CO_2 insufflation on arterial vasculature result in a dramatic increase in systemic vascular resistance (SVR), particularly during the initial phase of insufflation. Using impedance cardiography, Westerband et al. reported a 30 % reduction in cardiac index (CI) and a 79 % increase in SVR immediately after peritoneal insufflation to 15 mm Hg [7]. In addition, patient position can markedly affect the cardiovascular system; a 10–30 % reduction in cardiac output occurs when a patient is placed in Trendelenburg [8].

The respiratory system is also impacted by CO_2 insufflation and pulmonary compliance is reduced by 30–50 % in both healthy and obese patients [8]. Peak airway pressure, plateau pressure, and intrathoracic pressure are increased [9]. Maintenance of normocarbia and acid-base status may be challenging in patients with poor pre-operative respiratory

statuses. The main factors contributing to an increase in $PaCO_2$ and respiratory acidosis are the peritoneal absorption of CO_2, increased dead space in patients with coexisting lung disease, increased metabolism during surgery, inadequate ventilation, subcutaneous emphysema, and CO_2 embolism.

Obese patients undoubtedly benefit from minimally invasive surgery; however, there are challenges to anesthesia in this population. Arterial oxygenation is significantly impaired in overweight patients under general anesthesia in Trendelenburg position. Fluid replacement is also challenging, as crystalloids cause edema to form quickly around the face, eyes, and upper airway. Post extubation respiratory distress has been described, requiring emergent reintubation. Thus, fluid replacement should be restricted to 1–2 l over the course of the surgery using sufficient colloids. At the end of the surgery, it is crucial to ensure that significant laryngeal edema has not occurred while in steep Trendelenburg, and that the patient can breathe around the endotracheal tube with a deflated cuff prior to extubation [10].

Basic Set up for the Da Vinci® Robotic System

The da Vinci® Robotic System is composed of three components: the surgeon console, the patient-side robotic cart, and the InSite vision console (Fig. 74.2). The surgeon sits at the console away from the patient and uses a stereoscopic 3-dimensional viewer with hand manipulators and foot pedals, which control the robotic-assisted instruments within the patient. Ergonomic hand controls translate the 3-dimensional motion of the surgeon's hands into signals that directly control the robotic arms. The ratio of the surgeon hand motions to robotic arm motion can be modified through motion scaling. For example, a 5:1 ratio translates 5 inches of movement by surgeon into 1 inch of movement by the robotic arm. These ratios are preset. Foot pedals within the console are used for activation of electrosurgery, "clutching" or readjusting the hand controls, and switching between functioning robotic arms [11].

The patient-side robotic cart has telerobotic arms to which the EndoWrist® instruments attach. The robotic cart has four arms; one of the arms holds the laparoscope while the other two to three arms hold various laparoscopic surgical instruments. The InSite® vision console processes the images from the endoscope containing the stereoscopic cameras and dual optical lenses to the surgeon console where the operator has a 3-dimensional image of the surgical field.

Three people are directly involved in the robotic surgery: the surgeon, the bedside surgical assistant, and the scrub nurse. However, an anesthesiologist and circulating nurse familiar with the robotic laparoscopy can assist in making the procedure run efficiently (Fig. 74.3).

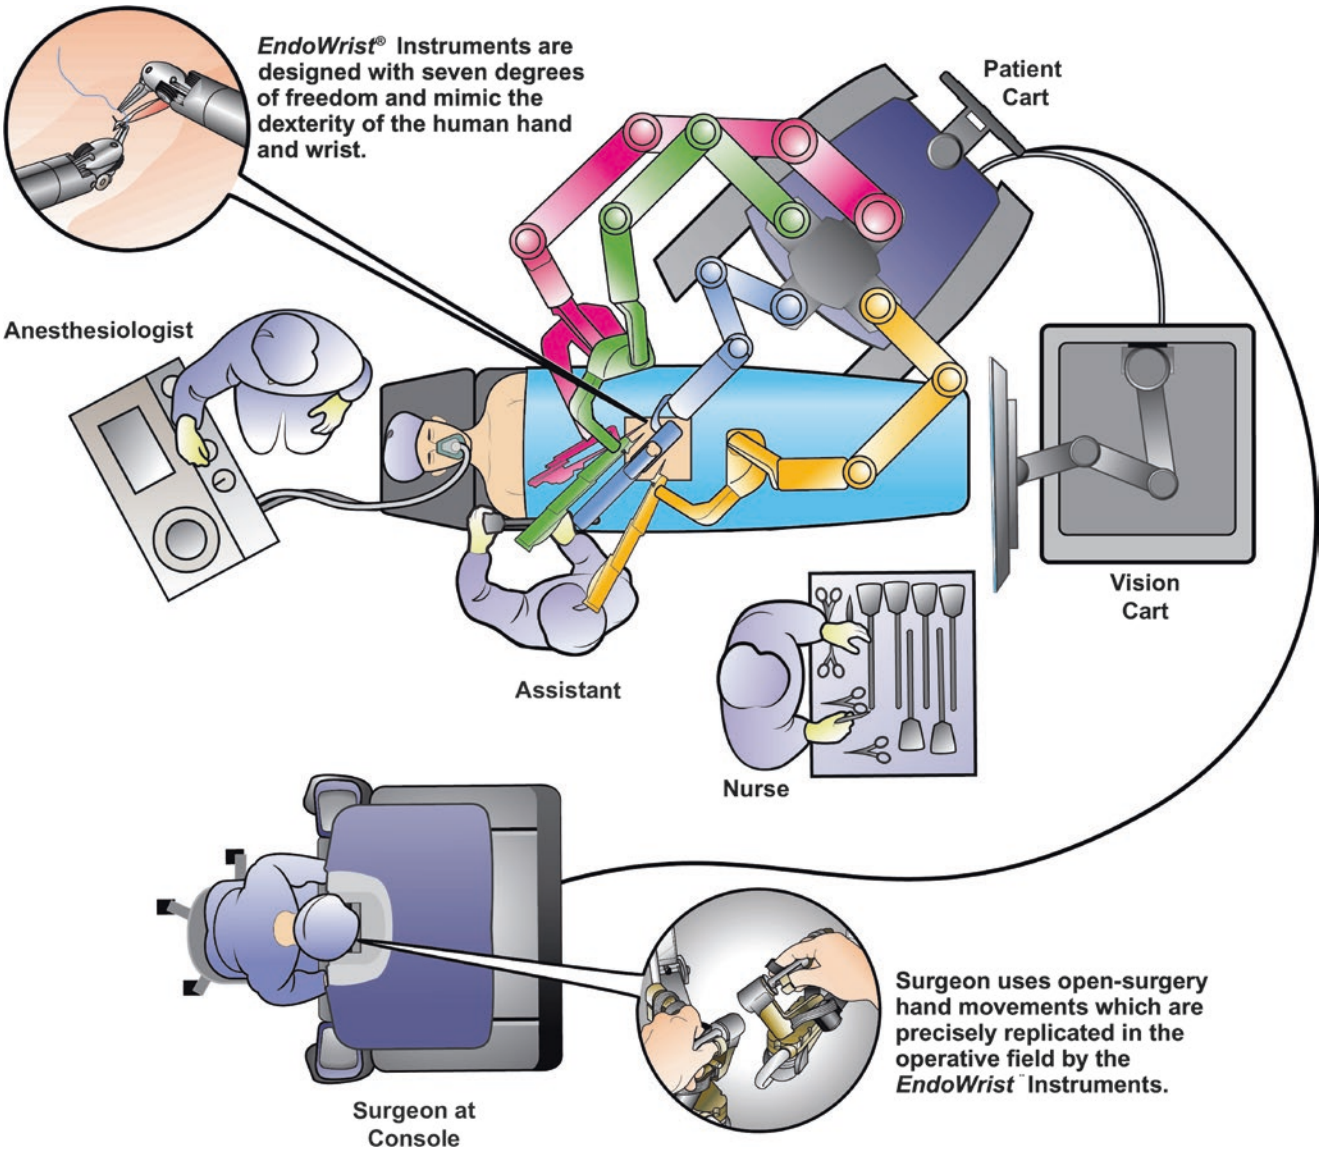

Fig. 74.3 General operating room set-up for the da Vinci® surgical system

The Robotic-Assisted Laparoscopic Hysterectomy (RALH)

Hysterectomy continues to be the most common gynecologic surgery in the United States. An estimated 600,000 women each year undergo hysterectomies for benign indications, most commonly uterine myomas, endometriosis, and uterine prolapse [12]. The goal of laparoscopic hysterectomy and laparoscopic-assisted vaginal hysterectomy is to convert abdominal hysterectomies to endoscopic ones [13]. A cross-sectional analysis of national discharge data in 2005 found that the most common route of hysterectomy was total abdominal hysterectomy (64 %), followed by vaginal hysterectomy (22 %), and laparoscopic hysterectomy (14 %) [14].

Though vaginal hysterectomy is the optimal and most minimally invasive approach, the inability to visualize the abdominal-pelvic anatomy is a disadvantage. The benefit of laparoscopic hysterectomy is the ability to visualize *in situ* the abdominal and pelvic pathology prior to removing the uterus and adnexa, if needed.

Different studies have compared laparoscopic hysterectomy with and without robotic assistance [15, 16]. It has been shown that the use of the robot is more time consuming and it could also be more expensive, however surgical outcomes are the same, except for a higher rate of vaginal cuff dehiscence associated with robotic assistance. In our experience, the robotic platform can be regarded as an "another instrument for laparoscopic surgery". It potentially allows to master suturing in lesser time and is less tiring when

operating on obese patients instead of adhering to the old fashioned exploratory laparotomy. It is simply another tool available to the gynecologic surgeon.

Patient Positioning

Similar to laparoscopic-assisted hysterectomy, preparing for a robotic-assisted hysterectomy begins with safe and appropriate patient positioning. The operating room table should be configured for gynecological procedures, with the ability to lower the bottom of the bed. A gel pad or another non-slip device should be placed between the operating room table and the patient in order to prevent the patient from sliding down after steep Trendelenburg has been established. Obese patients are especially prone to shift down the operating room table during surgery. This movement is problematic for both uterine manipulation and surgical field displacement. Shoulder braces should be avoided because of the risk of brachial plexus nerve injuries.

For the RALH, the patient is placed in low dorsal lithotomy position with arms padded and tucked to the side of the table (Fig. 74.4). Proper padding of pressure points prior to draping is extremely important to prevent tissue and nerve injury especially during longer procedures. A Foley catheter is placed to drain the bladder. A nasogastric tube (NGT) or orogastric tube (OGT) is placed to decompress the stomach and reduce the risk of visceral injury upon entry. Antibiotic prophylaxis should be given prior to the start of the case, cefazolin 1–2 g IV or clindamycin 600 mg IV plus gentamycin 1.5 mg/kg IV for patients with penicillin allergies [17]. Though it is a laparoscopic procedure, the RALH is still considered a surgical wound Class 2, a clean-contaminated wound.

Uterine Manipulation

An exam under anesthesia is performed to reassess the size and position of the uterus, to sound the uterus, and to measure the size of the cervix. The cervix size is assessed visually or with a hand held cervical sizer. There are several commonly used uterine manipulators which have a colpotomy ring that is essential for a successful colpotomy at the end of the laparoscopic hysterectomy procedure. The VCare® Uterine Manipulator (ConMed Corporation, Utica, NY) and the RUMI (Cooper Surgical, Trumbull, CT) are two examples. The VCare® is a disposable unit with its own colpotomy ring attached to a handle and vaginal occludes (Fig. 74.5). The KOH colpotomizer system® incorporates the RUMI handle, a choice of different sized colpotomy rings, and a selection of different sized tips. A vaginal balloon pneumo-occluder should also be assembled on the RUMI® uterine manipulator and inflated in the vagina to maintain pneumoperitoneum as the colpotomy is made (Fig. 74.6).

Laparoscopic Entry and Port Placement

After the uterine manipulator is placed and the colpotomy ring sits securely in the cervicovaginal junction, the surgeon can return to the patient's abdomen and establish pneumoperitoneum by various methods. A 12 mm port (Fig. 74.7. location A) is usually placed at the umbilicus, or higher depending on the size of the uterus, after pneumoperitoneum is obtained to 15 mmHg. A survey of the abdomen and pelvis is performed, noting the liver edge, gallbladder, fundus of the stomach, and appendix, in order to thoroughly search for extragenital endometriosis. Two 8 mm robotic trocars are placed bilaterally 10 cm lateral to the umbilicus and 2 cm

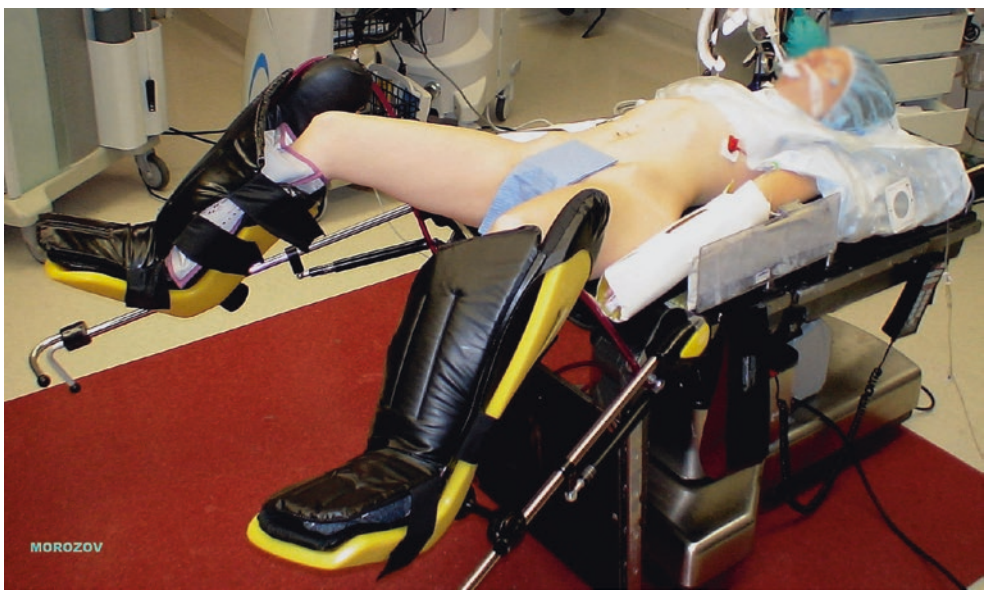

Fig. 74.4 Patient positioning for gynecologic robotic procedures. The patient is positioned in dorsal lithotomy using Allen stirrups with arms tucked to the side. Later on, steep Trendelenburg will be used

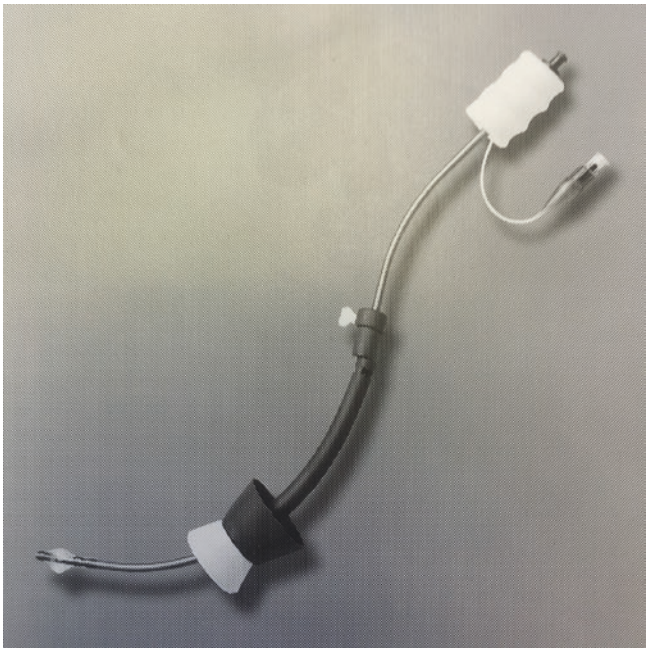

Fig. 74.5 VCare®, a commonly used uterine manipulator with a colpotomy ring

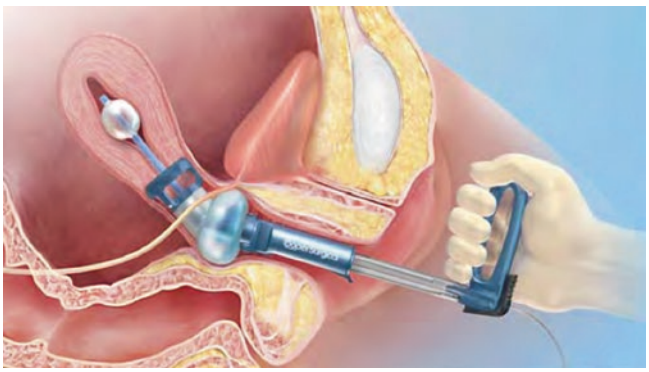

Fig. 74.6 RUMI®, a commonly used uterine manipulator with a colpotomy ring

above the level of the uterine fundus (Fig. 74.7. location B) under direct laparoscopic visualization. An accessory 5 mm trocar is placed between the umbilical port and the lateral port 3 cm caudal to the umbilicus (Fig. 74.7. location C). When the fourth robotic arm is used, that trocar is placed at least 8 cm lateral to the umbilicus and 8 cm cephalad to the right robotic trocar.

The operating room table is lowered, and the patient is placed in the maximum amount of Trendelenburg to allow optimal visualization with the bowel falling away from the pelvis into the upper abdomen. After the final degree of Trendelenburg is established and the patient-side robotic cart has been docked, no further table movements can be made.

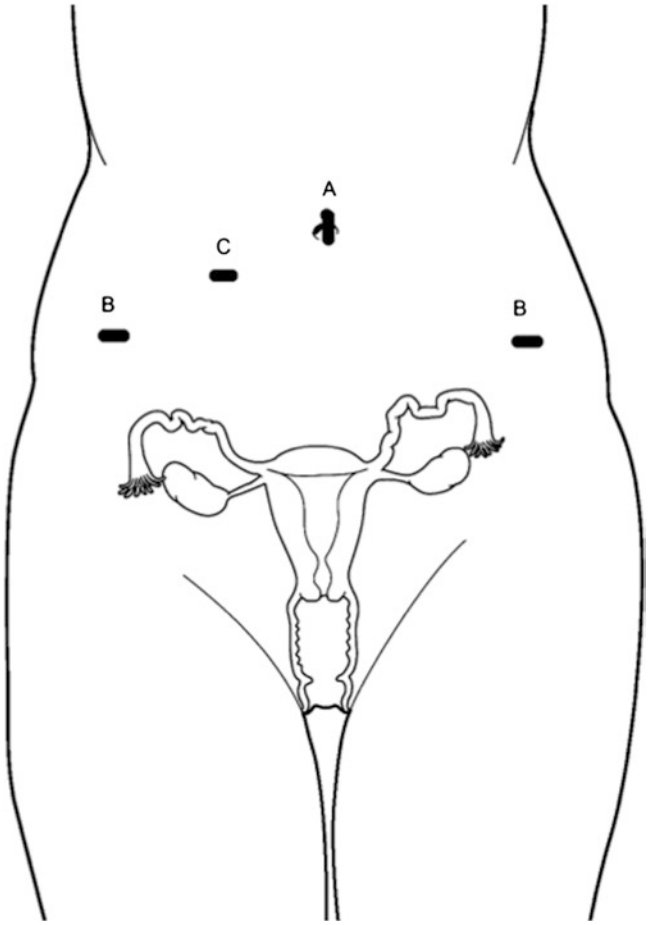

Fig. 74.7 Robotic port site placement for gynecologic surgery

The average set up time, defined as the time between switching from laparoscopy to the robot, is 16–18 min for an experienced OR team. This process includes docking the sterile draped robot, switching trocars, changing the camera, and attaching the surgical instruments. Disassembly time is 2.5–3 min on average [18, 19].

Docking the Bedside Robot

The traditional docking of the robotic cart for gynecological procedures is between the patient's legs. The advantage of this docking position is that the camera and working arms are placed in the same axis as the patient's torso. However, this position poses challenges for gynecologic procedures, as the bedside assistant is unable to access to the vagina and provide good uterine manipulation and exposure.

An alternative for gynecologic surgery is side docking at a 45° angle from the midline, with the central column of the robotic cart and the camera arm in line with the patient's contra lateral shoulder. This configuration allows the bedside

assistant easier access to the uterine manipulator and the vagina, should the uterine manipulator need to be adjusted during the surgery or if there is difficulty removing the uterus after the hysterectomy is completed. It also provides room for an intraoperative rectovaginal exam if needed to localize and palpate endometriotic nodules, in an attempt to overcome one of the drawbacks of the current robotic platform: the lack of haptics. This is an important disadvantage when considering treatment and resection of endometriotic nodules in the rectovaginal space using robotic assistance. The fibrotic tissue, consequence of severe disease, cannot be felt in the rectovaginal septum.

Once the patient-side robotic cart is docked, the robotic arms can be attached to the 8 mm trocars and the robotic endoscope and instruments can be inserted. Careful attention should be given to the robotic arms to prevent them from contacting the patient directly. Crush injuries to the patient may occur unintentionally if the robot is improperly positioned.

Switching the Laparoscopic Camera to the Robotic Scope

The endoscope typically used for gynecologic procedures, including hysterectomy, is the 12 mm 0-degree laparoscope that is introduced through the 12 mm umbilical port. There is a 30° laparoscope that is helpful for urogynecology cases in the lower pelvis. As in traditional laparoscopy, the camera and light source should be carefully monitored and never left directly on drapes in order to avoid fires and thermal injury to the patient. If the tip of the robotic endoscope becomes dirty or fogged during surgery, it should be removed from its robotic arm and cleaned with a proper solution and lens cloth in order to prevent scratching of the optics. Wiping the tip of the robotic endoscope on internal organs should not be done because the robotic endoscope is significantly hotter than standard endoscopes and will cause thermal damage to the viscera.

EndoWrist Instruments

The da Vinci® Robotic System has a selection of 8 mm EndoWrist® instruments for gynecologic surgery. Most of the robotic instruments (Fig. 74.8) have been adapted from traditional laparoscopic equipment. Among the most common and useful for RALH procedures are the monopolar curved scissors, fenestrated bipolar forceps, tenaculum forceps, mega needle driver, Gyrus PK® grasper (Olympus Company, Southborough, MA) (not pictured), and Harmonic scalpel® (Ethicon Endo-Surgery, Cincinnati, OH) (not pictured). These instruments can be snapped into the robotic 8 mm ports.

Robotic-Assisted Laparoscopic Hysterectomy Technique

The RALH technique is similar to the open hysterectomy. Initially, the round ligament is identified, desiccated with bipolar forceps at 25-35 W current and cut with the monopolar scissors (Fig. 74.9). The anterior leaf of the broad ligament is then incised towards the bladder and the vesicouterine reflection (bladder flap) is created. If the ovaries are to be removed, the infundibulopelvic (IP) ligament is identified along with the ipsilateral ureter, isolated and desiccated with bipolar electrosurgery or ultrasonic energy and cut with shears. The laparoscopic surgeon should skeletonize the ureter and uterine vessels, so their courses are properly identified and injures avoided (Fig. 74.10a, b). Ureterolysis is performed after proper identification of the ureter as it enters the pelvis at the pelvic brim. The retroperitoneum is then opened in the ovarian fossa superiorly to the ureter with aid of the CO2 laser. Hydrodissection is then accomplished with the Nezhat-Dorsey probe which is also used for blunt dissection if needed in case of dense scar tissue in this area. The ureter is then pushed inferiorly from the dissection area to a safe location after hydrodissection is completed. Small bleeders are cauterized at the same time dissection is performed with the CO_2 laser.

If the ovaries are to be conserved, then the utero-ovarian ligament is desiccated and cut. The anterior leaf of the broad ligament is then fully incised, completing the vesicouterine reflection anteriorly. The vesicouterine reflection is tented up using fenestrated bipolar and the bladder is gently dissected off the lower uterine segment and cervix using sharp dissection with the Endoshears or bluntly. The tendinous attachments between the bladder, cervix, and upper vagina may be dissected or desiccated (Fig. 74.11).

The uterine arteries are identified and skeletonized, allowing the ureters to fall further laterally for safe vessel sealing and division of the vessels. The cardinal ligaments are subsequently desiccated and divided. The uterine manipulator is helpful in retracting the uterus in the opposite direction, facilitating exposure of the uterine vessels. After the uterine arteries are divided, the bedside assistant performing the uterine manipulation should push the uterine manipulator cephalad to accentuate the edges of the colpotomy cup (Fig. 74.12). Deep infiltrating endometriosis can be dissected off the retrocervical areas with the CO2 laser and the Nezhat-Dorsey probe. Very careful dissection is performed specially if bowel adhesions are encountered.

Fig. 74.8 Selection of EndoWrist® instruments

At this point, the experience of the surgeon plays a major role in order to avoid bowel injuries.

The colpotomy is performed with the monopolar hot shears at 30 W cutting current. The uterus (and ovaries) can then be pulled through the vaginal cuff or if too large, it may be removed through extracorporeal morcellation in the vagina. Vaginal morcellation is performed with a long knife handle and a #10 blade, making circumferential incisions into the uterus while pulling outwards on the cervix. It is important to always keep the blade inside the myometrium and away from the surrounding vagina. A self retained retractor (Alexis® retractor, Applied Medical, CA) can

also be used to protect the vaginal walls during morcellation.

If supracervical hysterectomy is requested or vaginal access is limited, morcellation can be done through the anterior abdominal wall in a similar fashion.

A mini-laparotomy is performed (no more than 3–4 cm long) and a self retained retractor also used for exposure plus or minus a specimen bag for contained morcellation. Lahey clamps are used to exteriorize the uterus and extracorporeal morcellation is then performed in the same manner previously described. In light of the current controversy regarding uterine morcellation and the possibility of diagnosing a leiomyosarcoma, we recommend against the use of electromechanical devices for intracorporeal morcellation [20, 21].

If the uterus is small enough to be left in the vagina just below the vaginal cuff, then it can serve as a pneumo-occluder

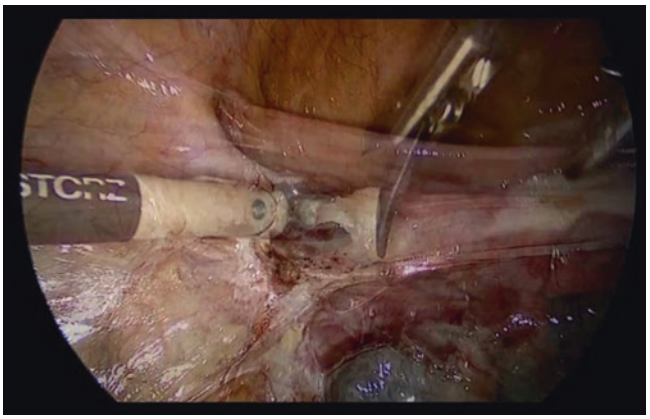

Fig. 74.9 The round ligament is identified, desiccated and cut with the monopolar scissors

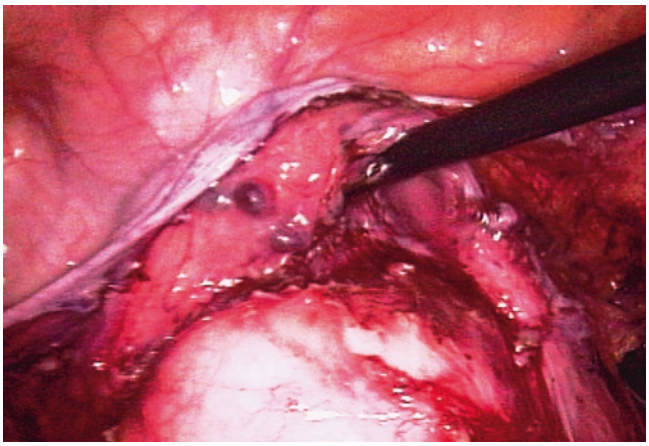

Fig. 74.11 Vesicouterine space after complete dissection

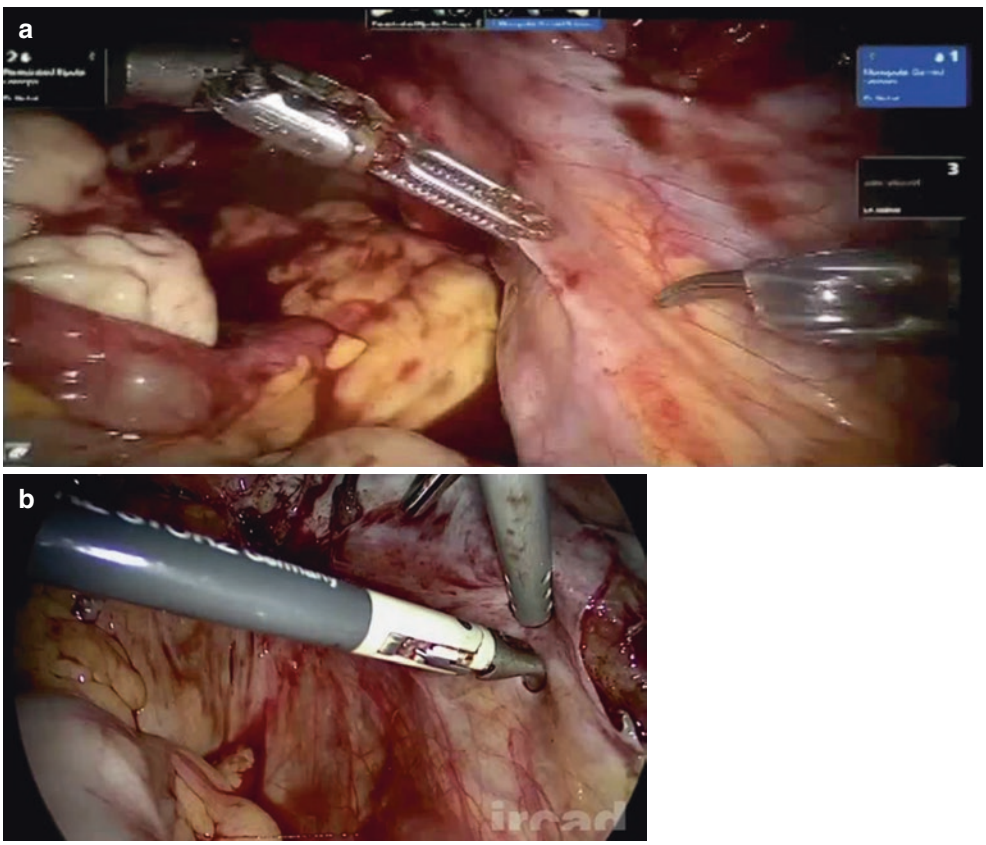

Fig. 74.10 (**a**, **b**) Ureterolysis. It is important to skeletonize the ureter in order to properly identify its course

Fig. 74.12 The colpotomy cup edges were accentuated with the correct placement and use of the uterine manipulator, allowing good exposure for colpotomy

or the balloon occluder can be replaced into the vagina after removing the specimen. Irrigation of the abdomen and pelvis and control of bleeding are performed prior to closing the vaginal cuff. Minor bleeding at the cuff can be controlled with cuff closure.

Excessive desiccation at the cuff should be avoided in order to prevent thermal damage to tissue and poor tissue healing which may lead to cuff breakdown and vaginal cuff dehiscence. The vaginal cuff can be securely closed with 2–0 Vicryl on at CT-1 needle via interrupted figure of eight stitches or with a running stitch and use of Lapra-ty® suture clips (Ethicon Endo-surgery, Cincinnati, OH).

Once the vaginal cuff is closed, the pelvis is irrigated a final time and examined for hemostasis. Desufflation of the abdomen and reinsufflation is another method of examining hemostasis under a physiologic lower intraabdominal pressure. For vaginal cuff support and prolapse prevention, the Moskowitz procedure is performed. The uterosacral ligaments are identified and a string suture is placed. Firstly, it transverses the right uterosacral ligament, then goes to the cardinal ligament under the uterine artery, followed by a very small bite posteriorly into the rectovaginal fascia, then over the left cardinal fascia and finally concludes its course at the left uterosacral ligament. An extracorporeal tie brings the cardinal ligaments, uterosacral ligaments and posterior vaginal fascia together in the midline. It provides excellent support for the vaginal cuff apex.

Cystoscopy at the conclusion of the hysterectomy is routinely performed to confirm the patency of the ureters and integrity of the bladder. Rates of bladder and ureteral injury during laparoscopic hysterectomy have been reported to be as high as 2.9 and 1.75 %, respectively [22]. One ampule of indigo carmine (1 ampule, 40 mg in 5 ml) is injected by IV approximately 5–10 min prior to the cystoscopy to aid in visualizing the patency of the ureters. If indigo carmine is not available, 200 mg of over the counter phenazopyridine (Pyridium®) given 30 min prior to procedure exerts the same effect. The dye should be visualized through both ureteral orifices. The bladder should also be inspected for sutures and thermal injuries.

Port sites larger than 10 mm should be closed to prevent trocar site herniation. These sites can be laparoscopically closed with a fascial closure device such as a Carter-Thomason CloseSure® System (Cooper Surgical, Trumbull, CT). A 0-Vicryl suture in a UR-6 needle can also be used for closure of the umbilicus fascia if the subcutaneous fat layer is not too thick, allowing proper identification of the fascia layer. The skin can be closed with Dermabond® (Ethicon Inc., Menlo Park, CA) or a subcutaneous stitch using 4–0 Monocryl suture.

Postoperative Care

The average length of stay for a robotic hysterectomy is less than 24 h. After the surgery and patient's recovery in PACU are completed, the patient can be restarted on a clear or regular diet if she is not experiencing nausea. Patients may ambulate on postoperative day 0. The Foley catheter can be removed immediately postoperatively, but more often it is left in the bladder overnight and removed the next morning. The patient can be discharged to home on postoperative day 1 with precautions for vaginal bleeding, vaginal discharge, abdominal pain, and fever. Six to eight weeks is recommended before the patient can resume vaginal intercourse to allow the vaginal apex to heal properly.

Complications of Robotic Surgery

According to Jonsdottir et al., the rates of intraoperative and minor postoperative complications have significantly decreased with the RALH procedure versus abdominal hysterectomy, while there was no difference in overall mean costs [23]. Comparing RALH to laparoscopic hysterectomy in a meta-analysis, the estimated blood loss, length of postoperative

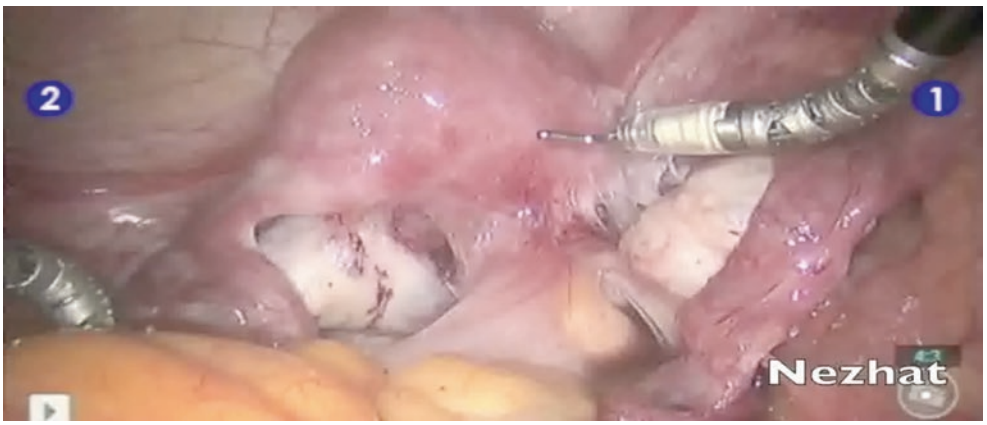

Fig. 74.13 Example of pelvic adhesions distorting the normal pelvic anatomy and increasing the risk of complications

hospital stay, and complications were comparable [24]. One perioperative complication found more frequently with both RALH and laparoscopic hysterectomy is vaginal cuff dehiscence with small bowel evisceration.

Though vaginal cuff dehiscence is rare, it is a serious and potentially life-threatening condition. Incidences of vaginal cuff dehiscence after robotic hysterectomy have been reported as high as 4.1 % (95 % CI 2.3–5.8 %) [25]. However, more recent literature suggests a lower incidence in laparoscopic hysterectomies 0.75 % (95 % CI 0.09–1.4), but the incidence is higher than that of abdominal 0.38 % (95 % CI 0.16–0.61) and vaginal 0.11 % (95 % CI 0.0–0.32) hysterectomies [26]. This difference suggests that vaginal cuff dehiscence may be occurring due to the use of electro-surgery to perform the colpotomy. The electro-surgery creates thermal cuff tissue damage and the devascularized tissue delays or even halts wound healing.

Ureter complications are another potential problem with laparoscopic and robotic-assisted hysterectomy. The ureters are commonly injured at the level of the IP ligament when this is transected prior to performing an oophorectomy. Another potential location for injury is where the ureters travel under the uterine arteries during uterine artery ligation, at the level of the uterosacral ligaments and during ureter insertion at the bladder dome when creating the vesicouterine space. If the anatomy is distorted due to the presence of leiomyomas or endometriosis, or adhesions from previous surgeries or history of pelvic inflammatory disease (Fig. 74.13), the risk for ureteral injury is even higher.

Most ureteral injuries are not identified or even suspected without cystoscopy [27–29]. Prompt recognition and management is essential in order to prevent further sequelae and patient morbitity, including multiple surgeries and organ loss. From our experience, we strongly recommended routine cystoscopy after every laparoscopic or robotic-assisted laparoscopic hysterectomy.

When dealing with endometriosis, prevention and recognition are the most important steps in order to avoid serious postoperative complications. Due to the severe adhesion formation that can be encountered, knowing the pelvic anatomy is crucial. Identification of the pelvic organs needs to be accomplished prior to attempting lysis of adhesions, ligation of vessels or treatment of the disease. Then, after the procedure is completed, we inspect the pelvic once again and perform cystoscopy and proctoscopy as indicated.

Conclusion

There is a clear trend in surgery, driven by patient demand, to perform less invasive approaches to common gynecologic procedures such as hysterectomy. The da Vinci® Robotic Surgical System enables gynecologic surgeons to convert complex cases such as hysterectomy, myomectomy, incontinence, microsurgical tubal anastomosis, and endometriosis cases, to endoscopic ones. Performing endoscopic surgery on the da Vinci® Robotic Surgical System has several advantages over traditional laparoscopy, such as high definition 3-dimensional visual imaging, greater dexterity with more degrees of freedom, and intuitive hand movements, which provide less-experienced laparoscopists with the confidence and technological support to master difficult endoscopic suturing and knot tying.

The advent of robotic surgery has enabled conversion of even more complex gynecologic procedures, including radical hysterectomy and fistula repair, especially in obese patients, to minimally invasive techniques [30–34]. This new technology may allow lower volume gynecologic surgeons to offer their patients procedures with clear health advantages – less pain, shorter hospital stay, fewer complications, and earlier return to activity and work [34].

Hysterectomy Techniques for Obese Patients

75

Amanda M. Hill, Lindsay Clark Donat, and Masoud Azodi

Introduction

Obesity poses certain challenges and risks to patients and surgeons in the perioperative period. Patients with obesity often have other comorbidities, which increase the risks of surgery and anesthesia. The increased adipose tissue makes positioning and surgical exposure more difficult. Patients are also at higher risk of cardiopulmonary events in the postoperative period.

The use of a robotic system such as the Da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA, USA) affords possible advantages when used for hysterectomy in obese patients [1–4]. While traditional laparoscopy can be ergonomically challenging, the robotic system allows the surgeon to sit comfortably at the console, providing improved ergonomics [5]. Robotic surgery also conveys the advantage of a third arm, controlled by the primary surgeon, which aids in visualization despite the increased adipose tissue obscuring the surgical field. Patients experience faster recovery when compared to open surgery, which is especially important in the obese population [6]. Women are able to ambulate and tolerate a regular diet more rapidly, decreasing the risk of venous thromboembolism (VTE) and ileus.

This chapter will outline the challenges, advantages, and additional considerations in the preoperative, intraoperative, and postoperative periods in patients with obesity undergoing robotically-assisted hysterectomy.

Preoperative Considerations

Like all surgical procedures, proper patient selection is an important consideration when planning to perform a robotic-assisted laparoscopic hysterectomy. Patients with obesity often have other comorbidities that must be considered when deciding on treatment options and optimally managed before proceeding with surgery. Typical indications for benign hysterectomy such as abnormal uterine bleeding, pelvic pain from adenomyosis or endometriosis, and even endometrial hyperplasia may be more appropriately managed medically (Table 75.1). It is important to weigh the risks and benefits of surgery in these patients to avoid potential complications of anesthesia and recovery. That being said, studies have shown no increased risk of surgical complications in obese patients compared with those of normal BMI [4, 7].

Obesity is associated with cardiovascular, pulmonary, and metabolic conditions. Patients with obesity are more likely to suffer from hypertension, coronary and peripheral vascular disease, ventricular hypertrophy, obstructive sleep apnea (OSA), hypoventilation due to restrictive or obstructive respiratory syndromes, dyslipidemias, diabetes mellitus, and decreased exercise tolerance [7–9]. It is essential that patients are evaluated by their medical doctor for a medical risk assessment prior to proceeding with elective surgery. They should also see a cardiologist and/or pulmonologist if they suffer from more severe cardiopulmonary disease or if specific conditions are uncovered during the preoperative evaluations. These specialists can offer recommendations to optimize the patient's clinical condition and thus reduce the risk of adverse perioperative cardiopulmonary outcomes.

Patients may also be unaware of existing medical problems due to lack of screening or if they have not seen a primary care physician. All patients with obesity planning elective surgery should be seen by a primary care physician to have appropriate screening tests prior to surgery. It is also beneficial for the patient to have a preoperative assessment with the anesthesiologist that will be caring for

them. The anesthesiologist may request additional tests or evaluation by specialists in order to prepare a safe plan to manage the patient's cardiopulmonary needs in the perioperative period.

Routine preoperative assessment should include a clinical evaluation, indicated routine blood work (complete blood count, blood type and antibody screen, basic metabolic panel), electrocardiogram, and chest x-ray [7–10]. Some authors suggest that routine chest x-ray is not necessary as it does not alter perioperative management [7, 8]. However, most recommendations call for chest x-ray in those over the age of 50, those with known heart or lung disease, or those with abnormal physical exam findings. Electrocardiogram is recommended for all patients with obesity given that obesity is a risk factor for heart disease [7, 8].

Patients with known cardiac disease or those with abnormal findings on routine preoperative assessment should be referred to a cardiologist for further testing such as echocardiography or a stress test. Routine echocardiogram and stress test are not recommended due to the low rate of abnormalities and lack of consequence on perioperative management [8].

Impaired pulmonary mechanisms due to obesity increase the risk of complications such as pneumonia, respiratory failure, pulmonary hypertension, and pulmonary embolism after surgery [9]. It also makes mechanical ventilation more difficult due to decreased compliance and increased intra-abdominal pressure leading to reduced lung volumes [9]. Patients with known pulmonary disease should be evaluated by their pulmonologist preoperatively. Polysomnography

(or sleep study) should be strongly considered due to the high prevalence (up to 40 %) of OSA in patients with obesity [8]. CPAP should ideally be initiated 6 weeks prior to surgery [8]. Routine spirometry is not recommended, unless COPD is suspected [8, 9]. Abnormal pulmonary function tests, when severe, can prompt planned intensive care unit admission [7].

As with any patient, patients with obesity undergoing robotic-assisted laparoscopic hysterectomy should have complete preoperative counseling including the indication for surgery, alternatives, and risks. The risk of complications related to the patient's underlying medical conditions should be clearly addressed, and special attention should be paid to risks of VTE and infectious complications, since obesity increases these risks [4, 9]. There is also an increased risk of conversion to an open procedure in obese patients [4]. Bowel preparation may be advisable to decompress the bowel, improving visualization of the surgical field [3]. Patients should have a good understanding and realistic expectations of the preparation for and recovery from surgery.

When operating on morbidly obese patients, the surgeon should be aware of the resources and limitations of the facility in which they operate. With the increasing prevalence of obesity, many hospitals and surgery centers are equipped with bariatric wheelchairs, lifts, and beds. The surgeon should be aware of the weight limits of the operating room tables and other special equipment required. Specially designed OR tables do exist in the case that a patient's weight exceeds the standard limit. However, some of these models have mobility limitations which could interfere with the degree of trendelenburg required for robotic-assisted laparoscopic hysterectomy. OR table accessories such as table extenders are often required for the obese patient. Most robotic-assisted laparoscopic hysterectomies will be done in lithotomy position using stirrups. The weight limit of the Basic Stirrups and Yellofins® Stirrups (Allen Medical Systems, Acton, MA) is 350 pounds (159 kilograms), while the Yellofins® Elite Stirrups (Allen Medical Systems, Acton, MA) can accommodate a patient up to 500 pounds (227 kilograms). Specially designed for larger patients, Ultrafins® (Allen Medical Systems, Acton, MA) can be used for patients up to 800 pounds (363 kilograms). The OR staff should be alerted to the special needs of the obese or morbidly obese patient to adequately prepare for transporting, positioning, and transferring the patient to prevent delays or embarrassment for the patient.

Intraoperative Considerations

Obesity adds complexity to all aspects of robotic-assisted laparoscopic hysterectomy, including patient positioning, anesthesia, and exposure and visualization. Robotic-assisted laparoscopic hysterectomy has many measurable benefits over laparotomy, including shorter hospital stay, less pain, faster return to normal activity, decreased incidence of post-operative ileus, fever, and wound infection, and improved quality of life [1–3]. This is particularly true for the obese patient. In this section we will address how obesity affects various aspects of robotic-assisted laparoscopic hysterectomy and strategies for combating obesity in the operating room.

Anesthetic Considerations

Obesity significantly increases the risk of preexisting medical conditions in women undergoing robotic-assisted laparoscopic hysterectomy. Adults with a BMI > 40 are at increased risk of diabetes mellitus, hypercholesterolemia, hypertension, and asthma [7]. Women with obesity have an increased oxygen demand, increased cardiac output, larger stroke volumes, increased vascular resistance, increased cardiovascular work and ultimately increased risk of heart disease [11]. These women are also at increased risk for congestive heart failure, pulmonary edema, and arrhythmias. The pulmonary system is also affected by obesity. The respiratory function in obese patients is characterized by reduced functional vital capacity, functional residual capacity, total lung volume, total lung capacity, and expiratory reserve volume [4]. Compromises to lung function are compounded in women with OSA or obesity hyperventilation syndrome [4]. Additionally, obese patients are at higher risk for aspiration, due to increase gastric volumes and delayed emptying [12].

Due to these physiologic changes, induction of general anesthesia is a critical step in the care of the obese patient undergoing robotic-assisted laparoscopic hysterectomy. Women with obesity experience a more rapid desaturation during the apneic episodes that take place during induction of anesthesia [13]. This can be counteracted by optimal pre-oxygenation of obese patients [4]. With induction of anesthesia, ventilation with a facemask is considerably more difficult as a result of the decreased lung compliance and increased airway resistance associated with obesity. It is notable that most patients who tolerate induction of anesthesia and supine positioning are able to tolerate pneumoperitoneum and trendelenburg positioning [4].

During the procedure, the anesthesiologist may employ specific ventilation techniques. Pressure control ventilation may be used to improve the lung ventilation-perfusion ratio, generate higher flow peaks, and improve alveolar recruitment [14]. Additionally, higher inspiratory pressures may need to be used if ventilatory compliance is reduced secondary to the weight of abdominal viscera when the patient is in steep trendelenburg position [15]. Breaks from trendelenburg positioning may be necessary to prevent

unsafe elevations of arterial carbon dioxide levels [4]. If the partial pressure of arterial carbon dioxide level increases, the robot should be undocked, the patient should be taken out of Trendelenburg position, and the abdomen should be desufflated. Once the partial pressure of arterial carbon dioxide level returns to normal, the patient can be placed back into Trendelenburg position, the abdomen can be insufflated, and the robot re-docked, allowing surgery to continue [4]. Obese women are also at increased risk of laryngeal edema, which may require prolonged intubation postoperatively [4].

In addition to considerations regarding airway management, intravenous access must also be considered. Multiple IV lines may be placed once the patient is in the operating room. Many anesthesiologists prefer to use invasive patient monitoring [4]. This may be particularly true for robotic-assisted laparoscopy, where the patient is more difficulty to access during surgery.

Positioning

Positioning obese and morbidly obese women for robotic-assisted laparoscopic hysterectomy can be challenging and may take additional time [3, 16]. In preparation for robotic-assisted laparoscopic hysterectomy, women are traditionally positioned in the dorsal lithotomy position with arms tucked at military position at the patient's sides. When positioning the patient, the use of a bariatric bed should be considered. Bariatric beds are wider, allowing for easier tucking of the arms, and have a lower profile to the floor. Bed extenders or sleds should be utilized if needed in order to ensure that the arms are secured [4]. Furthermore, moving the asleep obese patient into the dorsal lithotomy position can be challenging. It may take a team approach to safely position the patient. If airway management is not an issue, patient "self-positioning" into stirrups prior to anesthesia induction may be considered [3].

The patient should be securely positioned in order to prevent movement while in steep trendelenburg position. Downward movement may make the surgery more difficult and lead to nerve stretch injuries to the brachial plexus [17]. Anti-skid materials such as egg crate foam, gel pad, or surgical beanbag should be used to prevent slippage. Some surgeons prefer the use of shoulder braces. These should only be used when the patient's arms are tucked at the side [17, 18]. They should be placed over the acromioclavicular joint, as inappropriate placement can lead to brachial plexus injury [17, 18].

It is important to ensure correct positioning with ample padding, as obese patients are at greater risk for pressure sores and nerve injuries as compared to non-obese patients [4]. To reduce the risk of ulnar nerve injury, the arm should be pronated and liberally padded [18]. Care should be taken to pad the lateral aspect of the knee to avoid peroneal nerve injuries. Excess flexion (> 90°) of the hip and external rotation of the thigh should be avoided, as this can lead to sciatic, femoral, and lateral femoral cutaneous nerve injuries. Due to the complexities associated with positioning, surgeons should be aware of the increased time this may add to the surgical case [16, 19]. Figure 75.1 demonstrates some aspects of patient positioning.

Surgical Prophylaxis

Most surgical procedures for benign gynecologic indications are considered intermediate risk for VTE [20, 21]. Sequential compression devices are the standard prophylactic treatment for moderate risk procedures, defined as major abdominal

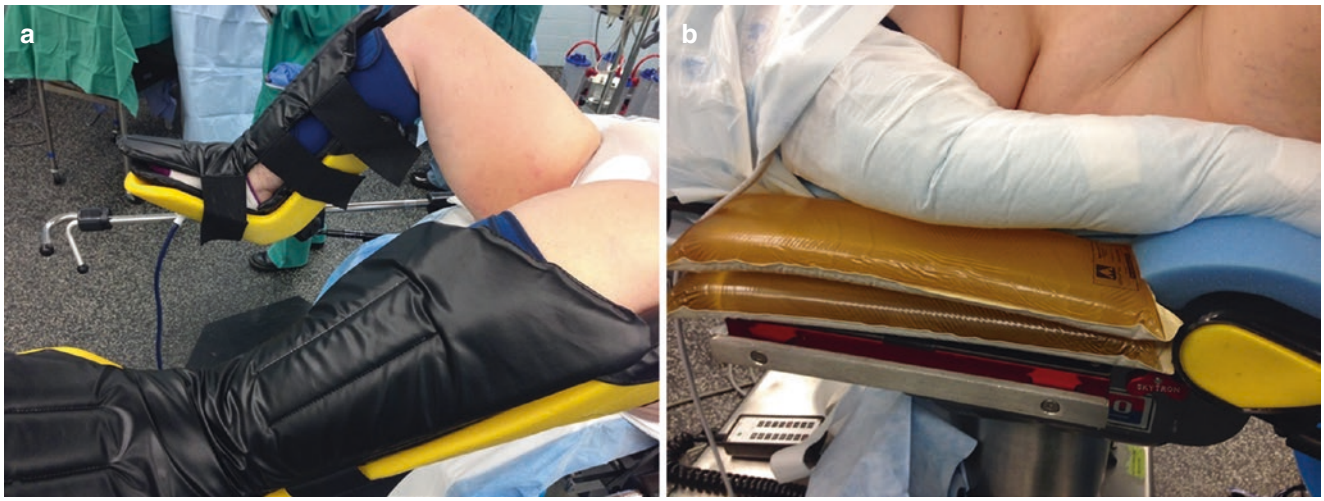

Fig. 75.1 Patient positioning utilizing Yellofins® Stirrups (**a**) and additional padding and a bed extender (**b**)

procedures lasting longer than 30 minutes [21]. It is important to ensure that there are appropriately sized devices available to adequately protect against VTE. If appropriately fitting devices are not available, pharmacologic prophylaxis with 5000 units of subcutaneous unfractionated heparin or 30–40 mg subcutaneous enoxaparin should be given prior to incision.

All women undergoing hysterectomy should receive appropriate preoperative antibiotics, adjusted for weight, for the prevention of postoperative infection. Antibiotics should be re-dosed after 3 hours or with an estimated blood loss over 1500 mL [22]. While there is no data in the gynecology literature, 2 g cefazolin has been shown to provide adequate coverage for clean-contaminated procedures in morbidly obese patients [23].

Abdominal Access and Trocar Placement

Abdominal access may be more challenging in obese patients. This is secondary to an increased distance from the skin to fascia and from the fascia to the peritoneum. Understanding the changes in anatomy is an important for ensuring a safe entry. The shortest distance between the skin and the peritoneal cavity is always through the umbilicus. As BMI increases it has been demonstrated that the umbilicus drifts caudad in relation to the aortic bifurcation [24, 25]. If choosing to enter at the umbilicus, a 90-degree entry should be utilized in order to maximize triangulation [4, 25]. In women with a large pannus, a supra-umbilical or left upper quadrant entry may be preferable, in order to maximize triangulation and access to the anatomy. Obesity is a risk factor for failed entry and pre-peritoneal insufflation [26]. Utilization of the open Hassan technique or left upper quadrant entry may minimize this risk [26]. If a left upper quadrant entry technique is chosen, the entry point should be in the mid-clavicular line, 2–3 cm below the subcostal margin [27]. An orogastric or nasogastric tube should be placed, and the stomach should be drained prior to entry.

When placing accessory trocars for robotic-assisted hysterectomy, it is important to consider the mechanics of the robotic movements as well as the anterior abdominal wall anatomy in the obese patient. When operating on the Da Vinci Surgical System, it is recommended that trocars be placed approximately 8–10 cm apart when moving laterally across the abdomen. The increased diameter of the abdomen may aid in appropriate trocar placement, and decrease the risk of arm collision. Additionally, as morbidly obese patients may have increased subcutaneous fat in the lower part of the abdomen or a pannus, trocar placement will be higher on the abdomen, closer to the level of the umbilicus [4] (Fig. 75.2). The use of long or bariatric trocars should be considered to overcome the increased thickness of the anterior abdominal wall [4]. Additionally, while placement of accessory trocars under direct visualization minimizes risk of injury, visualization of the inferior epigastric vessels and bladder may be limited [28] (Fig. 75.3).

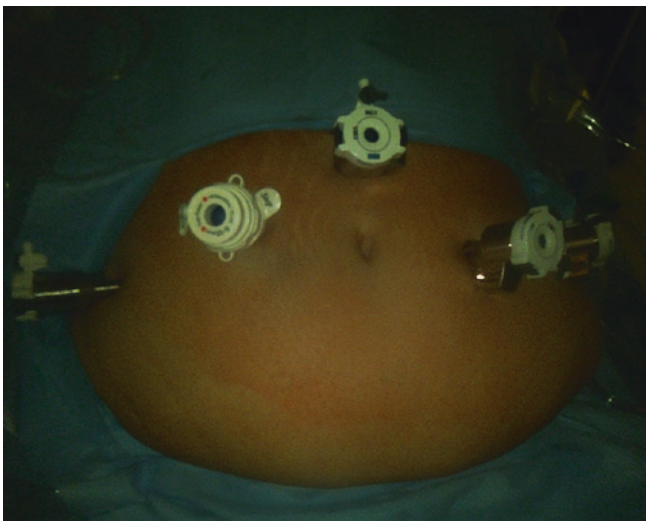

Fig. 75.2 Example of proper trocar placement for robotic assisted laparoscopic hysterectomy

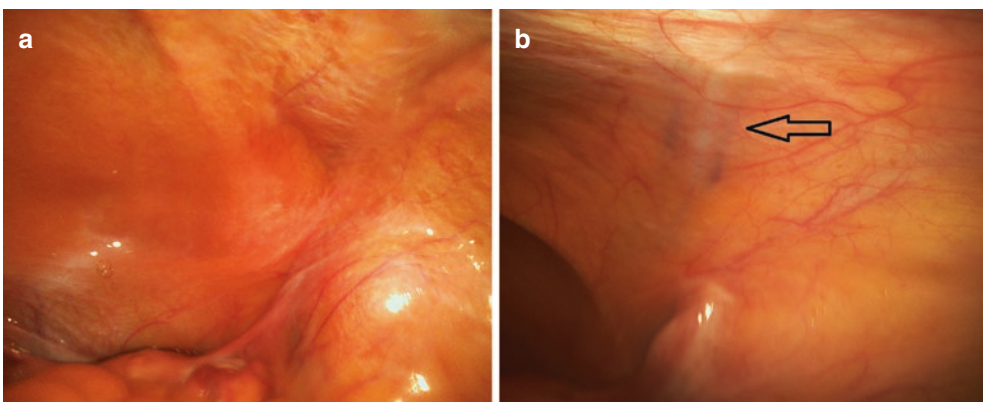

Fig. 75.3 The inferior epigastric vessels are unable to be visualized in an obese patient (**a**) compared to a patient with normal BMI (**b**)

Exposure and Visualization

Excess adiposity effects visualization and exposure of the surgical field (Fig. 75.4). During placement of the accessory trocars, the inferior epigastric vessels are not reliably visualized due to larger amounts of preperitoneal adipose tissue [28]. A comprehensive understanding of anterior abdominal wall anatomy is necessary to minimize risks of injury to these vessels.

Robotic-assisted laparoscopic hysterectomy traditionally requires the patient to be placed in steep trendelenburg position in order to displace the bowel cephalad and gain access to the pelvis [29]. Prior to beginning the surgery, a 2–5 minute trial of steep trendelenburg may be useful to assure the patient can tolerate the trendelenburg position. This should also be done after insufflation, but prior to beginning the operation. Generally if a patient is able to tolerate this trial, the patient is able to tolerate robotic-assisted laparoscopic surgery [30]. Often, despite steep trendelenburg positioning, exposure may be inadequate due to extra fat on the sigmoid colon (Fig. 75.5). This may be managed by utilizing additional assistant ports to introduce a laparoscopic fan to hold the bowel, or a stitch placed through the epiploic appendices and attached to the anterior abdominal wall drawing the bowel away from the surgical field [4, 19] (Fig. 75.6). Additionally, robotic-assisted surgery allows the surgeon to use the third arm as a retractor, which may be useful in the setting of a redundant colon or extra epipolic appendices.

Increased adiposity may also affect the urinary system. Studies have shown that identification of the bladder margins may be more difficult in obese patients [28]. This may lead to injury at the time of trocar placement or bladder dissection. Understanding anatomic landmarks, careful dissection of the bladder away from the uterine vessels, and skeletonization of the vessels may reduce the likelihood of injury. Backfilling the bladder may also allow the surgeon to better delineate bladder margins. While no studies have shown an increase in ureteral injury, transperitoneal visualization of the ureters is reduced in obese patients. Retroperitoneal identification may be required to appropriately identify the ureter (Fig. 75.7).

In general, increasing obesity is associated with prolonged operative time, prolonged time under anesthesia, and increased blood loss for patients undergoing laparoscopic and robotic-assisted laparoscopic hysterectomy [16, 29]. Interestingly one study by Siedhoff et al. demonstrated an increasing severity of complications in women undergoing laparoscopic hysterectomy with increasing BMI [16]. This may also be true in robotic surgery. In studies comparing robotic and laparoscopic surgery for the treatment of endometrial cancer, robotic-assisted surgery has been shown to have advantages, including decreased operative time and decreased estimated blood loss [29]. This may be related to improved visualization, improved dexterity to maneuver around fatty tissue, less surgeon fatigue, and improved exposure through retracting excess tissue with the 3rd robotic arm [19].

In summary, the surgeon should perform the same steps when performing a robotic-assisted laparoscopic hysterectomy on an obese patient, as compared to a non-obese patient. What differs is that anatomy may be obscured by increased adiposity. A complete understanding of pelvic anatomy and meticulous surgical technique can improve the surgeon's ability to identify the essential structure and safely complete a robotic-assisted laparoscopic hysterectomy in the obese patient.

Postoperative Considerations

Patients with obesity are at higher risk for postoperative complications. They have a higher rate of venous thromboembolism and resumption of ambulation may be more difficult particularly for the morbidly obese patient [9, 31]. They are also at higher risk of cardiopulmonary and metabolic problems related to underlying comorbidities. Routine postoperative recommendations should be encouraged in this population, in addition to some special considerations outlined below.

Postoperatively, patients are at risk of pneumonia and postoperative fever attributed to atelectasis [8, 9]. Incentive spirometer use is important to prevent atelectasis. Pain control is also essential to prevent splinting, which leads to poor lung expansion and atelectasis. One of the advantages of robotic surgery is the lower pain level that patients experience compared to open surgery [1–3]. This decreases the amount of narcotic use, and minimizes the risk of decreased

respiratory drive [9]. Many patients with obesity also suffer from OSA, and use of CPAP should be continued or initiated in the postoperative period [8, 9]. Even for patients without a diagnosis of OSA, positive pressure noninvasive ventilation may be required in the immediate postoperative period. Additionally, OSA increases the risk of coronary heart disease and heart failure, and these patients should be closely monitored for at least 23 hours after surgery [4, 8].

Obesity increased the risk of VTE, especially in women [31, 32]. Proposed mechanisms include enhanced platelet activity, increased clotting factors, and impaired fibrinolysis [32]. Early ambulation will decrease the rate of VTE by removing stasis of blood flow from Virchow's triad. Additionally, VTE prophylaxis is recommended in all patients hospitalized after surgery [4]. According to the 2012 CHEST Evidence-Based Clinical Practice Guideline, patients undergoing gynecologic surgery who are at moderate risk for VTE (Caprini score 3–4) should receive low-molecular-weight heparin (LMWH) or mechanical prophylaxis; those at high risk (Caprini score ≥5) should receive both; those undergoing surgery for cancer require 4 weeks of LMWH [33]. The Caprini score includes points for BMI greater than 25 and additional point for BMI over 40. Of note, the CHEST guidelines are not specific for laparoscopic surgery, and use of LMWH is controversial after laparoscopic or robotic surgery for benign disease [4, 34].

Starting a regular diet as soon as tolerated after surgery will decrease the rate of postoperative ileus, as well as expedite the resumption of the patient's home medications for diabetes, hypertension, and dyslipidemia. Most patients undergoing a robotic-assisted laparoscopic hysterectomy will be able to resume their usual diet the same day. Patients with diabetes mellitus should have a carbohydrate-consistent diet and tight blood glucose control, as elevated blood glucose levels can impair healing and increase the risk of infection [35].

In conclusion, robotic-assisted laparoscopic hysterectomy is an attractive option for the obese population, with many advantages such as decreased pain, shorter hospital stay, and faster return to daily activities. While these factors decrease the rate of complications, proper patient selection and attention to the unique challenges and comorbidities of this patient population are essential.

Robotic-Assisted Single-Port Laparoscopic Hysterectomy

76

Vito Cela, Nicola Pluchino, and Letizia Freschi

Introduction

The recent phenomenon of laparo-endoscopic single-site surgery (LESS) opened a new way to perform minimally invasive gynaecological surgery presenting a number of advantages over traditional laparoscopic surgery. However, LESS is challenging due to the lack of port triangulation, two dimensional view, poor ergonomic position for the surgeon and a steep learning curve overall for suturing. To potentially overcome these challenges, single-site robotic surgical platforms have been developed recently. Robotic surgical platforms may shorten the minimally invasive learning curve for select surgeons compared with traditional laparoscopy. A single-site robotic platform may also help to overcome some of the technical limitations of LESS (learning curve, instrument crowding, lack of triangulation, and loss of depth of perception/instability with current 2-dimensional flexible optics). Furthermore, the introduction of the da Vinci robotic system to single-site surgery, will further diminish the impediments that limit this minimally invasive technique.

Robotic-Assisted Single-Port Laparoscopic Hysterectomy

During the past years, the field of laparoscopy has undergone several changes and continuous efforts have been made to improve the morbidity and cosmesis of laparoscopic surgery with a special focus on miniaturization of equipment, evolution of robotic surgical units, and reduction of port size and number. Laparoendoscopic single-site surgery (LESS) is a term that covers a spectrum of surgical techniques that perform laparoscopic surgery by consolidating all ports into only one surgical incision. Although early results are encouraging, this should not disguise the technical difficulties associated with performing LESS procedure. LESS is challenging due to the lack of port triangulation (which lead to the clashing of laparoscopic instruments), two dimensional view, poor ergonomic position for the surgeon and a steep learning curve overall for suturing. New technologies such as flexible scopes, angle instruments and novel robotic platforms have improved the success and consistency of the single-port approach, leading to the inevitable hybridization of robotic technology with LESS surgery. As result, employment of the da Vinci surgical system (Intuitive Surgical, Inc., Sunnyvale, CA) allows greater surgical maneuverability and improves ergonomics during LESS. Preliminary advances in R-LESS (robotic laparoendoscopic single-site surgery) have been already documented in urologic and general, but just in last years have been analyzed the possible application of the robotic laparoendoscopic single-site technology to the gynecological surgery.

In 2011 Nam et al. described a series of seven women with a diagnosis of benign or malignant gynaecological disease concluding that RSSH is feasible and offers some potential advantages over standard robotic or laparoscopic surgery, i.e. minimally invasive access with a smaller scar, less pain and results comparable to those obtained using classical procedures [1]. In the same year, Escobar et al. published a pilot study aiming to evaluate the possible application of robotic laparoendoscopic single-site technology to gynecological surgery, analyzing feasibility and reproducibility of a dedicated da Vinci single-port robotic platform in cadavers for the performance of various gynecologic oncology procedures [2]. All surgical procedures were performed through a single 3–4 cm umbilical incision with a multichannel system that consisted of a wound retractor, surgical gloves, and two 10/12 mm and two 8-mm trocars. A 3–4 cm vertical umbilical skin incision via an open Hasson approach was made and then, the Alexis Wound Retractor (Applied

Medical, Rancho Santa Margarita, CA, USA) was inserted into the peritoneal cavity. The wrist portion of a size 7.5 surgical glove was fixed to the outer ring of the wound retractor. After making a small hole in the fingertips of the glove, two 10/12-mm and two 8-mm trocars were inserted, and the abdomen was insufflated with CO2 gas. After placing the robotic single-port access system, the overall procedure was similar to that of single-port transumbilical laparoscopic surgery.

However, in October 2011, has been performed the first worldwide case of robot-assisted laparoscopic single-site hysterectomy (RSSH) with the newly designed multichannel port (Intuitive Surgical) for the da Vinci surgical system [3].

Single-site instruments and accessories are designed for the Si version of the da Vinci Surgical System. The single-site port is a multichannel disposable access port with a target anatomy arrow indicator and room for four cannulae and an insufflation valve. Two curved cannulae are for robotically controlled instruments whereas the other two cannulae are straight: one is 8.5 mm and accommodates the high-definition three-dimensional endoscope, and the other is a 5-mm bedside-assistant surgeon port (Fig. 76.1). The docking clamps of the robot automatically recognize the shape of the single-site curved cannulas and reassign each master control to the slave instrument on the opposite side, compensating for the crossing of the curved cannulas. The system includes a range of 5-mm nonwristed, semirigid, and reposable instruments, including a monopolar hook, two bipolar instrument options (a fenestrated bipolar and a Maryland dissector), different types of graspers, curved scissors, a medium-large Hem-o-lok clip applier (Teleflex Medical), needle drivers, and a suction irrigator. Patients are placed in a modified dorsal lithotomy position, and extremities are separated and flexed using adjustable boot stirrups. Anti-skid methods (e.g., vacuum bean bag and gel pad) can be used, and maximum Trendelenburg position (>30°) has to be attained before the Da Vinci Si robot is docked between the legs. After the placament of bladder catheter, an uterine manipulator device ha sto be placed, when possible, in order to improve uterine mobilization. Port placement is performed by using Hasson's technique modified with a 2.0-cm omega-shaped intraumbilical incision (Fig. 76.2) down to the level of the fascia; this is entered and a finger sweep to check for adhesions is performed. Prelubrication of the single-site port with a sterile saline solution prior to introduction is recommended, then, port insertion can be reached utilizing two techniques, the "unfolded" and the "folded" port-clamping technique using an atraumatic clamp and grasping just above the lower rim before proceeding with insertion (Fig. 76.3); at last the arrow marking on the port is aligned with the target anatomy (uterus/pelvis). After an initial pneumoperitoneum at 20 mmHg, it can be reduced to 8 mmHg taking advantage of the strength of the its mobility before curved cannulae's insertion (Fig. 76.4). This step is important to ensure that there is adequate working space for the curved cannulae during the entire surgical procedure and that the instruments are fully supported. Adhesions have to be removed as necessary and loops of small bowel have to be folded, not pushed, back into the upper abdomen to expose the root of the mesentery.

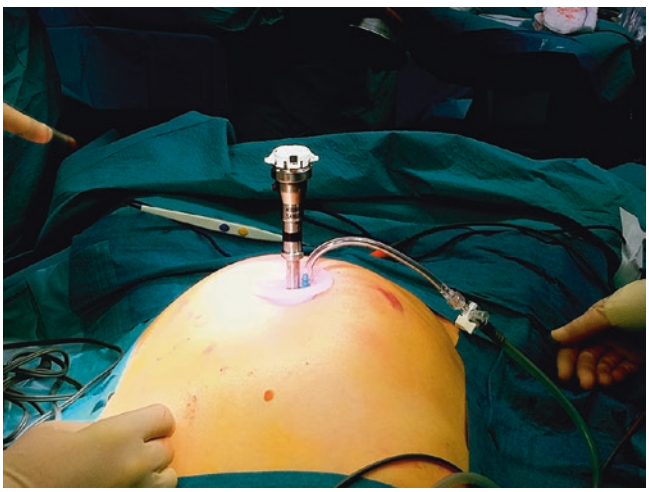

Fig. 76.5 Positioning of the 12-mm lubricated trocar for the robotic 30-degree scope

Once sufficient initial exposure is achieved, the cart can be docked and the 12-mm lubricated trocar for the robotic 30-degree scope and two 8-mm trocars for the robotic instruments are placed in a triangular way under direct visualization (Figs. 76.5 and 76.6). Through the 5-mm bedside-assistant port endoscopic suction, coagulation and cutting with electrothermal bipolar vessel sealer can performed. Placing the robotic single-port access system, As far as the surgical technique, the procedure is similar to that of multiport robot-assisted surgery: The ovaries are examined. The right round ligament is coagulated and transected (Fig. 76.7) and the retroperitoneal space is opened to identify the ureter (Fig. 76.8). Then, the infundibulopelvic ligament is securely skeletonized, coagulated and transected. The uterine arteries are skeletonized, coagulated and transected. The bladder and the attached peritoneal flap are developed using a monopolar hook and dissected below the colpotomy cup (Fig. 76.9). Both uterosacral ligaments are excised with the monopolar hook and the peritoneum on the posterior cervix is excised and divided from the cervix. Similar steps are performed

contralaterally. The anterior colpotomy (Fig. 76.10) and posterior colpotomy are performed with the monopolar hook and the vagina delineated with colpotomizer. The uterus and adnexae are then removed through the vagina. In cases of younger patients the ovaries could be preserved to avoid menopausal symptoms. (Fig. 76.11). As far as the vaginal cuff closure, it can be obtained in different ways according to

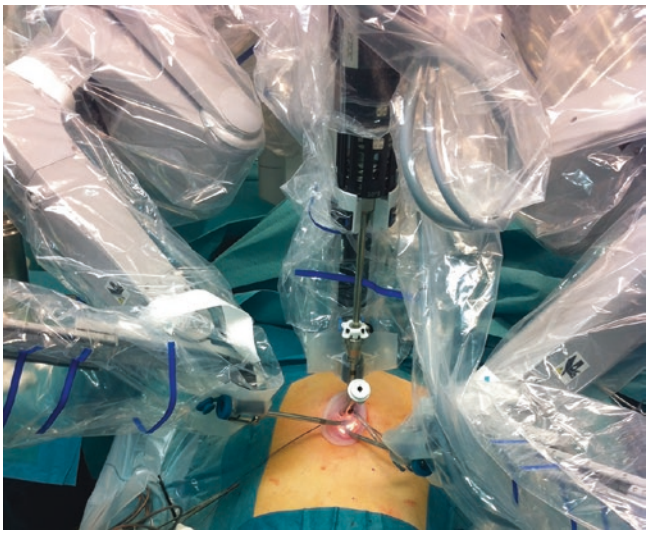

Fig. 76.11 Final single-site robotic port dock

the anatomical features of the vagina itself: with an intracorporeal barbed suture or intracorporeal interrupted figure-of-eight sutures (0 Vicryl™, Ethicon) or transvaginally with interrupted delayed absorbable suture of Vicryl 2/0 (Ethicon Inc., Somerville, NJ).

Discussion

Bogliolo et al. proposed also in some circumstances, such as a narrow vagina or the need of vaginal vault suspension, requiring a robotic approach to colporraphy, an intracorporeal suture with extracorporeal knots a particolar way to close the vaginal vuff. The procedure was performed introducing the 0 caliber polyglycolic acid suture (Vicryl ™; Ethicon) by the 10 mms trocar through the single site port. The number of suture in vaginal cuff closure was four and was performed with interrupted figure-of-eight sutures. The knots were pushed in to the pelvis by the use of Knot Pusher Storz device [4]. Undoubtedly, one of the greatest limitations of the single-site platform is that the semiflexible robotic instruments are not currently capable of articulation (as in multiport robotic surgery), ad the cannulas are rather long. This means that there are fewer degrees of freedom than with multiport robotic surgery and a very small distance between the instrument and the uterus. This makes the suture really demanding, not only in the tying of the incorporeal knots but also in the pulling of the vaginal tissue in the right direction (i.e., parallel to the needle) during the needle's passage.

Another important aspect, is that, according to current evidence, transvaginal suturing of the vaginal stump is associated with a lower incidence of vaginal dehiscence or general cuff complications compared with both laparoscopic and robotic suturing. Anyhow, the method of vaginal

cuff closure during robotic total hysterectomy should be simple and time efficient, with the risks of infection and vaginal cuff dehiscence minimized.

After hemostasis, the fascia was repaired with a 2/0 Vicryl interrupted stitches (Ethicon Inc.) and skin closed with 3/0 Ethilon interrupted stitches.

Cela et al. analyzed, in vivo, using a CUSUM method, the learning curve of robot-assisted single-site hysterectomy identifing two different phases of the learning curve of the procedure: phase 1, found to require six cases, can represent the initial learning curve phase, and phase 2 can represent the mastery phase, with a reduction in OT (operative time). When comparing the six initial cases with the last six cases any statistical difference in terms of morbidity was revealed, but a trend has been reported in terms of OT and CT (console time). These data suggest that after a learning curve phase, the surgeon may achieve a higher level of competence and consider offering this approach to patients presenting with more complicated cases. Furthermore, data demonstrated that large BMI or high uterine weight would have a negative impact on the surgical performance of RSSH by increasing the operative times, console times, or docking times. Based on these results, an increased BMI as well as high uterine weight is not associated with prolonged operative times.

These data are confirmed also by Bogliolo et al. in a recent retrospective analysis in which large BMI and short stature seemed not to have a negative impact on the surgical performance, suggesting that this innovative surgical technique should also be used for obese patients to achieve the goal of very minimally invasive surgery. Indeed, regarding overweight and obese patients, although they reported BMI $\geq$ 25 in 20 cases and BMI $\geq$ 30 in seven patients, laparoscopic conversion was required in only one case.

High uterine weight was significantly correlated with longer operative time, but it seemed not to prejudice good surgical outcome. Sixteen weeks were chosen as the size limitation because, according to our standard laparoscopic experience, large uteri could require supra-umbilical access, which is technically not recommended in single-site surgery.

Regarding hospital stays in their series, Bogliolo et al. reported a long hospitalization time on average because the two patients who experienced a complication were discharged on days 8 and 14 [5].

Two recent studies analyzed the role of robotic single-site approach to endometrial cancer.

Abdulrahman et al. [6] proposed the sentinel lymph node (SLN) biopsy as a safe and less morbid approach to full lymphadenectomy in endometrial cancer (EC) and demonstrated SLN biopsy and extrafascial hysterectomy utilizing the single-site robotic system, to be feasible and able to offer some benefits over traditional robotic surgery.

Mereu et al., instead, treated four patients with histological diagnosis of endometrial adenocarcinoma G1 and instrumental FIGO stage IA or IB with total single access robotic laparoscopic extra-fascial hysterectomy and bilateral salpingo-oophorectomy. The procedure was performed through a single trans-umbilical incision of 35 mm using a Da Vinci Robotic S System and a Gelport device with one 12 mm trocar for robotic 3D optic, two 8-mm trocars and one 5-mm trocar. Data confirmed the procedure to be technically feasible and reproducible in patients with low-stage endometrial cancer with optimal surgical outcome and postoperative course [7].

In 2014 Bogliolo et al. published an interesting retrospective series of perioperative data from ten consecutive patients who underwent robotic-assisted single-site laparoscopic hysterectomy (RSSH) for female-to-male transsexualim (FMT). Single-site robotic surgery was confirmed to be a valid choice in FMT reassignment surgery, with a low rate of complications, good pain control, and excellent aesthetic results with only a minor perioperative complication occurred and not directly related to single-site technique [8].

Recently, has been published a case of combined cholecystectomy and hysterectomy using the da Vinci surgical system with the single site platform providing a critical analysis of the technique, including limitations of current single-site technology. Data demonstrated the feasibility of performing general surgery and gynecologic procedures concomitantly using a robotic single site (RSS) surgical approach. Cholecystectomy and total hysterec-tomy were conducted uneventfully and they were performed in a relatively short time by surgeons with previous experience of RSS, working in a multidisciplinary robotic center [9].

In conclusion, over the past 10 years, many efforts have been made to reduce the surgical invasiveness of minimally invasive surgery. The evolution of the single-port technique in laparoscopy achieved the goal of reducing the number of ports, improving the cosmetic benefits, avoiding the potential morbidity associated with multiple incisions and minimizing postoperative pain and recovery time. However, LESS surgery is characterized by a longer operative time that is partially justified by the lack of the third operative instrument. Single-site robotic surgery has the same advantages as LESS, but the automatic reversion of the crossed instruments allows for far greater manoeuvrability and ergonomics compared with other single-site methods. However, actually we are still far from having a perfect system and are rather in the infancy of robotic single site. The robotic single-site platform has several limitations, including reduced extracorporeal triangulation and a limited repertoire of non-articulating instruments and electrosurgical options compared with conventional multiport robotic surgery [10, 11] (Table 76.1). Taken together, these limitations may require significant modifications in technique for the traditional robotic surgeon. Each aspect of the set-up, including the exact umbilical incision length and positioning of the port

Table 76.1 Pros and Cons of robot-assisted single site hysterectomy

PROS	CONS
Minimally invasive approach	Limited repertoire of non-articulating instruments and electrosurgical options
3D visualization	Costs
Improved surgeon dexterity	Reduced extracorporeal triangulation
Enhanced ergonomics	
Short learning curve	

and platform, had to be precise for the RSS instrumentation to operate efficiently.

The possible future use of flexible endoscopes will improve the practicality of robotic LESS and will may increase the range of its applications.

Advances in the field of robotics will hopefully overcome these limitations and provide improved triangulation, degrees of freedom, dexterity, visualization, and new instruments with different kind of energies. However, the introduction of the da Vinci robotic system to single-site surgery, will further diminish the impediments that limit this minimally invasive technique. Prospective comparison studies are needed, but preliminary results are encouraging and the development of robotic systems specific to RSS may define the new horizon of single-site surgery.

Robot-assisted Laparoscopic Pelvic and Paraaortic Lymphadenectomy

77

Jan Persson

Introduction

Pelvic and paraaortic lymphadenectomy is mainly used for staging of genital and other pelvic cancers. Both pelvic and paraaortic lymphadenectomy are well suited for laparoscopy with a low complication rate reported in large series from centers of excellence [1, 2]. Still, despite being described more than 20 years ago, traditional laparoscopic lymphadenectomy, in particular, the paraaortic type, has not been performed at most centers. This is probably due to the complexity of traditional laparoscopy and/or a lack of large enough volumes to introduce and maintain a new surgical approach. The da Vinci surgical robot (da Vinci ® Surgical System, Intuitive Surgical Inc., CA, USA) was approved for gynecological procedures in 2005. So far, four robot systems have been launched (da Vinci standard, S, Si and Xi systems) of which the first (standard) model is no longer kept active by the manufacturer. All models provide instruments with a wrist function at the tip, movement downgrading, tremor elimination, a stable 3-dimensional view of the operative field and an ergonomic working position. These features may help the surgeon overcome some of the limitations associated with traditional laparoscopic surgery.

As no prospective randomized studies compare robotic and laparoscopic pelvic and paraaortic lymphadenectomy alone, available data is restricted to case series with or without retrospective control groups, not seldom data from early robot adopters even using the first robot model with its limitations. Still, the overall conclusion is that robot assistance results in the same or better nodal yield, less bleeding and less conversions to open surgery, in particular in obese patients. [3–8].

Robot Assisted Laparoscopic Pelvic Lymhadenectomy

All models of the da Vinci robots can be used, although preferably a da Vinci Si or Xi system adapted for the near infrared fluorescent technique (Firefly) which allows for the use of Indocynaine green for detection of sentinel lymph nodes [9]. Ports should be placed for standard pelvic surgery as recommended for the respective systems. The S-Si robot may be docked centrally or side docked at surgeons' discretion whereas the Xi robot can be docked at various positions, usually from the side of the patient. In case of a simultaneous paraaortic lymphadenectomy port placement is adjusted accordingly as described below. Suitable robot instruments are; a monopolar scissors, a bipolar forceps and a grasper. For the assistant one or two trocars are needed for suction/irrigation, grasping, insertion of sponges and for retrieval of lymph nodes, the latter usually requiring a 12–15 mm trocar diameter. The procedure starts with inspection of the whole abdomen and pelvis to rule out disseminated disease. This is best performed before the robot arms and instruments are docked as this allows a complete abdominal overview including the liver and diaphragm and avoids unnecessary cost for robot instruments in case an immediate conversion to open surgery should be indicated.

The pelvic lymphadenectomy starts with developing the avascular planes and identifying landmarks from the aortic bifurcation and distally before any lymphadenectomy is performed. Sentinel lymph nodes (if such technique is applied) or otherwise cancer suspect nodes should be looked for and removed separately for frozen section. Lymph nodes should always be retrieved in a protective bag. It is important to avoid grasping directly on the lymph nodes with robot instruments as this otherwise may crush a potentially metastatic node with risk of tumor spread. In general, the dissection is most easily performed if tension of the tissue is applied and with dissection close to the adjacent vessels.

The presacral and common iliac node dissection starts with opening the peritoneum medial of the right common iliac artery to the level of the aortic bifurcation (Fig. 77.1).

© Springer International Publishing Switzerland 2018

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_77

This way, the right ureter and infundibulopelvic ligament are visualized and lateralized. The third robot instrument (usually the grasper) can be used to lift the sigmoid colon, the infundibulopelvic ligament and the ureter to expose the left common lymph node chain (Fig. 77.2). It is usually helpful to retract the sigmoid colon towards the left abdominal side wall with a sponge reinforced stitch. The hypogastric nerve should be identified at the level of the aortic bifurcation and saved (Fig. 77.3). With the whole presacral and common iliac nodal areas exposed the lymphadenectomy is performed starting with the area medial of the common iliac arteries and the presacral area (Fig. 77.4) followed by the lateral common iliac lymph node chains saving the genitofemoral nerves visualized as they run along the psoas muscles (Fig. 77.2).

The paravesical and pararectal spaces are then opened. This is most easily performed by lifting the round ligament cranially and medially creating a fold of the lateral broad ligament as a starting point (Fig. 77.5). The broad ligament is then incized laterally along the infundibulopelvic ligament and if needed the incision is prolonged lateral of the caecum/sigmoid colon for slight mobilization of the colon. The paravesical space, limited by the pubic bone, the obliterated umbilical artery, the upper paracervical tissue and the exter-

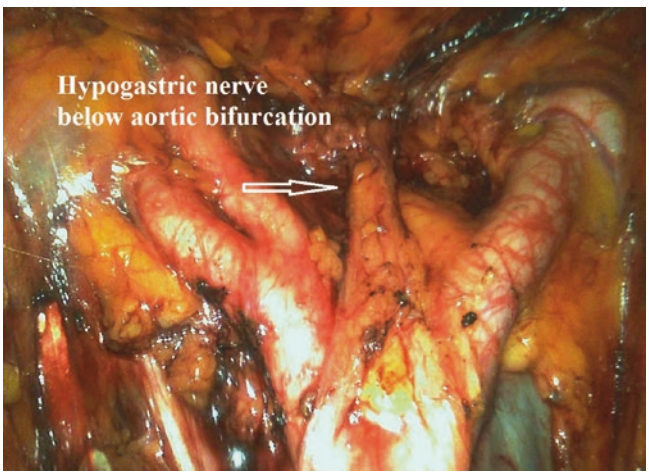

Fig. 77.3 The hypogastric nerve shall be isolated and saved

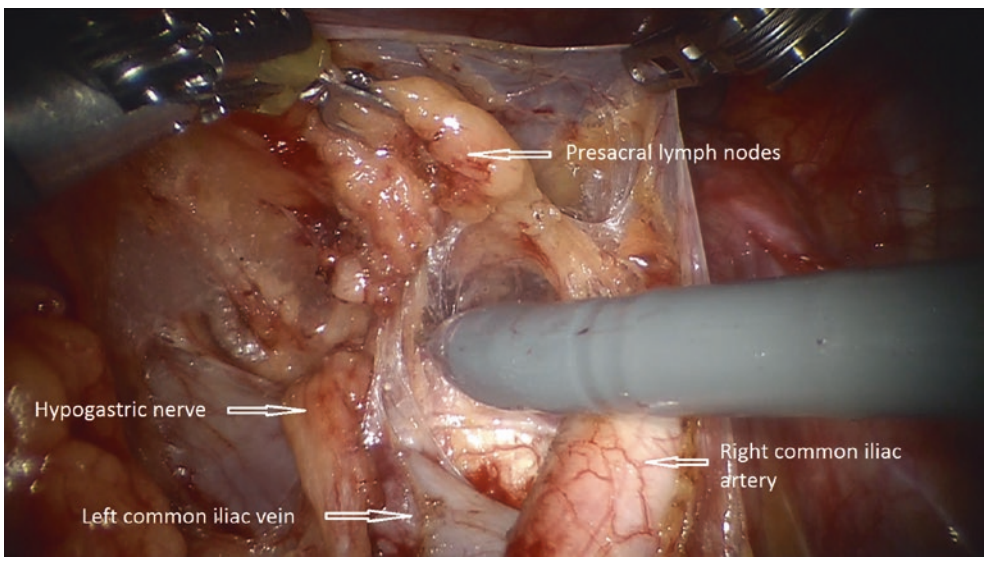

Fig. 77.4 Presacral nodal dissection

nal iliac vessels, is developed bluntly visualizing the course of the obturator nerve and associated deep blood vessels and lymph nodes (Fig. 77.6). Then the pararectal space is opened starting by identifying the ureter running along the medial broad ligament (ideally kept intact until later) and the hypogastric artery as medial and lateral borders (Fig. 77.7). Opened deeper, the pararectal space will display the deep uterine vein, the hypogastric nerve fibers and the origin of the obliterated umbilical artery where the uterine artery is usually found (Fig. 77.8). It is important to keep the upper parametrium (paracervical tissue) intact between the paravesical and pararectal spaces for a later radical hysterectomy or a separate upper paracervical parametrectomy and for not disrupting the lymphatics in case a sentinel node technique is applied (Figs. 77.7 and 77.9). The external iliac node dissection starts with the identification of genitofemoral nerve, usually serving as a lateral border. The superficial lateral lymph chain is then released from lateral to medial and folded over the external iliac artery and completed with the medial nodes and ideally removed en bloc (Fig. 77.10). The deep external nodes and the proximal obturator nodes are removed after the iliac vessels are mobilized medially to expose the obturator fossa and the proximal course of the obturator nerve (Fig. 77.11). Vessels from the ileopsoas muscle to the obturator nodal tissues can be coagulated at this stage as they are a common cause of bleeding during later lymphadenectomy in the obturator fossa (Fig. 77.11). Then, the remaining obturator nodes are removed en bloc following the obturator nerve sparing the obturator vein and exposing the pelvic floor (Fig. 77.12). A check of the whole pelvic retrieval area should be performed at the end.

Finally, it is worth mentioning some risks: It is important to avoid grasping the obturator nerve with the robot instruments as the constant grip force will risk damaging

the nerve. During the final proximal part of the obturator node dissection, if performed from the medial side, extra attention should be given to the nerve to avoid damage of the obturator nerve and hypogastric vein due to their close proximity (Fig. 77.13). A too deep and lateral dissection during the external node removal risks harming the lateral cutaneous femoral nerve (Fig. 77.14).

Robot Assisted Laparoscopic Paraaortic Lymphadenectomy

Paraaortic lymphadenectomy can be performed as a single procedure or in conjunction with pelvic lymphadenectomy and removal of pelvic organs. A retroperitoneal approach may be clinically beneficial in case the paraaortic lymphadenectomy is a single procedure, in particular in case of intraabdominal adhesions and in obese patients. However, with the retroperitoneal approach the space for robot arms is limited and there are no obvious overall advantages with the use of robots compared with traditional laparoscopy [9]. It is likely that the more slender robot arms of the new da Vinci Xi model will be advantageous but this remains to be seen. Therefore, and due to the fact that other procedures are often planned in the same session, a transperitoneal approach will most often be the choice for the robotic paraaortic lymphadenecomy. Principally, this can be performed in two ways: as a proximal prolongation of the pelvic lymphadenectomy along the aorta with the robot docked centrally between the patients legs or side docked for pelvic surgery. This requires ports placed higher than for pelvic surgery only and a steep Trendelenburg position of the patient (Fig. 77.15 and 77.16). This approach may be technically difficult, mainly due to obscuring bowel, and restricted access to the inframesenteric area particularly in obese and short patients [10, 11].

The alternative transperitoneal approach is to place the S or Si robot at the patients head or shoulder and dissect from caudal to cranial through a smaller opening of the

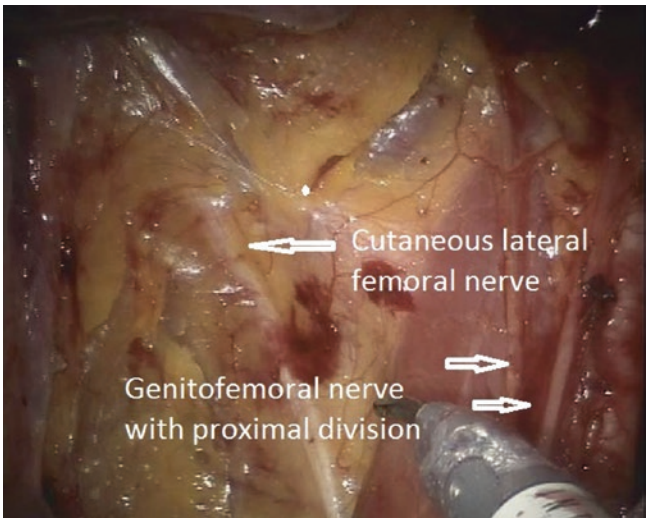

Fig. 77.15 Port placement for paraaortic and pelvic lymph node dissection with pelvic docking of a S-Si robot

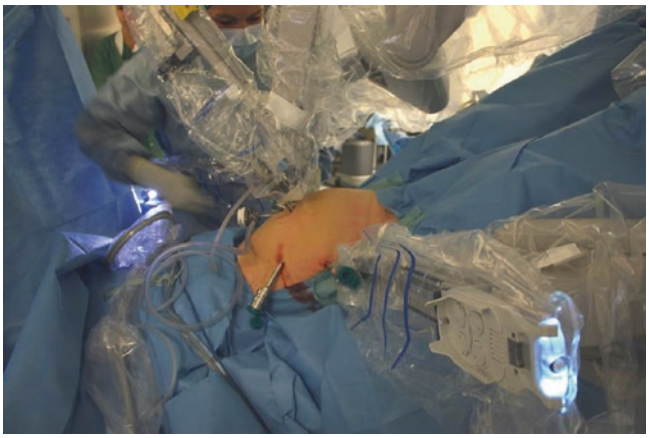

Fig. 77.17 A paraaortic lymphadenectomy with the Xi robot or S-Si robots with double docking starts with creating a tunnel under the bowel along the aorta starting opening the peritoneum below the aortic bifurcation.

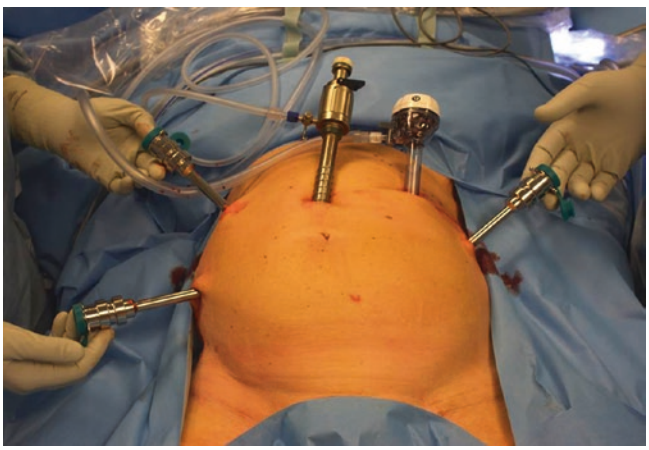

Fig. 77.16 The robot arms should be adjusted to reach the upper abdomen during paraaortic and pelvic lymph node dissection with pelvic docking of the S-Si robot

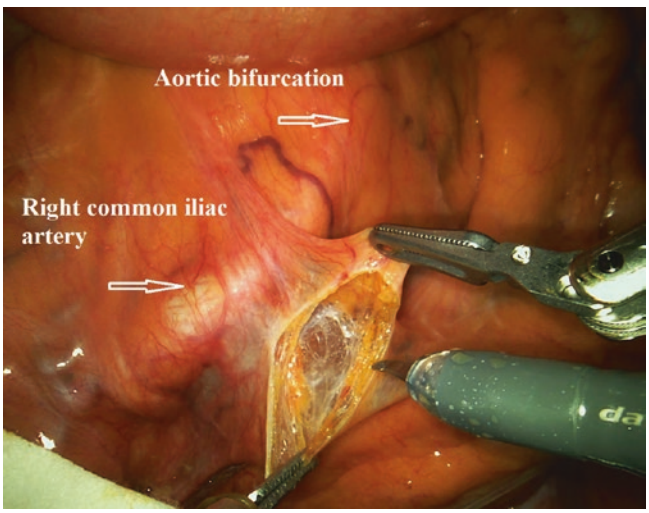

Fig. 77.18 The paraaortic lymph node dissection with the Xi robot starts with a small opening of the peritoneum just below the aortic bifurcation

peritoneum at the level of the bifurcation (Fig. 77.17). This may be beneficial to prevent the bowel from interfering with the surgical field but sometimes requires an additional higher port for optics and a separate upper abdominal assistant's port in case pelvic surgery will be performed during the same session. With the S-Si robots a de-redocking for later pelvic position after the patient has been rotated 180 degrees will be necessary ("double docking"). Alternatively, with the robot initially placed at patients shoulder it can be redocked in a pelvic side position with a smaller adjustment of patients position sideways ("double side docking") and a full 180 degree rotation, often time consuming and cumbersome for the anesthetist, can be avoided.

Using the da Vinci Xi model both these double docking alternatives can be omitted due to the " roof hanged" robot arm boom and the increased range of motion of the robot arms. Instead of a cumbersome rotation of the patient or double docking the robot arm boom can be rotated 180 degrees, either via a swift de-redocking and rotating the whole robot arm boom or by using the increased range of motion of the arms, with the robot fundament unchanged. A rotation of the whole robot arm set provides more space for the assistant using at least one suprapubic port which is necessary for assisting parallel to the robot instruments and for lifting the roof of the peritoneal tunnel created over the aorta (Figs. 77.18, 77.19 and 77.20).

The basic surgical principle for all approaches is similar. All surgery requires a good anatomical knowledge and awareness that approximately one third of patients have some vascular anomaly in the paraaortic area [12–14]. A preoperative

Fig. 77.19 Paraaortic lymphadenectomy with the Xi robot. Note position of the robot arm boom

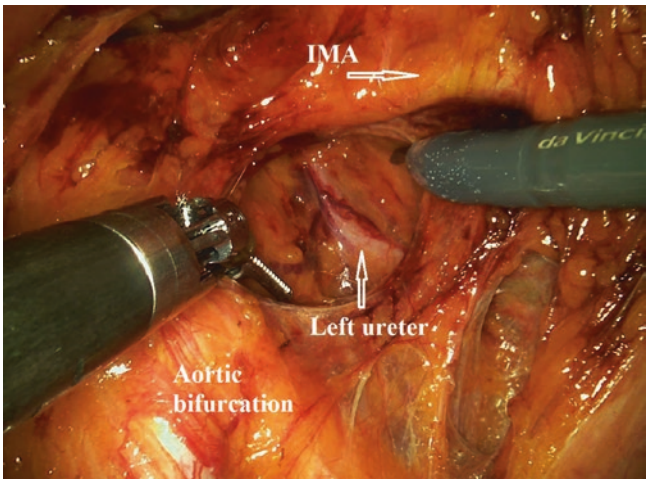

Fig. 77.21 Visualization of the left ureter and the IMA

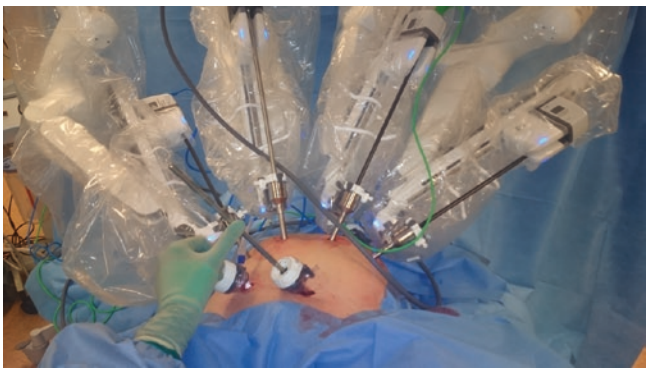

Fig. 77.20 Position of assistant and assistants trocars for a paraaortic lymph nodes dissection with the Xi robot

CT scan of the abdomen should include information on any major blood vessel anomalies and in case of enlarged lymph nodes an exact position of those related to easily identified vascular landmarks. It is particularly important that the whole staff is familiar with all used assistants instruments, hemostatic agents and that an emergency de-docking plan is implemented. Although conversion to open surgery due to bleeding rarely occurs, a laparotomy set including vessel repairing instruments should be readily available. The anesthetist should be asked to keep fluid balance on the negative side to avoid too distended veins. In all, everyone should be prepared and experienced with their respective tasks.

Usually, it is beneficial to use the Palmers' point entry and a similar position of the 12 mm assistants' trocar as this allows an intraabdominal overview of the position of the optics trocar and a partial removal of the lower falciform ligament that sometimes hinders an optimal position of the optics trocar. This entry point also allows for the release of midline oriented adhesions as well as diagnosing a previously unknown umbilical hernia. The incision for the optics trocar should be kept minimal to avoid leaking of gas and minimize the risk for the optics trocar to slide out if some retraction is necessary. For the same reason, it is often beneficial to use an optics trocar with outer ridges or a balloon trocar. The remaining trocars are then placed (Fig. 77.15). An overview of the abdomen to rule out disseminated disease should be performed before docking the robot instruments. The necessary degree of Trendelenburg is controlled from inside with the optics. After docking the robot the range of motion of the robot arms should be optimized to reach the paraaortic area (Fig. 77.16).

With the Xi robot or in case of double docking/patient rotation it is recommended to initiate the procedure as described above but also place at least one suprapubic assistant's port for the paraaortic dissection (Figs. 77.19 and 77.20). The paraaortic dissection starts with making a 5–6 centimeter peritoneal incision just below the aortic bifurcation as a tunnel opening (Fig. 77.18). With the aid of the fourth arm and instruments inserted via the supraumbilical assistant's port the roof of the tunnel is elevated simply by using the shafts of closed instruments inserted to the apex of the created tunnel. Then, before any attempts of lymphadenectomy, a gradual further cranial dissection to fully visualize the anatomical landmarks and potential vessel anomalies to the level of the left renal vein is performed (Figs. 77.21, 77.22 and 77.23). For finding the left supramesenteric part of the ureter, which is often runs deep, it is usually helpful to dissect the left ureter as far cranially as possible when exploring the left side inframesenteric part. The main left and right side hypogastric nerve branches is usually possible to preserve without compromising the lymphadenectomy (Fig. 77.24). The lymphadenectomy is performed from cranial to distal. The upper limit of the dissection can be marked with a titanium clip.

With this approach, the access is usually good, and with less obscuring bowel compared with the technique described

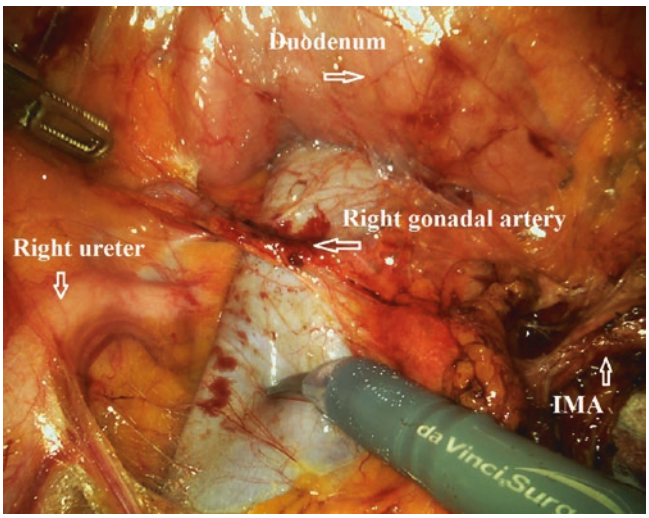

Fig. 77.22 Dissection of the paracaval right side visualizing the right ureter and gonadal vessels

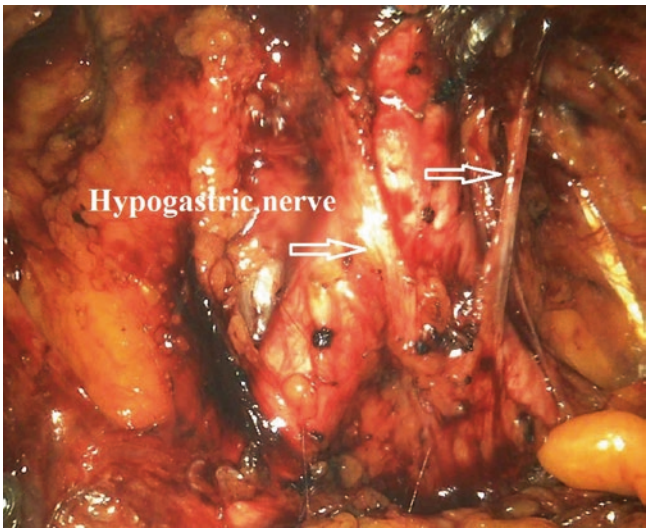

Fig. 77.24 The right and left branches of the hypogastric nerves can usually be preserved

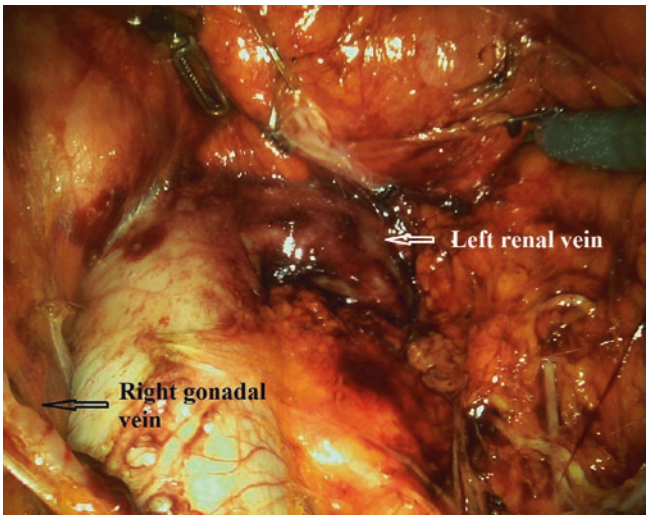

Fig. 77.23 Reaching the left renal vein with requires a gentle lift of the duodenum

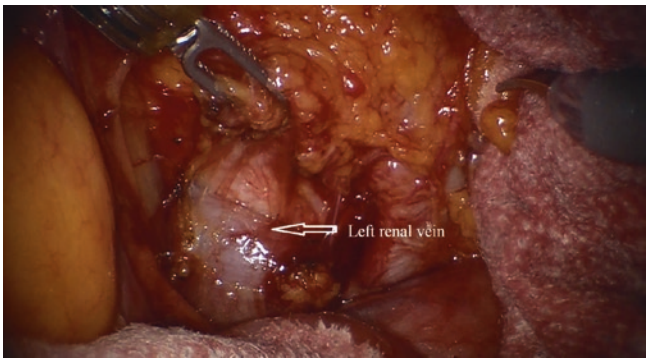

Fig. 77.25 Reaching the left renal vein with pelvic position of the S-Si robots usually requires help of two assistants retractors and sponges

below. The disadvantages are the need for one or two suprapubic assistant's ports, the need for rotation of the patient, and the lower robot port placement needed for an adequate angle related to the aorta. This results in a more perpendicular instrument angle for the lower paraaortic and upper pelvic lymphadenectomy and a shorter distance from the pelvic operative area to the optics with a decreased overview and more need for cleaning of the lens.

With the pelvic position of the robot, the operation starts with retracting the sigmoid colon against the left abdominal wall with one or two sponge reinforced sutures through appendices epiploicae. Then the caecum and ascending colon are mobilized by incizing the lateral peritoneum as far up as possible. The small bowel mesentery is often adherent to the IP-ligament and has to be released to allow the small bowel to retract cranially. The peritoneum is then opened medial of the right common iliac artery to the level of the aortic bifurcation and further to the inferior mesenteric artery (IMA) and the ureters, the IP-ligaments and the hypogastric nerve are visualized similar to the onset of a pelvic lymphadenectomy (Figs. 77.1, 77.2 and 77.3). The third robot arm grasper is useful for further lifting the sigmoid or retracting the right ureter and IP-ligament. The lower paraaortic and paracaval lateral areas are then opened carefully to clearly explore the vessel anatomy. Then the IMA is skeletonized and the dissection continued to reach the level of the left renal vein (Fig. 77.25). The role of the assistant at this stage is to lift the proximal peritoneal fold to prevent the small bowel from interfering with the surgical field, sometimes

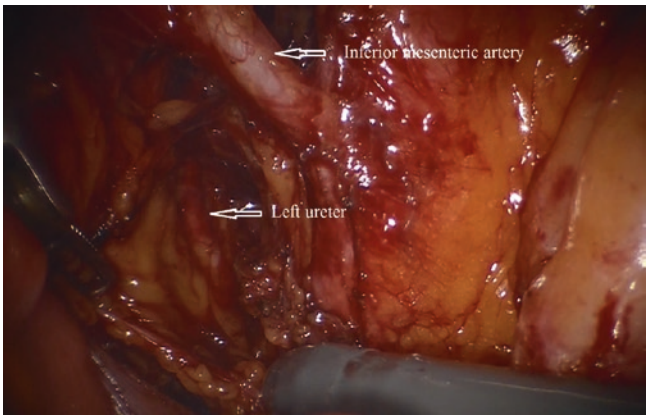

Fig. 77.26 The left supramesenteric part of the ureter must be visualized and lateralized before removing lymph nodes

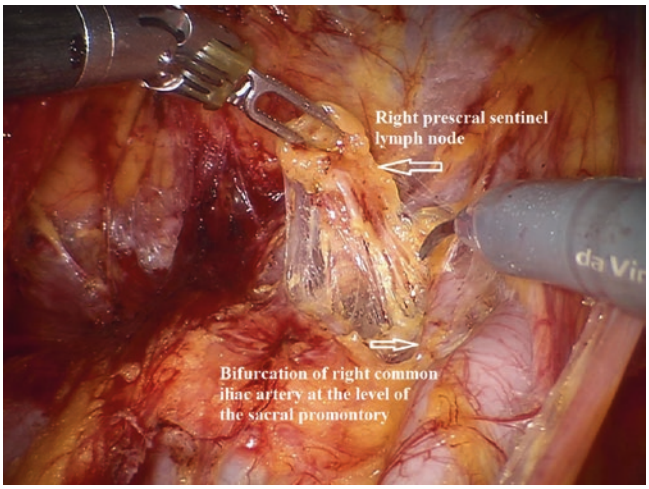

Fig. 77.27 Right side presacral dissection

requiring a second assistants' port and a several sponges. The third arm is used for retracting the left side of the peritoneal opening at desired level. The origin of the IP-ligaments and the gonadal arteries are identified as well as the ureters in the supramesenteric area, in particular on the left side where the course of the ureter is deeper (Fig. 77.26). The ureter must be lateralized before removal of the lymph nodes.

After exploring the whole operative field a final view of the vessel anatomy is obtained before the lymphadenectomy begins. The order of dissection is optional but it usually a good idea to start cranially and with the left supramesenteric paraaortic area as this tends to be the most difficult part, followed by the intraaortacaval and finally the precaval parts. Any bleeding from previous distal dissection may also be cumbersome when the supramesenteric dissection is performed. In case leaking of large amount of lymphatic fluid occurs, in particular if opaque/chylous, it is important to find the leak and close it with clips as it may be associated with later development of chylous ascites. A metal clip marking the proximal limit for the dissection is often appreciated by the radiooncologists. Finally the inframesenteric nodal dissection is performed compartmentwize. Attention should be given to free nodal tissue under the IMA which is easily overseen. It is usually possible to free and save the main branches of the hypogastric nerve running from right to left over the inframesenteric aorta via the aortic bifurcation and then further on presacrally (Fig. 77.24).

Effort should be made to achieve good hemostasis throughout the procedure, not only to reduce the risk for a major bleeding and conversion but to avoid time consuming hemostatic actions. Before nodal dissection it is recommended to have a laparoscopic sponge in the abdomen practical for simultaneous suction and compression of smaller bleeds i.e. from Fellows veins that usually stops with compression with or without help of surgical hemostatic agents. Smaller arterial bleeds are best controlled with clips or bipolar diathermia whereas vessel damage considered inappropriate for compression or diathermia may be sutured. Any attempt to repair a larger bleed should include a temporary control, i.e. by grasping with the robot instruments and only after optimizing the surgical and anesthesiological situation the actual repair should be attempted. It is for safety reasons important to strongly discourage from repeated unsuccessful attempts to control a bleed.

The near infrared fluorescent technique for detection of sentinel lymph nodes is available with the Xi and Si systems. By the use of an adapted light source, optics and software the used tracer (Indocyanine green) will appear green against a grey background. So far, no standardized technique of injection sites, dosing and timing for the use within gynecology are agreed on but several centers perform studies. A standardization must include knowledge of the lymphatic anatomy, a clear definition of sentinel lymph nodes and a defined stepwise surgical algorithm. The tracer has a rapid spread leading to many coloured lymph nodes which cannot all be defined as sentinel lymph nodes. Therefore, the afferent lymph vessel in each major lymphatic chain must be identified to define the node closest to the tumour (the sentinel lymph node). Hence the retroperitoneal dissection must be performed meticulously to avoid cutting lymph vessels. To avoid disturbance from tracer leakage during sentinel node remove, dissection of nodes preferably starts cranially, i.e. with the presacral nodes (Figs. 77.27 and 77.28) followed by the pelvic side walls (Figs. 77.29 and 77.30). In case of no uptake of tracer a full lymphadenectomy shall be performed. In this situation it is particularly important to look for macroscopically cancer suspect nodes.

Techniques for Gastrocolic and Infracolic Robotic Omentectomy

78

Gerald Feuer and Nisha Lakhi

Anatomy

The greater omentum is composed of a double layer of peritoneum and mainly fatty tissue. It extends from the greater curvature of the stomach, passes in front of the small intestines, and reflects on itself to ascend to the transverse colon (Fig. 78.1). The gastrocolic omentum extends from the greater curvature of the stomach to the superior aspect of the transverse colon [1]. When performing an omentectomy, the right border of the omentum can normally be identified at the ceacum and the left border at the splenic flexure. Identifying these landmarks may be useful for acquiring orientation during dissection.

Blood Supply

The right and left gastroepiploic vessels traverse the greater curvature of the stomach and provide the sole blood supply to the greater omentum. Three dominant omental vessels, along with smaller branches, arise from the gastroepiploic system and provide vascular supply to the omentum (Fig. 78.2) [1].

Function of the Omentum

The omentum has three main functions:

1. Fat deposition.
2. Functions as a secondary lymphoid organ.

The omentum contains secondary lymphoid tissue called "milky spots". It has been demonstrated that this tissue is a rich source of lymphocytes, macrophages and monocytes, which may aid in the removal of foreign material and bacteria. In addition, this tissue possesses antimicrobial and angiogenic properties through release of fibroblast growth factors and hence has a role in healing inflamed or ischemic tissue [2, 3].

3. Infection and Wound Isolation

The omentum is a mobile organ in the peritoneum. It serves to fix the viscera and isolate abnormal tissue or infection to limit its spread [2, 3].

Indications for Omentectomy

An omentectomy is indicated as part of the standard surgical staging for malignant ovarian neoplasms, borderline tumors, and primary peritoneal cancers (Table 78.1). It should be performed in cases even if there is not macroscopically visible disease [4]. The safety and feasibility of an omentectomy as part of a robotic staging operation for ovarian cancer has been documented in the literature [5]. Omentectomy should also be performed as part of the staging operation for serous papillary endometrial cancer, as this histological subtype of uterine cancer tends to spread transperitoneally and behaves in a manner similar to epithelial ovarian cancer [6].

In cases where there is no macroscopically visible disease on the omentum, the extent of omentectomy has not been elucidated, as there has been no study comparing total omentectomy, subtotal omentectomy, or omental biopsies alone for the purposes of staging and treatment of epithelial ovarian cancer [4]. In our practice, we perform an infracolic omentectomy as part of the general staging procedure, and include resection of the gastrocolic omentum in cases where

Note: The technique described is for performing an omentectomy utilizing the da Vinci® Si System (Si). Modifications of technique and port placement that are necessary when utilizing the da Vinci® Xi System (Xi) are mentioned where appropriate.

Robotic Infracolic Omentectomy

Port Placement and Docking

The optical port is positioned midline, approximately 22–24 cm (9 inches) above the symphysis pubis. Two lateral 8 mm robotic ports are introduced. The right 8 mm robotic port is positioned 10 cm lateral and 2 cm inferior to the optical port. The left 8 mm robotic port is placed 11–12 cm lateral and 2 cm inferior to the optical port. The left port is further lateralized in order to optimize dissection at the splenic flexure. If an assistant utilizes two ports, one 12 mm port is placed at the right lateral side of the patient 10 cm from the robotic port, and one 5 mm port in the right upper quadrant below the costal margin and midway between the left lateral port and the midline port. (Fig. 78.3).

The robot is centrally docked between the patient's legs, as this placement provides more range on the right side as compared to side docking (Fig. 78.4).

If utilizing the *da Vinci® Xi System* (Xi), the two lateral 8 mm robot ports are placed at the same plane as the optical port, each 9–10 cm lateralized from the midline (Fig. 78.5). It is not necessary to further lateralize the left robotic port to adequately reach the splenic flexure as in the Si model. For the Xi model, the robot can be docked centrally, but preferably from the patient's left side (Fig. 78.6).

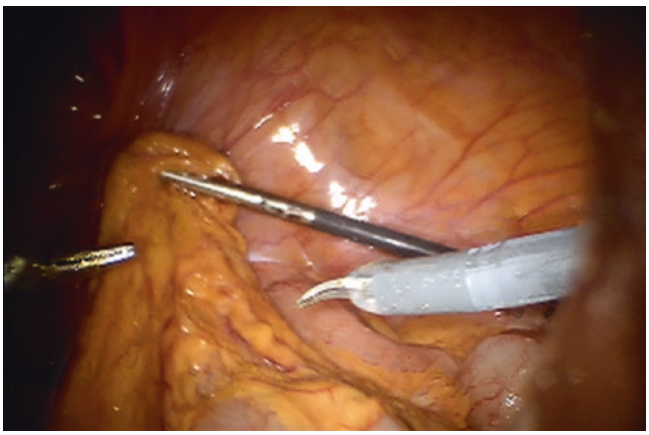

Fig. 78.8 Assistant pulling the omentum towards the pelvis

Role of the Assistant in Robotic Omentectomy

We describe a three arm technique for a robotic infracolic omentectomy. In this technique, the assistant has a critical role: The assistant laparoscopically maintains the omentum midline, pulls it deep into the pelvis, and provides countertraction. This allows for easier dissection and visualization throughout the procedure. It is important that the surgeon and the assistant work in tandem, maintaining equal traction and countertraction. If a skilled assistant is not available, a fourth arm can be employed to provide countertraction in the direction of the pelvis. The port would be placed in the same plane as the other robotic port on the left side, approximately 9–10 cm lateral for the Xi system and 10–12 cm lateral for the Si system. However the use of a fourth arm is less effective, as the fine, real-time adjustments a skilled assistant can make are difficult to duplicate with an additional robotic arm.

Procedure

At the start of the procedure, the assistant grasps the omentum at an area to the right of the mid-transverse colon and places it within the pelvis (Fig. 78.7).

The assistant or fourth arm maintains the position of the omentum toward the pelvis (Fig. 78.8), while the surgeon utilizes the left robotic arm to provide gentle traction immediately adjacent to area to be incised (Fig. 78.9). This aids in exposure of the anterior and posterior peritoneal reflections of the omentum, where the point of entry is made (Fig. 78.10).

The surgeon commences dissection at the mid-transverse colon (Fig. 78.11). Monopolar scissors are used to cut

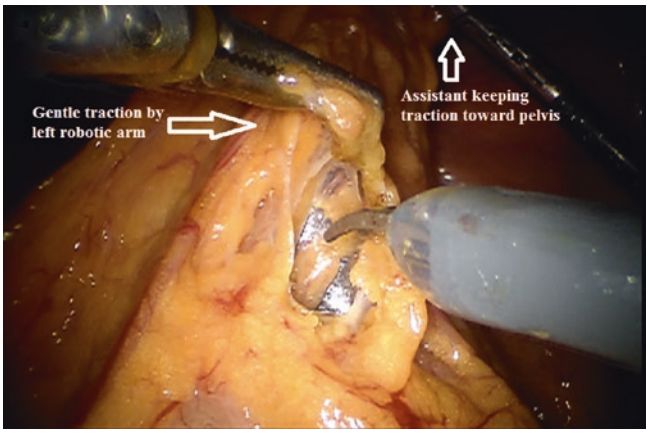

Fig. 78.9 Assistant maintaining the position of omentum in pelvis as the surgeon exerts gentle traction with the left robotic arm to reveal the peritoneal folds.

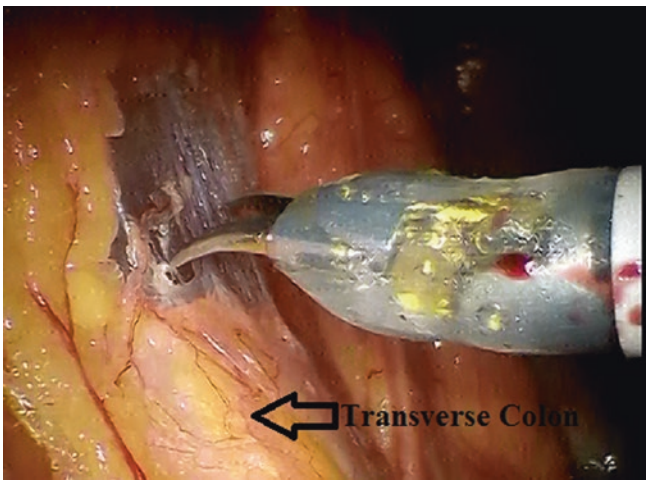

Fig. 78.10 The point of entry is made at the mid-transverse colon where the thin anterior posterior peritoneal fold can be visualized

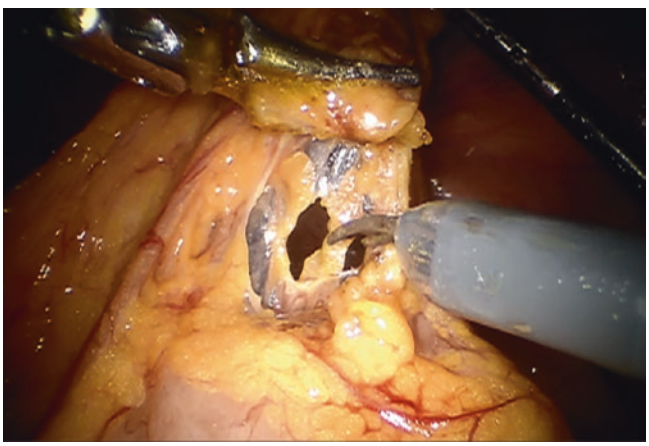

Fig. 78.11 Surgeon begins dissection by incising the peritoneal folds with the robotic scissors

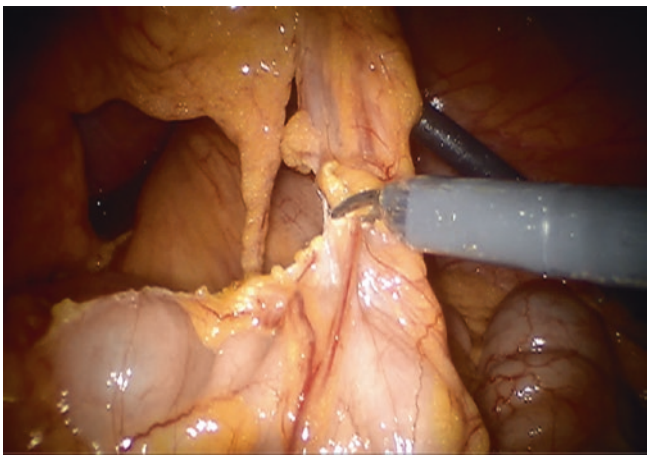

Fig. 78.12 Cutting current is used along the mid-transverse colon to incise the peritoneal folds. The assistant maintains traction of the omentum towards the pelvis.

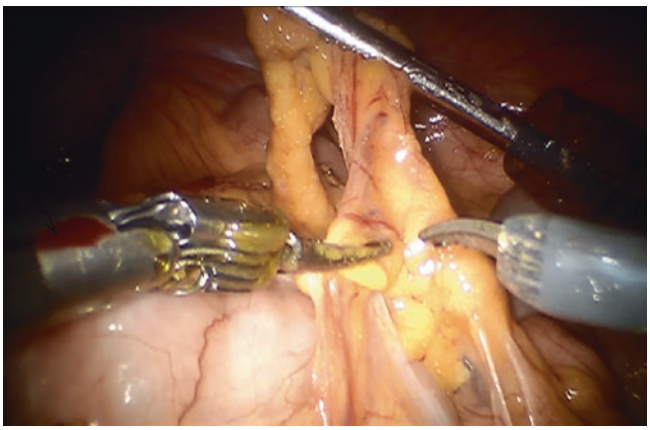

Fig. 78.13 Bipolar current being used to coagulate larger pedicles

the thin anterior and posterior peritoneal reflections (Fig. 78.12). Thicker vascular pedicles are first desiccated with bipolar cautery (Fig. 78.13). It is important to keep the bowel in direct visualization to avoid thermal injury (Fig. 78.14). In order to avoid thermal injury to the bowel, a distance of 3–5 mm from the bowel should be kept when using cutting current. A distance of 1 cm should be maintained when using coagulation current due to its increased thermal spread.

The surgeon continues dissection from the mid-transverse colon towards the ceacum (Fig. 78.15). This step can be more difficult in cases where the bowel is inadequately prepared or in obese patients that have abundant abdominal fat. In the obese patient, a useful trick to identify the peritoneal reflection along the transverse colon is to flip to omentum so that its posterior surface is visualized. The posterior surface can be followed to identify the transverse colon and find the peritoneal reflections.

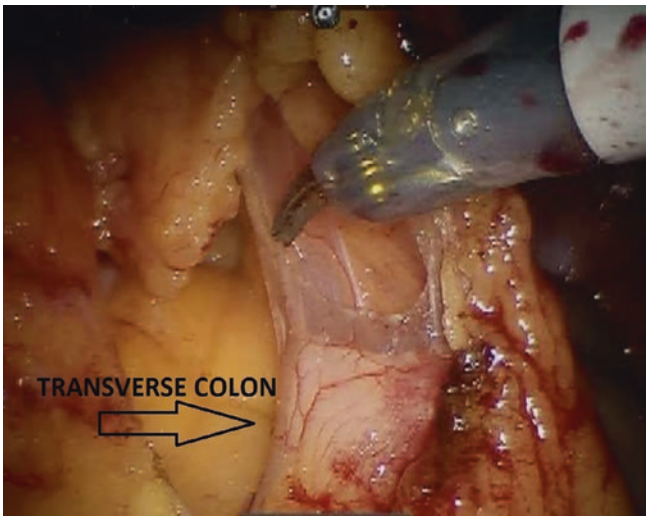

Fig. 78.14 A distance of 3–5 mm from the bowel should be maintained when using cutting current.

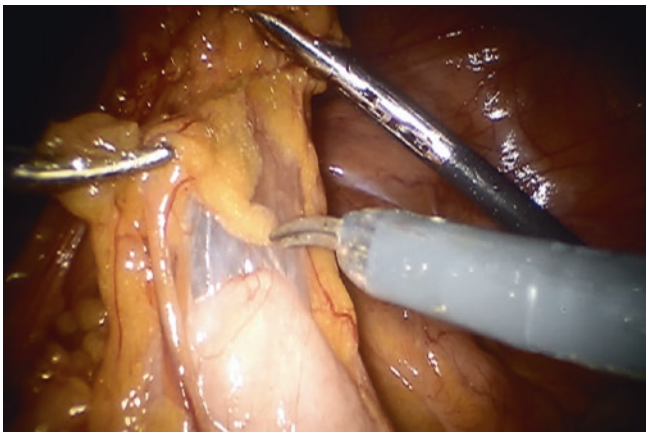

Fig. 78.16 Near the splenic flexure, the assistant is pulling the omentum towards the right lower quadrant as the surgeon uses the left robotic arm to pull up on the omentum, thereby revealing the peritoneal reflection.

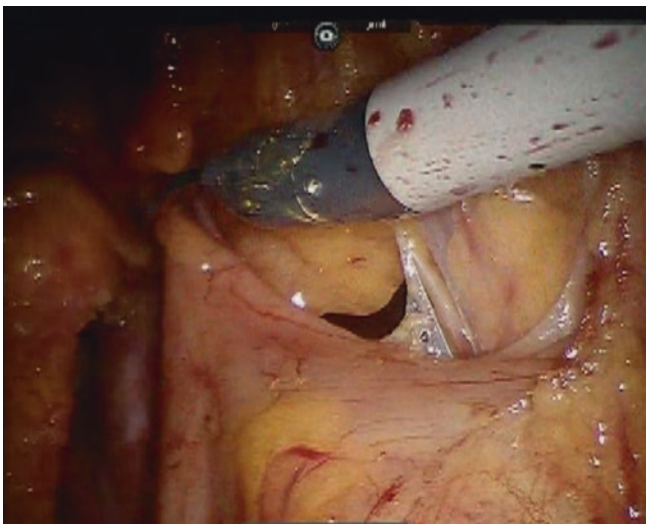

Fig. 78.15 Dissection along the mid-transverse colon towards the ceacum

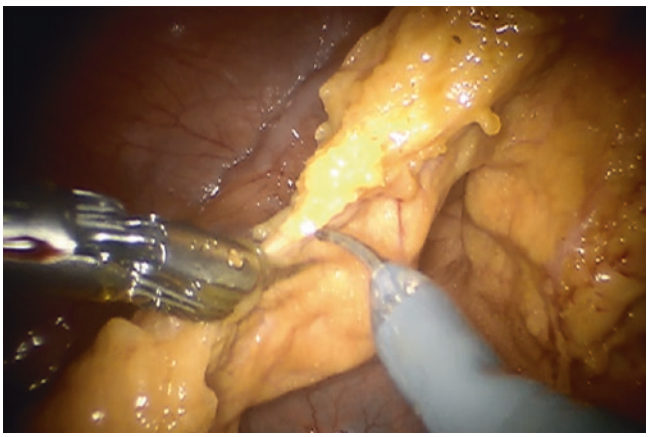

Fig. 78.17 Transection of the omentum after completion of infracolic omentectomy

In order for the procedure to be successful, the surgeon and the assistant have to make periodic adjustments in the amount and direction of traction and countertraction, so that the peritoneal reflections and transverse colon can be easily visualized.

After completion of dissection at the ceacum, the surgeon returns to the mid-transverse colon and dissects towards the splenic flexure. The ability to reach the splenic flexure is dependent on optimal placement of the left robotic arm. The first consideration is during the initial port placement, where the arm is placed 11–12 cm lateral left from the midline for the Si system. Placement of this port 9–10 cm from the midline is sufficient for Xi system. Second, at this point in the procedure, if the Si system is being utilized, the left robotic arm is redirected with the elbow manually pushed so that it is pointing toward the robot.

As dissection continues toward the splenic flexure, the assistant or fourth arm provides countertraction towards the right lower quadrant as the surgeon maintains upward traction (Fig. 78.16). The anterior and posterior peritoneal reflections are identified and cut with monopolar cautery. Vascular pedicles are identified and initially desiccated with bipolar cautery and cut with the robotic scissors with or without the utilization of cautery. Once one satisfactorily accomplishes the extent of dissection towards the splenic flexure similar to an open procedure, the specimen is transected using bipolar current or monopolar in combination with the robotic scissors (Fig. 78.17).

At the completion of the infracolic omentectomy, the omentum is tacked to the left pelvic sidewall using a surgi-

cal clip or a stitch. It is extracted vaginally at the completion of the hysterectomy and staging procedure. The omentum is grasped with a sponge stick and rotated clockwise during extraction. The key steps for infracolic omentectomy are summarized below (Table 78.2).

Robotic omentectomy, once mastered, can be performed with operative times similar to open and faster than laparoscipic omentectomies. However, some differences between robotic and other approaches should be noted. Compared to the laparoscopic approach, port positioning for robotic omentectomy is usually higher, as described. This is important, especially for the placement of the optical port, since its position is not easily interchangeable as it is in conventional laparoscopy. The higher position of the optical port in robotic surgery allows for visualization of both the upper abdomen as well as the pelvis. Laparoscopiclly, the camera can be moved to a suprapubic port and the surgeon can dissect in the upper abdomen via accessory ports. With the robotic approach, the optical port is fixed; therefore, the surgeon is more dependent on the assistant maintaining the position of the omentum in the pelvis. Additionally, access to the left upper quadrant toward the splenic flexure can be more difficult with the robotic approach. If there is no macroscopically visible disease, we generally terminate the infracolic omentectomy 10–15 cm (4–6 inches) from the splenic flexure, which is similar to an open procedure. Access to the left upper quadrant when using the Si model is optimized by further lateralizing the left robotic port and when approaching the splenic flexure, manually re-directing the left robotic arm, so that its elbow points towards the robot. Coordination between the surgeon and assistant, the robotic omentectomy can accomplished with efficiency similar to open and faster than laparoscopic approaches.

Robotic Gastrocolic Omentectomy

A gastrocolic omentectomy is performed when there is upper abdominal disease or macroscopic disease on the gastrocolic omentum. We initially make a laparoscopic assessment prior to docking the robot and decide if this procedure needs to be undertaken. If necessary, it is performed prior to the infracolic omentectomy that is described above. For the Si system, a double docking technique is necessary: first docking the robot over the patient's right shoulder for the gastrocolic dissection (Fig. 78.18), and then centrally docking the robot

Fig. 78.18 Docking of the *da Vinci® SI System* over the patient's right shoulder in preparation for a gastrocolic omentectomy

Table 78.2 Key steps for infracolic omentectomy procedure

Beginning of procedure 1. The omentum is laparoscopically placed in the pelvis. The assistant maintains traction throughout the procedure to keep the omentum in the pelvis rather than the upper abdomen. 2. Dissection begins at the mid-transverse colon, where the anterior and posterior peritoneal folds are identified and entered. 3. In order to identify the peritoneal folds, the left robotic arm pulls up on the omentum, exerting upward traction to assist in revealing the peritoneal reflections.
Middle of procedure 1. Dissection begins from the point of entry along mid-transverse colon and continues toward the caecum. 2. Cutting current with the monopolar scissors is used to dissect along the anterior and posterior peritoneal folds. 3. Once dissection to the caecum is complete, we return to the point of entry along the mid-transverse colon in order to dissect in the opposite direction, towards the splenic flexure. 4. At this point, if the Si system is being used, manually re-directing the left robotic arm, so that its elbow points towards the robot, can optimize dissection towards the splenic flexure. 5. Dissection continues along the anterior and posterior peritoneal folds as previously.
End of procedure 1. The extent of dissection is variable; however, if there is no grossly visible disease, we normally terminate dissection 10–15 cm (4–6 inches) from the splenic flexure. 2. In order to terminate the procedure, a point of transection is determined. Bipolar current is used to desiccate the thick fatty area of the omentum being transected, and robotic scissors are used to cut and free the specimen.

between the patient's legs to accomplish the infracolic portion. This is not necessary with the Xi system as the boom of the robot can be turned to approach multiple quadrants.

Procedure

To begin the gastrocolic omentectomy, the stomach is tented up (Fig. 78.19) and the peritoneal folds of the omentum are incised to the right of the midline with cutting current in order to enter the lesser sac (Fig. 78.20). It is useful to identify a thin area of peritoneum along the greater curvature of the stomach and enter the lesser sac from this point.

A robotic vessel sealer is helpful for dissection and maintaining hemostasis. The sealer is used in the left robotic arm and an atraumatic fenestrated grasper is placed in the right incised to the right of the midline robotic arm. The role of the assistant is to exert upwards traction on the stomach with an atraumatic grasper while the right robotic arm places downward traction on the omentum. This dynamic should be maintained throughout the dissection (Fig. 78.21).

The omentectomy is commenced from the point where the lesser sac was entered. The sealer is placed approximately 1–1.5 cm away from the short gastric arteries (Fig. 78.22). A double seal technique is used, in which the sealer is fired twice before cutting; this allows for a more hemostatic dissection. Dissection is continued along the greater curvature of the stomach toward the splenic flexure (Fig. 78.23).

Upon reaching the splenic flexure, the dissection is directed towards the transverse colon (Fig. 78.24). This facilitates the infra-colic omentectomy that can be continued from the pelvis. In order to define the limit of the omentetomy, it is important to make a detailed visual inspection of any residual disease so that it can be included with the specimen.

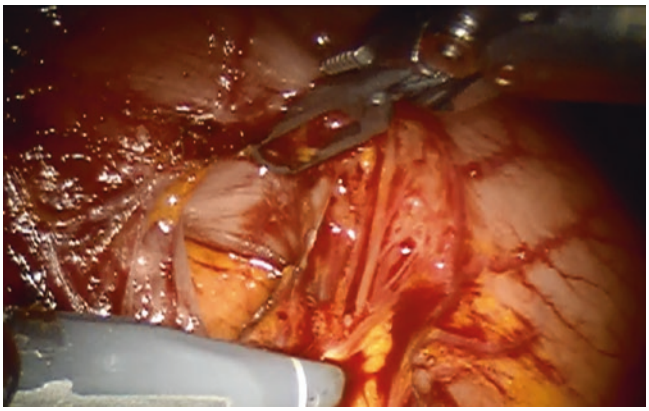

Fig. 78.20 Cutting current used to enter lesser sac

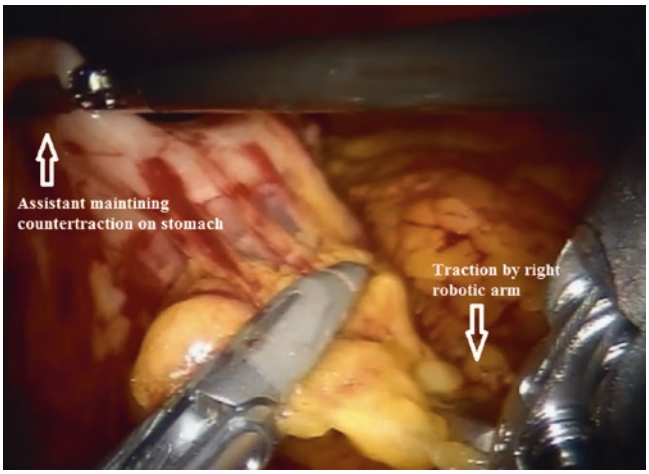

Fig. 78.21 The sealer is used in the left robotic arm. The assistant maintains upward traction on the stomach as the surgeon uses an atraumatic grasper in the right robotic arm to pull the omentum downwards

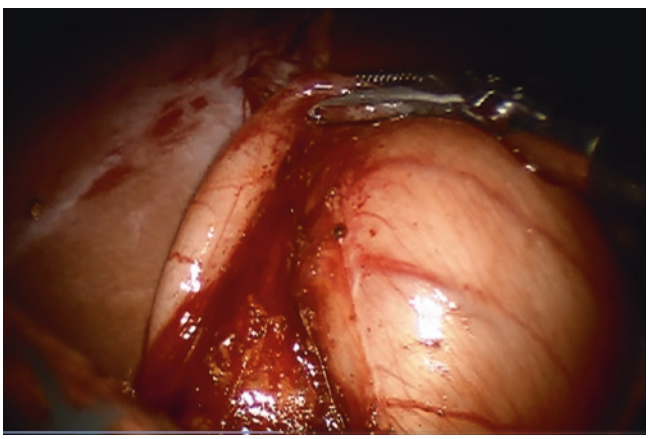

Fig. 78.19 The surgeon uses the robotic arm to grasp and tent up the stomach in order to identify point of entry to lesser sac

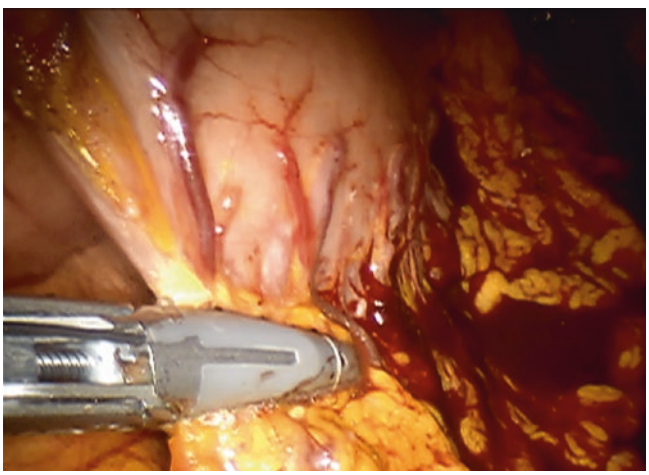

Fig. 78.22 The sealer is placed approximately 1–1.5 cm away from the short gastric arteries

Fig. 78.23 Dissection with the sealer along the greater curvature of the stomach towards the splenic flexure

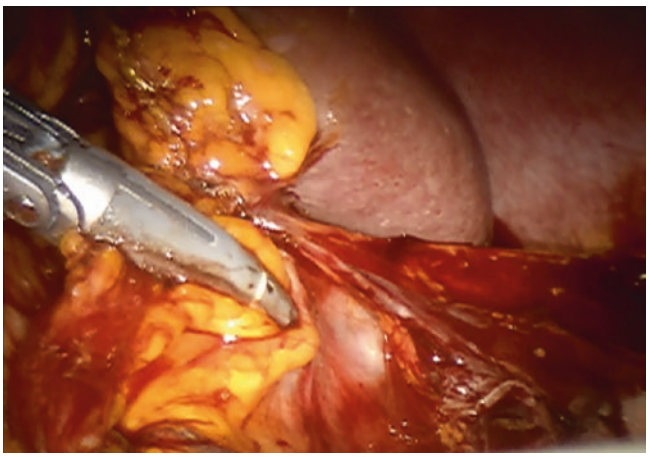

Fig. 78.24 Direction of dissection directed towards the transverse colon after reaching the splenic flexure

At this point the sealer is placed in the right arm and the atraumatic grasper in the left arm and dissection is continued for a short while to the right and then towards the transverse colon. This sets up dissection for the infracolic omentectomy as described above, and allows the entire omentum to be removed en bloc. If using the Si system, the robot is undocked from over the patient's right shoulder and re-docked centrally. This can be accomplished by either turning the patient's bed (with cooperation from the anesthesiologist) or mobilizing of the robot. For the Xi system one undocks, simply rotates the boom, re-docks, and then redirects the orientation for the new anatomy targeted.

Robotic-Assisted Laparoscopic Hysterectomy: Final Steps and Postoperative Considerations

79

Bahriye Aktas

Robotic surgery provides all the benefits of the laparoscopic technique with greater precision and effectiveness with no major difference regarding postoperative considerations and complications.

When the surgery is completed, an exploration of the upper abdomen and pelvis is required to control that there is no damage. Immediate intraoperative management of any damage is recommended for the best postoperative outcome.

Performing cystoscopy should not be done routinely, but in select cases cystoscopy is helpful after vaginal closure to check ureteral patency and for any signs of bladder injury. Please note that a normal cystoscopy does not exclude a delayed thermal injury to either the ureters or the bladder [1].

Vaginal cuff dehiscence after hysterectomy is a rare but severe postoperative complication. The rate of vaginal cuff dehiscence seems to have been shown to increase after both robotic and laparoscopic surgeries compared with that after the open approach [2]. However the incidence is significantly higher in total laparoscopic hysterectomy than laparoscopy assisted vaginal hysterectomy. Thus the vaginal closure technique is essential to avoid any cuff dehiscence. The intra – corporeal cuff suture seems to be superior to the vaginal suture to prevent the vaginal cuff complications [3]. Additionally abstaining from vaginal intercourse should be recommended to decrease the rate for postcoital vaginal cuff dehiscence.

Whereas adhesions are common after hysterectomies and could be the reason for delayed abdominal pain. To avoid accumulation of seroma a soft plastic drain sometimes is placed through one of the incisions, which usually will be removed before the patient goes home. There are a lot of ambiguous data with on the efficacy of agents against adhesions, but only a few of the various available pharmacological and non – pharmacological agents have been studied in randomized controlled trials [4].

Once the robotic assisted procedure is finished, all instruments and endoscopes and cannulas are removed. The cannulas will be removed after disconnecting the roboter arms. Subcutaneous emphysema could result from placement of the Veress needle into the extraperitoneal space or during prolonged procedures after using robotic assisted or laparoscopic techniques when cannulas are dislocated. Patient's companions should be told that during laparoscopic hysterectomy may secondarily occur subcutaneous emphysema as gas gains access through enlargement of the trocar incision in the parietal peritoneum and usually dissolves in 12–24 hours [5–8].

The port site skin incisions are closed with dissolving sutures or skin glue. Any 12 mm incisions and extended incisions for delivering specimen retrieval bag require fascial closure using 0 vicryl sutures to prevent incisional hernias. The skin is closed with 4–0 monocryl sutures in a continuous subcutaneous or intracutaneous fashion. The 5 mm incisions generally do not require fascial closure and are closed with single sutures with 4–0 monocryl or glue for better cosmetic results.

For reducing immediate postoperative pain, injection of local analgesia at all post incision sites is possible [9] but not necessary.

Subsequently, the sterile accessories and drapes can be removed and the patient will be transferred to the recovery room. The nurses and doctors will monitor patients' recovery as she wakes up and will continue monitoring until she is discharged from the hospital.

A post – operative assessment should be done at the same day of the surgery, including palpation of the abdomen, checking the drainage, if any was placed and looking for any vaginal bleeding. Checking the blood values is not necessary; accept there are clinical signs for postoperative hemorrhage.

In cases of postoperative vaginal cuff hematoma usage of antibiotics could be necessary to prevent any infections.

Single prophylactic doses and additional intraoperative doses in prolonged surgeries are useful and recommended.

The main indications to extend the application of antibiotics postoperatively are intraoperative interventions on the intestines or urinary tract.

In patients who underwent general anesthesia, the Foley catheter should be removed postoperatively when the patient is awake and no longer immobile. Mobilization of the patients should also be performed as soon as possible to prevent thrombosis, if indicated heparin should be given in patients at risk, especially patients with cancer diagnosis. During hospitalization patients should receive thrombosis prophylaxis, because thromboembolism is relatively common in gyneco – oncological surgery.

Against the past there are no special steps for rebuilding the diet after hysterectomy but flatulent foods should be avoided.

A discharge assessment will be performed including abdominal sonography to check the kidneys and a vaginal sonography to exclude any hematoma.

In most cases patients return to their routine activities 2 weeks after the operation. Final pelvic examination is usually indicated after 6–12 weeks, mainly are indicated for pain or pyrexia. Sexual activity may be allowed after a recovery time to avoid postcoital vaginal cuff dehiscence and infections as previously described. In general, patients can resume sexual relations after 8 weeks, may be later for patients at risk for impaired healing like obese patients and patients with diabetes.

A review of the literature published 2011 described a significant difference in number of major postoperative complications between robotic radical hysterectomy (9.6 %) and total laparoscopic radical hysterectomy (5.5 %). In the robotic procedure group were included 11 cases of vaginal cuff dehiscence, 10 cases of vaginal cuff abscess, and 5 cases of port site hernia [10]. Despite to these data, Estape et al. demonstrated that the incidence of postoperative complications was less in the robotic group (18.8 %) than either the laparoscopic group (23.5 %) or the laparotomy group (28.6 %). In the first group, one patient developed a pelvic abscess and another one a vaginal evisceration [11]. Two other studies did not observe any significant differences in postoperative outcomes [12, 13]. Similar early, less than 6 weeks, major postoperative complications in robotic radical hysterectomy (7 %), laparoscopic radical hysterectomy (6 %), and open radical hysterectomy (9 %) groups was described by Magrina et al. [13]. Overall postoperative complications rate of 12 %, including deep venous thrombosis (2.4 %), pyelonephritis (2.4 %), prolonged bladder catheterization of 21 days (2.4 %), and infection (4.8 %) was demonstrated by Lowe et al. [14]. Early mobilization and administering heparin in patients at risk for developing deep venous thrombosis, removing of the Foley catheter and treating prophylactically with an antibiotic intraoperatively could help to prevent these complications.

Robotic approach provides clear benefits of minimally invasive surgery, such as a reduced blood loss, a lower morbidity, and a faster recovery than open surgery. Although surgical outcomes are similar or slightly improved when compared to laparoscopy [15]. Complication rates and hospital stay are also similar for robotic and conventional laparoscopic surgery [16], indeed, current studies shows faster recovery time for patients underwent robotic surgery [17].

Overall there is no major difference between robotic – assisted hysterectomy and the laparoscopic hysterectomy regarding postoperative considerations and complications [18, 19].

Part X

Abdominal Hysterectomy and Extended Procedures for Benign and Malignant Indications

Abdominal Hysterectomy: Indications and Contraindications

80

Russalina Mavrova, Julia C. Radosa,
Ingolf Juhasz-Böss, and Erich-Franz Solomayer

Hysterectomy is the most common non-obstetric gynecologic procedure with an incidence of 3.6 per 1000 person-years in Germany in 2006; 4.8 per 1000 woman-years in Australia in 2003 and 5.1 per 1000 person-years in the US in 2004 [1, 2, 3]. Although the number of hysterectomies has decreased over the last decade [2, 4], it remains the gold standard for the treatment of benign uterine pathologies and part of the surgical treatment of gynecologic malignancies. Hysterectomy may be performed via abdominal, vaginal, laparoscopic or robotic approach. The choice of the surgical approach depends upon clinical circumstances, surgeon's technical experience and patients` preference. Furthermore a combination of techniques can be used and should be considered. When choosing the route and method of hysterectomy the patient's safety should be the most important factor. The cost effectiveness should not influence the choice of surgical approach. Many guidelines have been published regarding the best technique to perform hysterectomy. Although overall recommendations endorse a vaginal or minimal invasive approach as an alternative whenever feasible [5, 6] most hysterectomies (39.5 % in Germany in 2006; 40 % in Australia in 2003 and 54.2 % in the US in 2010) worldwide are performed via laparotomy [1, 2, 4]. Vaginal and laparoscopic hysterectomy are superior to open surgery in terms of less intraoperative blood loss, fewer postoperative infections, less postoperative pain, a shorter duration of hospitalization and a faster reconvalescence and resumption of normal daily activities [5, 7–10]. Improvement in postoperative quality of life and sexual function following laparoscopic or vaginal hysterectomy for benign uterine pathologies due to postoperative symptom relief have also been reported in the literature [11, 12]. However, analysis of hysterectomy rates worldwide shows that abdominal hysterectomy is performed most frequently [13–19] and still plays an important role in gynecologic surgery.

The most common indications for hysterectomy are uterine leiomyomas, pelvic organ prolapse, pelvic pain or infection (e.g. endometriosis, pelvic inflammatory disease), abnormal uterine bleeding and malignant/premalignant disease as shown in Table 80.1. Although hysterectomy is the treatment for most gynecologic malignancies, the vast majority of hysterectomies are performed for benign gynecologic diseases [4]. Open surgery offers the possibility of abdomino-pelvic exploration which is limited when using the vaginal approach. The following contraindications for the vaginal route are described in the literature: enlarged and bulky uterus (estimated uterine size exceeding the umbilicus), narrow vagina and pubic arch, undescended immobile uterus, supracervical hysterectomy, an extrauterine disease as adnexal pathology/severe endometriosis/adhesions and malignancies. Relative contraindications for the vaginal route are: nullipara [20, 21], prior cesarean delivery [22, 23] and elective salpingoophorectomy, as the success of removing the ovaries vaginally varies from 65 to 97.5 % [24–26]. The combination of a vaginal approach with laparoscopic surgery to facilitate vaginal hysterectomy, analogous to a laparoscopic assisted vaginal hysterectomy (LAVH), is not recommend in cases in which laparoscopic surgery alone is feasible as it offers no benefits. Consecutively, if a vaginal hysterectomy cannot be performed, surgeons should choose between the laparoscopic and the abdominal approach, as experience with robot-assisted hysterectomy is limited to date. Morbidity and mortality rates are higher for abdominal hysterectomy compared to minimal invasive surgery. Patients undergoing abdominal hysterectomy have a three times higher morbidity and mortality rate than those who undergo laparoscopic hysterectomy [27, 28]. They suffer more postoperative infections, a higher rate of incisional hernias, a higher rate of thromboembolic complications and tend to have a higher intraoperative blood loss. However the laparoscopic approach has its limitations too. A considerable disadvantage of laparoscopic

Abnormal bleeding	Atypical endometrial hyperplasia
Pelvic organ prolaps	Invasive endometrial cancer
Endometriosis	Ovarian cancer
Pelvic inflammatory disease	Fallopian tube cancer
Chronic pelvic pain	Gestational throphoblast tumors
Pregnancy-related pathologies	–

hysterectomy is the lengthen duration of surgery as it takes longer to perform than abdominal hysterectomy [29]. A meta-analysis performed by Walsh et al. in 2009 [30] compares total abdominal hysterectomy to total laparoscopic hysterectomy for benign indications. They found out that the only trade-off for a better outcome appears to be a longer operating time in the TLH group (WMD 22 min; 95 % CI 5–39 min; $p = 0.01$) compared to the TAH group. Another meta-analysis by Gendy et al. [31] published in 2011 compares vaginal hysterectomy to total laparoscopic hysterectomy for benign disease. They found out that TLH took longer to perform (WMD 29.3 min; $P = 0.003$) compared to VH. This is comparable to lots of other papers [32, 33] dealing with the same topic.

Abdominal hysterectomy is easier to perform and to learn compared to laparoscopic hysterectomy as the published learn curves in the literature show [34–36].

The equipment for an abdominal hysterectomy is broadly available in most institutions. The experience of the surgeon and his dexterity are important factors when choosing surgical approach. Another important parameter which should be taken into consideration is the duration of surgery. Surgeons should choose the surgical approach which helps reducing the duration of surgery, as prolonged exposure to anesthesia can lead to an unfavorable postoperative outcome, especially for patients with comorbidities.

In summary an enlarged and immobile uterus might be an indication for an abdominal approach. But there are no specific recommendations up to which uterus weight or size a laparoscopic approach should be preferred over an abdominal approach, as every author has its own definition of an enlarged uterus. Few studies report successful laparoscopic hysterectomy in cases of enlarged uteri [37–40]. Even a case report of a successful total laparoscopic hysterectomy of a 3030 g enlarged uterus exists in the literature [41]. It might be helpful to coagulate the uterine artery before starting with laparoscopic hysterectomy in cases of enlarged uteri to reduce intraoperative blood loss [42]. We recommend laparoscopic surgery of enlarged uteri only in specialized laparoscopic centers with experienced and advanced laparoscopic surgeons.

In uro-gynecology, the abdominal hysterectomy still plays an important role. As urogenital prolapse becomes more and more common because of increasing life expectancy, pelvic organ prolapse repair surgery is being performed more frequently. Vaginal vault prolapse is reported frequently after hysterectomy. Abdominal sacro-colpopexy is the gold standard for surgical repair of vaginal vault prolapse [43–45]. It is superior in patients´ outcome when compared to a variety of vaginal procedures including sacrospinous colpopexy, uterosacral colpopexy and transvaginal mesh [45, 46]. As a consequence abdominal sacrocolpopexy can be performed after hysterectomy in cases of upper vaginal prolapse. The Cochraine database report from 2013 [46] shows that abdominal sacro-colpopexy for upper vaginal prolapse was associated with a lower rate of recurrent vault prolapse on examination and less painful intercourse than vaginal sacrospinous colpopexy. Furthermore in single studies the sacro-colpopexy had a higher success rate on examination and lower re-operation rate than high vaginal uterosacral suspension and trans-vaginal polyprolene mesh. But these benefits must be balanced against a longer operation time, longer time to return to activities of daily life and increased costs of the abdominal approach. There are hints that laparoscopic sacro-colpopexy upholds the outcome of the gold standard abdominal sacro-colpopexy with minimal morbidity [45]. But prospective and randomized trials are needed to confirm these results. When counseling patients about alternatives for pelvic organ prolapse repair surgery numerous aspects have to be considered. Hysterectomy has been traditionally performed in cases of pelvic organ prolapse surgery. Nowadays, conflict data exist regarding the effectiveness of pelvic organ prolapse surgery with and without uterine preservation [47, 48]. Marschalek et al. [48] claim that uterus preservation at time of pelvic organ prolapse surgery is a safe and effective alternative for women who wish to preserve their uterus but is associated with more recurrent symptomatic prolapses. Nevertheless, the question regarding the superiority of either sacral hysteropexy or sacro-colpopexy has not yet been answered.

Morcellation can be needed while performing laparoscopic or vaginal hysterectomy, if the trocar opening or the

vaginal outlet is insufficient to pass the resected tissue. The power morcellator is an instrument with a fast rotating cylindrical knife which aims to divide the tissue into smaller pieces or fragments. Morcellation has been used in gynecologic surgery since 1993 and has become the subject of recent discussions because of the U.S. Food and Drug administration (FDA) safety warning about the use of power morcellation published in November 2014 [49] and the possible risk of spreading an undiagnosed uterine sarcoma or leiomyosarcoma, which may worsen patient's outcome [50]. Uterine sarcomas are difficult to diagnose preoperatively [51] and the risk of an unexpected uterine sarcoma following surgery for presumed benign uterine leiomyoma is low as the annual incidence of uterine sarcomas in the international literature ranges from 0.35 to 7.02 for every 100,000 women, depending on the investigated cohort [52].

Lin et al. [53] showed in their study published in 2015 that tumor morcellation irrespective of the access (abdominal, vaginal or laparoscopic) did not increase the abdominal-pelvic recurrence rate, but may be associated with lower DFS and OS in Stage 1 uterine leiomyosarcomas. There have been a number of attempts to increase the safety of morcellation, for example by morcellating within an insufflated bag, which might minimize the risk of spreading malignant cells while preserving the benefits of minimal invasive surgery [54]. Even if this risk is difficult to assess because of the rarity of uterine sarcomas, these risks should be discussed with the patient preoperatively.

A relative contraindication for abdominal hysterectomy is obesity, as it is known to be a risk factor for increased peri- and postoperative morbidity following abdominal hysterectomy [55]. Obese patients were shown to profit from vaginal or laparoscopic approaches, including robotic surgery, since these procedures show lower rates of postoperative wound healing complications and a faster mobilization compared to open surgery. An abdominal hysterectomy should be avoided in cases of obesity.

Abdominal hysterectomy plays an important role in gynecological oncology, as the majority of gynecologic malignancies are still operated on via laparotomy. This practice is likely to be maintained for women with ovarian cancer and advanced stages of cervical and endometrial cancer.

Women with ovarian cancer frequently have extensive pelvic and upper abdominal metastases. The role of laparoscopy in ovarian cancer is still controversially discussed, but there are attempts to assess the impact of laparoscopy in early-stage ovarian cancer [56, 57]. The standard treatment of advanced-stage ovarian cancer includes upfront surgery with intent to accurately diagnose and stage the disease and to perform maximal cyto-reduction and tumor debulking as this is the most important factor for patients´ survival [58–60].

Since minimal invasive surgery is gaining more and more importance and surgeons achieve more and more advanced laparoscopic skills, laparoscopic techniques are being used more frequently in the treatment of early-stage cervical and endometrial carcinoma [56]. Studies show that the use of laparoscopy in early-stage cervical and endometrial carcinoma in terms of oncologic effectiveness is equivalent to that of laparotomy [61–69]. Advanced-stage cervical and endometrial carcinomas occasionally require extensive surgery e.g. a pelvic exenteration and are indications for open surgery.

Certainly financial factors and the cost effectiveness should not influence the choice of the access or method of hysterectomy. But we want to discuss this aspect in this chapter as well. Many authors compare minimally invasive procedures such as laparoscopic and vaginal hysterectomy with the traditional abdominal hysterectomy method by evaluating clinical and economic outcomes. As soon as robotic-assisted hysterectomy became available, it also was compared to the laparoscopic, vaginal and abdominal approach. Cosson et al. [70] divided the costs of a procedure into direct and indirect costs. Direct costs are represented by hospital costs. These expenses vary from one country to another. Direct costs are on the one hand fixed expenses linked to the use of the hospital's infrastructure and equipment, and on the other hand variable expenses related to the amount of personnel, medical prescriptions or use of disposable equipment. Indirect costs are related to the loss of economic productivity of the patient during hospital stay and recovery resulting from the procedure. They depend directly on the country's welfare system and on the patient's incentive to resume work. The operative time, the length of hospitalization and the type of equipment used are the most important factors for the calculation. A longer operative time and length of hospitalization increase the costs; the use of basic equipment can reduce costs. All studies to date show longer operative times for laparoscopic hysterectomy compared to vaginal or abdominal hysterectomy as shown above. A simple vaginal hysterectomy is faster to perform than an abdominal hysterectomy when both options are possible [71]. Although laparoscopic hysterectomy implicate the longest operating times, it show the lowest morbidity rate, the best quality of life in patients and a shorter time of hospitalization compared to the abdominal route. All studies confirm that hospitalization is definitely longer after abdominal hysterectomy compared to laparoscopic and vaginal hysterectomy; for LAH 1.2–4.2 days; for VH 3–4.1 days and for AH 3.3–6.6 days [33, 72, 73]. According to the costs for the equipment, the costs for an abdominal hysterectomy are lower compared to the laparoscopic approach, but the costs for laparoscopy can be reduced with the use of bipolar coagulation, reusable trocars and the abandonment of automatic staplers and prosthetic devices such as endoclips [33, 70]. The shorter hospital stay

Table 80.2 Overview of the (relative) indications and contraindications of abdominal hysterectomy

Indications for abdominal hysterectomy	Contraindications for abdominal hysterectomy
Abdominal surgery in the past	Availability of vaginal or laparoscopic approach*
Enlarged, bulky uterus	Obese and overweight patients
Narrow vagina and pubic arch	–
Undescended immobile uterus	–
Supracervical hysterectomy	–
Extrauterine diseases	–
Adnexal pathologies	–
Severe endometriosis	–
Severe adhesions	–
Suspicion of sarcoma	–
Gynecological malignancies	–
Lack of surgeons experienced in laparoscopy or vaginal hysterectomy	–

in patients undergoing laparoscopic hysterectomy compensates for the increased procedure costs. Combining shorter hospitalization, convalescence and operative times, vaginal hysterectomy is undoubtedly the least costly intervention. It should therefore, whenever possible, be preferred to the other surgical routes. Sculpher et al. [74] found out that laparoscopic hysterectomy was comparable in terms of cost effectiveness to abdominal hysterectomy when taking all the points mentioned above into account. Rosero et al. [75] found out that the median cost of hospital care was $9788 (interquartile range $7105–12,780) for robotic hysterectomy and $7299 (interquartile range $5650–9583) for laparoscopic hysterectomy ($P<.001$). Hospital costs were on average $2489 (95 % CI $2313–2664) higher for patients undergoing robotic hysterectomy. Whrite et al. [76] presented comparable results. All the authors conclude that perioperative outcomes are similar between laparoscopic and robotic hysterectomy, but robotic assisted hysterectomy costs substantially more and is therefore not recommended.

Table 80.2 gives an overview of the indications and contraindications for choosing an abdominal approach. We describe them as "relative" indications and contraindications since most conditions are also applicable for laparoscopic surgery nowadays.

In conclusion, abdominal hysterectomy is a widespread technique and indicated whenever vaginal hysterectomy is not feasible. As laparoscopic surgery has gained more and more importance over the last decades it mainly replaces the abdominal route, but has its own limitations.

Furthermore it is important to avoid the lack of surgical skills for the upcoming generation that primarily learns endoscopic procedures instead of the conventional surgery and will have a lack of technical knowledge in "conventional" abdominal surgery. This knowledge is nevertheless fundamental for the oncogynecological surgery in cases of ovarian cancer, advanced cervical and endometrial cancer, all cases of benign gynecological diseases which need open surgery and in cases where a conversion to a laparotomy is needed.

Conflict of Interest Statement The authors organize laparoscopic training workshops and take part in presentations supported by Storz, Erbe, Johnson & Johnson and Takeda (category A).

Abdominal Hysterectomy: Preparation

81

Siew Fei Ngu and Karen K.L. Chan

Introduction

Abdominal hysterectomy is a major operation and can significantly impact on a woman's physical as well as mental wellbeing. Therefore, it is paramount that health care professionals should take all necessary precautions to ensure a successful surgical outcome with minimal morbidity and mortality. Additionally, it is important to allow adequate time for preparation prior to surgery. Each patient should be carefully assessed by both the surgeons and the anaesthesiologists before the operation. Close collaboration with other medical specialists may also be necessary in order to optimize the patient's pre-existing medical conditions.

The objectives of preoperative preparation include:

1. To ensure that the indication for the procedure is valid
2. To ensure patient is medically fit to undergo the procedure
3. To ensure precautions are taken to minimize risks of complications
4. To ensure the availability of extra resources that may be needed in the preoperative, intraoperative and postoperative period
5. To ensure that the patient understands the nature of the procedure and its benefits and risks

These objectives may be accomplished with the following preparation:

1. Assess the condition
   (a) What is the condition? What is the extent of the condition? Is surgery indicated for the condition?
   (b) Review medical history (e.g. patient's symptoms) and investigation results (e.g. imaging, histology)
2. Assess the patient
   (a) General condition (e.g. age, effect of the current disease)
   (b) Pre-existing medical condition, medications, allergies
   (c) Possibility of pregnancy (e.g. last menstrual period, contraception, pregnancy test)
3. Assess the need for resources
   (a) Need for involvement from other specialties
   (b) Need for special equipment or instrument
   (c) Need of extra postoperative care (e.g. intensive care bed)
4. Communication with the patient and her family
   (a) Counseling and written information sheet
   (b) Informed consent for the procedure

Medical History

A comprehensive medical history must be obtained, and should include current and past medical disease with specific questions to assess the performance status. Systematic physical examination is necessary to detect any signs of coexisting illnesses. The indications for preoperative investigations would depend on patient's age, diagnosis and risk of the procedure based on detailed history and physical examination. The baseline pre-operative investigations for abdominal hysterectomy should include complete blood count, and blood group and antibody screen. For some patients (e.g. oncologic patient), coagulation profiles, liver and renal function test, blood glucose level and chest X-ray may be necessary. Pregnancy test should be preformed shortly before surgery on all fertile women who could be pregnant. Electrocardiogram may be required in selected patients. Specific precautions and evaluation should be individualized, taking associated conditions and comorbidities into consideration. The guideline for some of the preoperative tests and its indications that is used in our unit is shown in Table 81.1. The general physical status is commonly classified according to the American

Table 81.1 Indications of preoperative investigations for elective surgery

1. Complete blood count
(a) Age > 60 years
(b) History or physical examination suggesting anaemia
(c) Known cardiac, pulmonary or renal disease, malignancy
(d) As baseline when heavy blood loss is anticipated
(e) Bleeding tendency as evidenced by history or physical examination
(f) Suspicious of infection
2. Coagulation profile (INR and APTT)
(a) Patient on warfarin or heparin
(b) Hepatic disease
(c) Bleeding tendency as evidenced by history or physical examination
3. Blood groups and antibody screen
(a) When heavy blood loss or transfusion is anticipated
4. Liver function test
(a) Hepatic disease, hepatitis carrier, chronic alcoholic
(b) Bleeding tendency as evidenced by history or physical examination
(c) Anticoagulant therapy
(d) Malnourished patient, patient on total parenteral nutrition (TPN)
5. Renal function test
(a) Cardiac disease
(b) Renal disease
(c) Diabetes mellitus
(d) Patient on drugs that can cause electrolyte disturbances, (e.g. diuretics, ACE inhibitor, corticosteroids) or drugs whose level may be affected by renal function (e.g. digoxin)
(e) As baseline for major surgery (e.g. bowel resection, hepatectomy)
(f) Age > 60 years
(g) Positive urine albumin
(h) Patient on TPN
(i) Patient having bowel preparation for surgery
(j) Recent vomiting or diarrhoea
6. Blood glucose level
(a) Diabetes mellitus, adrenal disease
(b) On corticosteroid or TPN
(c) Positive urine glucose
7. Arterial blood gas
(a) Moderate or severe respiratory disease
(b) Morbid obesity
(c) Cyanotic congenital heart disease
8. Chest X-ray
(a) Known or suspected malignancy
(b) Patient with cardiac or irreversible pulmonary disease (not asthma) as evidenced by history or physical examination who have not had a chest X-ray in the past 6 months
(c) Close exposure (e.g. family member) to tuberculosis in the past year
9. Electrocardiogram (ECG)
(a) Age > 50 years
(b) Cardiac disease as evidenced by history or physical examination
(c) Patient with cardiac risk factors (e.g. hypertension, vulvular heart disease, diabetes mellitus)
Note: Not required if ECG performed within past 3 months and condition stable
10. Pulmonary function test
(a) Moderate or severe respiratory disease
(b) Previous pneumonectomy
(c) Spinal scoliosis
(d) Neuromuscular disease (e.g. muscular dystrophy)

Table 81.1 (continued)

11. Cervical spine X-ray
(a) Down's syndrome
(b) Rheumatoid arthritis – require flexion and extension view
12. Pregnancy testing
(a) Routine for all women of childbearing age with possibility of pregnancy

Table 81.2 American Society of Anesthesiologists Physical Status Classification System

Classification	Definition
ASA I	Normal healthy patient
ASA II	Patient with mild systemic disease
ASA III	Patient with severe systemic disease
ASA IV	Patient with severe systemic disease that is a constant threat to life
ASA V	Moribund patient who is not expected to survive without the operation
ASA VI	Declared brain-dead patient whose organs are being removed for donor purposes

The addition of "E" denotes Emergency surgery

Table 81.3 Risk factors for perioperative major adverse cardiac events

Coronary artery disease
Unstable angina
<60 days after myocardial infarction (in the absence of coronary intervention)
History of cerebrovascular disease
Clinical heart failure or history of heart failure
Cardiomyopathy
Vulvular heart disease
Arrhythmias and conductive disorders
Pulmonary vascular disease (pulmonary hypertension)
Adult congenital heart disease

Society of Anesthesiologists (ASA) Physical Status Classification System (Table 81.2) [1].

Cardiovascular Risk

The American College of Cardiologist (ACC) and American Heart Association (AHA) Task Force has published a guideline on Perioperative Cardiovascular evaluation and management of patients undergoing noncardiac surgery [2]. The risk of perioperative major adverse cardiac events (myocardial infarction or death) can be predicted by assessing the clinical (Table 81.3) and surgical risks. The risk of perioperative major adverse cardiac events in patients undergoing noncardiac surgery can be predicted using a validated risk-prediction tool. For patients with a low risk of perioperative major adverse cardiac events, further investigations are not recommended before the scheduled surgery. However, patients with increased risk of perioperative cardiac complications should have cardiologist consultation and further investigations, which may include 12-lead electrocardiogram, echocardiography, assessment of left ventricular function (most commonly left ventricular ejection fraction), exercise testing with cardiac imaging and coronary angiography. It is important that the patients' condition is optimized preoperatively and this may require initiation or adjustment of medications or even cardiac interventions. In the past, patients at risk of infective endocarditis were given antibiotic prophylaxis before dental and certain nondental interventional procedures. However, the British Society for Antimicrobial Chemotherapy Guidelines for the prevention of endocarditis [3] and the American Heart Association Guideline on Prevention of infective endocarditis [4] recommended changes in clinical practice. Currently, antibiotic prophylaxis against infective endocarditis is not recommended for patients undergoing gynaecological procedures.

Hypertension

Hypertension is defined by World Health Organisation (WHO) as persistent elevation of blood pressure greater than 140/90 mmHg. Most patients with stable controlled diastolic blood pressure of less than 110 mmHg will tolerate surgery

without cardiac complication. Antihypertensive drugs should be taken up to the time of surgery and resumed early in the postoperative period.

Respiratory Risks

The risk of postoperative complications will be increased in patients with poor pulmonary function. It is therefore best to optimize the lung function preoperatively. Risk factors that predispose patients to pulmonary complications postoperatively include advanced age, smoking, obesity and known pulmonary disease. Smoking should be stopped for at least 4 weeks prior to surgery. Preoperative smoking cessation may also decrease wound complications. In patients with mild chronic obstructive airway disease and asthma, pulmonary status can be assessed using a simple peak flow meter. Patients with more severe impairment should have arterial blood gas analysis and pulmonary function tests. Adjustment of the bronchodilators and corticosteroids may be necessary to improve the control.

Diabetes Mellitus

The stress of surgery and anaesthesia could interfere with the glycaemic control in diabetic patients by increasing the production of catabolic hormones. This would induce glycogenolysis and gluconeogenesis, leading to hyperglycaemia. Hyperglycaemia impairs neutrophil functions and increases the risk of infection and wound complications. Consequently, the diabetic control should be maintained to as near to normoglycaemic range as possible. Table 81.4 describes the perioperative management for diabetic women on oral hypoglycaemics used in our unit. For those who are on insulin or have poorly controlled diabetes, review by the endocrinologists before surgery should be considered.

Anaemia

Anaemia is a common finding in patients undergoing hysterectomy for abnormal uterine bleeding (e.g. uterine fibroid with heavy menstrual flow). During preoperative preparation these patients should be identified and managed accordingly. Strategies to correct anaemia preoperatively include iron supplementation, medical treatment for heavy menstrual flow (e.g. suppression of menses with progestins or gonadotrophin-releasing hormone analogues), blood transfusion and erythropoiesis-stimulating agents.

Prophylactic Antibiotics

Abdominal hysterectomy carries a significant risk of infection, including surgical site infection (wound infection, pelvic infection, vaginal cuff cellulitis), urinary tract infection and septicaemia. Prophylactic antibiotics have been shown to reduce the risk of infection in women undergoing hysterectomy by half [5]. The choice of antibiotics depends on the likely infective organisms as well as local microbiological recommendations and cost. The agent must be given in a way that enables adequate serum and tissue levels before incision is made. Moreover, the therapeutic levels of the agent in serum and tissue should be maintained during surgery and for a few hours after the incision is closed. Cephalosporins are the most commonly used and studied antimicrobials for prophylaxis in abdominal hysterectomy. The recommended regimen for women undergoing abdominal hysterectomy is a single intravenous dose of cefazolin 1 g administered 15–60 min prior to the procedure or at induction of anaesthesia [6]. Other options of antibiotics are listed in Table 81.5. If bowel resection is expected or there is increased risk of bowel injury, e.g. from dense adhesions in endometriosis or ovarian debulking surgery, then additional antibiotics to cover anaerobes

Table 81.4 Perioperative management of women on oral hypoglycaemics

1. Place patient as first case in the morning.	
2. Omit oral hypoglycaemic agents on the day of operation.	
3. Check glucose level (Hemastix) just before the operation.	
4. For procedure lasting more than 1 h, start dextrose-insulin-potassium (DKI) infusion: 500 ml of 5 % dextrose with 6–8 units of actrapid and 10 mmol potassium chloride over 8 h. Potassium requirement should be adjusted according to the patient's pre-operative potassium level.	
5. Check glucose level every 4 h with the use of sliding scale (see below) in the postoperative period.	
6. Resume oral hypoglycaemiscs when the patient is feeding well postoperation	
Sliding scale:	
Glucose level (every 4 h)	*Actrapid (units) subcutaneously (every 4 h)*
<5	Consider reducing insulin dose in the DKI infusion
5–10	0
10.1–15	4
15.1–20	8
>20	12 and adjust insulin dose in DKI infusion

Table 81.5 Antibiotic prophylaxis for abdominal hysterectomy

Antibiotic agents (*given as single dose intravenously)*
Cefazolin 1–2 g
Cefotetan 1–2 g
Cefoxitin 1–2 g
Cefuroxime 1.5 g
Ampicillin/sulbactam 1.5–3 g
Alternative agents for patients with penicillin allergy
Clindamycin 600 mg plus gentamicin 1.5 mg/kg
Metronidazole 500 mg plus gentamicin 1.5 mg/kg
Ciprofloxacin 400 mg
Levofloxacin 500 mg
Moxifloxacin 400 mg

such as metronidazole may be administered. If patients have history of penicillin allergy, then clindamycin or metronidazole plus gentamicin or fluoroquinolone (levofloxacin, ciprofloxacin or moxifloxacin) may be used. Additional dose of prophylactic antibiotic may be given 3–4 h after the initial dose for prolonged surgery (>3 h) or when there is large blood loss (>1500 ml). In patients who are morbidly obese (BMI > 35), the antibiotic dosage may be doubled (e.g. cefazolin 2 g IV). Patient known to have bacterial vaginosis should be treated with metronidazole prior to undergoing hysterectomy.

Bowel Preparation

For surgery with high risks of bowel injury or that may require bowel resection, there is no significant evidence that patients benefit from mechanical bowel preparation or use of rectal enemas. Omission of mechanical bowel preparation has not been found to increase the risks of anastomotic leakage or wound infection in patients undergoing elective colorectal surgery [7], but it should be interpreted with cautious in the context of complex gynaecological surgery. Therefore, in selected patients, rectal enema may be given the night before surgery to prevent a loaded colon limiting access to pelvic surgery and to facilitate retraction of bowel away from the pelvis. Furthermore, bowel preparation may be considered in patients undergoing abdominal hysterectomy for gynaecologic cancers (especially ovarian cancer) and severe endometriosis, especially when pre-operative imaging suggests bowel involvement.

Thromboprophylaxis

Patients undergoing major gynaecological surgery are at increased risk of developing postoperative venous thromboembolism (VTE), with a 16 % risk of developing deep venous thrombosis and a 1 % risk of developing symptomatic pulmonary embolism in patients not receiving thromboprophylaxis [8]. Risk factors that may increase the risk of developing VTE are listed in Table 81.6. Thromboprophylaxis is recommended for patients undergoing gynaecological surgery who are considered to be at increased risk of VTE. Low dose unfractionated heparin or low molecular weight heparin (LMWH) has been shown to be effective at reducing the risk of VTE (Table 81.7). However, the administration of thromboprophylaxis to reduce the risk of VTE must be balanced against potential risk of major perioperative bleeding. The thromboprophylaxis may be continued for up to one week or until the patient is fully mobile. For selected patients undergoing major abdominal or pelvic surgery who are at high risk of developing postoperative VTE (e.g. patients undergoing major cancer surgery), prolonged administration of thromboprophylaxis for 4 weeks with LMWH should be considered [9]. Additional use of graduated compression stockings or other mechanical devices, such as intermittent pneumatic compression should be considered following major gynaecological surgery, especially if pharmacological thromboprophylaxis is contraindicated (e.g. patients with high risk of major bleeding) [10]. It is also important to encourage mobilization as soon as possible and to avoid dehydration (unless clinically indicated). The risk of postoperative VTE may also vary in different racial groups, thus the need of thromboprophylaxis should be assessed balancing the risk of VTE in the local population. Patients taking oestrogen-containing contraception or hormone replacement therapy should be advised to stop 4 weeks before scheduled surgery. In these patients, advise on alternative contraceptive methods should be provided to avoid possibility of unplanned pregnancy. For patients who are on long-term antiplatelet therapy (e.g. aspirin), the risks and benefits of stopping the drugs 1 week prior to surgery should be considered and if necessary advise from relevant specialist should be sought.

Table 81.6 Risk factors for venous thromboembolism

Age over 60 years
Previous VTE or first degree relative with VTE
Known thrombophilias
Obesity (BMI > 30)
Active malignancy or undergoing surgery for malignancy
Acute surgical admission with inflammatory or intra-abdominal disease
Prolonged surgery: Total anaesthetic and operation time > 90 min, or > 60 min if operation involves pelvis or lower limb
Reduced mobility
Intensive care admission
Dehydration
Use of oestrogen-containing contraception or hormone replacement therapy
Significant medical comorbidities (e.g. heart disease, metabolic, endocrine or respiratory disease, acute infection or inflammatory condition)
Varicose veins with phlebitis
Pregnancy and up to 6 weeks postpartum

Table 81.7 Thromboprophylaxis for abdominal hysterectomy

Low-dose unfractionated heparin 5000 U every 8 to 12 hourly (may start 2 h before surgery; for patients with renal failure)
Low molecular weight heparin Enoxaparin 40 mg daily Dalteparin 2500 U daily
Graduated compression stockings
Intermittent pneumatic compression devices

Obtaining Informed Consent

An inform consent involves a process of shared understanding and decision making between patient and clinician [11]. Prior to obtaining a woman's consent for operation, the clinician should ensure that she is fully informed, understands the nature of the disease for which it is being proposed, its prognosis, likely consequences and the risks of not receiving treatment, as well as any possible alternative treatments. In addition, the patient should be informed of possible complications, and that additional treatment for complications or unexpected findings may be required. Any uncertainties that the woman may have about the treatment of the condition should be explored. In preparing women for hysterectomy, the clinician should remember that this process might be stressful for them. Therefore, it is important for the clinician to provide information and obtain consent in an appropriate manner, taking individual needs of the women under consideration. For example, some women would prefer to involve their family members in the discussion and the process of seeking consent for the operation, while others choose to keep the information to themselves. A written information sheet on the intended operation is usually provided for the patient. The information should be in a language that the patient can understand. A written consent form is then signed by the patient and the doctor who provided the explanation of the procedure, ideally in the presence of a witness who is often a nursing staff and this is filed in the patient's medical records.

Geriatric Patient

Although age alone should not be a limiting factor in the decision for surgery, older patients may have multiple comorbid conditions that limit their functional capacity and recovery and increase the risk of morbidity and mortality. In addition to coronary artery disease, hypertension, congestive heart failure, pulmonary disease, renal impairment and diabetes mellitus, older patients have increased risk of nutritional deficiencies, impaired cognition and may have limited support at home. Older patients undergoing abdominal hysterectomy have increased operative risks especially cardiovascular, respiratory, thromboembolic and infectious complications. A thorough preoperative assessment including detailed medical and drug history is important for these patients in order to identify risk factors and optimise their status. Furthermore, to ensure adequate informed consent in elderly person, especially in those who have impaired mental status, the family member or the legal guardian should be informed about the procedure and any potential complications.

Obesity

Obesity (BMI ≥ 30) is associated with coronary artery disease, hypertension, dyslipidaemia, diabetes mellitus, obstructive sleep apnoea, obesity hypoventilation syndrome, reflux oesophagitis and osteoarthritis. Therefore, obese patients undergoing abdominal hysterectomy have increased surgical risks especially cardiovascular, respiratory and thromboembolic risks, as well as infectious complications. Additionally, they present significant challenges to the anaesthesiologists, which make early detailed preoperative anaesthetic assessment mandatory. The perioperative management of these patients also poses significant organisational and practical challenges. Patients who are obese may also require special operating tables and transfer trolleys that can accommodate their weight, and special surgical instruments (e.g. longer clamps, retractors). These patients may require intensive care beds in the early postoperative period and should ideally be arranged before the surgery. Obese patients should receive thromboprophylaxis and be encouraged to mobilise early to reduce the risk of venous thromboembolism.

Universal Protocol

The Universal Protocol was designed to prevent wrong patient, wrong procedure and wrong site surgery. It consists of a preoperative verification of the patient's identifying information, surgical site marking to prevent wrong site procedures, and a presurgical "time out" immediately prior to starting the planned procedure. Furthermore, the time out was recently extended to include the need for preoperative antibiotics and other essential medications (e.g. corticosteroid), the verification of correct patient positioning and availability of relevant documents, diagnostic images, instruments and implants. This protocol is applicable in the operating room as well as in clinical setting outside the operating room where invasive procedure requiring a patient's consent is performed.

Summary

Good preoperative care will minimise the complications from the operation as well as psychological distress caused.

Abdominal Hysterectomy: Instrumentation and Apparatuses

82

Siew Fei Ngu and Karen K.L. Chan

Introduction

Various surgical instruments are required to perform abdominal hysterectomy and surgeons must know the applications and limitations of the instruments. The aim of this chapter is to review the basic surgical instruments that are required for most abdominal hysterectomy and it is not intended to be a comprehensive list of all instruments available. The instruments included in this chapter are commonly used in our hospital for abdominal hysterectomy.

Scalpel

The first instrument used in abdominal hysterectomy is scalpel, which consists of a handle (Fig. 82.1) and disposable blade (Fig. 82.2). Scalpel blades are available in different shapes and sizes, commonly referred to blade number. The larger blades are used to rapidly perform an incision, while the smaller blades are used for making small incision and are safer when used in tight operative field (Table 82.1).

Scissors

The scissors are used to divide tissue. Apart from cutting, it can be used for blunt dissection by inserting the tips into a tissue plane and then opening the scissors. The scissors used in abdominal hysterectomy includes Mayo, Metzenbaum, Mayo-Harrington and Monaghan (Fig. 82.3). The scissors come with either straight or curved blades, and may have rounded or sharp tips. Mayo scissors have rounded tips, which can reduce accidental injury of tissue and are used to divide thick tissue (e.g. rectus sheath, vaginal cuff). Metzenbaum scissors are more delicate and have relatively shorter blades in proportion to the shafts compared to Mayo scissors. Metzenbaum scissors can be used to cut thinner tissue (e.g. peritoneum, adhesions) and to develop tissue planes in adherent or distorted tissue. Suture scissors are used to cut suture.

Needle Holders

A needle holder is used to hold curved needles as it passed through tissue. It is available in different sizes, depending on the size of needle used, and different lengths, depending on type of surgery performed. For most abdominal hysterectomy, the eight inch needle holder is suitable. Needle holders come in straight or curved version. Common types of needle holders used in abdominal hysterectomy are Ryder (straight) and Heaney (curved) (Fig. 82.4). Curved needle holders are useful in vaginal surgery where the angled head permits easier needle placement.

Tissue Forceps

Tissue forceps are used to grasp and hold tissue during cutting, dissection and suturing. It is available in various shapes and configuration, depending on its purpose (Fig. 82.5). The tissue forceps can be smooth or toothed. Smooth forceps are used to hold delicate and friable tissue, while toothed forceps are used to bite into tissue allowing a firm grasp with

Table 82.1 Role of scalpel blades in abdominal hysterectomy

Scalpel blades	Site of incisions
10	Hysterectomy pedicles Vaginal vault
11	Stab skin incisions (e.g. for drains) Incision and drainage procedure
15	Small skin incision (e.g. for drains)
20 or 22	Abdominal incision

minimal pressure. Ramsey tissue forceps are used for handling fascia (e.g. during sewing of rectus sheath). Adson forceps are usually used to approximate skin during placement of suture or staple. DeBakey forceps have fine long smooth tips that allow accurate control of delicate tissue deep in the pelvis. Other types of forceps commonly used during hysterectomy are Bonney, Russian, Martin and Potts-Smith forceps.

Clamps

Clamps can be used for grasping and applying traction to tissues (Figs. 82.6, 82.7, and 82.8). Babcock clamps are atraumatic and can be used to hold and grasp delicate tissues (e.g. fallopian tube, bowel) without causing injury. Allis forceps have serrated grasping surface and short teeth that will hold tissue firmly. During hysterectomy, it can be used to

Fig. 82.3 Scissors (from *left* to *right*): Straight Mayo, Curved Mayo, Metzenbaum, Mayo-Harrington

Fig. 82.4 Needle holders (from *left* to *right*): Ryder Fine, Ryder, Heaney CVD

grasp the anterior vaginal wall during entry into vagina. Littlewood and Lanes forceps have interlocking teeth at the tip that prevents slipping of tissues within the clamp and are usually used to grasp tough tissues (e.g. rectus sheath). Sponge holding forceps are used to hold folded sponges, which can function to retract tissue, soak fluid or blood, or apply antiseptic solution to the skin in preparation for operation. Ring forceps are used when a secure hold is required on tissues that would be traumatised by toothed forceps, or can also be used as sponge holding forceps.

Artery forceps (e.g. Birkett, Robert) are primarily used as haemostatic forceps to clamp vessels and allow ligation of those vessels. They can also be used to hold suture materials and grasp tissues. Robert artery forceps can be used to clamp the infundibulopelvic ligament during hysterectomy. Lahey forceps are right angle clamps and can be used to grasp vessels or for passing a ligature around a clamped pedicle. Kocker forceps are strong toothed tissue forceps used for grasping tough fascia (e.g. rectus sheath). They are available in straight and curved form, and have varying lengths. During hysterectomy, Kocker forceps can be placed immediately lateral to the uterus at each cornua to allow elevation, traction and rotation of the uterus.

Hysterectomy clamps are designed to control the rich vascular supply of the uterus during hysterectomy. There are numerous hysterectomy clamps available such as Moynihan, Ballentine and Heaney hysterectomy forceps (Table 82.2).

Fig. 82.6 Clamps (from *left* to *right*): Babcock, Littlewood, Lanes, Sponge holding forceps, Ring forceps

Fig. 82.7 Clamps (from *left* to *right*): Birkett artery forceps, Allis forceps, Lahey forceps

Fig. 82.8 Clamps (from *left* to *right*): Kocher forceps, Robert artery forceps, Moynihan hysterectomy forceps, Ballentine hysterectomy forceps

Table 82.2 List of clamps that may be used for abdominal hysterectomy

Hysterectomy pedicles	Clamps
Round ligament	Kocher
Uteroovarian ligament	Kocher, Heaney, Kelly
Infundibulopelvic ligament	Robert, Heaney, Kelly
Uterine vessels	Moynihan, Heaney (curved), Zeppelin
Cardinal ligament	Ballentine, Heaney (straight), Zeppelin
Vaginal fornix	Heaney (curved)

Fig. 82.9 Tenaculum (*left*), Vulsellum (*right*)

They are heavy crushing forceps with ridged shafts and are used to clamp the parametrial and paracervical tissues. Ideally, a hysterectomy clamp must be able to grasp and hold these tissues firmly until the pedicles are cut and ligated. Ballentine forceps have longitudinal serrations, which may be better for clamping the cardinal ligaments as this design reduce the risk of lateral slippage of tissue from the clamp.

Tenaculum and Vulsellum Forceps

During abdominal hysterectomy, tenaculum and vulsellum (Fig. 82.9) may be used to grasp the cervix to provide traction when cutting circumferentially around the vagina.

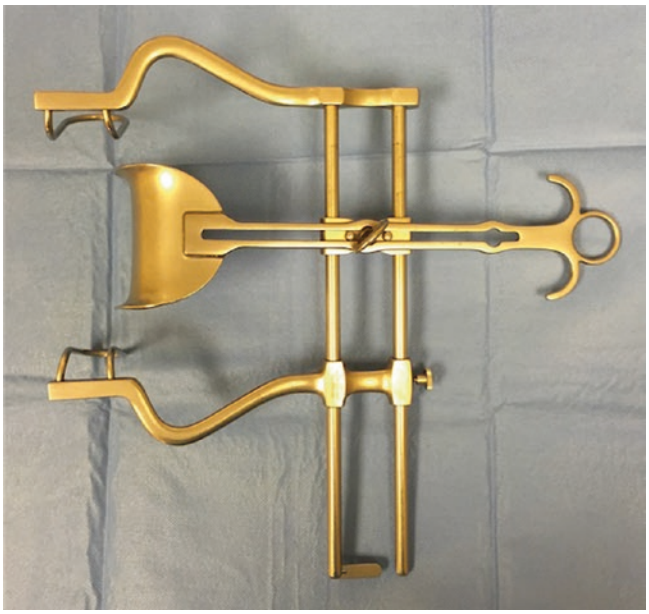

Fig. 82.10 Balfour self-retaining retractor

Tenaculum can also be used to grasp fibroid during myomectomy.

Retractors

Retractors are used to hold tissue out of the surgical field to improve exposure during operative procedures. Retractors can be manual (held by an assistant) or self-retaining (hold themselves in place). Balfour self-retaining retractor has two lateral blades and one additional retractor blade that can be used as bladder retractor or upper blade (Fig. 82.10). Bookwalter retractor is a self-retaining retractor that attaches to the operating table and consists of a circular ring to which a wide variety of retractors can be placed at any point. It is most useful for radical pelvic surgery or when operating on extremely obese patiens. Commonly used manual retractors during abdominal hysterectomy includes Deaver, Morris, Czerny and Malleable (Fig. 82.11).

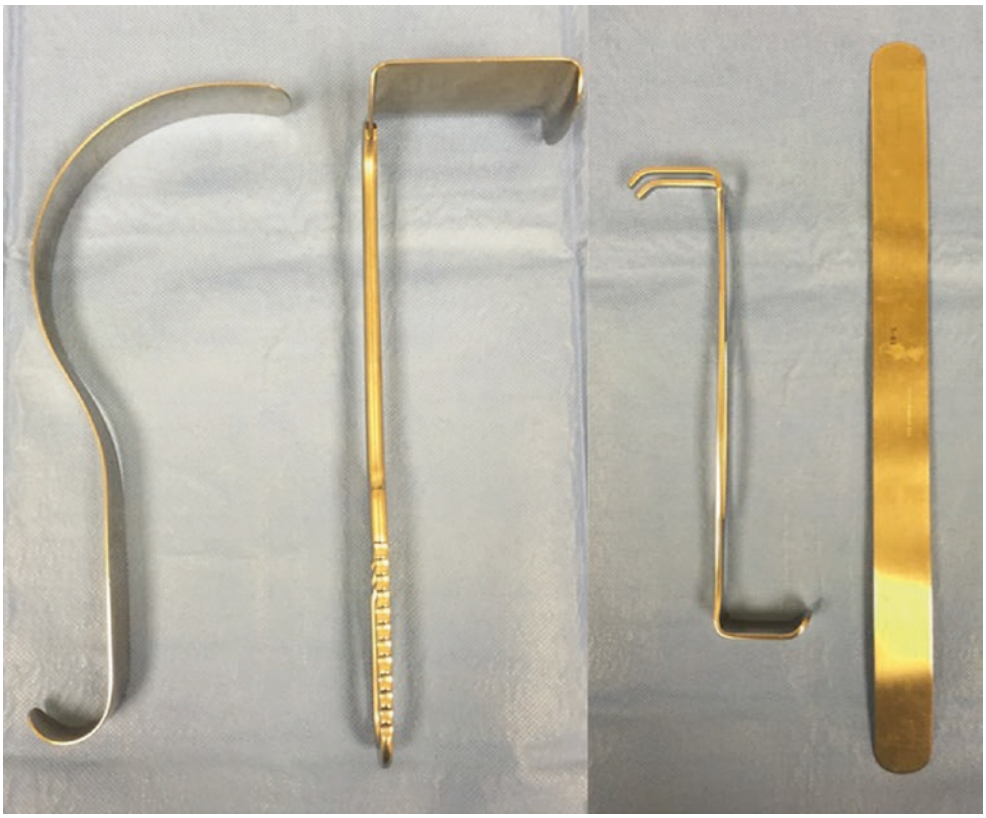

Fig. 82.11 Manual retractors (from *left* to *right*): Deaver, Morris, Czerny, Malleable

Needles and Sutures

Suture needles consist of the swage, the body and the point. Nowadays, most of the needles are swaged (eyeless) needles in which the suture is attached to the end of the needle, thereby forming a continuous unit. The body may be straight, half-curved or curved. Straight needles are designed for easily accessible tissues and can be used for skin closure during abdominal hysterectomy. Similarly, half-curved needles may also be used for skin closure. Curved needles facilitate passage of needle in confined space such as deep narrow pelvis. The curvature can range from 1/4, 3/8, 1/2 or 5/8 circle. The 1/2 circle is commonly used for hysterectomy pedicles, while 3/8 circle is frequently used for skin closure. The point of the needle comes in cutting, taper and blunt version. The cutting needle is usually used for cutting through though tissues (e.g. rectus sheath, skin). Taper point needles pierce and spread the tissue rather than cutting it, thus are used in easily penetrated tissues (e.g. peritoneum, bowel, bladder). Blunt point needles dissect through tissue and are usually used to prevent needle-stick injuries.

Suture material is designed to support the apposed tissue temporarily while allowing time for the tissues to recover enough tensile strength and maintain the apposition. The characteristics of an ideal suture include good tensile strength, flexible, easy to handle, provide adequate knot security, absorbable, inert, non-allergenic, atraumatic passage through tissue and resistance to infection. Sutures are available in natural or synthetic, absorbable or non-absorbable, and monofilament or multifilament types. Nowadays, natural materials (e.g. catgut, silk) have been mostly replaced with synthetic material. Compared to multifilament sutures (e.g. Vicryl), monofilament sutures (e.g. Monocryl, PDS, Ethilon, Prolene) have smooth surface, therefore produce less tissue trauma and reduce the risk of harboring microorganisms. Nonetheless, multifilament sutures are stronger and more flexible, allowing easier handling and knotting. Absorbable sutures (e.g. Vicryl, Monocryl, PDS) are used for temporary wound support, while non-absorbable suture (e.g. Ethilon, Prolene) provide permanent support in tissues that heal slowly (e.g. rectus sheath). Furthermore, sutures are divided into size based on their diameter, in which progressively larger size are numbered in increasing numerical order (e.g. 0, 1, 2), while progressively smaller size are indicated by increasing number of zeros (e.g. 0, 00 or 2/0, 000 or 3/0). Recently, some of the sutures are also available in antibacterial forms, which are aimed to reduce the risk of infection. Tables 82.2 and 82.3 shows the sutures or instruments that are commonly used for abdominal hysterectomy in our hospital.

Table 82.3 List of sutures/instruments that may be used for abdominal hysterectomy

Site	Sutures/instruments
Abdominal skin	MCP3213 – Ethicon Monocryl Plus Antibacterial Poliglecaprone 25, 3/0 gauge, PS 26 mm 3/8 circle cutting needle, 70 cm long. For subcuticular suture. MCP523 – Ethicon Monocryl Plus Antibacterial Poliglecaprone 25, 3/0 gauge, KS 60 mm cutting needle, 70 cm long. For subcuticular suture. W630 – Ethicon Prolene Polyprophylene, 3/0 gauge, KS 60 mm straight cutting needle, 75 cm long with beads and collars. For subcuticular suture. W795 – Ethicon Ethilon Polyamide 6, 2/0 gauge, KP-3 Conv 90 mm 3/8 circle cutting needle, 100 cm long. For interrrupted suture. Skin stapler
Rectus sheath	VCP371 – Ethicon Coated Vicryl Plus Antibacterial Polyglactin 910, CTX 48 mm 1/2 circle taper needle, 90 cm long. PDP9262 – Ethicon PDS Plus Antibacterial Polydioxanone, CTX 48 mm 1/2 circle taper needle, loop 150 cm)
Hysterectomy pedicles and vaginal vault	VCP9213 – Ethicon Coated Vicryl Plus Antibacterial Polyglactin 910, 1 gauge, MH-1 plus 31 mm 1/2 circle needle, 70 cm long. VCP247 – Ethicon Coated Vicryl Plus Antibacterial Polyglactin 910, 0 gauge, MH-1 plus 31 mm 1/2 circle needle, 70 cm long.

Electrosurgical Units

Nowadays, instruments that use electrosurgery or other energy source are commonly used for cutting and coagulation of tissues. Surgeons using this technique should understand the mechanism of action, how to prevent and mange potential complications and how to troubleshoot equipment. Electrosurgery employs high frequency electrical current to create heat within tissue cell to cut or coagulate tissue. The electrosurgical units available in operating theatre are used to produce high frequency electrical current, that does not stimulate muscle or nerve. The application of electrical current to tissue can result in vapourisation (cut), desiccation (coagulate deeply) or fulguration (coagulate superficially), depending on the setting of the electrosurgical units and the degree of contact between the tissue and surgical instrument. Dessication are created by direct contact of the instrument and the tissue, while fulguration and vapourisation are produced by holding the tip of the electrode at the tissue surface without direct contact.

The main output settings for the electrosurgical units are 'cutting' and 'coagulation'. With cutting mode, the electrosurgical units generates a continuous, low voltage current, concentrating the energy at a small area (high current density), resulting in rapid tissue heating, intense vibration within the cells and explosion of the cells (vapourisation). With coagulation mode, the electrosurgical units generates interrupted, high voltage current, dispersed over a large surface area (low current density), resulting in slower tissue heating compared to cutting mode, and dehydration effect (dessiccation). In addition, several "blend" modes are also available, utilising different proportion of cutting and coagulation currents. Blend modes improve the ability of cutting currents to coagulate small vessels during dissection, and coagulation currents to dissect tissue during haemostasis. Electrosurgery can be done with either a monopolar or a bipolar instrument (Table 82.4). During abdominal hysterectomy, electrosurgery can be used for abdominal incision, dissection of peritoneum or bladder, and vaginal vault incision.

Recently, a variety of more advanced electrosurgical devices are available such as Ligasure device, PlasmaKinetic tissue management system and Enseal. Furthermore, alternative energy sources have also been used, namely ultrasonic and laser energy. Examples of ultrasonic cutting and coagulating devices include Harmonic scalpel, Sonocision and Thunderbeat.

Table 82.4 Comparison of monopolar and bipolar electrosurgery

Monopolar electrosurgery	Bipolar elctrosurgery
Electrical current passes through a single electrode (e.g. cautery pencil) to the tissue	Electrical current passes between two electrodes (active and return) of a surgical instrument (e.g. forceps)
Electrical current passes through the patient and needs to exit the patient (through the least resistance path) to complete the current cycle	Electrical current is limited to the tissue between the two electrodes of a surgical instrument
A return elctrode pad (usually attached to the thigh of the patient during abdominal hysterectomy) is required for the current to exit the patient to complete the current cycle	A return electrode pad is not required
Possibility of alternate pathway for current flow which can be prevented by: Use of isolated generator system with return electrode pad Ensure return pad is applied properly to prevent skin burns Use of electrosurgical unit with sensors to detect poor contact Use lowest voltage necessary	Eliminate the possibility of alternate pathways for current flow
Avoid use in patients with implantable pacemakers/cardioverter defibrillators, cochlear implant or metal implant	Preferred in patients with implantable pacemakers/cardioverter defibrillators, cochlear implant or metal implant
May utilise either low voltage (cutting mode) or high voltage (coagulation mode) to achieve the desired tissue effect	Utilise low voltage (cutting mode) due to relatively low tissue impedence caused by vicinity of the two electrodes
Cutting mode: preferred when thermal spread is undesirable (e.g. adjacent to bowel or ureter) *Coagulation mode*: allows better penetration through high-resistance areas (e.g. adipose or scar tissue), preferred when fulgurating a large surface area with superficial bleeders	Less effective for cutting tissue as difficult to obtain adequate vaporization (may cause tissue to char and stick to surgical instrument)
Less effective for hemostasis: electrical current disperses within the blood causing inadequate tissue damage at the vessel lumen	Effective for hemostasis of vascular areas or small blood vessels of 3–7 mm (e.g. uterine artery)

Summary

Surgeons should know the applications and limitations of surgical instruments commonly used in abdominal hysterecomy.

Midline Laparotomy

83

Carol E.H. Scott-Conner

Vertical Versus Transverse Incisions

The ideal incision for laparotomy should provide adequate, if not excellent, access and exposure to the surgical field. It should be extensible, so that if unexpected findings were encountered at surgery, greater access could easily be achieved. Healing should be secure and relatively pain-free. Postoperative adhesion formation should be minimal, if not eliminated. The scar should be cosmetically acceptable. The healed incision should not hinder subsequent access to other parts of the abdomen for other purposes, or use of abdominal flaps for reconstructive surgery (for example, after mastectomy). It should permit stoma creation if necessary.

It should be obvious that no one single incision satisfies all of these criteria. This chapter (on midline laparotomy), and the chapter which follows (on transverse incisions), detail commonly used incisions for open gynecologic surgery and discuss the anatomy of the abdominal wall as it pertains to these procedures.

Advantages of Midline Incisions The vertical midline incision divides no major blood vessels or nerves; it can be made quickly and easily. It is easily extended from the lower midline up into the upper midline. Stomas can easily be sited on either side as needed. It is thus traditionally used for cancer surgery, where thorough and complete exploration and eradication of tumor deposits in the upper as well as the lower abdomen may be required.

Disadvantages of Midline Incisions Low transverse skin incisions such as the Pfannenstiehl and Maylard, low and hidden in a natural skin crease, provide excellent cosmetic outcomes. It has been proposed that these incisions may heal more securely than vertical incisions, and hence result in a decreased risk of hernia formation. In this respect, it is important to note that the Pfannenstiehl combines a transverse skin incision with a vertical midline fascial incision (see Chap. 75). It is thus a kind of hybrid incision.

The tantalizing proposition that transverse incisions might heal more securely is based largely upon observations that the overall pull of the abdominal wall muscles tends to distract vertical incisions, but runs parallel to transverse or oblique incisions. It has been difficult to demonstrate an advantage in individual trials using standard endpoints of "burst abdomen" or evisceration as a rare but catastrophic acute complication, and incisional hernia as a much more common and probably underreported event [1–4].

The aggregate evidence was considered strong enough, however, for the European Hernia Society [5] to issue a recommendation the "To decrease the incidence of incisional hernias it is strongly recommended to utilize a non-midline approach to a laparotomy whenever possible." Lack of systematic standardized follow up, including use of ultrasound to check for subclinical incisional hernias, has hampered progress in this area [5]. The pros and cons of the vertical midline incision, as compared with low transverse incisions, are summarized in Table 83.1.

Adhesions tend to form to the underside of any incision, and a long vertical midline incision may thus create a long line of adhesions which complicates subsequent abdominal access and may even result in postoperative small bowel obstruction. See Chap. 76 for further information on adhesions.

Implications for Subsequent Reconstructive Surgery (If Needed) While this is not a major consideration, it is worthy of discussion. Lower abdominal wall tissue is increasingly used in reconstructive surgery. Probably the most common application, and that familiar to most clinicians, is

Table 83.1 Advantages and disadvantages of vertical midline incision, compared with low transverse incisions typically used for gynecologic surgery

Advantages of vertical midline incision	Disadvantages
Versatile – provides exposure of any intra-abdominal structure	May not heal as securely (may be more prone to hernia formation)
Extensile – an incision made in the lower midline is easily extended into the upper if pathology dictates	Scar is unsightly
Compatible with stoma creation	May be more painful in immediate postoperative period
Repeat laparotomy through same incision through same or other purpose is feasible	Adhesions forming to upper part of incision may be more problematic for repeat operation
	Divides tissues of lower abdomen used for TRAM flap reconstruction (if needed later)

autologous reconstruction after mastectomy. Because the breast cancer population comprises a significant subset of women, it is important that surgeons operating upon women understand how abdominal tissue is used for reconstruction.

Use of autologous tissue provides all the advantages of using the patient's own tissues (rather than an implant) and provides a bonus in the form of a "tummy tuck." It is important to understand how incision choice might influence later reconstructive options, should the woman require them [6].

A variety of autologous flaps have been described, but for purposes of this discussion it is important to focus on only two of these. These are the TRAM (transverse rectus abdominis muscle) and DIEP (deep inferior epigastric) flaps.

TRAM flaps take tissue from the lower abdomen, including one of the rectus abdominis muscles. Pedicled TRAM flaps derive their blood supply from the (preserved) superior epigastric artery. Free TRAM flaps require microvascular anastomosis of one of the arteries supplying the flap to an artery in the region. For many years, before microvascular free flap techniques were widely available, the pedicled TRAM flap was the workhorse flap for autologous reconstruction. Many general surgeons learned, to their dismay, that an open cholecystectomy incision (an oblique right upper quadrant incision paralleling the costal margin which completely divided the superior epigastric vessels and rectus muscle on that side), common in the pre-laparoscopic cholecystectomy era, rendered subsequent ipsilateral pedicled TRAM flap reconstruction impossible.

The TRAM is still commonly used, either as a pedicled or a free flap. However, concerns about abdominal wall function after loss of a rectus muscle have fueled interest in the DIEP flap as an alternative.

DIEP flaps are free flaps that transfer only skin and subcutaneous fat, leaving intact the rectus abdominis muscle. They require microvascular anastomosis to a suitable artery in the field.

Many considerations influence the choice of flap. The bulk of missing breast tissue relative to the tissue available in the donor site, unilateral versus bilateral, vascular health of the woman (diabetes, smoking, atherosclerotic disease), and presence or absence of scars on the abdomen all must be considered. It is noteworthy that previous panniculectomy also may be a factor [7].

A lower midline incision divides the skin and fatty tissue down the middle. Typically, the reconstructive surgeon will then split the tissue down the middle. This is not a problem in obese women, but may be problematic in slender individuals where abdominal fat is limited.

If the deep inferior epigastric vessels have been ligated during a previous low transverse incision, then a TRAM flap is still possible (indeed, division of these vessels is sometimes performed several weeks prior to flap creation, in order to stimulate the superior epigastric vessels to grow) but a DIEP flap will not be possible.

How does this affect choice of incision for a gynecologic surgeon? Obviously, the necessities of the operation at hand must dominate clinical decision-making. But simply keep this in mind: all other things being equal, design of these flaps is more difficult and choice of options more limited if a woman has had a lower midline incision or a transverse incision which divides rectus muscle and regional arteries than if she has had a classic Pfannenstiehl. From the reconstructive surgeon's perspective, a Pfannenstiehl incision causes the least disruption. Fortunately, this corresponds to the incision of choice for many gynecologic procedures. See Chap. 75 for additional considerations with low transverse incisions which divide the rectus muscles and/or inferior epigastric vessels.

Anatomy of the Abdominal Midline

Superficial fascia The superficial fascia of the anterior abdominal wall is primarily adipose tissue above the umbilicus. Below the umbilicus, superficial fatty and deeper membranous layers may be appreciated. The membranous layer may form a barrier to extravasation of fluid, and is often included in suture closure of a midline incision.

The superficial fatty layer is typically thicker below the umbilicus, and in morbidly obese individuals may form a huge, edematous, dependent pannus that hangs down below the pubic region. In such cases, the normally relatively avas-

cular fat may contain very large subcutaneous veins. There is a fusion plane in the midline and access to the midline fascia may be obtained, once the subcutaneous veins are controlled, by traction and counter-traction. This midline fusion plane is often seen on CT scans as a vertical septum. This fusion plane can be exploited by the surgeon and used as an aid to identification of the midline during laparotomy.

Linea alba In slender individuals, the midline linea alba may be visible as a linear indentation running from xiphoid to pubis. It is formed from decussating fibers of the aponeuroses of the external oblique, internal oblique, and transversus abdominis (Fig. 83.1).

The linea alba is more robust above the umbilicus than it is below, because these fibers form the bilateral anterior and posterior rectus sheaths which completely enclose these muscles. The posterior rectus sheath terminates about 1/3 of the way from umbilicus to pubis in the arcuate line. Below the arcuate line, the posterior sheath is composed only of transversalis fascia. Incising the linea alba in the lower midline thus frequently exposes both rectus muscles directly,

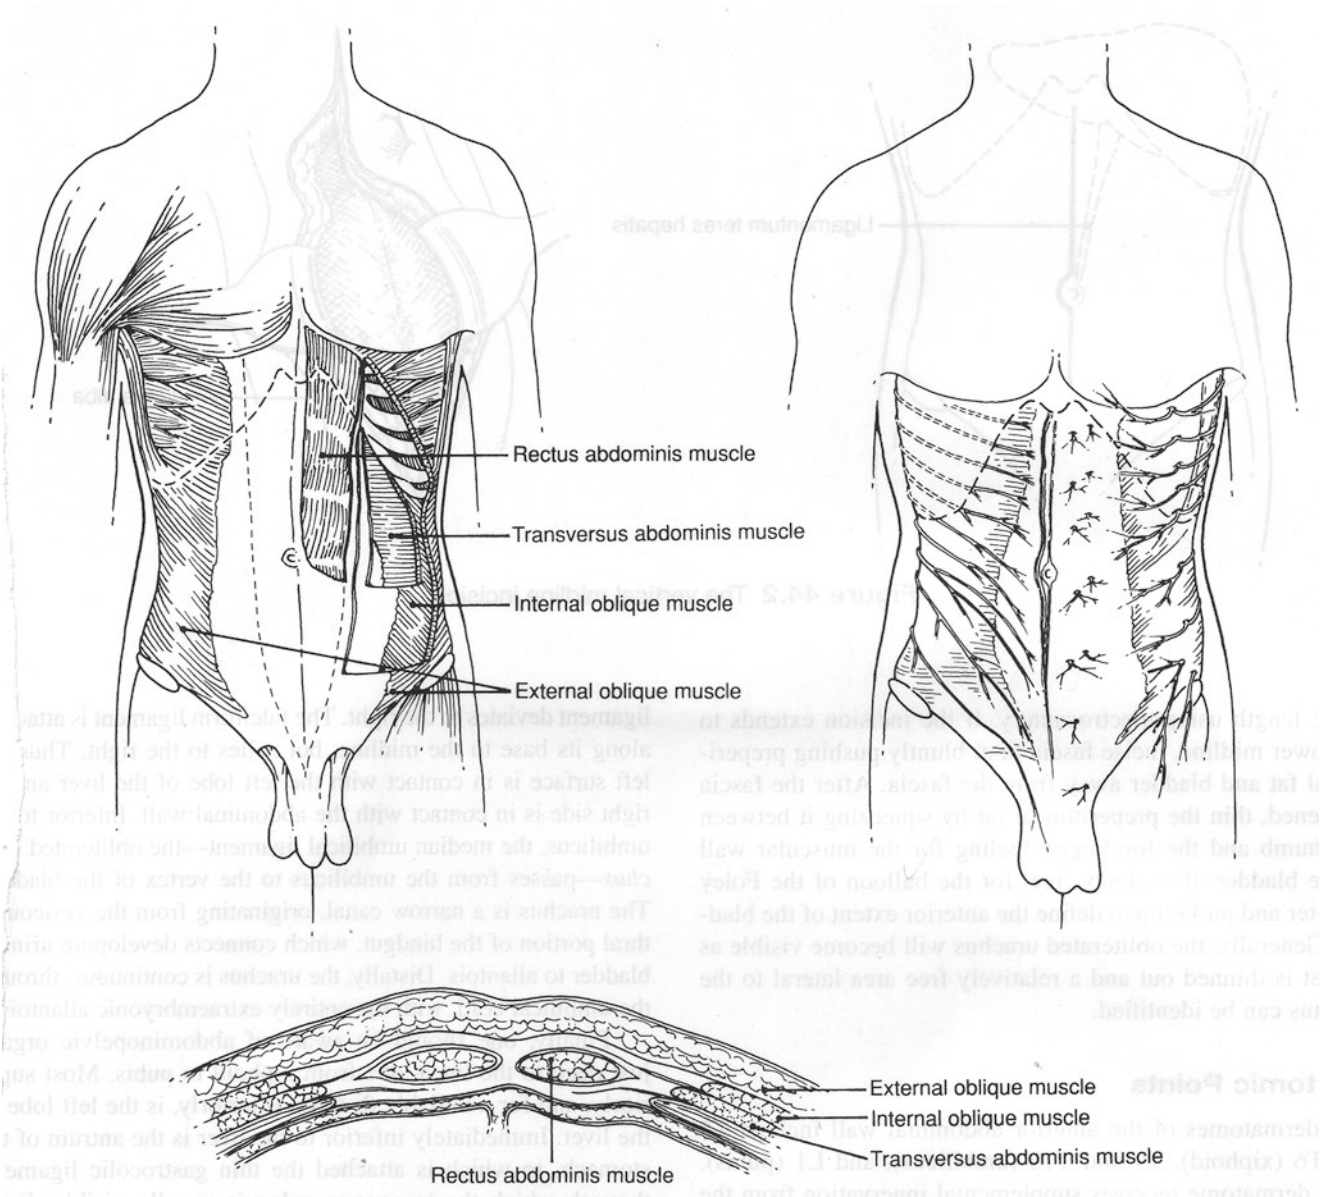

Fig. 83.1 The muscles and aponeurotic layers of the anterior abdominal wall. Laterally, the external oblique, internal oblique, and transversus abdominis muscle provide three strong muscle layers with fibers running in criss-crossing directions. Medially, these three muscles contribute aponeurotic fibers to the anterior and posterior rectus sheathes and form the decussating fibers of the linea alba (Reproduced from Fig. 44.1 Scott-Conner and Dawson [15], with permission)

sometimes creating the impression that the incision has deviated from the midline.

A very few small vessels and nerves pierce the linea alba to reach the skin, but no major vessels or nerves need be divided when an incision is made directly through this structure. Thus a major advantage of the midline incision is rapid, bloodless entry into the abdomen with no damage to motor or sensory nerves.

Muscles The paired, segmental rectus abdominis muscles originate from the pubis and run nearly vertically to insert upon the costal margin and xiphoid process. As they ascend, they become broader and the distance between them increases. They are encased within the strong fibrous rectus sheathes, which coalesce to form the midline linea alba as noted above. Segments of the rectus muscles are demarcated by fibrous inscriptions that create the appearance of a "six pack" on the abdominal wall of lean, muscular individuals. The inscriptions may be adherent to the rectus sheathes.

Each rectus muscle is innervated by multiple thoracoabdominal nerves, which approach obliquely from lateral to medial and run deep to the muscle in the rectus sheath [8]. This segmental innervation allows the rectus to be transected at any point without creating denervation and atrophy. The transected rectus simply forms another fibrous inscription as it heals. This property is exploited by general surgeons who create transverse or oblique incisions in the upper abdomen.

The blood supply comes from above and below. From above, the superior epigastric arteries pass on the deep aspect of the rectus. From below, the usually larger inferior epigastric arteries ascend deep to the rectus and enter the rectus sheath at the arcuate line. Typically the epigastric artery and vein anastomose, a feature exploited by reconstructive surgeons when they "delay" a flap by ligating the inferior epigastric artery. Small twigs of the lower six intercostal arteries also enter the rectus sheath from the lateral aspect.

All of this can be summarized to say that the rectus muscles, although they may be encountered in the midline, are easily retracted laterally without division of any significant vessels or nerves.

The paired pyramidalis muscles may be encountered in the space between the anterior rectus sheath and the rectus muscles. They are absent in about 20 % of individuals. These muscles originate from the pubic ligament and anterior surface of the pubis. Their fibers then run obliquely toward the midline to insert into the linea alba about halfway between the pubis and the umbilicus. Theoretically these muscles could tense the linea alba, but in reality they are of no known clinical significance. When encountered, they form an additional confirmation that the incision is truly midline. A low vertical midline incision is simply taken between the muscles, usually with electrocautery to minimize bleeding.

Other muscles of the abdominal wall are discussed in more detail in Chap. 75. These are, from superficial to deep; the paired external oblique, internal oblique, and transversus abdominus muscle. The external oblique muscle runs obliquely (as the name implies) from its origin on the lower ribs and become aponeurotic medially to form the anterior rectus sheath and decussate in the linea alba. It's aponeurosis also forms the inguinal ligament. Medical students use the image of "putting one's hands in one's pockets" to remember the way in which this muscle runs.

The internal oblique muscle lies deep to the external oblique. It similarly passes obliquely, but its fibers run nearly at right angles to the external oblique, arising from the inguinal ligament and adjacent structures to terminate in an aponeurosis which contributes to the anterior rectus sheath in the lower abdomen, and to both the anterior and posterior rectus sheath in the upper abdomen.

The deepest muscular layer laterally is the transversus abdominis muscle. Fibers arise from the inguinal ligament, iliac crest, and lower ribs. They run transversely, as the name implies, to become aponeurotic and contribute to the posterior rectus sheath in the upper midline. Deep to the transversus abdominis muscle lies the transversalis fascia (see below).

All of these broad, flat, muscles of the lateral anterior abdominal wall, take their innervation from segmental nerves, and derive their blood supply from multiple relatively small vessels in the area. Denervation or devascularization is not an issue during construction of incisions.

Finally, the manner in which fibers from these muscle layers cross over each other provides the basis for the gridiron or muscle-splitting incision used for appendectomy.

Innervation The anterior abdominal wall is innervated by thoracoabdominal nerves derived from T7-L1. These nerves approach the midline from each side, and are not at risk during creation of a midline incision. They are discussed in greater detail in the chapter which follows (Transverse Incisions).

Blood supply The largest vessels encountered in this region are the paired inferior and superior epigastric arteries and veins. As previously noted, these run deep to the rectus muscles, within the rectus sheath, and are not encountered in the midline. They are discussed further in the subsequent chapter (Chap. 75. Transverse Incisions).

Umbilicus The umbilicus is the cicatrix or scar where the fetal umbilical vessels and associated structures passed

through the linea alba. Skin and all fascial layers are fused together at this site. It is a potential weak spot through which hernias form. Traditionally, a midline incision passing through the mid-abdomen is carried to one side of the umbilicus, rather than through it. This allows more secure closure with a decent amount of subcutaneous tissue between fascia and skin.

Because the ligamentum teres hepatis runs from the underside of the umbilical plate to the liver (with the falciform ligament spanning the space between the ligamentum teres hepatis and the anterior abdominal wall), it is generally simplest to pull the umbilicus to the right when creating a midline incision through the mid-abdomen. This allows entry without division of the ligamentum teres hepatis and falciform ligament (unless needed for access to the liver).

Extraperitoneal (Preperitoneal) space Deep to the linea alba, extraperitoneal fat, endoabdominal fascia, and peritoneum are encountered. The transversalis fascia, a fibrous layer deep to the transversus abdominis muscles and superficial to the extraperitoneal fat, becomes more robust laterally (see Chap. 75). A well-defined plane exists between the transversus abdominis muscle and this fascia laterally, and that plane can be exploited to enter the retroperitoneum. Medially, it is less robust, and in the midline it is rarely surgically apparent, although a variable amount of fat will be encountered superficial to the peritoneum. This extraperitoneal fat may be brushed aside from the midline to expose the transparent peritoneum, and brushed inferiorly to push the urinary bladder out of the surgical field.

Urinary bladder and median umbilical ligament The median umbilical ligament (urachus) travels from the underside of the umbilicus to the apex of the urinary bladder. The urachus is usually just a fibrous remnant. Occasionally cysts or residual patency of the urachus may be encountered in the midline.

As a vertical incision is extended down toward the pubis, the fat becomes thicker and the bladder may be encountered. In the absence of previous surgery or other local pathology, the urinary bladder lies reasonably free within the extraperitoneal fat. Thus, in the usual situation, pushing the extraperitoneal fat downward and away from the pubis will suffice to protect the bladder from harm during the creation of a midline incision. Sharp dissection may be required if adhesions are present.

Parietal peritoneum The glistening parietal peritoneum lines the abdominal wall and is continuous with the visceral peritoneum which covers the internal abdominal organs. It has little or no strength, and its single layer of epithelial cells rapidly reconstitute themselves, thus it is simply divided during entry into the abdomen and not sutured closed at closure (see section which follows).

Creating the Vertical Midline Incision

Incision Drape the entire abdomen so that the incision can be extended as needed. In the obese patient, make sure that the pannus is hanging straight down rather than over to one side or the other. Mark the landmarks and the incision, especially in the morbidly obese, as it is easy to lose the midline in the fatty pannus. Reliable bony landmarks include the xiphoid and the pubis. Many surgeons start with a relatively short incision and then extend it if justified by surgical findings.

The skin incision is generally made with scalpel and deepened with electrocautery. The so-called "skin knife" is generally not used for subsequent dissection, more because it will have become dull than for concerns about infection. As you progress, take care not to "buttonhole" a large and pendulous pannus inferiorly. Remember that the umbilicus is generally displaced caudally in morbidly obese individuals. If necessary, again palpate the pubic bones under the pannus and the costal margin and xiphoid process to get dependable landmarks [9].

Take care around the umbilicus If the incision is taken into the upper midline, curve your incision around the left side of the umbilicus (Fig. 83.2). If you are standing on the patient's left side, this is most easily done by having your first assistant, who is standing to the right, pull the umbilicus to the right. Be aware that small occult umbilical hernias are quite common.

Pull the fat apart to expose the midline Take advantage of the fusion plane in the abdominal midline by traction and counter-traction, which may actually pull the fat apart for you. Use scalpel or cautery sparingly to help the separation process until the midline fascia is fully exposed. Recognize the midline by the characteristic decussation of fibers as previous noted.

Clean the fascia Lightly clean the subcutaneous fat (and umbilicus) from the underlying fascia just enough to allow easy subsequent closure. Avoid doing this for more than 1 cm, as this is likely to increase bleeding and create more dead space for subsequent fluid collection.

Incise the fascia Open the fascia at a convenient point in the midportion of the incision. Yellowish fat and transparent

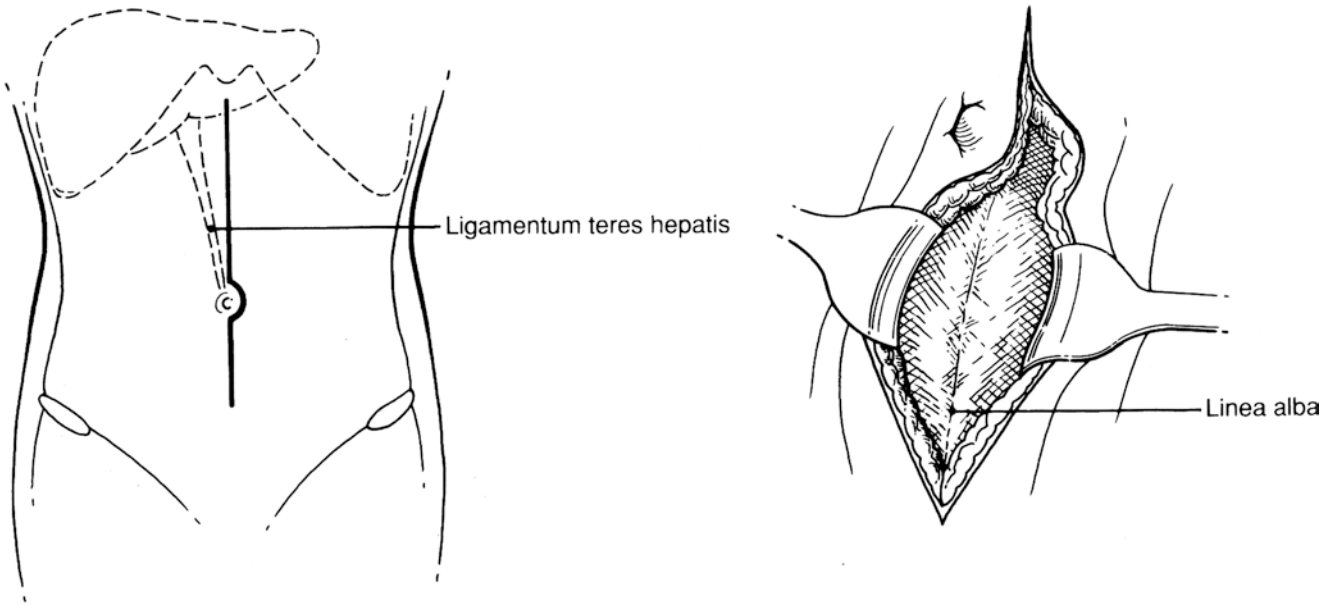

Fig. 83.2 In the upper abdomen, take the incision to the left of the umbilicus in order to leave undisturbed the underlying ligamentum teres hepatis which connects the underside of the umbilical plate to the liver (Reproduced from Fig. 44.2 Scott-Conner and Dawson [15], with permission)

peritoneum should be revealed. Gently push the extraperitoneal fat and peritoneum downward and incise just the fascia for the entire length of the incision. In the lower abdomen, the paired rectus muscles may appear confluent (due to lack of posterior sheath). Gently tease these apart from cephalad – where the separation will be more evident – to caudad, working parallel to their fibers.

Divide the pyramidalis muscles in the midline, if necessary – In the 80 % of so of individuals who have these muscles, you will encounter them in the rectus sheath. Divide them along the midline with electrocautery.

Enter the peritoneum Look for a transparent region and, if necessary, sweep the extraperitoneal fat to left and right to find such a place. Entry through a transparent portion will allow you to easily avoid underlying bowel and to minimize bleeding. Elevate the peritoneum with forceps and open it sharply, with due care to avoid injury to underlying small or large intestine. Keep in mind that pulling up on the edges of the peritoneum will increase your safety margin, pushing down will decrease it.

Push the bladder inferiorly As you extend the peritoneal incision inferiorly, push the extraperitoneal fat and peritoneum downward to protect the urinary bladder. It is often possible to leave the inferior couple of centimeters of peritoneum intact and simply displace it out of the way. A fibrous urachus can be simply divided with electrocautery. In the rare event that you encounter a more substantial tubular urachus that may be partially patent, simply clamp and secure it close to the dome of the bladder with absorbable ties or suture-ligatures.

Explore the abdomen and place fixed retractors Confirm the pathology, document any additional findings, and adjust your surgical plan if needed. The initial exploration is best done with hand-held retractors. Perform this exploration in a systematic fashion, working clockwise or counterclockwise as you prefer. Pay particular attention to the liver, undersurface of the diaphragm, and omentum, but do not ignore the rest of the viscera.

Repeat laparotomy While the general topic of adhesions is considered in greater depth in Chap. 76, a few words on repeat laparotomy are in order. Adhesions and small occult hernias are possible after any kind of previous surgery, even laparoscopic. Adhesions tend to form wherever injury has taken place, and may be especially tenacious at sutures. Hence there is a tendency for dense adhesions to line a previous midline incision. Take special care when opening the abdomen in this situation. It is not at all unusual to need to perform a midline laparotomy in a patient who has had a previous midline incision. In this case, if at all possible, enter the abdomen just above the previous incision. Work circumferentially around areas of dense adhesions and repair any partial or complete enterotomies as needed.

Be especially vigilant in the lower abdomen as previous dissection may have displaced the urinary bladder cephalad to its usual location, and it may be bound up in scar tissue.

Careful sharp dissection is the safest technique to use. See Chap. 75 for further details.

Closing the Vertical Midline Incision

Final check before closure Make sure all counts are correct and that you have obtained meticulous hemostasis. Place any displaced viscera back in their normal position. If omentum is available, bring it down and allow it to lie under the incision and over the surgical field, where it can provide a natural barrier against adhesions. Agents used for prevention of adhesions are discussed in Chap. 76 – if desired, place these at this point. Make sure that you have good neuromuscular blockade. Do not try to close a "tight" abdomen – visceral injury may result, or your fascial sutures may tear through. If necessary, place a flexible visceral retractor (such as the FISH® Glassman Visceral Retractor, Adept-Med International, USA) under the incision. Metallic ribbon retractors may be used to serve a similar purpose and are preferred by some surgeons.

Peritoneal closure not needed Separately closing the peritoneum is not necessary and may cause additional adhesions [5, 10, 11]. It adds another step to the operation, prolongs operative time, and may increase postoperative pain (because of sensory innervation). The European Hernia Association recommends against it. The peritoneum will reconstitute itself within about 24 h. This is a good general rule, regardless of the kind of incision (vertical or transverse) that one is closing.

Close the fascia He European Hernia Association recommends single layer aponeurotic closure; using a continuous, small-bite suturing technique, using a suture:incision length ratio of at least 4:1, with a slowly-absorbable synthetic suture [5].

Most surgeons close with a running suture of a heavy synthetic monofilament absorbable suture, such as an 0 PDS™II (Ethicon Corporation, USA) [12, 13]. The suture is available in a looped form in which both ends of the suture are swaged into the needle hub, and in the usual form. The looped form eliminates the need for the initial knot and effectively increases the strength of the suture (by doubling the amount of suture material used).

The European Hernia Society notes that no recommendation on size of sutures can be made due to lack of data [5].

To use a looped running suture, place your initial bite at one end of the incision, preferably the end at which exposure is most difficult. The reason to start at the most difficult place is that it will only get more difficult to place bites of suture as the incision closes. You will then secure this bite by passing the suture needle through the loop. The only knot that you will need will be at the opposite end of the incision and will either be buried in fat or will need to be buried (see below). In time, the entire suture, including the knot, will dissolve but this can be painfully slow and aggravating to deal with in thin patients.

To bury the knot, leave the needle attached as you knot the suture and then run the needle carefully under the last couple of bites, superficial to the fascia, and apply strong traction to pull the knot down under at least one of these bites. This will cause the knot to lie horizontally, with the tails buried, rather than vertically, with the tails sticking up.

To use a non-looped suture, be aware that the mid-portion of the incision will be the easiest to close as you progress, and that the two ends may be the most difficult. For this reason, many experienced surgeons prefer to use two sutures, and to start one at each end, meeting at the middle. This is not always necessary, but may be helpful in the obese patient.

In high-risk closures, some have advocated placing a piece of reinforcing mesh over the incision as a further safeguard against incisional hernia [5]. The precise role for this in routine surgery remains to be delineated, and it may complicate repeat operation.

Closure of subcutaneous tissue It may be useful to close the membranous part of the subcutaneous fascia with a few interrupted absorbable sutures. This does not contribute to the strength of the closure, but may, by minimizing dead space, discourage fluid accumulation. Drains are not routinely used in this space, even in corpulent individuals.

Skin closure An excellent cosmetic result may be obtained with carefully applied skin clips or with sutures. Many patients fear suture removal and most do not like clips. They appreciate a subcuticular suture, usually done with a running absorbable monofilament suture and optionally reinforced with strips or skin "glue" [14].

Other vertical (non-midline) incisions Other vertical incisions that are made to the right or left of the midline have little to recommend them and several significant disadvantages. A brief review of the terminology may be helpful, along with a discussion of their associated problems.

The classical paramedian incision **The classical paramedian incision** is made parallel to the midline and only a few centimeters away from it. The anterior rectus sheath is incised vertically and the rectus muscles are retracted laterally without damaging or dividing any neurovascular structures. The posterior sheath is then incised vertically. Theoretically, such

an incision could be made directly over a structure of interest and might provide a more secure closure because the anterior and posterior rectus sheaths are closed separately. In actual practice, these incisions work better in the upper abdomen than in the lower abdomen (where the posterior sheath is flimsy to nonexistent) and they significantly limit subsequent options for repeat laparotomy. There is nothing to commend this incision for exposure in the pelvic region.

Rectus-splitting and pararectus incisions are even worse, because part of the rectus muscle is denervated. These are obsolete incisions, mentioned only to be condemned. Always keep in mind that the rectus is a segmental muscle, and that it should be retracted laterally.

Vertical incision in the patient with an old paramedian incision Most surgeons try to avoid parallel incisions because of concerns about devascularizing the strip of tissue between the two scars. In the rare event that repeat laparotomy is required in a patient with an old paramedian incision, and that a vertical incision is needed for exposure, most surgeons will incorporate the old paramedian incision into their new incision, curving the new longer incision back to the midline above (or below) the paramedian. No data are available on outcomes. This is simply an area where the surgeon must be prepared to individualize, and here some familiarity with the anatomy of a paramedian incision may be helpful. The crucial thing is to remember to retract the rectus muscle laterally rather than splitting it or retracting it medially, to avoid neurovascular structures.

Carol E.H. Scott-Conner

Transverse Incisions Versus the Vertical Midline Incision

In 2015, the European Hernia Society published their guidelines on closure of abdominal incisions, and included the recommendation that transverse incisions be used whenever possible [1]. Fortunately for the gynecologic surgeon, the low transverse incisions commonly used for gynecologic surgery provide many desirable characteristics and are used whenever possible. The primary alternative to these transverse incisions is the vertical midline incision, which is unparalleled for extensibility and access to all aspects of the abdomen (see Chap. 74). These advantages and disadvantages are summarized in Table 84.1 (for low transverse incisions) and Table 84.2 (for high transverse incisions).

Advantages of Transverse Incisions

Because of the direction of pull of the abdominal muscles, transverse incisions may heal more securely than vertical incisions [1–5]. Low transverse incisions are easily concealed under clothing and may fade to invisibility if hidden in the natural skin crease above the pubis or just above the pubic hair line. They provide direct exposure of the pelvic organs without dissection above the pelvis and thus might result in less adhesive small bowel obstruction (although this is unproven). A low transverse incision might be combined with a panniculectomy in obese women, either to facilitate exposure or as part of a planned procedure to spare a patient a second operation. The Pfannenstiel incision does not compromise subsequent use of lower abdominal tissue for TRAM or DIEP flap.

Disadvantages of Transverse Incisions

Even when extended as far as possible, transverse incisions do not provide equal access to the upper and lower abdomen. Compared with vertical incisions, transverse incisions may be more painful (especially the upper abdominal ones) and the lower abdominal ones compromise stoma placement. They may involve slightly greater operative time and more potential blood loss compared with the vertical midline incision. Elevation of flaps (as with the Pfannenstiel incision) or combination with panniculectomy may increase the chances of a wound complication such as hematoma or infection. Division of the deep inferior epigastric arteries during construction of a Maylard or Cherney incision may compromise subsequent use of a free flap of lower abdominal tissue for reconstructive purposes [6, 7]. Upper transverse incisions such as the subcostal, extended subcostal, or chevron incision may denervate part of the abdominal wall causing eventration. These upper abdominal incisions also compromise subsequent TRAM flap creation.

Implications for Subsequent Reconstructive Surgery

Autologous tissue is valued for reconstruction of soft tissue defects after mastectomy or radical surgery. The skin, adipose tissue, and (sometimes) muscles of the lower abdominal wall form a convenient source. Because the breast cancer population comprises a significant subset of women, it is important that surgeons operating upon women understand how abdominal tissue is used for reconstruction. For convenience of the reader accessing this book electronically, some information given in Chap. 74 is repeated here.

Use of autologous tissue provides all the advantages of using the patient's own tissues (rather than an implant) and provides a bonus in the form of a "tummy tuck." It is important to understand how incision choice might influence later reconstructive options, should the woman require them.

Table 84.1 Advantages and disadvantages of low transverse incisions typically used for gynecologic surgery, compared with the vertical midline incision

Advantages of low transverse incisions	Disadvantages
May heal better with lower incidence of hernia or dehiscence	Not as versatile or extensile
Cosmetically excellent scar	Less compatible with stoma creation
Pfannenstiel does not compromise subsequent use of lower abdominal tissue for TRAM or DIEP flaps	Ligation of deep inferior epigastric arteries during Maylard or Cherney may limit reconstructive options
Less formation of adhesions to small bowel	
May be combined with panniculectomy to enhance exposure or if desired by patient	Divides tissues of lower abdomen used for TRAM flap reconstruction (if needed later)
Does not compromise reoperation through vertical midline incision	Takes slightly longer and may be associated with greater blood loss

Table 84.2 Advantages and disadvantages of upper abdominal transverse or oblique incisions (such as subcostal, extended subcostal, or chevron), compared with vertical midline incision

Advantages of upper abdominal transverse incisions	Disadvantages
Excellent exposure of upper abdominal structures, particularly liver and diaphragm	Poor exposure of rest of abdomen
Reoperation after long vertical midline incision may allow surgeon to avoid adhesions	Scar is unsightly
May heal more securely than vertical midline incision	Dividing nerves may cause denervation (ballooning) of a large part of abdominal wall
Provides particularly good exposure in individuals with a wide costal arch	Not such good exposure in slender individuals with narrow costal arch
	Divides superior epigastric artery and thus pedicled TRAM flap reconstruction (if needed later) is impossible
	May be more painful in immediate postoperative period

A variety of autologous flaps have been described, but for purposes of this discussion it is important to focus on only two of these. These are the TRAM (transverse rectus abdominis muscle) and DIEP (deep inferior epigastric) flaps.

TRAM flaps take tissue from the lower abdomen, including one of the rectus abdominis muscles. Pedicled TRAM flaps derive their blood supply from the (preserved) superior epigastric artery. Sometimes the inferior epigastric artery is ligated as a first step, in order to cause the superior epigastric artery to enlarge. Thus, incisions in the lower abdomen which entail ligation of the inferior epigastric artery do not jeopardize subsequent creation of a pedicled TRAM flap.

Free TRAM flaps require microvascular anastomosis of one of the arteries supplying the flap to an artery in the region. For any free flap, it is crucial that the reconstructive surgeon assess local blood supply of the donor tissue. For many years, before microvascular free flap techniques were widely available, the pedicled TRAM flap was the workhorse flap for autologous reconstruction. Both the free and pedicled TRAM flap are rendered impossible after an upper abdominal Chevron (or subcostal) incision) because this incision divides the superior epigastric artery.

The TRAM is still commonly used, either as a pedicled or a free flap. However, concerns about abdominal wall function after loss of a rectus muscle have fueled interest in the DIEP flap as an alternative.

DIEP flaps are free flaps that transfer only skin and subcutaneous fat, leaving intact the rectus abdominis muscle. They require microvascular anastomosis of the deep inferior epigastric artery to a suitable artery in the recipient field. Previous ligation of the deep inferior epigastric artery renders this option impossible. It is thus important that gynecologic surgeons document ligation of these arteries during performance of Maylard or Cherney incisions. Reconstructive surgeons have been cautioned to check these vessels with Doppler ultrasound or other modalities when planning a DIEP flap on a patient with a long low transverse incision [7].

Many considerations influence the choice of flap. The bulk of missing breast tissue relative to the tissue available in the donor site, unilateral versus bilateral, vascular health of the woman (diabetes, smoking, atherosclerotic disease), and presence or absence of scars on the abdomen all must be considered. It is noteworthy that previous panniculectomy also may be a factor [6].

A lower midline incision divides the skin and fatty tissue down the middle. Typically, the reconstructive surgeon will then split the tissue down the middle. This is not a problem in obese women, but may be problematic in slender individuals where abdominal fat is limited.

If the deep inferior epigastric vessels have been ligated during a previous low transverse incision, then a TRAM flap

is still possible (indeed, division of these vessels is sometimes performed several weeks prior to flap creation, in order to stimulate the superior epigastric vessels to grow) but a DIEP flap will not be possible because the vascular trunk will be gone.

How does this affect choice of incision for a gynecologic surgeon? Obviously, the necessities of the operation at hand must dominate clinical decision-making. But simply keep this in mind: all other things being equal, design of these flaps is more difficult and choice of options more limited if a woman has had a lower midline incision or a transverse incision which divides rectus muscle and regional arteries than if she has had a classic Pfannenstiehl. From the reconstructive surgeon's perspective, a Pfannenstiehl incision causes the least disruption. Fortunately, this corresponds to the incision of choice for many gynecologic procedures. If it is necessary to ligate one or both deep inferior epigastric arteries, document this in the operative note.

Combination with Panniculectomy

Panniculectomy consists of surgical removal of the pannus, the hanging apron of excess skin and fatty tissue overlying the pubic region in morbidly obese patients (or those who have lost large amounts of weight). Typically, the umbilicus is displaced inferiorly from its normal location. The fold under the pannus is difficult for patients to clean and often colonized by Candida and various bacteria. With a surgical panniculectomy, the umbilicus may be retained and moved to a more normal location, or may simply be excised. Excision of the umbilicus, while clearly the simplest option surgically, may not be acceptable to some patients.

Abdominoplasty, also termed a "tummy tuck", combines panniculectomy with a procedure to tighten sagging abdominal muscles. It is commonly performed in women who have lax abdominal muscles and excess fatty tissue after completion of their childbearing years.

Panniculectomy or abdominoplasty are most often performed as a separate procedure rather than combined with intra-abdominal surgery. Panniculectomy was first combined with ventral hernia repair to enable stronger hernia repair and was demonstrated to be safe and effective. In some instances, it has been combined with gynecologic surgery. It was initially described as a way to facilitate access to the pelvis for radical pelvic surgery. This has been described as "medically necessary" panniculectomy [8–10].

It has subsequently been employed electively in selected patients who are undergoing gynecologic surgery through a low transverse incision and who desire panniculectomy [10–12]. Concerns have been raised about combining a clean procedure (panniculectomy) with a contaminated one (hysterectomy) but a recent review using the American College of Surgeons National Surgical Quality Improvement Project data base (NSQIP) indicated that a combined abdominoplasty-hysterectomy procedure actually carried a lower morbidity than the morbidity of the two individual procedures [13]. This review supported the addition of abdominoplasty to those patients undergoing abdominal hysterectomy who would otherwise undergo a second, separate procedure, to attain a better contour.

When considering combining panniculectomy with gynecologic surgery, there are several potential disadvantages to consider. First, it is important to note that body contouring can be a complex operation, involving resection of tissue around the entire torso (to attain a normal body habitus). The procedure is best performed after planned weight loss has been achieved, rather than incidentally during performance of another procedure. "Dog ears" of redundant tissue at the lateral aspects of a simple elliptical panniculectomy (as described in this chapter) are common and may be bothersome to the patient. It is thus crucial that both patient and surgeon have realistic expectations when panniculectomy is performed during gynecologic surgery. Consent is obtained for both procedures and the panniculectomy is performed first.

Second, panniculectomy, even the limited form described below, may be accompanied by sufficient blood loss to require transfusion. It requires significant undermining of the upper flap. Seromas are common. It significantly prolongs operative time. Infection of the operative site will be more difficult to manage than the usual sort of deep wound infection, simply by virtue of the size of the dissected field in the subcutaneous tissues.

Panniculectomy (as noted above) also eliminates some tissue commonly used for reconstructive surgery. Flaps of lower abdominal skin, fatty tissue, and (sometimes) muscle are employed for reconstruction after breast cancer surgery and sometimes used in other locations.

Anatomy of the Abdominal Wall

Superficial fascia The superficial fascia of the anterior abdominal wall is primarily adipose tissue above the umbilicus. Below the umbilicus, superficial fatty and deeper membranous layers may be appreciated. The membranous layer may form a barrier to extravasation of fluid, and is sometimes sutured to decrease dead space during wound closure.

The superficial fatty layer is typically thicker below the umbilicus, and in morbidly obese individuals may form a huge, edematous, dependent pannus that hangs down below the pubic region. In such cases, the normally relatively avascular fat may contain very large subcutaneous veins.

Linea alba and umbilicus The linea alba is visible in slender individuals as an shallow indented line running from xiphoid to pubis. It marks the midline of the anterior abdominal wall. It is formed from decussating fibers of the external oblique, internal oblique, and transversus abdominis aponeuroses. This relatively avascular structure is incised during performance of vertical midline incisions.

Muscles of the lateral abdominal wall Laterally, three broad flat muscles (the external oblique, internal oblique, and transversus abdominis muscles) comprise the abdominal wall. Medially, all three become aponeurotic and contribute to the rectus sheathes and linea alba. The most superficial of these muscles is the external oblique. Muscular fibers of the external oblique arise from the 5–12 ribs, laterally seeming to interdigitate with muscular slips from the serratus anterior muscle. These fibers course medially and inferiorly ("as if putting one's hands in one's pockets"). The portion of the muscle arising from the lowest ribs inserts upon the iliac crest, and the remainder of the muscle becomes aponeurotic and forms part of the anterior rectus sheath, to terminate in the decussating fibers of the linea alba.

The internal oblique muscle lies deep to the external oblique. The fibers of these two muscles run nearly at right angles to each other, creating a gridiron effect. Fibers of this muscle arise from the inguinal ligament, iliac crest, and lumbodorsal fascia. Medially this muscle similarly becomes aponeurotic. It contributes to the anterior and posterior rectus sheath and linea alba in the upper abdomen, and to the anterior rectus sheath and linea alba only in the lower abdomen.

The transversus abdominis muscle forms the deepest muscle layer of the lateral abdominal wall. Lying just deep to the internal oblique, its fibers run almost directly medially from their origin on the inguinal ligament, the iliac crest, and the lower ribs. In the medial half, this muscle also becomes aponeurotic and contributes to the posterior rectus sheath in the upper abdomen, and the anterior rectus sheath in the lower abdomen, as well as the linea alba.

Rectus abdominis muscle The paired, segmental rectus abdominis muscles originate from the pubis and run nearly vertically to insert upon the costal margin and xiphoid process. As they ascend, they become broader and the distance between them increases. They are encased within the strong fibrous rectus sheathes, which coalesce to form the midline linea alba as noted above. Segments of the rectus muscles are demarcated by fibrous inscriptions that create the appearance of a "six pack" on the abdominal wall of lean, muscular individuals. The inscriptions may be adherent to the rectus sheathes.

Each rectus muscle is innervated by multiple thoracoabdominal nerves, which approach obliquely from lateral to medial and run deep to the muscle in the rectus sheath [14]. This segmental innervation allows the rectus to be transected at any point without creating denervation and atrophy. The transected rectus simply forms another fibrous inscription as it heals. This property is exploited by gynecologic surgeons during creation of the Maylard incision, and by general surgeons who create transverse or oblique incisions in the upper or lower abdomen.

The blood supply of the rectus muscles comes from above and below. From above, the superior epigastric arteries pass on the deep aspect of the rectus. From below, the usually larger deep inferior epigastric arteries ascend deep to the rectus and enter the rectus sheath at the arcuate line – above which, there is a well-defined posterior rectus sheath. Typically the epigastric artery and vein anastomose, a feature exploited by reconstructive surgeons when they "delay" a flap by ligating the inferior epigastric artery. Small twigs of the lower six intercostal arteries also enter the rectus sheath from the lateral aspect.

All of this can be summarized to say that the rectus muscles, because of their segmental innervation and dual blood supply, can be transected to construct a transverse incision at any level of the abdominal wall with minimal long-term morbidity.

Innervation In general, the muscles of the anterior abdominal wall derive their innervation from branches of the lower thoracic nerves, as well as the iliohypogastric and ilioinguinal nerves. Innervation is segmental, and comes from lateral to medial with the individual nerves following an oblique path slanting slightly inferiorly as they enter the muscles. Nerves are found deep to the muscles that they innervate.

The ilioinguinal or iliohypogastric nerves may be encountered during the creation of low transverse incisions, and should be spared to avoid the formation of painful neuromas. If that rule is followed, the transverse incisions used in gynecologic surgery do not denervate muscles. High transverse incisions used in general surgery, such as a subcostal incision, cross the course of several of these nerves and thus may result in denervation and subsequent ballooning (termed "eventration") of a large portion of the abdominal wall.

Blood supply The two major (paired) named arteries of the anterior abdominal are the superior epigastric artery and the inferior epigastric artery. The superior epigastric artery, generally the smaller of the two, arises from the internal thoracic artery and passes inferiorly deep to the rectus muscle in the rectus sheath. The larger inferior epigastric artery (sometimes termed the deep inferior epigastric artery, to differentiate it from the smaller superficial inferior epigastric artery) arises from the external iliac artery. The inferior epigastric and superior epigastric arteries commonly anastomose in the

mid-abdomen and hence ligation of the inferior epigastric artery is generally well-tolerated, except in patients with severe vascular pathology (who may be dependent upon collaterals for circulation). Laterally, three large arteries – the 10th and 11th intercostal arteries and the subcostal artery may be encountered, primarily in the upper abdomen. These may similarly generally be ligated with impunity. In the medial aspect of the lower abdomen, the superficial inferior epigastric artery may be encountered in the subcutaneous tissues running from the femoral artery toward the umbilicus. More laterally in the lower abdomen, the deep circumflex iliac artery runs in the subcutaneous tissues parallel to the inguinal ligament. In brief, all of these regional arteries may be ligated. Most are accompanied by paired veins.

Extraperitoneal (preperitoneal) space Deep to the linea alba, extraperitoneal fat, endoabdominal fascia, and peritoneum are encountered. The transversalis fascia, a fibrous layer deep to the transversus abdominis muscles and superficial to the extraperitoneal fat, is the major component of the endoabdominal fascia. It becomes more robust laterally. Dissection superficial to this fascia allows access to the retroperitoneal space without entering the peritoneum. This extraperitoneal dissection is easier laterally, where the transversalis fascia is well-defined. Medially, it is less robust, and in the midline it is rarely surgically apparent, although a variable amount of fat will be encountered superficial to the peritoneum. This extraperitoneal fat may be brushed aside from the midline to expose the transparent peritoneum, and brushed inferiorly to push the urinary bladder out of the surgical field.

Umbilicus The umbilicus is the cicatrix or scar where the fetal umbilical vessels and associated structures passed through the linea alba. Skin and all fascial layers are fused together at this site. It is a potential weak spot through which hernias form. When a panniculectomy is performed, decision must be made whether to preserve the umbilicus or sacrifice it. Preserving the umbilicus will generally require repositioning it cephalad (as the panniculectomy will, of necessity, pull it even farther down from its usual position).

Urinary bladder and median umbilical ligament the median umbilical ligament (urachus) travels from the underside of the umbilicus to the apex of the urinary bladder. The urachus is usually just a fibrous remnant. Occasionally cysts or residual patency of the urachus may be encountered in the midline. Division of the median umbilical ligament allows the bladder to be gently displaced inferiorly as the peritoneal cavity is entered. The urinary bladder lies in fatty tissue of the retropubic space (anteriorly) and in loose visceral connective posteriorly where it lies on the cervix of the uterus and anterior vaginal wall.

Transversalis fascia This thin aponeurotic membrane is well developed laterally and becomes more tenuous medially. It is found between the transversus abdominis muscle and the parietal peritoneum. It is a major component of the endoabdominal fascia, which forms a kind of sac within which the peritoneum and intraperitoneal organs are found. The transversalis fascia is the first major structure which an incipient hernia must breach.

Parietal peritoneum the glistening parietal peritoneum lines the abdominal wall and is continuous with the visceral peritoneum which covers the internal abdominal organs. It has little or no strength, and its single layer of epithelial cells rapidly reconstitute themselves. While studies have shown that there is no strength benefit to closure of the parietal peritoneum [15, 16], some surgeons will close a deep layer of transversalis and peritoneum together after creating a transverse incision which divides muscles. This effectively "compartmentalizes" the wound, so that any bleeding from the transected muscles will be contained in the wound, rather than spilling into the peritoneal cavity.

Transverse Incisions Used in Gynecologic Surgery

Pfannenstiel

The Pfannenstiel incision is used when limited exposure to pelvic organs is desired, such as is needed for surgery for benign gynecologic pathology. It is also used for specimen extraction after laparoscopic surgery of all sorts (including, for example, laparoscopic splenectomy. It provides a seemingly-ideal combination of strength, adequate access, and excellent cosmetic result. The limitations of this incision include the need to create a flap to expose the peritoneum, and the limited exposure.

The classic Pfannenstiel incision (Fig. 84.1a, red line) begins with a relatively short skin incision in or just above the suprapubic skin crease. Typically this incision is 10–13 cm long, curves gently upwards like a smile, and is centered on the midline. It has been said that an incision "the length of an Allis clamp" will prove adequate for Caesarian section. Once encountered, the anterior rectus sheathes are divided sharply along the same line as the skin incision, and flaps are then raised cranially in such a manner as to elevate the anterior sheath and expose the underlying rectus abdominis muscles Fig. 84.1b). The peritoneum and transversalis fascia are then divided in a vertical fashion to enter the abdomen (Fig. 84.1c).

Closure involves suturing the linea alba together with running or continuous slowly absorbable sutures [17–19]. As previously noted, there is no virtue in attempting to separately close the peritoneum.

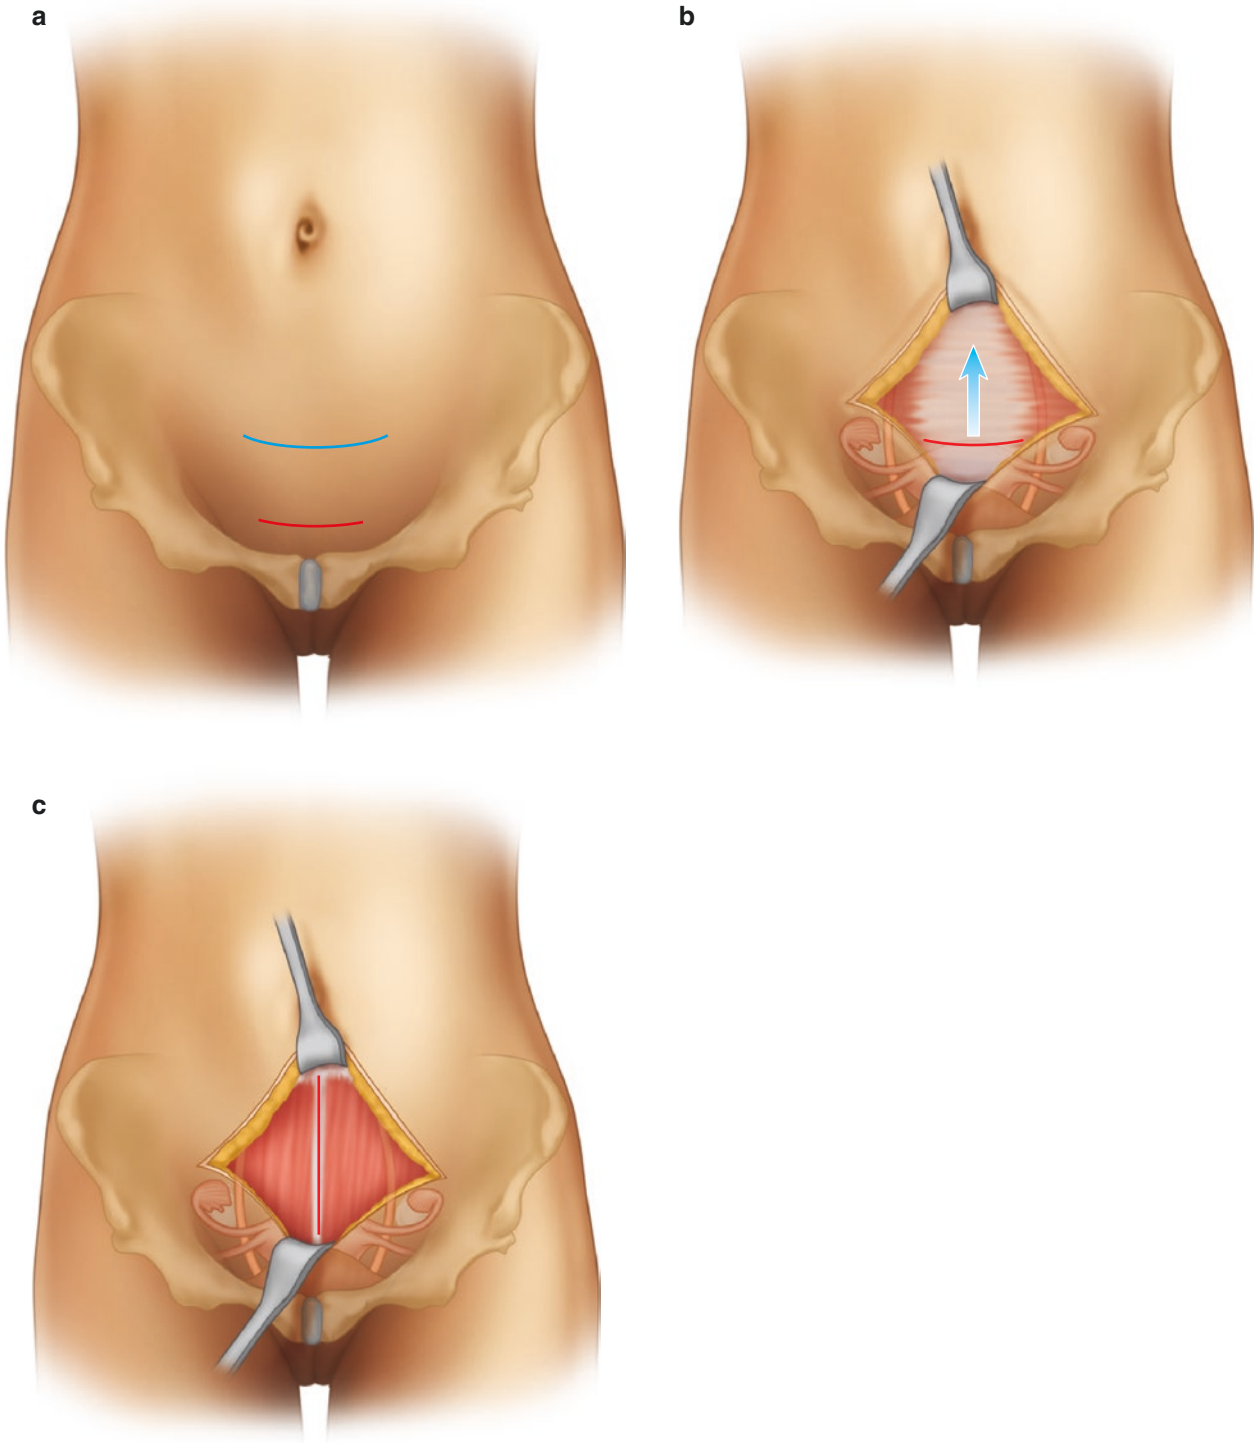

Fig. 84.1 (**a**)The Pfannenstiel incision begins with a relatively short incision in or just above the pubic skin crease. (**b**) The Pfannenstiel incision dissection is continued by incising the anterior rectus sheath and linea alba along the red line. This fascial flap is then elevated cephalad (*blue arrow*) to expose the underlying rectus muscles. Note that the extent of the skin incision and retracted subcutaneous tissues are exaggerated in this figure for clarity. (**c**) The Pfannenstiel is completed by incising the vertical midline between the rectus muscles. Note that the extent of the skin incision and retracted subcutaneous tissues are exaggerated in this figure for clarity (Reproduced with modifications from Scott-Conner [23])

Several variations of the incision have been described. These attempt to combine the advantages of the incision, as originally described, with greater exposure.

Joel Cohen (Sometimes Written Joel-Cohen)

This is a modification of the Pfannenstiel in which the skin incision is made significantly higher than the natural skin line (Fig. 84.1a, blue line), about 1 cm inferior to the line between the anterior superior iliac spines [20]. It was originally described for use in Caesarian sections and still may be used for this purpose in slender women. The remainder of the incision is the same as the Pfannenstiel. Less dissection under the fascial flaps is required, the incision may extend a bit longer, and it appears to be able to be made much more rapidly.

Misgav Ladach

The Misgav Ladach incision is another transverse incision that can be made rapidly and with minimal blood loss, yet heals securely [21]. It, too, is primarily used for Caesarian sections. This incision begins with a transverse incision identical to the Joel Cohen, but deep dissection is completely different. Dissection progresses transversely through the subcutaneous fat and superficial fascia to the anterior rectus sheathes and linea alba. This is opened transversely for about 2 cm and then surgeon and first assistant insert two to three fingers of each hand and manually stretch the fascia open cranially and caudally. The rectus muscles are then pulled apart. The parietal peritoneum is similarly opened with a small incision and the incision extended by pulling it apart. In addition to rapid entry and good healing, this approach minimizes the use of sharp instruments deep in the incision and thus may be preferred when exposure to blood-borne pathogens is a particular concern.

The only closure that is required is closure of the anterior rectus sheathes and linea alba. Classically, only a few interrupted sutures are placed in the skin to allow loose closure and reduce the risk of wound infection.

The general surgeon will find the method of stretching open the layers rather than cutting them very reminiscent of techniques used to open "muscle-splitting" gridiron incisions such as those used for open appendectomy.

Küstner

This incision starts with a skin incision similar to the Pfannenstiel, but somewhat longer. The incision is deepened through the subcutaneous fat and flaps are raised superficial to the anterior rectus sheathes. A vertical midline incision is then made through fascia and peritoneum.

This incision has little to recommend it. Elevating the subcutaneous tissues is frequently bloody and time--consuming, the fascial incision although vertical is not extensible as the true vertical midline incision is. It is sometimes, mistakenly, referred to as a Pfannenstiel variant.

Maylard

This incision begins like the Pfannenstiel, but after transecting the anterior rectus sheath transversely, the surgeon divides both rectus abdominis muscles (Fig. 84.2a–c). The muscles may or may not be re-approximated during closure. This incision provides better access for difficult pelvic operations. Although some surgeons try to preserve the deep inferior epigastric arteries, most ligate and divide them before transecting the rectus muscles.

Cherney

In this variation, after transversely dividing the anterior rectus sheath, the rectus abdominis muscles are detached from the pelvic bones and rolled upward out of the way (Fig. 84.3a, b). This is thought to better preserve the strength of the anterior abdominal wall, compared with dividing the rectus muscles, but evidence is lacking. It may also be easier to re-attach the rectus muscles than to attempt to re-approximate them after division. It may be easier to preserve the deep inferior epigastric arteries when the muscles are detached rather than transected, as these arteries approach the rectus muscles from laterally are may not be encountered so close to the pubis. The muscles are re-attached to the anterior rectus sheath inferiorly, rather than the pubis, to avoid causing osteitis. Closure is facilitated by flexing the operating table.

Other Transverse Incisions: Subcostal and Chevron Upper Abdominal Incision

In a difficult reoperative case, access to the upper abdomen may be gained by a transverse (oblique) subcostal or bilateral subcostal (chevron) incision (Fig. 84.4). The subcostal incision is made parallel to and several fingerbreadths (3–4 cm) below the costal margin. All layers of the abdominal wall are transected along this line. It is particularly important to maintain an upper flap of muscular and aponeurotic tissue on the upper aspect, rather than allowing the incision to wander cephalad up towards the ribs. This upper flap will be utilized during closure.

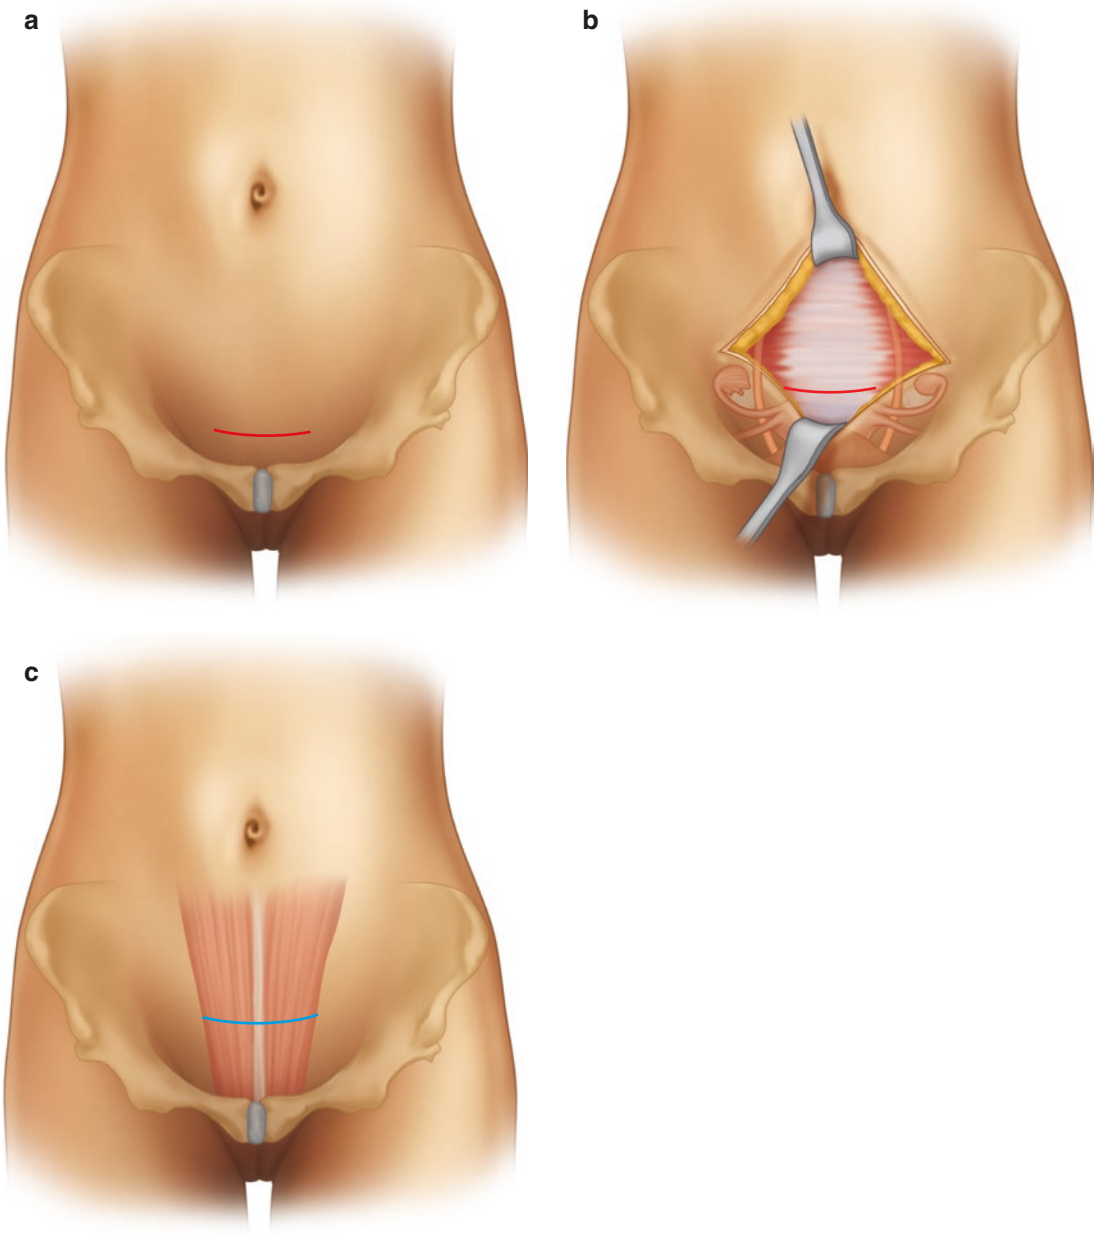

Fig. 84.2 (**a**) The Maylard incision is made with a skin incision similar to the Pfannenstiel. Typically, the incision is made a bit longer than the classic Pfannenstiel. (**b**) The fascia is incised transversely (again, like the Pfannenstiel), but flaps are not developed under the fascia. . Note that the extent of the skin incision and retracted subcutaneous tissues are greatly exaggerated in this figure for clarity. (**c**) The underlying rectus muscles are divided along the incision line. Typically both deep inferior epigastric vessels are ligated and divided during creation of this incision. Again, please note that the extent of the skin incision and retracted subcutaneous tissues are exaggerated in this figure for clarity (Reproduced with modifications from Scott-Conner [23])

A subcostal incision may be made on one side (for example, the right side to access the biliary tree) and extended across the midline partially or completely as needed. A complete bilateral subcostal incision provides superb access to the upper abdomen and heals well, but may be quite painful. These incisions are usually closed in two layers, concentrating upon fascial/aponeurotic closure rather than on any attempt to actually re-approximate the muscles. Generally the first layer of the closure is the posterior rectus sheath and, laterally, transversus abdominis muscle.

Less often, straight transverse incisions (usually unilateral) may be made for open right colon resection or for pediatric surgical procedures.

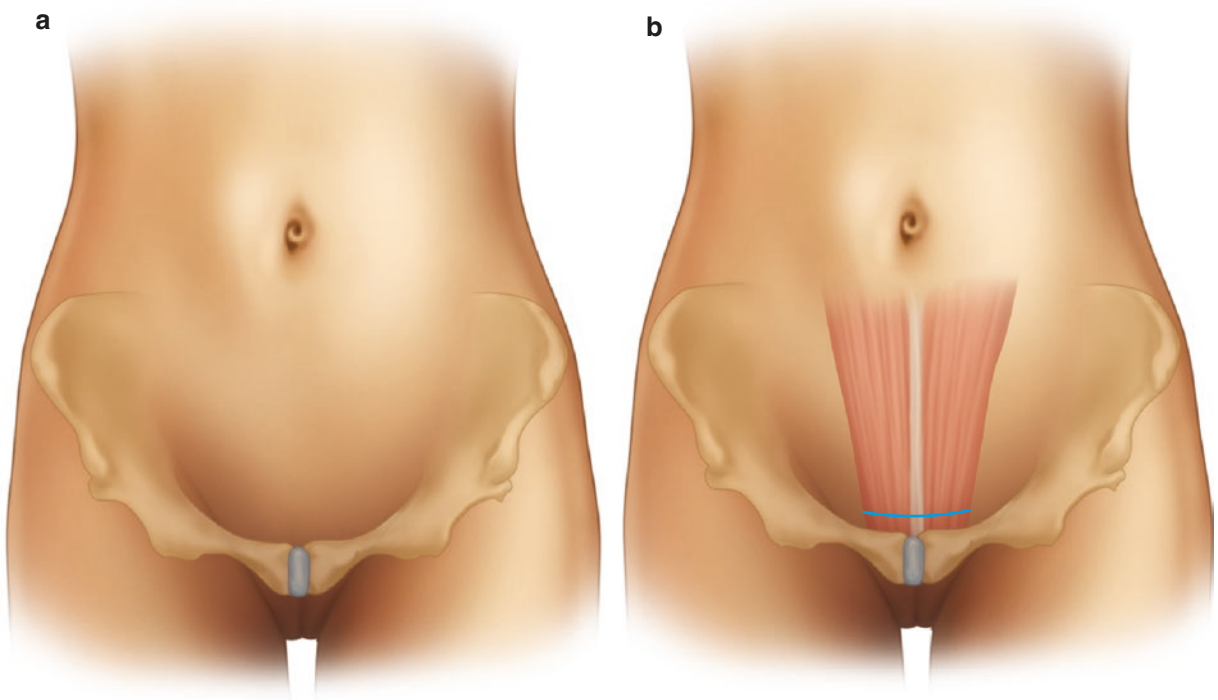

Fig. 84.3 (**a**) The Cherney incision is made with a skin incision similar to the Pfannenstiehl. The incision may be made a bit longer if necessary. (**b**) The fascia and underlying rectus muscles are incised low, close to their attachment on the pubic bone. Note that the extent of the skin incision and retracted subcutaneous tissues are exaggerated in this figure for clarity (Reproduced with modifications from Scott-Conner [23])

Options When Additional Exposure Is Needed

The low transverse incisions used for gynecologic surgery are chosen when the need for exposure of the upper abdomen is not anticipated. Sometimes, despite the best preoperative evaluation and workup, a surgeon may encounter unexpected pathology that requires exploration and access greater than that afforded by the initial incision.

There are basically two options in this situation. The first option, if only a bit more exposure in the pelvis is required, is to extend the incision. When exposure of the upper abdomen is required, it is often best to simply close the transverse incision and create a second, upper midline incision. As with all things, it is prudent to warn the patient of this possibility before the procedure. Options are summarized in Table 84.3.

Extending the Pfannenstiel Incision

Some small amount of additional exposure can be obtained by detaching the rectus muscles at the inferior aspect of the incision, as is done for the Cherney incision. This is preferred over the alternative of dividing the rectus muscles because it will prove easier to close (and potentially less bloody) than the Maylard.

Extending the Cherney or Maylard Incision

Both incisions can be extended laterally by ligating and dividing the deep inferior epigastric arteries (if not already done) and then dividing all layers of the abdominal wall in a transverse oblique fashion along the line of the incision. Excellent retroperitoneal exposure can be obtained by extending the incision obliquely or even farther to create a hockey-stick (Fig. 84.5a, b). Experience from renal transplant literature suggests that the oblique incision heals better than the hockey-stick, but there is only limited data [22].

Although these maneuvers will significantly enhance exposure of the pelvis, pelvic retroperitoneum, and lower abdominal organs, these do not generally provide sufficient access to the upper abdomen.

Creating and Closing the Pfannenstiel Incision

Mark an incision in a natural skin crease approximately 3 cm above the pubic symphysis and extending in a gently curvilinear fashion for a total length of 10–14 cm. Incise skin and subcutaneous tissue along this line until the fascia of the anterior abdominal wall is encountered. This fascia will constitute the anterior rectus sheath and linea alba medially.

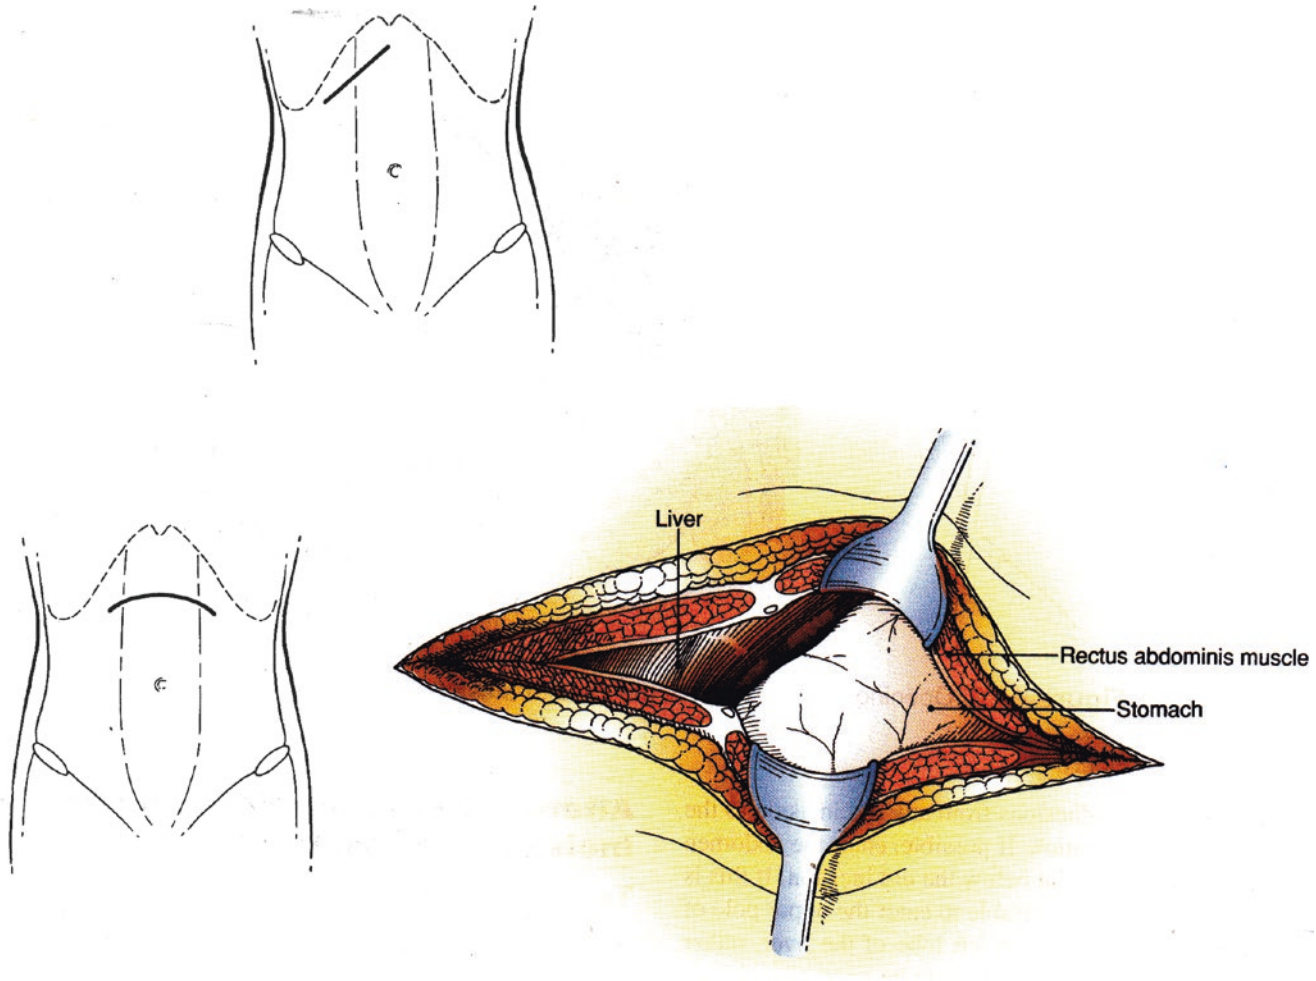

Fig. 84.4 The subcostal incision may be made on either the right or the left side, depending upon the area to be accessed. The right subcostal incision is the most common, because it provides superb access to the gallbladder and extrahepatic biliary tree. The bilateral subcostal, here shown as a relatively short incision, may be extended as needed on either side. With all subcostal incisions, musculoaponeurotic layers are divided along the line of incision (Reproduced from Scott-Conner [23])

Table 84.3 Options for additional exposure when the initial incision is a low transverse one and unexpected pathology is encountered

Initial incision	Options for additional exposure
Pfannenstiel	Convert to Cherney Incision Close Pfannenstiel and create vertical midline
Cherney	For greater exposure (especially retroperitoneal) on one side, extend that side laterally and upward as a "hockey-stick" incision Close and create vertical midline
Maylard	"Hockey-stick" incision as noted above Close and create vertical midline

Elevate it from the underlying rectus abdominis muscles and divide it transversely without damaging the muscles. Then dissect cephalad in the plane between the divided fascia and the underlying muscle for 8–10 cm. Leave the subcutaneous fat of the upper flap adherent to the anterior rectus fascia. Coagulate any small perforating vessels as encountered. Gently separate the rectus abdominis muscles in the midline, elevate the transversalis fascia and parietal peritoneum and divide it vertically between the two rectus muscles.

Closure begins with meticulous hemostasis. Do not close the peritoneum. Allow the rectus muscles to return to the midline. Suture the anterior rectus sheathes and midline fascia with a running suture of heavy slow-absorbing material, such as 0 PDS.

Creating and Closing the Cherney Incision

Mark an incision similar to that used for a Pfannenstiel but extending farther on each side to about 3–4 cm below and medial to the anterior superior iliac spine. Frequently, the incision is made slightly higher than a Pfannenstiel (3–8 cm above the pubis), and less curved. Deepen this through subcutaneous tissues until the fascia of the anterior abdominal

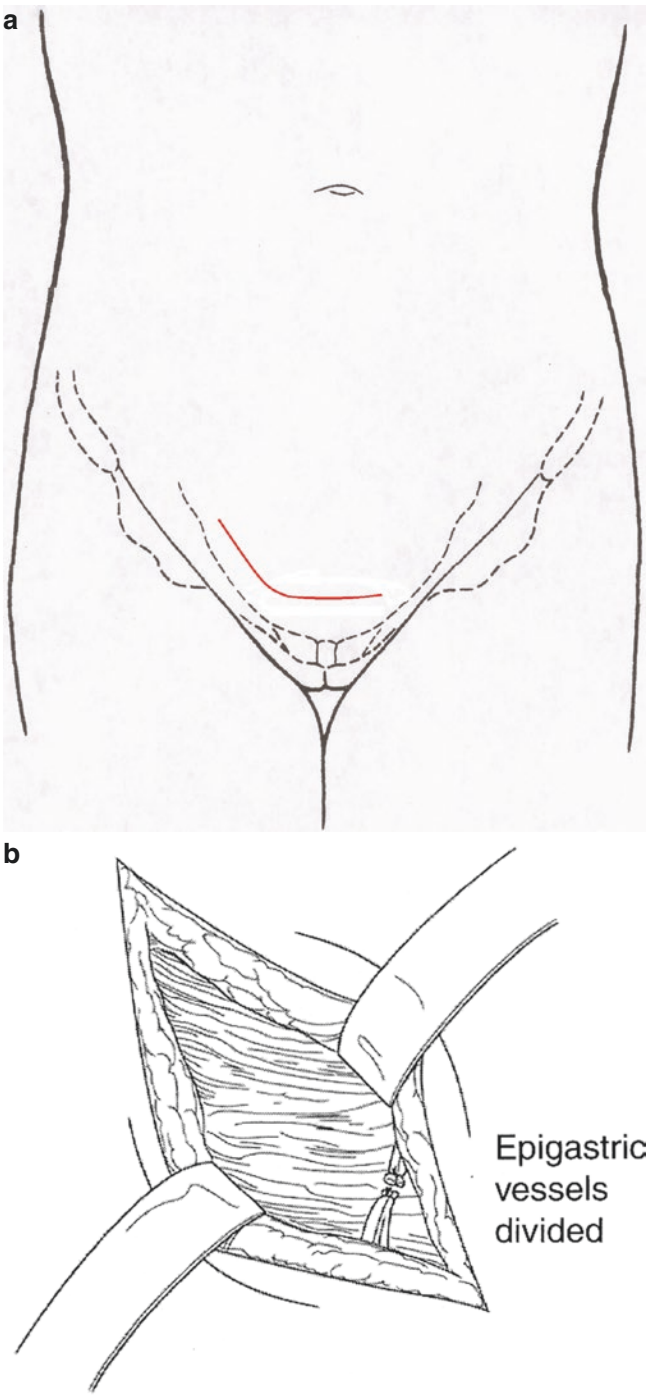

Fig. 84.5 (**a**) The Maylard (or Cherney) incision may be extended laterally on either side as a hockey stick (*red line*). If unilateral exposure is needed (for example, for a retroperitoneal node dissection), an oblique incision (*blue line*) may be preferable. (**b**) The hockey stick or oblique incision (shown here) requires division of all fascial and aponeurotic layers along the incision line. The deep inferior epigastric artery must be divided (if not already done (Reproduced from Scott--Conner [23])

wall is encountered. Elevate the anterior rectus sheath from the underlying rectus muscles and divide the anterior rectus sheathes along the same line as the skin incision. Take care to retain sufficient fascial tissue inferiorly to allow secure closure. Detach the rectus abdominis muscles from their insertion upon the pubic symphysis and roll them cephalad to expose the transversalis fascia and peritoneum. Incise the peritoneum transversely, taking care not to injure the inferior epigastric vessels which will usually be lateral to the operative field. Be aware that nerve injury has resulted from placement of the deep blades of fixed retractors in the lateral inferior aspect of this incision (and the Maylard). Make sure that any self-retaining retractor blades are placed on the incision, not on the psoas muscle.

To facilitate closure, flex the operating table and ensure that muscle relaxation is adequate. Many surgeons close the peritoneum with a simple running suture. Re-attach the rectus abdominis muscles to the underside of inferior flap of the anterior rectus sheath, rather than to the pubis. Use interrupted horizontal mattress sutures of 0 PDS or some similar slowly-dissolving synthetic material. Then close the rectus sheath and midline fascia with a running suture of 0 PDS or a similar material.

Creating and Closing the Maylard Incision

Mark an incision similar to that described above for the Cherney incision. Deepen this through the anterior rectus sheath as described for the Cherney incision. Elevate the rectus muscle on each side from underlying transversalis fascia and divide it slowly and gradually with electrocautery. Be vigilant about identifying and carefully cauterizing small muscular arterioles, which may go into spasm and retract into the muscle. These can cause postoperative hematomas. Try not to injure the inferior epigastric vessels. If injured, secure these with ties and divide them. Incise the transversalis fascia and parietal peritoneum transversely. Take care with fixed retractors as noted for the Cherney incision.

During closure, it is important to recheck hemostasis from the divided rectus muscles. It is not unusual for small muscular arterioles to go into spasm and cause bleeding in the early postoperative period. Closure of the parietal peritoneum is prudent, as it will confine any bleeding to the wound, essentially excluding it from the peritoneal cavity. It is not necessary to re-approximate the rectus muscles for abdominal wall strength. Some surgeons do this to reinforce hemostasis. If attempted, flex the operating table and ensure relaxation. Use interrupted horizontal mattress sutures to bring the cut edges of the muscles together. As with any situation where sutures are placed under some tension through tissue that does not hold suture well, place all of your sutures first, then have an assistant pull them all up so that you can tie them. This allows the tension to be borne along the entire length of the suture line, rather than concentrated upon one suture. Next, close the anterior rectus sheath with a running suture of 0 PDS.

Combination with Panniculectomy (Fig. 84.6)

Assess the amount of pannus to be removed by elevating the redundant tissue. Be conservative. The most straightforward (but not necessarily the cosmetically optimal) approach is to outline a skin incision that extends from the lumbar regions laterally to curve above and below the umbilicus. If it is necessary to preserve the umbilicus, make a separate skin incision around it. Deepen the incisions through subcutaneous fat to fascia, and take care to ligate the large subcutaneous veins as encountered. The Harmonic Scalpel ™ has been described for this purpose. Obtain meticulous hemostasis. Cover the exposed fat with damp laparotomy pads or towels to avoid dessication.

Proceed with the gynecological incision, procedure, and fascial closure in the usual fashion.

Undermine the superior flap of skin and subcutaneous fat sufficiently to allow it to slide down and approximate without tension to the inferior flap. If the umbilicus is to be preserved, select an appropriate location, taking care that it lies on the midline, and create a skin hole and subcutaneous tunnel. Obtain meticulous hemostasis. Pull the umbilicus through the new incision and secure it with fine interrupted synthetic absorbable sutures. This is not much different than placing a stoma. Many surgeons place closed suction drains under the upper flap before suturing it to the inferior flap. Consider a compressive dressing.

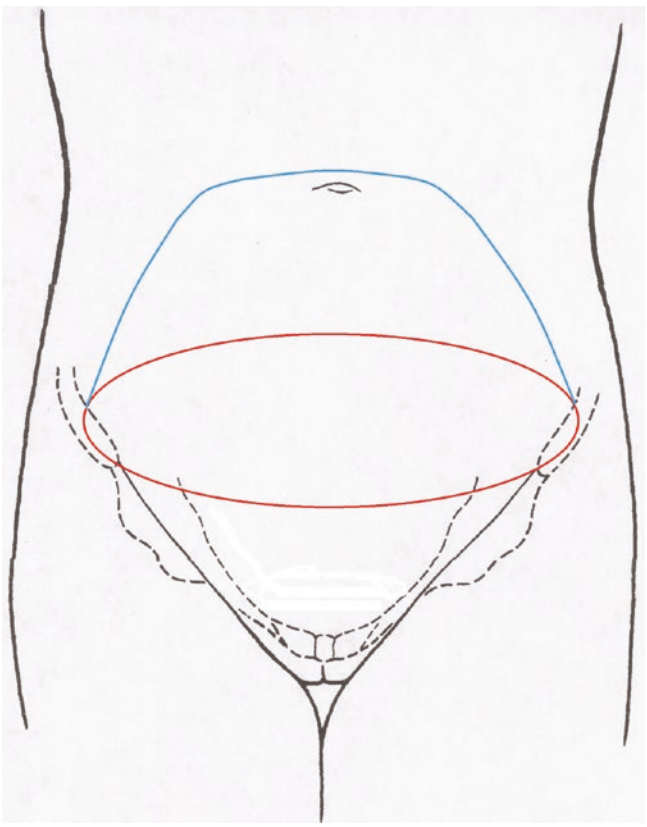

Fig. 84.6 A modest panniculectomy may be performed to enhance exposure or as an adjunctive procedure. The skin incision, shown in red, may be taken below the umbilicus (as shown here) or above the incision. The two ends of the incision generally must be tailored to avoid flaps of redundant tissue or dog ears. Skin, superficial fascia, and fat are removed within the outline of the ellipse so that the underlying musculoaponeurotic layers of the abdominal wall are cleanly seen. Generous undermining (*shown in blue*) is required to allow flap closure. If the umbilicus has not been excised, it will need to be repositioned cephalad (Reproduced with modifications from Scott-Conner [23])

Oblique and Hockey Stick Extensions

To obtain greater exposure at the lateral aspect of a Cherney or Maylard incision, mark a skin incision extending laterally and obliquely slightly cephalad. In the extreme case, the lateral aspect of this incision may be extended upwards in a so-called Hockey-stick configuration. Ligate and divide the deep inferior epigastric vessels (if not already done). Divide subcutaneous tissues and all muscular and aponeurotic layers of the abdominal wall as encountered. Preserve, if possible, any nerves (ilioinguinal or iliohypogastric) that are encountered. Close the medial aspect of the incision in the normal fashion, and the lateral extension in two layers as described below.

Subcostal and Chevron Incision

To make a classic subcostal (Kocher) incision, outline an oblique skin incision approximately 4 cm inferior and parallel to the costal margin on the side of interest. Do not hesitate to extend the incision across the midline if necessary to achieve adequate exposure. Divide the subcutaneous tissue along the same line until fascia is encountered. At the lateral aspect, the 8th thoracic nerve may be encountered and may need to be divided. The larger 9th thoracic nerve should be protected. These nerves are less likely to be injured if the incision is extended medially rather than laterally. Open the anterior rectus sheath and divide the rectus muscle with electrocautery. Take time to secure any small arteriolar bleeders in the muscle belly, as these may go into spasm and rebleed during the postoperative period. Ligate and divide the superior epigastric vessels in the rectus sheath.

The easiest place to enter the abdomen is through the posterior rectus sheath, which is well-developed above the umbilicus. Divide the peritoneum and confirm atraumatic entry. Extend the fascial and peritoneal incision medially and laterally for the full extent of the incision.

These incisions are usually closed in two layers using running synthetic slowly-absorbable suture such as 0 PDS. The first layer incorporates peritoneum, posterior rectus sheath (medially) and transversus abdominis and internal oblique (laterally). The second layer consists of anterior rectus sheath medially and external oblique laterally.

Adhesions

85

Carol E.H. Scott-Conner

As surgeons, we want the abdominal incision to heal securely. If a bowel resection has done, we want the anastomosis to heal without leakage or stricture. These are all good and necessary outcomes from wound healing. We want to avoid hypertrophic skin scar formation and the formation of intra-abdominal adhesions. Unfortunately, the goal of secure wound healing without scar formation, including adhesion formation, remains elusive. Intra-abdominal adhesions form when the raw surfaces created during surgery heal together in an undesired manner. This is the topic of this chapter.

The first part of this chapter gives a brief overview of current knowledge of the pathogenesis of adhesion formation, and then segues into prevention strategies. While this information may seem to be of less value if fertility preservation is not a consideration, adhesions cause substantial morbidity in other ways, so this information is important for all surgeons.

The second part of the chapter deals with strategies for opening the abdomen and lysing adhesions. It includes information on identifying and fixing inadvertent enterotomies and the special surgical considerations involved when radiation enteritis is suspected or possible.

The Magnitude of the Problem

In the developed world, adhesions after previous surgery are the leading cause of small bowel obstruction [1, 2]. The Surgical and Clinical Adhesions Research Study (SCAR) used the Scottish NHS Medical Record Linkage Database to determine that the ten-year risk of readmission for adhesions after open gynecologic surgery was 4.5 % [1]. In a subsequent report, the same group looked at adhesion-related readmissions after gynecological laparoscopy or laparotomy [2]. Caesarian sections were excluded. They analyzed records from 24,046 patients and determined that laparoscopic gynecologic surgery (with the exception of laparoscopic sterilization) did not diminish the risk of subsequent adhesions when compared with open gynecologic surgery [2]. The risk of subsequent readmission was lowest after laparoscopic tubal sterilization procedures, and highest after laparoscopic adhesiolysis or cyst drainage [2]. Thus any intervention in the peritoneal cavity may set the stage for subsequent adhesion formation that may be sufficiently severe as to require later intervention.

Adhesions cause four general types of problems: pain, impaired fertility, small bowel obstruction, and difficult re-entry if second laparotomy required. The extent to which adhesions cause pain is somewhat controversial and beyond the scope of this chapter. Similarly, fertility preservation is not a consideration when hysterectomy is performed (although much of what we know about adhesion prevention comes from the gynecological fertility literature) and will not be discussed here. Thus the two areas of concern that are emphasized in this chapter are prevention of small bowel obstruction (as a complication of adhesions), and difficulty in performing a laparotomy if adhesions are present.

Pathogenesis of Adhesion Formation

As noted above, adhesions form between areas of injury. To a certain extent, they represent the natural healing response. Thus, it is predictable that adhesions will form to the underside of any incision, whether that is a formal laparotomy incision or the stab wounds associated with laparoscopic trocar placement.

Patients who have had remote peritonitis (for example, from a ruptured appendix or perforated duodenal ulcer) will often have adhesions related to that inflammatory process in addition to any adhesions they might exhibit from undergoing surgery. Such adhesions may even form in the complete absence of surgical intervention. A classic example of this would be perihepatic adhesions seen in Fitz-Hugh-Curtis

syndrome as a sequela of previous previous gonococcal or chlamydial infection.

Endometriosis or pelvic inflammatory disease may similarly elicit a fierce inflammatory reaction, including formation of localized adhesions. Such adhesions may cause pain and infertility, and create difficulties in identifying tissue planes in the pelvis. While the general principles outline here are applicable to this situation, the majority of this chapter will deal with adhesions created by previous surgery.

Suspect adhesions any time a patient has undergone previous surgery, including laparoscopic surgery. While laparoscopic surgery eliminates the large raw surface associated with a major laparotomy incision, it may still be associated with local tissue trauma, creation of raw surfaces in the region of dissection, and the implantation of biomaterials.

Be particularly wary of performing laparotomy in patients who have had previous mesh repair of ventral incisional hernias.

Tissue injury and hypoxia cause oxidative stress which increases a variety of inflammatory mediators (Table 85.1) all of which have been implicated in adhesion formation [3, 4]. Unfortunately these mediators are also crucial for normal wound healing; for this reason, systemic or intraperitoneal agents targeting adhesion formation have largely failed. Barrier agents have proven some efficacy and are discussed in the subsequent section.

As fibrinous adhesions form, the fibrinolytic system is activated. A balance is thus created between adhesion formation and resolution (Fig. 85.1).

In addition to tissue injury, biomaterials elicit a "foreign body response" when implanted deliberately (such as when sutures are placed, or mesh used to close a ventral hernia defect) or accidentally (such as lint shed from laparotomy pads or powder from surgical gloves – both of these have been minimized by modern manufacturing processes). The first part of this response consists of a nonspecific protein adsorption phase that is not seen in the normal process of wound healing [5]. Thus, from the earliest phase, reaction elicited to sutures and other biomaterials starts down a pathway toward fibrosis.

Just as scars remodel over time, so do adhesions. General Surgeons traditionally prefer to re-enter the abdomen either very early (within the first week or so) or very late (after 6–12 months) in the postoperative period, in order to mini-

mize problems with adhesions. If surgery has been limited to the pelvis (as, for example, hysterectomy) and the subsequent pathology report reveals an unexpected neoplasm that requires reoperation, gynecologic surgeons should be aware that delay beyond a week or two will make reoperation a bit more difficult. The primary difficulty lies in adherence of loops of small bowel to the incision and to each other. If surgery has been performed through a Pfannenstiel incision and limited to the pelvis, this is less likely to be an issue.

Early in the postoperative period, adhesions are largely fibrinous and loops of bowel may be easily separated without damage to adherent bowel. That early postoperative period rapidly gives way to a phase in which adhesions may be dense, vascular, and difficult to differentiate from bowel.

With time, the adhesions become "mature." During the maturation phase, many fibrinous adhesions probably dissolve, many adhesions become filmy and easy to deal with and others become dense and problematic. It is difficult to predict how adhesions will progress in an individual patient, or which adhesions will progress to dense fibrosis. It appears likely that anything that potentiates and perpetuates the inflammatory part of the cycle (as opposed to fibrinolysis) will lead to locally dense adhesions.

Prevention of Adhesions

A list of tactics for adhesion prevention are given in Table 85.2. First, it is crucial to emphasize general principles of gentle tissue handling. These include sharp dissection with complete hemostasis, avoiding mass ligatures, exposing only the area needed for surgery, and keeping exposed tissues moist. Meticulous hemostasis is important. Accumulation of serum and/or blood triggers fibrin clot formation and subsequent inflammation and fibrosis [6–12].

Second, if possible, place omentum under any upper abdominal incision and interpose it between anastomoses and the incision. Obviously, if omentectomy is part of a cancer operation, this is simply not feasible. But in most other situations omentum is available and should be used. Omentum can also be used to fill dead space and help prevention of fibrin clot formation.

If the omentum does not reach to a surgical site deep in the pelvis, create a vascularized omental pedicle by studying the vascular arcades, ligating the vascular arcade on one side and then developing a long tongue of omentum based upon the preserved arcade. In this manner, omental pedicles long enough to reach the brain have been created, so it can surely be made to reach into the pelvis!

Such an omental pedicle is a useful barrier to interpose between vaginal cuff and rectum, or to place over any bladder repair. Note that the barrier agents described later in this section may actually increase the risk of anastomotic leak and cannot be used for this purpose. Omentum, on the other hand, may help improve the local blood supply.

Omentum does not prevent adhesion formation but helps decrease the chance that a loop of bowel will become densely adherent to the incision or that a fistula between an anastomotic site and the incision will form.

No systemic therapy has proven safe and effective as everything that might potentially inhibit adhesion formation also interferes with wound healing [9]. A variety of agents have been investigated and local intraperitoneal or topical agents that can be applied directly to the surgical field have emerged as the most promising [11].

Instillation of various solutions such as Dextran or heparin into the peritoneal cavity has similarly not been particularly effective [9]. Gels are used for delivery of topical ("barrier") agents during laparoscopic surgery, primarily for fertility preservation. Most studies on these agents use fertility preservation as an end-point and hence may be of less value to the surgeon performing hysterectomy.

Barrier agents are interposed between the raw surfaces (such as the underside of the incision, or the pelvic floor after radical pelvic surgery) and the viscera. Three such agents have emerged as effective. These are: expanded polytetrafluroethylene (PTFE), hyaloruonic acid, and hyaluronate-carboxymethylcellulose membrane (Seprafilm). Studies have also shown that oxidized regenerated cellulose is effective in decreasing adhesion formation but data for prevention of small bowel obstruction is lacking [10].

These are generally available as sheets. They must be cut to size and handled with dry instruments. Careful hemostasis must be attained before placement of the barrier agent. The

[b]Separate closure of the peritoneum has not been shown to decrease adhesion formation. If peritoneum is closed separately, use fine absorbable suture

agent is then carefully and gently introduced over the desired area, such as the underside of the incision or a raw area following pelvic dissection.

Barrier agents are not without problems. PTFE does not dissolve and must eventually be removed; thus its use is primarily limited to ventral hernia repair (where the lack of adhesion formation is a distinct benefit). In one systematic review and meta-analysis, Seprafilm decreased the rate of adhesion formation but increased the risk of intra-abdominal abscess and anastomotic leak [6]. The manufacturer's literature on Seprafilm states that it should not be wrapped directly around a fresh anastomosis, due to data from a post-approval study. A variety of previous studies designed to tackle the separate problem of anastomotic leakage have shown that isolating the anastomosis from the peritoneal cavity by wrapping it with anything other omentum increases leakage. Thus it does not appear prudent to place any of these agents directly against a bowel anastomosis or suture line. It should be noted that more recent meta-analysis did not confirm adverse events directly related to barrier agents, but studies vary in end-points and are often industry-sponsored [12].

Choice of Incision When Adhesions Are Likely

If at all possible, avoid an initial entry through the middle of an old incision. The easiest way to do this is by using an incision that goes in a different direction. Thus, when faced with a scar from an old vertical midline incision, a transverse incision may be an ideal choice. Table 85.3 lists some suggested options for various situations. The most difficult situation is midline re-entry in the setting of a previous long vertical midline incision ("from xiphoid to pubis"). In this situation, re-enter the abdomen through the upper part of the incision. Here you will encounter the left lobe of the liver and the stomach, which are more tolerant of injury and easier to repair than loops of small bowel (which will be encountered as the incision progresses inferiorly).

Of course, cosmetic considerations may dictate reoperation through the same incision. In such a case, it is important to be aware that the procedure may be complicated by local adhesions in the region of the incision.

Consider using ultrasound to map out adhesions to the underside of the incision. The "visceral slide" maneuver has been used to identify adhesion-free areas for laparoscopic trocar placement [12] and can easily be adapted to map out areas relatively free of adhesions under a laparotomy incisions. In this situation, the "adhesion-free" area would be the site chosen for initial entry into the peritoneum.

The visceral slide maneuver is based upon the observation that, in the absence of adhesions to the parietal peritoneal, loops of bowel and any other underlying viscera move a significant distance up and down (cranial and caudad) with respiration. Thus, the ultrasound transducer is placed with the long axis of the transduced parallel to the incision and underlying structures are visualized. With the transducer held steady, the awake patient is instructed to breathe deeply (or the anesthesiologist is asked to manually ventilate the patient in such a manner as to cause exaggerated respiratory excursions. Visceral slide is defined as "craniocaudal movement of the viscera greater than 50 % of the width of the screen, suggesting that the visualized viscera moved in an unrestricted manner" [13]. Several videos are available on YouTube under the topc "Visceral Slide", of which the one referenced by Minaker et al. [13] was accessed here (https://www.youtube.com/watch?v=dIyZ8Rd1T1E&feature=youtu.be) on September 19, 2015.

Table 85.3 Choice of incision in previously-operated abdomen

Old incision	Region desired to access	Options
Vertical midline or paramedian	Pelvis	Cherney, Maylard, or Pfannenstiel
Low vertical midline	Entire abdomen	Long vertical midline with initial entry through upper half of incision
Long vertical midline	Entire abdomen	Long vertical midline with initial entry through upper half of incision (over liver) Long vertical midline with ultrasound adhesion mapping to define best entry site
Upper abdominal vertical midline or paramedian	Pelvis	Low vertical midline Pfannenstiel, Cherney, or Maylard
Upper abdominal vertical midline	Entire abdomen	Long vertical midline with initial entry through lower half of incision
Long vertical midline or upper abdominal midline	Upper abdomen	Upper abdominal transverse incision such as a Kocher or chevron incision Re-enter old incision, consider ultrasound mapping
Upper or lower abdomen paramedian incision	Entire abdomen	Incorporate old paramedian in part of a long vertical midline incision to avoid "parallel incisions"

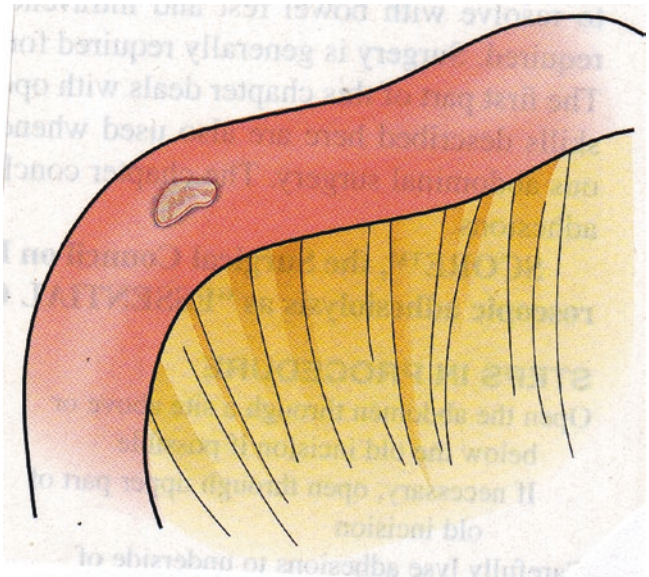

Fig. 85.2 A small button of peritoneum or fascia may be left adherent to small bowel if necessary (From: Scott-Conner [19], Fig. 88.1b with permission)

Lysis of Adhesions

As noted above, make the initial entry into the abdomen through an area likely to be free of underlying adherent small intestine. Tactics for this are described above. Generally, adhesions will be most dense along the line of the previous incision. Thus, once entry into the peritoneum is accomplished, gentle exploration of the underside of the incision both visually and by digital palpation helps establish the extent of the problem.

Do not attempt to open the entire extent of the fascial incision at once. Rather, having entered through a safe area, gradually extend the fascial incision as adhesions are lysed. Sometimes this is easily done, but at other times great patience is required. Do not hesitate to leave a small amount of peritoneum, scar tissue, or even a bit of old suture material adherent to a loop of densely adherent small intestine (Fig. 85.2). This is far preferable to chancing an intestinal injury by meticulously trying to separate bowel from incision.

Have an assistant elevate the abdominal wall by placing Kocher or Allis clamps on the edge of the fascia. You can then work under the fascia to take down adherent loops of bowel (Fig. 85.3).

Avoid use of electrocautery and use sharp dissection with Metzenbaum scissors or scalpel. When adhesions are very dense, sharp dissection by shaving a layer of abdominal wall off and allowing it to remain adherent to the bowel is the best approach. A scalpel is the best tool for this type of dissection.

If possible, pass a finger or two behind the loop of bowel and gently pull downwards as you work (Fig. 85.4). Be aware that the adhesion may have a greater tensile strength than the adherent small bowel. Do not tear the small bowel by pulling too hard on it.

Once the entire length of the incision is open and all adhesions to abdominal wall have been lysed, proceed with exploration as planned. It may not be necessary to lyse all remaining adhesions. Remember, adhesions form to areas of injury, so adhesiolysis is apt to result in formation of more adhesions.

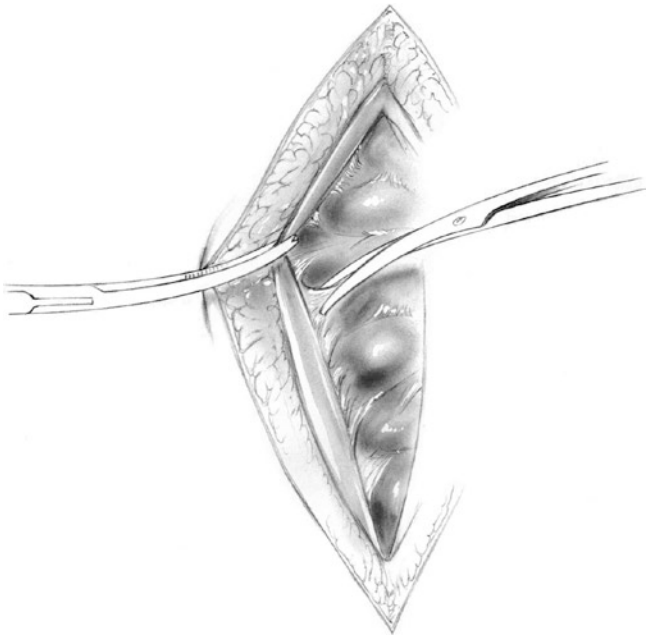

Fig. 85.3 With an assistant elevating the abdominal wall, sharply lyse underlying adherent loops of bowel (From: Scott-Conner [20]. Fig. 44.1 with permission)

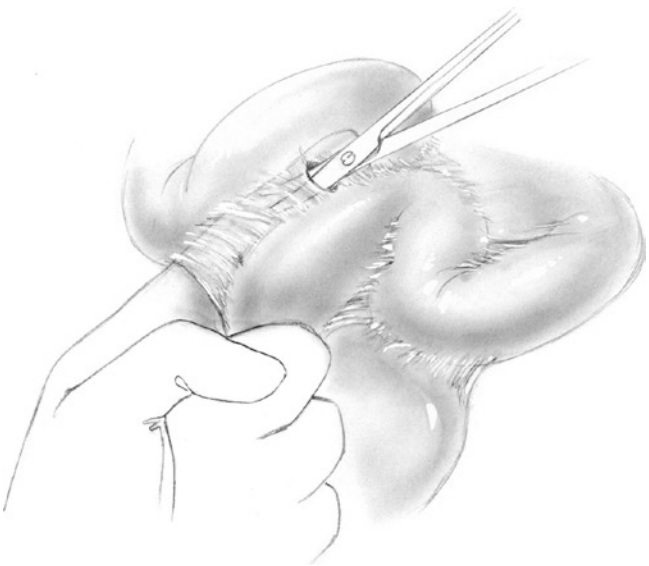

Fig. 85.4 Pass a finger behind adhesions, if possible, to define them better. Then sharply lyse the adhesio. (Scott-Conner [20]. Fig. 44.3 with permission)

Keep in mind the basic purpose of your operation, and only lyse those adhesions relevant to that purpose. In other words, if you enter the abdomen planning to do a radical hysterectomy for endometrial carcinoma and encounter a cocoon-like encasement of most of the small intestine by adhesions from previous surgery, consider carefully whether lysing these adhesions is important to your cancer surgery. Do not lyse adhesions simply because they are there.

An exception might be band-like adhesions from abdominal wall to underlying viscera or between loops of viscera; these can be sites for future small bowel obstruction due to internal hernia formation. Such bands are easily divided.

Dealing with Inadvertent Enterotomies

Unfortunately, even with the best surgical technique, the bowel is sometimes injured. This is most likely to happen during entry into the abdominal cavity. Injuries may be partial thickness or full thickness.

A difficult situation arises when bowel is injured early in the initial phases of laparotomy, when the loop of intestine is only partially exposed and often still adherent to the underside of the abdominal wall. Liquid small intestinal contents (succus entericus, or succus) pour out freely. Anticipate this possibility and have suction and laparotomy pads readily at hand so that succus can be contained. The hole is likely to get larger as the loop of bowel is freed. Try to limit the extent of injury by continuing your careful dissection. If necessary, put a stitch in to control the flow of succus but do not attempt repair until the loop is completely freed. A limited injury to the antimesenteric surface of the bowel (the commonest site) may be repaired transversely with the gastrointestinal suturing technique of your choice. There is much to be said for the security of an old-fashioned hand-sutured two-layer repair in this situation.

While it is beyond the scope of this chapter to describe techniques for bowel anastomosis, these are well-described in standard textbooks of general surgery. The surgeon who is not confident in the use of these techniques is urged to consult a more experienced colleague if bowel repair is required.

If a segment of bowel has multiple injuries or is otherwise battered, a limited segmental resection with primary anastomosis is a good choice. Here surgical staplers may speed resection and closure.

Partial thickness injuries may or may not require repair. If the injury extends into or through the submucosa, repair is prudent. Assess this by gently squeezing the loop of bowel to cause the segment with the injury to balloon out (Fig. 85.5).

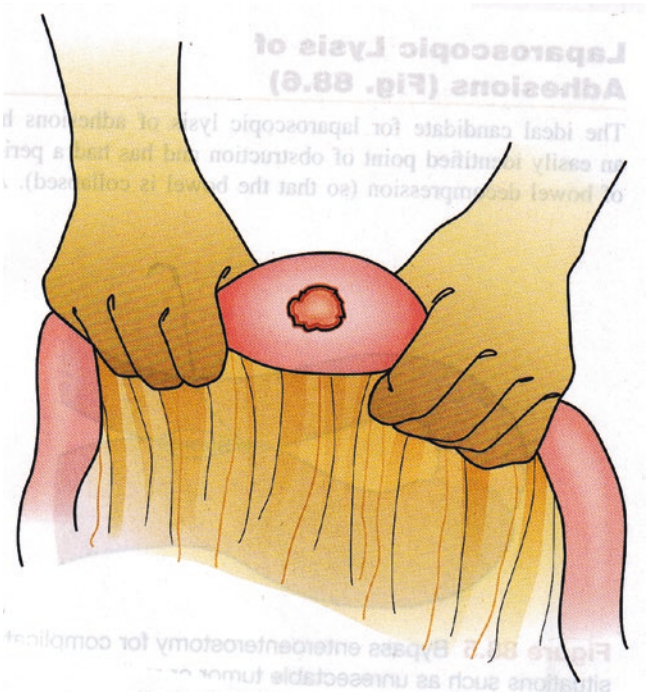

Fig. 85.5 A partial thickness injury requires repair if it "balloons" out when the segment of bowel is squeezed (From: Scott-Conner [19], Fig. 88.3a with permission)

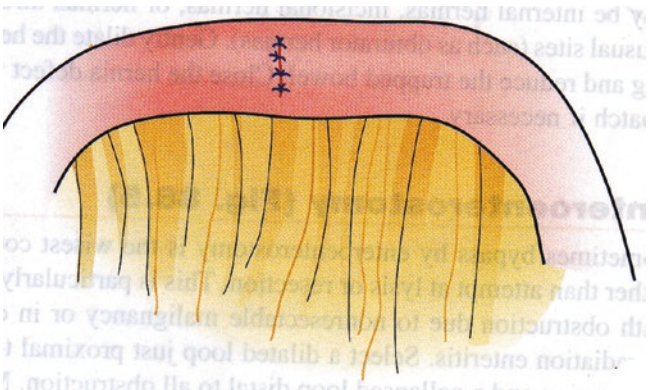

Fig. 85.6 Repair a partial-thickness bowel injury with several interrupted sutures that reapproximate the outer layers of bowel (From: Scott-Conner [19], Fig. 88.3b with permission)

If the injured area protrudes beyond the contour of the bowel, then the injury is deep and should be repaired. Do this with a couple of simple interrupted sutures placed in such a manner as to reapproximate the outer layers of the bowel (Fig. 85.6).

If a partial thickness injury does not balloon out, it may not require repair. However, in any doubtful situation, it is better to repair than to risk delayed perforation.

Radiation Enteritis

Radiation damages healthy tissues, including bowel. Acute radiation effects, and tactics for prevention of radiation injury are beyond the scope of this chapter. The important thing to recognize is that radiation damage to the small intestine and adjacent tissues is a chronic, progressive condition. Be wary when operating upon any patient who has a history of pelvic radiation.

The "magic window" for operating within a radiated field is very narrow; only about 6–8 weeks after radiation therapy has been completed. This is the time interval classically employed for planned resection after radiation has been administered, for example when low anterior resection of the rectum is done after radiation with or without chemotherapy. After this time, surgery becomes slowly but inexorably more difficult and more dangerous as the late effects of radiation dominate the clinical picture.

The late effects of radiation include tissue fibrosis and obliteration of small blood vessels causing a progressive obliterative endarteritis. A vicious cycle is established in which the resulting ischemia potentiates the formation of additional fibrosis, thus worsening the ischemia; and any new vessels and lymphatics that form are telangiectatic and dysfunctional [14, 15].

For the surgeon, normal tissue planes may be lost, and radiated tissue does not heal well. For the gynecologist, the tissues of concern are primarily small intestine and ureter. An additional consideration is that dead space created during dissection may not fill in normally, and a vascularized flap (such as rectus muscle) may be necessary.

All of this implies that entry into the abdomen and adhesiolysis must be undertaken with special care. An inadvertant enterotomy in radiated bowel creates the potential for devastating complications. Simple repair of an enterotomy made in radiated bowel is unlikely to heal well, and segmental resection with primary anastomosis in unaffected bowel is the best approach. Sometimes it is easy to determine the most severely affected bowel by its thickness and fibrotic appearance, but not always [16–18].

Often, when the previous radiation was pelvic, the area affected is the terminal ileum, and it is fairly well demarcated. In other cases, the delineation between normal and radiated bowel can be difficult to ascertain. The surgeon must strike a balance between preservation of small bowel length and desire to create an anastomosis in "normal" bowel.

The largest experience with radiation enteritis comes from specialized teams doing planned bowel resection when other treatment has failed [16–18]. Surgery of this kind is appropriately viewed as a last resort. Their experience suggests that anastomotic leakage can occur in up to 30 % of patients undergoing resection, with 40–60 % of patients requiring repeat surgery. Careful preoperative preparation, including correction of nutritional deficits, smoking cessation, physical therapy, and use of a critical path detailing the preoperative and postoperative management have improved results somewhat. Hyperbaric oxygen treatment has been used to assist healing, although benefit is difficult to prove [16–18].

Comorbidities and Abdominal Hysterectomy

86

Katherine Nixon and Christina Fotopoulou

Pre-admission Review

Before any planned hysterectomy it is advisable for patients to be seen in a pre-admission clinic. In this setting their medical history can be established and any pre-operative investigations carried out. For the majority of patients, planned for abdominal hysterectomy due to a malignancy, it is recommended to check a full blood count, renal profile, liver profile and clotting, plus have a valid group and save or cross match available for the day of surgery. In the case of ovarian malignancy where neo-adjuvant chemotherapy has been used, it is vital to know when the last cycle of chemotherapy has been given and have an up to date white cell- and neutrophil level as these may be reduced. Albumin level may also be low as a reflection of nutritional status and fluid balance; this may affect intra and post-operative fluid management. An ECG is usually performed to pick up possible pre-existing cardiac conditions and if there is suspected respiratory disease, lung function tests may also be recommended along with a chest xray. Any concerns should be raised with the surgical and anaesthetic teams involved.

Key Points

1. Be pro-active with investigating and optimizing patients' condition pre-operatively
2. Involve multi-disciplinary team with the planning of procedures

Obesity

Patients who are overweight or obese have a significantly higher risk of complications peri- and post operatively. High BMI can affect both the practicalities of the procedure and the medical outcomes for the patients involved. A multidisciplinary approach is needed to help these patients on their surgical pathway. Patients should be weighed either in clinic or on admission to the ward and theatre staff need to be informed in advance if a patient is significantly overweight, to ensure the correct theatre bed and transport trolleys are used. Different equipment may be needed by the surgical team e.g. longer instruments for the deeper pelvis or larger retractors. From an anaesthetic point of view, obesity provides obstacles with IV access, medication dosing and response, ventilation and monitoring. Increasing weight has been shown to trend with higher risk of surgical complications such as bleeding and injury to surrounding structures.

Post operatively there is a larger incidence of Deep venous thrombosis and pulmonary embolus amongst the overweight population undergoing abdominal hysterectomy. During surgery it is therefore recommended to provide prophylaxis with either TED stockings or ideally devices such as Flowtron boots. Post-operatively therapeutic prophylaxis with low molecular weight heparin should commence as soon as deemed clinically safe. Early mobilization is important and physiotherapists can help with this on the ward.

Obesity also has an associated increased risk of wound breakdown and infection post abdominal hysterectomy [3]. This may affect the type and position of abdominal entry and closure method. It is important to avoid abdominal folds in the presence of a pannus where possible as this will be the area most likely to be colonized with bacteria and yeasts. Fast absorbable sutures with antibacterial coating agents such as Tricosan decrease wound infection rates and do not appear to increase the hernia rate, after midline abdominal incision, compared with slowly absorbable sutures [1]. The development of incisional hernia is significantly increased in patients with a BMI > 30 kg/m^2.

Specialised wound care post-operatively is essential to decrease the risk of infection. Tissue viability is a concern

with all surgical patients but especially the obese and specialist teams can be used to help prevent skin breakdown and pressure sores.

Key Points
1. High BMI increases surgical complications
2. MDT involvement essential e.g. tissue viability, physiotherapists
3. VTE prophylaxis with low molecular weight heparin, early mobilisation

Diabetes

Linked to rising obesity levels are increasing rates of type 2 diabetes [2]. These patients may require more input pre, peri and postoperatively. Cardiac events are more likely to occur in this group of patients therefore they should always have had an ECG prior to surgery. Blood sugar control may be affected by being nil by mouth for surgery therefore, where possible, these patients should be operated on first thing. Intra-operatively blood sugars should be monitored and it may be necessary to start an insulin sliding scale which should be continued until eating and drinking can be resumed post-operatively and normal medication regimes recommenced.

Incidence of diabetes is increased in postmenopausal women, due to the lack of ovarian affect on glucose uptake and insulin sensitivity [2]. The additional performance of bilateral salpingoophorectomy (BSO) at the time of the hysterectomy in premenopausal women may negatively impact the overall hormonal axis, therefore women with diabetic predisposition may be at higher risk of developing insulin resistance and, subsequently, diabetes. Review of diabetic status may be advised in follow up.

Cardiovascular studies have also shown that, after surgery, young premenopausal women who had undergone BSO had higher levels of atherogenic and stress-induced lipids. They also tended to have higher circulating levels of epinephrine and stress-induced systolic and diastolic blood pressure compared to women who had undergone hysterectomy only. This is consistent with the hypothesis that presence of ovarian hormones plays a key role in determining a woman's risk factor status [4].

Key Points
1. Be conscious of at risk populations for pre-operative assessment and post operative follow up

Anaemia and Blood Transfusion

Transfusions are more common amongst patients having open procedures generally but especially in the presence of malignancy. Patients are often anaemic beforehand and with the presence of masses, large debulking procedures and potential clotting derangement the need for a transfusion is likely to increase. All patients undergoing hysterectomy should be consented for transfusion prior to surgery. In cases of patients refusing transfusion like in the case of Jehovas witnesses, the case should be discussed with all members of staff involved to ensure an appropriate and safe management plan is agreed upon. The patient's wishes regarding all blood products should be obtained and documented clearly, patients may have a written advanced directive confirming which if any blood products they will accept.

In cases where transfusion is refused, haemoglobin levels should be optimized as much as possible pre-operatively, testing for deficiencies with bloods for haematinics can be useful in guiding prescription of folic acid, ferrous preparations or B12. In the absence of malignancy and if auto--transfusion is accepted by the patient, Cell Saver® equipment should be organized and on standby in theatre if available.

Intra-operatively, the use of diathermy equipment for dissection and coagulation is advised in order to reduce blood loss; this can also be aided through administration of antifibrinolytic medications such as Tranexamic Acid. Use of haemostatic agents like Floseal® or Tachosyl® may also help.

Key Points
1. Discuss transfusion with all patients and discern their wishes
2. Optimise pre-operative haemoglobin
3. Use of intra-operative techniques for haemostasis

Respiratory Diseases

Identifying pre-existing comorbidities is vitally important both for the surgeon but also for the anaesthetic team. Abdominal hysterectomy is a major procedure and can take from less than one to several hours depending on the extent of surgery required. Respiratory conditions (such as COPD, asthma or fibrotic lung disease) can affect ventilation during the surgery, increase the risk of hospital acquired pneumonia and prolong recovery and hospital stay. Pre and post procedure it may be recommended for patients to have nebulisers, any regular inhalers should be prescribed and their use encouraged. Specialist chest physiotherapists and use of

incentive spirometry on the ward may help to reduce the risk of post-operative atelectasis and infection.

Preoperative ergometry exercises can additionally quantify and predict the level of stress that a patient might tolerate postoperatively.

Key Points

1. Pre-operative involvement of Anaesthetists and recommended investigations
2. Post-operative use of physiotherapists and spirometry equipment to improve respiratory function

Radical Surgery

A radical hysterectomy may be recommended for patients with early stage cervical cancer. This procedure involves removal of the uterus, cervix, top of the vagina, and as much parametrial tissue as possible ± pelvic and para-aortic lymph node dissection ± bilateral salpingoophorectomy.

All abdominal hysterectomies can be complicated by previous surgery, the presence of endometriosis or previous infection which may have caused adhesions. These will increase the risk of surgical complications and this is more apparent in radical surgery where navigation of the abdominal planes is vital for operative safety and outcome.

Because of the location and extensive nature of the surgery, ureteric injury is more common than with a routine extra fascial hysterectomy. Ideally, these injuries will be recognized at the time of surgery and repair/stenting can take place straight away, alternatively, if not noticed they may present post-operatively. One should be suspicious of a ureteric injury in the presence of deranged renal function, haematuria or reduced urine output post op.

Bladder dysfunction is also significantly increased in this population of patients compared to routine hysterectomy due to denervation of the bladder. Either an indwelling or suprapubic catheter should be left in the bladder for the immediate post-operative period. Patients unable to void or with high residual urine volumes following removal of their catheter may need to have the indwelling catheter replaced for a longer time period or carry out intermittent self catheterisation. Most voiding difficulties will resolve within 2–3 weeks.

With radical surgery, especially when used in conjunction with radiotherapy, although a rare complication, there is an increased frequency of uretero-vaginal/vesical fistulas which can cause significant morbidity to patients' bladder and sexual function. Studies investigating sexual dysfunction following radical hysterectomy, looking at different factors both physical and mental, have found that although sometimes present in the post-operative period it is short lasting and less severe than experienced by patients undergoing radiotherapy [5].

Key Points

1. Radical surgery may be indicated for certain conditions
2. The extent of the surgery should be discussed with patient and balanced against potential complications/comorbidites and resultant quality of life
3. Bladder dysfunction is the most common complaint following radical surgery

Advanced Age

Decreased physiologic reserve and increased number of underlying medical disorders affecting the older patient cohort results in a basic elevated risk for intra- and postoperative complications. This is evident in cases of large uterus, with high intra-operative blood loss and in the presence of additional risk factors like malignancy. Various preoperative assessment scores, for the elderly, have been developed, however, none has so far been validated for the gynaecological population or for the hysterectomy procedure. A preoperative geriatric assessment tool, commonly used for elderly women with endometrial cancer planned for abdominal hysterectomy, is PACE (Pre-operative assessment of cancer in the elderly) [6]. This should be routinely incorporated into the pre-operative evaluation and operability assessment of elderly patients, prior to indication for surgery, in order to balance the risks and benefits of the procedure in this more fragile population.

Final Points

All surgical procedures require a multidisciplinary approach to ensure the right patient is receiving the right care. Pre-existing conditions may influence the management before admission and the type of procedure planned. It is important to know both the patient's medical history and social situation pre-operatively to help predict how they might behave clinically and psychologically post-operatively.

Patients must be counselled thoroughly about the benefits and risks of the procedure. Patients with little support at home may require longer hospital care, or transfer for

respite care during their recovery. Patients who are more frail from medical conditions or age may not be suitable, from a performance status point of view, for more radical procedures and this must be discussed with them and possible alternatives offered, as surgery in these cases could reduce quality of life whilst not prolonging it. Patient centred care should be the focus of management and surgical planning.

Subtotal Abdominal Hysterectomy

87

Zouhair Amarin

Introduction

Anatomically, the uterus consists of two parts, the uterine body and the cervix. A total hysterectomy involves the removal of both the uterine body and the cervix; a subtotal hysterectomy involves the removal of only the uterine body, leaving the cervix insitu (Fig. 87.1). Subtotal hysterectomy is also referred to as supracervical hysterectomy.

The first abdominal hysterectomy, a subtotal operation, was performed by Charles Clay in Manchester, England in 1863, unfortunately the patient died [1, 2]. Subtotal hysterectomy remained the standard type until the late 1920s, when total abdominal hysterectomy was introduced in 1929 by the American surgeon E. H. Richardson, to avoid serosanguinous discharge from the cervical stump and development of carcinoma of the cervix [3]. Subsequently this method became the predominant way of removing the uterus for both malignant and benign disease of the uterus [4–7].

In the last three decades, there has been some evidence of a shift from performing total abdominal hysterectomy to subtotal abdominal hysterectomy as a less invasive procedure for treating benign gynaecological disorders [8–13].

Abdominal hysterectomy, total or subtotal, is the most commonly performed major gynecologic operation [14], and is the second most frequently performed surgical procedure (after cesarean section) for women who are of reproductive age [15]. There is considerable variation in rates between countries, ranging between 1.2 per 1000 and 5.4 per 1000 women [16, 17]. Almost 20 % of women will have a hysterectomy by the age of 55 years [10, 18]. The rates of hysterectomy for benign indications are decreasing. Uterine leiomyoma remains the most common benign indication for hysterectomy [19].

Hysterectomy is usually highly effective in curing serious conditions. A substantial number of women have marked improvement in their symptoms following hysterectomy, as well as significant improvement in their overall physical and mental health [20], but like any other surgery, hysterectomy has certain risks and side effects [21]. In the treatment of menorrhagia, hysterectomy is associated with a decrease in lower abdominal pain, but has no beneficial effects on back pain [22].

It has been suggested that hysterectomy may disrupt the blood supply to the ovaries. Research demonstrated that the postmenopausal ovary remains a critical source of androgen throughout the lifespan of older women. The clinical consequences of lower testosterone levels years after oophorectomy are unknown [23].

Estrogen levels fall sharply when the ovaries are removed at hysterectomy. This is often referred to as "surgical menopause". It has been shown that risk of subsequent cardiovascular disease is substantially increased for women who had hysterectomy before the age of 50 [24, 25]. Other studies have found that osteoporosis and increased risk of bone fractures are associated with hysterectomies [26, 27]. "Surgical menopause" before the age of 45 is associated with a fivefold mortality from neurologic and mental disorders [28]. Reconsideration of prophylactic oophorectomy at hysterectomy has been suggested [23].

The risk of vaginal prolapse is approximately doubled after hysterectomy, total or subtotal [29]. There are some reports of an increased risk of the relatively rare renal cell carcinoma after hysterectomy [30]. The increased risk is more prevalent in young women, and may be related to an undiagnosed hereditary leiomyomatosis and renal cell cancer syndrome. On extremely rare occasions, sexual intercourse after total hysterectomy may cause a transvaginal evisceration of the small bowel [31].

Despite the prevalence of hysterectomy for treatment of benign gynecologic conditions, providers worldwide have been adopting minimally invasive surgical techniques. Surgical practice is being transformed from primarily open hysterectomy to traditional laparoscopic and minimally invasive hysterectomy, for all types; total, subtotal and vaginal hysterectomy; with a dramatic increase in the percentage of

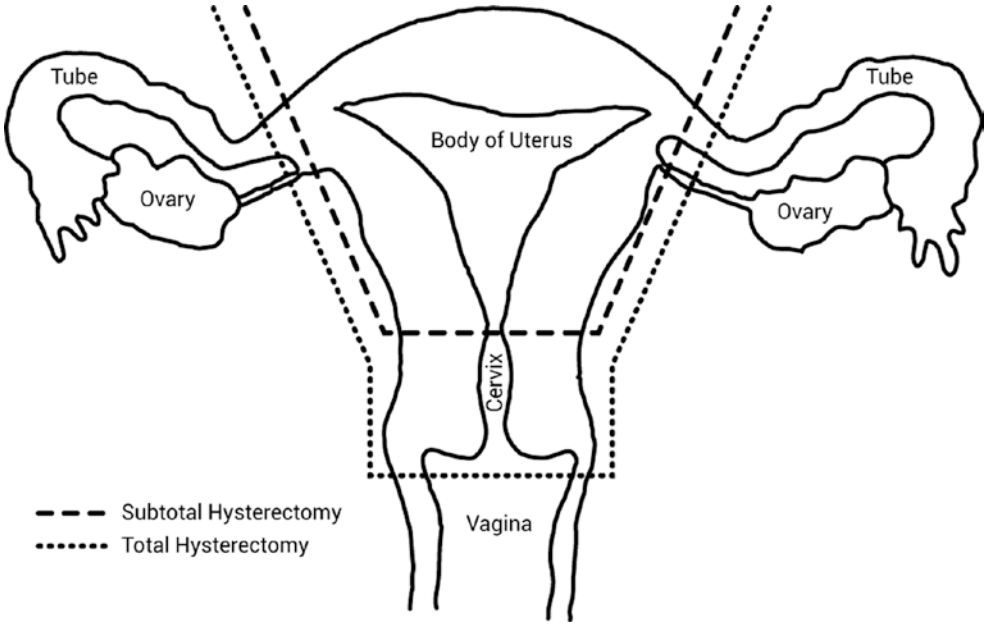

Fig. 87.1 Diagram showing difference between subtotal and total hysterectomy

robotically assisted hysterectomies. This paradigm shift is fueled by patient demand. Laparoscopic surgery is now the primary modality for performing hysterectomy amongst minimally invasive subspecialists. In some centres, the majority of hysterectomies are performed as outpatient procedures [32, 33].

Subtotal hysterectomy may be preferable to total hysterectomy because it may be technically easier to perform. Excising the uterine cervix at total abdominal hysterectomy is anatomically the most disruptive part of the operation since it disrupts the local nerve supply and anatomical relationships. Subtotal abdominal hysterectomy requires less mobilization of the bladder and less risk of injury to the ureters. It is also associated with less anatomical disruption, and perhaps, is associated with less adverse effects than total hysterectomy.

A meta-analysis of 34 studies comparing total and subtotal abdominal hysterectomy found that the operation time, peroperative bleeding, and postoperative complications were significantly lower in subtotal hysterectomy [34].

A randomised controlled trial of total compared to subtotal hysterectomy with 1 year of follow up, subtotal abdominal hysterectomy had a shorter operation time and less perioperative bleeding than total abdominal hysterectomy. Median operation time was 70 min (range: 34–165 min) for the subtotal abdominal hysterectomy group, and 85 min (range: 35–255 min) for the total abdominal hysterectomy group. The median per-operative bleeding was 250 mL (range: 10–2500 mL) for the subtotal abdominal hysterectomy group and 400 mL (range: 25–4500 mL) for total abdominal hysterectomy group [35].

After subtotal abdominal hysterectomy, residual amounts of endometrial tissue would be associated with cyclical vaginal bleeding in premenopausal women where the ovaries have been conserved. To prevent this, most gynaecologists advocate routinely "reverse conization" of the cervix, followed by endocervical cautery to ablate the cervical epithelium down to the transformation zone. In the author's series, utilizing this approach in subtotal abdominal hysterectomy, there have been no cases of cyclical vaginal bleeding in women whose ovaries were conserved, or in those who were prescribed combined hormone replacement therapy [36].

The concern that cancer might develop in the cervical stump should not be considered a justification for routine use of total abdominal hysterectomy as continued screening would cover this concern, considering that the risk of cervical cancer after subtotal abdominal hysterectomy is less than 0.1 % [37]. Nevertheless, after subtotal abdominal hysterectomy, women need to have regular Papanicolau smears testing and a minority of women may experience slight cyclical bleeding [35].

Abdominal hysterectomy is often combined with bilateral oophorectomy. Evidence is lacking to guide hormone replacement prescription following subtotal abdominal hysterectomy and bilateral oophorectomy [38]. Until such evidence become available, it is felt that hormone replacement therapy should include progesterone.

Although hysterectomy has been performed for over 150 years, an area of persistent controversy is whether the subtotal procedure, when the cervix is conserved, confers any benefits over total hysterectomy. Debate rages among gynaecologists themselves as to whether there are any benefits of one procedure over the other, hence the wide global variation in the comparative rates of subtotal and total hysterectomy.

In a survey regarding the attitude and practice of gynecologists to subtotal versus total abdominal hysterectomy, almost half of respondents always removed the cervix. The

Mortality

indication being the future risk of cervical cancer. The most common reason for subtotal hysterectomy was the intraoperative surgical difficulty. Few counseled women regarding the advantages and disadvantages of either total or subtotal hysterectomy [20, 39].

To compare the short-term and long-term outcomes of subtotal hysterectomy with total hysterectomy for benign gynaecological conditions, the main objectively measurable parameters of morbidity and mortality are listed in Table 87.1.

In general, the majority of studies demonstrate that the quality of life does improve from baseline (before surgery), regardless of the type of surgery. Many women feel that without the symptoms and trouble for which they have had the operation in the first instance, their life is improved thereafter [20, 22].

Urinary Function

Injury to the urinary tract is a frequent cause of litigation after total abdominal hysterectomy [40]. It occurs in 0.5–3.0 % of cases [41]. There is a lack of evidence from randomized controlled trials regarding ureteric or bladder injuries following subtotal abdominal hysterectomy compared to total abdominal hysterectomy. As probably would be expected, if such a difference does exist, it would be in favour of subtotal abdominal hysterectomy.

There is no evidence of a significant difference in the post-operative prevalence of stress incontinence, urinary urgency, urinary frequency, nocturia, urgency incontinence, poor stream, interrupted stream, and incomplete emptying between subtotal hysterectomy and total hysterectomy [42–44].

Urinary incontinence and vaginal prolapse may develop 10–20 years after hysterectomy, total or subtotal [45]. The risk for urinary incontinence is approximately doubled within 20 years after hysterectomy, with 2.4 fold increased risk for surgery for urinary stress incontinence following hysterectomy in general [46, 47].

Bowel Function

There is no evidence of a difference in the rates of constipation or incontinence of stools between the abdominal subtotal and total hysterectomy [43].

Sexual Function

The majority of women report improvement in sexual life after hysterectomy for benign indications, total or subtotal. A smaller proportion of women report worsening of sexual life [48]. Some patients who undergo a hysterectomy for chronic pelvic pain may continue to have the same problem after hysterectomy, total or subtotal, and may develop dyspareunia [49].

The frequency of intercourse, desire for intercourse, orgasm frequency, initiation of intercourse, dyspareunia and overall sexual outcome did not differ significantly between subtotal abdominal hysterectomy versus total abdominal hysterectomy [50–54].

Women contemplating a vaginal, laparoscopic, or abdominal hysterectomy for the management of benign uterine disease should be reassured that hysterectomy is usually associated with improved quality of life, including improved sexual function, whether or not the cervix is removed [42, 53, 55].

Quality of Life and Psychological Outcome

In general, women show improvement following both total and subtotal hysterectomy, with no significant differences between them in the amount of anxiety, depression, somatic symptoms and social function, between baseline (before surgery) and post-operative measurements [42].

Operation Time

The length of time required for surgery is significantly shorter for subtotal abdominal hysterectomy when compared with total abdominal hysterectomy [43, 44, 56]. The blood loss is significantly less in subtotal abdominal hysterectomy compared with total abdominal hysterectomy. In a randomised controlled trial of total compared with subtotal hysterectomy with one-year follow up results of 11 departments of obstetrics and gynaecology in Denmark, the median operation time was 70 min (range: 34–165 min) for the subtotal abdominal hysterectomy group and 85 min (range: 35–255 min) for the total abdominal hysterectomy group, $P < 0.0001$]. The median per-operative bleeding was 250 mL (range: 10–2500 mL) for the subtotal abdominal hysterectomy group and 400 mL (range: 25–4500 mL) for the total abdominal hysterectomy group ($P < 0.0001$) [27].

A meta-analysis of 34 studies comparing total and subtotal abdominal hysterectomy found that the operation time, peroperative bleeding, and postoperative complications were significantly lower in subtotal hysterectomy [35].

Perioperative and Postoperative Morbidity

In a study by the author to assess the morbidity of hysterectomy, 134 patients undergoing hysterectomy for benign gynaecological conditions were retrospectively analyzed, of which 90 (67 %) had total abdominal hysterectomies, and 44 (33 %) subtotal abdominal hysterectomies.

Menorrhagia constituted the commonest indication for both types of procedure (89.5 %). The majority of patients undergoing total abdominal hysterectomy (79 %) were given prophylactic antibiotics, in contrast to only 32 % of those undergoing subtotal abdominal hysterectomy [57].

The incidence of short term complications that included post-operative pyrexia, urinary retention, blood loss, hematoma formation, need for post-operative analgesia, low post-operative haemoglobin levels, blood transfusion, wound infection, wound re-suturing, urinary tract infection, and presence of vaginal vault granulation tissue for subtotal abdominal hysterectomy were lower than those for total abdominal hysterectomy. On the other hand, there was a higher incidence of abscesses, wound infection, pyrexia, use of antibiotics and longer hospital stay in the total-hysterectomy group [57].

With regard to intermediate and long term outcomes, there is no evidence of significant differences in the rates of persistent pain after discharge, pelvic prolapse or gynaecological cancer between the two types of hysterectomy. Less than 10 % of the subtotal abdominal hysterectomy patients experience cyclical vaginal bleeding [41].

Hysterectomy is a common, routine operation with comparatively rare serious complications. However, younger women, women with more vascular pelvis, who undergo hysterectomy, are at most risk of experiencing severe complications both intraoperatively and postoperatively, with a crude mortality rate of 3.8/1000 (2.5–6.4) [58]. The mortality rates for hysterectomy associated with pregnancy or cancer, standardized for age and race, are higher than for procedures not associated with those conditions. Hysterectomies associated with pregnancy or cancer constitutes around 10 % of all hysterectomies, but the majority of deaths occur among this category of patients [59]. As mortality at abdominal hysterectomy is such an infrequent event, there are no meaningful statistical comparisons comparing mortality of subtotal abdominal hysterectomy versus total abdominal hysterectomy.

Hysterectomy is occasionally performed as a peripartum procedure. Although uncommon in modern obstetrics, peripartum hysterectomy is mostly performed as an emergency procedure to control torrential life-threatening haemorrhage as a life-saving procedure [60–62].

Peripartum hysterectomy can be defined as the removal of the corpus uteri alone or with the cervix at the time of a caesarean section, or within the puerperium. The operation may be performed as an emergency or as a planned procedure [61, 62].

Despite advances in medicine and surgery, peripartum hysterectomy is associated with high rates of morbidity and mortality, with considerable differences in its incidence in different parts of the world, with higher figures in low-resource countries, while developed countries generally report lower rates [62, 63].

Emergency peripartum hysterectomy is more common following caesarean section than vaginal deliveries, with a significant association between emergency peripartum hysterectomy and previous caesarean section and placenta pre-

via. There is an increased incidence of previous caesarean section in patients with placenta previa and in patients with adherent placenta [64–74].

Worldwide, the incidence of emergency peripartum hysterectomy is rising. This is due to the rising caesarean section rate, and the concomitant rise in malplacentation and multiple births [75, 76].

Elective peripartum hysterectomy may be performed in women with an antepartum diagnosis of placenta accreta or stage IA2, IB1 and IIA1 cervical carcinoma [77]. Severe postpartum infection unresponsive to antibiotic therapy and placental site vessel subinvolution are potential indications for the procedure [78, 79].

Adequate resuscitation and prompt decision making for hysterectomy would contribute to decreasing maternal morbidity and mortality. Time is critical in decreasing the likelihood of coagulopathy, severe hypovolemia, hypothermia, and acidosis [80].

For peripartum hysterectomy, an experienced senior obstetrician with an experience in obstetric hysterectomy should be present at surgery. Of concern however, is the limited experience of performing emergency hysterectomy among some obstetricians. Emergency peripartum hysterectomy being performed by an experienced senior obstetrician would significantly reduce operating time, blood loss, number of units of transfused blood and maternal morbidity [81–83].

Patients at risk of caesarean hysterectomy should be scheduled for delivery at a time when appropriate ancillary staff with high-risk anesthetists, interventional radiologists and urologists are readily available [84]. Women should be counseled about the procedure, issues related to ovarian conservation and possible need for recovery in an intensive care unit. Some women that receive an emergency peripartum hysterectomy are primigravid. The fertility-ending nature of emergency obstetric hysterectomy can be devastating [85].

Peripartum hysterectomy may be either subtotal or total. Subtotal hysterectomy may be may be technically easier with shorter operating time, less blood loss, less risk of urological injury and lower morbidity. The cervix may be difficult to identify in a patient whose cervix is fully effaced and dilated, especially in cases of consumption coagulopathy that results in heavy hemorrhage that interferes with proper exposure [8, 86].

In cases of peripartum hysterectomy for placenta previa accreta, increta and percreta and if the cervix is involved in the haemorrhage, total hysterectomy will be necessary. The fetus is delivered through a classical uterine incision, and the intact placenta is left in situ while the hysterectomy is completed [87].

The technique of peripartum hysterectomy, total or subtotal, is similar in principle to that of abdominal hysterectomy for nonobstetric indications (in gynecology), except for the remarkable anatomical and physiological changes in pregnancy that result in gross enlargement and distention of all pelvic blood vessels. In addition, the parametrial tissues tend to be greatly oedematous and friable, rendering the procedure more surgically challenging.

The acute loss of blood and the unplanned nature of surgery render the conditions less than ideal to perform the procedure of peripartum hysterectomy. Compared with nonobstetric hysterectomy, peripartum hysterectomy is associated with higher rates of morbidity and mortality [88, 89].

In a population-based analysis to compare the morbidity and mortality of peripartum hysterectomy with nonobstetric hysterectomy. Bladder and ureteral injuries were more common for peripartum hysterectomy. Rates of reoperation, postoperative haemorrhage, wound complications, venous thromboembolism were all higher in women who underwent peripartum hysterectomy. In multivariable analysis, the odds ratio for death from peripartum compared to nonobstetric hysterectomy was 14.4 (95 % confidence interval 9.84–20.98) [88].

During peripartum hysterectomy, the application of tourniquet (catheter) around the uterine cervix can reduce blood loss. This is facilitated by the use of transillumination, where the avascular spaces in the broad ligament, at level of a transverse lower caesarean incision, can be identified. This would compress the uterine arteries and reduce blood loss. Subtotal hysterectomy is usually performed at this level. It is recommended that all pedicles should be doubly ligated.

There appears to be resurgence in subtotal hysterectomy. This review confirms that subtotal hysterectomy is faster with less blood loss and urinary tract injuries. With reverse conization of the endocervix in addition to endocervical cautery would significantly decrease, if not eliminate, the cyclical vaginal bleeding. In the case of peripartum hysterectomy for postpartum haemorrhage that is due to uterine atony, specially where there is an element of consumption coagulopathy, subtotal hysterectomy may save time and decrease blood loss, that are important in the setting of this emergent procedure.

It is important that women are adequately counseled prior to and after subtotal hysterectomy regarding the need for routine cervical screening. Furthermore, hormone replacement therapy ought to be of the combined type if prescribed to women who have undergone the operation of subtotal hysterectomy.

Cervical Stump Extirpation

88

Marcella L. Roenneburg

The subtotal or supracervical hysterectomy was described as "one of the safest major operations performed within the abdominal cavity by Bland in 1924 [1]. In this era without blood transfusions or antibiotics, the supracervical hysterectomy decreased blood loss, did not require entry into the bacteria filled vagina, and rarely caused ureteral injuries. Wharton in 1943 described the total hysterectomy as a much more serious and difficult operation with more accidents, complications and mortality. At this time, mortality for a subtotal hysterectomy when performed for fibroids was 1–2.5 % while total abdominal hysterectomies for benign pathology such as endometriosis and tubo-ovarian abscesses carried a mortality risk of 3–6.5 %. Death was most commonly due to peritonitis, shock, hemorrhage and pulmonary embolism. Wharton noted that injury to the ureter and bladder was ten times more frequent with total hysterectomies and vesico-vaginal fistulas were more likely to occur associated with bladder injury in a total hysterectomy. Given a 0.45 % subsequent risk of cancer arising in the cervical stump at that time, the subtotal or supracervical hysterectomy was the preferred route [2].

Over the next 30 years there was a slow, steady transition to total abdominal hysterectomies with subtotal/supracervical hysterectomies coming to represent only 1 % of all hysterectomies [3]. There were several contributing factors. E. H. Richardson developed the intrafascial technique for total abdominal hysterectomies significantly contributing to the safety of the procedure [4]. Antibiotics became more widely available. In addition, the Red Cross' experience in blood donation and transfusion services for the US military during WWII was expanded to begin a nationwide program for civilians in 1948 [5]. At this time, more gynecologists were being trained and hysterectomies were less commonly being performed by general practitioners and general surgeons. The remaining subtotal/supracervical hysterectomies were more likely to be performed when the surgeon encountered distorted pelvic anatomy, operative difficulties such as with pelvic inflammatory disease or advanced endometriosis, or when the patient's co-morbidities required a shorter, less risky procedure. In other words, when less bladder dissection, less bleeding and shorter operating time was desirable, the supracervical hysterectomy could be performed. Subsequent excision of the cervix was expected to be a difficult procedure and was generally performed via an abdominal laparotomy.

Supracervical hysterectomies noted a resurgence in popularity in the late 1990's with the onset of minimally invasive or laparoscopic hysterectomies. Laparoscopic subtotal or supracervical hysterectomies were performed to decrease operating time, blood loss, and postoperative vaginal dehiscence. In addition, they could be performed without laparoscopic suturing skills. Therefore gynecologic surgeons today are more likely to encounter patients who require excision of the cervical stump, also known as a trachelectomy.

Common indications for extirpation of the cervical stump include cyclic bleeding, prolapse, pelvic mass, pain, and severe cervical dysplasia/carcinoma in situ or cervical cancer. The risk of cervical cancer in the remaining stump is 0.7 % and unchanged by the prior subtotal hysterectomy [6]. The American College of Obstetrics and Gynecology reports 1.5 % of patients required a second surgery to remove the cervix less than 3 months from the time of their original subtotal hysterectomy, and 23 % of women required return to the operating room for excision of the cervical stump at a mean of 14 months from their first surgery. Vaginal bleeding is experienced by 11–17 % of women having undergone a subtotal hysterectomy [7]. The most common complications of excising the cervical stump include infection and bleeding in 9 % and bowel injury in 2 % [8]. Fewer complications are noted with a vaginal approach when compared to an abdominal excision. The approach however, is often dictated by the indication for the return for extirpation with a vaginal approach being more commonly performed for prolapse and

the abdominal approach more commonly used for pelvic masses [8]. The bladder and/or rectum could have been used to re-peritonealize the pelvis after the supracervical hysterectomy and therefore care must be taken not to injury these organs during the cervical stump resection. After a sacrocolpopexy in which mesh grafting was placed over the cervical stump to repair the anterior and posterior vaginal walls as well as provide apical support, subsequent extirpation of the cervical stump will be more difficult. Dense adhesions should be expected with increased risks of bladder and bowel injury during dissection. Additionally, previous surgery may have altered the path of the ureters and therefore the ureters may be adhered to the cervical stump. It is important that the ureters be identified and if necessary be dissected free from the cervix.

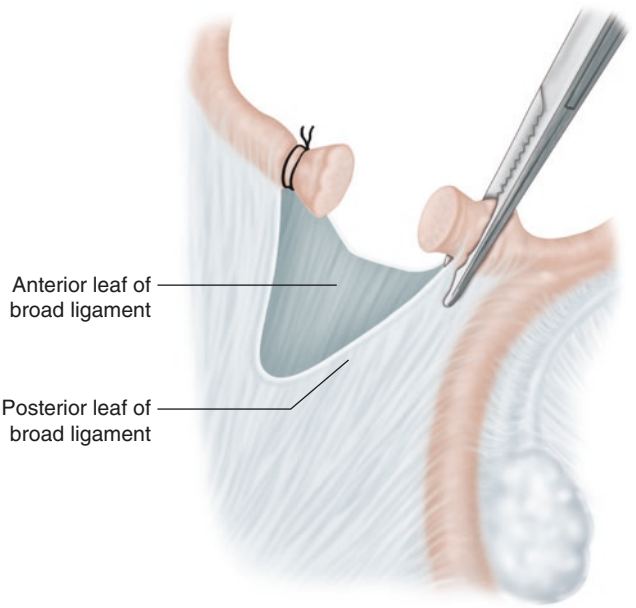

Fig. 88.1 Transection of round ligament and opening of the leaves of the broad ligament (From Wheeless and Roenneburg [9])

Procedure

The patient is placed in a supine position and a transverse or vertical incision is made in the usual fashion to open the abdomen. Once a self-retaining retractor is placed, bowel is packed away and the patient is placed in a moderate Trendelenburg position. The Fallopian tubes and ovaries, as well as the round ligaments, may be adherent to the cervix. In addition the bladder and peritoneum may be closed over the cervical stump. The best way to begin the procedure is to identify the previously transected round ligaments as they enter the pelvic side wall. The stumps of these fibromuscular bands of tissue should be easy to locate in their position anterior and laterally in the pelvis before they exit through the inguinal canals. The round ligaments are clamped with a curved clamp such as a Kelly or curved Heaney clamp. An interrupted 0 synthetic absorbable suture is placed distally underneath the ligament and tied down. A second suture is placed proximal to the clamp and again tied down. This proximal stump remains connected to the medial portion of the peritoneum or may be connected to the cervical stump (see Fig. 88.1). The round ligaments can then be transected with a Mayo scissors or with cautery which opens access to the retroperitoneal space. Accessing the retroperitoneal space allows identification and if necessary dissection of the ureter. Previous surgery and disease can significantly alter the expected course of the ureters. Once the transected round ligaments are elevated, a plane of dissection will be easier to identify, and the surgeon will be able to incise the anterior leaf of the broad ligament in order to begin dissecting the bladder from the cervix (see Fig. 88.2). Counter traction for easier dissection is provided by elevating the cervical stump cephalad with a tenaculum. The posterior leaf of the broad ligament can also be incised. If it is advisable to remove the Fallopian tubes and ovaries,

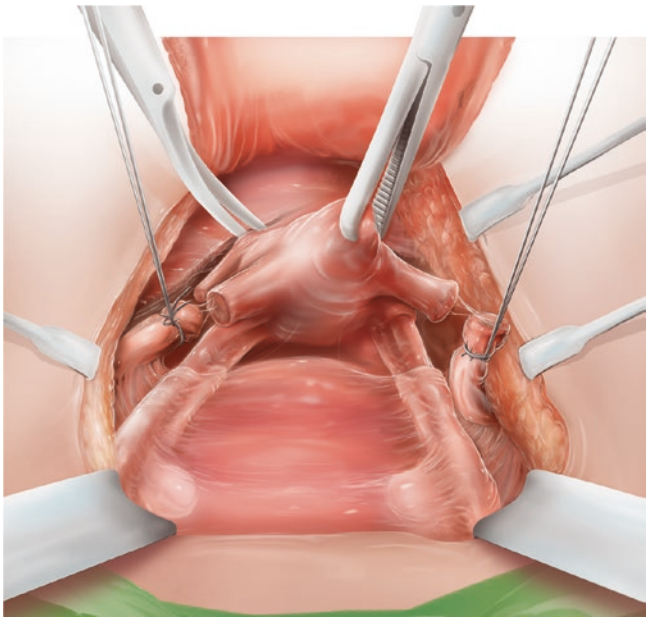

Fig. 88.2 Elevation of round ligament to incise the anterior leaf of broad ligament assists in beginning dissection of bladder from the cervix

the infundibulopelvic ligament with the ovarian artery and vein can be doubly clamped with a Kelly or curved Heaney clamp at this juncture (see Fig. 88.3). A ligature of 0 or 2–0 synthetic absorbable suture is tied down around the pedicle while carefully opening or "flashing" the clamp and then re-clamping the pedicle. A transfixion suture is then placed through the pedicle and tied down on both sides while

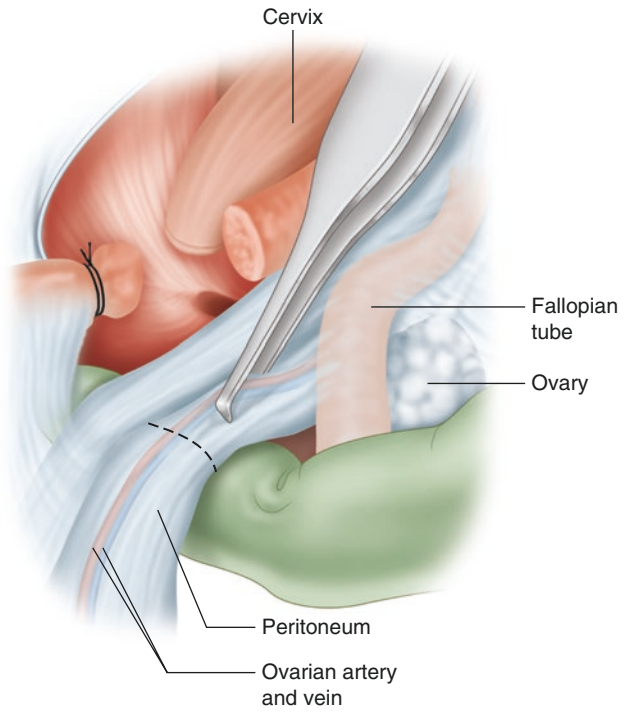

Fig. 88.3 Identifying the infundibulopelvic ligament with the ovarian artery and vein (From Wheeless and Roenneburg [9])

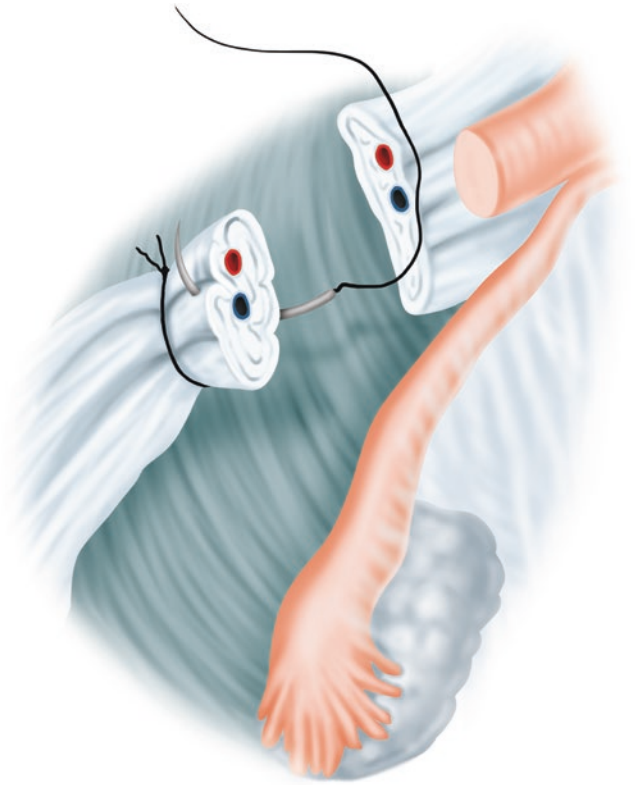

Fig. 88.4 Transfixion suture of should be placed distal to the first ligature to prevent hematoma formation (From Wheeless and Roenneburg [9])

releasing the clamp. This transfixion suture should be placed distal to the first ligature to prevent hematoma formation (see Fig. 88.4). Once again, the ureter should be identified prior to placing clamps and ligatures to prevent any damage. The vesicoperitoneal fold is then elevated with a bladder blade or curved Deaver retractor while counter traction is placed on the cervical stump. The filmy attachments of the bladder to the cervix can be identified and taken down with blunt or sharp dissection (see Fig. 88.5). If previous surgery or disease has caused extensive adhesions, sharp dissection rather than blunt dissection should be performed. Blunt dissection with a sponge stick or the operator's finger in the case of dense adhesions can cause shearing and tearing with increased risk for incidental cystotomy and subsequent vesicovaginal fistula formation.

A straight Heaney or Masterson clamp is used to clamp the cardinal ligament for a distance of approximately 2 cm by sliding off the cervical stump and clamping immediately lateral to the cervix. The cardinal ligament is then transected with knife or scissors taking care to leave a barrel shaped portion protruding from the clamp. Transecting the ligament too close to the clamp can cause the ligament to slip out of the Heaney or Masterson clamp (see Fig. 88.6). This pedicle is suture ligated with a 0 synthetic absorbable suture and the process is repeated on the contralateral side.

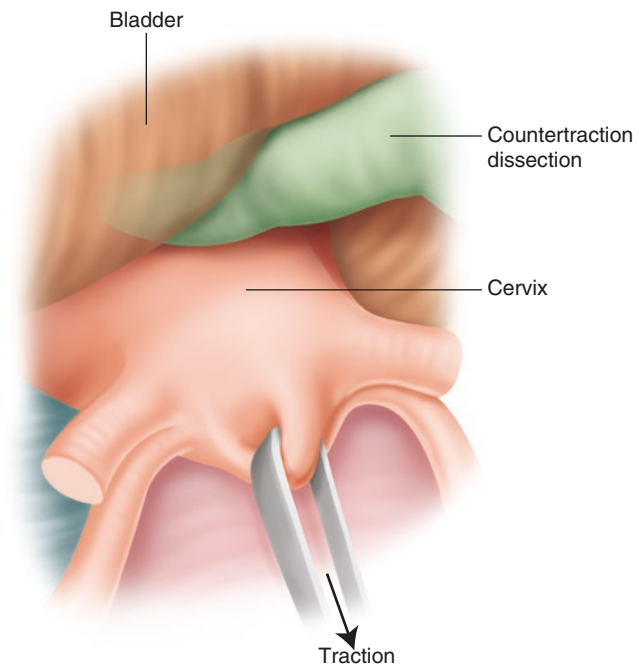

Fig. 88.5 Traction on the cervix and counter traction on the bladder assist the blunt or sharp dissection of the filmy attachments between the cervix and bladder required to develop the bladder flap (From Wheeless and Roenneburg [9])

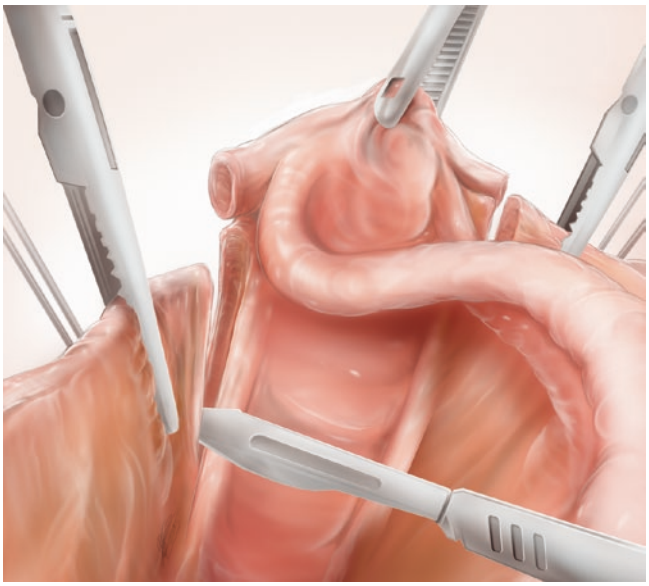

Fig. 88.6 The cardinal ligament is clamped and then transected taking care to leave a barrel shaped portion protruding medially to the clamp.

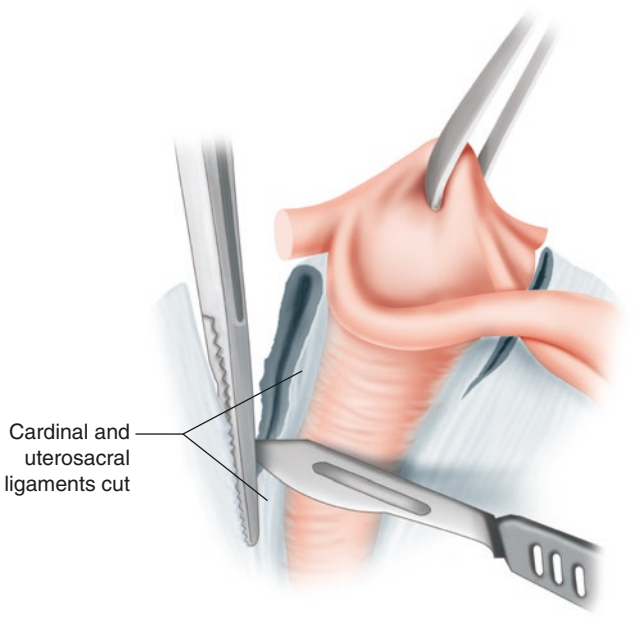

Fig. 88.7 Second and possibly third pedicles are taken in a similar fashion. The final pedicle should include the uterosacral ligaments to begin resuspension of the vagina (From Wheeless and Roenneburg [9])

Second and third pedicles as needed are performed in a similar fashion. The operator's thumb and index finger are used to palpate the distal edge of the cervix. The final pedicle should include the uterosacral ligament (see Fig. 88.7). Including the uterosacral ligament in the final cardinal ligament pedicle will begin re-suspension of the vaginal cuff which will be completed when the uterosacral ligament is included in the vaginal angle suture.

With continued cephalad traction on the cervical stump the vagina is entered anteriorly via a stab incision using a scalpel or by incision with a Mayo scissors (see Fig. 88.8). A curved Mayo scissors or the curved Jorgenson's scissors is used to circumferentially excise the cervical stump from the vagina. The curved scissors allows the inner blade to be snugged up against the cervix to help maintain as much vaginal length as possible. The vaginal edges are picked up with Ochsner or Kocher clamps at 12, 3, 6 and 9 o'clock. Figure of eight 0 synthetic absorbable sutures are placed at the angles of the vagina and must include the uterosacral ligaments for re-suspension of the vagina as the uterosacral ligaments have no anatomic attachment to the vagina (see Fig. 88.9). Care should be taken not to place sutures beyond the previous ligament sutures to prevent hematomas.

The vaginal cuff can then be reefed 360 ° for hemostasis with a running locking 2–0 or 0 synthetic absorbable suture to allow the cuff to remain open and allow drainage. If the vaginal cuff gapes open widely, it can be partially closed

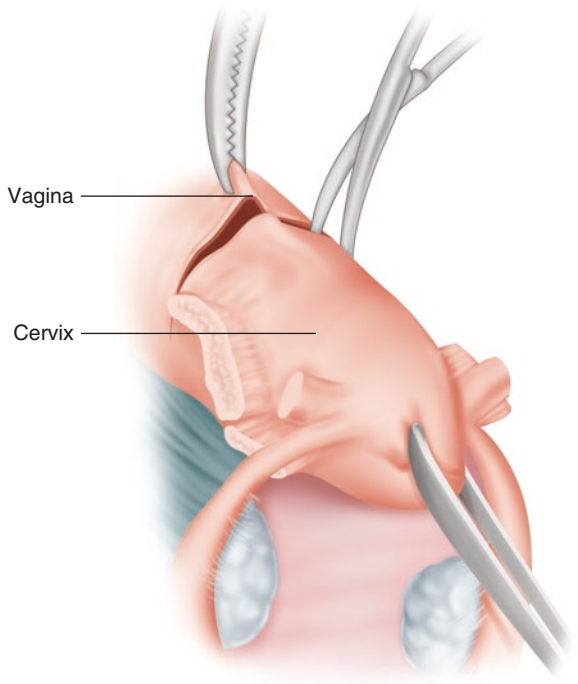

Fig. 88.8 The anterior wall of the vagina is entered sharply aided by cephalad traction on the cervical stump. Scissors are used to circumferentially excise the cervical stump from the vagina (From Wheeless and Roenneburg [9])

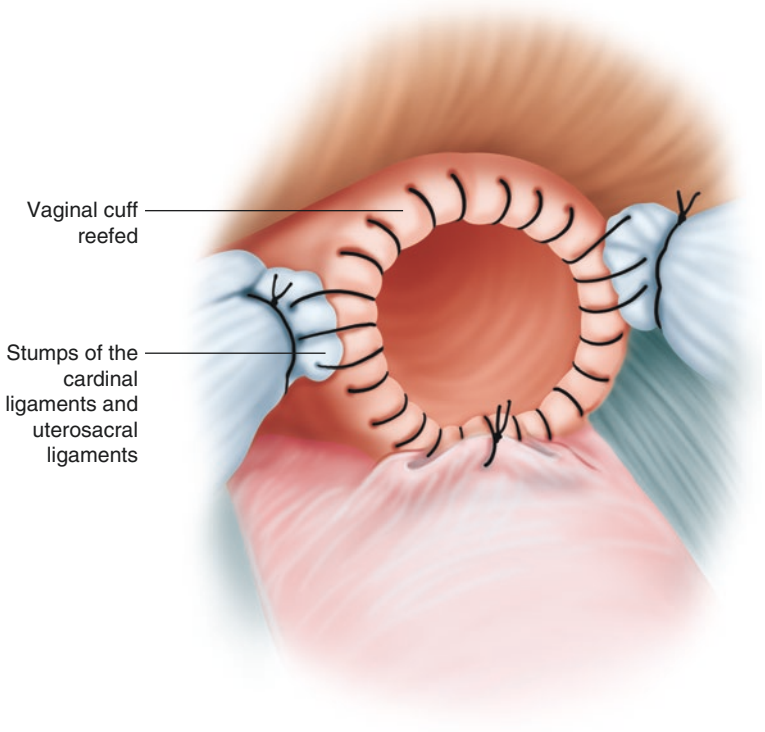

Fig. 88.9 Angle sutures are placed in the vaginal cuff and should include the uterosacral ligaments to re-suspend the vagina. The vaginal cuff is reefed for hemostatsis

with interrupted figure of eight sutures. Complete closure of the vaginal cuff increases risks for postoperative febrile morbidity and abscess formation.

The pelvis should then be thoroughly irrigated or washed and care taken to ensure hemostasis. It is not necessary to reperitonealize the pelvis. The abdominal incision can then be closed in the usual fashion. Post-operative care is similar to an abdominal hysterectomy with early ambulation and early resumption of a regular diet.

Cervical stump extirpation is not a common procedure, but when indicated it can be performed with a low risk of complications.

Total Abdominal Hysterectomy in Benign Conditions: Hysterectomy Techniques for the Normal-Sized and Small Uterus

89

Engelbert Hanzal

Not too many years ago this would have been one of the prime chapters in a book about hysterectomy, which highlights how much progress has been made in terms of technique, concept and attitude to surgery of the uterus and today this piece reads already like something slightly anachronistic and almost historic. Are there still indications for open abdominal hysterectomy in a normal-sized or small uterus for benign conditions at all? At first sight there are none. A few absolute indications remain and there are special chapters in this book dealing with those, with the exception of the still more experimental uterine explantation for transplantation, possibly the most complex type of hysterectomy ever performed up to now [1]. Often, when thinking of open hysterectomy the uterus will be enlarged or a malignant or otherwise difficult condition, like endometriosis or dense adhesions present; but even in these clinical situations one will always want to carefully consider vaginal or laparoscopic approaches first and seek contraindications to these – which are becoming increasingly rare – before resorting to laparotomy. As far as indications are concerned, there are no differences to those for laparoscopic hysterectomy in benign, premalignant or – like in a few cases of early invasive cancer of the cervix or endometrium – malignant conditions. This is to say that given adequate mobility and vaginal compliance in these indications, the vaginal approach should always be favoured and tested for feasibility – if necessary under anesthesia – also in nulliparous patients. Some rare opportunities to come across a normal-sized or small uterus in a patient with an indication for hysterectomy may include an operation by another surgical specialty with a need for laparotomy. In some low resource settings, however, open abdominal hysterectomy may still be an acceptable alternative, when laparoscopic equipment is unavailable and a vaginal approach not feasible.

E. Hanzal
Gynecology and Gynecologic Oncology, Medical University of Vienna, Vienna, Austria
e-mail: Engelbert.hanzal@meduniwien.ac.at

The following assumes an already laparotomized patient (including checklists, antibiotic prophylaxis etc.), where exploration, and adhesiolysis has already been performed. Please refer to the respective chapters on laparotomy techniques and adhesiolysis for detailed descriptions on procedures and steps before the actual hysterectomy. Here we will describe just one technique of simple extrafascial hysterectomy used widely with a few modifications, but there is no way to cover all the different and possibly equally effective techniques used worldwide. This chapter leans heavily on an surgical atlas now out of print which has served the author well for over 20 years in the circumstance of open operations in gynecologic oncology [2]. The paucity of clinical data, randomly comparing different types of techniques in terms of suture material, instruments used, use of cautery, exact sequence of steps, etc. suggests that there may only be marginal and clinically unimportant differences. But this is only an assumption and there may well be unsafe techniques out there, so it is far from advisable to use an "anything goes" type of approach for any hysterectomy. Techniques need to be adequately standardized, trained and examined in the surgical skills lab and afterwards in the operating theater, before it is safe to assume that someone masters the surgery enough to perform it safely on a patient [3].

For this atlas, the author describes the technique he is most familiar with – albeit less so in recent years, where the laparoscopic approach has continually replaced indications for primary laparotomy (Table 89.1). He uses monopolar cautery (with a straight, narrow blade and extension wherever necessary), for incisions (including skin) and dissection, a pair of Péan clamps for manipulating the uterus, two slightly curved clamps and another two sharply curved clamps with a longitudinal jaw-profile for transection of parametrial tissue and ligaments. Occasionally, a number 10 (or similar curved-blade) scalpel, Metzenbaum scissors and strong parametrial scissors, straight needle-holders (long and medium sized), surgical and anatomical (or DeBakey) forceps all in an adequate length to facilitate use deep down in the pelvis, complete a basic set of instruments, readily

Table 89.1 Checklist for open abdominal hysterectomy suitable for training (objective structured assessment of technical skills [2])

Place 2 Péan clamps across broad ligament medial to the adnexa to manipulate uterus and to put tissues under tension
Palpate uterine cervix
Doubly ligate and transect right round ligament after applying tension and incise peritoneum medially across the bladder to the left side and laterocranially to expose extraperitoneal space
Always apply upward traction on peritoneal surfaces to facilitate cutting and to allow air to enter extraperitoneal space to facilitate vision of extraperitoneal anatomy
Identify right ureter and ovarian vessels on medial leaf of peritoneum
Incise medial leaf of peritoneum between ovarian vessels and ureter ("avascular space of Graves"), carry the incision medially to lateral margin of uterus and laterally to pelvic brim
If adnexa is to be removed, ovarian vessels are clamped, transected and clamps replaced by figure-of-eight stitches; when preserving ovaries, tube is transected and ovarian ligament clamped and ligated
Treat left adnexa in analogous fashion
Pull bladder peritoneum caudad and anteriorly to expose tissue between bladder and cervix, then carefully dissect bladder downwards staying in the middle and away from vessels of bladder pillar on both sides
Palpate cervix and finish creation of bladder flap when encountering anterior vaginal wall approximately 1 cm below the cervix
Skeletonize, clamp (at a 90° angle with sharply curved clamps) and transect uterine vessels at the level of the uterine isthmus and replace clamps with figure-of-eight stitches
Clamp (with slightly curved clamps), cut and suture cardinal ligaments with figure-of-eight stitches downward in portions of no more than 3 cm, as many as needed to reach the level of the vaginal fornices
Always place clamps medially to those placed before to avoid ureteral damage
Place two sharply curved clamps across vagina just below cervix and transect vagina to deliver uterus
Replace clamps by figure-of-eight stitches thereby closing the vaginal cuff
Check for and control bleeding if necessary

available in most operating theaters worldwide to permit open abdominal hysterectomy. For simplicity, all stitches are performed with atraumatic 0-polyglactin sutures.

Accessing the Extraperitoneal Space

With two Péan clamps placed across the broad ligament medially to the adnexa, the uterus can be manipulated and put under tension. The cervix is palpated between thumb anteriorly and the other fingers resting in the pouch of Douglas. The right round ligament is stretched out firmly, then suture ligated and transected. With the peritoneum still under tension, allowing air to enter into the areolar tissue of the endopelvic fascia, the peritoneal incision is carried medially towards the bladder and over the midline to the other side, then latero-cranially across the iliac vessels and parallel to the ovarian vessels. The ligature securing the stump of the round ligament can be left long and tagged to facilitate upward traction of the lateral peritoneal edge. Small bleeding vessels are controlled by monopolar cautery to have a clear operating field. This will ease visualisation of the psoas muscle with the overlying genitofemoral nerve, iliac and ovarian vessels, and the ureter, which crosses over the common iliac artery and runs down the medial leaf of the peritoneum to the posterior aspect of the broad ligament to pass under the uterine vessels. By placing the hand in the pouch of Douglas and the thumb laterally into the bottom of the peritoneal opening, the ureter can almost invariably be palpated. A clicking sound can be heard, when sliding the ureter between the fingers. The part of the medial peritoneal leaf between ovarian vessels, ureter and lateral edge of the uterus is sometimes called avascular space of Graves. This is now incised or bluntly perforated and the incision carried medially towards the uterus and laterocranially towards the pelvic brim to skeletonize the ovarian vessels. The same procedure is performed on the other side if necessary in an analogous fashion.

Treatment of the Adnexa

In case of complete adnexal removal, the ovarian vessels on the right side are now clamped, cut, suture ligated and thereby tube and ovary mobilized. The paradigm shift that now sees the tubes as origins of at least some types of epithelial ovarian cancer has led to the suggestion to remove the oviducts whenever possible [4]. Therefore, if the ovaries are to be preserved, the fallopian tube is transected off the mesosalpinx, which can elegantly be performed by monopolar cautery alone (as long as the mesosalpinx is cut by cautery slowly and immediately adjacent to the tube), a clamp placed over the ovarian ligament and the clamp replaced by a figure-of-eight stitch, leaving the ovary intact and separating it from the uterus. Treatment of the adnexa is repeated on the other side if necessary in analogous fashion.

Creating a Bladder Flap

With the bladder gently pulled caudad and anteriorly the endopelvic fascia of the vesicouterine space is exposed and with Metzenbaum scissors or monopolar cautery the collagen fibers are separated to dissect the bladder off the cervix. Initially it is important to stay in the middle of the cervix, that can be palpated by hand or with the instrument to avoid bleeding from the bladder pillars. Eventually, connective tissue from the cranial parts of the bladder pillars will be taken down to create a satisfactory bladder flap that extends downward at least 1 cm beyond the anterior cervical lip. Although in simple (i.e. non-radical) abdominal hysterectomy the ureter is never dissected out of the broad ligament, one can and should still imagine and palpate its course because it always passes in close proximity of the structures developed, cut and sutured during hysterectomy.

Ligating the Uterine Vessels

The uterine vessels are now skeletonized by incising the posterior leaf of the peritoneum towards the uterosacral ligaments and by carefully cutting or pushing away the connective tissue of the broad ligament to expose the vascular bundle. A sharply bent clamp is placed perpendicularly across the uterine vessels by letting it slide off the cervix to also encompass vessels near the uterus at the level of the isthmus. The deeper this clamp is placed, the nearer it will be to the ureter so placing it high is an important safety step. The clamp is replaced by a figure-of-eight stitch.

Division of the Cardinal and Uterosacral Ligaments

Resorting to slightly curved clamps, the tissue of the broad ligament is now grasped parallel to the cervix by letting the jaws of the clamp slide off of the cervix from medially to laterally. Care is taken to always have the stump of the previous portion lateral to the clamp to avoid ureteral damage. Also, the portion taken with the clamp should never exceed 3 cm in length, because too much shrinking of the tissue after suture ligation could lead to ureteral kinking. This may especially be the case in women with a small uterus and an elongated cervix. Often in this situation more than 3 clamps are necessary on each side to achieve satisfactory transection of the parametrial tissue without the risk of kinking the ureter. The clamps can be placed with the convexity facing the cervix or away from it, whichever is easier to handle. In both cases the critical issue is having the jaws of the clamp as near the uterus as possible and medially to the previous bite of the clamp. Every clamp is replaced by figure-of-eight stitches after having transected the tissue with cautery, scissors or scalpel taking care to stop cutting approximately 2 mm before reaching the tip of the clamp. Otherwise retrograde bleeding from the uterovaginal vascular plexus can ensue, leading to unnecessary blood loss and blurring or the operating field. Palpation of the cervix will determine, when the level of the vaginal fornices is reached. In the case an elongated cervix often 2 – 4 clamps are necessary to achieve this goal.

Completing the Hysterectomy

With sharply curved clamps, the vagina is grasped at the level of the fornices perpendicular to the vaginal axis by letting the jaws of the clamps slide off of the cervix downward to the apical vagial wall, the tips facing each other. By cutting the tissue between clamps and cervix, the apical vagina is transected along with the uterosacral ligaments and the uterus with tubes or adnexa falls away to be sent off for pathology. The clamps are then replaced by figure-of-eight stitches, whereby the uterosacral ligaments automatically become sutured to the vaginal apex. The gap between the two ligatures at the top of the vagina medially can be left open for drainage, however, the author always closes it with a z-stitch to avoid postoperative discharge. In the absence of studies showing a benefit for vaginal drainage after hysterectomy this seems reasonable. In the case of postoperative hematoma or abscess formation, which occurs in about 1.3 – 2.8 % of patients [5, 6] usually around the 4th postoperative day, the vaginal sutures can be removed from vaginally and the cuff opened to allow infectious material to drain vaginally. Alternatively, the vagina can be opened by cautery, scalpel or scissors at the level of the anterior fornix and transected openly, allowing visualization of the upper vagina, which is sometimes beneficial when vaginal pathology like endometrial implants are suspected. In these cases, two angle sutures are placed through the lateral fornices and uterosacral ligaments, which are tagged to facilitate vaginal cuff closure with running sutures.

Today, open hysterectomy for the normal-sized and small uterus in benign indications is mainly a theme from the past. Whenever such a case crops up in a surgical schedule it should be viewed with utmost scrutiny for possible alternatives, like vaginal or laparoscopic hysterectomy, or minimally invasive procedures sparing the uterus altogether. It is to be expected that even in low-resource settings this operation will soon be obsolete.

Total Abdominal Hysterectomy in Benign Indications: Hysterectomy Techniques for the Large Uterus

90

Atul P. Munshi and Sujal A. Munshi

Hysterectomy is an operation frequently done in routine Gynec practice worldwide. It is difficult to get exact incidence as many surgeries are not reported. The National Surveillance data from USA showed that 6,00,000 hysterectomies were performed yearly of which approximately 90 % were done for benign condition [1]. In India and other Asian countries with less availability of conservative modalities to mass population and reluctance for these methods, the number is even higher.

Abdominal hysterectomy was more common than vaginal route (65 v/s 35 %) for many decades. But for past one and a half decade worldwide vaginal and Laparoscopically assisted hysterectomies are becoming increasingly popular and now secure an larger proportion than ever before amongst all procedures performed.

History

In November 1843 Charles Clay performed the 1st hysterectomy in Manchester England; earlier hysterectomies were supra cervical or subtotal. In 1929, Richardson M.D. performed the first Total Abdominal Hysterectomy.

Indications

- Benign Diseases
  - Abnormal Uterine Bleeding
  - Leiomyoma
  - Adenomyosis
  - Endometriosis
  - Pelvic Organ Prolapse with other pathology
  - Pelvic Inflammatory Diseases
  - Chronic Pelvic Pain
  - Pregnancy Related Conditions
  - Miscellaneous
- Traumatic
  - Uterine Perforation
  - High Cervical Tear
  - Rupture Uterus
- Obstetrical
  - Intractable Atonic PPH
  - Morbidly Adherent Placenta
- Prophylactic Hysterectomy
  - BRCA1/BRCA2 positive
  - HNPCC gene positive

Current trend is to remove the uterus from the natural orifice (vaginal). Traditionally accepted, contraindications to the vaginal route, including: uterine enlargement (uterine weight estimated >500 g or uterine size more than 20 weeks); vagina deemed "too narrow" (e.g., vagina narrower than 2 fingerbreadths, especially at the apex); lack of uterine descent and mobility; presence of adnexal disease; prior pelvic surgery; malignancy; contracted pelvis; and need to explore the upper abdomen [2]. However, these traditional indications for laparotomy have been challenged [3, 4]. When vaginal hysterectomy is not possible, it is suggested that a laparoscopic approach might avoid the need for abdominal hysterectomy; however, the length of the surgery increases as the scope of the surgery performed laparoscopically increases and these procedures require greater surgical expertise [5, 6].

Preoperative Counseling

The reasons for the hysterectomy, risk and benefits of the procedure, alternatives and outcome should be discussed in detail. Informed consent with thorough exploration of patient preferences and expectations is particularly important. In the decision to proceed with hysterectomy is made by woman and her physician based upon functional impairment, childbearing plans, response to medical therapy and discussion of alternatives.

Other Treatment Modalities

1. Uterine Artery Embolization and Myomectomy may be used to treat Symptomatic Leiomyoma.
2. Pain control services may be able to return patients with intractable pelvic pain to a functional status without surgery.
3. Endometrial ablation may be an effective therapy for excessive uterine bleeding.
4. Medical Therapy with GnRH analogs can help reduce discomfort associated with endometriosis.
5. Endometrial Hyperplasia can sometimes be treated medically with progestin.
6. Conization (Cold Knife, Loop Electro cautery) may be adequate therapy for some women with high grade CIN/CIS.

Once the decision for the hysterectomy has been made, physician and the patient must decide together on the route of surgery and the type of surgery to be performed. The route chosen depends upon the woman's clinical findings and surgeon's preference. Risk and benefits of Oophorectomy and proposed plan for keeping or removing ovaries should be discussed with patient before surgery.

Preoperative Preparations

- Through counseling with written and informed consent.
- Complete History and Physical Examination.
- Routine Blood Ix.
- Special Tests according to Patient's Medical Condition.
- Chest X-Ray in women with Cardio Respiratory disease.
- Intravenous Pyelogram or CT Scan of abdomen and pelvis in women with uterine or extra uterine pelvic mass
- Pap smear to rule out cervical neoplasia.
- Recent Pregnancy test in Reproductive aged women prior to Hysterectomy.
- Bowel preparation prior to pelvic surgery to facilitate exposure and reduce trauma to bowel caused by retraction and packing. (Usually laparoscopy or laparotomy – abdominal hysterectomy, bowel preparation is necessary to evacuate fecal material. Rectal suppository or enema previous night or early morning before surgery is advocated by many surgeons. Empty bowels reduces chances of injury during surgery and allows proper packing to keep them away from operative field.)
- Clear liquid diet on the day prior to surgery.
- One or two fleet enemas, the evening prior to surgery.
- A laxative suppository immediately on arising on the morning of surgery, will evacuate residual faeces in sigmoid and prevent contamination of field during surgery.
- Routine use of intravenous antibiotics given immediately prior to induction of anesthesia – second generation cephalo-sporine are commonly used.
- If necessary, the pubic and/or vulvar hair should be clipped with an electric clipper or even scissors rather than shaved.
- Shaving prior to surgery has been shown to increase the risk of wound infection and cellulites.

Types of Hysterectomy

Depending upon the extent of removal of the uterus and adjacent structures, following types are described.

- Total Hysterectomy – Removal of the entire uterus with cervix.
- Subtotal – Removal of the body or corpus leaving behind the cervix.
- Panhysterectomy – Removal of uterus along with removal of tubes and ovaries of both the sides. The term "Hysterectomy with Bilateral Salpingo-Oophrectomy" is preferred.
- Extended Hysterectomy – Panhysterectomy + Removal of cuff of vagina.
- Radical Hysterectomy – Removal of uterus, tubes and ovaries of both sides, upper one third of vagina, adjacent parametrium and draining lymph glands of the cervix. **(Not for benign conditions.)**

Operative Technique

After obtaining adequate anesthesia, examination under anesthesia is performed. Foley's catheter is recommended in most cases. Vagina cleaned with antiseptic solution. Skin preparations followed by placement of surgical drapes is carried out.

Skin incision may be transverse or vertical and is determined by variety of factors, such as need for exploration, of upper abdomen, size of uterus, presence of prior incision and desired cosmetic results. If prior incision exists, parallel scars are undesirable.

In a uterus where the fundus is at level of umbilicus or above it and patient having previous vertical scar (previous CS or laparotomy) longitudinal incision is preferable.

In other cases of patients having Pfannenstiel scar, transverse incision is preferable. Even in larger uteri transverse incision may be used in case of difficulty in delivery of the uterus, muscle cutting may be resorted to.

The peritoneal cavity is entered and the upper abdomen and pelvis explored for unexpected pathology and to confirm suspected pathological findings. Cytological sampling of peritoneal fluid or peritoneal washings, may be collected if indicated because of possible malignancy.

The wound edge should be protected with moist laparotomy packs or towels before placing retractor blades.

To begin, the pelvic organs are mobilized by dividing omental, intestinal or abdominal wall adhesions, as indicated.

A large Kelly clamp is placed across each uterine cornu, running down the side of the uterus across the round ligaments. This allows uterine elevation and prevents back bleeding when the round ligaments are divided. The uterus is manually deviated to the patient's left, stretching the right round ligament. The round ligament is suture ligated, clamped & divided.

Anterior broad ligament is incised along the vesicouterine fold, separating bladder peritoneum from lower uterine segment.

If ovaries are to be retained, the uteroovarian ligament on each side is clamped with Heaney clamp, cut and ligated with both free tie and suture ligature. The medial clamp at uterine cornue will control back bleeding.

If ovaries are to be removed, infundibulopelvic ligament is cut, ligated with free tie followed by suture ligature. Tying pedicle before suturing it prevents formation of an expanding hematoma through inadvertent puncture of ovarian vessels.

Bladder is then sharply dissected off the lower uterine segment and cervix. Uterus is then retracted to one side of pelvis, placing the lower uterine ligaments on stretch. Any loose connective tissue overlying the uterine vessels is sharply removed to skeletonize the vessels and a curved Heaney clamp is placed perpendicular to the uterine artery at the junction of the cervix and body of uterus. The opposite side is managed in a similar fashion, the uterine arteries cut and suture ligated.

If Rectum required mobilization from posterior cervix, posterior peritomeum between uterosacral ligaments just beneath the cervix and rectum is incised. The cardinal ligament and any remaining broad ligament are divided by placing a straight Heaney clamp medial to uterine vascular pedicle for a distance of 2–3 cm parallel to the uterus. Pedicle is cut and ligated with a suture ligature. Procedure is completed on contralateral side. A series of pedicles may be required depending upon the size of the uterus.

The pubovesicocervical fascia is then dissected off the lower uterine segment and cervix. A curved Heaney clamp is placed inside the fascia on each side of uterus to incorporate the uterosacral ligaments and upper vagina just below cervix. Care should be taken to avoid foreshortening the vagina. Uterus is resected using scissors.

Numerous techniques have been described for vaginal cuff closure one effective method is to place a figure of eight suture of 0 or 2–0 gauge synthetic absorbable suture between the tips of the two clamps. This suture is used for both traction and hemostasis.

Sutures are placed at the tip of each clamp and pedicle is transfixed with suture ligature. This suture incorporates the uterosacral and cardinal ligament at the angle of the vagina.

Vaginal cuff can also be left open to heal secondarily. If this method is used, a running suture is used for hemostasis along the cuff edge. The pelvis is thoroughly irrigated with warm saline or Ringer's lactate solution. Meticulous hemostasis is assured. Urethral and Bladder integrity are confirmed. Abdomen closed in layers.

Technique of Removal of Large Uterus

Many a times large uterus has specific problems. Pelvic anatomy is distorted and in cases having multiple fibroids (myoma) or a big adenomyoma, delivery in the incision before clamping is often difficult, to overcome this

- Take adequate incision (vertical or muscle cutting transverse)
- Carefully separate adhesion of previous surgery or endometriosis
- At times removal of big fibroid (myomectomy) may be needed to reduce the size.
- First few clamps can be applied keeping the uterus in abdomen itself.
- Big uterus has increased blood supply so proper ligation and complete hemostasis is essential (Fig. 90.1).

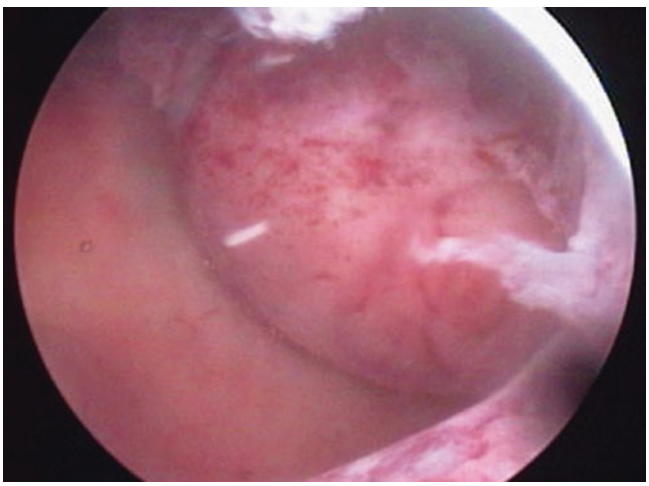

Fig. 90.1 Picture of large uterus

Postoperative Care

If a catheter is used, it can be removed any time around morning following surgery or even before that.

Intravenous fluids are generally administered for the first 24 h to ensure that patient remains well hydrated especially if she experience any nausea or vomiting.

Postoperative colonic stasis lasts for approximately 3 days but does not require nasogastric decompression or preclude early feeding.

Ambulation and deep breathing encouraged.

For adequate pain control, patient controlled analgesia can be utilized.

Instructions on Discharge

- Resume normal daily activity as quickly as possible.
- Walking and stair climbing are encouraged.
- Tube baths or showers are permissible.
- Avoid heavy lifting for 4–6 weeks to minimize stress on healing fascia.
- Vaginal intercourse is also discouraged to allow the vaginal cuff to heal completely which is usually at around 6 weeks.
- Driving should be avoided till full mobility returns & analgesics no longer required.
- The patient should inform her surgeon if she experience:-
  a. Increase in pain.
  b. Persistent nausea or vomiting.
  c. Bleeding heavier than menses.
  d. Any signs/symptoms of infection.

Complications [7]

Immediate

1) During Operation→
   - Hemorrhage.
   - Injury to adjacent structures like bladder, intestine, ureter.
   - Anesthetic hazards.
2) Postoperative→
   - Shock – hypovolaemic
   - Urinary – Retention, Cystitis, Anuria
   - Incontinence – Overflow, Stress, True
   - Pyrexia (vault cellulitis, UTI, Thrombophlebitis, Cystitis, etc.)
   - Hemorrhage (Primary, secondary or Vault)
   - Hematoma
   - Wound Dehiscence
   - Paralytic ileus and intestinal obstruction
   - Phlebitis
   - DVT
   - Pulmonary Embolism

Remote Complications

- Vault Granulation
- Vault Prolapse
- Prolapse of fallopian tube
- Incisional Hernia
- Post-operative adhesion formation
- Early Menopause
- Mortality

Some Special Considerations (For Benign Lesions)

- Age and Parity:
  An ideal condition is that the patient preferably be in the perimenopausal age group with family completed. However, operation may have to be done under forced circumstances even in comparatively young age group or unmarried or nulliparous women. Ex- contemplating myomectomy.
- Total or Subtotal:
  The preferred surgery is always a total hysterectomy unless there is a sufficient reason to leave behind cervix. Pap smear must be normal.
- Indications of subtotal/supracervical hysterectomy are—
  (i) Difficult tubo ovarian mass.
  (ii) Pelvic endometriosis involving rectovaginal septum.
  (iii) Obstetric causes.
  (iv) Sudden deterioration of general condition either due to blood loss or anesthetic complications while contemplating to perform total hysterectomy.
- Advantages (subtotal):
  (i) Reduced operative & postoperative morbility.
  (ii) Reduced vaginal shortening and vault prolapse.
  (iii) Increased sexual satisfaction.
- Risks (subtotal):
  (i) Cervicitis with abnormal vaginal discharge.
  (ii) Stump carcinoma (1 %)

Difficult Hysterectomies

When extensive pathology exists, the surgeon must alter the approach with full awareness of normal anatomy and the deviation from normal that has been produced by this pathologic process. Fundamental principles in removing an

organ include isolation and ligation of its blood supply and dissection and removal from the surrounding tissue without injury to adjacent vital organs, nerves, or vessels. The ability to identify the ureter outside the area of pathologic changes and to follow its course through the field of dissection is essential. **A retroperitoneal approach** is extremely helpful in the isolation and removal of adherent adnexa. The ureter should be left attached to the peritoneum as much as possible but can be isolated from it if the adjacent pathology is densely adherent. If extensive bowel adhesions are suspected, the bowel should be appropriately prepared. An enterotomy can then be primarily closed with drainage established and a temporary colostomy avoided. Thorough knowledge and recognition of the anatomy will allow the surgeon to alter the standard hysterectomy as required by existing pathology with the minimum potential for injury or morbidity in these difficult cases.

Approach to Retoperitoneum in Difficult Hysterectomies

The retroperitoneum is entered by extending the incision on posterior leaf of broad ligament cephalad, remaining lateral to both the infundibulopelvic ligament and iliac vessels. Blunt or sharp dissection clears the loose connective tissue overlying the external iliac artery. The ureter is identified crossing the common iliac artery by following the external iliac artery cephalad to bifurcation. Ureter is left attached to the medial or posterior leaf of the broad ligament so as not to disrupt its blood supply.

The same procedure is completed on the opposite side. The left ureter is usally more medial than the right. If patient has extensive pelvic disease, the ureter must be dissected down towards bladder as far as necessary. The position of the ureter should never be assumed and must always be kept under direct visualization. The perivesical and perirectal spaces may be created to facilitate safe hysterectomy particularly if there is distortion of anatomy by pelvic pathology. Any problems encountered intraoperatively can safely and quickly be addressed when the spaces have been developed.

- Preservation of Ovaries:
  Amidst controversy, it seems rational to preserve the ovaries in premenopausal women, if they are found healthy. Routine removal after age of 45 is no more practiced.
- Advantages:
  (i) Menopausal symptoms appear less.
  (ii) Ovarian function continue till the expected time of spontaneous menopause, so less incidence of osteoporosis and atherosclerosis.
- Drawbacks:
  (i) Malignancy or Benign neoplasm.
  (ii) Residual ovarian syndrome.
  (iii) Chronic pelvic pain and dyspareunia.
  (iv) Chance of Re-laparotomy.
- Early Removal is required:
  (i) If the ovaries are diseased in inflammatory process or involved in neoplastic condition with patient around the age of 40 or earlier.
  (ii) H/o ovarian cancer in first degree relative of patient.

Hormone Replacement Therapy is to be considered when ovaries are removed.

Removal of Fallopian Tube

Recently, the distal Fallopian tube has attracted considerable attention not only as site of origin for serous cancer in women with *BRCA* mutations, but also as the anatomical location where the majority of serous ovarian cancers apparently develop.

Terminology for Tube Removal

(i) When the ovaries are removed. (Salpingo-oophrectomy)
(ii) When the tubes are diseased but ovaries are conserved due to young age. (Salpingectomy).

Treatment for Prolapse of the Uterus: Cervico-Sacropexy (CESA) and Cervico-Recto-Sacropexy (CERESA)

91

Wolfram Jaeger

Introduction

Prolapse

The term "prolapse" is used when the internal genitalia have lost their original position within the body and protrude along the vertical axis. It is not a disorder which appears from one moment to the other but a continuous development which may take several years. Prolapse usually starts in the second part of life – it is a problem associated with aging.

The pelvic organ prolapse quantification (POP-Q) system differentiates 4 stages "on that way out" (POP-Q I – IV) and is valuable for describing, quantifying and staging uterine and vaginal vault prolapse [1].

However, the distribution of stages is unequal. While the positions of the leading part from 1 cm above the hymenal ring to totally outside is subdivided into 3 stages (II, III and IV), the equally long distance within the body from the top of the vagina (e.g. −10 cm) to −1 cm is termed stage I.

A further characterization of the anterior vaginal wall can be achieved by the points A and B. These points in combination with D and the total vaginal length are defined simply on distances to the hymenal ring. They are helpful to describe anatomical prolapse quite precisely.

Prolapse has a close relationship to urinary incontinence [2].

The absolute frequency of urinary incontinence in patients with prolapse is difficult to determine. Most of these patients have reached an advanced age and they either do not appear at a clinic with a minor prolapse or they do not complain about urinary incontinence (UI). Up to 50 % of patients who were hysterectomized because of uterine prolapse had urinary incontinence (UUI) [3].

The number of patients increases with age so that an absolute percentage cannot be determined.

W. Jaeger
Urogynecology, University of Cologne, Köln, Germany
e-mail: wolframjaeger@gmx.de

For physiological purposes some other aspects should be taken into consideration as they may be important in the mechanisms of continence. Especially the anterior vaginal wall deserves further characterization [4].

These may be the parts of the vagina below the urethra, below the urethral-vesical junction, the area where the bladder adheres to the anterior vaginal wall and the fixation site of the bladder and the anterior cervix.

The role of these different areas is not clear. However, the area above the urethral-vesical junction was described by PETROS as the "zone of critical elasticity" – an area where the brain receives its information about the filling state of the bladder and thereby starts or inhibits voiding [4].

In that area a movement with the anterior blade can easily induce the feeling of urgent need to void or not during vaginal examination.

Etiology

The exact aetiology and the pathophysiology of genital prolapse are unknown.

The observation that prolapse is a continuous development argues strongly against the rupture of a "holding structure". The function of the "holding apparatus" diminishes over time; therefore, it is tempting to speculate that a continuous influence is important for the reduced elasticity of the respective tissues [5].

Because prolapse is an absolutely rare phenomenon in animals, the upright body position could be essential. It has been hypothesized that the pressure on the pelvic structures which hold the pelvic organs (uterus, vagina, ovaries, bladder and rectum) is increased by the upright body position. As premise, it is taken that a special critical "pressure" must exceed the "holding forces".

One aspect of increased pressure on this pelvic holding apparatus is pregnancy (baby, uterus and amniotic fluid) and the mechanisms of birth.

© Springer International Publishing Switzerland 2018

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_91

Increasing body weight as a continuous development seems plausible; however, prolapse is irrespective of body weight.

During pregnancy the pressure on the pelvic floor increases; however, the physiological development of the baby, uterus and amniotic fluid during pregnancy do not directly exert their whole pressure on the pelvic floor since the anterior part of the abdomen does not remain in its normal position but bulges.

The power vectors under these conditions are probably not directed at the critical parts of the "holding apparatus".

Pelvic Anatomy

The delivery of the baby leads to dramatic changes in the outlet part of the uterus, cervix (as special closing structure), vagina and the muscular outlet ring (including the connective tissue in that area) of the vaginal introitus.

In contrast to the anatomy of a woman outside of pregnancy, the respective diameters of the "birth tunnel" for the baby (predominately head) need to dilate massively.

The most dramatic changes take place in the cervical channel which has to increase its diameter from some millimetres to about 10 cm, which means a hundredfold increase in diameter. Compared to these changes the increase in the diameters of the vagina and the introitus are marginal (two to threefold); however, a diameter which may reach to 10 cm means a massive extension of these structures.

In a few hours the muscular uterine contractions lead to an increase of the anatomical outlet and shortening of the cervix. Despite the fact that the pre- and perinatal changes are most dramatic in the cervix, a cervical rupture during delivery is a rare event. Prolapse after delivery is an even more seldom event.

The stretching and the later reduction to normal size must be influenced by the increasing hCG, estrogen and progesterone levels during pregnancy.

After the delivery of the baby the correct anatomical reconstruction of the internal genitalia is also influenced by the reduction of these hormones and by prolactin which induces oxytocin release after suckling and thereby contractions of the uterus muscle.

Uterine Prolapse and Urinary Incontinence

A considerable number of women become urinary incontinent after childbirth [6].

However, this incontinence is reversible as it usually disappears after some weeks.

It has been hypothesized that this incontinence is based on the "stretched" pelvic-holding structures at the end of pregnancy. This assumption is based on the difference in the incidence of incontinence between women who delivered spontaneously and those who were delivered by cesarean section (CS). In women with CS the incidence of UI is significantly lower than in women who delivered spontaneously [7].

Forty percent of women suffering from genital prolapse also report UI [2].

It was assumed that UI and genital prolapse were two different disorders which only coincide by chance.

During a retrospective analysis based on personal interviews we could demonstrate that more than 50 % of women who had a vaginal hysterectomy because of prolapse stage II–IV of the uterus also presented with mixed urinary incontinence. The same numbers were reported by others who stated that up to 50 % of all women with vaginal hysterectomy developed stress and urge urinary incontinence thereafter [3].

On the other hand the remaining women with prolapse did not develop UI.

Therefore, prolapse alone cannot be the only reason for UI but UI is often associated with prolapse!

Pathophysiology of Prolapse and Incontinence

According to the above mentioned observations prolapse is probably based on a defect of the "holding apparatus" perhaps combined with some hormonal influences and genetic disposition. The ensuing laxity of the anterior vaginal wall leads to urinary incontinence. The uterus is probably not the etiological responsible factor for prolapse; therefore, a causal treatment must focus on the repair of the holding structures [4].

Prolapse is a disorder which usually appears after menopause. However, when it appears hormonal treatments can no longer repair the damage.

From observations that incontinence disappears some months after delivery, it was concluded that estrogens may be effective in strengthening the respective tissues in the pelvic floor [8].

Therefore, estrogens are often used as first treatment in women with urinary incontinence. The connective tissues can be strengthened by estrogens; however, it is difficult to achieve any effects if the women are already postmenopausal. Most likely the respective receptors can no longer induce the effects on the target tissues.

This may be caused by the diminished number of functioning E2 receptors in the target tissue or by damage to the tissue itself.

As target tissue, the connective tissue of the small pelvis with its body-position-specific "holding function" cannot be repaired. Estrogen replacement therapies cannot repair the prolapse or the incontinence.

In experiments with the corpses of rhesus monkeys, the change to an upright position led to an increased tension of the

left and right USL which could be seen most effectively when the bladder of the monkey was filled with 80 ml saline solution.

When the bladder fills, the position of the bladder in the pelvis increases the pressure on the different surrounding tissues and structures, probably dependent on the different body positions. In the standing and sitting position one could assume that the pressure of the full bladder will exert its power mainly on the upper vaginal wall.

To characterize this position, one has to consider that the length of the urethra differs somewhere between 2.5 and 4.5 cm. That means that the entrance of the urethra into the bladder is somewhere between 3.5 and 5.5 cm from the entrance of the vagina (assuming that the additional 1 cm is the part between the entrance of the vagina and the introitus urethrae).

This correlates with the "zone of critical elasticity" of PETROS. This may be different in the prone position when the pressure is more directed to the lateral parts of the bladder or lying on the back where the pressure is more horizontal [4].

However, the pressure on the vaginal wall is transmitted to the holding structures. This is the anatomical fixation at the vaginal entrance and the cervix. The cervix, however, transfers this pressure to its holding structure – the USL.

(Interestingly enough the fixation points of the USL at the backside of the cervix are nearly exactly opposite the highest fixation points of the bladder at the front side of the cervix.)

In analogy the position of the vagina can be compared with a bridge with two pylons in the front and in the back: the pubo-urethral ligament (PUL) and the USL [4].

Because, according to developmental research, the USL are derived from the uterus and not from the presacral area, it must be important that women have two USL at the cervix and not only one. These two USL do not arise from the same point at the cervix but have two different origins at a distance from each other, depending on the size of the cervix. It can be speculated that this distance improves the three dimensional stability of the pelvic floor and especially of the position of the bladder. By increasing the distance between the origins of the USL the stability of the bladder position is increased.

Therefore, prolapse treatment needs to focus on the holding apparatus and especially on the USL. Since in patients with prolapse the structures of the USL diminish by two thirds in their muscle and elastic tissue composition, the USL cannot only be repaired but must be replaced.

Pelvic Floor and Standardization of the Operations

The premise of the CESA and CERESA operations is a standardised surgical replacement of the USL (Fig. 91.1).

Standardised operation means that the operation will be performed in every patient in exactly the same way: identical length of tapes which is guaranteed by stitch marks on the

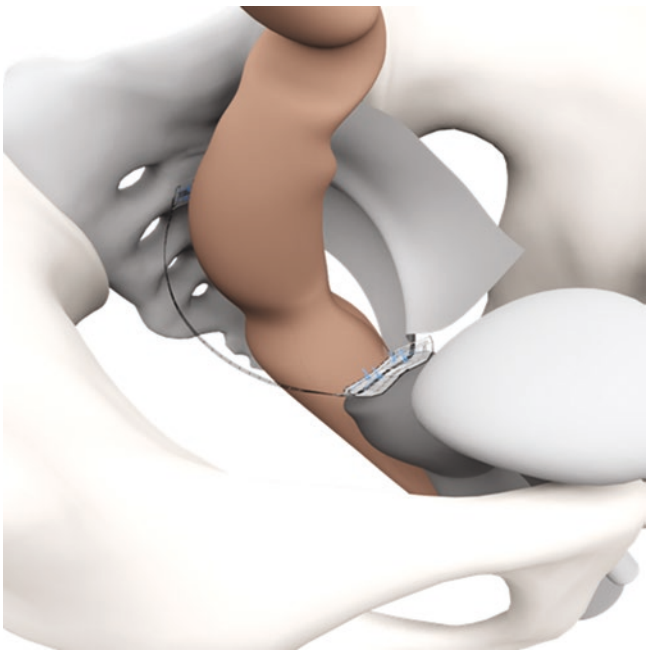

Fig. 91.1 The CESA structure was sutured to the cervical stump and the os sacrum. The USL tapes of the structure run retroperitoneally

structure, defined fixation sites at the cervix and in front of S1/S2. The structures are pulled through the peritoneal fold of the USL and thereby placed retroperitoneal at a defined channel.

Considering the great variety of women's shapes one would expect that the lengths of the USL are different in every woman; however, this is not the case.

In obstetrical textbooks the diameters between the bony structures in the small pelvis are identical in all women irrespective of weight, parity or racial derivation. This has been confirmed by extensive MRT measurements by several institutions [9].

For this reason we hypothesized that the ligaments in the small pelvis, especially the USL and the PUL, are also of identical length or differ only slightly in all women after puberty.

Therefore, we decided to implant USL structures of the same length in every woman. According to the literature and our own measurements we arrived at the conclusion that the length of the USL is between 8.5 and 9.0 cm. According to the literature we decided to implant 8.8 cm long USL structures with a distance between each other of 4 cm at the "bridge" in CESA (Dynamesh CESA, FEG, Aachen, Germany) [10].

CESA and CERESA as Prolapse Surgery

Prolapse is a disorder of the "holding apparatus" of the uterus.

If this apparatus loses its strength, the held structures will give way according to the laws of gravity.

According to the "bridge allegory" of PETROS, the "tows" which hold the lane continuously lose their tension. These "tows" of the bridge are the pelvic connective tissues and probably most importantly, the uterosacral ligaments (USL) [4].

Because prolapse does not occur from one day to the next, it is not an accidental happening which leads to prolapse.

Prolapse is mainly a disorder of the postmenopausal woman. Therefore, it seems reasonable to speculate that the drop in hormones after menopause plays an essential role in this development.

Estrogens can be effective in preventing softening of the connective tissues. Estrogen replacement therapy (ERT) is preventive in this respect; however, estrogens cannot repair an already existing defect.

For this reason, treatment of prolapse must consist of repairing the existing defects.

The defects can be repaired by reparation of the most important "tow" which is the USL [4].

The observation that women who were hysterectomized because of uterine prolapse tend to develop a vaginal vault prolapse thereafter clearly indicates two aspects:

The uterus cannot be the leading cause for prolapse and the underlying disorder has not been effectively treated. We do not know how to treat the chronic disorder but we propose to repair the "tows" of the bridge.

CESA and CERESA as Incontinence Surgery

The bilateral replacement of the USL by the CESA or CERESA structures demonstrated that even patients suffering from urge urinary incontinence were cured of this complaint [11].

So far there is no explanation for this finding.

However; the success rates decrease with increasing age which indicates an underlying problem which is age dependent.

The PVDF Tapes

Polyvinylidene fluoride (PVDF) monofilaments were used as the material of choice for the construction of four new implants to augment the USL.

The augmentation of the uterosacral ligaments was performed using a narrow but open-pore sling structure of 4 mm width, made of high strength PVDF filaments (Dynamesh CESA and Dynamesh CERESA, Dynamesh VASA and Dynamesh VARESA, FEG Textiltechnik mbH, Aachen, Germany). The large-pored structure avoids the formation of a scar strand and the encapsulation with a fibrotic granuloma of the tape. It also enables the ingrowth of fatty tissue [12].

This allows the long-term and constant mobility of the newly formed ligaments.

Stitch marks on the right and left sides ensure that the identical ligament length is restored. For CESA we took an 8.8 cm long USL.

The anterior fixation site is 3 cm x 4 cm.

Additional Rectopexy (CERESA)

If a rectopexy has to be performed (CERESA), a non-resorbable suture 3–0 is placed in front of the marked posterior fixation sites. Special tapes have been developed for this procedure (Dynamesh CERESA). The sutures grab the mesorectum on both sides and are tied on the anterior net structure of the tape in that area.

Repair of the Anterior ("Cystocele") and Posterior ("Rectocele") Vaginal Wall

The decision to perform an additional repair of the anterior or posterior vaginal wall i.e. a vaginal colporrhaphy has to be taken at the end of surgery and should only be performed when points Aa, Ba or C are >-2 cm (-1, 0, +1, $\geq$+2).

Before the Operations

Explanation of the Operation

During the explanation of the Cervico-Sacropexy (CESA) or Cervico-Recto-Sacropexy (CERESA) the surgeon must know what should be done if a cervix-conserving operation cannot be performed. A current PAP smear must have been obtained. The possibility that the operation could end as a hysterectomy without any USL replacement must be discussed with the patient. Furthermore, the patient has to decide whether she wishes to keep the tubes and ovaries or have them removed.

Clinical and Ultrasound Examination

The examination has to rule out malignancies and must detect possible myoma. It has to be decided how to treat the respective findings. Myoma are usually resected by supracervical hysterectomy.

Bowel Cleansing

One day before surgery the patient must have a bowel cleansing as for a colonoscopy. If the bowel is not absolutely empty, the operation can become very difficult because the diameter

of the "working place", especially in front of S1/S2, may be only a few centimeters.

Note: Every additional centimeter makes it easier.

Body Weight

If the patient has a body weight exceeding 100 kg, we abstain from the operation due to the feasibility of the surgical techniques.

Bladder

A catheter is placed at the beginning of surgery.

At the end of surgery it is advisable to fill the bladder with blue saline solution to detect any possible injuries.

Antibiotic Coverage

Cephalosporines are administered according to the body weight as a single dose injection immediately at the start of surgery.

Anti-coagulation

Coagulation must be controlled. If the patient is under anti-coagulant treatment, adaptations must be started before surgery.

Note: Even chronic aspirin treatment can cause heavy bleeding which is difficult to control.

In some cases it is prudent to consider the help of a hematologist.

A bleeding of the venous plexus in front of the os sacrum is one of the leading causes for severe bleedings during these operations. If electrocautery cannot control the bleeding, compression with a swab has to be performed for several minutes.

The control of this bleeding can become very difficult if the patient is under anti-coagulation treatment.

Pre-operative Interactive Talk ("Time-Team-Out")

We calculate the operation time for a CESA, from opening the peritoneum until closing the peritoneum, to be 70–150 min (for CERESA 10 min longer).

The remaining time is used for "cut and final closing of the skin". This is dependent on the experience of the surgeon.

The overall operation time is usually calculated as 120–150 min.

Blood loss is calculated at 100–200 ml.

Pre-operative Measurements

Prolapse Measurement

The vagina is examined and a clamp is placed at the cervix (Fig. 91.2). A newton meter is placed at the clamp and a force of 10 N (1 kg) is exerted at the clamp (Fig. 91.3). The distance between the cervix and the hymenal ring is measured (Fig. 91.4).

The index finger is then placed at the clamp at the side of the hymenal ring. The clamp is opened and the distance between the cervix and the hymenal ring is measured.

Opening the Abdominal Cavity (According to the Internal Institutional Standards)

The dermal incision should be horizontal ("cesarean section"). It is between 8 and 12 cm according to the pre-rectoral fatty tissue.

After opening the peritoneum, we prefer placement of a rectangular frame.

The first step is to decide whether the operation can be carried out as planned.

If ovarian cysts complicate the situation, these should be removed and examined. The aim of this part of the operation is to "empty" the pouch of Douglas as much as possible.

Therefore, the bowel and the small intestines have to be out of the small pelvis.

We use two surgical towels. With the first towel we place the small intestine into the upper abdominal cavity. With the

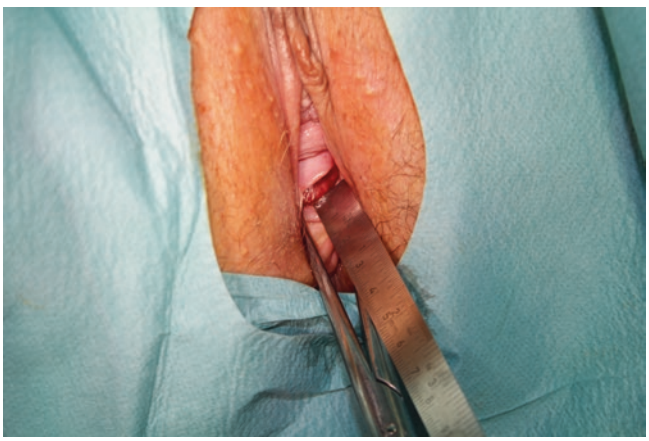

Fig. 91.2 Before surgery the distance between the cervix and the hymenal ring is measured. A clamp is placed at the lateral cervix

Fig. 91.3 With a newton meter a defined tension of 10 N (1 kg) is placed at the clamp

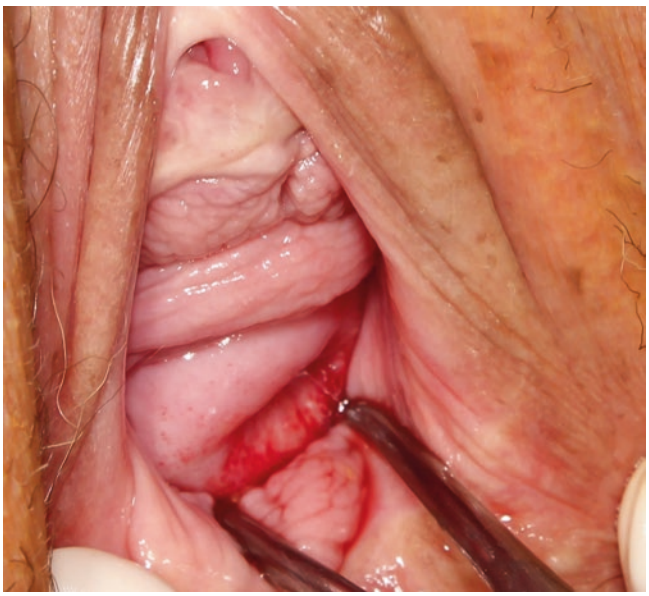

Fig. 91.4 In this case, under these measuring conditions the cervix comes to the hymenal ring. Therefore, according to this measurement the distance of Point C is 0. (This standardized measurement is not the POP-Q system, but uses its definitions of the points and distances.)

second towel (which is folded into a rectangular shape) we move the descending and ascending large intestine upwards. At the end of this step the pouch of Douglas should be free of intestine apart from the sigmoid colon. Especially the pelvic rims (the transition into the small pelvis) must be clearly visible in order to make incisions there without any problem.

Dissection of the Tubes and the Ovaries from the Uterus

The adnexa are identified at the uterine corpus. They are dissected by coagulation and cut (Figs. 91.5 and 91.6).

The uterine vessels are coagulated and cut (Figs. 91.7, 91.8, 91.9 and 91.10).

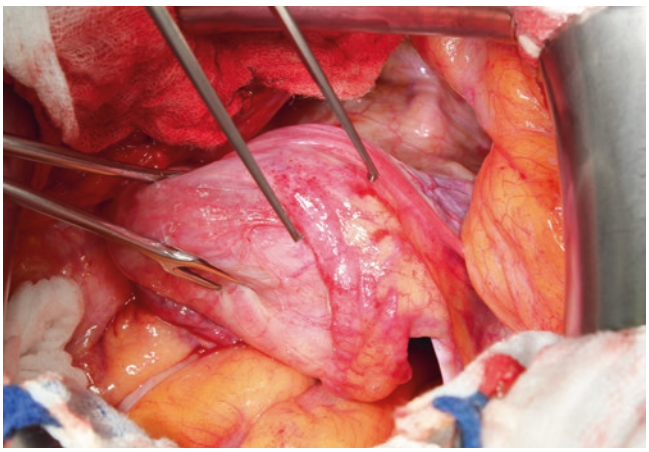

Fig. 91.5 After opening of the abdomen the uterus is grabbed with a hooked clamp. The forceps demonstrate the right adnexa on top of a myoma of the uterine corpus. The round ligament and the tube are clearly visible

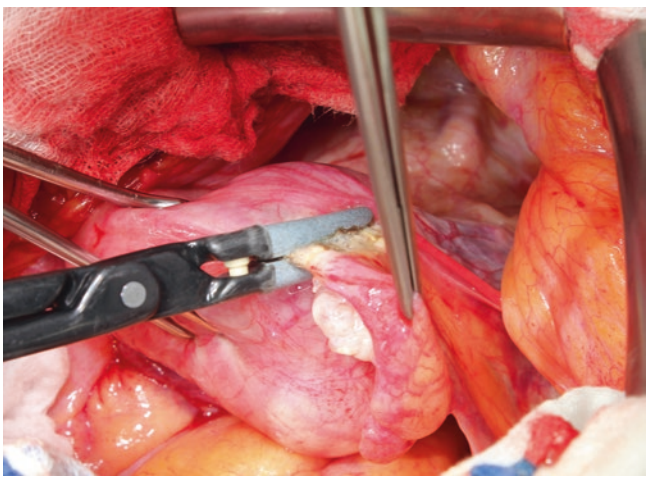

Fig. 91.6 The right adnexa are cut and cauterized

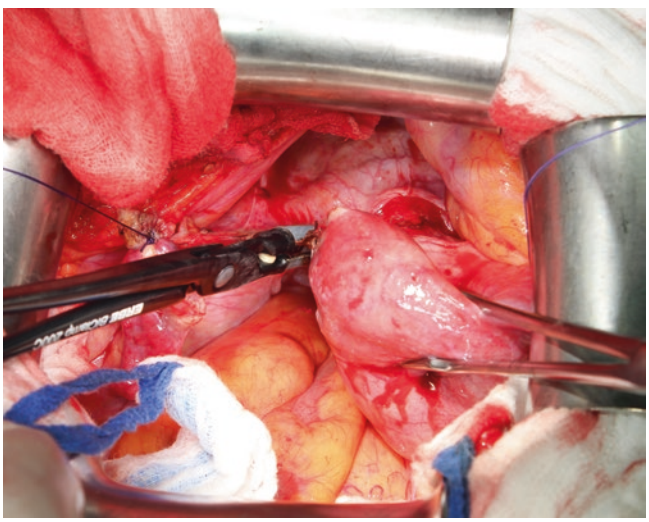

Fig. 91.7 The same is done on the left side and the parametrium is cut until the cervix region is reached

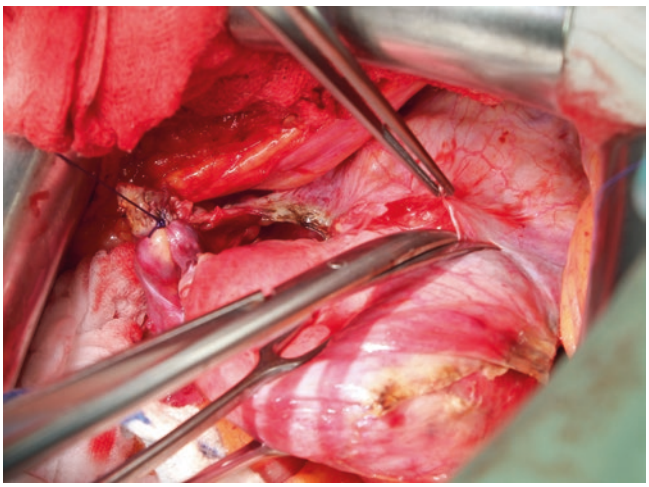

Fig. 91.8 The bladder peritoneum is incised. The bladder remains at the cervix

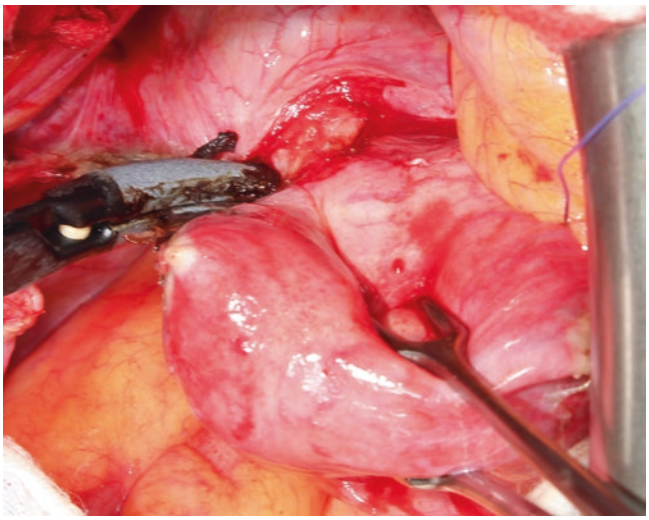

Fig. 91.9 The left parametrium is coagulated. Take care to coagulate the left uterine vessels – vein and artery.

Identifying the Peritoneal Folds of the Uterosacral Ligaments (USL)

The next step of surgery is the demonstration of the USL.

(In patients with a previous supracervical hysterectomy the cervical stump is identified. We then place a strong suture (Vicryl 1–0) into the cervical stump as a holding suture.)

The uterus is pulled vertically towards the outside of the abdominal cavity. With increasing tension the peritoneal folds of the USL will become visible at the backside of the cervix.

The origins of the USL at the uterus can always be identified. The origins of the USL are at the posterior part of the cervix. The USL arise nearly opposite the insertion side of the bladder at the anterior side of the cervix.

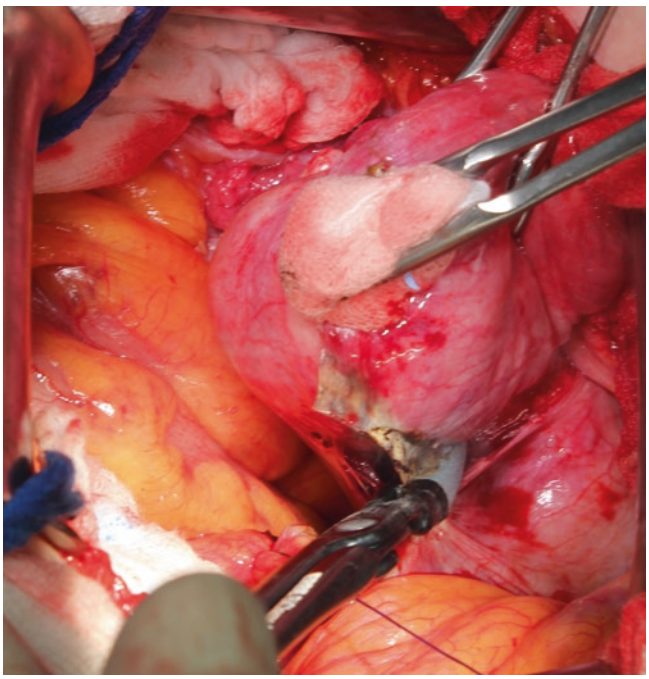

Fig. 91.10 The right parametrium is coagulated and incised. Take care that the uterine vein and artery are cauterized

The two origins diminish within 1 or 2 cm from the cervix and continue their way to the sacrum as folds of the peritoneum. These folds contain the remnants of the USL.

If the peritoneal fold of the USL cannot clearly be identified, then a swab is placed in front of S2 and the pre-sacral peritoneum is pushed medially until the USL (peritoneal fold) becomes visible.

The USL extend beyond the peritoneum into the small pelvis. The urether is located higher at the pelvic wall. Be sure to identify the ureter from its path into the small pelvis until the region of the cervix.

The middle parts of the USL (especially in women suffering from prolapse) cannot be identified with the surgeon's eye; however, this is not important as only the peritoneal coverage (fold) is important for the correct placement of the structures.

The peritoneal folds of the USL end at the level of S2. The USL structures reach up to the sacral spine in the area between S1 and S2.

Note: At this stage the surgeon should get an impression of the length of the cervix in order not to cut the entire cervix.

The length of the cervix below level 0 varies in most women. The remaining cervical stump should be about 2 cm. In patients with an elongated cervix one has to assess if the cervix has to be shortened.

In postmenopausal patients the uterus and the cervix may be so small that a VASA structure could be more suitable.

Definition of Level 0

The points at the cervix where the USL originate are delineated. An imaginary horizontal line between these points of origin is called "level 0" (zero).

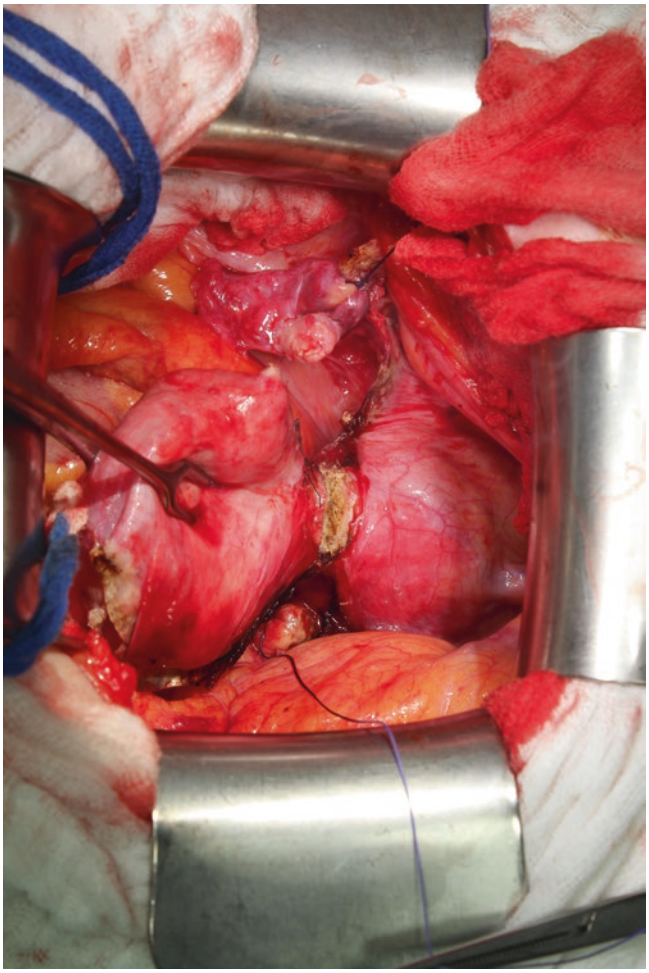

Fig. 91.11 The cervix is incised where the bladder reaches the cervix. This is the place where the USL reach the cervix at the backside

A small horizontal incision ("mark") is made at the backside of the cervix at the level 0 (Fig. 91.11).

Take care that the incision is only used as a "mark" at which the corpus of the uterus is dissected. Too big marks could cause bleedings of the uterine artery or vein which are absolutely unnecessary at this point of time.

The supracervical hysterectomy is performed at the height of the "level 0".

One has to consider the length of the remaining cervix. Usually it is between 1 and 2 cm. If the remaining cervix is longer than 2 cm (given that the level 0 was correctly defined), one has to decide if the cervix has to be amputated from the vagina. We deliberately decided to leave these "extra-long" cervices.

Note: In sexually active patients the above aspect must be considered. In some circumstances a cervical resection could be necessary.

Supracervical Hysterectomy (SH)

To be able to see the USL, the uterus has to be elevated. The cutting level of the SH will be in the range of level 0, i.e. very close to the beginning of the bladder on the anterior cervix.

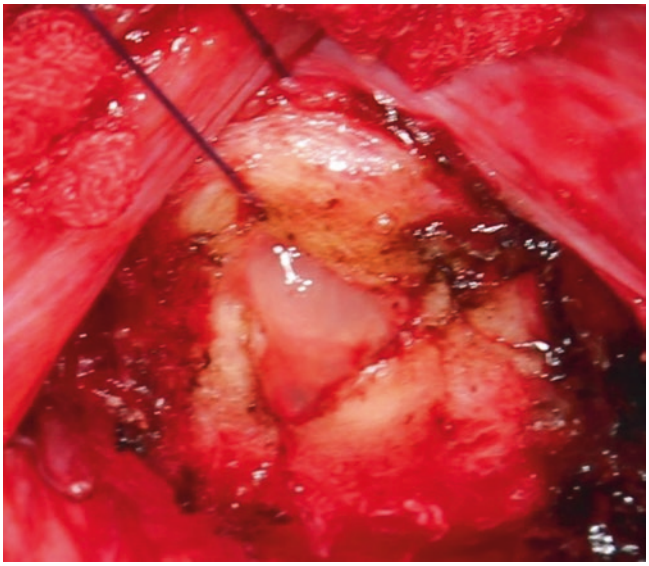

Fig. 91.12 After the cervix has been cut, a "holding suture" is placed and armed with a clamp. This will help to "navigate" the cervix during further operation

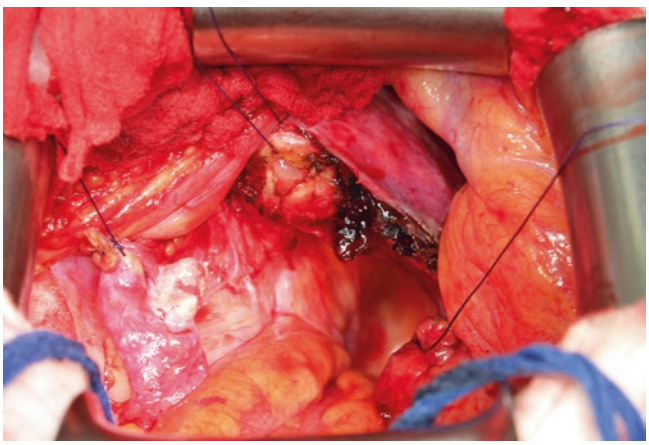

Fig. 91.13 The uterus is then removed

Therefore, grasp the bladder with a forceps and identify this place ("bladder insertion") at the cervix.

The corpus will later be resected at the level 0.

The supracervical hysterectomy can be performed according to the clinical standards.

Note: Abstain from dissecting the bladder from the cervix. This fixation of the bladder is essential and should not be destroyed!

Usually level 0 lies at or slightly below the insertion of the uterine artery and vein. Keep in mind that these vessels therefore come from the lateral part of the pelvis and not along the uterine body.

After supracervical hysterectomy, it is easier for the next steps to fix a holding suture at the anterior ("bladder") side of the cervical stump. This facilitates placement of the next sutures and peritonealization at the end of surgery (Figs. 91.12 and 91.13). The holding suture in not knotted so that it can be removed easily.

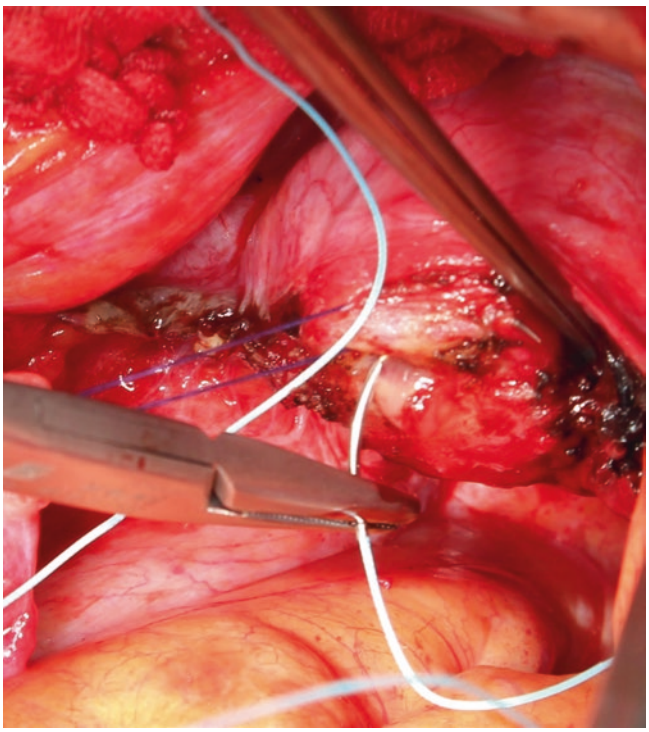

Fig. 91.14 The non-resorbable sutures are placed at the cervical stump. The first stitch grabs the right anterior quadrant

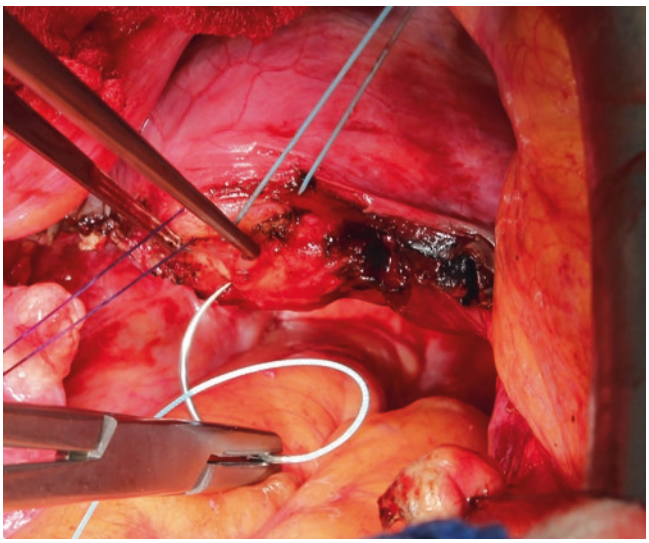

Fig. 91.15 The second stitch grabs the right posterior quadrant

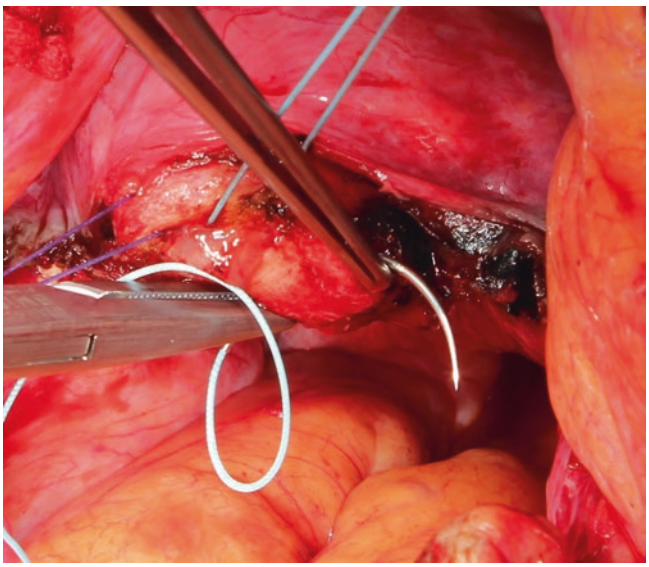

Fig. 91.16 Note: Avoid injuring the uterine vessels

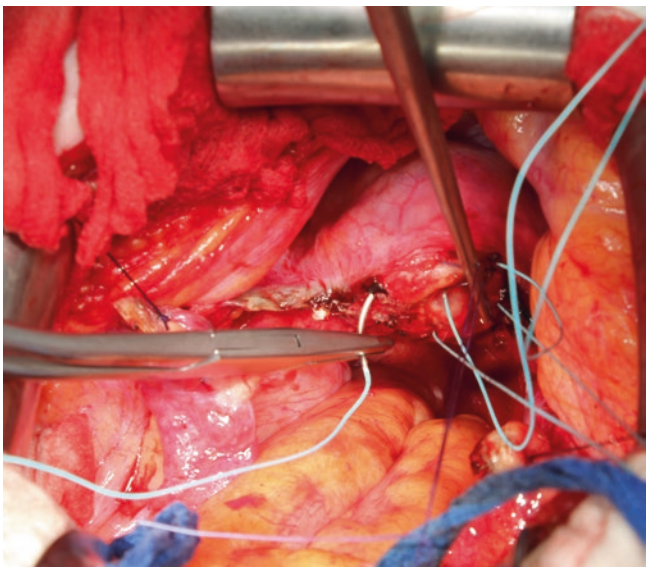
Note: If the vagina was opened during any steps of the CESA or CERESA, there is a high risk of the development of pelvic infections.

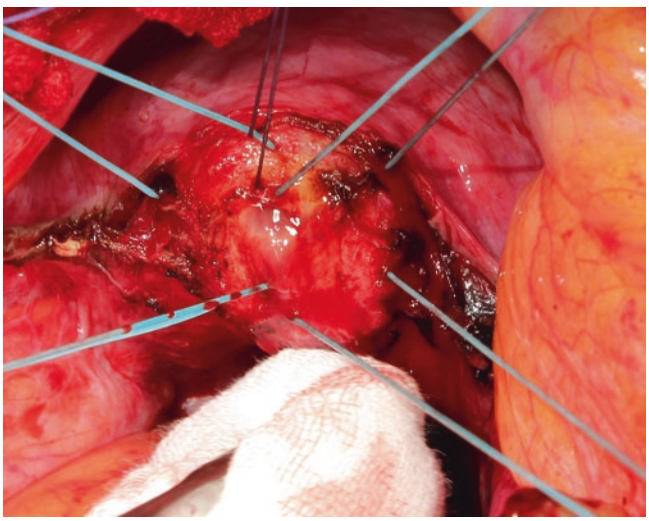
In premenopausal patients the infection rate is definitively higher than in postmenopausal patients.

Fixation of the Tapes at the Cervical Stump



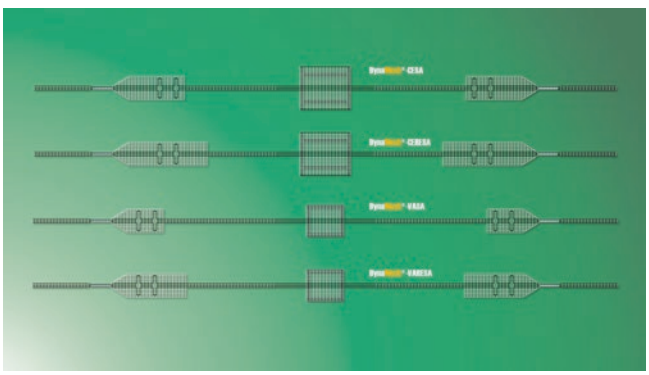
Four non-resorbable sutures 2–0 are placed at all 4 quadrants of the cervical stump (Figs. 91.14, 91.15, 91.16, 91.17 and 91.18). Special care should be taken that the stump of the cervix is totally covered by the mesh structure ("bridge") and secured by the sutures, "like linen on a table".

Care should be taken that the distance between the USL after suturing the bridge is 3 cm to ensure a stable horizontal fixation of the vagina and bladder. Furthermore, the holding vectors must be on the anterior vaginal wall, i.e. in the part of the cervical stump close to the bladder.



The four stitches should not pass through the cervical channel.

Thereafter, the CESA or CERESA structure has to be chosen (Figs. 91.19, 91.20 and 91.21). In patients with a very small uterus it may be necessary to use a VASA or VARESA mesh!



After placing the CESA mesh on the cervical stump, the sutures are pulled through the net structure between the USL ("bridge") and carefully tied (Figs. 91.22, 91.23 and 91.24). The sutures must not cut the cervical tissue. The sutures are not used to hold the "bridge" tightly to the uterus but just to keep the "bridge" in position.

Flg. 91.17 The third stitch is placed in the left anterior quadrant

Flg. 91.18 The four sutures were placed

Flg. 91.19 Several structures can be compared. The CESA and CERESA USL tapes are 0.5 cm shorter than the VASA/VARESA USL-tapes. The "bridge" (anterior fixation side") is 3 cm x 4 cm. The augmentation of the uterosacral ligaments is performed using a narrow but open-pore sling structure of 4 mm width, made of high strength PVDF-filaments (Dynamesh CESA, Dynamesh CERESA, FEG Textiltechnik mbH, Aachen, Germany)

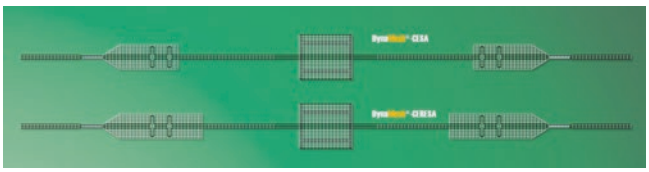


Fig. 91.20 CESA (top) and CERESA (bottom) tape

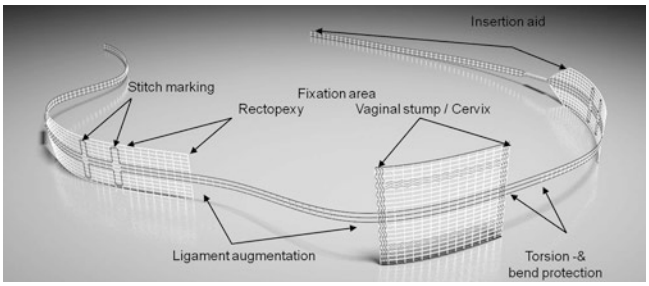

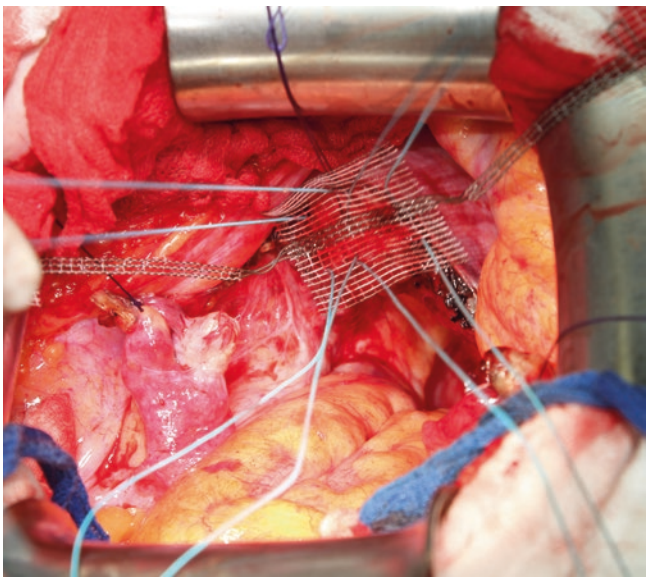

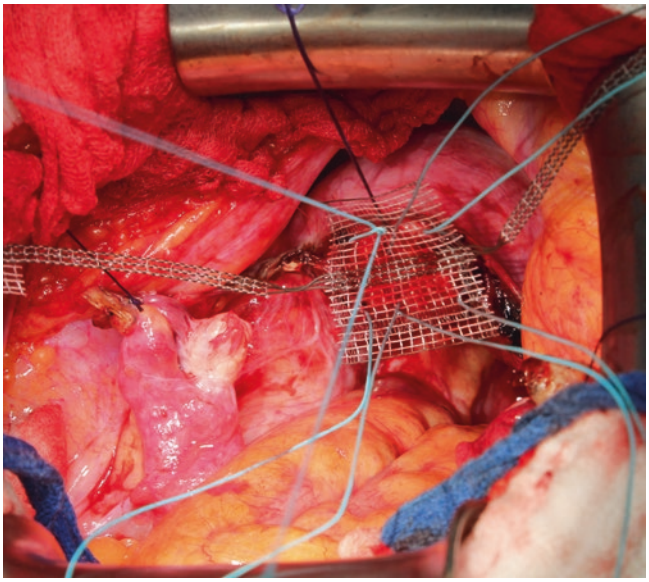

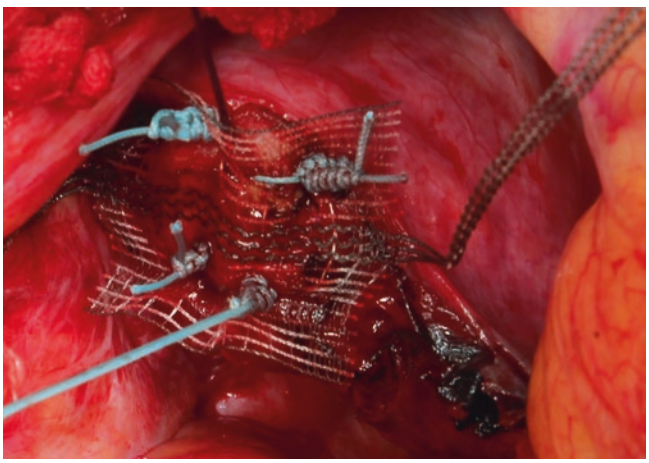

Fig. 91.21 The details of a CERESA tape. The ligament augmentation is from the end of the "bridge" to the first stitch marking. This distance is 8.8 cm. In the CERESA structure – as shown here – before the stitch markings a mesh is added for rectopexy. After placement of the structure in the USL peritoneal fold, the insertion aid is cut

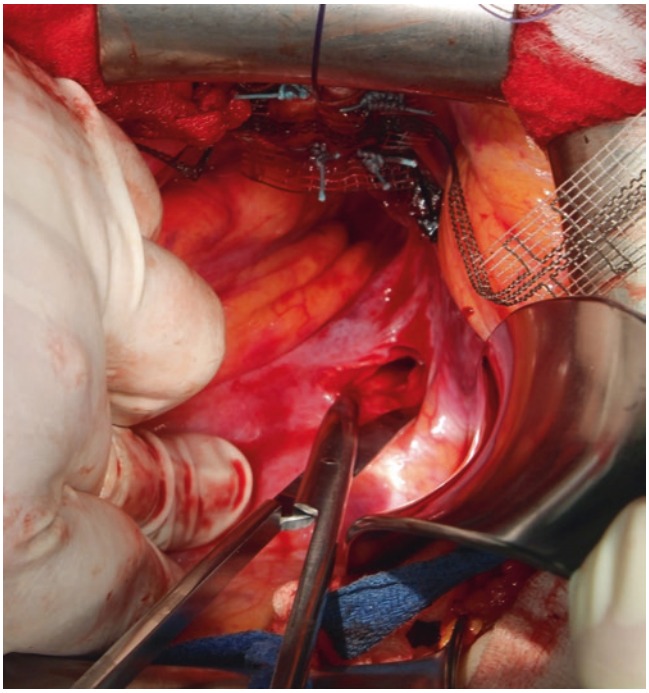
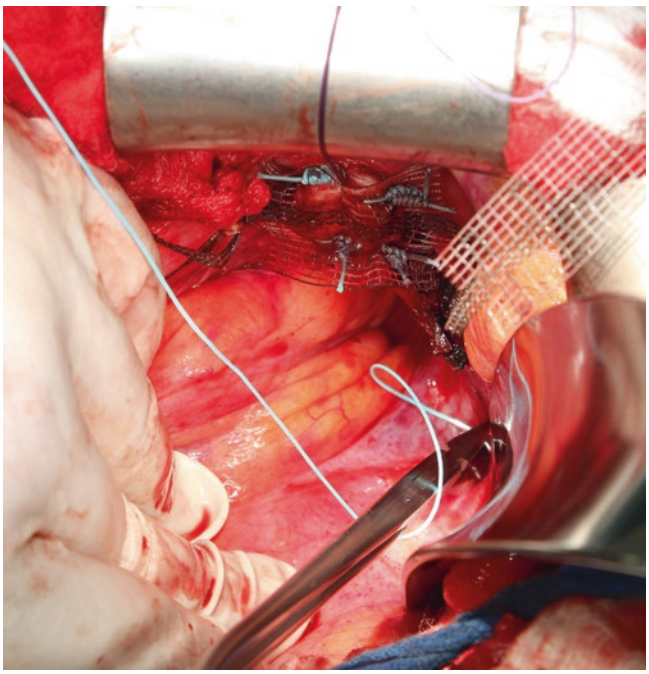


Flg. 91.22 The sutures are placed through the "bridge" of the structure and the structure is placed on the cervical stump



Flg. 91.23 The sutures must not be tied so tightly that the vaginal wall builds folds. The aim of these sutures is just to fix the "bridge" at the cervix

Flg. 91.24 The sutures were cut

Flg. 91.25 The peritoneum on the right side is incised. The incision is on top of the USL in front of S1/S2

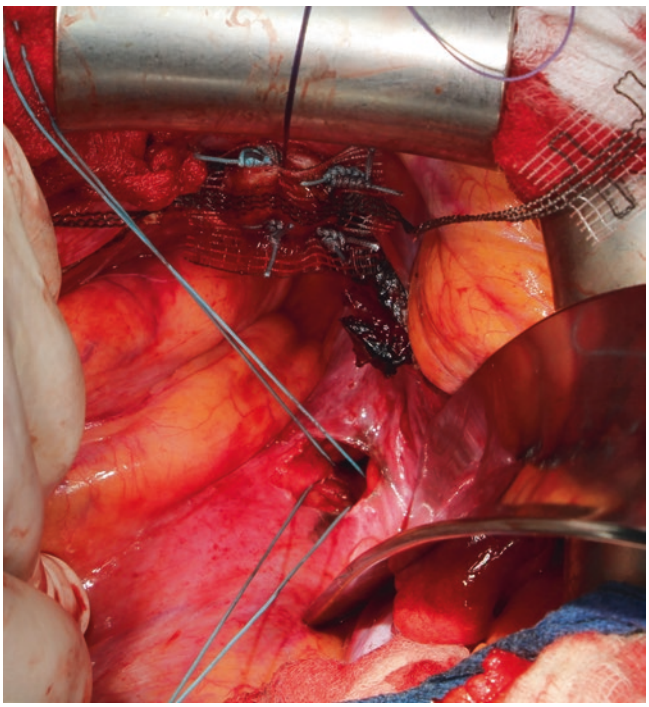
Flg. 91.26 After preparation of the prevertebral fascia, the first suture is placed horizontally. The suture is armed with a clamp which is put on the head part of the frame

Preparation of the Posterior Fixation Site

After the USL have been identified, the incisions at the sacrum are placed horizontally, 0.5 cm above the insertion side in front of S1/S2 (Fig. 91.25).

An incision along the USL (from cervix to sacrum) should be avoided since the "original" peritoneal folds protect the tape structure from adhesion formation. Furthermore, the folds form the intended anatomical "semi-circle" formation when the structures are under tension. The PVDF structures do not form fibrotic adhesions to this peritoneal fold; therefore, it remains movable.

The incision is usually above the first vertebra (S1). From these incisions the pre-vertebral fascia is prepared. Be aware of the hypogastric nerve and take the nerve laterally from the stitches later on. Identify the presacral artery and vein and coagulate them at 2 cm lengths so that the needle cannot injure these vessels. Two non-resorbable sutures 2–0 are placed horizontally in this fascia, one below and one higher at a distance of about 1 cm from each other. They are armed with a clamp and placed at the top of the wound (Figs. 91.26 and 91.27).



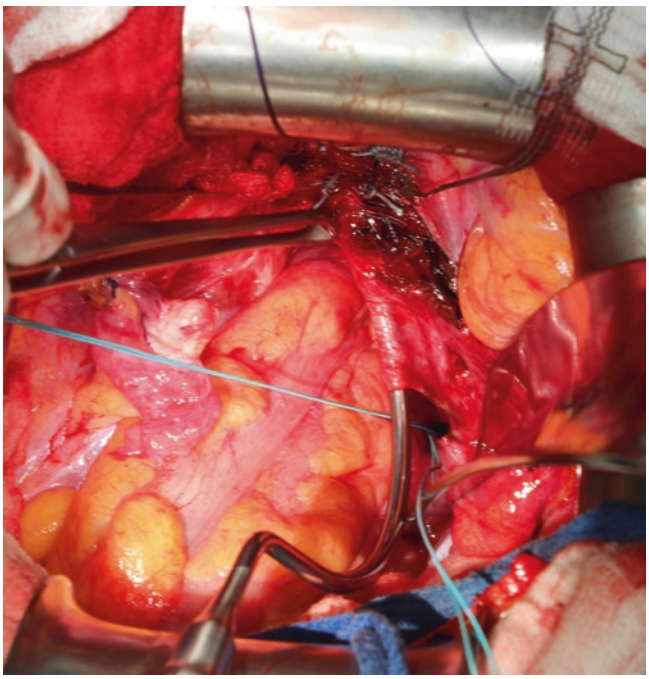


Fig. 91.27 The second suture is placed below and armed with a clamp. The clamp is put at the foot of the frame

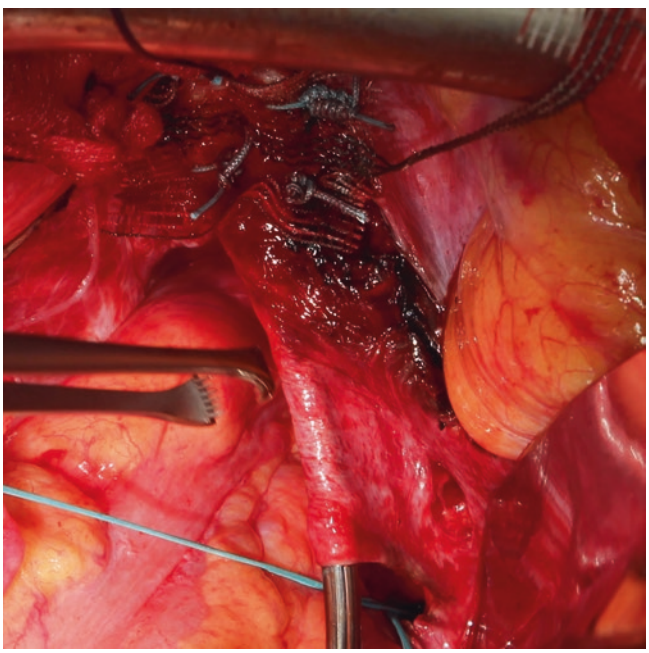
Flg. 91.28 The trocar is brought into the peritoneal fold of the USL.



Placement of the New USL

For the next step, care must be taken to avoid injury to the peritoneal fold of the USL.

A small trocar, as usually used for a TVT placement, is pulled through the peritoneal fold of the USL from the back to the base at the vaginal end (Figs. 91.28, 91.29 and 91.30). Care must be taken not to injure the stumps of the uterine vein or artery which were cut during the previous hysterectomy. Bleeding can be difficult to identify since the blood tends to flow through the peritoneal channel to the opening incision in front of S1/S2.

Advice: If the origin of the bleeding cannot easily be identified, this may cause considerable problems for the surgeon. In this case a 3–0 vicryl suture can be placed in the paracervical tissue close to the cervical stump. It should be placed in a double stitch manner in the region of the vessels until the bleeding stops.

Note: Leave the suture untied until you want to close the peritoneum. You can then draw the suture. Usually, thereafter, no more bleeding will occur.

Flg. 91.29 The trocar is pushed forward to the cervix

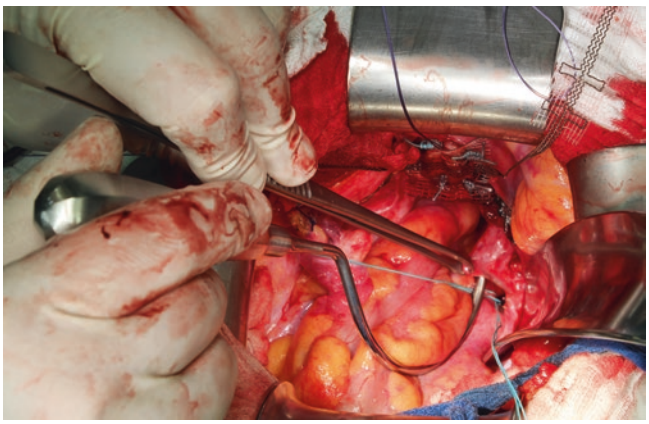


Fig. 91.30 At the cervix the tip of the trocar is placed forward towards the origin of the USL

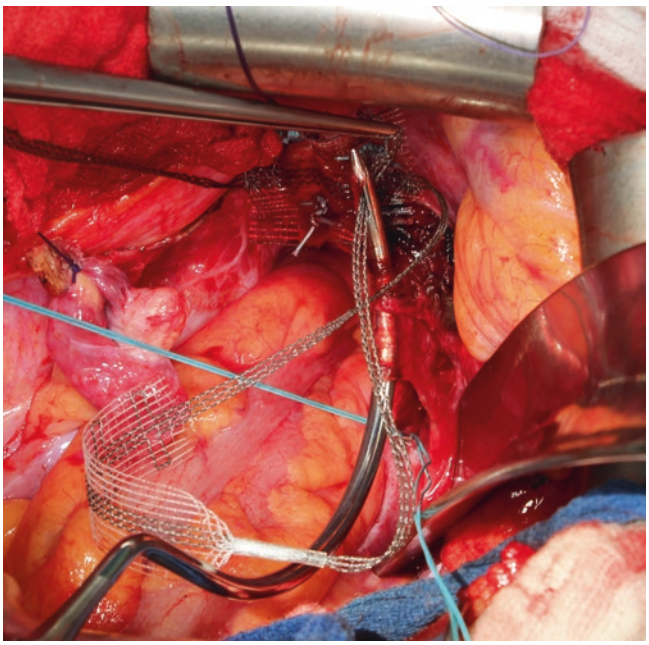

Fig. 91.31 After perforation with the trocar the insertion aid is put into the hole at the tip of the trocar

The insertion aid of the tape is pulled through the hole at the top of the trocar and the trocar is then pulled backwards to the sacrum (Figs. 91.31 and 91.32).

When the fixation mesh appears out of the "channel", it is placed where it should be fixed.

The previously-placed sutures are pulled through the marked fixation sites on the tape; the insertion aid is cut (Figs. 91.33, 91.34 and 91.35). At the end of this step the incisions at the sacrum is closed (Fig. 91.36).

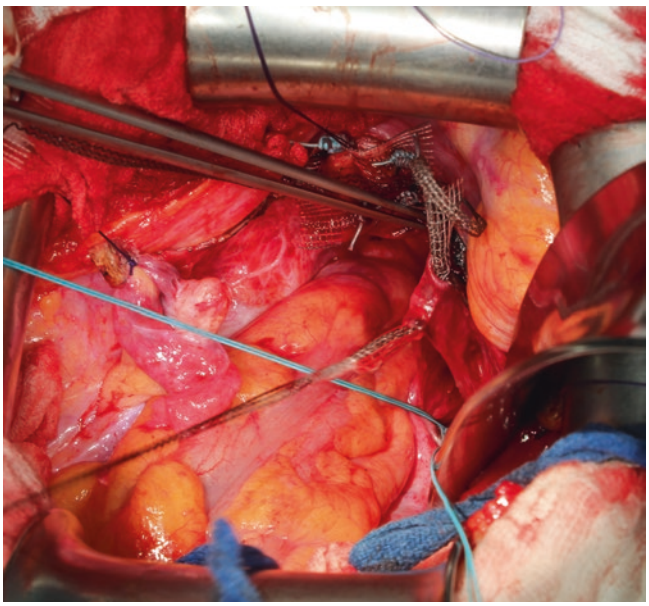

Fig. 91.32 Care must be taken when the posterior part of the mesh with the suturing marks are pulled through the channel. An injury of the uterine vessels could lead to bleeding which will appear at the posterior fixation side!

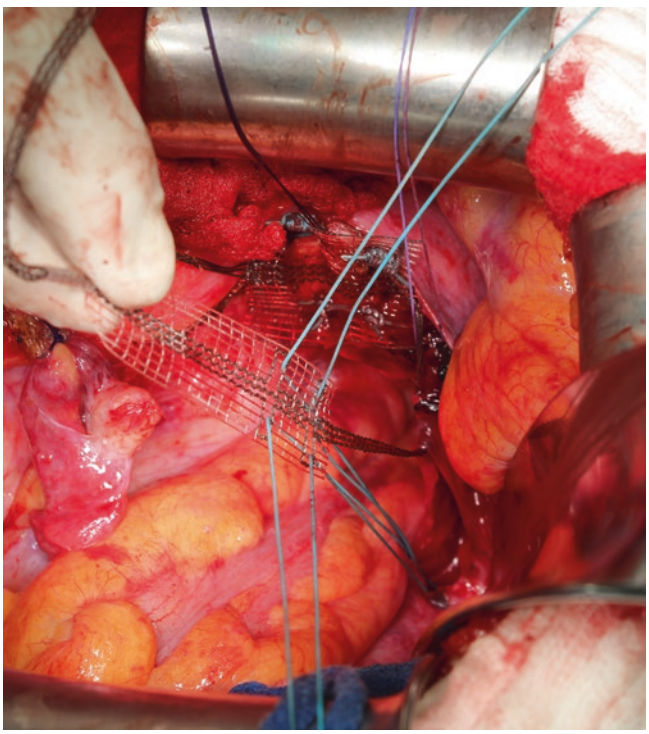

Fig. 91.33 The sutures are placed through the suturing marks

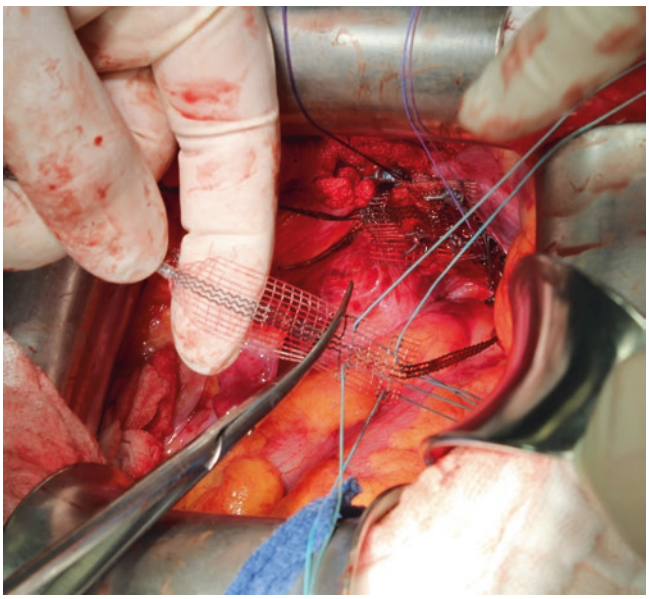

Fig. 91.34 Thereafter the insertion aid is cut

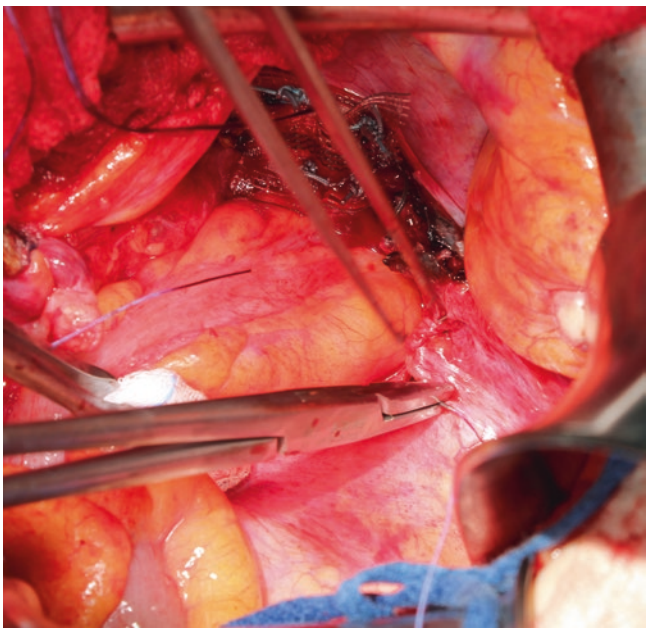

Fig. 91.36 The peritoneum is closed with a running suture

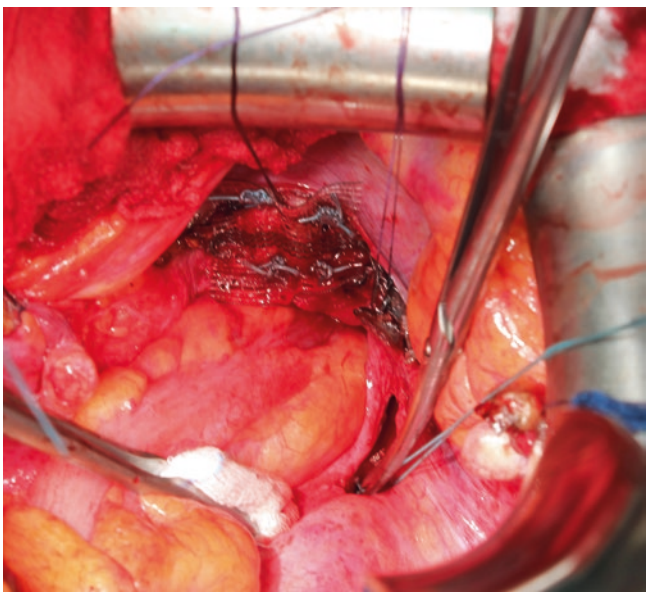

FIg. 91.35 After both sutures have been tied the ends are cut

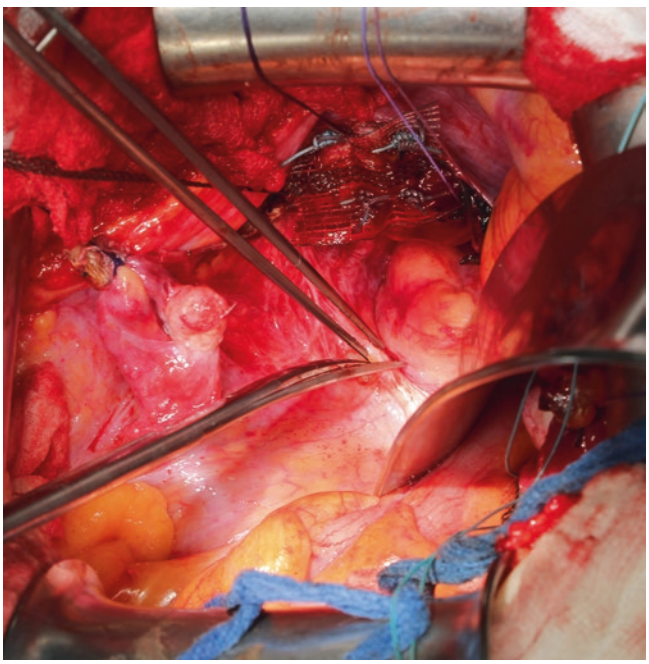

Fig. 91.37 The peritoneum on the left side is incised at the end of the left peritoneal fold of the USL in front of S1

The same procedure is then performed on the left side.

The left side is a little more difficult because the meso-sigma crosses the fixation side.

The sigma/rectum needs to be pushed to the right side. This can be done either with a retractor held by an assistant, or the surgeon takes the sigma in one hand and pulls it in the respective direction.

The surgeon then palpates the retroperitoneal sutures on the other (right) side. This palpatation will help to find the respective identical fixation site on the left side. With the other hand, the incision is placed as on the other side (Figs. 91.37 and 91.38).

When the posterior fixation sites are prepared – two sutures on the left and two sutures on the right side of the sigma colon – the sutures are armed with clamps and pulled aside (Figs. 91.39 and 91.40).

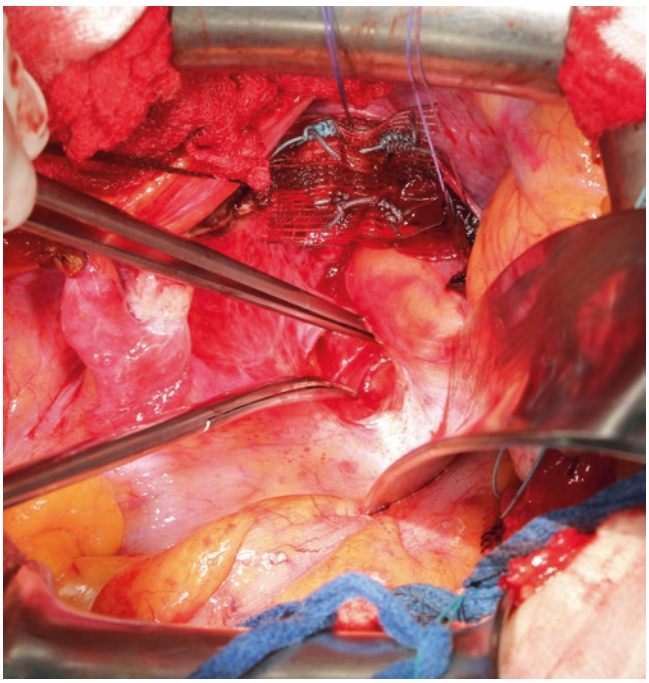

Fig. 91.38 The prevertebral fascia in front of S1 is prepared

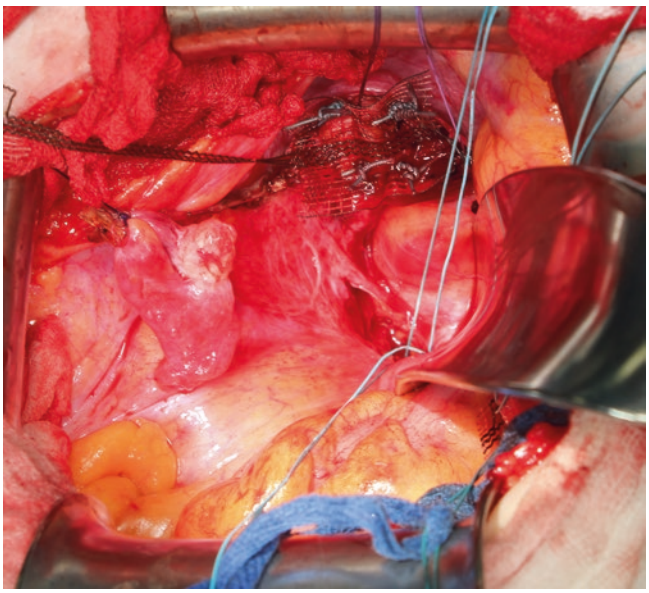

Fig. 91.40 A second suture is placed below the first and armed with clamps as on the left side

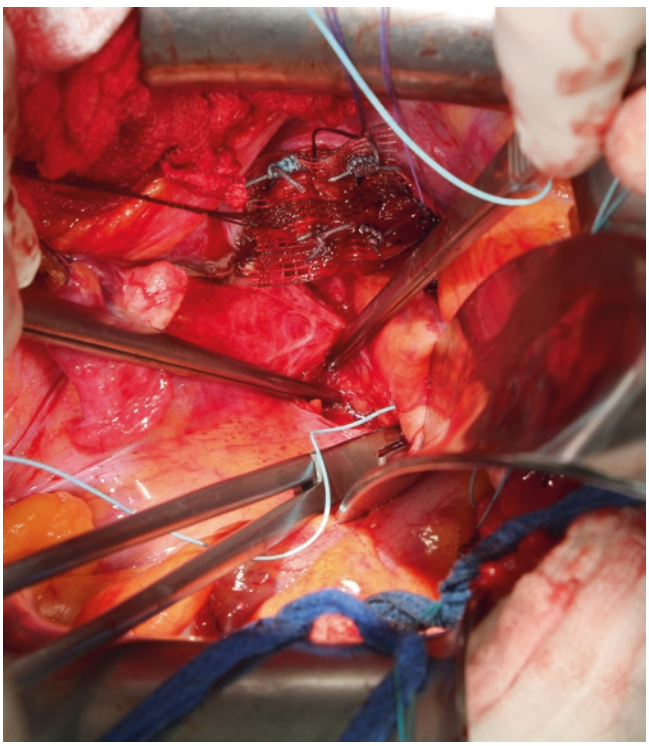

Fig. 91.39 The sutures are placed as on the left side

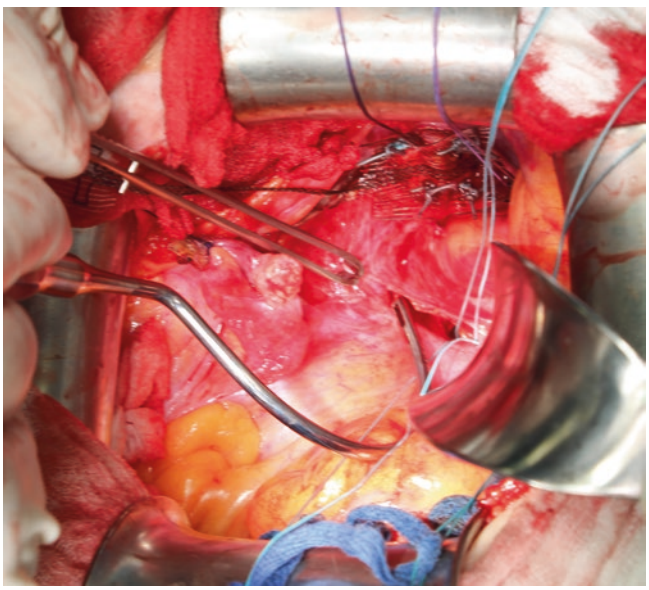

Fig. 91.41 The trocar is brought into the peritoneal fold and pushed forward to the cervix

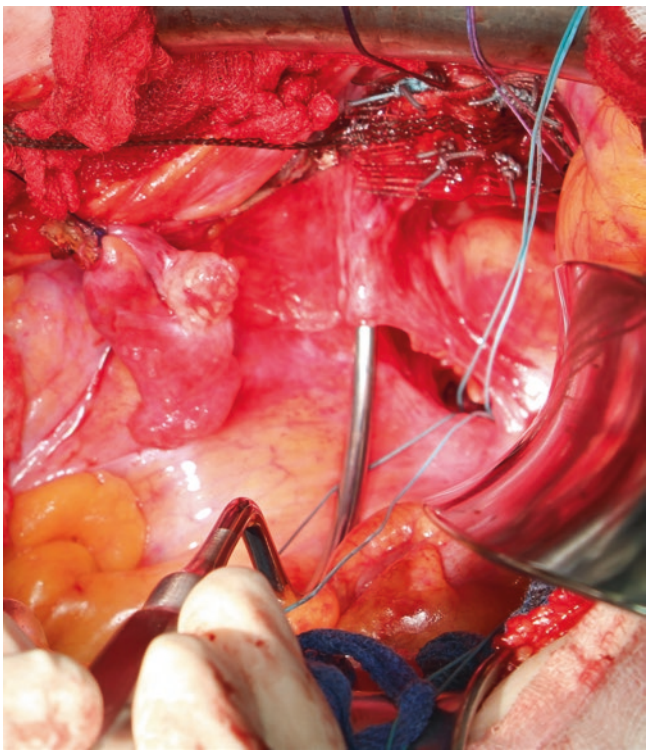
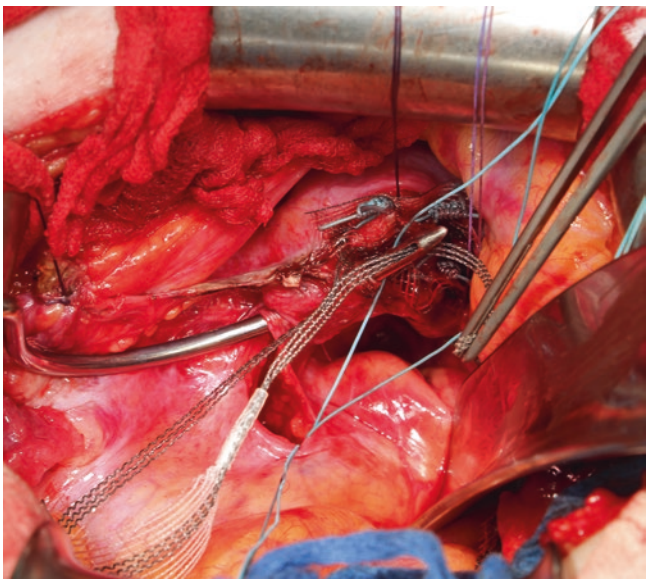


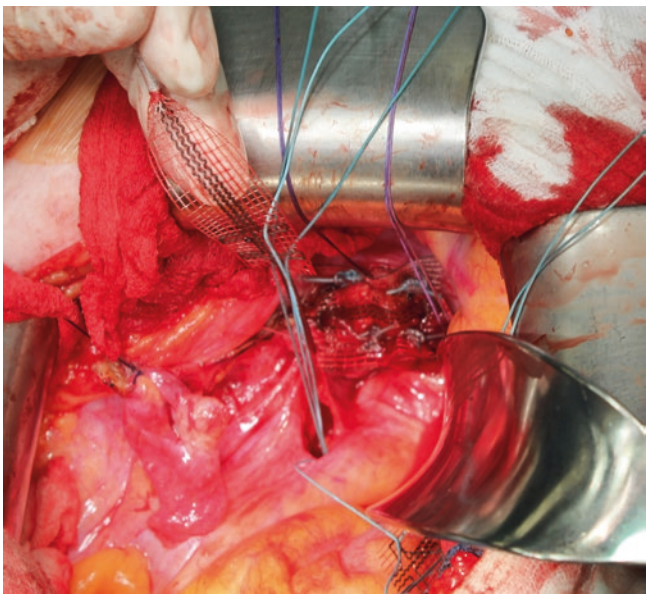
The trocar is placed at the opening and the peritoneal "channel" of the USL is used as the entrance for the trocar (Figs. 91.41 and 91.42).

The insertion aid is pulled through the hole in the trocar and the trocar is pulled backwards with the structure (Figs. 91.43 and 91.44).

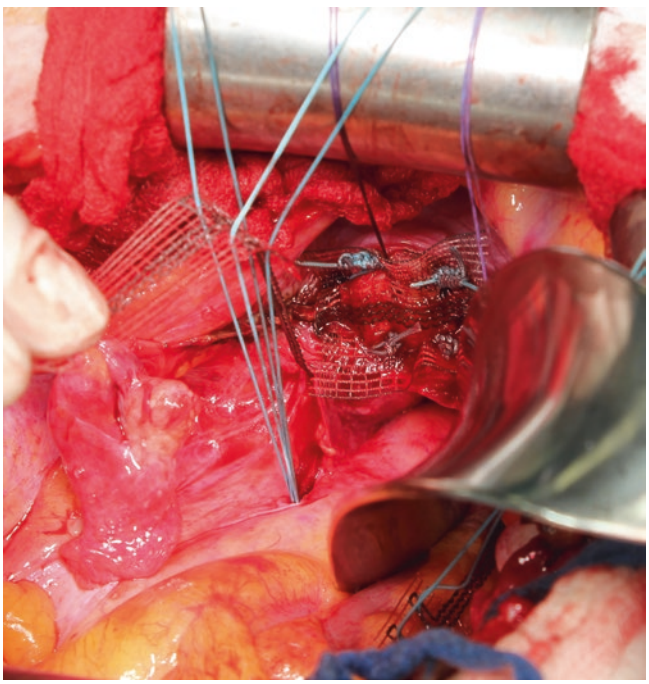


The sutures are pulled through the markings at the structure – each on one side – and the insertion aid is cut (Figs. 91.45 and 91.46).

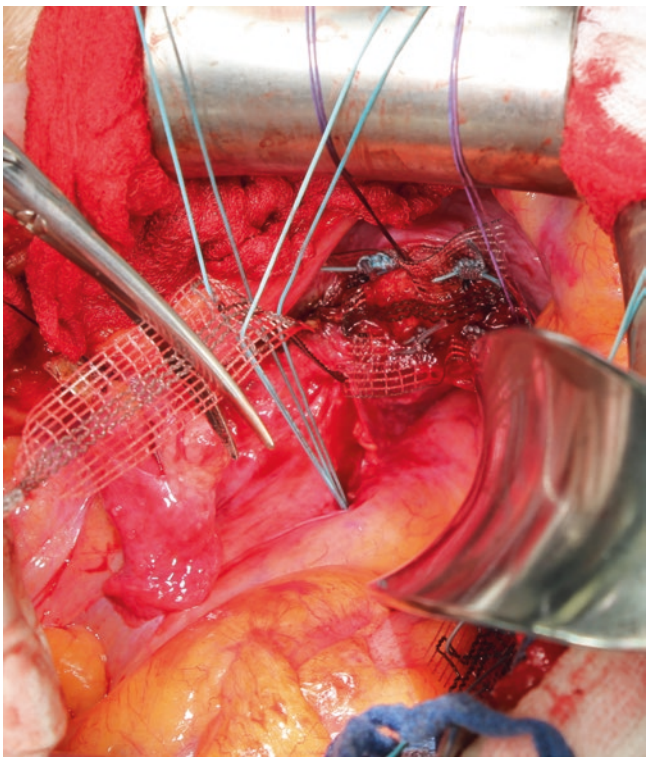
(In case a CERESA is indicated, the anterior mesh in front of the marking at the structure is taken and a non-resorbable suture takes a part of the mesorectum and sutures that to the CERESA structure (Figs. 91.47 and 91.48).



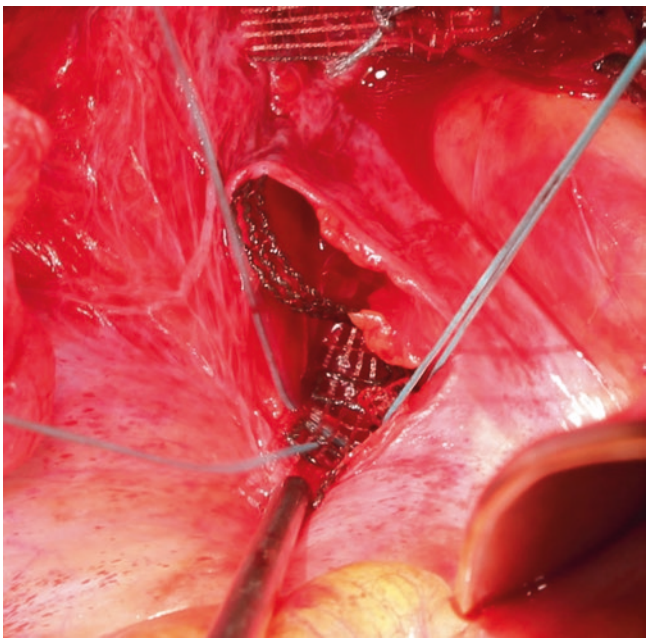
Thereafter the peritoneum is closed (Figs. 91.49).



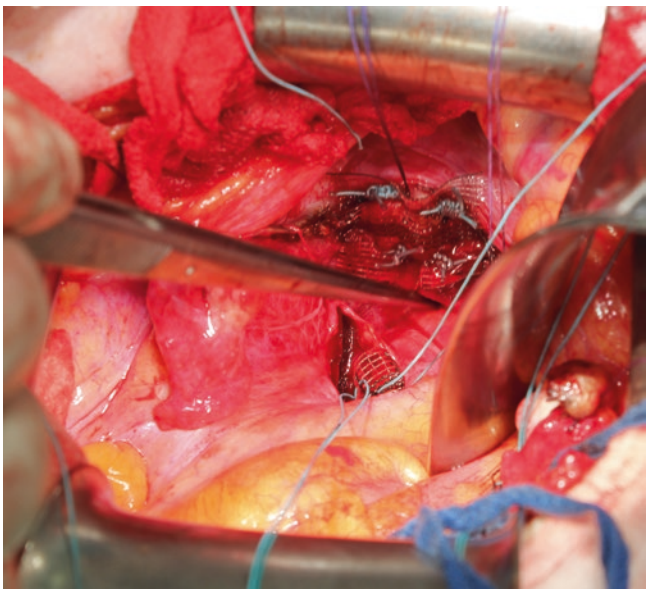
Flg. 91.42 At the cervix the trocar perforates the USL, as on the left side



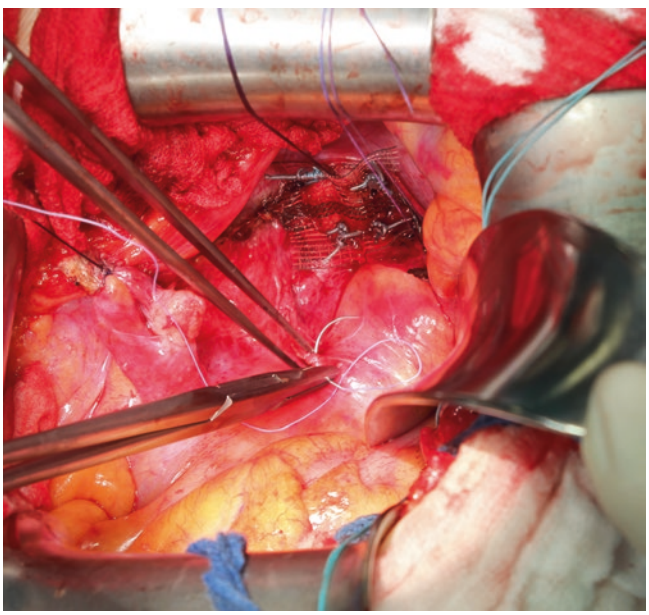
Flg. 91.43 The insertion aid is placed into the hole of the trocar



Flg. 91.44 After the structure has been pulled though the channel of the USL, the sutures are placed at the respective marks. Note: The sutures are always placed on one side of the mesh, either above or below the black strip



Flg. 91.45 Both sutures are placed



Flg. 91.46 The insertion aid is cut

Flg. 91.48 In CERESA a additional suture is placed in the mesorectum

Flg. 91.47 The sutures are tied

Flg. 91.49 The peritoneum is closed with a running suture

Closing the Peritoneum on the Cervical Stump

The cervical stump is peritonealized with the bladder and Douglas peritoneum. All sutures and the whole net structure ("bridge") must be covered by peritoneum (Figs. 91.50, 91.51, 91.52 and 91.53U).

Thereafter the towels are removed.

After removal of the towels 150 ml saline solution is added to prevent the drying out of the sigma epithelium leading to adhesion formation.

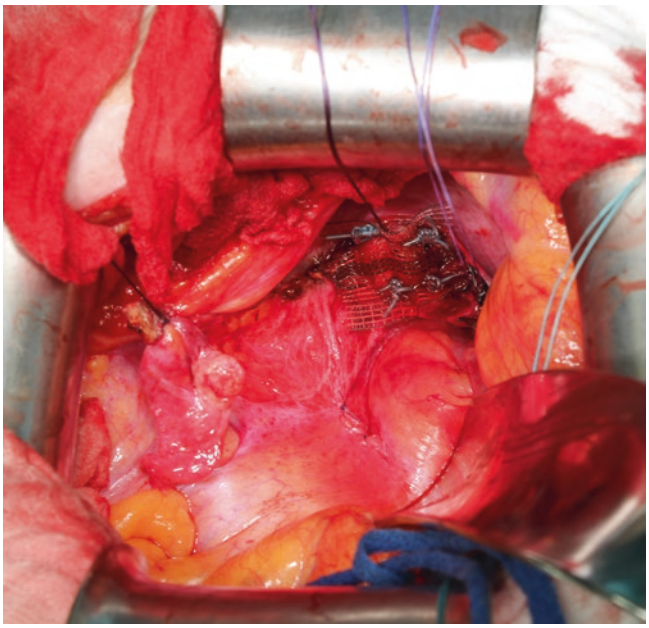


Fig. 91.50 The suture at the cervix is pulled and the cervix is elevated

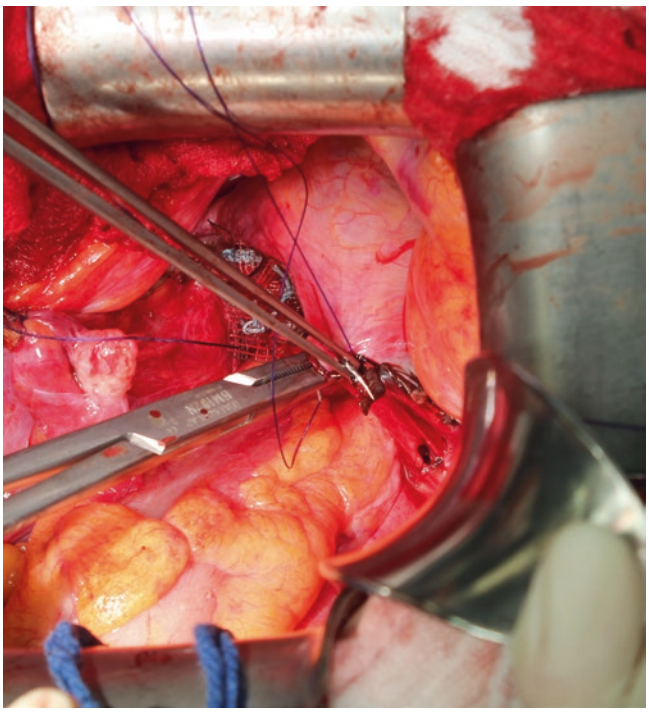

Fig. 91.51 The peritoneum is closed above the cervical stump so that everything is covered by the peritoneum

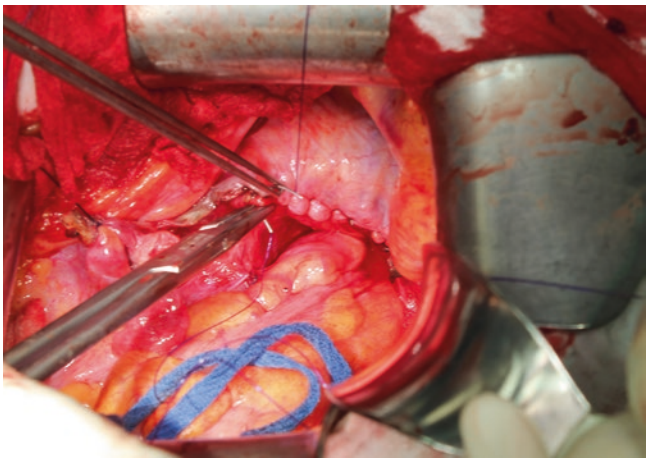

Fig. 91.52 The peritoneum above the cervix is closed

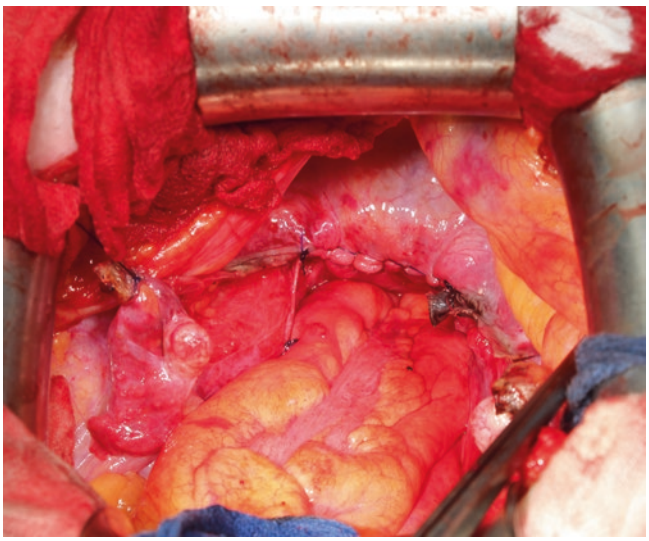

Fig. 91.53 View into the small pelvis after CESA

Additional Rectopexy (CERESA)

If a rectopexy has to be performed (CERESA), a non-resorbable suture 3–0 is placed in front of the marked posterior fixation sites. Special tapes have been developed for this procedure (Dynamesh CERESA). The sutures grab the mesorectum on both sides and are tied on the anterior net structure of the tape in that area.

Repair of the Anterior ("Cystocele") and Posterior ("Rectocele") Vaginal Wall

The decision to perform an additional repair of the anterior or posterior vaginal wall i.e. a vaginal colporrhaphy has to be taken at the end of surgery and should only be performed when points Aa, Ba or C are >2 cm (−1, 0, +1, +2…..).

At the end of the surgery the position of the cervix is controlled (Figs. 91.54, 91.55, 91.56 and 91.57).

Fig. 91.54 At the end of the operation the clamp is placed at the cervix as in the beginning

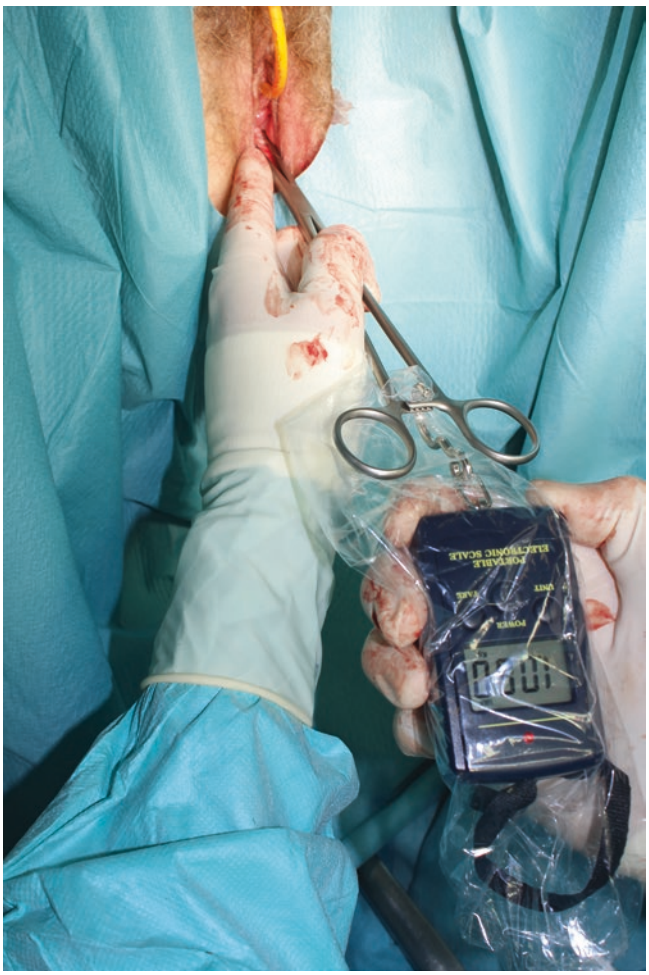

Fig. 91.55 The tension with 10 N is applied to the clamp. The index finger is placed on the clamp where the clamp reaches the hymenal ring

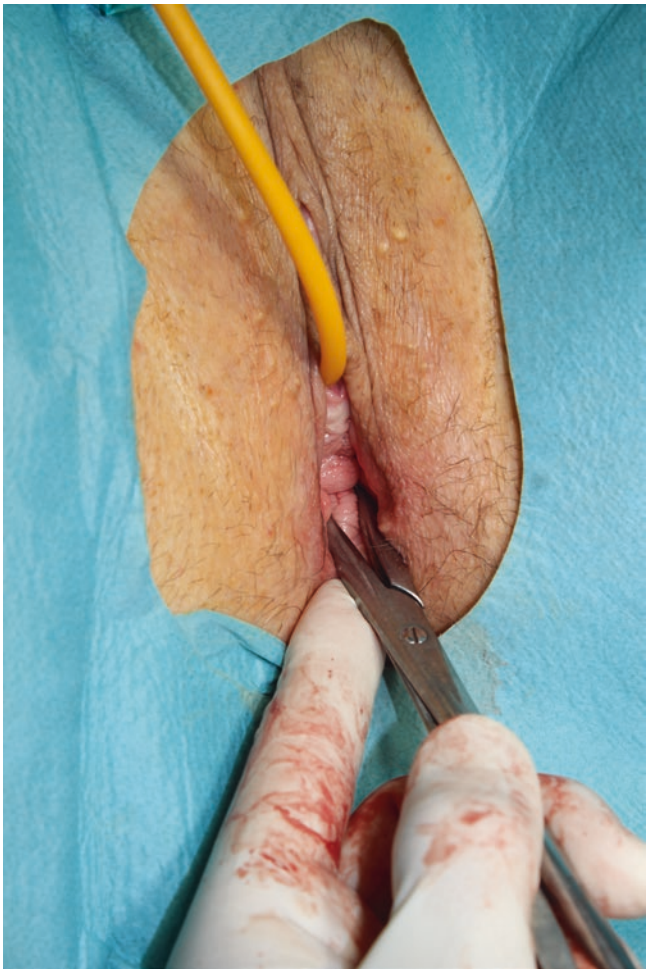

Fig. 91.56 The length is measured and reflects the position of the cervix (under tension under total muscle relaxation)

Fig. 91.57 The length is then measured and noted

Vaginal Vault Prolapse: Replacement of the Uterosacral Ligaments by Vaginosacropexy (VASA) or Vaginorectosacropexy (VARESA)

92

Wolfram Jaeger

Introduction

Prolapse

Vaginal prolapse describes the descending apex of the vagina. After hysterectomy the vagina is closed. Some surgeons leave the vaginal stump as it is, others suture the stump to the surrounding tissues [1].

The pelvic organ prolapse quantification (POP-Q) system differentiates four stages "on that way out" (POP-Q I – IV). So far there are no recommendations for different treatments according to POP-Q stages. Therefore, the POP-Q system is just a description of the actual anatomical status at the time of examination.

A further characterization of the vaginal wall can be achieved by the points A and B.

Per definition, point A is 3 cm upwards from the hymenal ring along the vagina [2].

At the anterior vaginal wall Aa is considered to be the area at the end of the urethra. Therefore, a shortening of point Aa indicates a descent of the urethra. This can be caused by an insufficient support of the urethra; however, one has to take into account that the length of the urethra differs considerably. Usually the length of the urethra varies between 2 cm and more than 4 cm in different women [3].

A point Aa at 3 cm, therefore, describes either a point at the urethral bladder junction or a point close to the middle of the urethra.

For this reason, the actual length of the urethra should be measured and then decided if the urethra is still in its original position or not.

W. Jager
Urogynecology, University of Cologne, Köln 50931, Germany
e-mail: wolframjaeger@gmx.de

The role of these different areas is not clear. However, the area above the urethral-vesical junction was described by PETROS as the "zone of critical elasticity" – an area where the brain receives its information about the filling state of the bladder and thereby starts or inhibits voiding. In that area a movement with the anterior blade can easily induce the feeling of urgent need to void or not during vaginal examination [4].

Etiology

The exact etiology and the pathophysiology of vaginal prolapse are unknown.

One could assume that the vagina is kept in its position by the holding forces of the uterus. When these "forces" diminish, the uterus descends and the vagina accompanies that prolapse. If the uterus is resected, the "holding forces" must be cut to remove the uterus. This then leads to a diminished suspension of the vagina. The vagina is then kept in position mainly by the paravaginal tissues.

Vaginal Prolapse and Urinary Incontinence

A considerable number of women become urinary incontinent after hysterectomy.

Forty percent of women suffering from vaginal vault prolapse also report UI [5].

During a retrospective analysis based on personal interviews we could demonstrate that more than 50 % of women who had a vaginal hysterectomy for prolapse stage II to IV of the uterus also presented with mixed urinary incontinence. The same numbers were reported by others who stated that up to 50 % of all women with vaginal hysterectomy developed stress and urge urinary incontinence thereafter [6].

Repair of Prolapse Leading to Incontinence

One of the most convincing observations that the vagina in associated with urinary incontinence came from long-time follow-up studies of prolapse surgery.

Women suffering from vaginal vault prolapse were operated by sacrocolpopexy (SCP) or sacrospinous fixation (SSF).

All patients were continent at that time.

Of these patients, 35 % developed urinary incontinence within 2 years of surgery, irrespective of which treatment modality – SCP or SSF – was chosen [7]. In another study it was found that 7 years after SCP 81 % of the patients were incontinent [8].

An additional BURCH operation reduced the percentage by only 10 %.

These results demonstrated that SCP and SSF can induce urinary incontinence. The question remains how and why not immediately after surgery rather than some years later.

SCP and SSF are considered to be two clearly defined operations [9].

However, several steps of the operations are not defined.

How tight must be the fixation of the vagina to the presacral fascia in SCP or at the sacrospinous ligament in SSF?

This could be an important facet of the operation but it is not defined but subject to the opinion of the surgeon.

Therefore, SCP and SSF are only the "family names" and not the definition of the members of the family.

However, the high long-term failure rate of 80 % in 7 years indicates that some other aspects could also be important which have not yet been evaluated.

Both procedures – SCP and SSF – have in common that the vagina is pulled to one side, either at the sacrum (in SCP) or on the sacrospinous ligament (SSF).

Compared to the suspension of the bilateral USL the SCP and SSF are unbalanced.

The bilateral replacement of the USL by VASA or VARESA does not induce urinary incontinence but, in contrast, can cure incontinence [10].

One could assume that the bilateral suspension of the anterior vaginal wall is important in respect to urinary continence.

Pelvic Floor and Standardization of the Operations

The premise of the CESA and VASA operations is a standardised surgical replacement of the USL (Fig. 92.1).

Standardised operation means that the operation will be performed in every patient in exactly the same way: identical length of tapes which is guaranteed by stitch marks on the structure, defined fixation sides at the cervix (or vaginal stump) and in front of S1/S2. The structures are pulled through the peritoneal fold of the USL and thereby placed retroperitoneal at a defined channel.

Considering the great variety of women's shapes one would expect that the lengths of the USL are different in every woman. However, this is not the case.

In obstetrics several diameters are well defined and the length of these diameters is the same all over the world. In the respective obstetrical textbooks these diameters between the bony structures in the small pelvis are identical in all women irrespective of weight or parity or racial derivation.

This has been confirmed by extensive MRT measurements by several institutions [11].

We therefore hypothesized that also the ligaments in the small pelvis especially the USL and the PUL are of identical length or differ only in small ranges in all women after puberty.

We therefore decided to implant USL structures with the same length in every woman. According to the literature and our own measurements, we arrived at the conclusion that the length of the USL is between 8.5 and 9.0 cm [12].

In hysterectomized patients we deliberately decided that probably 0.5 cm of the vagina had been resected. Therefore, we decided that the VASA and VARESA structures must be 0.5 cm longer than the CESA and CERESA structures.

The USL part of the VASA structure is 9.3 cm long and the fixation site at the vaginal stump is smaller (2 × 3 cm) (Dynamesh VASA and Dynamesh VARESA, FEG, Aachen, Germany).

The standardization of VASA covers several uncertainties. Especially the length of the vagina after hysterectomy is different in every patient. This is not the case in patients who have undergone a supracervical hysterectomy.

For all other patients who had a previous hysterectomy the length of the remaining vagina does not substantially influence prolapse surgery.

However, in patients who underwent an operation for uterine prolapse an anterior colporrhaphy was usually additionally performed. By this procedure a substantial part of the subvesical vaginal skin is resected. The extent of skin resection is defined by the individual surgeon and therefore differs between patients. The effects of these surgical resections of skin and the closure of the endopelvic fascia on incontinence are not predictable.

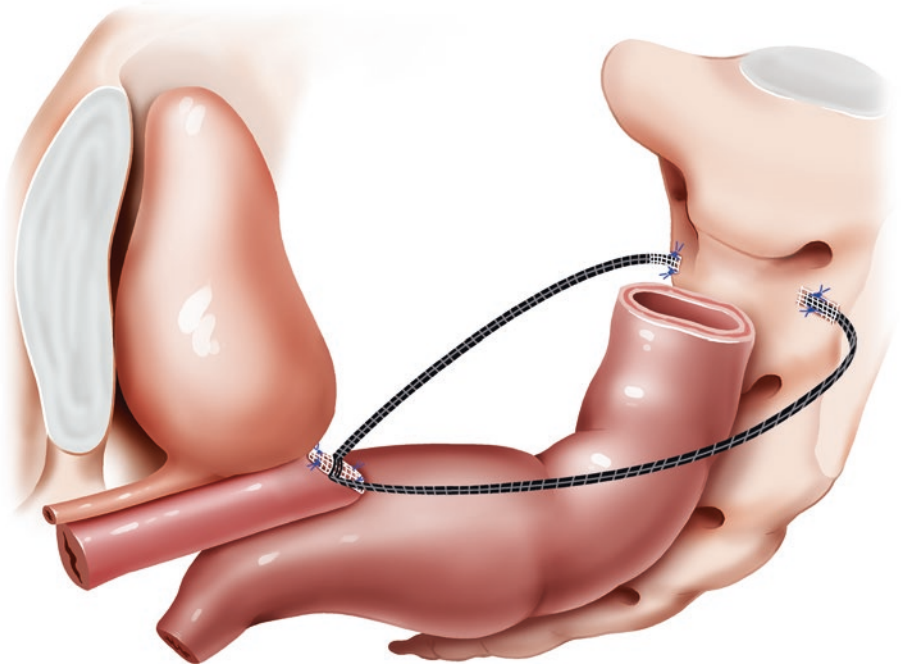

Fig. 92.1 VASA: The VASA structure was sutured to the vaginal stump and the os sacrum. The *black-marked middle* of the fixation site at the vaginal stump should be exactly on the scar. The USL tapes of the structures run retroperitoneally

Before the Operations

Explanation of the Operation

The surgeon has to explain to the patient that the sutures which fix the net structure ("bridge") at the vaginal stump could perforate the vaginal skin. The suture will then be visible in the vagina. In such a case the sutures can be cut from the vagina after 6 weeks. By that time the bridge will remain in position without the suture.

Note: the surgeon has to consult with the patient whether she wishes to keep the tubes and ovaries or have them removed.

Body Weight

If the patient has a body weight exceeding 100 kg, we abstain from the operation, due to the feasibility of the surgical techniques.

Bowel Cleansing

One day before surgery the patient must have a bowel cleansing as for a colonoscopy. If the bowel is not absolutely empty, the operation can become very difficult because the diameter of the "working place", especially in front of S1/S2, may be only a few centimeters.

Fig. 92.2 VASA: Equipment used for VASA, VARESA, CESA, CERESA, Uterosacropexy and Uterorectosacropexy. For VASA and VARESA a rectal probe is placed in the vagina

Note: Every additional centimeter makes it easier.

In the Operation Theater

Equipment

The standard equipment for abdominal gynecological surgery is used.

(Fig. 92.2).

The instruments should be as long as the surgeon requires.

For pre-operative examination and measurements an extra table is prepared (Fig. 92.3).

Fig. 92.3 VASA: Equipment for vaginal examination before surgery. A clamp is used to secure the vaginal vault during surgery

Fig. 92.4 VASA: A posterior blade is placed into the vagina after catheterization of the patient. A prolapse of the anterior vaginal wall is visible

Bladder

A catheter is placed at the beginning of surgery.

At the end of surgery it is advisable to fill the bladder with blue saline solution to detect any possible injuries.

Prolapse Measurement

The anterior vaginal wall is examined to decide if a colporrhaphy should be performed (Fig. 92.4). A special clamp takes a part of the vaginal scar and a newton meter is placed at the clamp (Fig. 92.5).

A power of 10 N is exerted at the clamp – the index finger is then placed at the clamp at the side of the hymenal ring. The clamp is opened and the distance between the the vaginal scar and the hymenal ring is measured (Fig. 92.6).

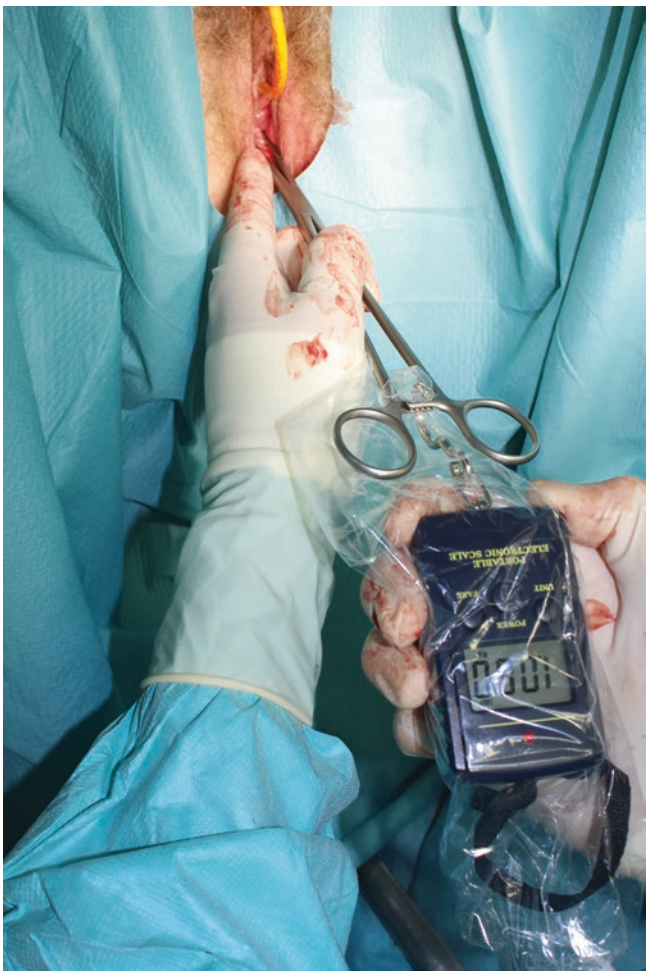

Fig. 92.5 VASA: At the end of the clamp a newton meter is placed with a hook. A standardized tension of 10 N is exerted at the clamp

Fig. 92.6 VASA: The index finger is placed at the clamp in the region of the hymenal ring. The clamp is opened and the distance between the *top* of the finger and the *top* of the clamp is measured (in this case 3.3 cm)

Fig. 92.7 VASA: The probe is wettened and placed into the vagina to move the vagina during further surgery

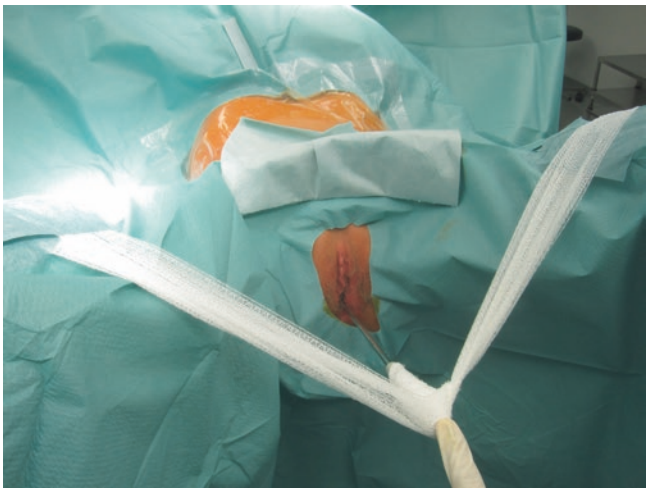

Fig. 92.8 VASA: The probe is then fixed in its position

Vaginal Phantom

A plastic phantom has to be placed in the vagina before the start of the operation (Fig. 92.7). It is important that different sizes of these phantoms are available according to the width and length of the vagina.

The phantom should be fixed to remain in the vagina during surgery; however, one must be able to move it during surgery (Fig. 92.8).

Antibiotic Coverage

Cephalosporines are administered according to the body weight as a single dose injection immediately at the start of surgery.

Anti-coagulation

The coagulation must be controlled. If the patient is under anti-coagulant treatment adaptations must be started before surgery.

Note: Even chronic aspirin treatment can cause heavy bleeding which is difficult to control.

In some cases it is prudent to consider the help of a hematologist.

A bleeding of the venous plexus in front of the os sacrum is one of the leading causes for severe bleedings during these operations. If electrocautery cannot control the bleeding, compression with a swab has to be performed for several minute. The control of this bleeding can become very difficult if the patient is under anti-coagulation treatment.

Pre-operative Interactive Talk ("Team-Time-Out")

We calculate the operation time for a VASA, from opening the peritoneum until closing the peritoneum, to be 60–90 min (for VARESA 10 min longer).

The remaining time is used for "cut and final closing of the skin". This is dependent on the experience of the surgeon.

The overall operation time is usually calculated as 90–130 min.

Blood loss is calculated at 50–100 ml.

The Tapes

The main requirements for the USL structure and tapes were that the USL should not shrink and also not lead to massive fibrosis which would make the USL structures unmovable.

The above pre-requisites were achieved by using polyvinylidene fluoride (PVDF).

PVDF monofilaments were used as the material of choice for the construction of four new implants to augment the USL.

The size of the fixation site at the vaginal stump is 2 × 3 cm.

The augmentation of the USL was performed using a narrow but open-pore sling structure of 4 mm width, made of high strength PVDF filaments. The length of the USL tapes is 9.3 cm.

Dynamesh VASA and Dynamesh VARESA structures are used for the respective operations (FEG Textiltechnik mbH, Aachen, Germany).

Opening the Abdominal Cavity (According to the Internal Institutional Standards)

The dermal incision should be horizontal ("cesarean section"). It is between 8 and 12 cm according to the pre-rectoral fatty tissue.

After opening the peritoneum we prefer placement of a rectangular frame with a 25 cm diameter.

The first step is to decide whether the operation can be carried out as planned.

If ovarian cysts complicate the situation, these should be removed and examined. The aim of this part of the operation is to "empty" the pouch of Douglas as much as possible. Therefore, the bowel and the small intestines have to be out of the area (Fig. 92.9).

We use two surgical towels. With the first towel we place the small intestine into the upper abdominal cavity. With a second towel, which is folded into a rectangular shape, we move the descending and ascending large intestine upwards. At the end of this step the pouch of Douglas should be free of intestine apart from the sigmoid colon. Especially the pelvic rims (the transition into the small pelvis) must be clearly visible to make incisions there without any problem.

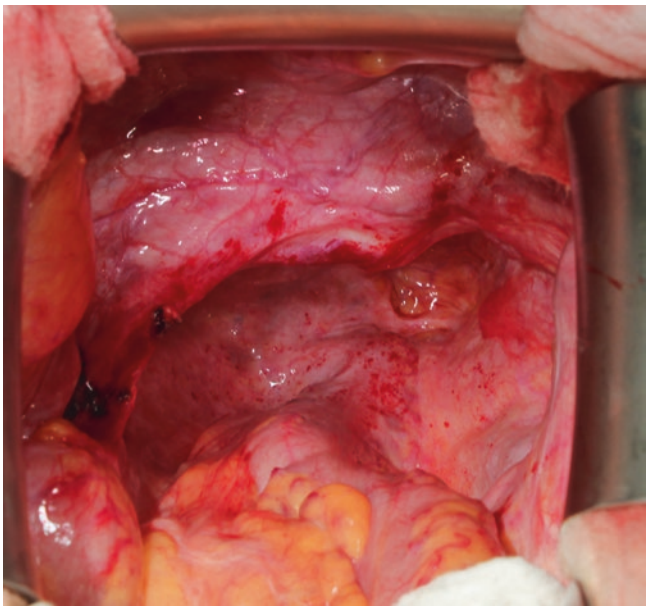

Fig. 92.9 VASA: View into the pelvic cavity ("pouch of Douglas"). The bowel has been pushed back into the upper abdomen and is held there by two towels. The *left tube* and some adhesions have been removed, the stumps have been cauterized. The USL cannot be seen in this situation

Identifying and "Clearing" of the Vaginal Scar After Previous Hysterectomy

The VASA or VARESA structures must be placed on the vaginal skin.

However, after previous hysterectomy several different anatomical situations can be found. (If a supracervical hysterectomy was performed previously and a cervical stump can be identified the operation is continued as CESA.)

If the uterus has been totally removed, the end of the vagina must be identified.

This can be done by pushing the intravaginal phantom straight forward. Take care not to place the phantom in a pre-existing rectocele. Usually the scar of the vaginal vault is very close to the bladder (Fig. 92.9).

According to the hysterectomy technique of the previous surgeon the scar at the end of the vagina can be covered by some remaining structures from the adnexa. Some surgeons suture the tubes together and fix them at the top of the vaginal scar, while others tie the round ligaments together and place them on top of the vaginal scar.

These structures must be resected so that an area of about 2 × 3 cm is prepared at the scar of the vaginal vault. Care must be taken that the VASA or VARESA structures are placed exactly at the top of the scar and not on the posterior vaginal wall, i.e. on a rectocele.

Identifying the Peritoneal Folds of the Uterosacral Ligament (USL)

To find the USL, one has to grab the vaginal vault.

The origins of the USL at the uterus are cut during hysterectomy. The remaining USL are attached to the vaginal scar during closure of the vaginal wound after hysterectomy.

Often the peritoneal fold of the USL cannot clearly be identified (Fig. 92.9).

Therefore, a swab is placed in front of S2 and the presacral peritoneum is pushed medially until the USL (peritoneal fold) becomes visible (Figs. 92.10 and 92.11).

The origin of the USL at the cervix has usually already been resected so that only the peritoneal fold can be found at the scar. A USL cannot be seen with the surgeon's eye. However, this is not important as only the peritoneal coverage (fold) is important for the correct placement of the structures.

The peritoneal folds of the USL end at the level of S2. The USL structures reach up to the sacral spine in the area between S1 and S2.

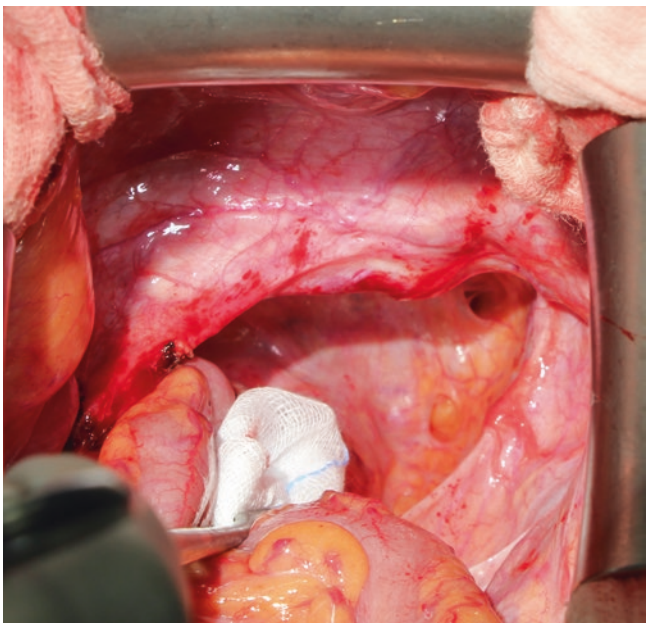

Fig. 92.10 VASA: A swab is placed in front of the second sacral vertebra. The peritoneum is pushed slightly to the *left* and the *right* USL can be identified

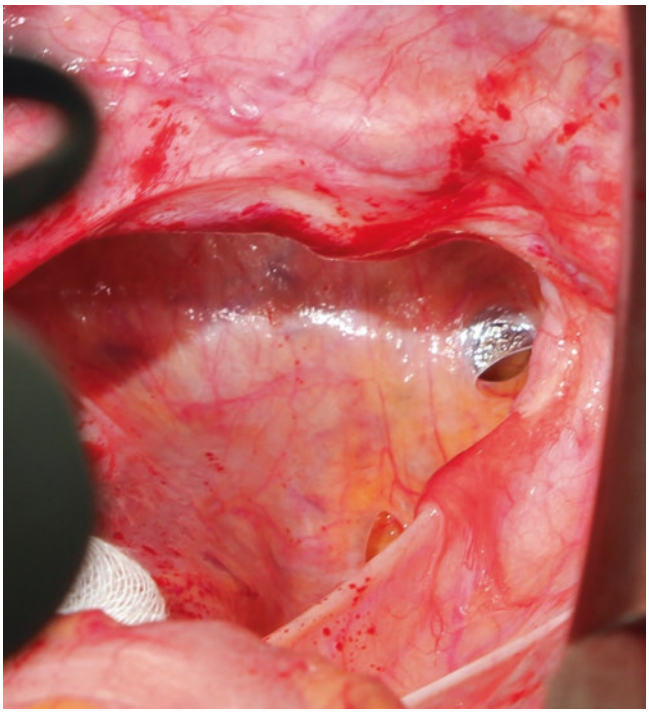

Fig. 92.11 VASA: The *right* USL. The end of the USL at the vagina is the scar which needs to be identified. Any further tissue above the scar of the vaginal vault must be dissected

Fixation of the Structures at the Anterior Fixation Side: The Vaginal Stump

After the vaginal stump (scar) has been cleared of other tissues and the scar has been identified, the phantom in the vagina must be pulled upwards. The Foley catheter in the bladder is identified, grabbed and pulled at the highest part of the bladder to find the end of the bladder.

According to the technique of the surgeon who performed the hysterectomy, the vaginal stump might be covered by the round ligaments which have been tied together. Another alternative is that the end of the tubes which were resected from the uterus might be tied together and fixed at the vaginal stump.

All these structures must be removed and put aside or resected (Figs. 92.12, 92.13, 92.14, 92.15, 92.16 and 92.17).

Identify the scar and place two stitches parallel to the scar, two in front and two behind the scar (Figs. 92.18, 92.19, 92.20, 92.21, 92.22 and 92.23).

The decision must now be taken which structure is to be used (Figs. 92.24, 92.25 and 92.26).

The VASA or VARESA structure is brought into the abdominal cavitiy and placed at the vaginal stump. All sutures are pulled through the net structure of the "bridge" and should be equally distributed in all four quadrants of the vaginal stump (Figs. 92.27, 92.28, 92.29 and 92.30).

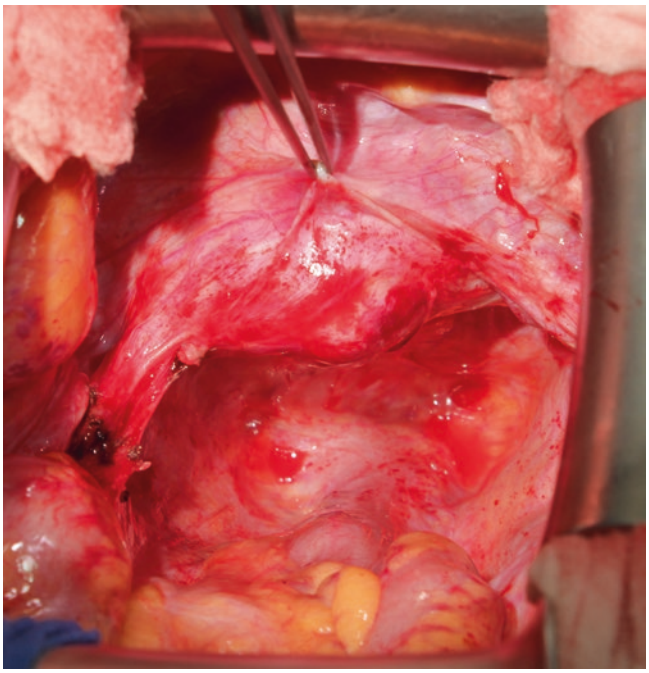

Fig. 92.12 VASA: The phantom in the vagina is pulled forward and the peritoneum of the bladder edge is elevated with forceps. In the case of a rectocele the phantom in the vagina will probably elevate the rectocele which will cause problems in identifying the scar and the anterior vaginal wall of the vagina

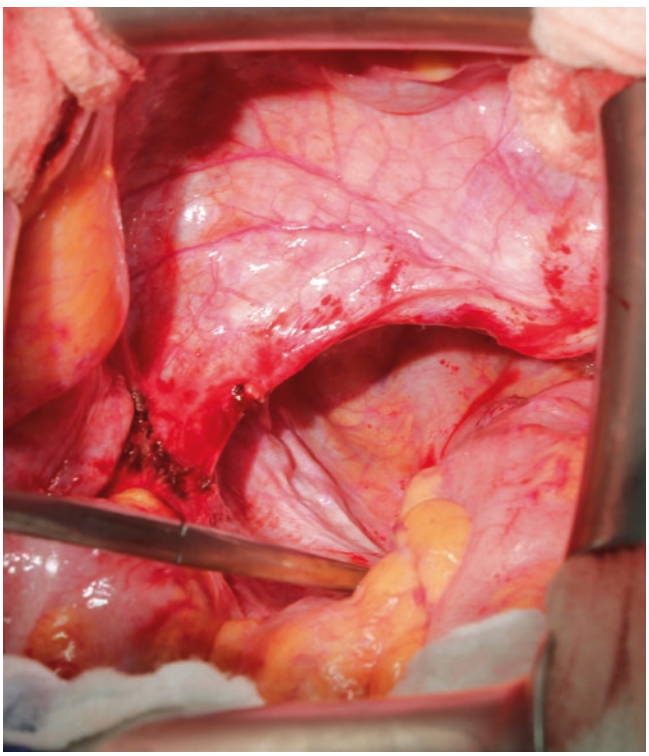

Fig. 92.13 VASA: The *left* USL is demonstrated in the same way as the *right*

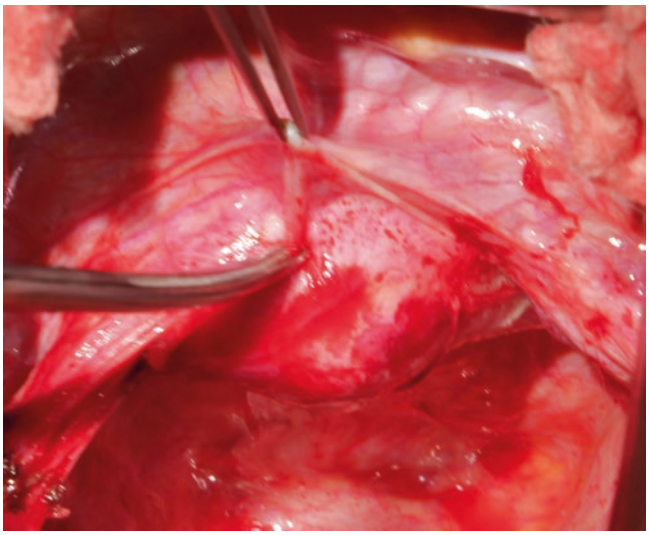

Fig. 92.14 VASA: The bladder peritoneum is elevated and incised. The phantom elevates the vaginal vault

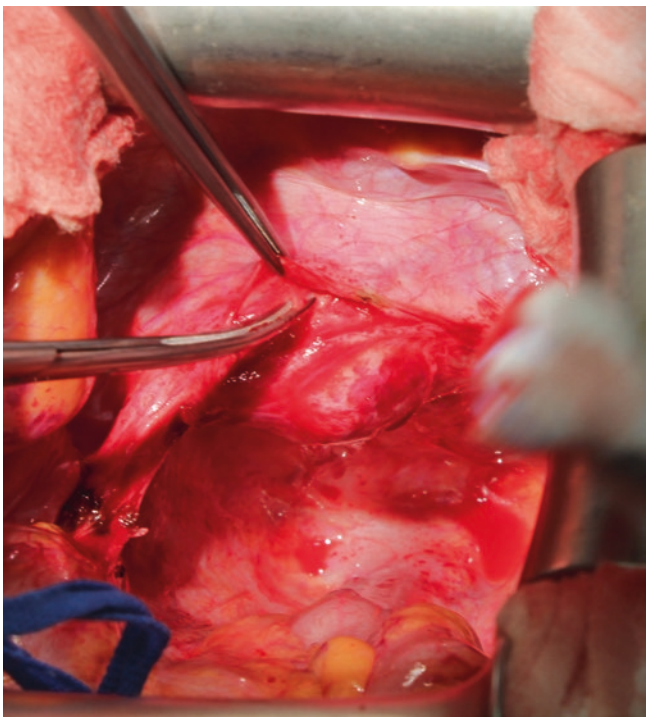

Fig. 92.15 VASA: The anterior wall is freed of the physiological adhesions to the bladder on an area of about 1 cm above the vaginal scar

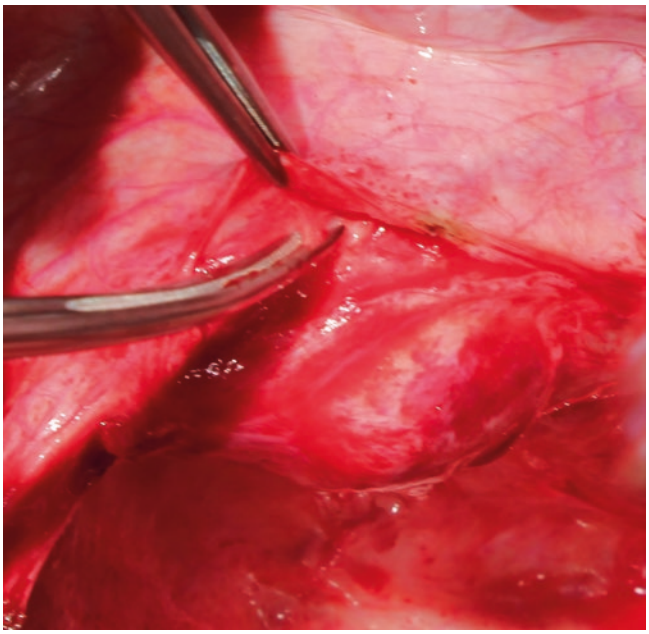

Fig. 92.16 VASA: The scar of the vaginal vault. The anterior and posterior vaginal vault are dissected from the above lying tissues on an area of about 2 × 3 cm

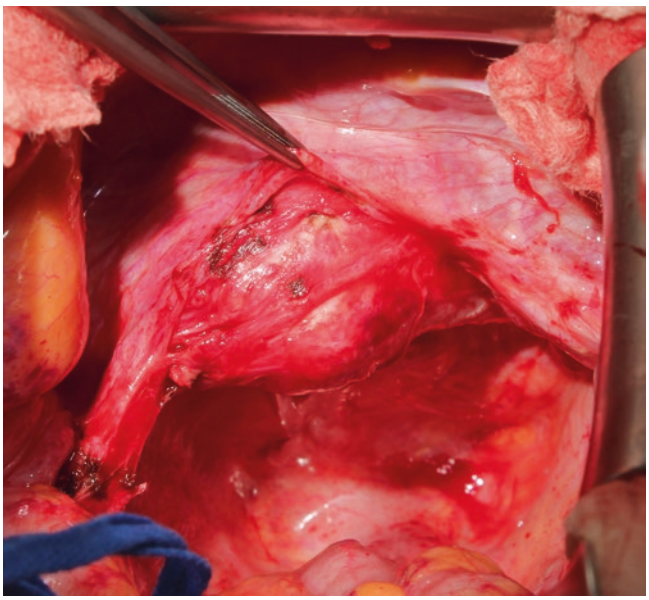

Fig. 92.17 VASA: Minor bleedings are coagulated

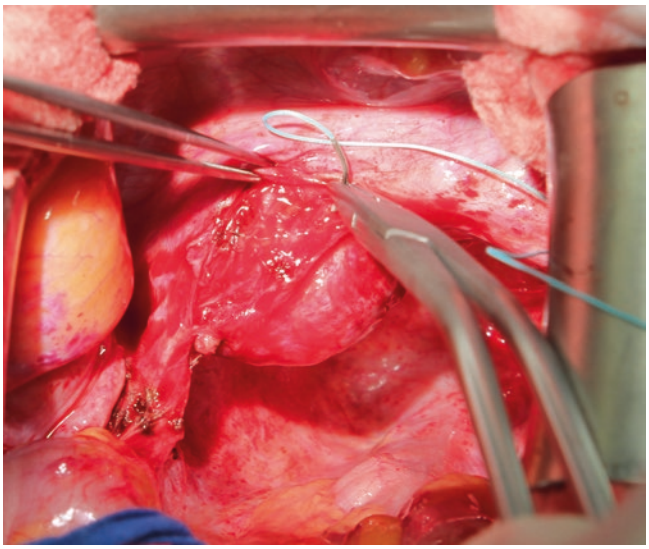

Fig. 92.18 VASA: Four sutures are placed at the vaginal vault. The first suture is from the *right* corner on the anterior vaginal wall to the *middle* of the anterior vaginal wall

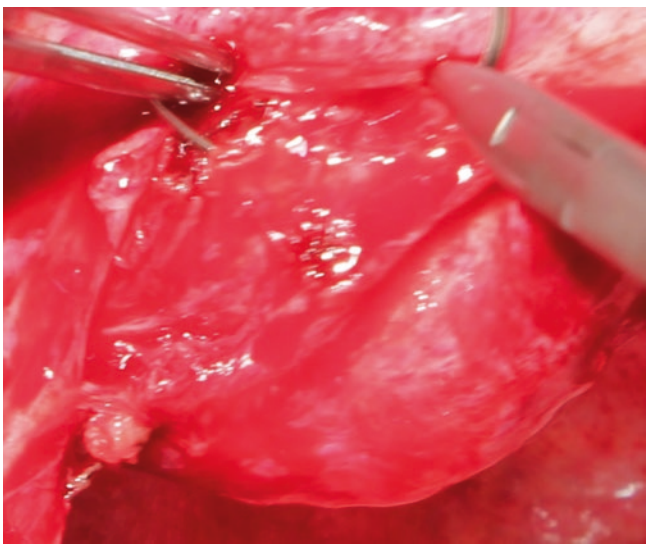

Fig. 92.19 VASA: The stitch and the suture are in the vaginal skin. If the suture can be seen at the end of the vagina at the end of surgery, it can remain there for three 3 months. Thereafter the "bridge" will be fixed at the vaginal vault and the suture can be cut from the vagina and pulled out

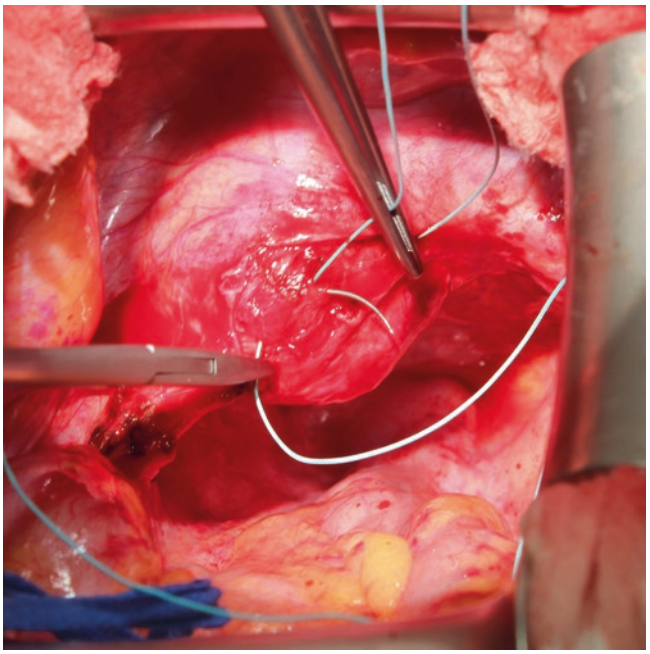

Fig. 92.20 VASA: The second suture is from the *left* outer side of the anterior vaginal wall to the *middle* of the anterior vaginal wall

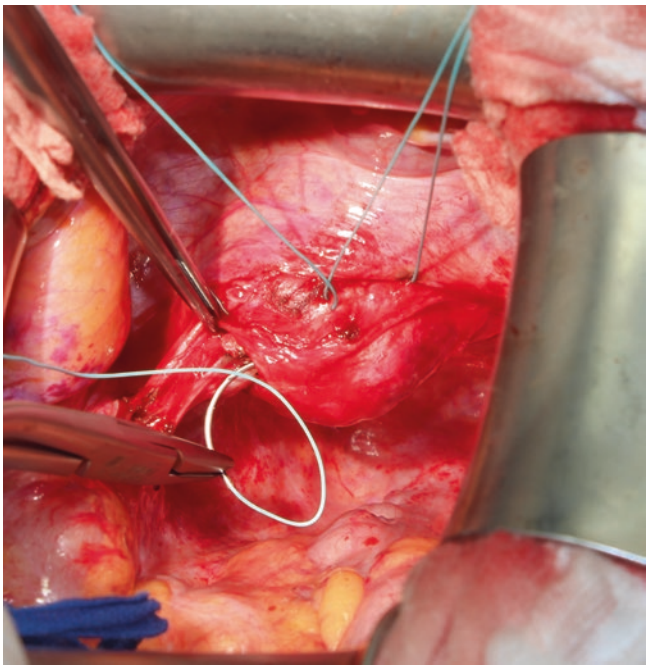

Fig. 92.22 VASA: The next two sutures are placed beyond the scar of the vaginal vault

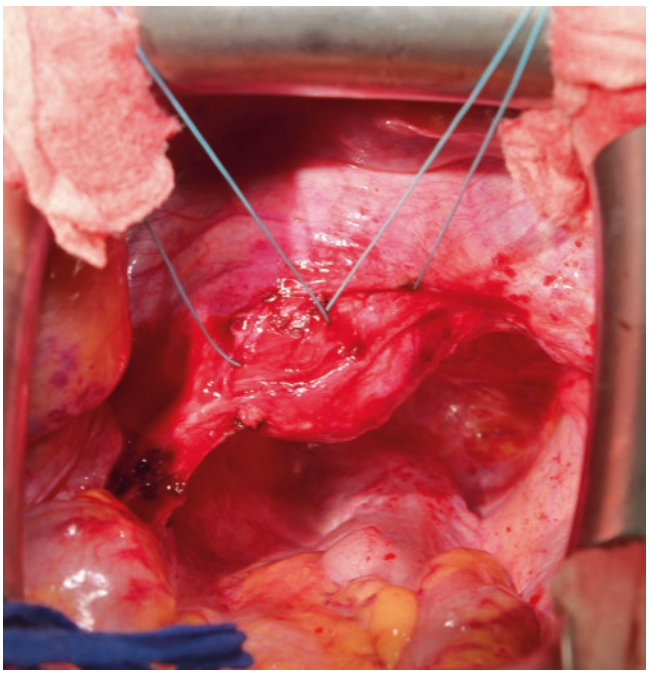

Fig. 92.21 VASA: The anterior sutures are placed and armed with two clamps

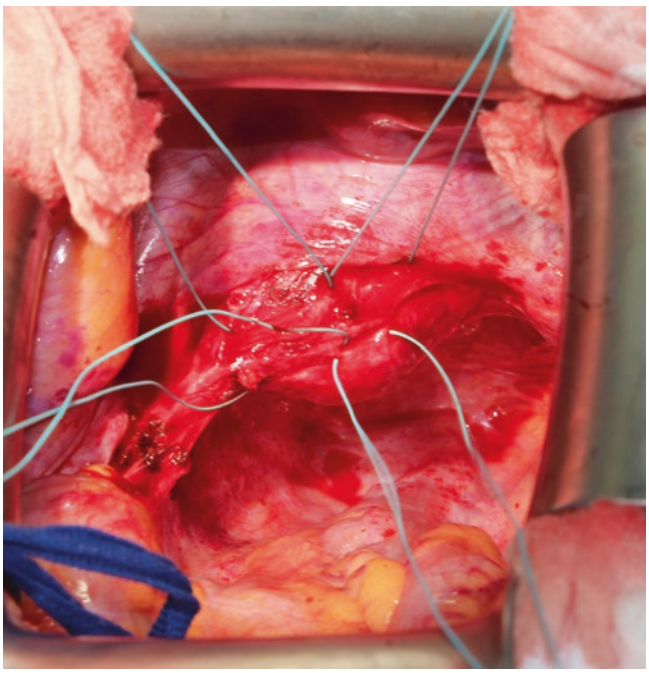

Fig. 92.23 VASA: All four sutures are placed

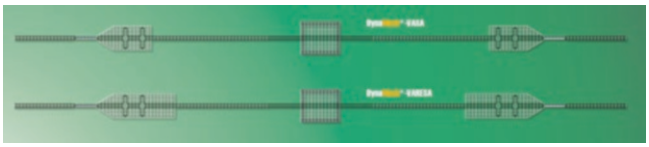

Fig. 92.24 VASA: The VASA and VARESA structures. The size of the "bridge" is 2 × 3 cm and the length of the USL is 9.3 cm. In the VARESA structures the posterior fixation side is prolonged by a 1 cm mesh on both sides for rectopexy sutures. Note the stitch marks at both anterior fixation sites. The parts on the outside of the suture marks are cut when the tape is placed. The augmentation of the uterosacral ligaments is performed using a narrow but open-pore sling structure of 4 mm width, made of high strength PVDF filaments (Dynamesh CESA, Dynamesh CERESA, Dynamesh VASA and Dynamesh VARESA, FEG Textiltechnik mbH, Aachen, Germany)

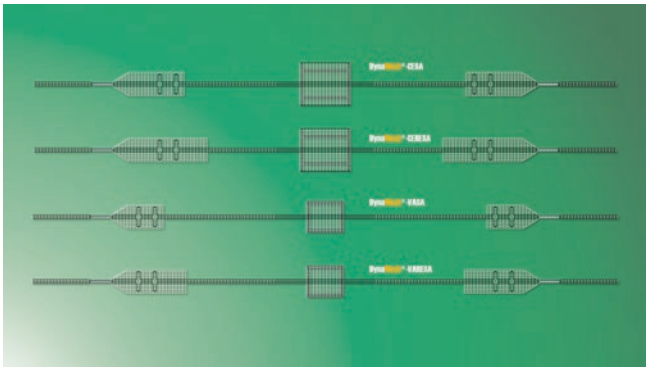

Fig. 92.25 VASA: Comparison of the CESA and CERESA tapes. The USL in these structures is 8.8 cm since the vagina has its normal length. The "bridge" is 3 × 4 cm, adapted for larger cervical stumps

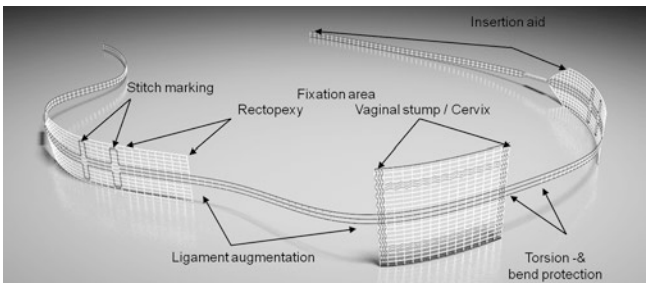

Fig. 92.26 VASA: Demonstration of the details of the structures (as an example of a CERESA structure). The 3 × 4 cm mesh in the middle is the part which is sutured to the vaginal vault (or cervical stump). In the *middle* of both sides of the "bridge" the USL augmentation is inserted. At the end of both ligament augmentations stitch marks are placed to define the correct fixation sites of the structures. The insertion aid on both sides are cut when the sutures are placed in the structure

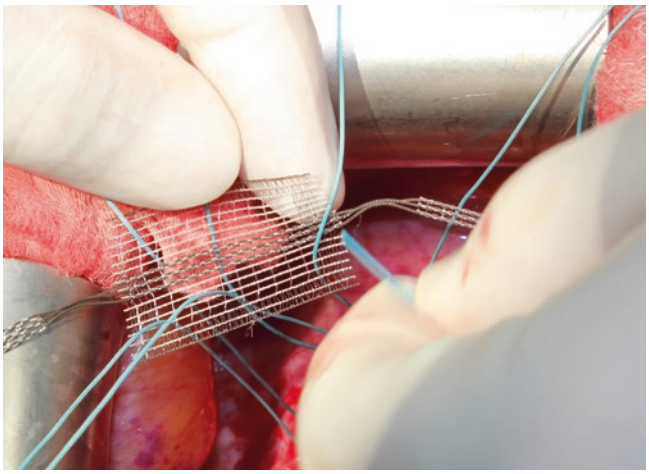

Fig. 92.27 VASA: The sutures are pulled through the "bridge" so that they fit easily onto the vaginal vault

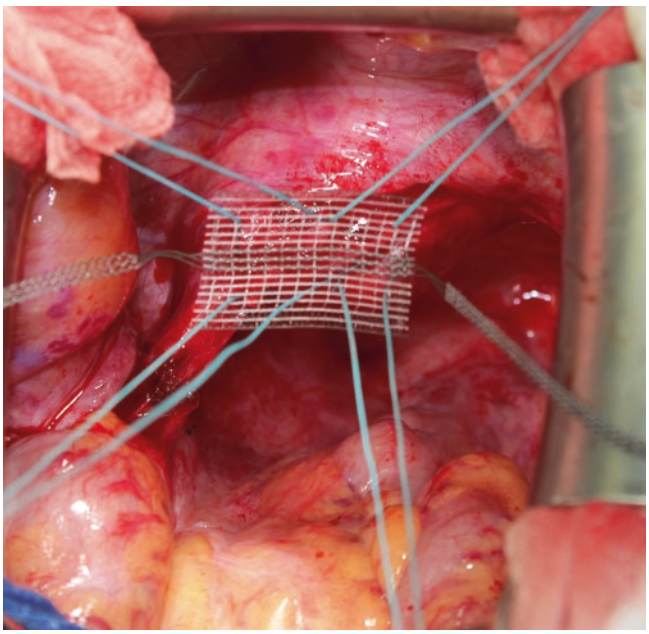

Fig. 92.28 VASA: All sutures are placed

They are tied and cut (Fig. 92.31).

*Advice: I*f the sutures can be seen in the vagina at the end of surgery, leave them in place.

They can be cut 3 months after surgery. By this time the net structure of the tape has formed a secure attachment with the vaginal vault.

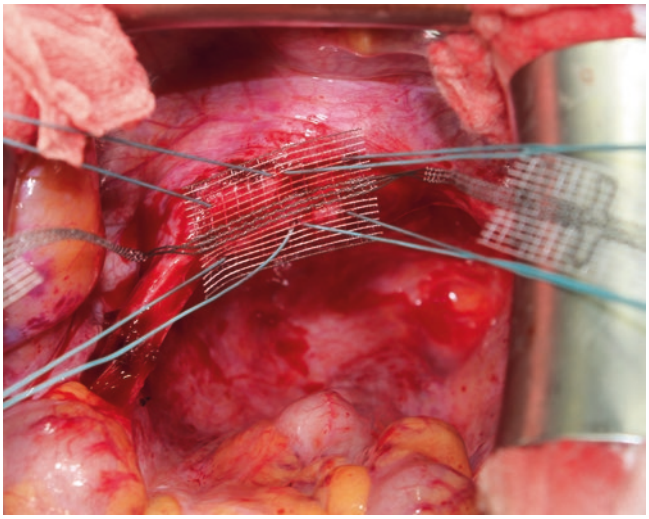

Fig. 92.29 VASA: The "bridge" is placed at the vaginal vault

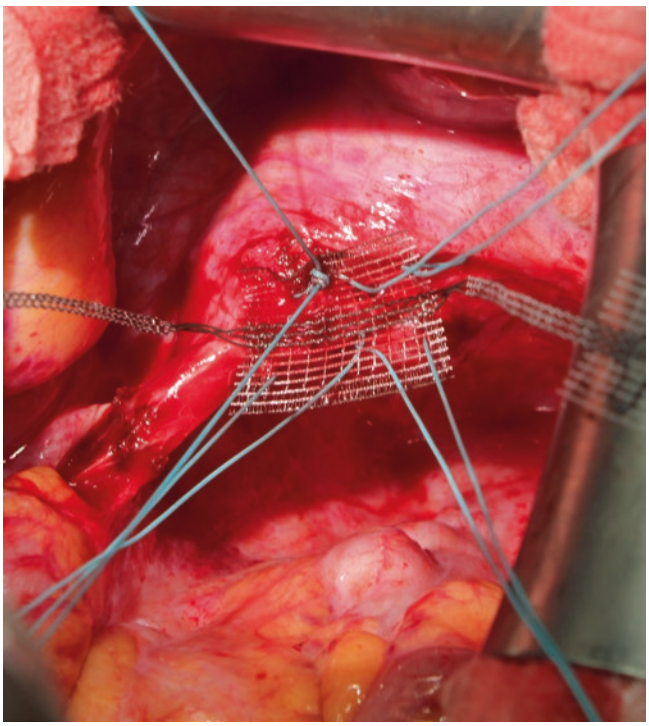

Fig. 92.30 VASA: The sutures must be tied carefully so that the vagina is not put in folds. The aim is to place the mesh of the "bridge" like a "cloth on a table"

Preparing the Posterior Fixation Site

After the USL have been identified, the incisions at the sacrum are placed horizontally, 0.5 cm above the insertion side in front of S1/S2 (Figs. 92.32 and 92.33).

An incision along the USL (from cervix to sacrum) should be avoided since the "original" peritoneal folds protect the tape structure from adhesion formation. Furthermore, the folds form the intended anatomical "semi-circle" formation when the structures are under tension. The PVDF structures do not form fibrotic adhesions to this peritoneal fold, therefore, it remains movable.

The incision is usually above the first sacral vertebra (S1) (Fig. 92.33). From this incision the pre-vertebral fascia is prepared. Be aware of the hypogastric nerve and take the nerve laterally from the stitches later on (Fig. 92.34). Identify the presacral artery and vein and coagulate them at 2 cm lengths so that the needle cannot injure these vessels. Two non-resorbable sutures 2-0 are placed horizontally in this fascia, one below and one higher at a distance of about 1 cm from each other (Figs. 92.35 and 92.36).

Advice: The four sutures in front of S1 have a lateral and a medial part. The **lateral** part of the sutures should be left **longer** before put in a clamp. When they are pulled through the posterior fixation sites, these **lateral parts of the sutures** always go through the **lower** part of the structure (the 3-L rule:"lateral, long, low").

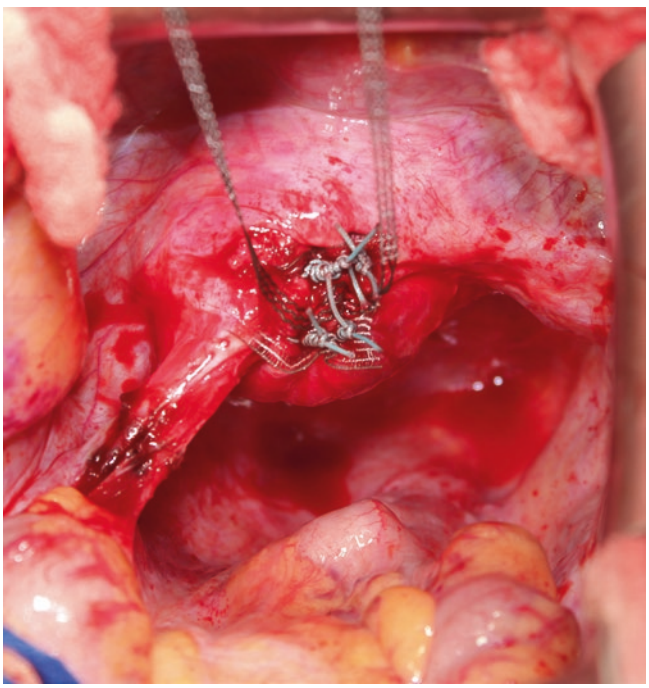

Fig. 92.31 VASA: The insertion aids of the USL are armed with clamps and the clamps are placed at the operation frame

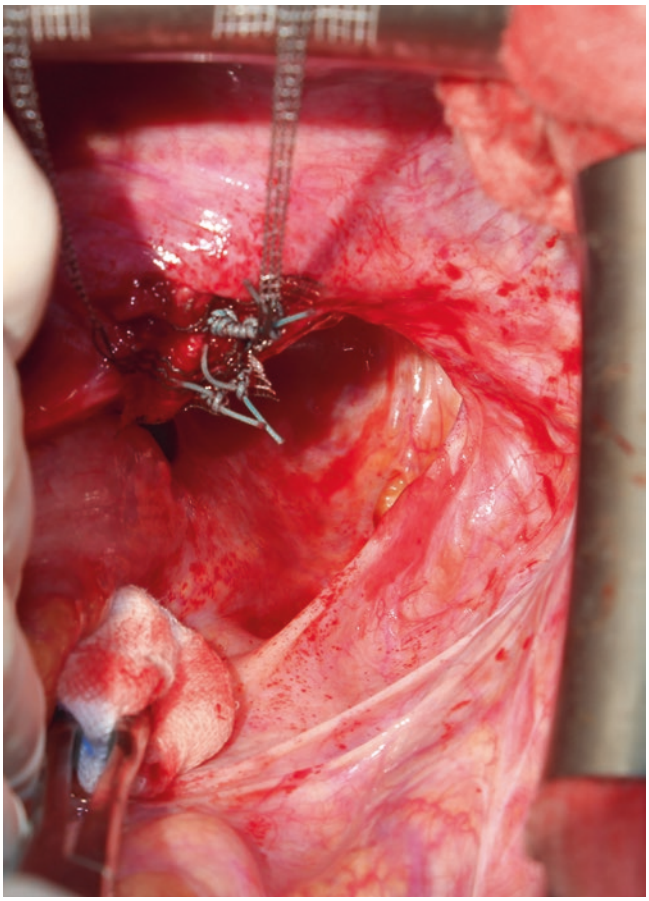

Fig. 92.32 VASA: With the help of the swab and a little pull at the *right* clamp with the "new USL", the *right* peritoneal fold of the USL can be identified

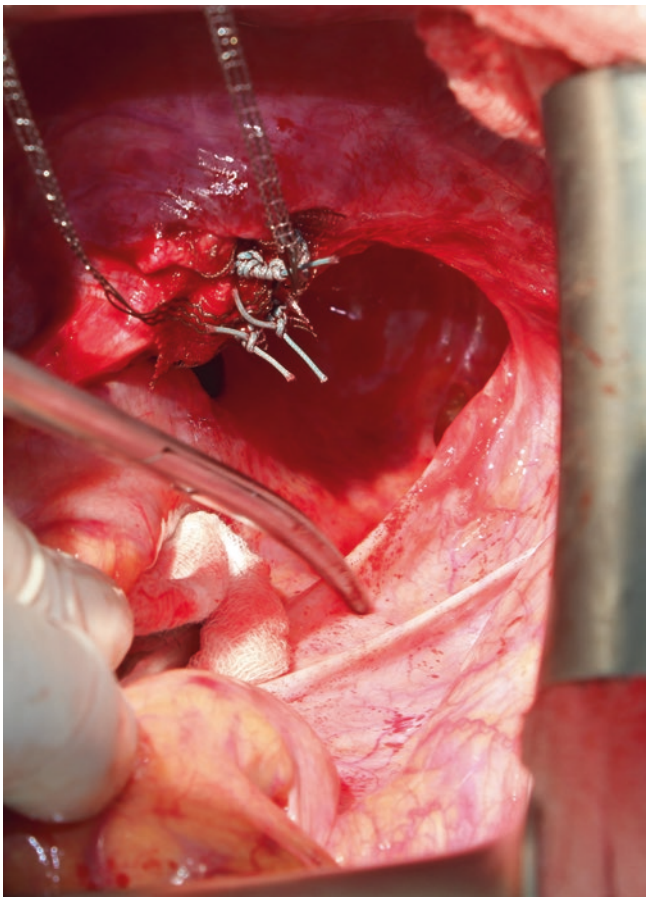

Fig. 92.33 VASA: The incision of the peritoneum is horizontal (in order not to destroy the peritoneal fold) at the height of S1

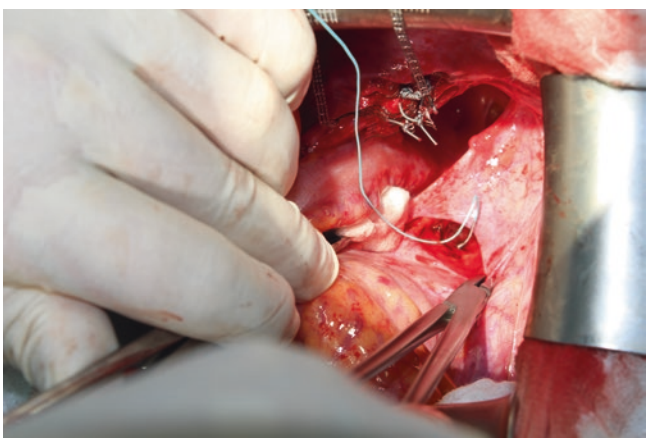

Fig. 92.34 VASA: Two sutures are placed in front of the S1/S2 prevertebral fascia. (The index finger of the left hand is at the promontorium)

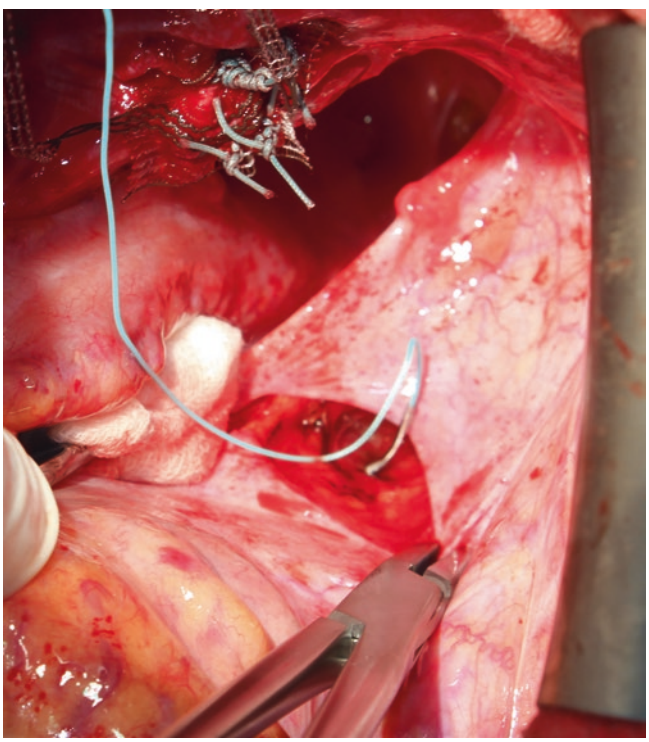

Fig. 92.35 VASA: The stitches are placed from far lateral to medial (Note: The lateral part of the suture should be *left* long, the medial part of the suture short! Makes it easier later on!)

Placement of the New USL

For the next step, care must be taken to avoid injuries of the peritoneal fold of the USL.

A small trocar, as usually used for a TVT placement, is pulled through the peritoneal fold of the USL from the back to the base at the vaginal end (Figs. 92.37, 92.38 and 92.39).

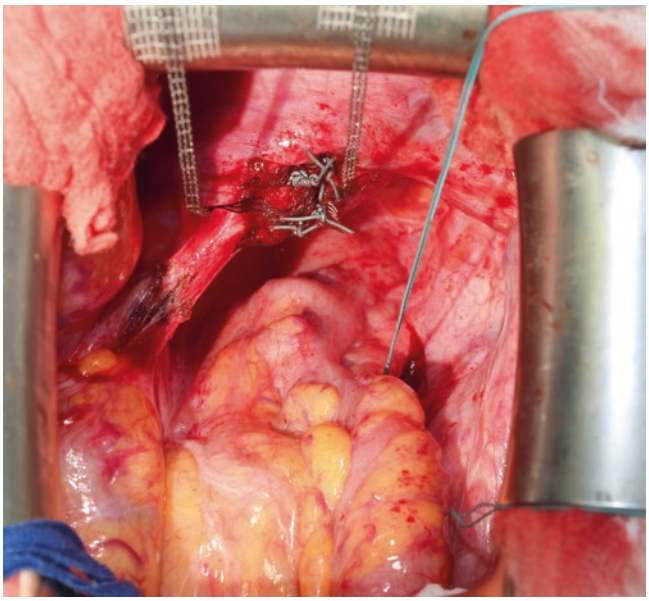

Fig. 92.36 VASA: The lower suture is armed with a clamp and placed on the *foot* side of the frame. The upper suture is armed with a clamp and placed on the *bottom* side of the frame

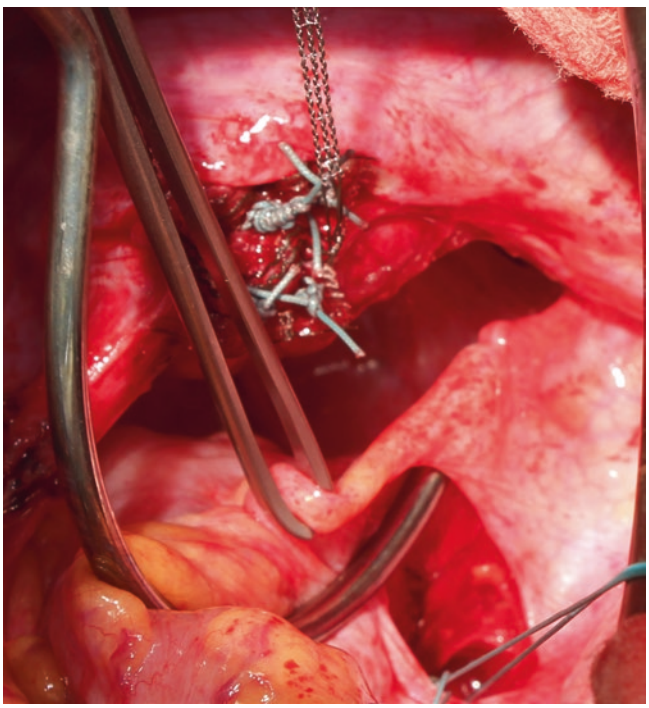

Fig. 92.37 VASA: The peritoneal incision in front of the sacrum is grasped and a TVT trocar is pushed into the peritoneal fold of the USL

Care must be taken not to injure the stumps of the uterine vein or artery which were cut during the previous hysterectomy. Bleeding can be difficult to identify since the blood tends to flow through the peritoneal channel to the opening incision in front of S1/S2. If the origin of the bleeding cannot be identified, this may cause considerable problems for the surgeon. In that case a 3-0 vicryl suture can be placed close to the vaginal end at the region of the vessels in a double stitch manner until the bleeding stops.

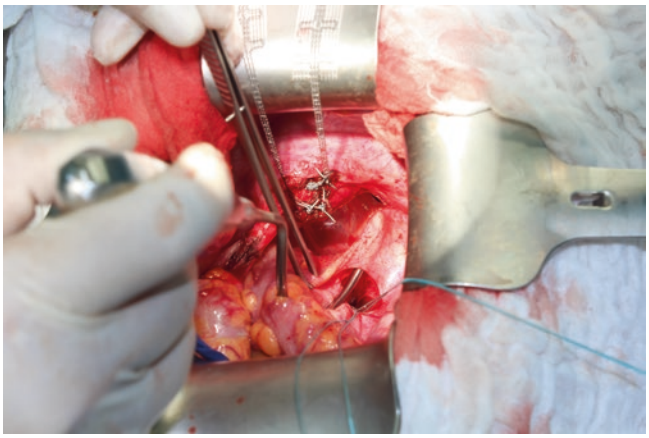

Fig. 92.38 VASA: For the first few centimeters the direction of the trocar is lateral

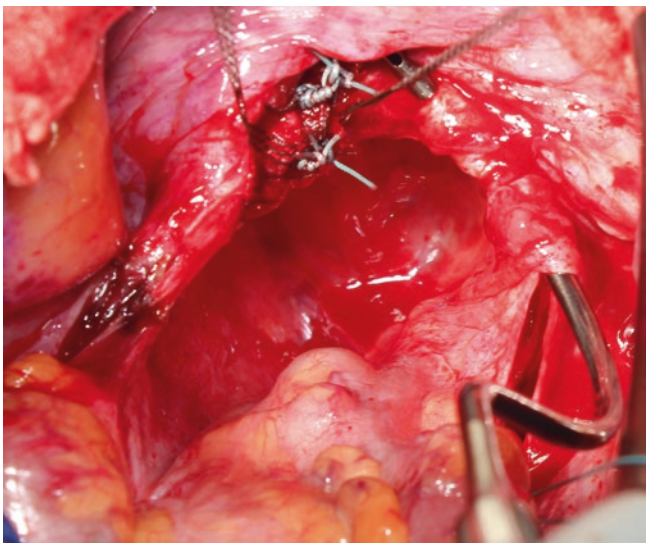

Fig. 92.39 VASA: Afterwards the direction of the trocar is toward the vaginal stump

Note: Leave the suture untied until you want to close the peritoneum. You can then draw the suture. Usually, thereafter, no more bleeding will occur.

The insertion aid of the tape is pulled through the hole at the top and pulled backwards to the sacrum (Fig. 92.40).

During this pulling action the net structure of the tape can injure the uterine artery or vein leading to bleedings; therefore, the pull should be done carefully. Bleedings cannot definitively be prevented; however, it is important that the surgeon immediately detects the origin of the bleeding.

The USL structure and the mesh are then pulled through the USL fold. This is performed easily, as in an empty channel. When the fixation mesh appears out of the "channel", it is placed where it should be fixed.

Fig. 92.40 VASA: The trocar is pushed through the *right* edge of the vaginal stump and the edge of the insertion aid is placed through the hole of the trocar

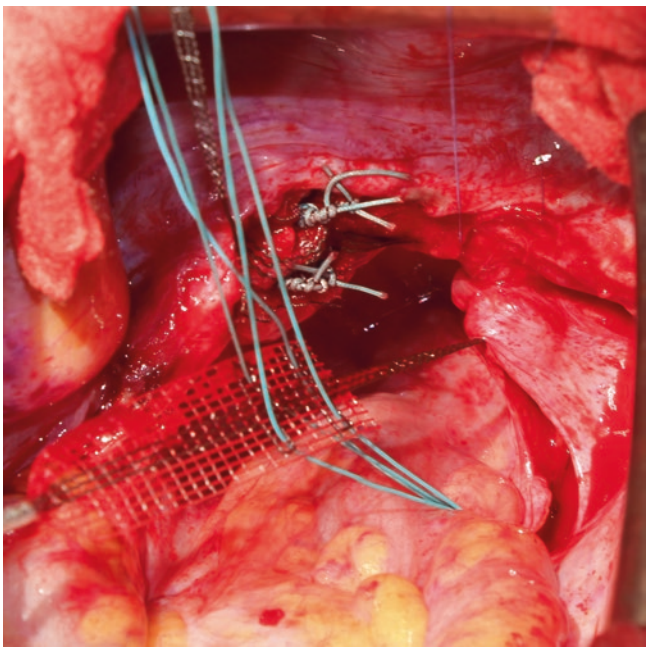

Fig. 92.41 VASA: The previously placed sutures are pulled through the suture marks at the end of the *right* USL structure

The previously-placed sutures are pulled through the marked fixation sites on the tape, the insertion aid is cut (Figs. 92.41, 92.42 and 92.43).

The new PVDF structure holds the vagina "with open arms" and not with "stretched out arms". Thereafter, the sutures are tied.

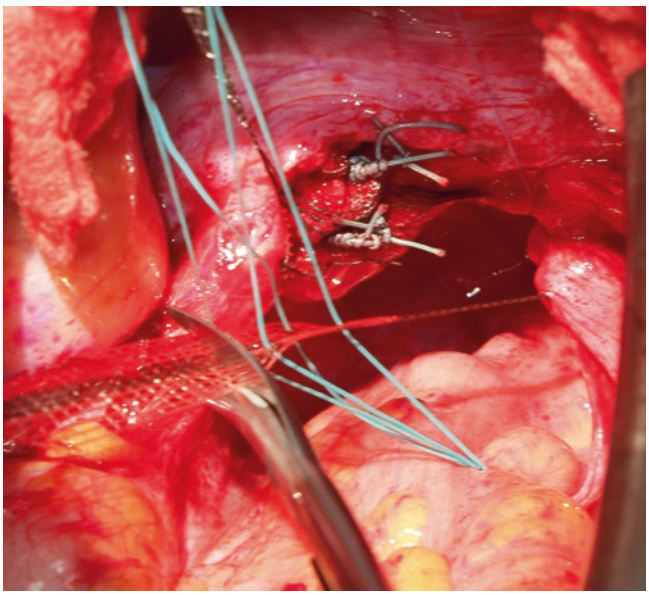

Fig. 92.42 VASA: After the two sutures have been placed, the insertion aid is cut

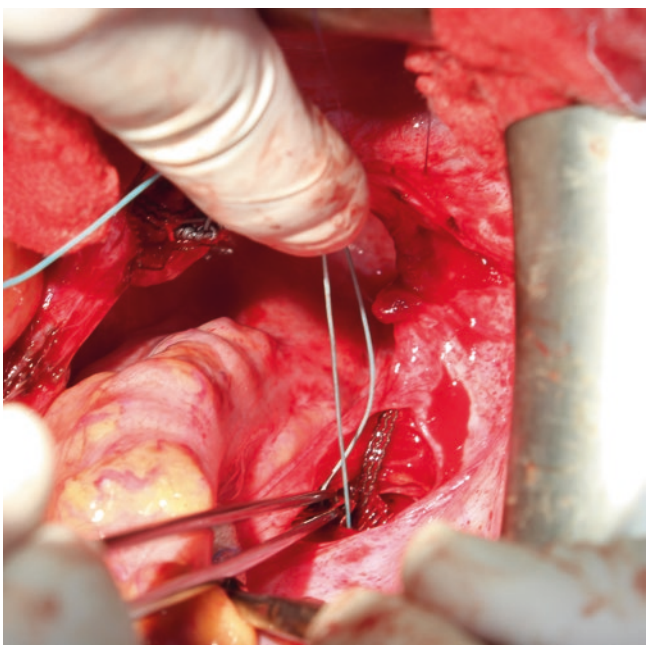

Fig. 92.43 VASA: The sutures are then tied

To prevent adhesion formation the incision side is closed with 4-0 Vicryl sutures (Fig. 92.44).

The same procedure also needs to be done on the left side.

The left side is a little more difficult since the meso-sigma crosses the fixation side.

The sigma/rectum needs to be pushed to the right side, this can be done either with a retractor held by an assistant, or the surgeon takes the sigma in one hand and pulls it in the respective direction (Fig. 92.45).

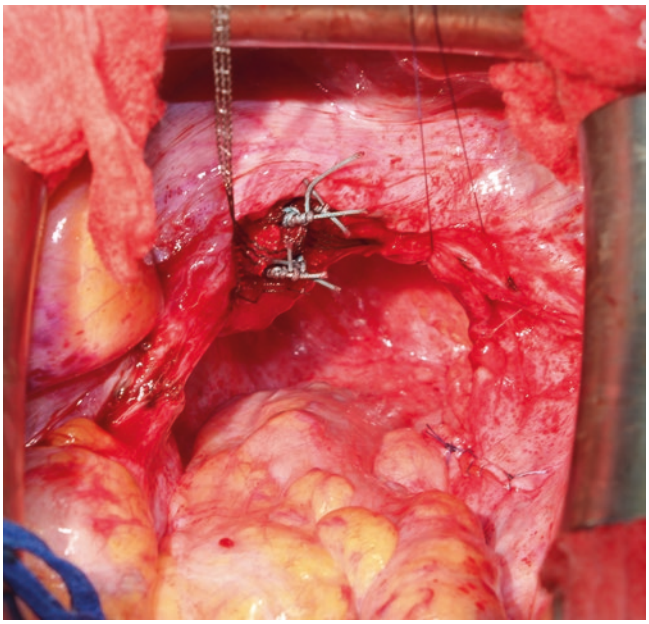

Fig. 92.44 VASA: Thereafter the peritoneum is closed with a running suture

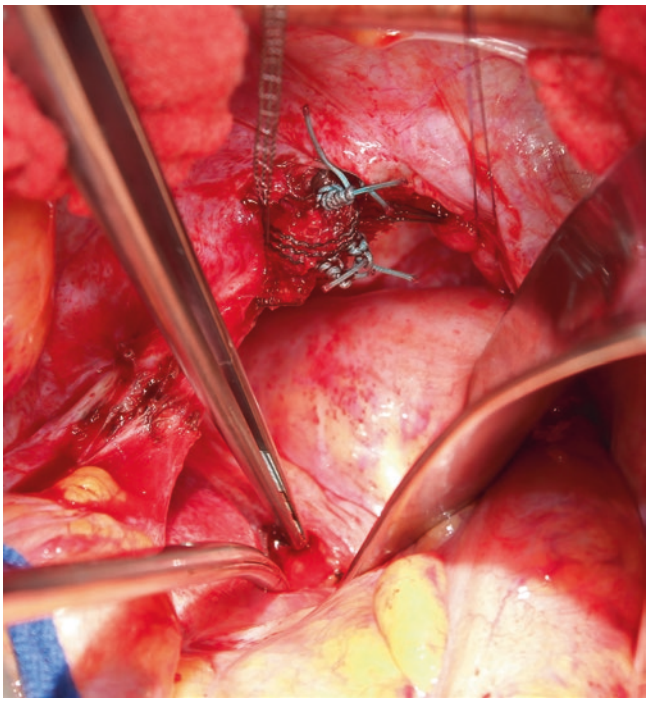

Fig. 92.45 VASA: The operation continues on the *left* side with the incision of the peritoneum in front of S1/S2

The surgeon then palpates the retroperitoneal sutures on the other (right) side. This palpatation will help to find the respective identical fixation site on the left side (Fig. 92.46).

With the other hand the incision is placed as on the other side.

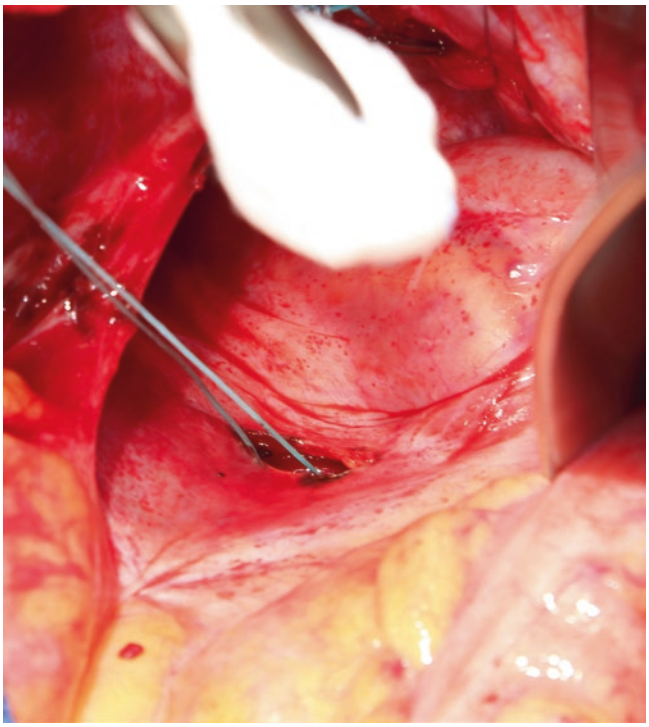

Fig. 92.46 VASA: The first suture is placed horizontally

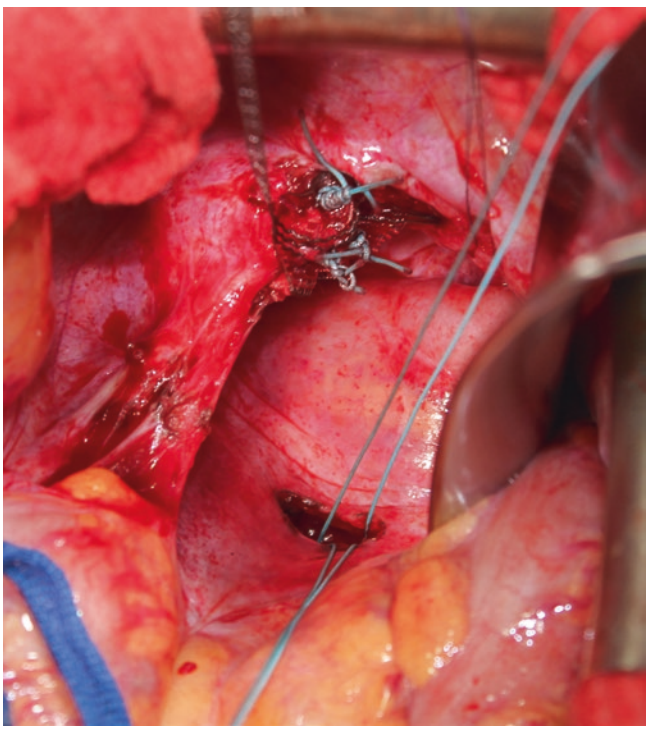

Fig. 92.47 VASA: Both sutures are placed

The same procedure as on the right side is then performed (Figs. 92.47, 92.48, 92.49, 92.50, 92.51 and 92.52).

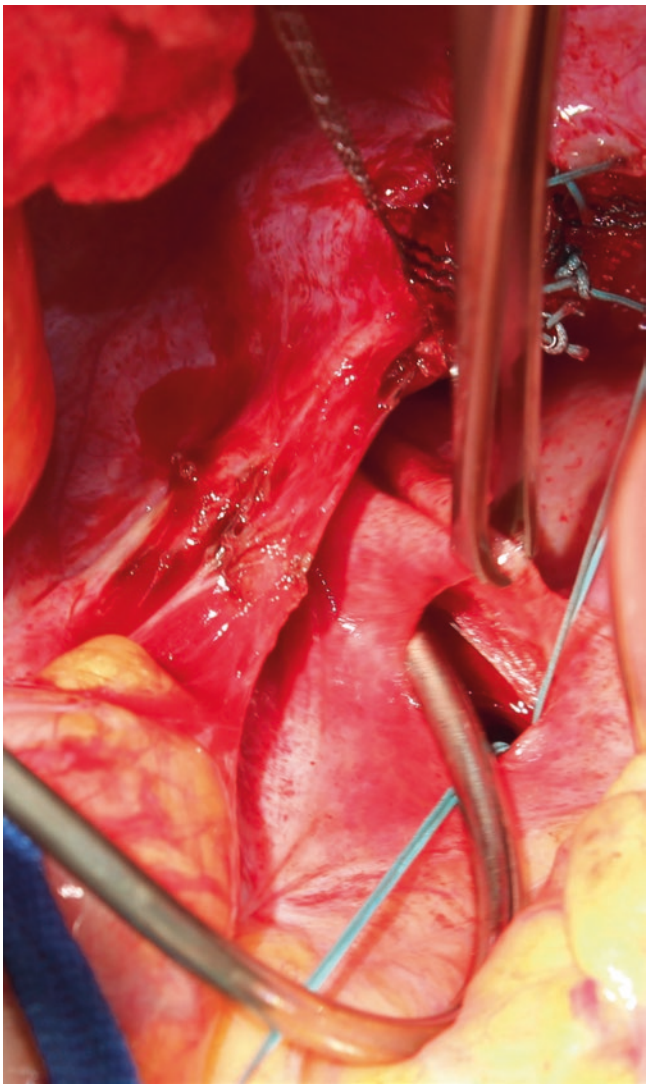

Fig. 92.48 VASA: The trocar is then inserted as on the *right* side

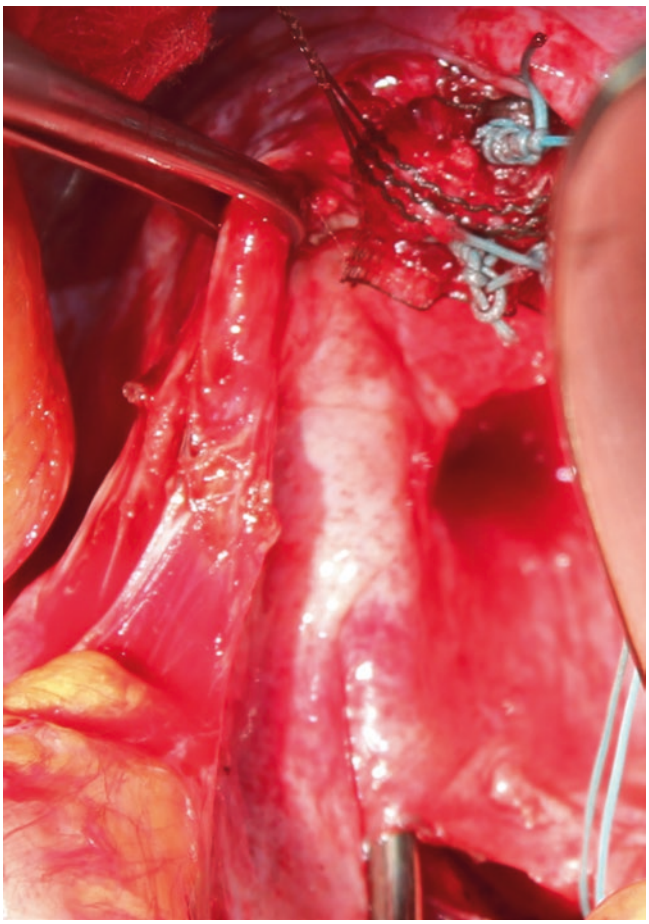

Fig. 92.49 VASA: The *top* of the trocar is brought forward to the corner of the *left* vaginal vault

After removal of the towels, we add 150 ml saline solution to prevent the drying out of the sigma epithelium and possible adhesion formation (Fig. 92.56).

Closing the Peritoneum on the Vaginal Stump

After the posterior fixation sites have been closed, the vaginal stump is peritonealized with the bladder and Douglas peritoneum (Fig. 92.53).

In order to get enough peritoneum to cover the net, take peritoneum from the posterior vaginal wall in the pouch of Douglas up to 2 cm from the scar and suture it to the bladder peritoneum (Fig. 92.54).

Take care that no suture or net is left uncovered by peritoneum otherwise adhesions will follow which can make the system "stiff and unmovable" (Fig. 92.55).

Additional Rectopexy (VARESA)

If a rectopexy has to be performed (VARESA), a non-resorbable suture 3-0 is placed in front of the marked posterior fixation sides. Special tapes have been developed for this procedure (Dynamesh VARESA). The sutures grab the mesorectum on both sides and are tied on the anterior net structure of the tape in that area.

Postoperative Vaginal Examination

This examination must reveal whether the sutures can be seen at the vaginal stump; they do not need to be removed immediately. After 3 months the sutures can be resected. By

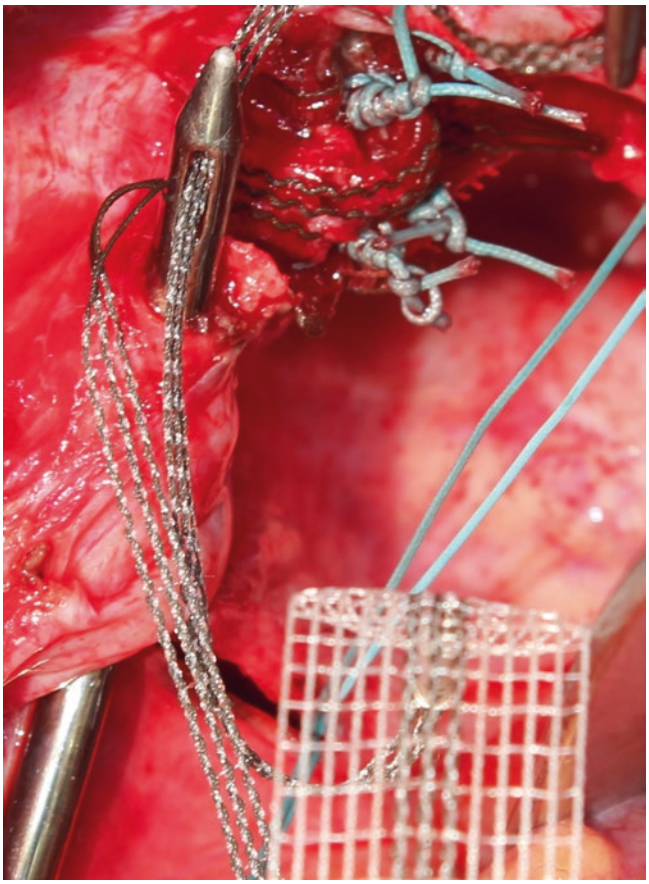

Fig. 92.50 VASA: The insertion aid is placed through the hole of the trocar and the *left* structure is pulled through the channel of the USL

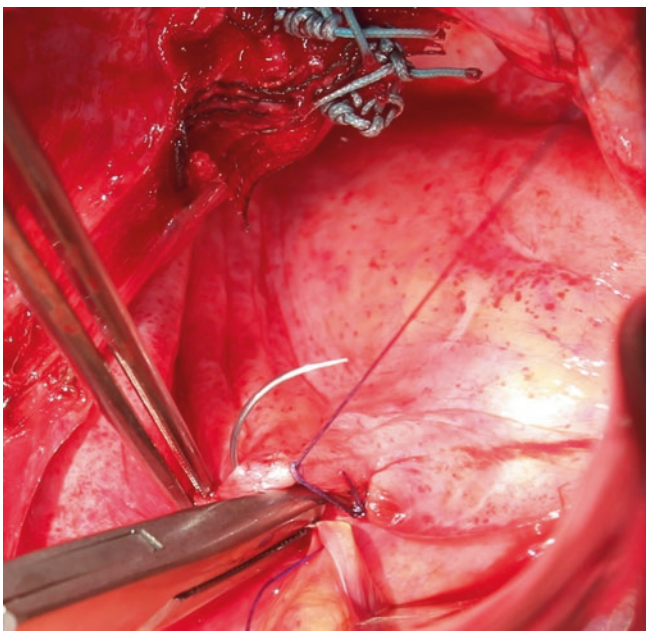

Fig. 92.52 VASA: The peritoneum is closed with a running suture

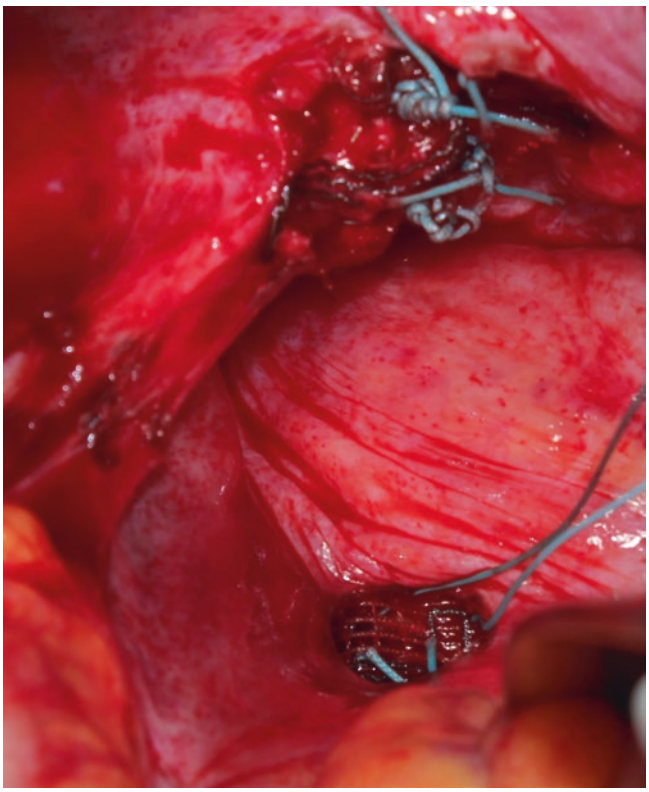

Fig. 92.51 VASA: The sutures are placed through the markings of the structure, tied and cut

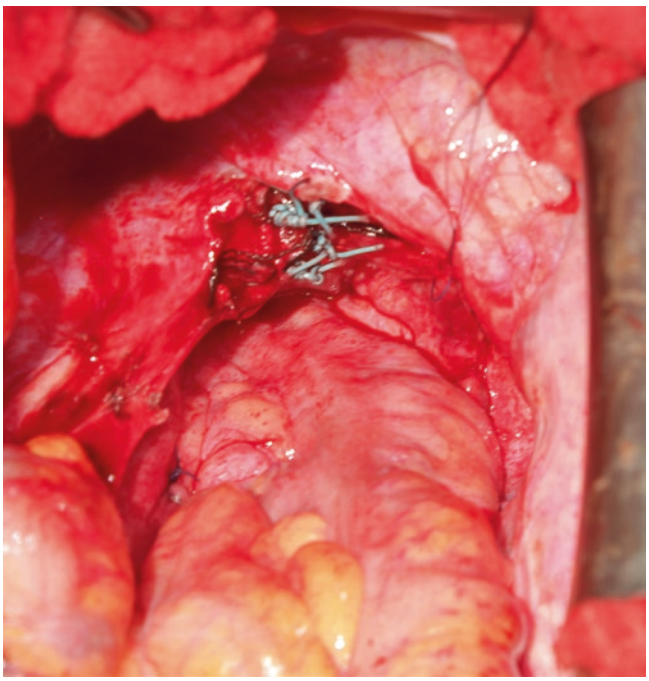

Fig. 92.53 VASA: View into the pelvic cavity after placement of the structure and closure of the posterior peritoneal incisions

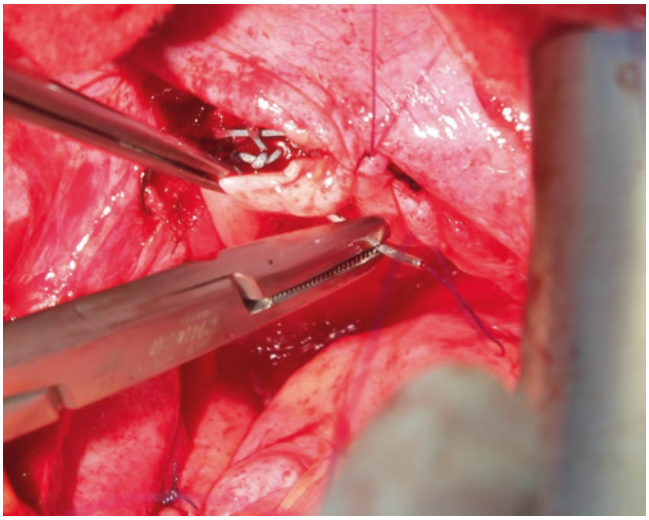

Fig. 92.54 VASA: The peritoneum at the end of the vagina is closed to cover the structure and the knots to prevent adhesions

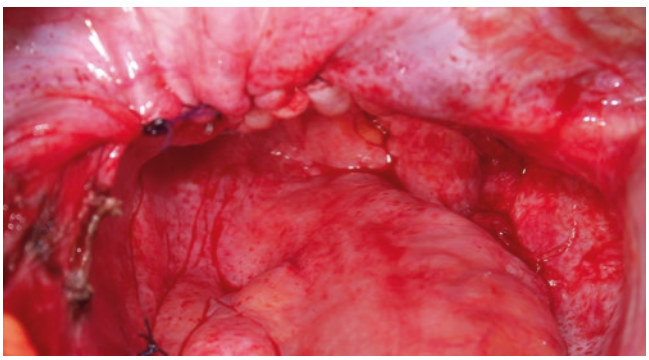

Fig. 92.55 VASA: The anterior wound is closed

that time the "bridge" is enclosed in the fibrotic tissue at the stump which holds the "bridge" in position.

The decision to perform an additional repair of the anterior or posterior vaginal wall i.e. a vaginal colporrhaphy has to be taken at the end of surgery and should only be performed when points Aa, Ba or C are >2 cm (−1, 0, +1, +2…..). Therefore, the same measurements as at the beginning of the operation are repeated (Figs. 92.57, 92.58, 92.59 and 92.60).

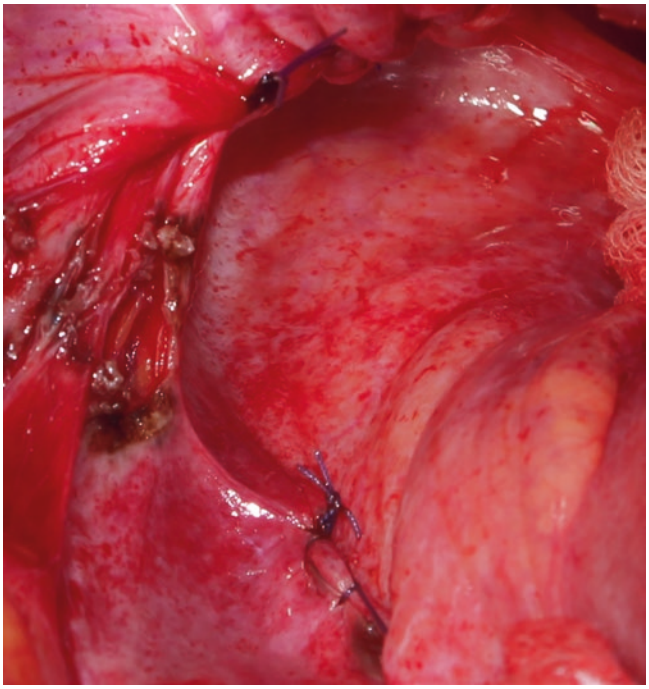

Fig. 92.56 VASA: At the end of these steps the new USL structures are placed and covered with peritoneum. The operation towels are removed. Before closure we add 150 ml saline solution to the pouch of Douglas so that the bowel is wettened to prevent adhesions

Fig. 92.57 VASA: View into the vagina after VASA

Fig. 92.58 VASA: A catheter is placed and remains for 2 days until the patient can reach the toilet without help during the night. The clamp is placed at the vaginal stump as at the beginning of the surgery

Fig. 92.59 VASA: The clamp is pushed with ten newton horizontally. The index finger marks the region of the clamp where the hymenal ring was

Fig. 92.60 VASA: At the end of the VASA the vaginal stump can be pulled down under traction to −5 cm from the hymenal ring

Wolfram Jaeger

Introduction

Prolapse

The term "prolapse" is used when the internal genitalia have lost their original position within the body and protrude along the vertical axis. It is not a disorder which appears from one moment to the other but a continuous development which may take several years. Prolapse usually starts in the second part of life – it is a problem associated with aging.

The pelvic organ prolapse quantification (POP-Q) system differentiates four stages "on that way out" (POP-Q I–IV) and is valuable for describing, quantifying and staging uterine and vaginal vault prolapse [1].

So far there are no recommendations for different treatments according to POP-Q stages. Therefore, the POP-Q system is just a description of the actual anatomical status at the time of examination.

A further characterization of the vaginal wall can be achieved by the points A and B.

Per definition, point A is 3 cm upwards from the hymenal ring along the vagina [1].

At the anterior vaginal wall Aa is considered to be the area at the end of the urethra; therefore, a shortening of point Aa indicates a descent of the urethra. This can be caused by an insufficient support of the urethra; however, one has to take into account that the length of the urethra differs considerably. Usually the length of the urethra varies between 2 cm and more than 4 cm in different women [2].

A point Aa at 3 cm, therefore, describes either a point at the urethral bladder junction or a point close to the middle of the urethra.

For this reason the actual length of the urethra should be measured and then decided whether the urethra is still in its original position or not.

W. Jaeger
Urogynecology, University of Cologne, Köln 50931, Germany
e-mail: wolframjaeger@gmx.de

The role of these different areas is not clear. However, the area above the urethral-vesical junction was described by PETROS as the "zone of critical elasticity" – an area where the brain receives its information about the filling state of the bladder and thereby starts or inhibits voiding. In that area a movement with the anterior blade can easily induce the feeling of urgent need to void or not during vaginal examination [3].

Etiology

The exact aetiology and the pathophysiology of genital prolapse are unknown.

The observation that prolapse is a continuous development argues strongly against a rupture of a "holding structure". The function of the "holding apparatus" diminishes over time. Therefore, it is tempting to speculate that a continuous influence is important for the reduced elasticity of the respective tissues [4].

Because prolapse is an absolutely rare phenomenon in animals the upright body position could be essential. It has been hypothesized that the pressure on the pelvic structures which hold the pelvic organs (uterus, vagina, ovaries, bladder and rectum) is increased by the upright body position. As premise it is taken that a special critical "pressure" must exceed the "holding forces".

One aspect of increased pressure on this pelvic holding apparatus is pregnancy (baby, uterus and amniotic fluid) and the mechanisms of birth.

Increasing body weight as a continuous development seems plausible; however, prolapse is irrespective of body weight.

During pregnancy the pressure on the pelvic floor increases; however, the physiological development of the baby, uterus and amniotic fluid during pregnancy do not directly exert their whole pressure on the pelvic floor since the anterior part of the abdomen does not remain in its normal position but bulges.

The power vectors under these conditions are probably not directed at the critical parts of the "holding apparatus".

Uterine Prolapse and Urinary Incontinence

A considerable number of women become urinary incontinent after childbirth [5].

However, this incontinence is reversible as it usually disappears after some weeks.

It has been hypothesized that this incontinence is based on the "stretched" pelvic-holding structures at the end of pregnancy. This assumption is based on the difference in the incidence of incontinence between women who delivered spontaneously and those who were delivered by caesarean section (CS). In women with CS the incidence of UI is significantly lower than in women who delivered spontaneously [6].

Forty percent of women suffering from genital prolapse also report UI [7].

It was assumed that UI and genital prolapse were two different disorders which only coincide by chance.

During a retrospective analysis based on personal interviews we could demonstrate that more than 50 % of women who had a vaginal hysterectomy because of prolapse stage II–IV of the uterus also presented with mixed urinary incontinence. The same numbers were reported by others who stated that up to 50 % of all women with vaginal hysterectomy developed stress and urge urinary incontinence thereafter [8].

On the other side the remaining women with prolapse did not develop UI.

Therefore, prolapse alone cannot be the only reason for UI but UI is usually associated with prolapse!

Pathophysiology of Prolapse and Incontinence

According to the above mentioned observations prolapse is probably based on a defect of the "holding apparatus" perhaps combined with some hormonal influences and genetic disposition. The ensuing laxity of the anterior vaginal wall leads to urinary incontinence. The uterus is probably not the etiological responsible factor for prolapse; therefore, a causal treatment must focus on the repair of the holding structures [3].

Prolapse is a disorder which usually appears after menopause. However, when it appears hormonal treatments can no longer repair the damage.

From observations that incontinence disappears some months after delivery, it was concluded that estrogens may be effective in strengthening the respective tissues in the pelvic floor [9].

Therefore, estrogens are often used as first treatment in women with urinary incontinence. The connective tissues can be strengthened by estrogens; however, it is difficult to achieve any effects if the women are already postmenopausal. Most likely the respective receptors can no longer induce the effects on the target tissues.

This may be caused by the diminished number of functioning E2 receptors in the target tissue or by damage to the tissue itself.

As target tissue, the connective tissue of the small pelvis with its body-position-specific "holding function" cannot be repaired. Estrogen replacement therapies cannot repair the prolapse or the incontinence.

In experiments with the corpses of rhesus monkeys, the change to an upright position led to an increased tension of the left and right USL which could be seen most effectively when the bladder of the monkey was filled with 80 ml saline solution.

When the bladder fills, the position of the bladder in the pelvis increases the pressure on the different surrounding tissues and structures, probably dependent on the different body positions. In the standing and sitting position one could assume that the pressure of the full bladder will exert its power mainly on the upper vaginal wall.

To characterize this position, one has to consider that the length of the urethra differs somewhere between 2.5 and 4.5 cm. That means that the entrance of the urethra into the bladder is somewhere between 3.5 and 5.5 cm from the entrance of the vagina (assuming that the additional 1 cm is the part between the entrance of the vagina and the introitus urethrae).

This correlates with the "zone of critical elasticity" of PETROS. This may be different in the prone position when the pressure is more directed to the lateral parts of the bladder or lying on the back where the pressure is more horizontal [4].

However, the pressure on the vaginal wall is transmitted to the holding structures. This is the anatomical fixation at the vaginal entrance and the cervix. The cervix, however, transfers this pressure to its holding structure – the USL.

(Interestingly enough the fixation points of the USL at the backside of the cervix are nearly exactly opposite the highest fixation points of the bladder at the front side of the cervix.)

In analogy the position of the vagina can be compared with a bridge with two pylons in the front and in the back: the pubo-urethral ligament (PUL) and the USL [4].

Since, according to developmental research, the USL are derived from the uterus and not from the presacral area, it must be important that women have two USL at the cervix and not only one. These two USL do not arise from the same point at the cervix but have two different origins at a distance from each other, depending on the size of the cervix. It can be speculated that this distance improves the three dimensional stability of the pelvic floor and especially of the position of the bladder. By increasing the distance between the origins of the USL the stability of the bladder position is increased.

Therefore, prolapse treatment needs to focus on the holding apparatus and especially on the USL. Since in patients with prolapse the structures of the USL diminish by two

thirds in their muscle and elastic tissue composition, the USL cannot only be repaired but must be replaced.

Pelvic Floor and Standardization of the Operations

The premise of the CESA, VASA and Uterosacropexy operations is a standardised surgical replacement of the USL (Figs. 93.1, 93.2, 93.3, 93.4 and 93.5).

Standardised operation means that the operation will be performed in every patient in exactly the same way: identical length of tapes which is guaranteed by stitch marks on the structure, defined fixation sites at the cervix and in front of S1/S2. The structures are pulled through the peritoneal fold of the USL and thereby placed retroperitoneal at a defined channel.

Considering the great variety of women's shapes one would expect that the lengths of the USL are different in every woman; however, this is not the case.

In obstetrical textbooks the diameters between the bony structures in the small pelvis are identical in all women irrespective of weight, parity or racial derivation. This has been confirmed by extensive MRT measurements by several institutions [9].

For this reason we hypothesized that the ligaments in the small pelvis, especially the USL and the PUL, are also of identical length or differ only slightly in all women after puberty.

Therefore, we decided to implant USL structures of the same length in every woman. According to the literature and our own measurements we arrived at the conclusion that the length of the USL is between 8.5 and 9.0 cm [10].

In patients who want to keep the uterus we decided to use the VASA/VARESA structures (Dynamesh VASA and Dynamesh VARESA, FEG, Aachen, Germany) (See figs. 92.24, 92.25 and 92.36 in Chapter 92).

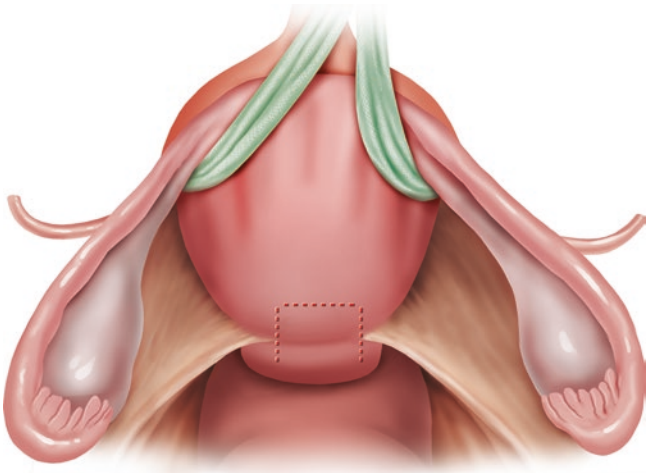

Fig. 93.1 Uterosacropexy: The uterus is held by a small tape pulled through the parametrium. The incision side at the cervix/corpus is marked with a *red line*

Additional Rectopexy (CERESA)

If a rectopexy has to be performed (CERESA), a non-resorbable suture 3-0 is placed in front of the marked posterior fixation sites. Special tapes have been developed for this procedure (Dynamesh CERESA). The sutures grab the mesorectum on both sides and are tied on the anterior net structure of the tape in that area.

Repair of the Anterior ("Cystocele") and Posterior ("Rectocele") Vaginal Wall

The decision to perform an additional repair of the anterior or posterior vaginal wall i.e. a vaginal colporrhaphy has to be taken at the end of surgery and should only be performed when points Aa, Ba or C are −2 cm (−1, 0, +1, ≥+2).

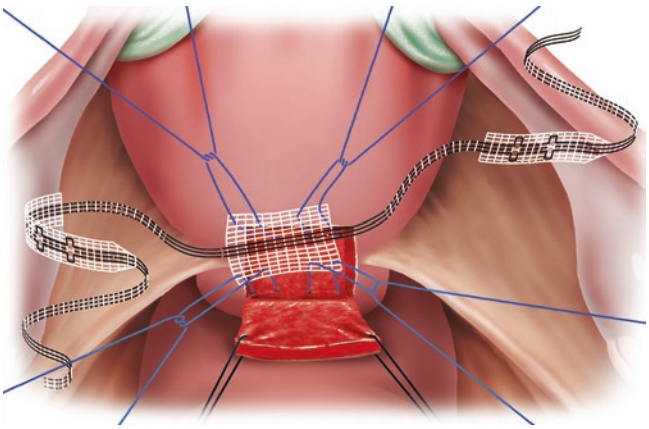

Fig. 93.2 Uterosacropexy: A muscle flap is incised at the back of the uterus. The site of the incision was chosen so that the new USL of the structure could easily be pulled into the peritoneal fold of the original USL. Four stitches were placed in each quadrant of the implantation site and the holding part of the structure ("bridge"). The muscle flap is armed with two lateral stitches

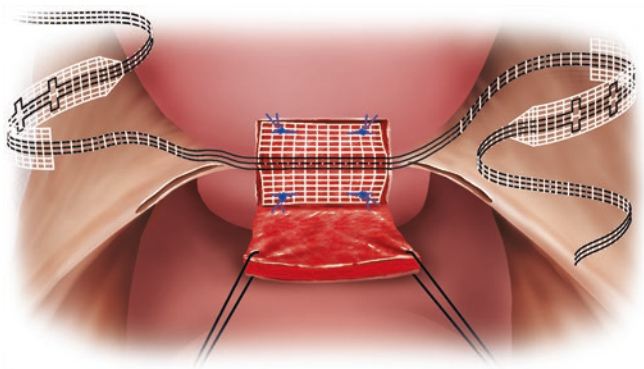

Fig. 93.3 Uterosacropexy: The four sutures were tied and the peritoneal folds of the USL were incised. (Take care not to injure the uterine artery and/or vein!)

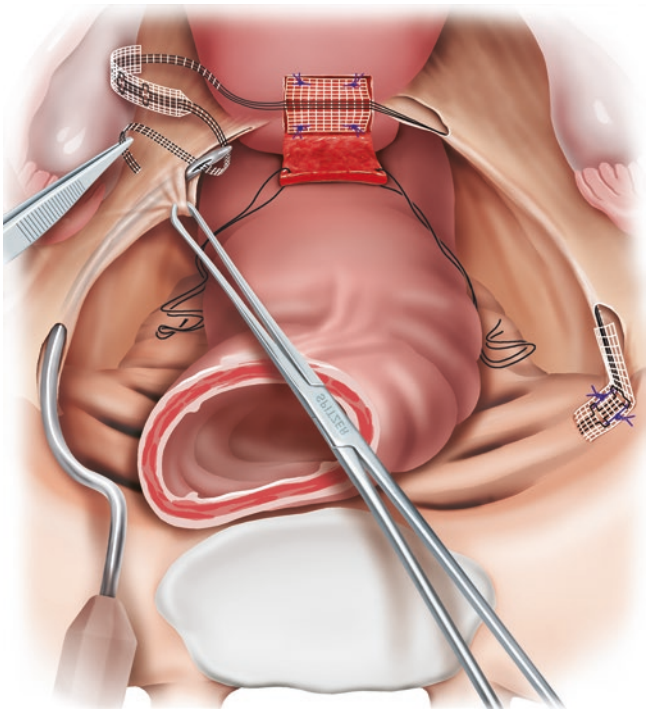

Fig. 93.4 Uterosacropexy: The right USL of the structure has been placed under the peritoneal fold. It was sutured to the os sacrum with two horizontal sutures. On the left side the trocar is pushed through the USL channel and the *top* of the insertion aid of the trocar. The trocar is pulled backwards and the left USL of the structure is brought into place

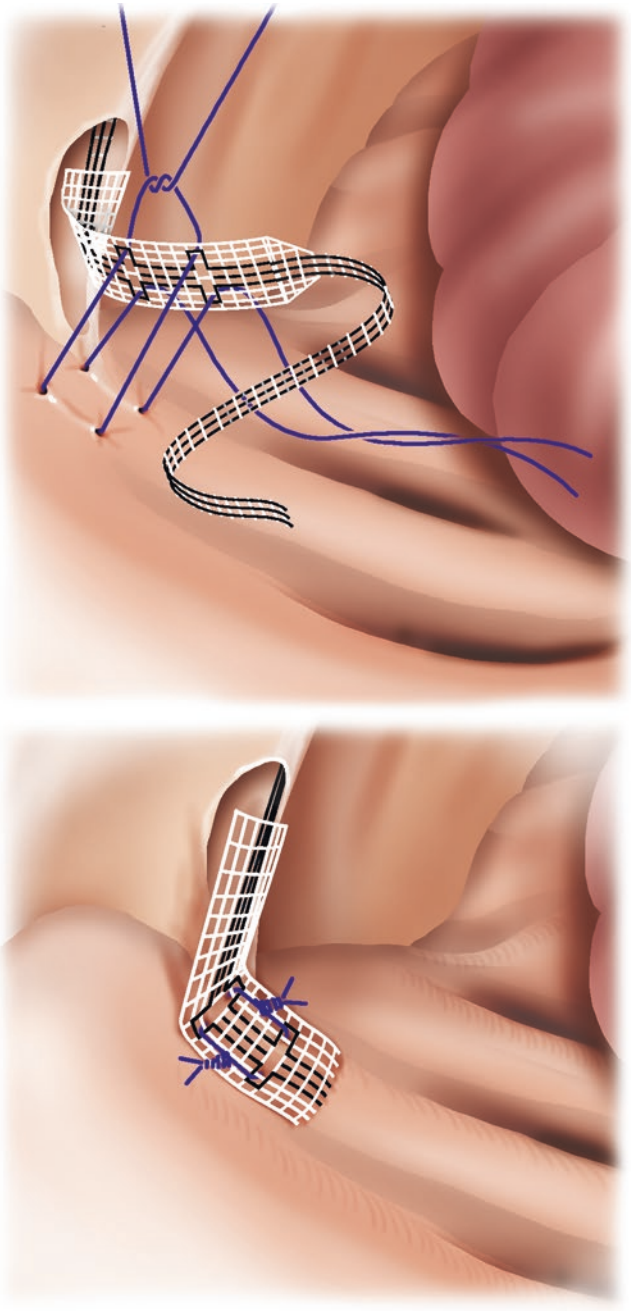

Fig. 93.5 Uterosacropexy: The fixation in front of S2 is shown. The stitches go through the marked areas of the fixation site. The stitches are horizontally. They are pulled tight and thereafter the peritoneal incision closed

Uterus-Sacropexy and Uterus-Recto-Sacropexy

Before the operation the uterine prolapse is measured. This can be done by taking the cervix with a clamp and pulling it horizontally with a force of 10 N (1 kg) (Fig. 93.6) (also see figures 92.4 and 92.5 of Chapter 92).

During this examination the anterior vaginal wall is examined to decide whether an additional repair of the anterior wall is necessary. The rugae indicate that this is not necessary in this case.

Opening of the Abdominal Cavity (According to the Internal Institutional Standards)

The dermal incision should be horizontal ("cesarean section") between 8 and 12 cm according to the pre-rectoral fatty tissue. After opening the peritoneum we prefer placement of a rectangular frame with a 25 cm diameter.

The first step is to decide whether the operation can be carried out as planned. The reasons being, firstly the size of the uterus could be a problem. If the diameter of the corpus is enlarged by myomas, it is recommended to resect to reduce the diameter of the uterus. Secondly, if ovarian cysts complicate the situation, these should be removed and examined. The aim of this part of the operation is to "empty" the pouch of Douglas as much as possible.

Therefore, the bowel and the small intestines have to be out of the area.

We use two surgical towels. With the first towel we place the small intestine into the upper abdominal cavity. With a second towel, which is folded into a rectangular shape, we move the descending and ascending large intestine upwards. At the end of this step the pouch of Douglas should be free of intestine apart from the sigmoid colon. Especially, the pelvic rims (the transition into the small pelvis) must be clearly visible in order to make incisions there and to avoid any complications.

Fig. 93.6 Uterosacropexy: Before the operation the cervix is fixed with a clamp and pulled horizontally downwards with a force of 10 N (1 kg). In this case a prolapse of the uterus POP-Q stage 3 was found

Fig. 93.7 Uterosacropexy: The right peritoneal fold of the USL can be identified

The Sequence of the Different Steps of the Operation Is Different to Those of CESA or CERESA and VASA or VARESA

The reason for the above is that as soon as the new structures are tied at S1/S2, the uterus can no longer be moved; therefore, the closure of the uterus flap must be carried out beforehand.

Identifying the Peritoneal Folds of the Uterosacral Ligaments (USL)

The first step of surgery is the demonstration of the USL.

To find the USL, the uterus must be grabbed with one hand (usually the left hand for right-handers) (Fig. 93.7).

The uterus should be pulled in the opposite direction to the USL being sought (Figs. 93.8 and 93.9).

The origins of the USL at the uterus can always be identified. The origins of the USL are at the posterior part of the cervix. They arise nearly opposite the insertion side of the bladder at the anterior side of the cervix.

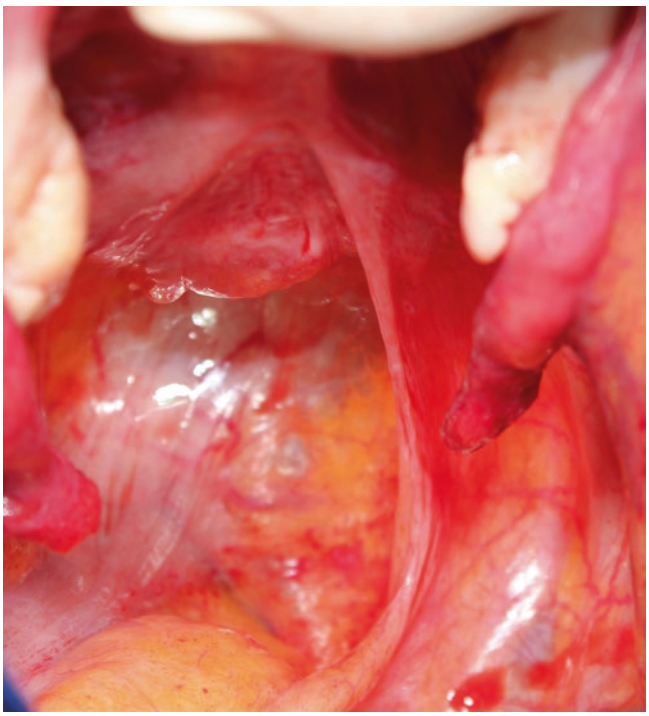

Fig. 93.8 Uterosacropexy: The right USL

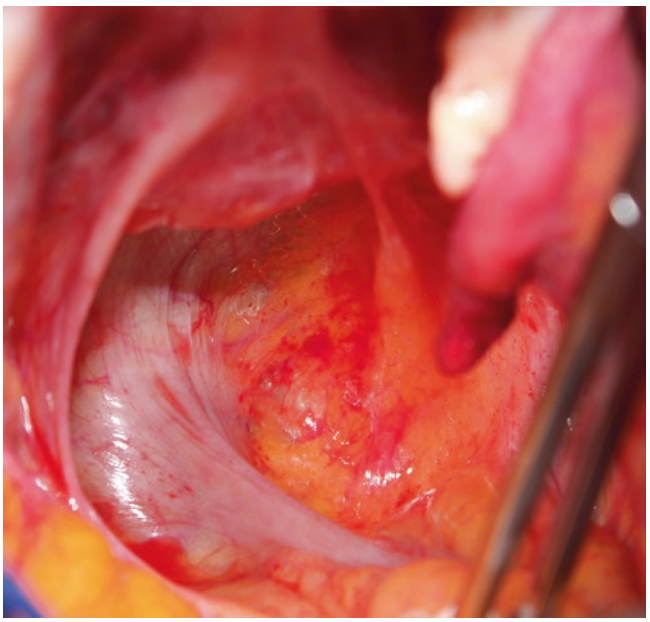

Fig. 93.9 Uterosacropexy: The left USL

Fig. 93.10 Uterosacropexy: The musle flap is prepared. The incision starts 0.5 cm below the origin of the USL at the cervix on both sides

Preparing the Anterior Fixation Side: the Uterus

Definition of Level 0

The upper points at the cervix where the USL originate are delineated. An imaginary horizontal line between these points of origin is called level 0 (zero).

The incision made at the backside of the uterus and cervix is an inverted U: upside down!

The aim is to prepare a muscular flap at the backside of the uterus with its basis at the cervix.

The incision begins just below level 0 on the backside of the cervix. The incision starts a little below level 0, medial of the origin of the USL at the cervix (Figs. 93.10 and 93.11).

The "length" of the flap should be between 2 and 3 cm depending on the size of the cervix.

The distance between the upside incision and the down-side incision ("the width") should be as large as possible depending on the size of the uterus. It is usually between 1 and 3 cm (Fig. 93.12).

Take care not to incise the uterine artery and vein on each side!

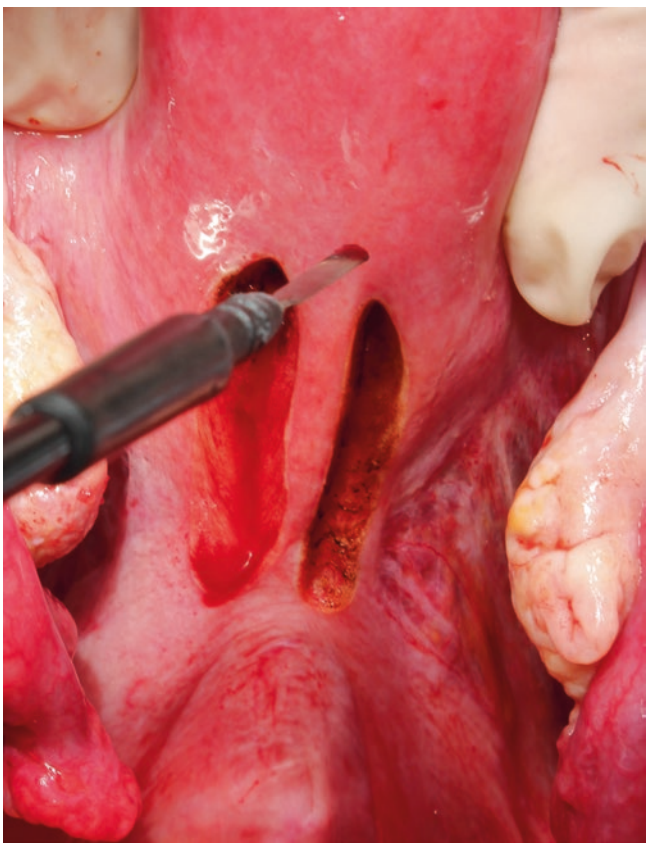

Fig. 93.11 Uterosacropexy: The anterior part is cut

Fig. 93.12 Uterosacropexy: The size of the flap is cut

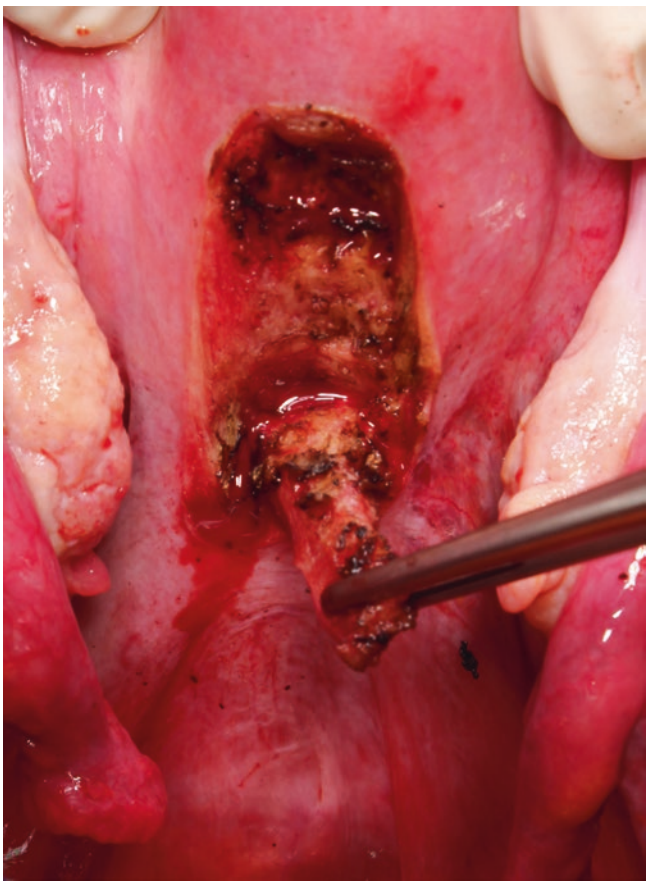

Fig. 93.13 Uterosacropexy: The flap is pulled downwards

The incision should be 3 mm wide and performed with an electrical knife.

In this way an inverted U-shaped flap is formed (Fig. 93.13).

A small incision is made in the parametrium close to the round ligaments. A loop is pulled through one of these holes, placed around the uterus and pulled out at the other hole. The ends of the loop are armed with a clamp (Figs. 93.14 and 93.15). The clamp is then placed at the frame, exerting some tension on the uterus.

The peritoneal folds of the USL end at the level of S2. The USL structures reach up to the sacral spine in the area between S1 and S2.

Preparation of the Posterior Fixation Site

After the USL have been identified, the incisions at the sacrum are placed horizontally, 0.5 cm above the insertion side in front of S1/S2 (Fig. 93.16).

An incision along the USL (from cervix to sacrum) should be avoided since the "original" peritoneal folds protect the tape structure from adhesion formation. Furthermore, they

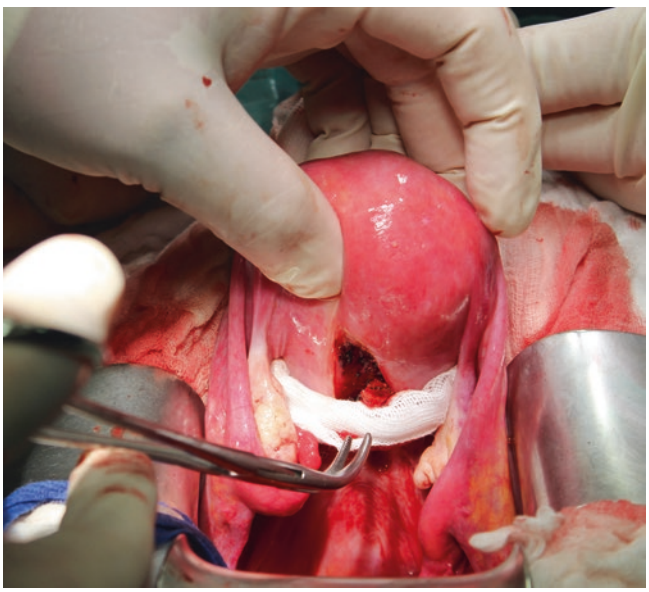

Fig. 93.14 Uterosacropexy: The parametrium is incised on both sides of the uterus and a small towel is put through these holes and armed with a clamp

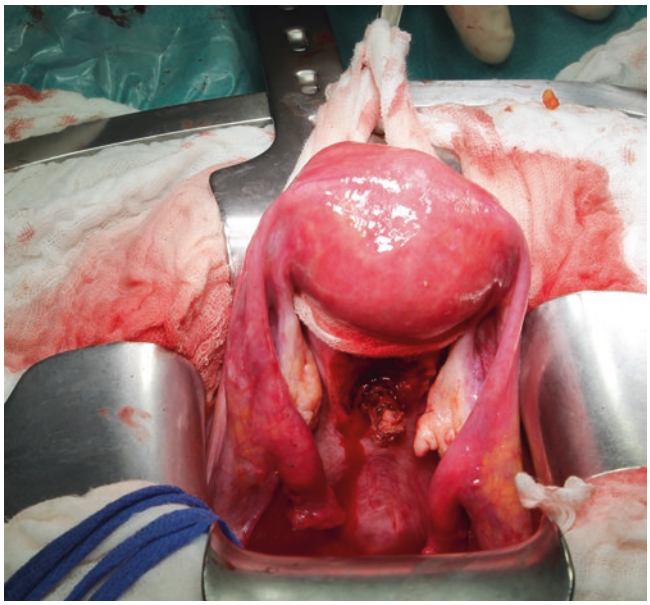

Fig. 93.15 Uterosacropexy: The uterus is fixed by this towel at the frame to make the operation easier

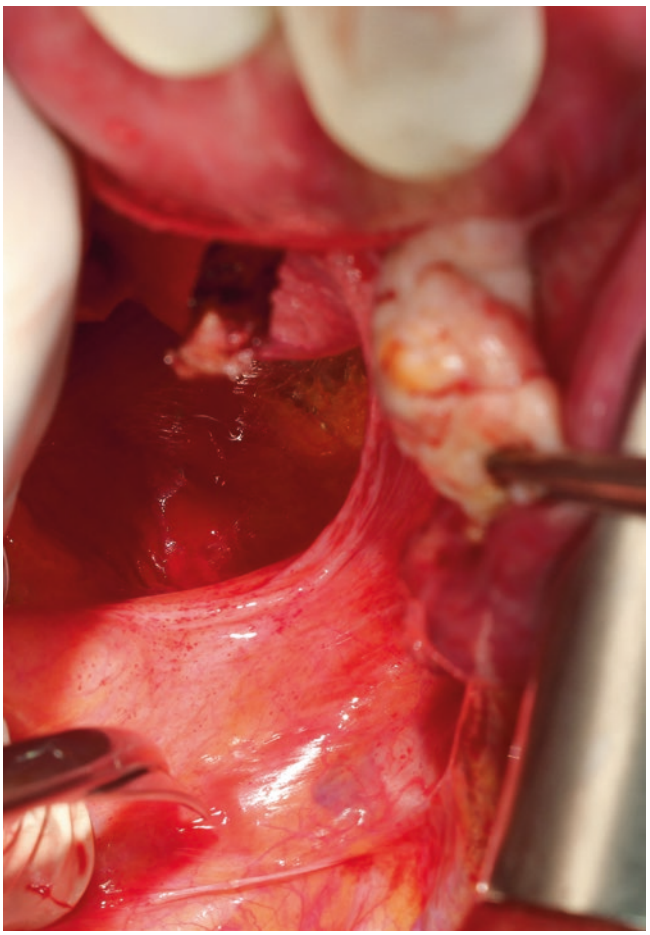

Fig. 93.16 Uterosacropexy: The right peritoneum is tied and the incision site is identified, lateral to the USL in front of S1/S2

form the intended anatomical "semi-circle" formation when the structures are under tension. The PVDF structures do not form fibrotic adhesions to this peritoneal fold, therefore it remains movable.

The incision is usually above the first vertebra (S1). From these incisions the pre-vertebral fascia is prepared (Fig. 93.17). Be aware of the hypogastric nerve and take the nerve laterally from the stitches later on. Identify the presacral artery and vein, and coagulate them at 2 cm lengths so that the needle cannot injure these vessels (Fig. 93.18).

Two non-resorbable sutures 2-0 are placed horizontally in this fascia, one below and one higher at a distance of about 1 cm from each other (Figs. 93.19, 93.20 and 93.21). They are armed with a clamp and placed at the top of the wound.

The same procedure also needs to be carried out on the left side (Fig. 93.22).

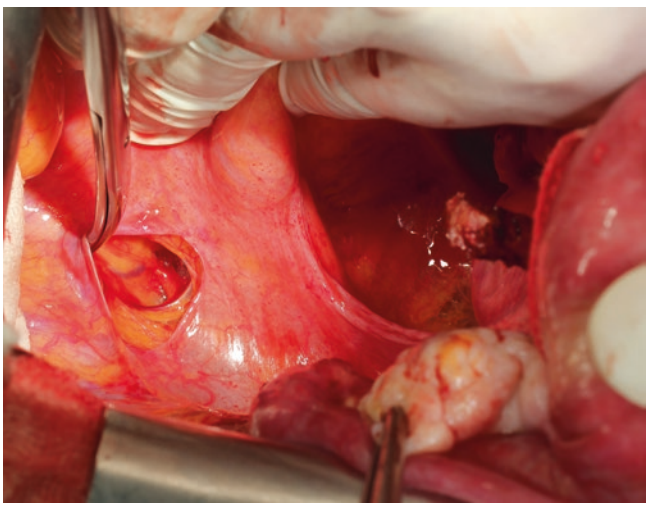

Fig. 93.17 Uterosacropexy: The peritoneum is incised and the fixation sides in front of S1/S2 are freed of fatty tissue

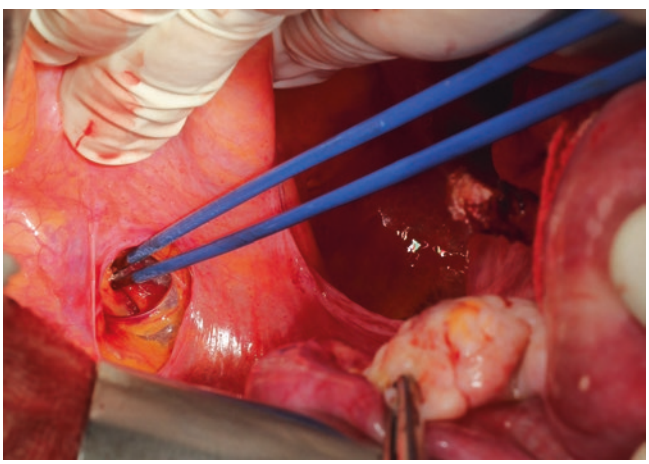

Fig. 93.18 Uterosacropexy: The sacral artery and vein are cauterized

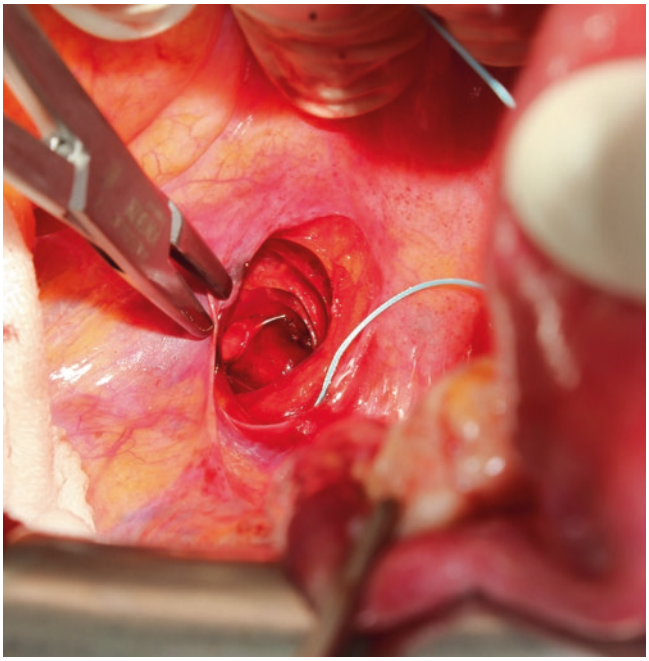

Fig. 93.19 Uterosacropexy: The first stitch is placed

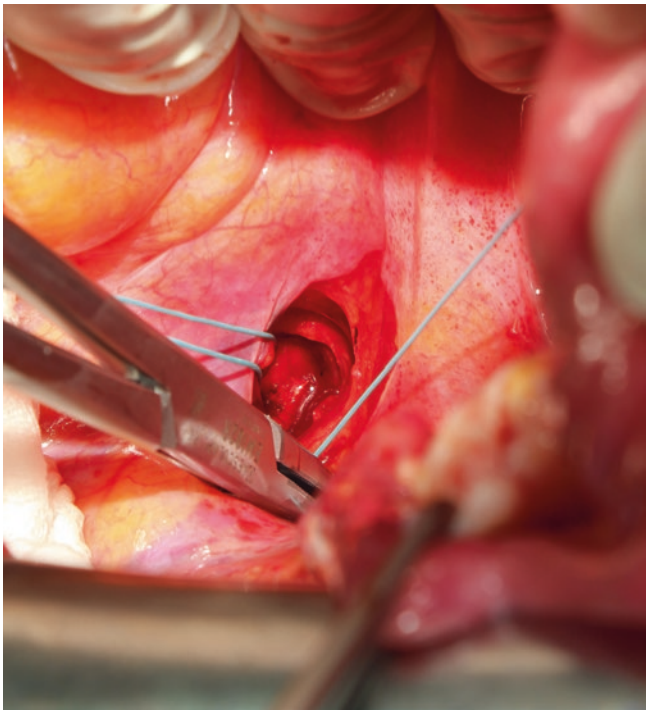

Fig. 93.21 Uterosacropexy: A second stitch is placed horizontally below the first. The sutures are armed with clamps and placed on side of the frame (Note: The sutures are not tied at this phase of the operation!)

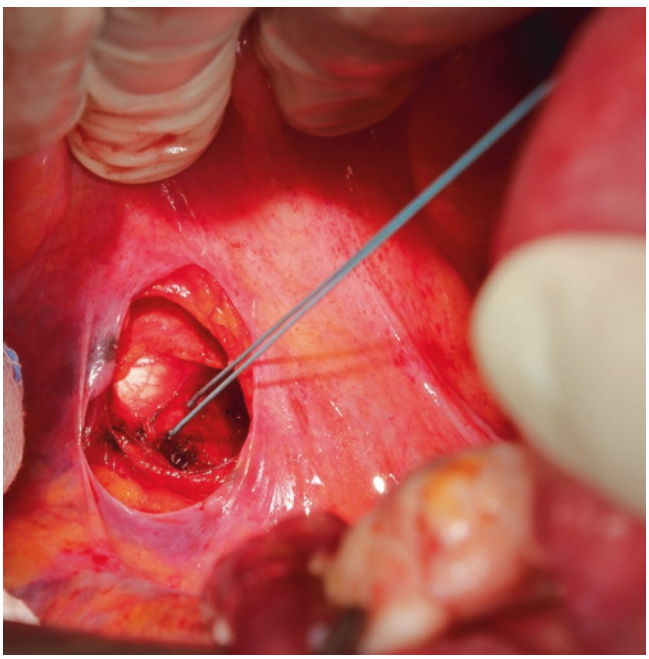

Fig. 93.20 Uterosacropexy: The suture is armed with a clamp

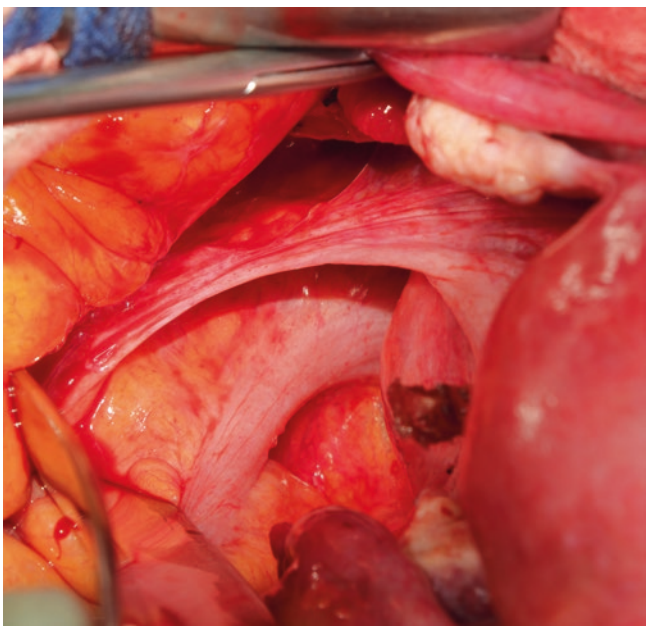

Fig. 93.22 Uterosacropexy: The USL of the left side is demonstrated

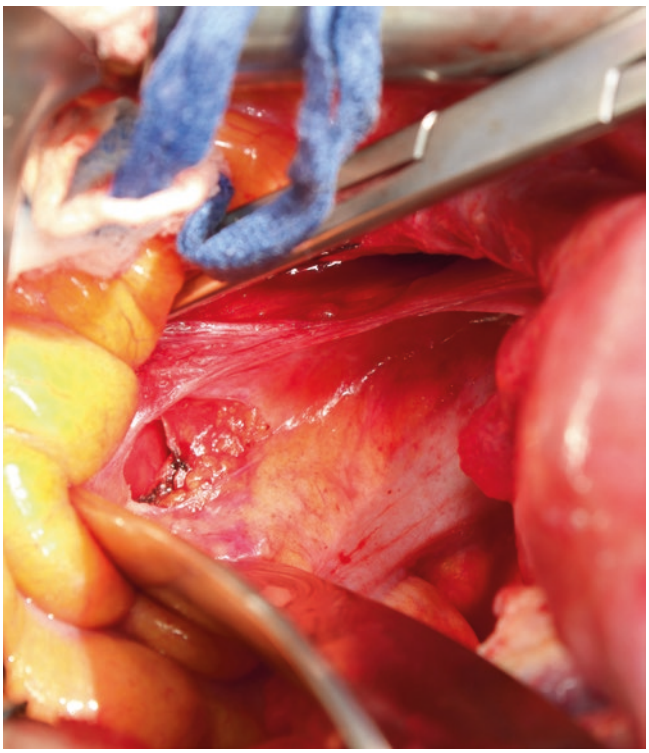

Fig. 93.23 Uterosacropexy: The presacral area is prepared

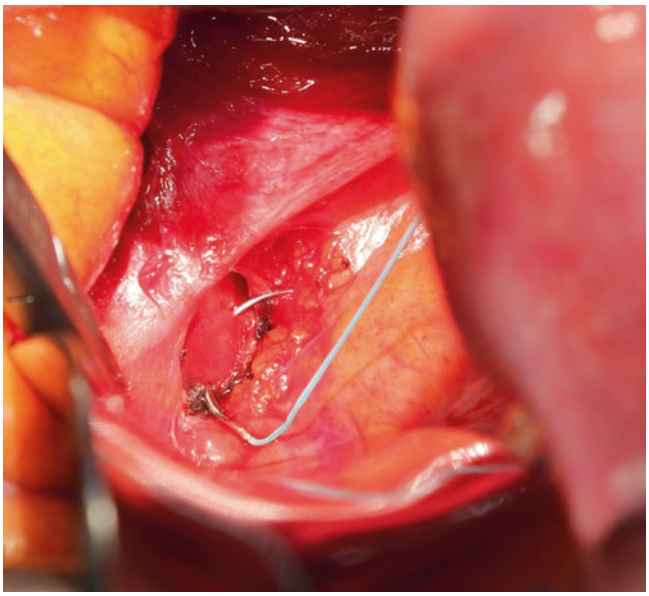

Fig. 93.24 Uterosacropexy: The first stitch is placed

The left side is a little more difficult, since the meso-sigma crosses the fixation side. Therefore, the sigma/rectum needs to be pushed to the right side. This can either be done with a retractor held by an assistant or the surgeon takes the sigma in one hand and pulls it in the respective direction.

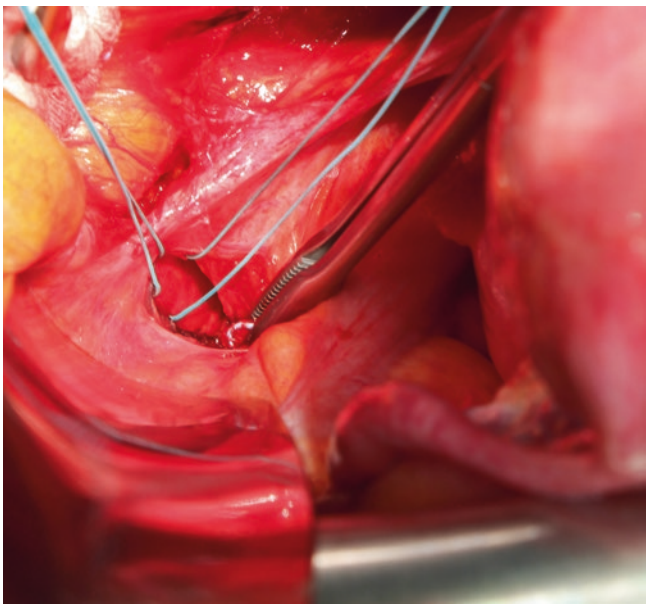

Fig. 93.25 Uterosacropexy: The second suture is placed below (Note: The sutures are not tied at this phase of the operation)

The surgeon then palpates the retroperitoneal sutures on the other (right) side. The palpatation will help to find the respective identical fixation site on the left side. With the other hand the incision is placed as on the other side.

After the posterior fixation sites have been prepared – two sutures on the left and two sutures on the right side of the sigma colon – the sutures are armed with clamps and pulled aside (Figs. 93.23, 93.24 and 93.25).

Advice At the end of surgery you must define the higher and the lower suture and the medial and the lateral part of the suture. Therefore, put the upper sutures with a clamp in the direction of the patient's head. Put the clamp with the lower sutures on the outside, on the left or the right of the patient. The stitches for the sutures run from lateral to medial on the right side and from medial to lateral on the left side. Leave the suture end of the lateral stitch long and on the medial side short ("lateral is long").

Placement of the New USL

For the next step, care must be taken to avoid injury to the peritoneal fold of the USL.

The structure can be either a CESA or a VASA tape according to the size of the uterus (Fig. 93.26).

Four sutures are placed in the prepared fixation site at the back of the cervix/corpus area (Figs. 93.27, 93.28, 93.29, 93.30, 93.31, 93.32 and 93.33).

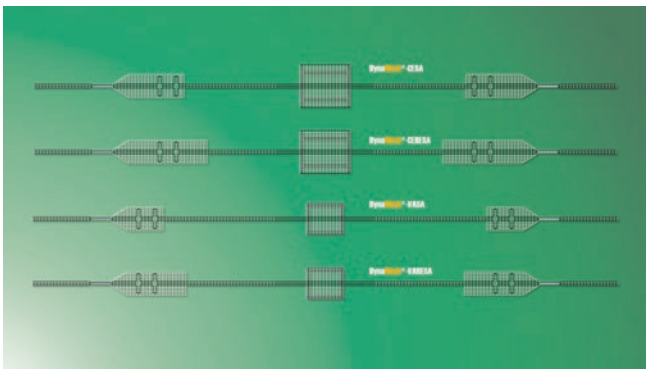

Fig. 93.26 Uterosacropexy: The augmentation of the uterosacral ligaments is performed using a narrow but open-pore sling structure of 4 mm width, made of high strength PVDF-filaments (Dynamesh CESA, Dynamesh CERESA, Dynamesh VASA and Dynamesh VARESA, FEG Textiltechnik mbH, Aachen, Germany). Theoretically each of the four structures could be used. For smaller cervices we use the VASA or VARESA structures. For younger women a larger structure of the CESA or CERESA type can be indicated

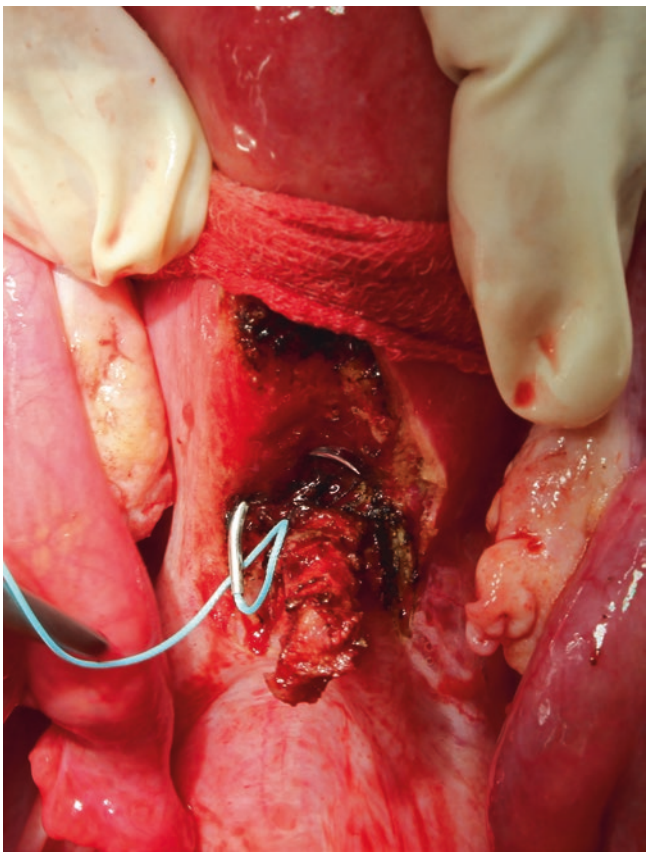

Fig. 93.27 Uterosacropexy: The first suture is placed in the lower left quadrant of the uterus/cervix region

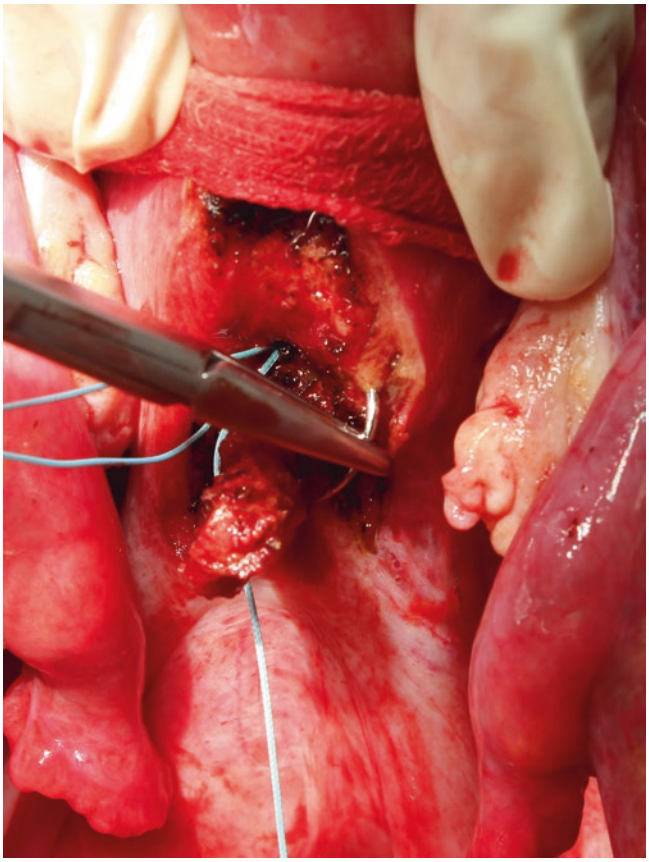

Fig. 93.28 Uterosacropexy: The second suture is placed on the *lower* right quadrant

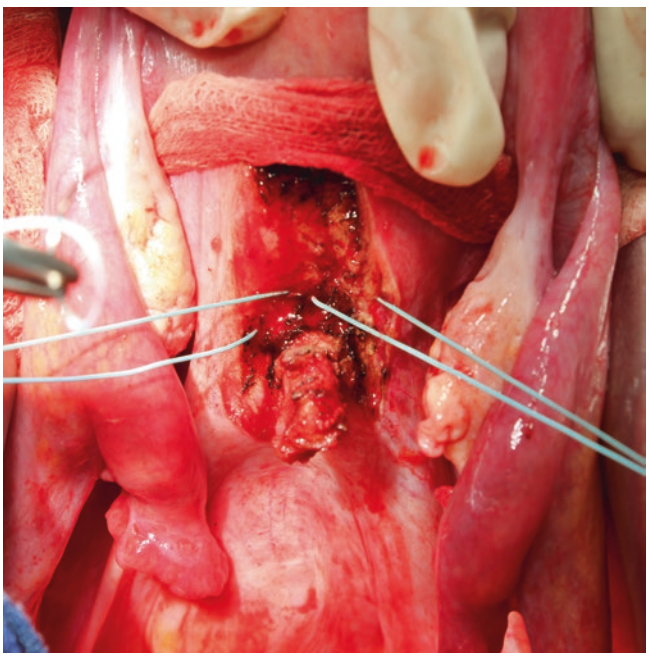

Fig. 93.29 Uterosacropexy: The two sutures of the lower quadrants are placed

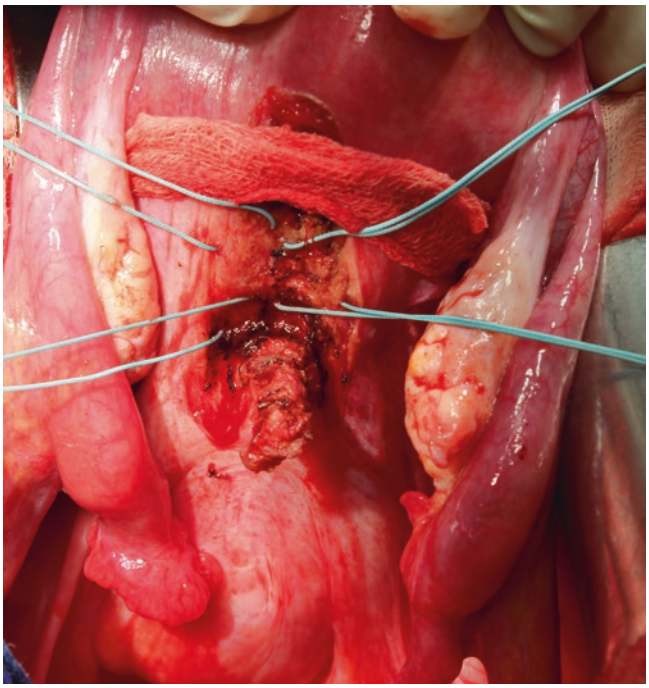

Fig. 93.30 Uterosacropexy: All four sutures are placed

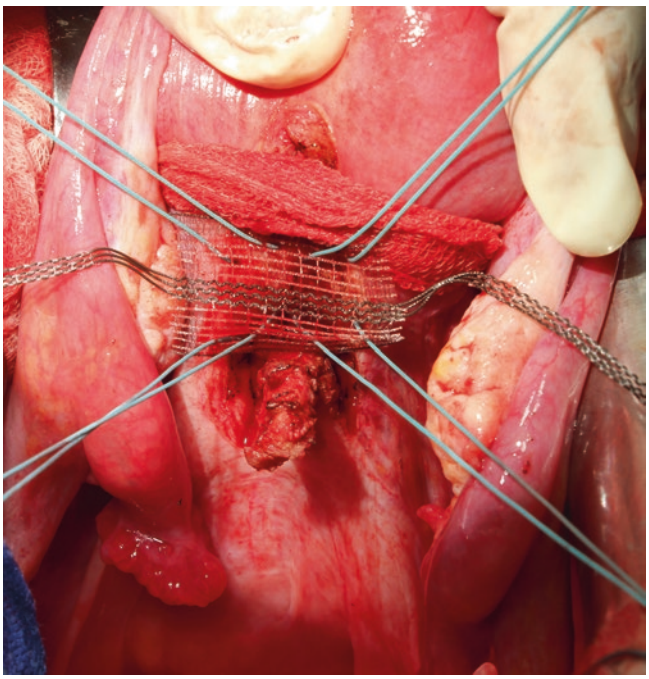

Fig. 93.32 Uterosacropexy: The USL of the structure are demonstrated

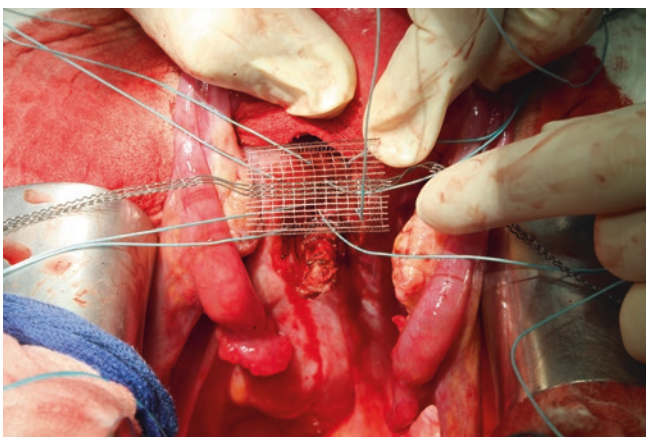

Fig. 93.31 Uterosacropexy: The sutures are pulled through the structure (Dynamesh VASA)

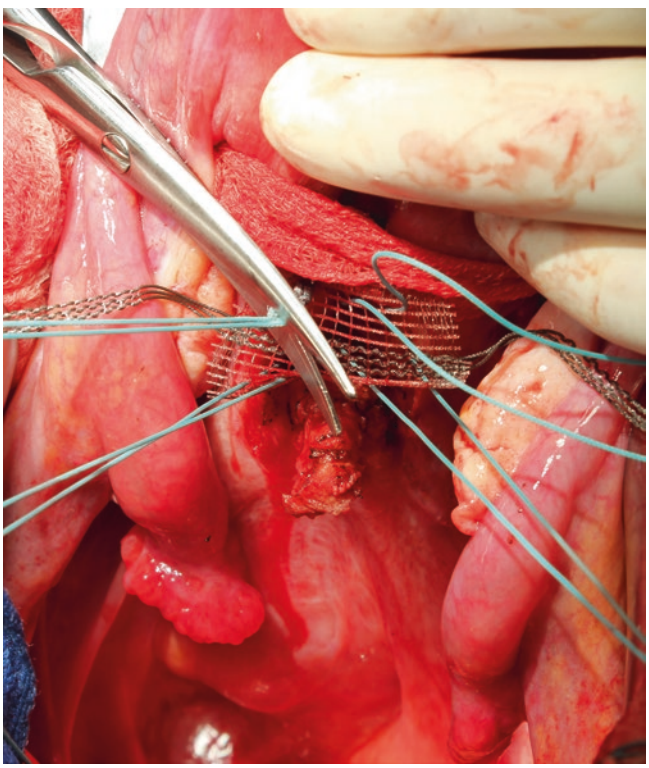

Fig. 93.33 Uterosacropexy: The sutures are cut

The bridge is sutured at the backside of the cervix (Fig. 93.34).

A small trocar, as usually used for a TVT placement, is pulled through the peritoneal fold of the USL from the back to the base at the cervix (Figs. 93.35 and 93.36).

Care must be taken not to injure the uterine vein or artery which was cut during the previous supracervical hysterectomy. If bleeding occurs at this moment, the respective vessels should be identified and coagulated precisely. They can easily follow the original paths of the USL on both sides.

The insertion aid of the tape is pulled through the hole at the top of the trocar (Fig. 93.37). The trocar is then pulled backwards towards the sacrum. This pulling action should be performed very carefully (Fig. 93.38).

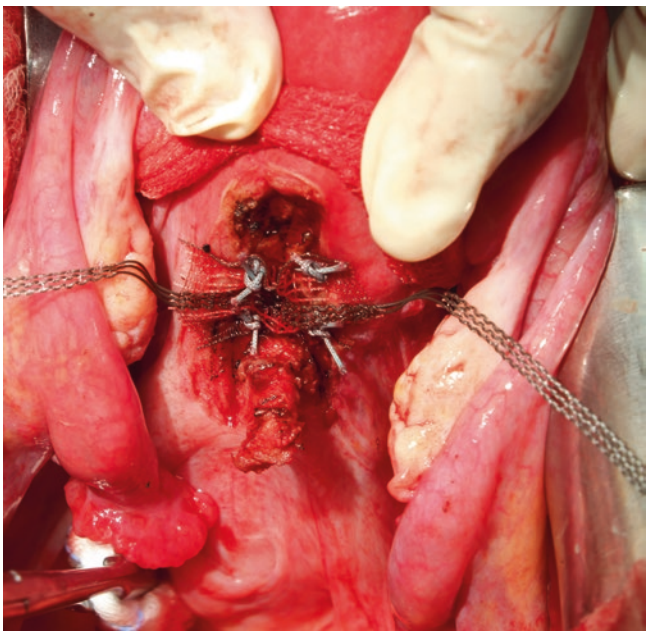

Fig. 93.34 Uterosacropexy: The "bridge" is fixed at the cervix/corpus of the uterus

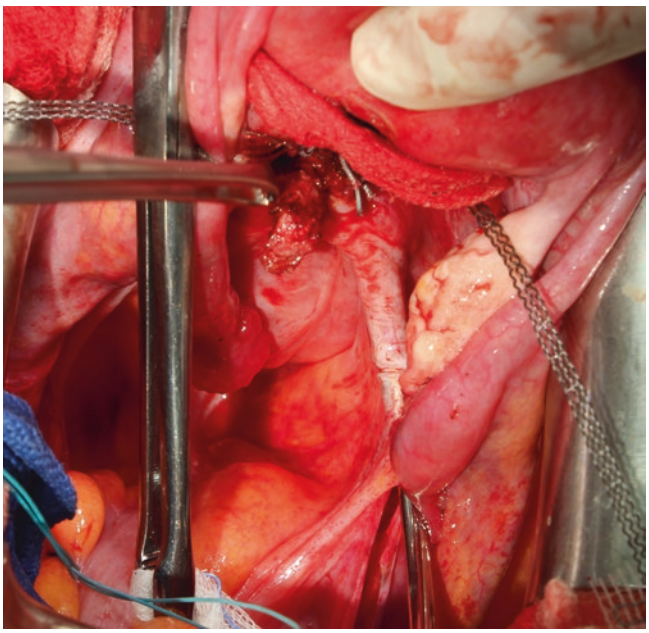

Fig. 93.36 Uterosacropexy: The trocar is pulled forward towards the origin of the USL

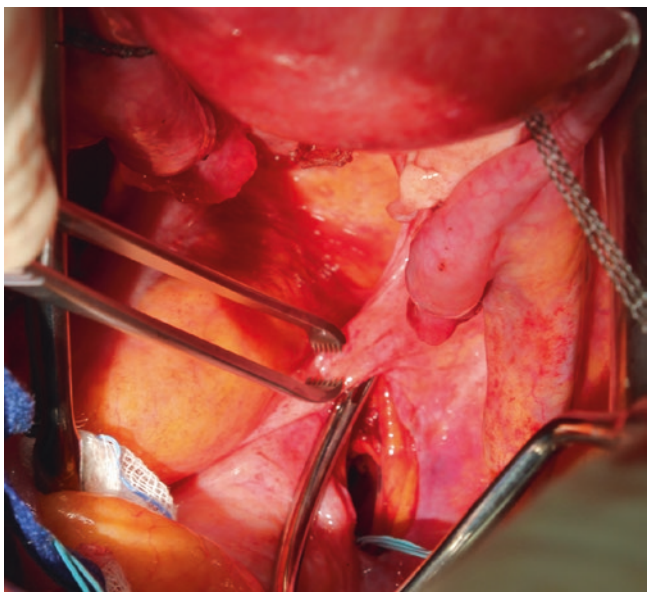

Fig. 93.35 Uterosacropexy: The trocar is inserted in the right peritoneal fold of the USL

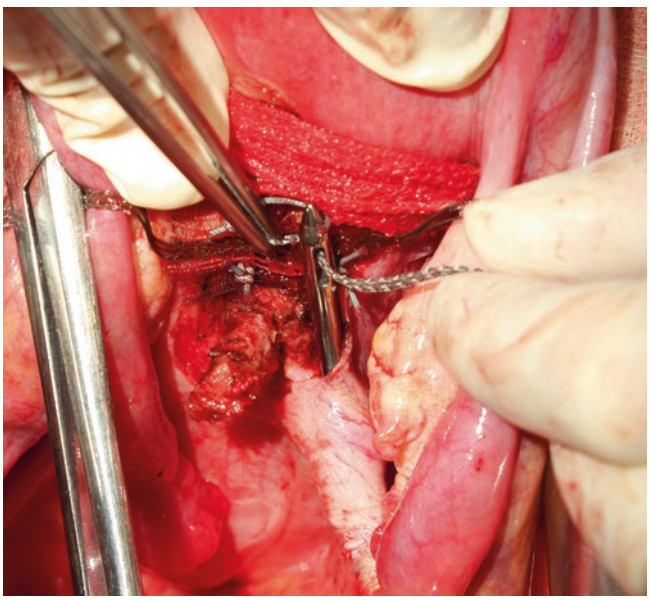

Fig. 93.37 Uterosacropexy: The top of the trocar is pushed through the origin of the USL. The insertion aid is placed through the hole of the trocar

Bleeding cannot definitively be avoided; however, it is important that the surgeon immediately detects the origin of the bleeding.

The USL structure and the fixation mesh are then pulled through the USL fold. This is performed easily – as through an empty channel. When the fixation mesh appears out of the "channel", it is placed where it is to be fixed (Fig. 93.39).

The previously-placed sutures are pulled through the marked fixation sites on the tape (Figs. 93.40, 93.41 and 93.42). The upper suture is placed on the lateral part of the fixation mesh, the lower suture on the medial part of the mesh. Once this has been done, the longer arms of the sutures are placed laterally and the shorter ones medially. The insertion aid is cut.

The new PVDF structure holds the cervix "with open arms" (not with "stretched out arms"). Both sutures are armed and placed again laterally or upwards until they are tied at the end of the operation (Figs. 93.43, 93.44, 93.45 and 93.46). The same steps are then repeated on the left side (Figs. 93.47 and 93.48).

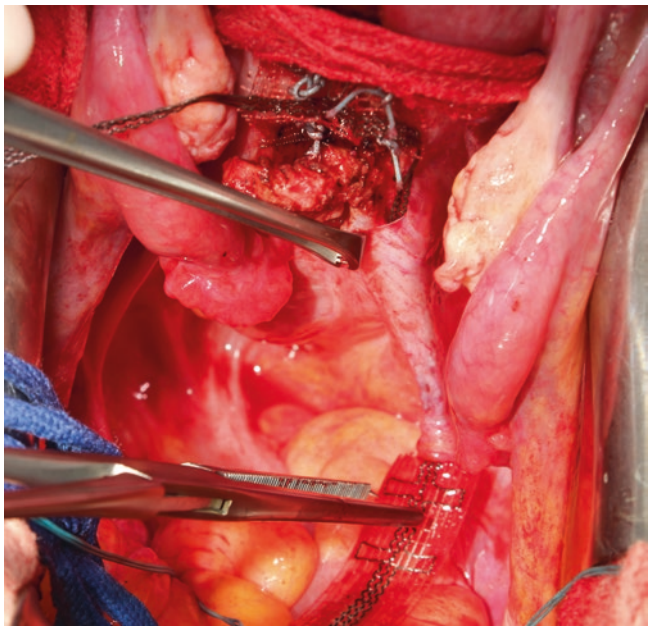

Fig. 93.38 Uterosacropexy: The structure is pulled through the channel of the USL

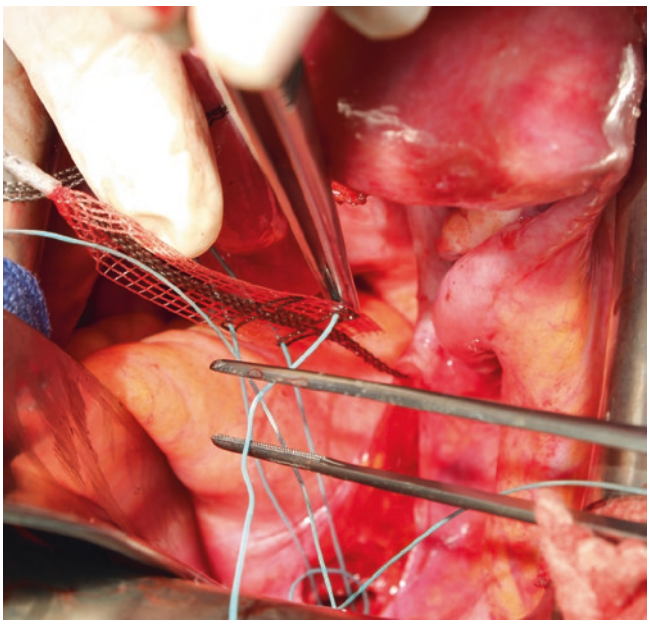

Fig. 93.40 Uterosacropexy: The preplaced sutures are pulled through the suture marks

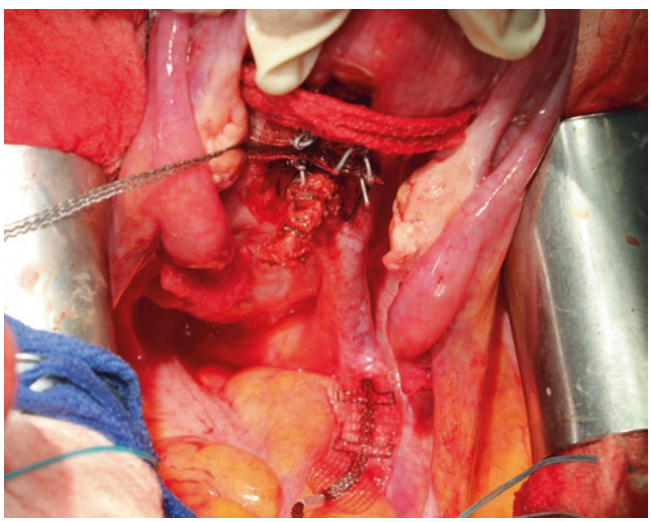

Fig. 93.39 Uterosacropexy: The structure is placed as it should be

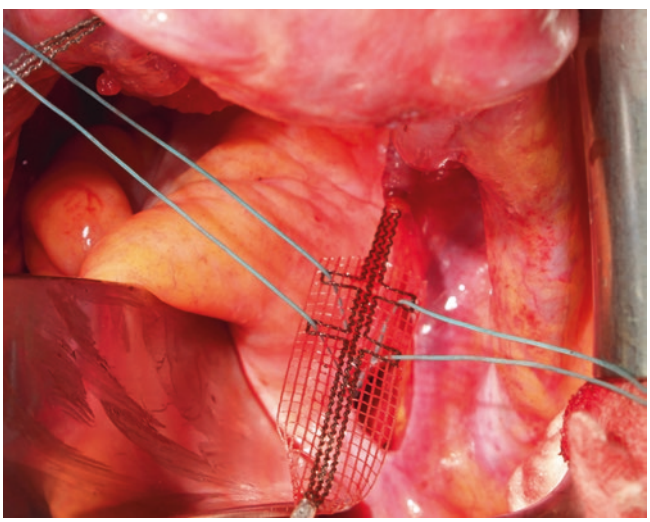

Fig. 93.41 Uterosacropexy: All two sutures are pulled through the mesh structure

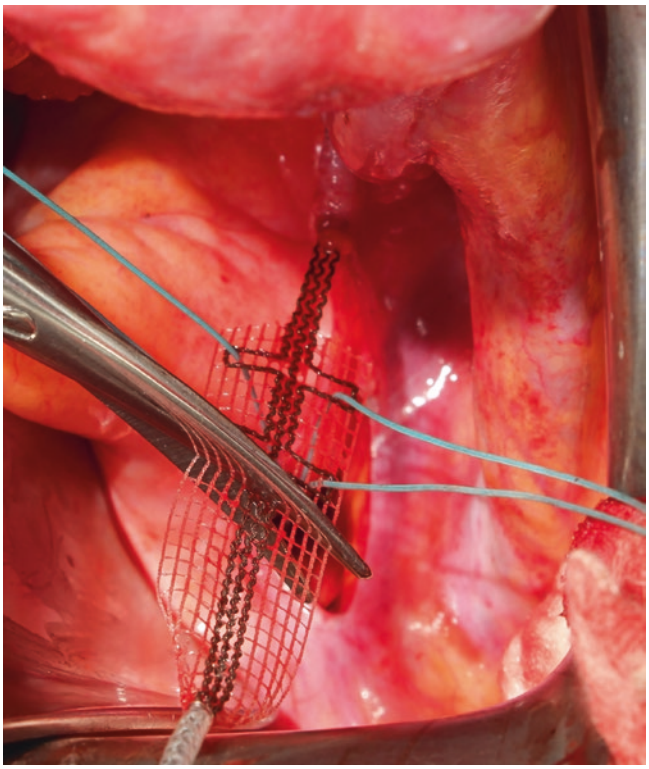

Fig. 93.42 Uterosacropexy: The insertion aid is cut (Note: The sutures can be tied at this part of the surgery or at the end of the surgery)

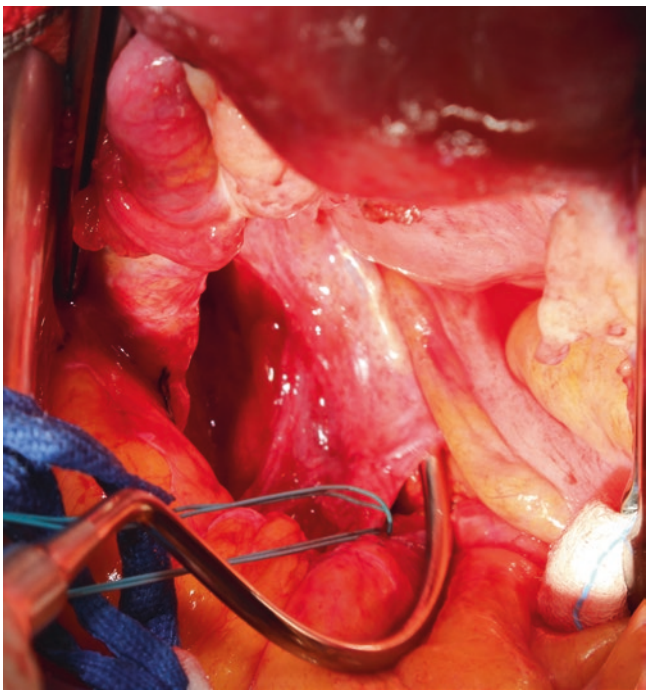

Fig. 93.43 Uterosacropexy: The same procedure is performed on the left side. Insertion of the trocar

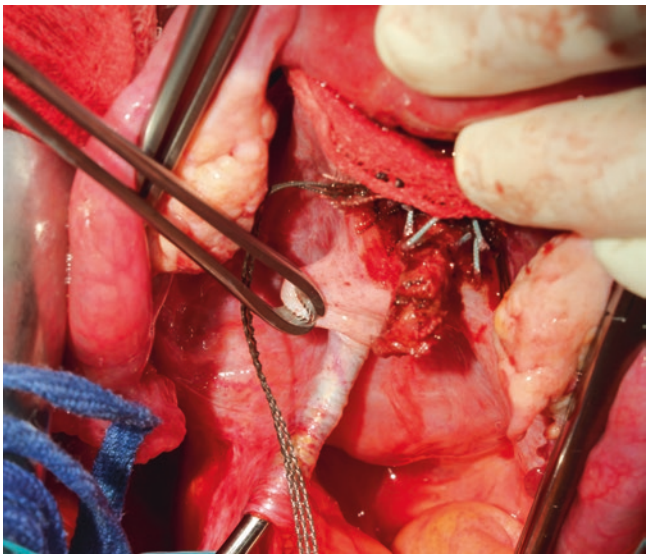

Fig. 93.44 Uterosacropexy: The trocar is pushed forward towards the origin of the left USL

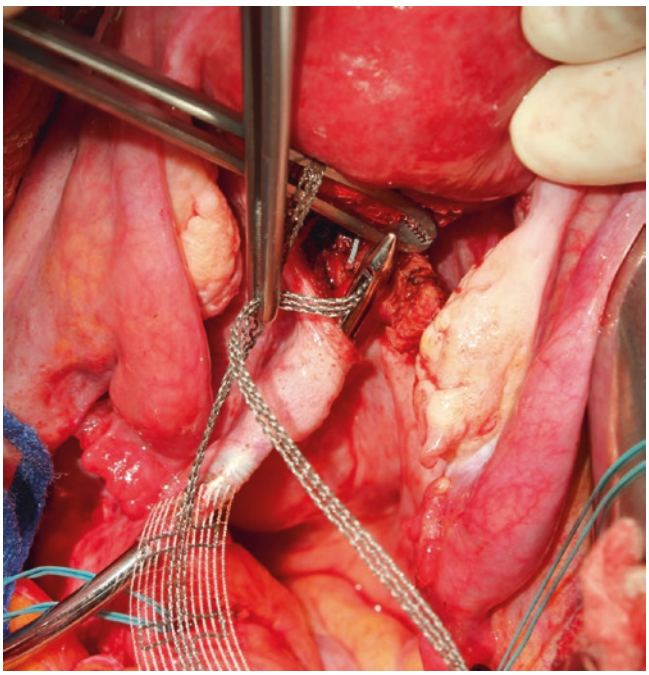

Fig. 93.45 Uterosacropexy: The insertion aid is pulled through the hole of the trocar

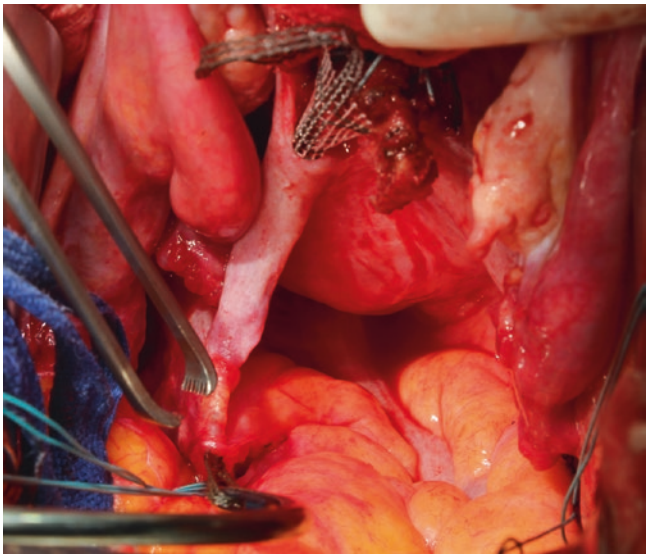

Fig. 93.46 Uterosacropexy: The trocar with the insertion aid is pulled through the channel of the USL

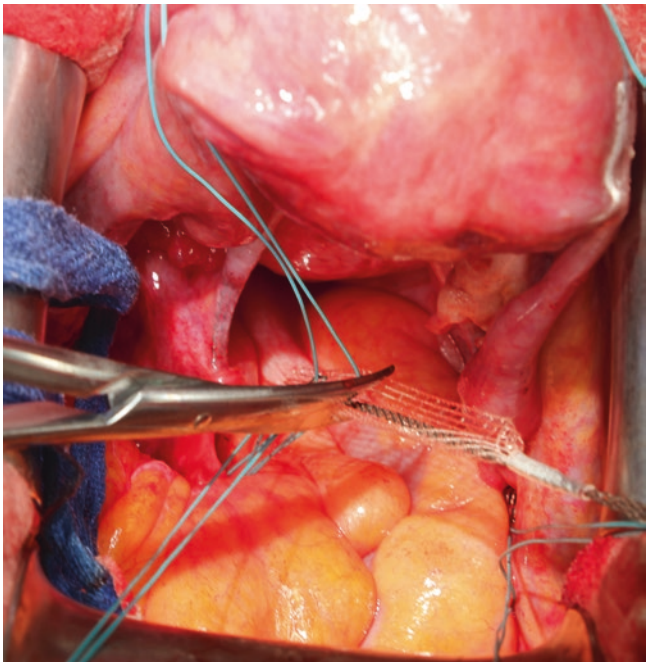

Fig. 93.48 Uterosacropexy: The insertion help is cut

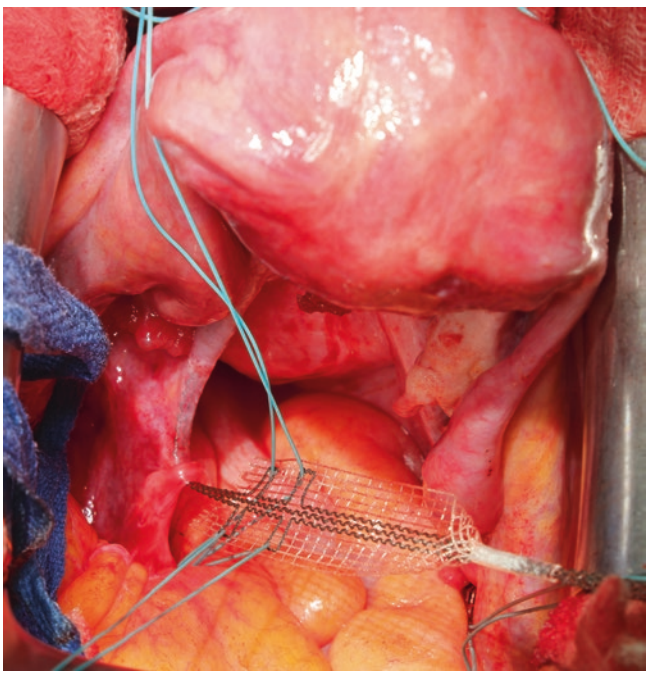

Fig. 93.47 Uterosacropexy: The sutures are placed through the marked sites on the tape

The sutures should not be tied at this moment! (This would lead to a smaller space for closing the uterine flap at the end of surgery.)

Closing the Backside of the Uterus

The next step is the closure of the uterus flap!

The flap usually shrinks considerably within a few seconds.

The closure or replacement of the flap should be started with a single suture in the middle of the flap to define the center and the top of the flap (Fig. 93.49).

Thereafter, a continuous suture (PDS 4-0) with a small needle adapts the flap again to the uterus. If any part of the mesh tape is still visible, it should be resected to avoid adhesion formation in that area afterwards (Figs. 93.50, 93.51, 93.52, 93.53 and 93.54).

After finishing that step, the uterus can be placed back into the peritoneal cavity. Therefore, remove the loops which hold the uterus. The holes in the parametrium do not need to be sutured.

The sutures of the posterior fixation site in front of the os sacrum are then tied (Fig. 93.55).

As the last step, the peritoneum on the posterior fixation side is closed to prevent adhesions (Fig. 93.56).

After removal of the towels, a 150 ml saline solution is added to prevent the drying out of the sigma epithelium and possible adhesion formation (Figs. 93.57, 93.58 and 93.59).

After closure of the abdomen, the vaginal examination demonstrates that a repair of the anterior vaginal wall is unnecessary (Fig. 93.60).

The final prolapse is documented (Fig. 93.61).

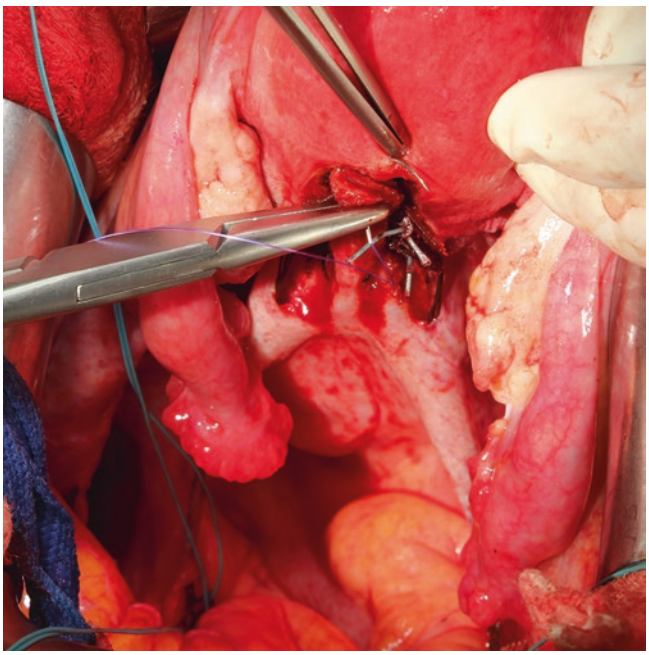

Fig. 93.49 Uterosacropexy: The flap at the end of the uterus is sutured to the uterus/cervix (Note: The flap will shrink considerably within a few seconds)

Total Abdominal Hysterectomy with Electrosurgical Bipolar Vessel Sealing

94

Ilgın Türkçüoğlu and Rauf Melekoğlu

Introduction

Hysterectomy is the most commonly performed major gynecological surgery in gynecology practice [1]. It is the most common non–pregnancy-related gynecologic surgical procedure carried out in the United States [2]. It has been estimated that one in three women will have a hysterectomy by the age of 60 [3, 4]. A large proportion of hysterectomies are performed abdominally or laparoscopically, and fewer than 30 % are performed vaginally in most series [1]. Laparoscopic hysterectomy has several advantages to abdominal hysterectomy, with less intraoperative blood loss; less wound infection, slighter postoperative pain, an economically shorter hospital stay and rapid return to normal activities (Table 94.1). Further, there are very few contraindications to laparoscopy like cases with a cardiopulmonary disease that may not tolerate pneumoperitoneum and/or Trendelenburg positioning. Therefore laparoscopic hysterectomy may replace abdominal hysterectomy in cases where vaginal hysterectomy is not accessible [5–8]. Nevertheless, laparoscopic hysterectomy needs surgical skills, and everyone may not be able to perform a laparoscopy. Also, it is associated with longer operating time and a greater risk of trauma to the bladder or ureters compared to abdominal hysterectomy [9]. Although recent data have shown an increase in rates of minimally invasive hysterectomy, the majority of hysterectomies continue to be performed through abdominal routes [10, 11]. Another important issue is the extensive use of laparoscopy by some clinics. Therefore the new generation obstetrics and gynecology residents may graduate without learning how to perform a hysterectomy through abdominal route well. The current chapter focuses on the surgical procedure of hysterectomy through abdominal route, as well as the use of electrosurgical bipolar vessel sealing systems. The route of the hysterectomy can be chosen by the surgeon according to the need of patient and/or the skills of the surgeon. The indication of the abdominal hysterectomy is mentioned in Table 94.2.

Hemorrhage is the most frequent complication during abdominal gynecologic surgery. To reduce hemorrhage-related morbidity, adequate hemostatic techniques are essential during surgical procedures. In open procedures, conventional mechanical hemostatic techniques that use sutures or clips are the most frequently used methods to control bleeding. After the introduction of laparoscopy, lasers and different electro-thermal and ultrasonic coagulation modalities gained importance [12]. Each modality has its strengths and weaknesses. All of the mechanical methods introduce foreign bodies into the patient and, perhaps with the exception of sutures, carry an increased cost. Clips are easily placed but require accurate vessel dissection and have a considerable risk of dislodgement during tissue manipulation. In laparoscopic surgery, mechanical hemostatic techniques are almost completely replaced by coagulation techniques that use mono- or bipolar coagulation (electrical energy converted to thermal energy) and ultrasonic devices (mechanical energy converted to thermal energy). Lasers carry such a high associated capital investment that they are rarely used in general gynecologic surgery [13]. Different coagulation techniques have some advantages over others (Table 94.3).

Ultrasonic technology controls bleeding through the use of ultrasonic vibration. The vibrating blade induces a rapid rise in temperature resulting in the denaturation of proteins to form a coagulum that seals the vessel [14]. This technique produces minimal amounts of smoke, and the depth of penetration of the energy lateral to the intended focus is also minimal [15]. Although the ultrasonic technology has the ability to achieve hemostasis with limited

Table 94.3 Different hemostatic techniques in gynecological surgery

Techniques	Mechanism	Advantages	Disadvantages	Expected thermal spread
Monopolar electrocoagulation	Electrical current created in the electrosurgical unit passes through a single electrode to the tissue, causing the desired tissue effect	Due to higher voltage the coagulation mode achieves better penetration through high resistance areas, such as fatty tissue or scar tissue More applicable when fulgurating a large surface area with superficial bleeders, such as might be encountered following ovarian cystectomy	The greatest degree of thermal spread in tissues	2.3 mm – >20 mm (it's dependent upon application time and setting)
Bipolar electrocoagulation	Electrical current created in the electrosurgical unit is confined to the tissue between the two electrodes of the surgical instruments	A separate return electrode (i.e., dispersion pad) to return current is not needed. Ideal when dealing with vascular areas or 3–7 mm blood vessels such as the uterine artery	Less effective for cutting tissue since adequate vaporization is difficult to achieve	2–22 mm

Table 94.3 (continued)

Techniques	Mechanism	Advantages	Disadvantages	Expected thermal spread
Ultrasonic cutting and coagulation device	Convert ultrasonic energy into mechanical energy at the functional end of the instrument. A piezoelectric crystal in the hand piece generates vibration at the tip of active blade at 55,500 times per second over a variable excursion of 50–100 μm. This results in rupture of hydrogen bonds and produces heat, which leads to denaturation of proteins and eventually, separation of tissue	Minimal thermal spread Decreased tissue charring and smoke formation No risk of electrical injury due to absence of electrical current within the patient Versatile instrument allowing the surgeon to dissect, cut and coagulate using one instrument	Potential for extensive thermal spread at high energy levels for more than 5 s The limited ability to coagulate vessels larger than 3–5 mm Increased cost of disposable instruments User dependent nature of the instrument	0–3 mm. (It's dependent upon application time and setting)
LASER (Light Amplification and Stimulated Emission of Radiation)	Laser energy is generated when electrons jump from higher to lower energy levels during their circuits around the nucleus. The energy created induces molecular vibration and thermal energy upon contact with the target tissue	Can be used to cut, coagulate, ablate or image tissue	The safe and appropriate use of lasers requires a trained clinician with a working knowledge of laser delivery systems. Long periods of continuous exposure of the laser beam or insufficient cooling time can lead to excessive tissue heating	Changes upon the type of medium, modes of operation and application time
EBVS devices	Applies a precise amount of bipolar energy and pressure to fuse collagen and elastin within the vessel walls. This results in a permanent seal that can withstand three times the normal systolic pressure	Seals vessels up to 7 mm Minimal thermal spread The generator for this device uses a feedback controlled response system to ensure adequate tissue sealing	More cost since these devices are disposable	1.1 mm for the EnSeal® tissue sealing and hemostasis system 1.8 mm with the 10 mm LigaSure® device 4.4 mm with the 5 mm LigaSure® device 6.3 mm with the Gyrus Plasma Trissector®

collateral thermal damage, it is only labeled for vessels up to 3–5 mm in diameter, thereby restricting its application in many procedures [13].

Monopolar high-frequency electrical energy is the oldest method used to coagulate vessels; however, it induces local heating and tissue damage. Due to potential capacitive coupling and spark generation, its use is associated with the risk of electrical injury to the bowel and other organs [16]. Conventional bipolar electrosurgical technology is safer than monopolar energy as the current flows between the two electrodes of the instrument and so reduces collateral damage. Bipolar coagulation enables the surgeon to operate at lower currents thereby decreasing the effect on other organs [15].

Vessel sealing systems use bipolar electrocoagulation as the technology. (Insert Fig. 94.1) Most vessel- sealing devices use a tissue-based feedback program to regulate the dosage of applied energy. Due to this feedback system, less energy is required, and, based on in vitro studies, it is reported that these devices have reduced local tissue damage in comparison to conventional bipolar devices. Potentially, they, therefore, represent a decreased risk of injury to adjacent structures. Further, vessel-sealing devices are indeed more effective than other electrothermal or ultrasonic devices regarding reduced coagulation time, fewer complications, and lower total costs during laparoscopic and open surgical procedures.

Fig. 94.1 Handset of various electrosurgical bipolar vessel sealing systems

Electrosurgical Bipolar Vessel Sealing Systems

Vessel-sealing technology is a variant of bipolar electrosurgical technology. It is a combination of a precise amount of bipolar electrocoagulation (high current, low voltage) and pressure on the tissue that leads to the denaturation of the collagen and elastin in the vessel walls and a fusion of these into a hemostatic seal [17]. The electrothermal bipolar vessel sealing (EBVS) system was shown in several animal studies to achieve hemostasis in small, medium, and large arteries. EBVS system is increasingly being used in a variety of surgical procedures [18]. High-frequency electrosurgery has traditionally been the workhorse in the operating room, and the recent development of electrosurgical bipolar vessel sealing systems offers the abdominal surgeon a safe and effective alternative hemostatic method.

EBVS system provides some advantages, including ease of handling and fast hemostasis that does not require the use of foreign bodies that should remain in the surgical site. These advantages are not only useful in laparoscopy but also in open procedures, leading to an increase in the implementation of these techniques in open procedures as well.

The EBVS system consists of a specialized electrosurgical generator and handset and can effectively seal vessels and vascular bundles up to 7 mm in diameter. This new energy-based technology uses an alternate form of electrosurgery to denature collagen and elastin in vessel walls and subsequently reform these proteins into a hemostatic seal. The performance of this technology, reflected in the seal burst strength, depends on the application of mechanical energy or pressure in conjunction with the delivery of electrical energy. The simultaneous delivery of mechanical and electrical energy remodels the vessel tissue to form a desiccated absorbable collagen seal out of native vessel protein.

During activation, the specific electrosurgical generator measures both voltage and current to monitor tissue response. As tissue impedance changes because of resistive heating, voltage and current will vary accordingly. When tissue response indicates a successful seal, a cool cycle is entered, during which time the device position is maintained and no power is delivered. After the cooling period, the generator emits an audible tone to indicate cycle completion. On average, the entire sealing and cooling cycle take approximately 5 s (Fig. 94.2) [13].

In March 2006 the NHS—Purchasing and Supply Agency—Center for Evidence- based Purchasing published the "Report 06008: Electrosurgical vessel sealing systems" [19] describe five electrosurgical devices. More recently two other EBVS have been introduced to the market [20]. All the instruments clamp the vessel, or tissue bundle, and deliver a high-frequency electrical current to achieve heating within the tissue. The prongs should remain relatively cool, so the instrument does not tear the tissue when the clamp is released. The combination of temperature and pressure shrinks and denatures collagen and other cellular proteins in an irreversible process. The structure of collagen changes as its bonds become broken and it forms a gel-like substance that acts as a glue between vessel walls. To achieve this effect the tissue needs to be heated to between 70 and 95 °C, sufficient for collagen and elastin in the tissue to convert into gelatin. As the gelatin cools under compression, it becomes an effective seal, which can withstand considerable pressures. Tissue and vessels can appear flexible, transparent and plastic-like when fusion is complete [21].

Several industry supported animal studies have compared different EBVS systems (Table 94.4). The sealing time, burst pressure of the seal, seal width, and radial thermal damage has been found different with different EBVS systems, [22] however all of the EBVS systems have been used safely in different surgical procedures, providing adequate hemostasis with similar seal quality [20].

In the clinics, EBVS systems have safely been used in various surgical procedures providing adequate hemostasis. Besides, several other advantages of EBVS systems have also been shown. Systematic review and meta-analysis of the randomized controlled trials comparing EBVS systems with mechanical hemostatic method (clamping- suture ligation, clips) or other hemostatic devices (mono-polar, bipolar cautery) in various surgical procedures consisting most commonly of hemorrhoidectomy, hysterectomy and thyroidectomy found the operation time, blood loss, postoperative pain and complication rates less with EBVS systems [12, 18, 23]. For the gynecological operations, the use of EBVS systems

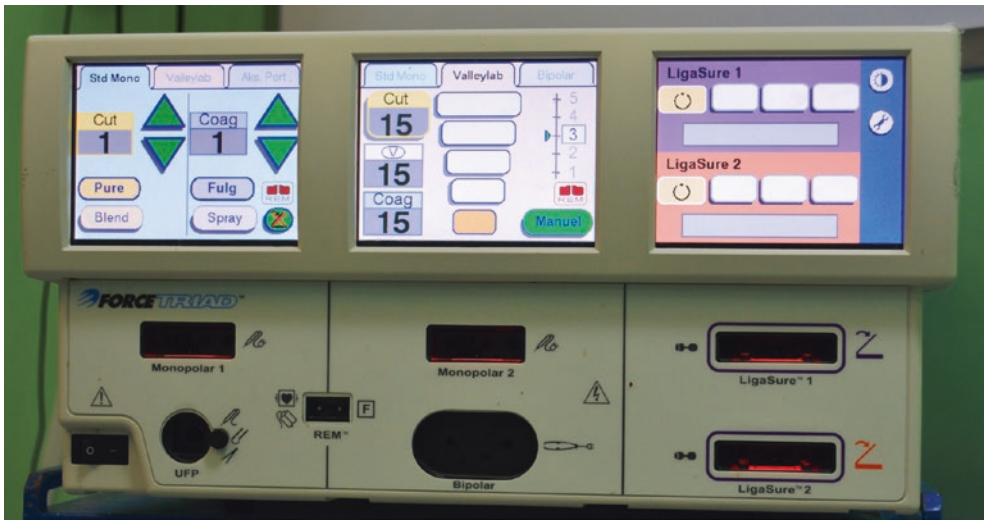

Fig. 94.2 Specialized electrosurgical generator measures both voltage and current to monitor tissue response

Table 94.4 Comparison of electrosurgical bipolar vessel sealing systems

Techniques	Mechanism	Advantages	Disadvantages	Expected thermal spread	Maximum lateral tissue temperature (measured by needle thermistor placed 2 mm from edge)
LigaSure® DEVICE	This system applies a precise amount of bipolar energy and pressure to fuse collagen and elastin within the vessel walls	Minimal sticking and charring A feedback-controlled response system to ensure adequate tissue sealing. Consistent seals with burst pressure above 150 mmHg for a majority (80 %) of repeated applications. Shortest vessel sealing and cutting time compared with other devices	Cost	1.8 mm with the 10 mm LigaSure® device 4.4 mm with the 5 mm LigaSure® device	55.5 °C
EnSeal® DEVICE	Provides vessel sealing by combining a compression mechanism with thermal energy. Controlled energy delivery utilizing NanoPolar thermostats to reach collagen denaturation temperatures in seconds, which are maintained at approximately 100 °C throughout the power delivery cycle	Seal strengths up to seven times the normal systolic pressures on vessels up to 7 mm A cutting mechanism to allow one-step sealing and transection of vessels and soft tissues Uniform pressure along the full length of the instrument jaw. Narrowest seal width and less denaturation of adventitial collagen in vessel	Cost Vessel sealing and cutting time is longer than other devices. Slightly greater amounts of particulates/smoke. Greater wall injury to proximal inner wall layers	1.1 mm	58.9 °C

(continued)

Table 94.4 (continued)

Techniques	Mechanism	Advantages	Disadvantages	Expected thermal spread	Maximum lateral tissue temperature (measured by needle thermistor placed 2 mm from edge)
Gyrus Plasma Trissector® DEVICE	Vapor-pulse mode delivers high energy to grasped tissue, creating vapor zones, ultimately resulting in uniform coagulation of tissue. PlasmaKinetic tissue-cutting mode allows simultaneous cutting and coagulation of tissue with bipolar energy	Pulsed bipolar energy, allows intermittent tissue cooling, which limits lateral thermal spread and tissue sticking. Instrument identification feature automatically detects the optimal settings for the specific instrument	Lower burst pressures when compared to other systems. Produce significantly higher amounts of particulates/smoke compared to other devices	6.3 mm	64.5 °C
BOWA Arc 350 DEVICE	Electrosurgical unit can be configured for use with a range of modular instruments: LIGATOR for laparoscopic sealing and TissueSeal for open surgery sealing	Has a good range of operating modes and a useful range of pre-programmed power settings, covering most of the commonly performed surgical procedures	All the instruments are reusable but the open instruments require single-use electrodes It is not intuitive to use, requiring frequent reference to the operator's manual	Not supplied	Not supplied
Martin Maxium DEVICE	Electrosurgical unit generator can use Seal- Safe technology and specialist instruments for vessel sealing: marLap for laparoscopic surgery and marClamp for open surgery	The generator is easy to operate with responsive operating buttons in a logical LCD screen design All are reusable	It offers 37 different pre-programmed output settings, which may be confusing for some users	Not supplied	Not supplied

decreased the operation duration, blood loss and postoperative pain with similar complication rates, in vaginal hysterectomy [11, 24, 25]. This beneficial effect was found more pronounced in difficult cases [26]. Also in cases undergoing a radical hysterectomy, the use of EBVS systems resulted in less blood loss during surgery and similar postoperative complication rates. However, the surgery time was similar to the conventional surgical technique [27]. Albeit the beneficial effect of EBVS systems in vaginal hysterectomy and radical hysterectomy, such an advantage in the operation time and blood loss could not be shown in the abdominal hysterectomy [28–30]. Only a randomized controlled trial showed the postoperative pain lower and recovery time shorter with EBVS system use [28]. Nevertheless, EBVS system use in the abdominal hysterectomy was as safe as the conventional surgical method with similar complication rates. Also, the tissue damage was similar in the EBVS system use the conventional surgical method [30].

Procedure

Before starting the abdominal hysterectomy procedure, all patients must be subjected to detailed history taking and physical examination including general examination, abdominal examination and pelvic examination. The pelvic examination must include assessment of the uterine size, mobility and descent, as well as the presence of adnexal mass. Performing a preoperative transvaginal ultrasonography to assess the volume, size of the uterus, gross uterine pathology and any adnexal pathology is necessary. The preoperative laboratory investigation must include hemoglobin

value and hematocrit percent, biochemical analysis of the liver and kidney functions, as well as the electrolyte levels, the thyroid function tests and the serologic tests for blood-borne viral infections.

Surgery is started with the performance of an incision on the anterior abdominal wall. A transverse supra-pubic incision (pfannenstiel type) or midline infra-umbilical incision is preferred according to the uterine size and mobility and the presence of a malignant and/or huge adnexal mass. Abdominal hysterectomy using electrosurgical vessel sealing systems starts by securing the round ligament. (Fig. 94.3) To use the EBVS device the electrodes on the hand-piece are placed across the hysterectomy pedicles (round, infundibulopelvic ligaments, uterine artery and utero- sacral-cardinal ligaments), so that the tissue is interposed between the jaws of the hand- piece in the center of the electrode. The handle is then closed until it latched into place in the tightest ratchet position. The coagulation hand pedal is pressed until a characteristic 2-tone sound from the machine confirmed complete coagulation of tissue. After the feedback-controlled response system is delivered the appropriate amount of energy required to seal the tissue, the flow of current is automatically halted to minimize heat transmission to the surrounding tissues. The hand pedal is then released, the coagulated tissue is cut, and the electrode is released by squeezing the handle of the handset until it unlocked [20]. In the other type of EBVS device, coagulation and cutting processes occur simultaneously. The coagulation hand pedal is pressed, and simultaneously we squeeze the handle to apply compression to the grasped tissue, but during that compression, the blade advances perpendicular to the electrodes and cut the tissue. In that system, 3-tone sound direct the surgeon in a way that the cutting process should be half way the electrode when the second sound tone is heard. The coagulation and cutting process is completed by the third sound [31].

After electrocoagulating the round ligament, the space between the anterior and posterior leafs of the broad ligament is entered. Then, a window is created on the posterior leaf of the broad ligament to seal the infundibulopelvic ligament or the utero-ovarian ligament and fallopian tube proximally in abdominal hysterectomies with or without salphingo-oophorectomy, respectively (Fig. 94.4).

Same steps should be applied to the other side of the uterus as well. Next, the anterior leaf of the broad ligament bilaterally and the peritoneum over the vesico-uterine pouch are dissected horizontally at the level of the uterine isthmus, to reduce the urinary bladder from the lower segment of the uterus, till the upper segment of the anterior vaginal wall (Fig. 94.5). Dissection of the peritoneum can be accomplished with an EBVS device or with an ultrasonic device.

Next, the uterine artery is visualized and sealed at the level of uterine isthmus by EBVS bilaterally. For avoiding ureteral injury during the uterine artery sealing we prefer to open retro-peritoneum and visualize the ureter. Identification and dissection of ureters before the sealing process will secure them from the lateral thermal damage of EBVS devices (Fig. 94.6).

The utero-sacral ligaments and the cardinal ligaments are electrocoagulated bilaterally with the EBVS device (Fig. 94.7).

Then an incision is made on the anterior vaginal wall just beneath the cervix and the vagina is entered with the aid of

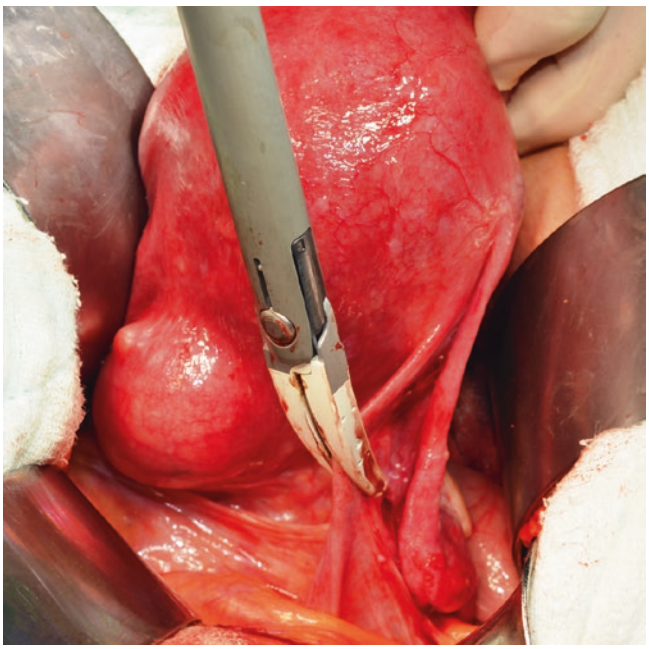

Fig. 94.3 Electrocoagulation of the round ligament with EBVS device

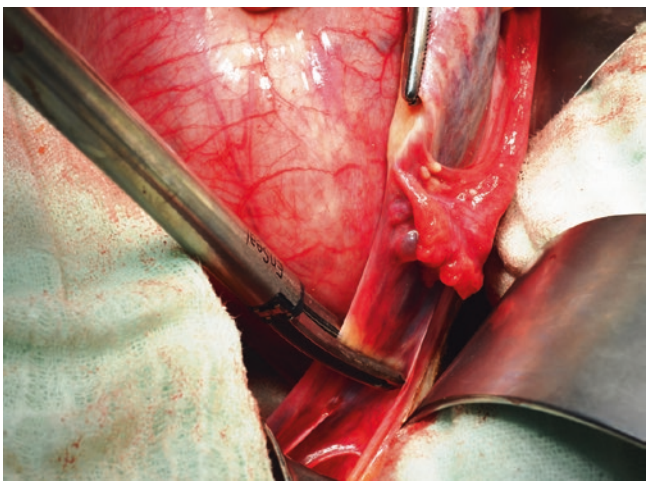

Fig. 94.4 Sealing the infundibulopelvik ligament with EBVS device

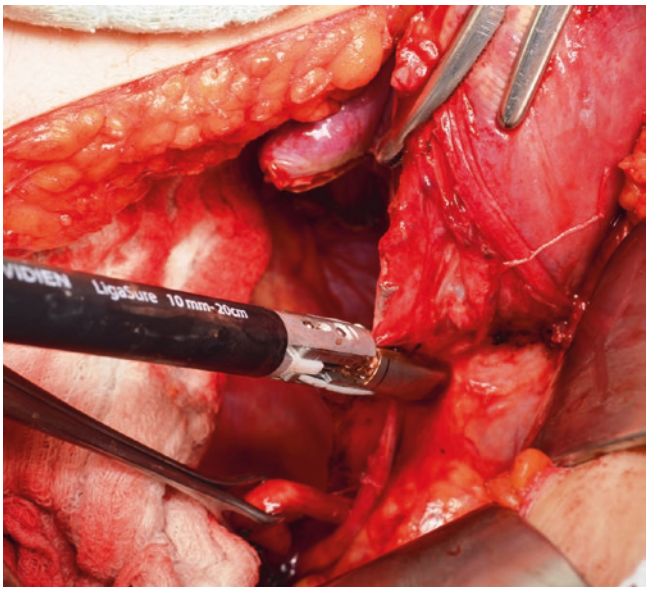

Fig. 94.6 Sealing the Uterine artery with EBVS device. Identification and dissection of the ureter for avoiding ureteral injury during the sealing. For demonstrating, ureter is hold by Babcock clamp

monopolar cautery or ultrasonic technology. The vaginal vault is dissected circumferentially with EBVS device. The other option is to grasp the vagina horizontally from lateral to medial bilaterally with the clamps just under the level of the cervix and to dissect the vaginal vault with EBVS above the clamps (Fig. 94.8).

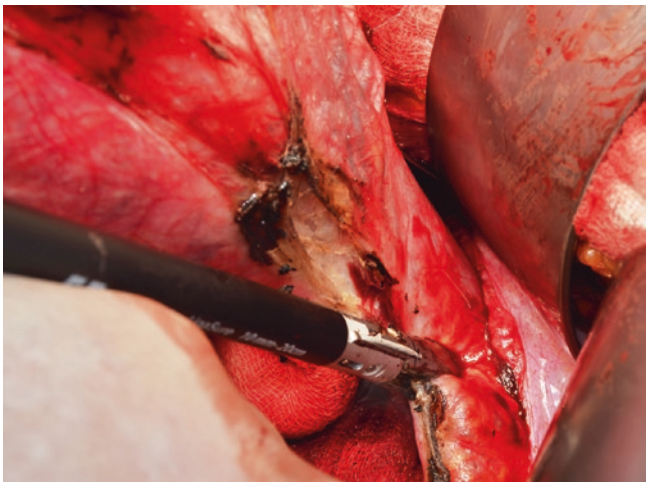

Fig. 94.7 Electrocoagulation of the cardinal ligament with EBVS device

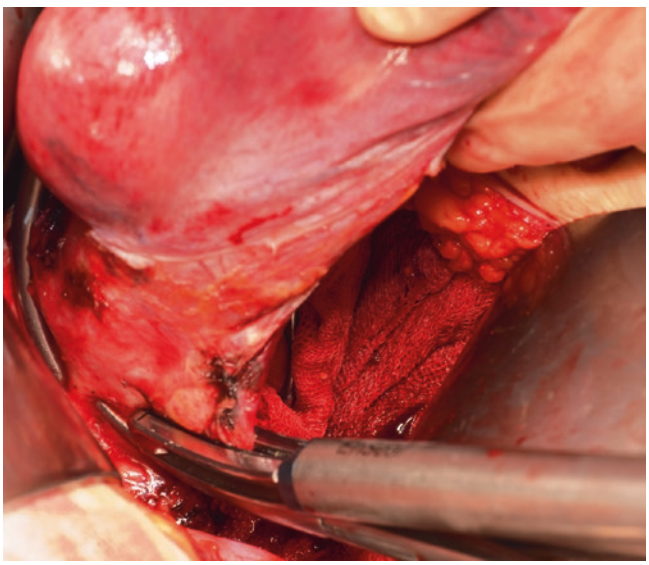

Fig. 94.8 The vagina grasped horizontally from lateral to medial bilaterally with the clamps just under the level of cervix and dissection of the vaginal vault with EBVS above the clamps

After extraction of the uterus, vaginal vault is closed continuously by using a size 0 absorbable suture.

After vaginal vault closure, the pelvis is thoroughly irrigated with warm saline or Ringer's lactate solution. Meticulous hemostasis at all pedicles is confirmed. The bladder and ureters are inspected than the operation is finished (Fig. 94.9).

Conclusion

An alternative to suture ligation of vascular pedicles is the use of electrosurgical bipolar vessel sealing

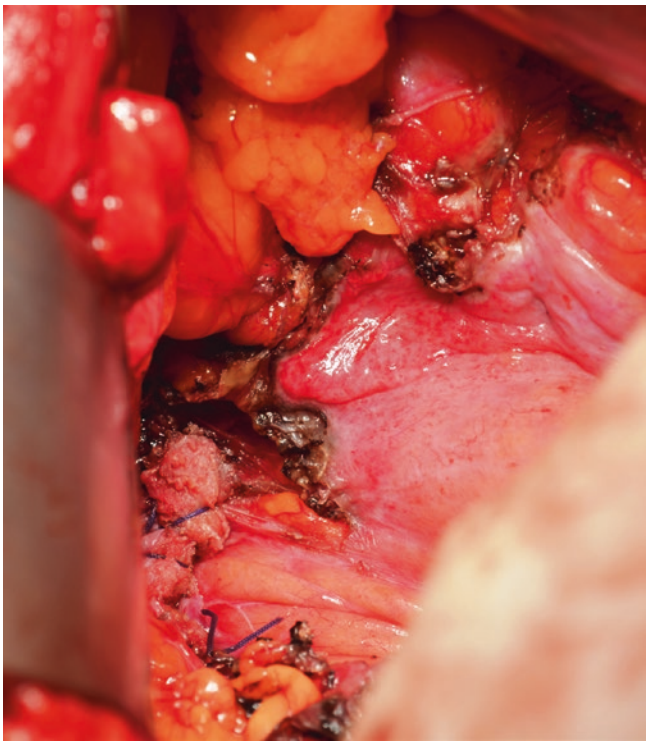

Fig. 94.9 After vaginal vault closure, the view of the operation field and the pedicles

systems. Growing evidence supports the safety of EBVS systems in various surgical procedures, as well as the gynecological surgeries. The current literature does not support the decrease in the duration of surgery and the amount of blood loss in abdominal hysterectomies, as in the vaginal hysterectomy or radical hysterectomy. However, the current evidence is too small to make a conclusion. Nevertheless, in our practice we think that the EBVS devices facilitate access, minimize procedural time and decrease blood loss relative to sutures when the competent surgeon is equipped with such devices. In respect to postoperative pain and recovery time, EBVS systems seem advantageous over classical surgical techniques. EBVS systems at least provide a more comfortable postoperative period and faster recovery, after abdominal hysterectomies performed for benign pathologies. Currently, there is no study analyzing the costs of EBVS system use for the gynecological operations. Nevertheless, despite the higher costs of these disposable devices, shorter operation time, less postoperative pain, faster recovery may decrease the hospital stay and total hospital costs. This may even reflect time to return to the work as for the laparoscopy. As related costs and use of materials differ considerably between the countries and even hospitals, the cost analysis should be interpreted with caution, and these calculations will probably be beneficial for centers performing large numbers of surgical procedures per year.

Peripartum Hysterectomy

95

Alexander Strauss

Introduction

Maternal mortality rates worldwide decrease, − 34 % while the incidences in industrialized countries rise, + 16 % (1990–2008, WHO). Peripartum hemorrhage (PPH) remains a main cause of maternal mortality. Among 600.000 maternal deaths worldwide hemorrhage accounts for 140.000 every year (25 %). The incidence of an obstetrical blood loss >1000 ml complicates 0.5–1 % of all deliveries in Germany. Life-threatening maternal bleeding is defined as a blood loss of >1500–2000 ml or >150 ml/min within 20 min or >50 % of the individual total blood volume (= 9 % of body weight) in less than 3 h. Peripartum hysterectomy (PH), the most dramatic operation in modern obstetrics, is defined as a hysterectomy performed at the time, or within 24 h of delivery. As the operation is uncommon only limited individual experience may be gained by the obstetrical surgeon. Emergency peripartum hysterectomy (EPH) is an unequivocal marker of severe maternal morbidity and, in many respects, the treatment of last resort for severe PPH [1]. Hysterectomy following cesarean section (CS) was first described by Porro and at that time was used to prevent maternal mortality due to PPH [2]. The unplanned nature of EPH and the need for performing it expeditiously already delineate concerns associated with this potential life-saving approach. Moreover the acute loss of blood renders the patient in a less than ideal condition to undergo an emergency surgical intervention. The incidence of EPH ranges from 0.24 to 8.7 ‰, with the higher figures usually found in low-resource countries. More common EPH is following CS (0.17–8.7 ‰) than vaginal deliveries (0.1–0.3 ‰) [3]. This increase in incidence in some countries can be attributed to rising CS rates and concomitant abnormal placentation in subsequent pregnancies (Canada, 1991–2000, EPH-rate almost doubled from 0.26 to 0.46 ‰, RR 1.7, 95 % CI 1.48–2.08) [1, 4–8]. There are reasons to believe that PH-rates may continue to rise as other factors than CS-rates contribute to the namely trend: among others assisted reproductive treatment and multiple pregnancy (twins 6× and higher order multiples 24× compared to singleton-pregnancies) [9]. Initially in peripartum emergency situations an algorithm of conservative measures to control uterine hemorrhage (responsible for 25 % of direct maternal deaths) is attempted to avoid morbidity and sterilization as a result of hysterectomy [10]. For those patients, who inevitably require hysterectomy, clear decision making and immediate performance of the procedure (without using multiple conservative measures) leads to a lower blood loss/transfusion requirement and a better outcome [11]. Nevertheless maternal morbidity from PH ranges from 26.5 to 31.5 % and mortality varies from 2.8 to 23.8 % with a mean of 4.8 % [12].

Indications for EPH

The predominant indication for EPH is severe uterine hemorrhage due to abnormal placentation (45–73.3 %), uterine atony (20.6–43 %) that cannot be controlled by conservative measures or uterine rupture (11.4–45.5 %) [13–16]. Traditionally, uterine atony was the most common indication for EPH. The use of modern oxytocic drugs has greatly improved the conservative as well as the surgical treatment of uterine atony. Recent studies however indicate trend of changing indications towards abnormal placentation [3, 8]. Further potential causes for ERH are severe intra- or postpartum uterine hemorrhage following leiomyoma or laceration of uterine vessels and severe postpartum infection unresponsive to medical therapy. Concerning the patients history first of all previous CS (21–59 %), with a risk rising parallel to the increasing number of previous cesarean deliveries (Table 95.1), maternal age, multiple gestation, multiparity and cesarean delivery in the index pregnancy (64–82 %) induce

Table 95.1 Estimated risk for PH in different categories of women [17]

Category	Risk of requiring PH (range)
Woman undergoing their first delivery vaginally	1 in 30,000 (1: 17,000–152,000)
Woman undergoing their first delivery by CS	1 in 1700 (1: 1300–2300)
Subsequent delivery in woman who had had one previous CS	1 in 1300 (1: 1000–1600)
Subsequent delivery in woman who had had two or more previous CS	1 in 220 (1: 180–270)

Table 95.2 Risk factors/indications for EPH (multiple reference possible) [1, 3–8, 17, 23]

Maternal factors	Placental factors	Fetal factors
Uterine atony (21–53 %)	Placenta previa (34 %)	Fetal macrosomia
Coagulopathy	Placenta ac−/in−/percreta (39–45 %)	Polyhydramnios
Uterine rupture (8–46 %)	Abruptio placentae (6 %)	Multiple gestation (twins OR 6.30, 95 % CI 1.73–23.0)
Precipitate or prolonged labor (protracted oxytocin use)	Retained placenta (1: 300)	
Pelvoperitonitis/sepis (8 %)	Previous abnormal placentation	
Uterine anomaly/myoma (1–2 %)		
Cervical cancer (<1 %)		
Multiparity, ≥3 (OR 2.30, 95 % CI 1.26–4.18)		
Advanced maternal age, >35 years (OR 2.42, 95 % CI 1.66–3.58)		
Maternal obesity		
Augmentation of labor (OR 2.0)		
CS in actual pregnancy (OR 7.13, 95 % CI 3.71–13.7)		
Extension of uterine incision at CS (6 %)		
Previous CS, 1 CS (OR 2.14, 95 % CI 1.37–3.33), ≥2 CS (OR 18.6, 95 % CI 7.67–45.4)		
Previous primary postpartum hemorrhage		
Previous uterine surgery: manual placental removal (OR 12.5, 95 % CI 1.17–133.0), curettage (OR 1.48, 95 % CI 0.95–2.29), myomectomy (OR 14.0, 95 % CI 1.31–149.3)		

PH-risks. Nevertheless from recent data one can conclude that there is a considerable variability in the incidence of EPH worldwide (Netherlands 0.33 ‰, 95 % CI 0.20–0.46, Israel 0.48 ‰, 95 % CI 0.35–0.60, Canada 0.55 ‰, 95 % CI 0.44–0.67, Germany 0.68 ‰, 95 % CI 0.59–0.77 and United States 0.77 ‰, 95 % CI 0.73–0.81) [17], and it varies with obstetric practice in each center [18]. Preplanned PH may be performed in patients diagnosed with placenta previa ± placenta ac−/in−/percreta or cervical/ovarian cancer. Risk-factor-listing for EPH is registered in Table 95.2.

Abnormal Placentation

Pathology in placentation (localization, invasion) is the most common indication for PH (Fig. 95.1). The combination of factors including high parity, advanced maternal age, number of previous CS, previous uterine surgery (e.g. curettage) strongly increase the likelihood of placenta previa and increase the risk of abnormal adherent placenta (Fig. 95.2) [11]. The association between abnormal placentation and prior cesarean delivery suggests that an increase of EPH is directly related to general rise of the number of CS performed [11, 13–16]. The risk of placenta previa after one previous CS (0.2 %) is increased by 47 fold in patients with four previous CS (9 %) [14]. The incidence of previous CS between 60 % in patients with adherent placenta and 75 % in patients with placenta previa [15]. Patients with placenta previa and scarred uterus had a risk of 16 % undergoing EPH compared to 3.6 % in patients with unscarred uterus [11, 13, 14]. Furthermore, the probability for EPH is higher in patients with placenta previa and accreta (in−/percreta) than in patients with placenta previa alone (Fig. 95.3).

Prediction: The predisposing risk factors can be determined to a certain extent by performing antenatal ultrasound with color Doppler and magnetic resonance imaging (MRI). However, high MRI-cost and the need for experienced operators in obstetrical ultrasound impede early diagnosis (Fig. 95.4) [19].

Fig. 95.1 Placenta previa – ultrasound: placenta overlaps internal os of the cervical canal

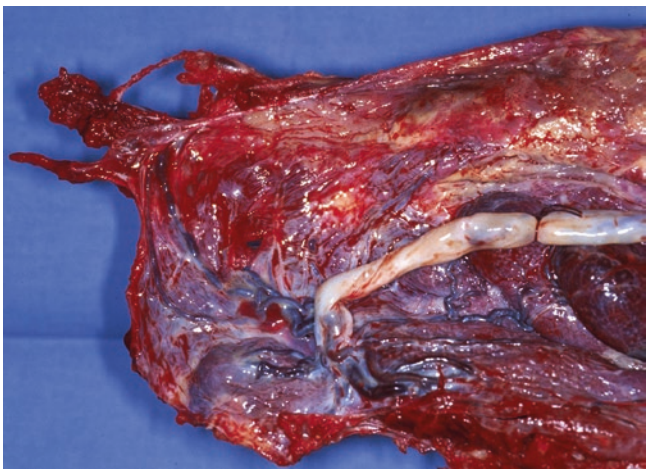

Fig. 95.3 Placenta increta – postoperative specimen: placenta with infiltrated/inextricable myometrial tissue (in left upper angle of the figure)

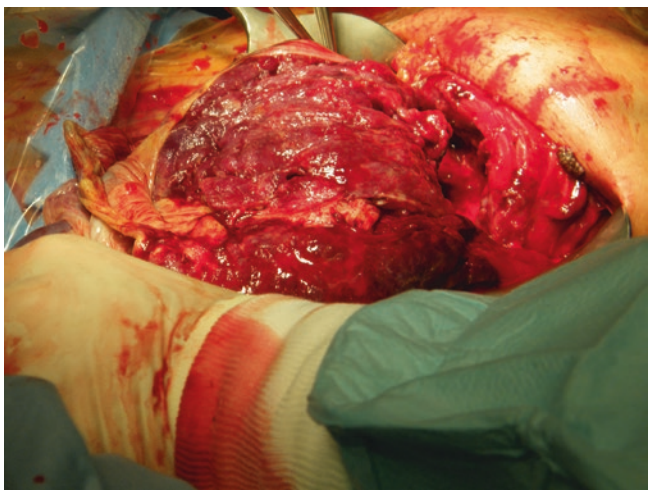

Fig. 95.2 Placenta previa accreta – intraoperative finding: due to an abnormal adherence of the placenta to the uterus an anatomic accurate separation of placenta tissue from the uterine wall fails during CS

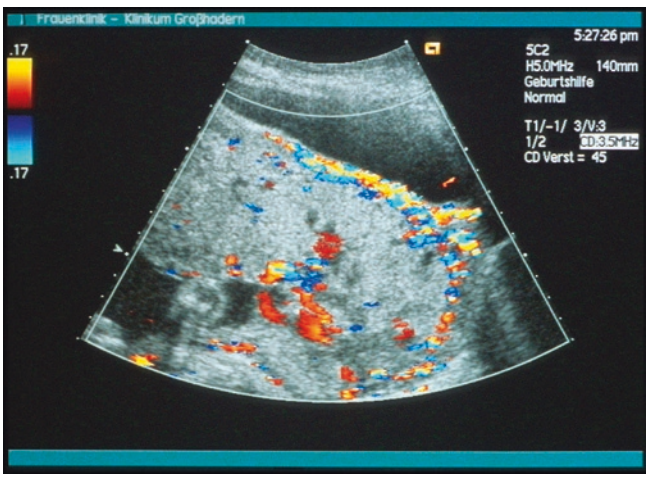

Fig. 95.4 Placenta increta – Doppler-ultrasound: longitudinal scan of the color coded depiction of highly vascularized invasion of the anterior uterine wall allows prenatal anticipation of placenta previa increta

Uterine Atony

Uterine atony is a frequent indication for EPH. Excessive uterine distension (e.g. fetal macrosomia, twins, and polyhydramnios), preeclampsia, nulliparity, induction, prolonged, augmented and/or obstructed labor with the consequence of uterine anergy to all uterotonics are risk factors for uterine atony possibly requiring surgery [11, 13–15]. While atony was traditionally the leading cause for EPH, its relevance for surgery today is reduced due to the development of effective pharmacologic treatment strategies (e.g. prostaglandins) as well as non-pharmacologic therapy options (e.g. balloon compression devices, organ preserving compressing sutures) (Fig. 95.5) [20].

Uterine Rupture

External trauma, such as motor vehicle accident, fall or assault is relatively rare cause of uterine perforation or rupture with potentially detrimental consequences for mother and fetus (Fig. 95.6). Obstetrical risk factors for uterine rupture are multiple previous uterine operations (e.g. CS, myomectomy, precedent uterine rupture) resulting in a scarred hollow organ (Figs. 95.7 and 95.8). If the rupture is extensive and hemorrhage cannot be contained by suture of the lacerated area, hysterectomy may be necessary. In addition, rupture of the intact uterus can occur in multiparous women in response to inappropriate use of oxytocic agents in the first and second stages of labor [1].

Uterine Trauma

Traumatic laceration of the uterus can occur with delivery especially when a variety of obstetric maneuvers (e.g. ventouse or forceps delivery, manual removal of the placenta or its fragments) or instrumental manipulation (curettage) is necessary. Second stage of labor or CS in in with the fetal head deeply impacted in the lower uterine segment may be associated with lateral cervical laceration potentially engaging major paravaginal/paracervical vessels. On rare occasions, the extent of this tear may necessitate hysterectomy, especially if one or both uterine arteries are lacerated and a hematoma obscures the surgical repair [21].

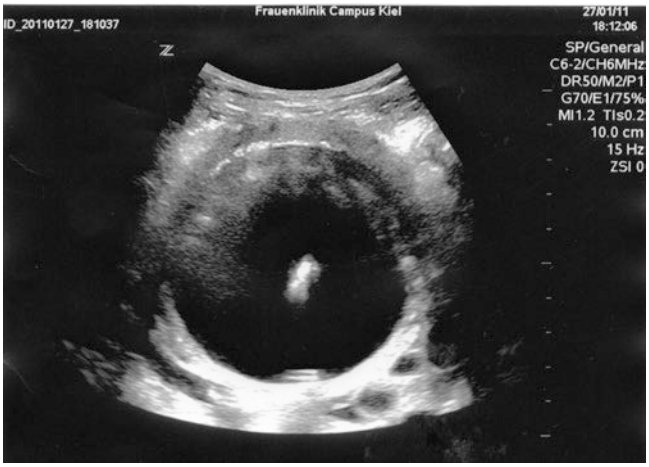

Fig. 95.5 Uterine atony – ultrasound: conservative therapy using a transvaginal inserted intrauterine balloon device

Abruption of Placenta

As a rare indication abruption of placenta may cause heavy bleeding leading to DIC (Figs. 95.9, 95.10, 95.11 and 95.12). Under peculiar circumstances placenta abruption can be associated with extravasation of blood into the myometrium to such an extent as to make the organ unresponsive to uterotonic agents (= Couvelaire uterus). It has to be adopted, however, that in the majority of cases of abruptio placentae with Couvelaire uterus, the response to oxytocic drugs is appropriate and the hemorrhage is due to DIC rather than failure of the uterus to contract [1, 22].

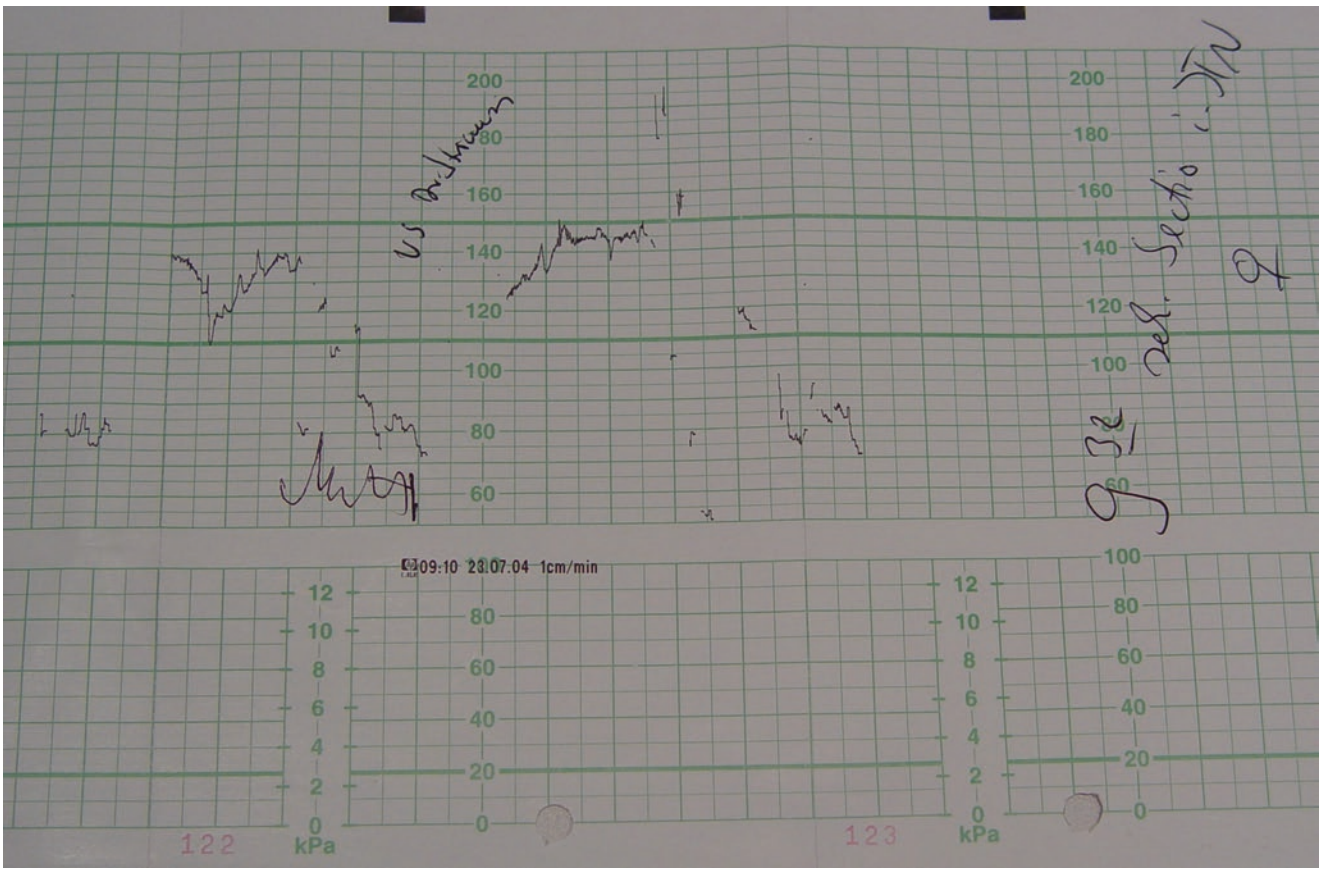

Fig. 95.6 Uterine rupture – peripartal cardiotocography with signs for severe fetal hypoxia due to maternal bleeding and acute placental insufficiency following uterine rupture (neonatal parameters at birth: pH 6.86, BE −-23.6 mmol/l, pCO2 71.9 kPa, PO2 26.9 kPa, Hb 13.9 g/dl)

Fig. 95.12 Abruption of placenta – placental macroscopy: abruption of a third of placenta identifiable by adherent hematoma

Sepsis

In the era of modern antibiotics, sepsis is an uncommon reason for PH. However, it still may be necessary in cases of extensive uterine infection (endo−/myometritis) or endo−/myometrial abscess, in which antibiotic treatment fails to control the infection. Other septic causes of secondary PPH include cesarean scar infection and necrosis, arteriovenous fistula formation secondary to uterine trauma or infection/endomyometritis associated with retained placental fragments. All may rarely require PH [1].

Therapeutic Management

The antenatal presence of an increased likelihood for severe PPH (e.g. sonographic signs of pathology in placentation) can facilitate risk adapted consultation, referral or in the end prenatal transfer of patients at risk to a tertiary care facility. However, in case of necessity 24 % of patients requiring EPH are transported to another facility immediately after their index episode [23]. In trying circumstances this conflict of aims regarding uterus-preserving-management versus EPH needs an individualized balance between ineffectively spending excessive time on non-surgical techniques leading to a delay of moving to hysterectomy. Due to the complexity of the surgery and decision making, the involvement of an experienced obstetrician at an early stage is mandatory. Proper (sequential) conservative and surgical measures such as uterotonics (oxytocin, prostaglandin), fluid replacement (crystalloid), uterine massage/cooling, vaginal/cervical tear-repair, manual/instrumental removal of placenta, uterine packing (balloon), recombinant-activated factor VIIa (success rate 76 %) or tranexamic acid are options in attempting uterine conservation particularly in (young) patients to whom future fertility is important [24]. As surgery is inevitable, before hysterectomy is performed, hemostatic (compression) sutures, pelvic vessel ligation, uterine or hypogastric artery embolization or pelvic packing for (diffuse) bleeding are last options (Fig. 95.13). In case organ preservation is likely to fail or has already failed, further delay in performing EPH is unacceptable, as postponement leads to increase in blood loss, transfusion requirement, operative time, disseminated intravascular coagulation (DIC), more frequent/prolonged admission to ICU (41 %, range 17.6–77) and maternal mortality (4.8 %, range 2.8–23.8) [11–16].

Surgery

The technique of PH is similar in principle to that of total abdominal hysterectomy (TAH) in gynecology. A number of anatomical and physiological changes during pregnancy are responsible for potential intraoperative impediments requiring adaptation of surgery in the peripartum setting [1]:

Emergency Peripartum Hysterectomy (EPH)

EPH is a most demanding obstetric surgery performed in trying circumstances of life-threatening hemorrhage/disease.

1. In case of massive hemorrhage most important EPH should be performed early enough to avoid irrepressible DIC:

   command variable of peri−/intraoperative coagulation management are:

   prothrombin time (PT) >50 %; partial thromboplastin time (PTT) <50 s; thrombocytes >50/nl; fibrinogen >150 mg/dl; Ca++ > 0,9 mmol/l; pH > 7,2; hemoglobin >8 g/dl; patients body temperature >35 °C.
2. The surgical team consists of the most experienced obstetric surgeon available, operatively sustained by two to three skilled assistants, one or two midwifes, a team of neonatologists and an appropriate staff from the department of anesthesiology and intensive care (Fig. 95.14).
3. Abdominal access can be accomplished by Pfannenstiel incision (especially if a previous transverse scar is present) or lower midline incision (provides better exposure) depending on indication and urgency required (Fig. 95.15).
4. If CS is required, the common steps of a cesarean delivery are to be performed first.
5. The type of hysterotomy used is guided by obstetric indications; however, a low vertical incision is less likely to extend and lacerate the uterine vasculature. In case a disruption of the placenta localized in the lower uterine segment (previa, in−/percreta) is to be avoided by modi-

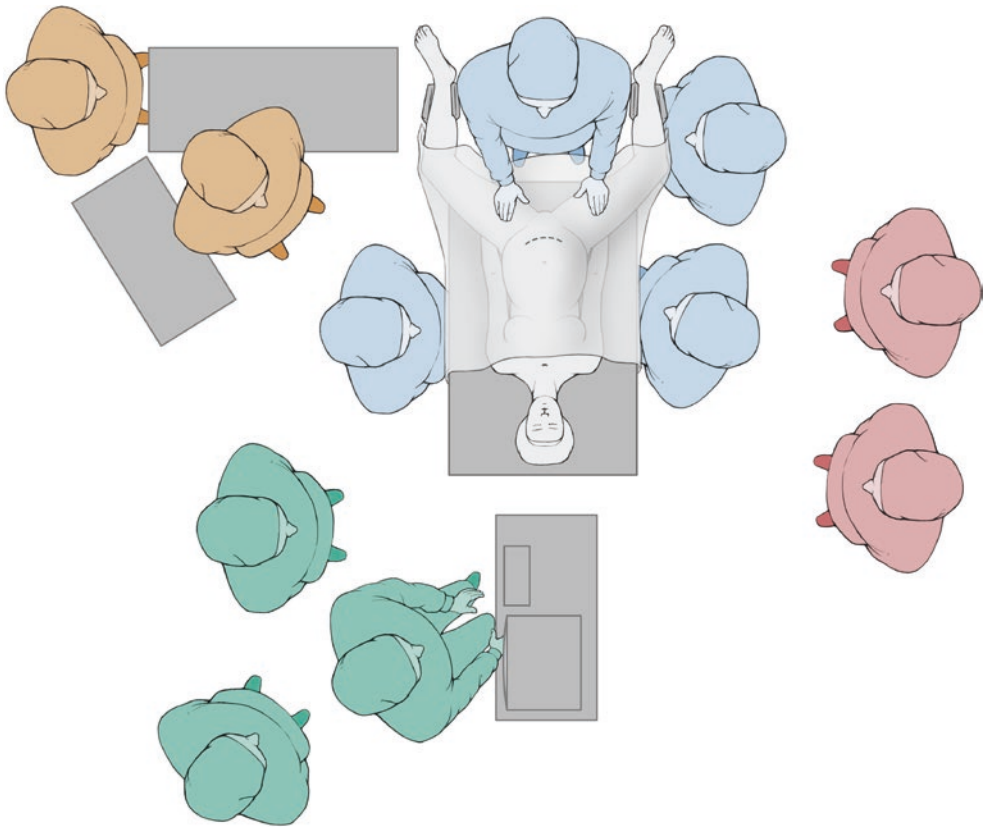

Fig. 95.14 Surgical setting – surgical setting and team needed when performing peripartum hysterectomy. Surgical team: (1) Most experienced obstetrical surgeon available (*grey*) – tasks: decision making, specific information to team, performing surgery. (3) Experienced obstetricians (*grey*) – tasks: organize patients transport, information transfer to team, patients disinfection, assistance during surgery. (1) Theater nurse (*orange*) – tasks: preparation of instruments, assist changing dressings of surgical team, patients desinfection and sterile covering, selecting and passing instruments to the surgeon. (1) Circulating nurse (*orange*) – tasks: assist preparation of instruments, assist changing dressings of surgical team, patrolling the operating room to make sure that everyone stays sterile, counting instruments, drapes and other equipment. (2) Midwifes (*red*) – tasks: perform patients transport to theater, assist patients positioning on the operating table, place urinary catheter, provide specific obstetrical medication care, take care of placenta and neonate (if necessary). Anesthesia team: (2) Anesthesiologists (*green*) – tasks: patient contact, anamnesis, patient monitoring, provide anesthesia, intraoperative patient monitoring and handling, postoperative patient care, patients transport to intermediate care unit/ICU. (1) Anesthetic nursing staff (*green*) – tasks: patient contact, administration of sodium citrate, i.v. access, assisting patient monitoring, assisting intra- and postoperative patient care, assisting patients transport to intermediate care unit/ICU

fications of the uterine incision: longitudinal corporal incision or even incisions through the uterine fundus or posterior wall are applicable.

6. After delivery of the fetus and the decision to proceed with PH, the placenta is expressed unless there is no known pathologic placentation.
7. To minimize blood loss hysterotomy is closed running suture. Reapproximation of the myometrium optimizes uterine contractility and decreases the likelihood of uterine atony.
8. Round ligament, fallopian tube, utero-ovarian ligament and the avascular upper segment of broad ligament are grasped with atraumatic (straight) clamps (Kocher) on each side, and the uterus is kept under upward traction to constrict the uterine vasculature and control blood loss from the uterine arteries and collaterally the ovarian arteries.
9. As the uterine and ovarian vessels are enlarged and distended and the adjacent pelvic tissues are edematous and extremely friable, care should be taken to place clamps and ligations between (especially at the tips) (Fig. 95.16).
10. The broad ligament is then incised anteriorly to the point where the vesicouterine peritoneum was dissected off the lower uterine segment to create and step by step displace the bladder flap below the operative field. In patients having had previous surgery (most) tissue scaring/adhesion is frequent. As a result, sharp dissection of vesicouterine pouch is necessary and implicates attention to avoid lateral dissection into the highly vascular bladder pillars (Fig. 95.17).
11. Scarring from previous surgery, particularly previous CS, is a common complicating feature of PH and

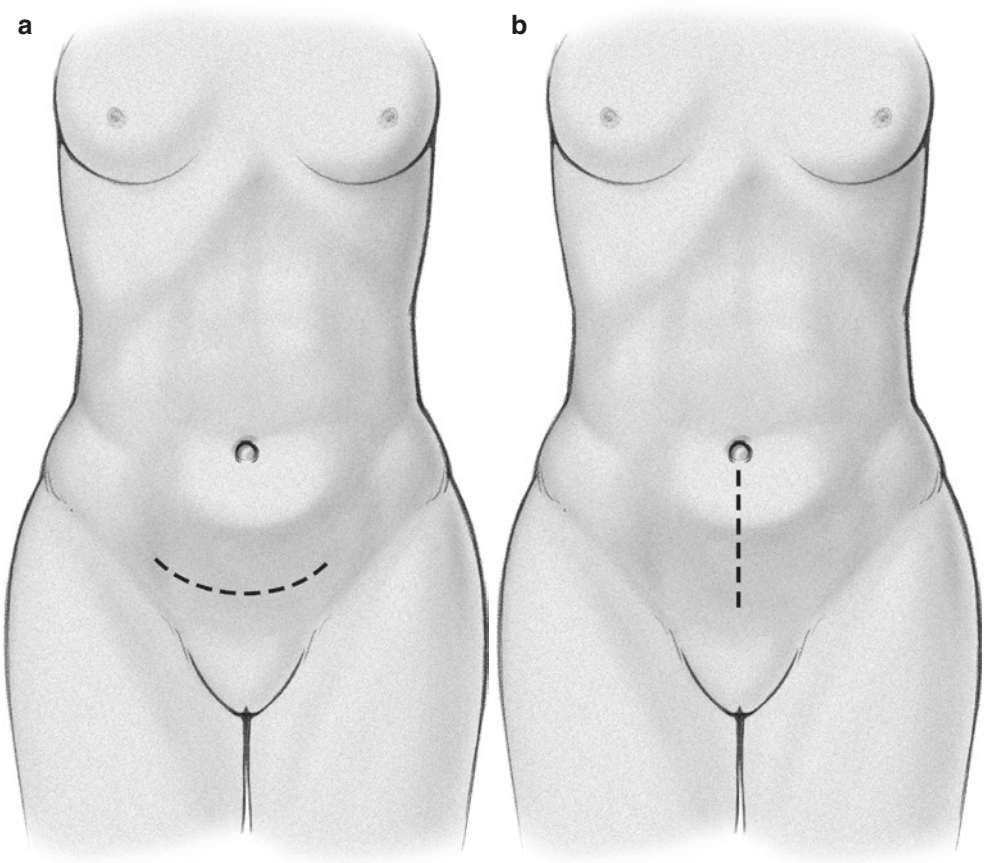

Fig. 95.15 Transabdominal access in peripartum hysterectomy – Pfannenstiel incision (**a**) vs. lower midline incision (**b**)

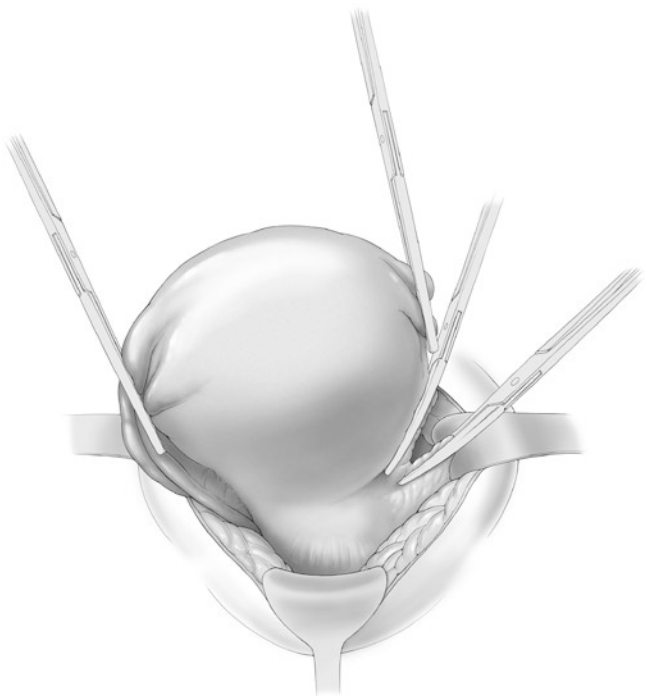

Fig. 95.16 Parametrial Dissection – surgical procedures are to be performed according to the vulnerable tissue characteristics

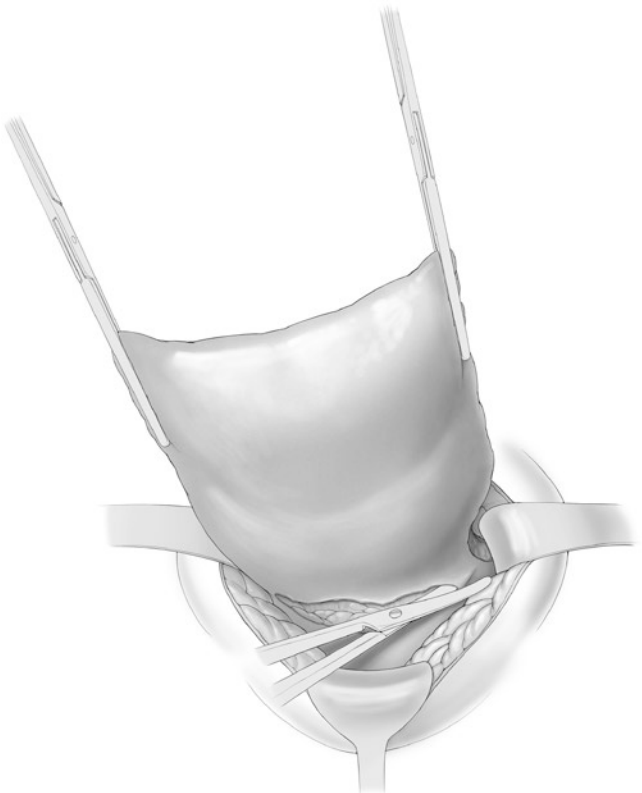

Fig. 95.17 Bladder flap dissection – incision of vesicouterine peritoneum and atraumatic displacement of the urinary bladder from the adjacent lower uterine segment

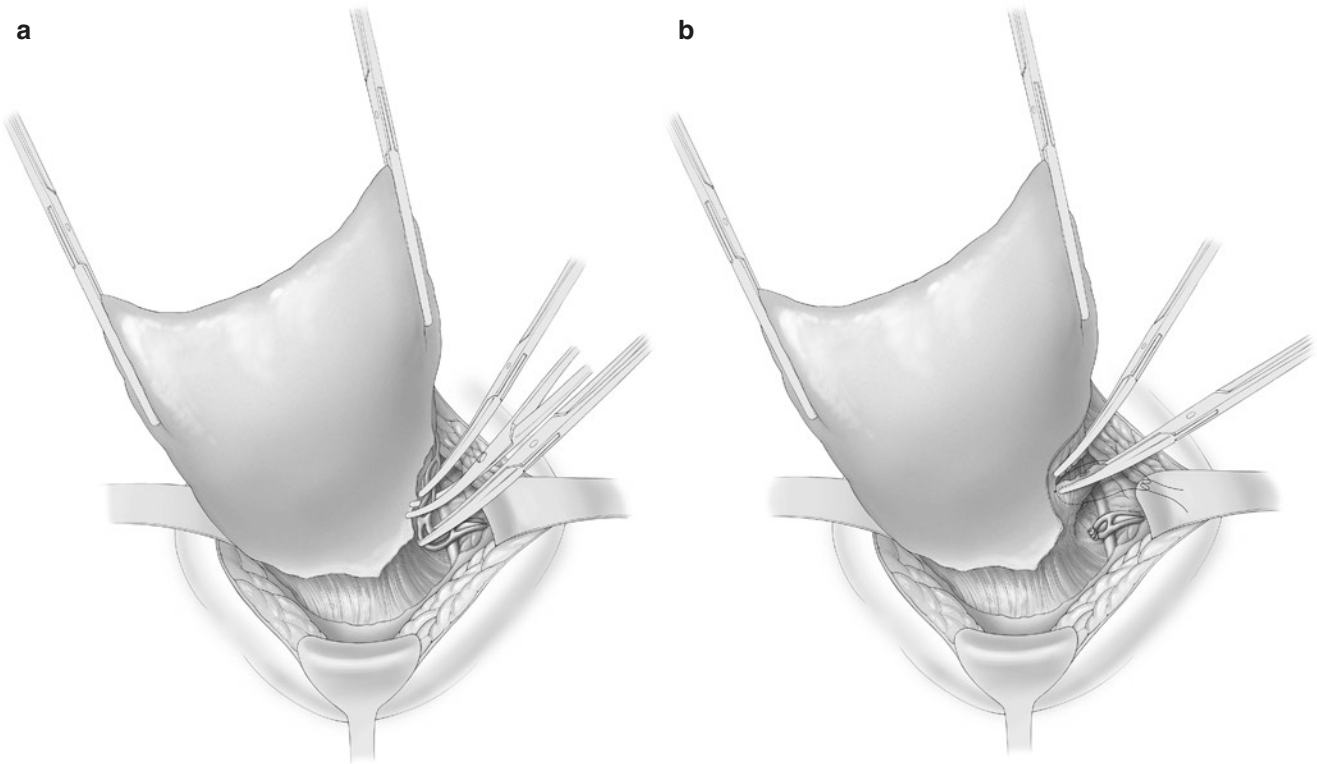

Fig. 95.18 Vicinity of ureter – safety precautions (close to uterine wall surgery) are recommended when dissecting (**a**) and ligating (**b**) uterine vessels

increase complication rates of surgical activities in the vesicouterine pouch and parametric space.

12. Posteriorly, the broad ligament is incized laterally and parallel to the infundibulopelvic ligament to expose the retroperitoneum. Careful dissection parallel to the course of the ureter allows visualization of the retroperitoneal space and the ureter throughout its course.
13. Uterine vessels, significantly enlarged in pregnancy are double clamped atraumatic exactly against the lateral wall of the uterus and cervix and ligated by sutures carefully incorporating the tissue tip. Once the procedure is performed bilaterally blood loss should rapidly diminish. The use of a second clamp on the specimen side reduces back-bleeding from the uterus, which can obstruct the operative field.
14. Ureters should be avoided by placing all clamps tight to the lateral uterine boundary (medial to those used to secure the uterine arteries) (Fig. 95.18).
15. Large hematomas especially in the broad ligament and/or retroperitoneal space distort anatomic relations and defy attempts at direct clamping and suturing (difficult orientation). A solution may be free dissection near the lateral pelvic wall and ligation of uterine vessels near to their origin from the internal iliac artery or, failing this, the internal iliac (hypogastric) artery itself can be isolated and ligated. In drastic emergencies, the aorta may be compressed/clamped for a time to stop bleeding while regaining a clear view on the bleeding sites (Fig. 95.19).

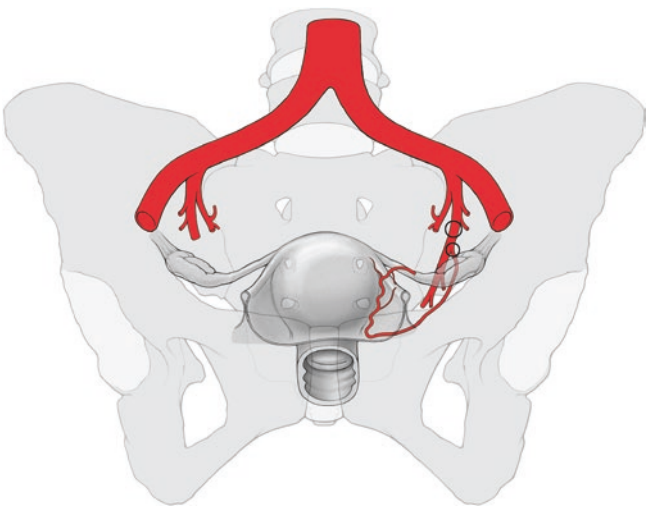

Fig. 95.19 Vessel ligation – in order to stop uterine bleeding, feeding vessels (uterine artery, internal iliac artery) are ligated distant to the uterine wall

16. Once the cardinal ligament dissection reaches the lower limit of the cervix, the vagina is entered, usually at the last pedicle. Identification of the lowest extent of the

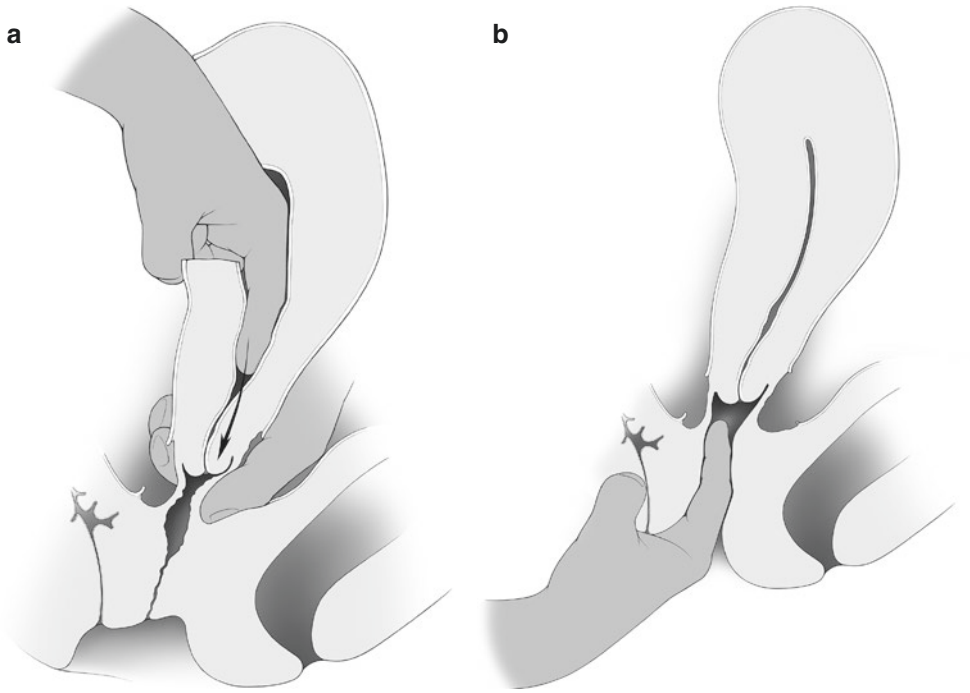

Fig. 95.20 Identification of cervical-vaginal boundary – due to pregnancy-related tissue alteration the vaginal fornix is difficult/impossible to be differentiated from the caudal edge of cervix uteri by traditional means of hysterectomy in gynecological patients. Solving this problem transcervical (**a**) or transvaginal (**b**) palpation may be helpful

dissection is the junction of the cervix and vagina usually to be felt between the thumb and forefinger by palpating. When the cervix is dilated, it can be difficult to discern its lower end. If a uterine incision has been made, digital inner identification of the cervical rim is possible. It is safest to incise the vagina posteriorly, identify the rim of cervix and then proceed anteriorly. If transcervical identification fails, transvaginal examination allows selective clipping of the boundaries of the cervix (Fig. 95.20).

17. Curved clamps and scissors are used to dissect the vaginal fornix and circumscribe the upper vagina to complete the dissection (Fig. 95.21).
18. The vaginal epithelium is very friable and must be handled gently. Surgical management of the vaginal cuff consists of supporting angle sutures followed by either interrupted sutures to close the vaginal cuff or to leave the cuff open and to secure hemostasis of the anterior and posterior cuff edges with a continuous nonlocking suture in order to allow drainage until spontaneous re-peritonealization occurs (Fig. 95.22).
19. If the surgeon is suspicious that the integrity of the bladder wall has been breached at any time during the operation, the bladder may be filled retrograde with an opaque solution and the operating field inspected for extravasation of the solution. If there has been an inadvertent cystotomy, the area is dissected so that two layers of 3/0 polyglactin or equivalent suture, with the second layer imbricating the first, can be placed without tension. Accordingly, a bladder dye-filling is to be implemented again after repair of any bladder injury. When bladder repair is necessary, postoperative antibiotic coverage and Foley catheter drainage of the bladder should be continued for 7–10 days.

Fig. 95.21 Clamping and dissection of vaginal fornix allows complete organ removal

Table 95.3 Adverse maternal/fetal sequelae in % among patients undergoing EPH [10, 17, 18, 23]

Blood transfusion	81–100
Acute posthemorrhagic anemia	81
Vaginal cuff hematoma/infection	14
DIC	< 1
Bladder/urinary tract injury	6–21
Cystotomy	3
Repair procedures on the urinary system	9
Fistula (vesicovaginal 0.9 %, ureterovaginal 0.2 %)	1
Ileus	3
Embolism	2
Fever	1–27
Wound infection/wound dehiscence	5–8
Urinary tract infection	18
Puerperal sepsis	2
ICU admission (duration median 2 days, range 1–26)	56–84
Readmission to hospital (within 30 days of surgery)	17
Reoperation	8–25
NICU admission (newborn)	19
Stillbirth	5
Neonatal mortality	1–4

20. If the integrity of the ureters is in doubt, and after any extensive repair of bladder injury, postoperative cystoscopy can confirm urine coming from each ureteric orifice. This test may be facilitated by giving intravenous indigo carmine and waiting 10–15 min. Alternative, radiological diagnosis is achieved by excretion urogram. If lower urinary tract injuries are not diagnosed until the postoperative period, clinical morbidity is increased, diagnostic and surgical management is much more complex [25].
21. During/following PH traumatized tissues at the base of the pelvis may continue to bleed despite ligation of obvious bleeding pedicles. Diffuse superficial blood loss is associated with the fragile tissue situation in pregnancy, a general hyperemia and/or DIC. In these cases the application of systemic (tranexamic acid intravenous bolus 1–2 g, if bleeding persists infusion of 6–10 mg/kg/h, recombinant-activated factor VIIa) and local hemostatic agents (superficial bleeding areas) or a pelvic pressure pack (abdominal compresses) can provide hemostasis and offer time, either permanent or temporary, until hematological stability and/or vascular embolization is achieved. Packs are removed, usually within 72 h. Alternatively compressing the aorta for a short time allows blood component replacement to catch up with a possible coagulopathy.
22. Intraoperative blood salvage (cell saver) recovering blood lost during surgery and re-infusing it into the patient (autologous autotransfusion) is an option to be implemented in every EPH and a fortiori in preplanned PH.
23. In addition/complementary interventional radiology may be an invaluable tool. Hypogastric artery embolization can play a role during PPH-management pre- or postoperatively. Selective embolization can stop bleeding without the need for a (second) surgical procedure.
24. Postoperative complications after EPH (vaginal cuff hematoma and febrile infection or abscess formation, sepsis, abdominal wound seroma/hematoma/infection) are similar to those after any abdominal hysterectomy performed for gynecologic indications but augmented by the unplanned type of surgery (Table 95.3).
25. To optimize a holistic patient care, postoperative requirements and logistics are to be anticipated and organized early during PH. Maternal intensive care facilities and in case neonatal resuscitation and intensive medical treatment for a potentially depressed newborn are to be prepared. In case EPH had to be performed outside from a center, postoperative transport of mother and/or newborn is to be already considered/logistically planned early during surgery.
26. Postoperative care: thromboprophylaxis with heparin should be instituted as soon as hemostasis is secure and perioperative antibiotic prophylaxis is to be continued for several days.
27. Following surgery most women are physically and emotionally traumatized by the rapid sequence of major complications, culminating in the loss of her uterus (fertility-ending nature procedure). After the initial postoperative recovery, the patient/family should receive a

comprehensive outline of events and supportive follow-up from the obstetrician responsible for the surgery (head of department).

28. Detailed and timed documentation including the preoperative events, indications and therapeutic/surgical details is to be put into writing not only by the responsible surgeon but by all team members involved in the whole perinatal process.

Preplanned Peripartum Hysterectomy (PH)

Preplanned PH is primary considered for prenatally diagnosed placenta in- or percreta ± placenta previa concomitant with completed family planning (see Fig. 95.4). When PH is planned in advance, the surgeon has the advantage of a complete preoperative evaluation of the patient including her hematologic and coagulation status. General preoperative triage decisions derived from requirements concerning hospital infrastructure (perinatal center) and the facilities/experience levels of all medical disciplines involved, direct patients management prior to hospital admission. Furthermore local surgical logistics can be optimized if CS combined with PH (e.g. antizipate procedures/problems, choose an experienced team, prepare necessary instruments and sutures before the operation) is preplanned. Timing of surgery depends on risk assessment balancing the hazard of hemorrhage versus fetal maturation with increasing gestational age. During planned surgery simultaneous CS is performed prior to hysterectomy. After delivery of the fetus the hysterotomy, performed at the far side of the placenta (previa), is relocked with the objective of avoiding additional blood loss and a restoration of a surgically familiar anatomical site. After cord clamping the placenta is left untouched in utero. From this point on surgical management follows the recommendations of EPH (Fig. 95.23). Premise for supracervical surgery would be a placenta-free, not-lacerated lower uterine segment and an indication for PH that does not compel the cervix to be excised (e.g. sepsis).

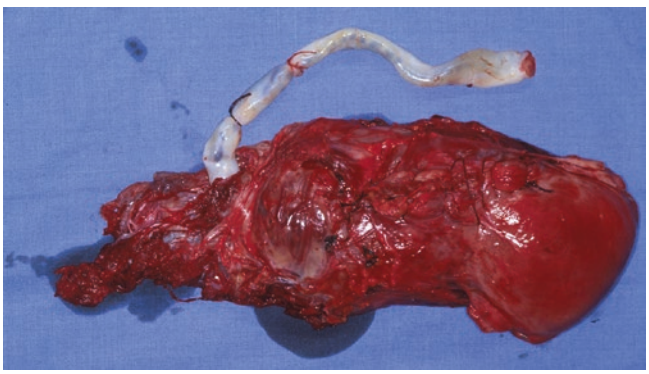

Fig. 95.23 TAH – postoperative PH-specimen: preplanned CS followed by simultaneous PH for placenta previa percreta leaving the placenta in situ during hysterectomy

Surgical Technique

There are several ways to accomplish the special problems posed by PH successfully. TAH is the traditional surgical method of EPH. It is essential in all cases of active bleeding from lower uterine segment as subtotal abdominal hysterectomy is not effective in management of placenta ac−/in−/percreta located in the lower uterine segment with the cervical branch of uterine artery being intact [8]. Furthermore, the potential risk of malignancy developing in the cervical stump, the need for regular cytology or bleeding/discharge associated with the residual cervical stump PH is to be taken into account when it comes to decision making concerning surgical techniques (see Fig. 95.14). If the cervix and paracolpos are not involved as the source of hemorrhage, abdominal supracervical hysterectomy (ASH) is adequate to achieve hemostasis. Supracervical surgery requires a lesser complex surgical technique, reduces operating time, leads to lesser blood loss, diminishes the need for blood transfusion and intra- and postoperative complications (e.g. persistence/diffuse bleeding, injury of urine bladder or ureter). The reduction of surgical radicalness by the decision of performing ASH is significantly influenced by patient's condition, indication for EPH, surgeon's experience and the probability of complications (Table 95.4). If ASH is performed, the uterine corps is amputated with a scalpel/electrical bistoury by cutting superiorly to the ligated uterine arteries. The cervical stump is approximated in an anterior-to-posterior fashion using interrupted sutures. Special care should be taken to avoid the bladder (Fig. 95.24). Currently the proportion of ASH performed for EPH ranges regional highly different from 17 [23] to 97 % [4].

Surgeon's Experience

In the recent years decreasing rates of abdominal hysterectomy for gynecological conditions impede a transfer of valu-

able experience with the procedure from gynecology to the more complex circumstances the obstetrician faces when performing PH. For the general obstetrician the average chance of performing EPH is once in 11 years [14]. Despite experienced surgery, reoperation rates (e.g. unplanned revision, planned removal of abdominal compresses) are to be expected to be as high as 23.6 % (range 7.8–38) [1]. EPH being performed by an experienced surgeon significantly reduces the operating time, number of units of blood transfusion, reoperation rates and hospital stay. As a consequence a risk-factor-stratified centralization of selected patients is to be advocated.

Abdominal Hysterectomy for Obese Patients

96

Emad Mikhail

Introduction

Since 1980, obesity has become a frequently encountered health problem in both children and adults and in all racial, ethnic, and socioeconomic groups [1]. The National Institutes of Health defines a normal BMI as 18.5–24.9 kg/m^2. Overweight is defined as a BMI between 25.0 and 29.9 kg/m^2. Class I obesity is a BMI between 30 and 34.9 kg/m^2, class II obesity is a BMI between 35.0 and 39.9 kg/m^2, and class III obesity is a BMI of >40 kg/m^2 [2]. Obesity is becoming a challenging health problem worldwide and in the United States, where national estimates indicate that 35.5 % of the adult population is obese (defined as a body mass index (BMI) ≥30) [3]. It has been shown that obesity is directly related to increased morbidity and mortality, where in adults ages 30–74, mortality from all causes increases in proportion to the degree of obesity [4]. Obesity is associated with an increased risk of morbid conditions (including hypertension, diabetes mellitus (DM), obstructive sleep apnea, and hypercholesterolemia) as well as malignancies such as endometrial and postmenopausal breast cancer [5]. Not only that but also, wound complications, surgical site infections, and venous thromboembolism remain a major source of morbidity for obese patients undergoing abdominal surgery [5].

Hysterectomy is one of the most frequently performed surgical procedures in the United States [6]. Minimally invasive approach for hysterectomy is more favorable due to its well-known benefits including; less blood loss, fewer perioperative complications, less postoperative pain, shorter hospital stay, quicker recovery time and better cosmesis. Despite these benefits, more than half of the hysterectomy procedures in the United States are performed through laparotomy incisions [7]. Recent studies have shown that increasing BMI was associated with increased rate of open hysterectomy in the United States [8]. Due to increased costs associated with minimally invasive approaches for hysterectomy [9], it is estimated that the percentage of abdominal hysterectomy is even higher in developing countries.

Research has shown that the metabolic comorbidities of obesity are directly related to the increased risk of perioperative complications. Surprisingly the overall mortality and composite morbidity in the obese patient without metabolic complications undergoing general surgery actually has been shown to be lower than that of normal-weight patients in a phenomenon referred to as the "obesity paradox" [10].

For patients presenting for hysterectomy, the impact of obesity on a particular patient's risk of surgery must be weighed prior to deciding upon the route of hysterectomy [11]. Obese patients experience some of the greatest differential benefit from performance of a hysterectomy in a minimally invasive route compared to an open procedure [12].

If increasing weight is associated with a higher risk of the operation, then the benefits of surgery must also increase proportionately. So, in morbidly obese women, risks-benefits should be evaluated and discussed and other non-surgical treatment options should be pursued before exploring surgical options [12]. Since the risks associated with increased BMI were dependent on the route of surgery and were mainly seen in patients undergoing abdominal hysterectomy [13], special attention should be employed during the perioperative care of obese women undergoing abdominal hysterectomy, which will be discussed in this chapter.

Pre-op Assessment/Testing

The perioperative care start with the surgical decision-making during the office visit. It is recommended that obese surgical patients undergo a thorough history and physical examination before undergoing a surgical intervention. The importance of this step is magnified in obese women due to

the possible co-morbidities associated with obesity including hypertension, diabetes, and asthma. In obese patients with DM, blood glucose evaluation and counseling the woman on the importance of euglycemia to improve postoperative wound healing is important. On the other hand, routine screening of the obese patient for diabetes before surgery is not recommended [5]. Surgical clearance is usually obtained from the patient primary care physician in order to optimize the operative outcome. Obesity is associated with increased risk of skin infections. An evaluation for fungal or bacterial skin infections should also be performed prior to surgery, and appropriately treated, in order to prevent post-operative infections [14].

Pulmonary function testing on all patients is not currently recommended but screening for obstructive sleep apnea (OSA) should be considered, as the prevalence of undiagnosed OSA is 24 % [15].

Cardiology consultation may be beneficial in obese patients who have abnormal EKG changes or other comorbidities including hypertension and diabetes [16].

Anesthesia Considerations

Obesity can be challenging for administering anesthesia and controlling the airway, not only at the time of intubation, but throughout the entire procedure. Clear communication and collaboration with the entire surgical team is paramount to successful and safe surgery. The anesthesia team should perform pre-operative airway evaluation as excessive fat around the neck, a short neck, and limited jaw and neck movement can lead to difficult intubation [17].

Functional residual capacity, expiratory reserve volume, and total lung capacity are decreased with increasing weight [18]. This decrease in the functional residual capacity can lead to quicker oxygen desaturation and apneic episodes in the obese patient [19]. Anesthesiologists may use pressure control ventilation to improve the lung ventilation-perfusion ratio [20].

Positioning and Pre-op Preparation

Proper positioning of the obese patient is very important to maximize exposure and reduce the risk of injury. Some operating room (OR) tables may not be wide enough to support the patient, but extenders are available for most operating beds. Larger beds for morbidly obese patients are recommended if available. Operating tables typically accommodate 205 kg, although some tables can accommodate 455 kg [5]. The patient should be allowed to transfer themselves to the OR table. After the patient is transferred to the OR table, proper positioning and appropriate padding is necessary [11]. The skin preparation before incision can be challenging in obese patients with multiple skin folds. Additionally, multiple kits may be necessary for abdominal skin preparation [5].

Surgical Techniques

Commonly used abdominal incisions in gynecologic surgery include the Pfannenstiel, Cherney, and Maylard transverse incisions and median and paramedian vertical incisions. In obese patients, the abdominal wall anatomy is distorted by a large panniculus.

The vertical incision has the advantage of being easy to perform; it can be accomplished quickly, because the midline is the least vascular area of the abdominal wall, and provides excellent exposure to the pelvis. The principal blood supply to the anterior abdominal wall is from the inferior epigastric vessels, which are located laterally in the rectus sheath posterior to the rectus abdominis muscles, and these vessels are avoided by the mid-line incision [21]. The paramedian incision is performed over the medial or lateral position of the rectus muscle, and provides the same exposure as the median incision. Additional benefit for the paramedian incision over the midline incision in the obese patients is doubtful. The principal problem associated with the midline incision is that it has the highest rate of wound dehiscence when compared with all other incisions. Dehiscence rates as high as 2–3 % have been reported in obese patients [22].

When compared to patients with low BMI, the umbilicus is located caudad to its normal position in the obese patients [23]. If a midline incision is made, it is essential to take care not to 'buttonhole' the pannus [24]. The midline incision is made by first retracting the panniculus caudad, below the inferior margins of the symphysis, to avoid an incision in the anaerobic subpannicular fold. The fascial incision is always extended up to the symphysis [25]. Although midline or vertical incisions are associated with more postoperative pain, dehiscence and hernia formation, but with correct closure, the latter two can be minimized [26].

A Pfannenstiel incision is the most common transverse incision for pelvic surgery, and is made one to three fingerbreadths above the pubic symphysis. It is associated with greater wound strength and better cosmesis compared with vertical incisions. However, a Pfannenstiel incision provides limited exposure for the entire abdomen and requires more time to attain a sufficient surgical field [27]. The Pfannenstiel incision is used extensively in gynecologic surgery because of its excellent cosmetic result, low incidence of hernia and dehiscence, and earlier return to ambulation. This incision is associated with an increased hematoma rate and should be used with caution in patients with an abnormal coagulation profile [28]. If a transverse incision is made, care should be

taken to avoid the area under the panniculus as wound complications will be higher [24].

In the Maylard incision, the rectus muscles are cut and the inferior epigastric vessels are ligated. On the other hand the Cherney incision is a modified transverse incision in which the tendinous insertion of the rectus muscles are cut. In our experience with the obese patients, the benefits of all types of transverse incisions are over weighted by the limited access provided, so we routinely use mid line incision in the morbidly obese patients.

Regardless of the type of incision, we recommend using scalpel for the incision, as multiple animal studies have shown that the use of electrosurgery leads to increased tissue damage and decreased tensile strength. Despite the inconsistent results in human subjects concerning the impact of electrosurgery use on wound complications, in a study by Kolb et al., electrosurgery use was found to be an independent risk factor for the development of wound complications [29]. Wounds with large areas of "dead space" remain hypoxic. A surgical incision into thick subcutaneous tissue with increased tissue damage due to electrosurgical effects may lead to such an environment [30].

Pulmonary function should also be considered when planning an incision. In a study where patients with chronic obstructive pulmonary disease were randomly assigned to midline or transverse incisions, after a transverse incision, these patients had better postoperative lung function and fewer pulmonary complications. However, no difference was seen in patients without preoperative pulmonary disease [31].

Abdominal wall retraction is of utmost importance to provide good visualization in obese patients. Due to the increased thickness of the anterior abdominal wall, retraction can be challenging. There are many available techniques for abdominal wall retraction. We routinely use self-retaining retractors, to free the hands of the assistant surgeon. Some handheld models, like the Deaver and Richardson, remain in use today. Self-retaining retractors that have been widely used in gynecology include: Bookwalter retractor, Balfour-Doyen retractor, Alexis O retractor. We prefer using the bookwalter retractor, as different blade length is available to allow for different depths of the abdominal wall. Also the angle of retraction can be changes easily due to the ratchet system [32]. The iliohypogastric and ilioinguinal nerves are branches of the lumbar plexus that course along the abdominal oblique muscles and innervate the overlying skin in an oblique distribution inferomedially from near the level of the anterior spine of the iliac crest. Postoperative pain due to injury of these sensory nerves occurs, in particular with Pfannenstiel incisions [33]. Particular attention – during performing or closing Pfannenstiel incisions or during prolonged abdominal wall retraction- should be paid to decrease the risk of injury to those nerves. Also the femoral nerve is at risk of injury due to abdominal wall retraction, care must be taken with the placement of the pelvic blades to minimize that risk [34].

We utilize the same basic steps for performing open hysterectomy described elsewhere, with special consideration to the following:

Packing of the bowels is of special importance particularly in obese patients. The cecum and sigmoid are packed first with separate packs, and a third rolled or folded pack is placed in the center behind the superior retractor blade to hold back the small bowel [25]. Moist laparotomy sponges are preferred, and also it is recommended to decrease the duration of packing to the needed minimum.

Ureteric identification is important during hysterectomy and can help in preventing injuries. The ureter can be identified easily transperitoneally in thin patients as there is minimally amount of retroperitoneal fat, but in obese patients with increased retroperitoneal adiposity, it may be difficult to visualize the ureter in this manner [35]. On the contrary in obese patients, retroperitoneal dissection and ureterolysis is usually needed to visualize and identify the ureter.

For women undergoing abdominal hysterectomy, increased BMI was shown to be associated with increased odds of heavy bleeding during surgery (defined as >1000 mL of estimated blood loss) [odds ratio (OR) = 3.64; 95 % confidence interval (CI), 2.90–4.56] [13]. Achieving hemostasis can be challenging in obese patients, but it can be obtained with meticulous dissection. Type and screen should be ordered, in case blood transfusion will be needed.

The Use of Drains

Meta-analyses have shown that the effect of using a subcutaneous drain in obese women undergoing laparotomy remains controversial, Kozol et al. conducted a randomized trial of 98 morbidly obese patients and found no difference in wound infection, skin separation, or hematoma in patients who had closed suction drainage of the subcutaneous space or patients who had stay suture closure of this space [36]. Since no significant benefit was established with the routine use of drains, we do not recommend routine prophylactic drainage.

Fascial Closure

We routinely use PDS (Ethicon, Somerville, NJ) or Maxon (Medtronic, Minneapolis, Minnesota) to close midline laparotomy incision in obese patients. In a prospective randomized multicenter trial by Wissing et al., that included 1491 patients randomized into four different fascial closure techniques; interrupted closure with polyglactin; continuous closure with polyglactin; continuous closure with polydioxanones,

and continuous closure with nylon, concluded that polydiaxanone (PDS), or a similar suture, was the best choice as it had a hernia rate almost as low as nylon, but with less pain and with fewer sinus tracts [37].

Subcutaneous Closure

The management of subcutaneous tissue in the obese population remains controversial, in a study that included 222 patients, no significant difference was found in wound complications between the study arms, 1-suture approximation of Camper's fascia, 2- closed suction drainage of the subcutaneous space, or 3- no intervention as a control group [38].

In a RCT by Naumann et al., where 245 women with at least 2 cm of subcutaneous fat were randomized to closure of Camper's fascia (with 3/0 Vicryl) or no closure with cesarean delivery, a significant difference was found in the rate of wound disruption [39]. Despite the fact that we could not find a similar study for open hysterectomy, we adopted subcutaneous closure for all patients with more than 2 cm thickness of subcutaneous tissues.

We prefer Skin closure using subcuticular absorbable monofilament sutures. Two other advantages of absorbable monofilament are its high tensile strength and better anti-inflammatory properties [27].

Surgical Site Infection (SSI)

In a recent large retrospective study, certain risk factors have been shown to be associated with surgical site infections in patients undergoing abdominal hysterectomy including; overweight (OR, 1.7; 95 % CI, 1.2–2.5; p = .004), obesity (OR, 3.2; 95 % CI, 2.3–4.5; p = .001), operative time >180 min (OR, 1.8; 95 % CI, 1.2–2.6; p = .002) [40]. The relationship between SSI and obesity and operative time is interchanging. It has been shown that duration of operation greater than the 75th percentile was associated with increased odds of SSI in the multivariable analysis [41]. On the other hand, obesity is associated with increased operative time [8]. But also it is worth mentioning that obesity has also been shown to be independently associated with SSI specifically after abdominal hysterectomy.

When choosing an incision type, special attention must be paid to the excess soft tissue of the obese patient in relation to the body core [1]. In addition, increased dead space may lead to an increase in wound fluid acting as a suitable culture medium for contaminating microorganisms [30].

The pooled rate of surgical site infection (SSI) after abdominal hysterectomy as reported by the National Healthcare Safety Network for 2006–2007 was 1.7 % [42]. Before routine use of prophylactic antibiotic regimens, SSI rates reported for abdominal hysterectomy were 9 % or higher [30, 43, 44].

Risk factors for SSI identified with multivariable analysis include obesity, depth of subcutaneous tissue, use of abdominal approach, and inadequate antimicrobial prophylaxis [41]. Morbid obesity was associated with the greatest odds of incisional SSI, with a dose-response relationship between risk and increased BMI [41]. When prophylactic antibiotics are warranted, some have advocated a 2-g prophylactic cefazolin dose in those patients who weigh more than 80 kg, with an increase to 3 g for those who weigh more than 120 kg [45].

Postoperative Venous Thromboembolism

The incidence of venous thromboembolism after gynecologic surgery varies significantly and depends on the diagnostic modality. When diagnosed by I-125 fibrinogen leg scanning, approximately 14 % of patients undergoing gynecologic surgery for benign indications develop thromboembolism [46]. When diagnosed clinically only 3 % were diagnosed with DVT [47]. Obesity is associated with increased risk for developing venous thromboembolism (VTE) [48]. The incidence of VTE for open hysterectomy was higher (0.6 %, 81/12,733) than minimally invasive hysterectomy (0.2 % 73/31,434, P < .001) [49]. In a large retrospective study that included 9917 patients, overweight patients were found to be at a higher risk for thrombotic events than both obese and ideal BMI patients [50]. Authors assumed that this finding is attributed to the increased use of prophylactic anticoagulant therapies in the obese, which may explain this apparently paradoxical observation [50].

Early ambulation is highly recommended as immobilization is a major risk factor for development of VTE, with a ninefold increase seen in patients on bed rest [47]. Intermittent pneumatic compression has been shown to reduce the incidence of venous thromboembolism in a gynecologic oncology patient population [51]. We recommend using a perioperative validated scoring system to stratify the patient's risk for developing VTE and use compression devices and/or pharmacologic anticoagulation as indicated. One of the commonly used scoring systems is the Caprini Score [52], which is one of two scoring systems used by American College of Chest Physicians (ACCP) for risk stratification [53].

These risk stratification systems will advice practitioners according to the individualized patient score on which method or combination of methods better suits the patient's risk.

Conclusion

Obesity is not only a challenging health problem but also it affects surgical decision-making [11]. Significant increased in perioperative morbidity is seen in obese

patients undergoing open hysterectomy, which can be decreased through an appropriate risk stratifying perioperative care.

Wertheim-Meigs Abdominal Radical Hysterectomy and Lymphadenectomy

97

Giorgio Bogani, Andrea Papadia, Francesco Raspagliesi, and Andrea Mariani

The authors declared no conflict of interest.

No funding were obtained for the present investigation.

The Wertheim-Meigs surgical procedure is an operation performed for the management of selected case of uterine or vaginal carcinomas (including uterine carcinoma involving the uterine cervix and/or the upper vagina). In the late years of the 1800, Ernst Wertheim developed this procedure characterized by the extirpation of the uterus within its surrounding structures (i.e., parametria). However, the high morbidity and mortality rates reported by the Viennese physician in comparison to the standard treatment (i.e., radiotherapy) used for the management of cervical carcinoma, discouraged the widespread diffusion of this operation. Notwithstanding, in 1944, Joe Vincent Meigs, re-popularized this operation developing the modified Wertheim hysterectomy, characterized by the removal of all pelvic nodes within the uterus and the parametria.

In the present era, radical hysterectomy represents the mainstay of treatment of many gynecologic malignancies [1–3]. In fact, technical and technological improvements allow the execution of an abdominal radical hysterectomy (ARH) in a safe and effective way, thus allowing the extirpation of the tumor and reducing damage on surrounding tissue (i.e., bladder, bowel and vagina) that are injured by radiotherapy.

Indications for the execution of ARH include: early stage cervical cancer, locally advanced stage cervical cancer after the execution of neoadjuvant chemotherapy, FIGO stage II endometrial cancer and gynecologic sarcomas extending beyond the uterine corpus [1–3]. Although several studies underlined how minimally invasive surgery (i.e., laparoscopic and robotic-assisted surgery) improve short and medium-term outcomes of patients undergoing radical hysterectomy, in comparison to open abdominal operation, the majority of radical hysterectomies are still performed via abdominal incisions [4]. In this chapter we describe the technique of the standard Wertheim-Meigs surgical procedure and pelvic lymphadenectomy.

Wertheim-Meigs Radical Hysterectomy

To perform this procedure, the patient is placed in a dorsal (supine) lithotomic and Trendelenburg position to facilitate intraoperative pelvic organs exposure of the operative field. Pelvic examination is performed. A Foley catheter is placed in the bladder. Examination under anesthesia is paramount to assess status of the cervix, vagina, parametria as well as uterosacral ligaments. Examination is performed in the same session of surgical treatment; but when the status of vagina and parametria is not clear, it should be performed in a separate previous session. A careful selection of the incision site is needed and depends on the basis of patient's characteristics (e.g., body habitus, previous scars). After the execution of an abdominal incision (midline or transverse), the pelvis and the upper abdomen are carefully explored. Generally, a midline incision is preferred, since it allows an accurate exposure to the upper abdomen and aortic lymph nodes. A retractor is used to keep an adequate operating field. The intestine is packed in the upper abdomen, thus allowing to expose the pelvis. The uterus is pulled on using clamps placed on the cornua bilaterally. First, the uterus is located to

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_97

the patient's right. The left round ligament is placed on stretch and incised close to the pelvic sidewall. The anterior leaf of the left broad ligament is opened along with the uterine-bladder peritoneal fold. These steps are carried out on the oppose site. The peritoneum above the bladder is grasped and elevated. Scissors are used to dissect the uterovescical fold. The bladder is sharply dissected caudally, from the anterior upper vagina (at least 3–4-cm). The posterior leaf of the broad ligament is opened, exposing the infundibulopelvic ligament. The ureter is identified at the level of the common iliac vessels and it is separated from the infundibulopelvic ligament. If the ovaries have to be removed, the infundibulopelvic ligament is clamped, cut and doubly suture-ligated. The tubes and the ovaries are tied to the clamps holding the uterus. If the ovaries have to be preserved, the posterior leaf of the broad ligament is further incised parallel and inferior to the infundibulopelvic and utero-ovarian ligaments. The utero-ovarian ligament is then clamped, cut, and ligated, and the ovary is tucked in the upper abdomen (at the end of the procedure they will be suspended to the lateral pelvic wall, outside of the radiation field, and clips will be placed to allow their identification at postoperative imaging studies).

Next, the iliac vessels are identified: common iliac, external iliac, and internal iliac vessels and the ureter are exposed on both pelvic sides (Fig. 97.1). A pelvic lymphadenectomy (PL LND) can be performed before or after completing the radical hysterectomy (in this chapter the technique of PL LND is reported below). In some instances, surgeons prefer to excise nodes before the execution of radical hysterectomy. The nodes are sent for frozen section analysis and in case of documented lymph node metastases the procedure is aborted in favor of a chemoradiotherapic management, thus reducing morbidity of a combined treatment (surgery plus postoperative adjuvant pelvic chemoradiotherapy for positive nodes) [5].

Paravesical and pararectal spaces are developed with blunt dissection to gain access to the lateral parametria (Fig. 97.2). The round ligament is ligated and divided close to the pelvic sidewall. The pelvic peritoneum is then opened parallel to the infundibolopelvic ligament cranially up to the level of the common iliac vessels. The retroperitoneum is then developed bluntly. The paravesical space is opened by dissecting medial to the junction of the external iliac and circumflex veins and lateral to the bladder and obliterated umbilical artery, down to the pelvic floor. The landmarks of the paravescical space are the obliterated umbilical artery and the bladder wall medially, the levator ani muscle caudally, the external iliac vessels and the obturator fossa laterally and the cardinal ligament dorsally. First, the obliterated umbilical artery is identified and pulled medially with the bladder wall, then the areolar space is developed bluntly between external iliac vessels laterally and obliterated umbilical artery and bladder medially down to the levator ani muscle. Similarly, the pararectal space is developed bluntly between the rectum and the ureter medially, the sacrum ventrally, the pelvic sidewall and the internal iliac vessels laterally. The landmarks of the pararectal space are the ureter and the rectum medially, the sacrum caudally, the internal iliac vessels and the pelvic sidewall laterally and the cardinal ligament ventrally. After having opened the pelvic sidewall peritoneum, the adnexa il pulled medially. The ureter is identified via blunt dissection and pulled medially, separating it from the structures of the pelvic pelvic sidewall. First, the areolar tissue between external iliac vessels laterally and ureter medially is developed bluntly; then the areolar tissue between internal iliac vessels laterally and rectum medially

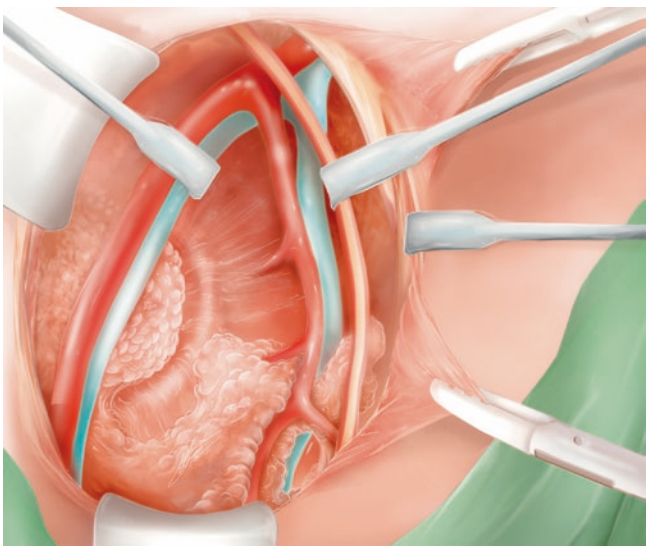

Fig. 97.1 Retroperitoneal pelvic space

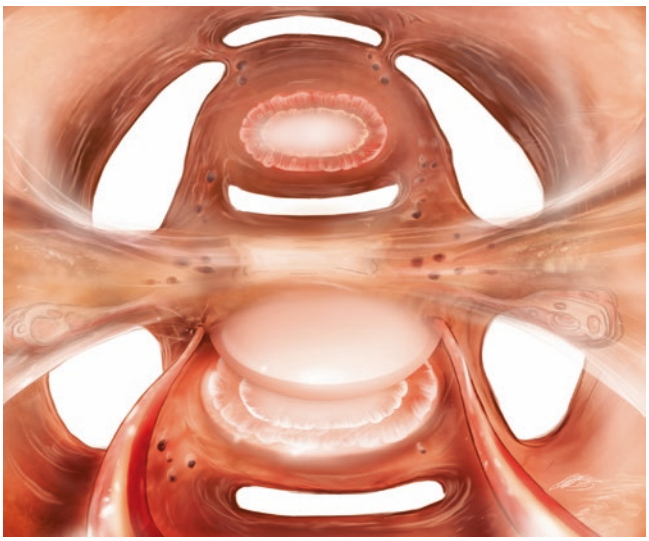

Fig. 97.2 Pelvic spaces

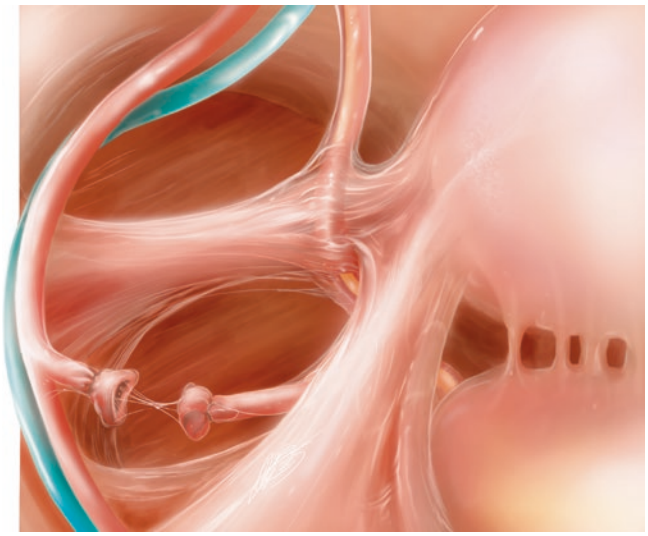

Fig. 97.3 Section of uterine artery

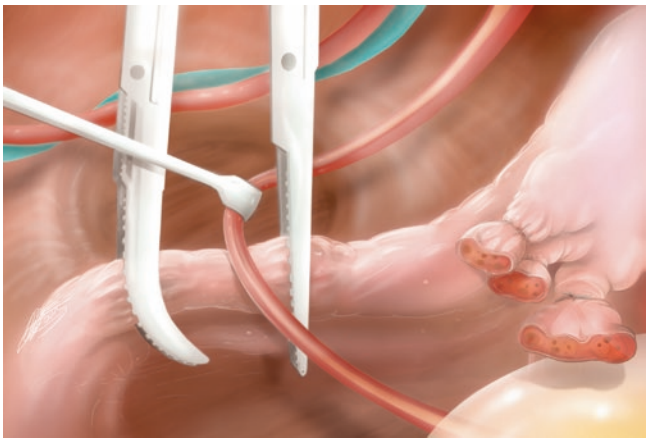

Fig. 97.4 Dissection of Wertheim's tunnel

is developed in the same manner. An accurate palpation of the parametria is necessary to assess the extension of the tumor beyond the uterine cervix. The ureters have to be gently dissected for their entire course in the pelvis to the point where the ureter enters in the parametrial tunnel of Wertheim. Both the ureters should be placed within a vessel-loop for their traction. A backward traction on the ureter is essential to allow its safe dissection from the paracervical tissue.

Then the uterine vessels are identified; tracing proximally the upper vesical artery may facilitate the identification of the uterine artery. On each side, after its skeletonization, the uterine artery is double ligated at its origin from the hypogastric artery (Fig. 97.3). Similarly, the uterine veins (superficial and deep) are ligated and mobilized medially. The deep uterine vein represents the caudal limit of the dissection. The lower part of the lateral parametria, containing the splancnic nerves has to be preserved during this step. In order to do so, the deep uterine vein is identified, ligated and cut. The distal stump of the vein is lifted ventrally and medially and the tissue just underneath it dissected medially until the cross with the ureter is reached. This allows for a preservation of the splancinc nerves. Then the caudal part of the ureter is dissected from the parametria and mobilized medially too (Fig. 97.3). The dissection of Wertheim's tunnel, within the uterovescical ligament, is usually performed using a right angle clamp along the superior border of the ureter. In this step a gentle traction on the ureter is paramount to avoid damages of the ureter (Fig. 97.4). The uterovescical ligaments are divided, thus releasing the ureters free. At this point, the uterus is pulled on ventrally. The posterior leaf of the broad ligament is incised. The posterior peritoneum is opened from the broad ligament to the pouch of Douglas. The rectum is dissected from the upper part of the posterior vaginal wall, in order to develop the recto-vaginal space (for approximately 4 cm). During this step, the rectum must be pulled dorsally, to facilitate the dissection of the correct plane, thus reducing rectal injuries.

Then, the uterosacral ligaments are identified, isolated, clamped and tied. The lower part of the uterosacral ligaments, containing the parasympathetic nerves have to be preserved during this step. The paravaginal tissue at the inferior margin of the dissection is clamped, cut, and tied. The vagina is clamped using two right-angle Heaney or Zeppelin clamps and transected approximately 3 cm below the cervix. The specimen including the uterus, upper vagina, parametria and uterosacral ligaments is removed from the surgical field. The vaginal cuff is closed using two continuous interlocking running sutures. The abdominal and pelvic cavity have to be irrigated in order to check hemostasis. Routine use of suction drains has to be avoided. Then, if indicated other procedures are performed on the basis of clinical indication. Incision is closed in layers.

Lymphadenectomy

Systematic PL LND was defined as the removal of all lymphatic tissue in the external iliac and internal iliac regions and in the obturator fossa. The borders of the dissection are: the psoas muscle laterally, the hypogastric artery medially, the obturator fossa posteriorly, the origin of the epigastric artery caudally, at the level of the circumflex vein, and the bifurcation of the common iliac artery cranially. When PL LND is performed with radical hysterectomy the pelvic retroperitoneal structures (i.e., ureters, iliac vessels and pelvic nerves) are already identified and the retroperitoneal pelvic spaces are already developed. PL LND is started with the removal of all lymphatic tissue from the common iliac artery and vein (Fig. 97.1).

Therefore, the iliac vessels are retracted medially. The lymphatic tissue is detached from the psoas muscle, retracted laterally. Usually, the obturator nerve is identified during this step, at the level of iliac bifurcation. In order to access to the lymphatic tissue located in the obturator fossa, the external iliac vessels are retracted laterally. The obturator nerve is freed from the lymphatic tissue. This latter is isolated from vessels, nerve and the vascular part of the cardinal ligament. The femoral ring represents the caudal border of the specimen. Lymphatic pedicles are identified and closed using clips or sutures. At the end of the procedure, the external iliac artery and vein, the internal iliac vessels, the iliac artery bifurcation, and the obturator nerve are fully exposed.

Although the standard treatment of cervical cancer does not require the execution of para-aortic lymphadenectomy (PA LND), this procedure can be performed if indicated. Generally, the upper margin of the dissection for cervical cancer patients is the origin of the inferior mesentery artery; while in endometrial and ovarian cancer the upper limit is represented by the renal vessels. The medial surgical margin is the prevertebral fascia; while the psoas muscles is the lateral margin. During PA LND all lymph nodes close to the aorta, the cava and between these two vessels are dissected.

The spaces are developed by blunt and sharp dissection and only bipolar coagulation is used for blood and lymphatic vessels sealing. Before starting with PA LND, the ureter is identified, separated from the ovarian vessels and displaced laterally. Lymphatic tissue is removed en-bloc and separately from each side. Caution must be exercised in order to avoid damages of the inferior mesentery artery, accessory vessels to the lower renal pole as well as lumbar vessels. No closure of the peritoneal layer is performed.

Conclusion

In the present chapter, we described the classical "Wertheim-Meigs radical hysterectomy". However, we have to stress that the term "radical hysterectomy" encompasses various degrees of radicality. In particular, several authors proposed a modification of the technique, but anatomical nomenclature was unclear and classification between different procedures is not based always on anatomical landmarks. For this reason, in 2008, Querleu and Morrow proposed a new classification based on strict anatomical criteria. In this classification, type C radical hysterectomy corresponds to the classical "Wertheim-Meigs radical hysterectomy" [1, 6]. Interestingly, in this classification, the Authors defined two subcategories of type C radical hysterectomy: type C1 and C2 characterized by preservation and no preservation of the autonomic nerves, respectively [1, 6]. Accumulating evidence supports the embrace of type C1 instead of type C2 procedures. In fact, type C1 radical hysterectomy upholds oncologic results of conventional type C2 operation, minimizing postoperative pelvic dysfunctions and enhancing postoperative course [7–10]. Oncologic control and tailored radicality are key points in order to improve patients' quality of life. Further studies on radical hysterectomy are warranted in order to improve patients' care.

Okabayashi Radical Hysterectomy

98

Tsutomu Tabata

Introduction

In 1912 Wertheim [1] reported on the results of his first 500 patients using his technique for radical cervical cancer surgery, subsequently his name was assigned to the procedure and all of the modifications to his original procedure are to this date collectively referred to as *Wertheim*. Wertheim was ingenious with two things: Firstly he set goals of prognostic improvement rather than just developing the procedure, that is, he investigated prognosis by statistically analyzing outcomes of surgeries performed. Secondly, with resected specimens, the extent of lesions and presence or absence of metastasis was histopathologically examined. However there were initially some problems with this approach, for example removing only the swollen lymph nodes.

In 1919 Latzko and Schiffman [2] built on the Wertheim method by proposing that a lymph node dissection be performed first, followed by separating the three parts of the uterine supporting ligaments: uterosacral ligaments, cardinal ligaments and vesicouterine ligaments.

The Okabayashi procedure was introduced in 1921 [3, 4]. Features of this surgery formula, similar to Latzko's, advocated separating the uterus support tissue in three parts: the uterosacral ligament, cardinal ligament and vesicouterine ligament. The characteristic feature of the Okabayashi surgical formula was that the anterior and posterior layers of the vesicouterine ligaments were dissected allowing extensive resection of parametrial and paravaginal tissue. This part of the procedure was the most significant change to Latzko's technique. In addition, with concern to the regional lymph nodes, it emphasized the systematic dissection of all lymph nodes rather than only removing the swollen lymph nodes. Both Latzko and Okabayashi have been reported on separately.

The Okabayashi type radical hysterectomy has been passed down in Japan with some improvements having been made. Especially, by Dr. Fuji [5] of Kyoto University who reported on the nerve sparing Okabayashi radical hysterectomy procedure. However, most of the surgical technique is almost the same today as the original. In this chapter, I would like to explain the Okabayashi surgical technique as it is performed today in Japan.

With regard to the order of surgery, there are some differences between the original Okabayashi procedure and the one now [6, 7]. First the original Okabayasi procedure had a radical hysterectomy followed by lymphadenectomy. However for now we are performing lymphadenectomy before radical hysterectomy, because after lymphadenectomy we can see more clearly in pelvic anatomy. Next in the original method a pararectal and paravesical space are developed after the treatment of cardinal ligament, but now we expand these spaces first. This is because expanding the side spaces exposes the ligaments more clearly, thus making the operation more convenient.

The patient is placed in the lithotomy position, with the pelvis high and the surgeon on the left side of the patient. The abdominal cavity is reached through a lower abdominal midline incision. Immediately after laparotomy the degree of cancer progression is observed to determine whether surgery is to be performed. In the cases shown here, in preoperative pelvic examinations, infiltration into both sides of the paracolpium was observed in MRI images with cases that had been diagnosed as Stage IIb (see Figs. 98.1 and 98.2).

Ligation of Round Ligament and Exposure of the Retroperitoneal Space

First the uterus is held by two long Kocher forceps. The round ligament is transected and the peritoneum between the bladder and the uterus is incised (see Fig. 98.3). The opera-

bility is checked to see if it is possible to divide between the uterus and the bladder. If it is judged to be possible, the peritoneum on the lateral aspect of the broad ligament is incised further in a lateral direction along with the infundibulopelvic ligament in the cranial direction (see Fig. 98.4). When the retractor is pulled to the cranial side across the surface of the common iliac artery, the ureter can be found. Then pulling the rectum in the opposite direction from the external iliac artery can give the tension to the broad ligament, and it is possible to make a cavity between the ureter

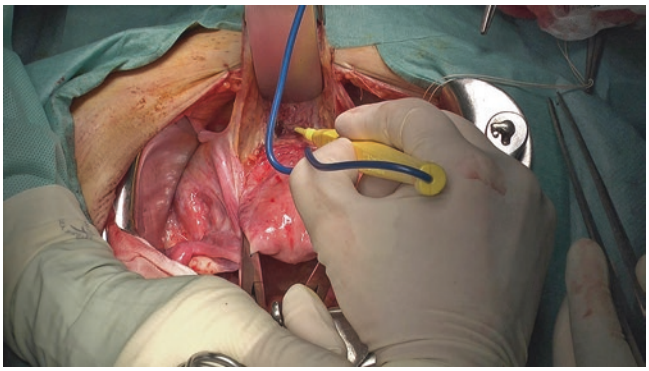

Fig. 98.3 Dissection of the peritoneum uterovesical fold and separation of the bladder. The right round ligament has been clamped, cut, and ligated. The peritoneum of the uterovesical fold has been opened. The vagina is then separated with an electric scalpel from the bladder which is pressed by a retractor and then it is determined whether or not cancer has metastasized to the bladder

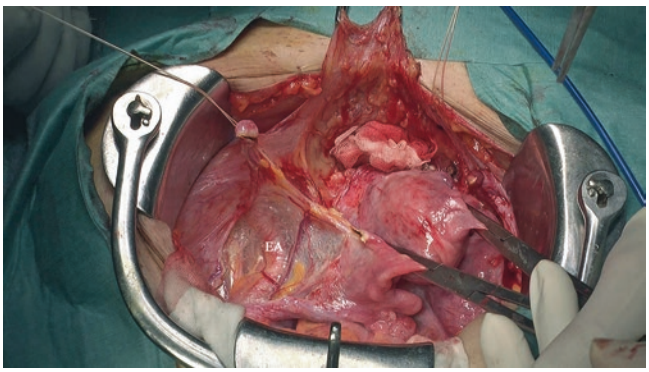

Fig. 98.4 Expansion of the retroperitoneal space. The left round ligament has been cut and the peritoneum has been opened. The external iliac artery (*EA*) is clearly seen

and the umbilical ligament. Thus a pararectal space is easily exposed, because there is little fatty tissue in this space. Furthermore, when the round ligament is pulled outward and the umbilical ligament is pulled to opposite site from this ligament; the surface of paravesical space is then exposed. The dissection is carried laterally until levator ani muscle located at the bottom of paravesical space (see Fig. 98.5). In the original Okabayashi method, the pararectal and paravesical space are developed after the treatment of cardinal ligament, but developing these side cavities first allows for an easier look at the operative area. These spaces did not exist naturally and must be created artificially.

Lymphadenectomy

For regional lymph node dissection please refer to other sections. Briefly, peripheral lymph nodes are gathering to the cervix and such lymph nodes are totally extracted as en bloc lymphadenectomy. Extracted lymph nodes are as follows: Common iliac lymph node, external iliac lymph node, lateral

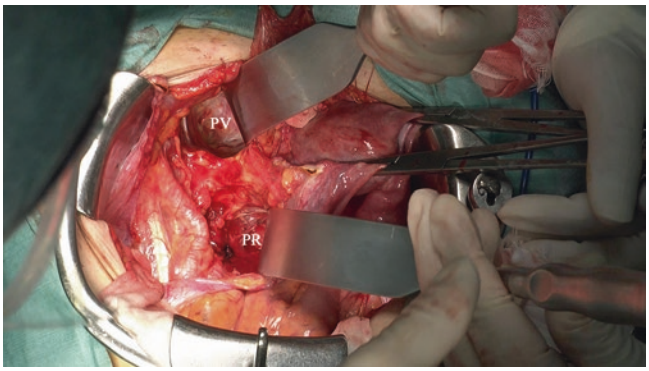

Fig. 98.5 Expansion of the paravesical and pararectal spaces. After developing the paravesical (*PV*) and pararectal (*PR*) spaces, two retractors are placed into both spaces. The tissue between the paravesical and pararectal spaces contains the cardinal ligament and the uterine artery

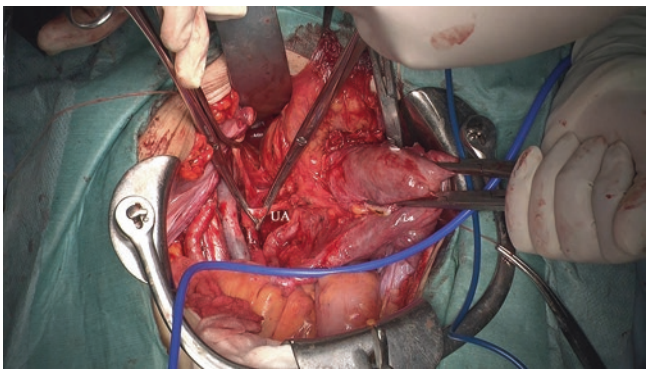

Fig. 98.7 Left uterine artery dissection and ligation. The uterine artery (*UA*) is clamped outside and laterally to the ureter, slightly distal the branch of the internal iliac artery

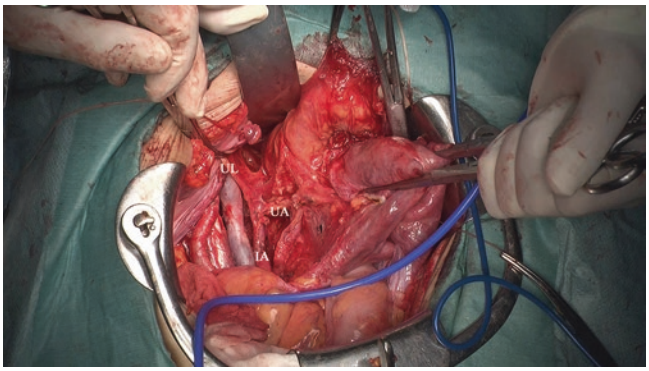

Fig. 98.6 Exposing the uterine artery. When the uterus is held well over to the right side and the umbilical ligament (*UL*) is pulled outward, the uterine artery (*UA*) which branches from the internal iliac artery (*IA*) is exposed in the pararectal space

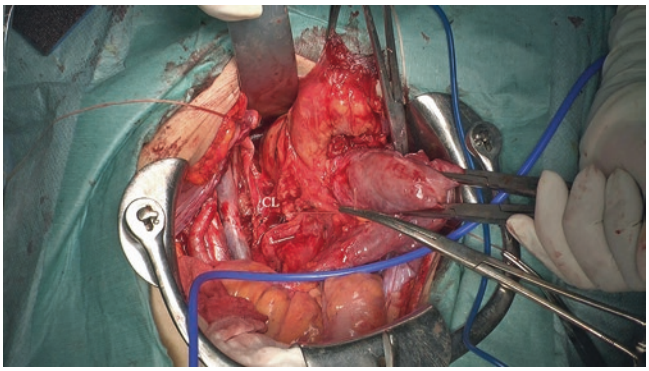

Fig. 98.8 Exposing the cardinal ligament (*CL*). After dividing the uterine artery, the cardinal ligament is exposed beneath the uterine artery

suprainguinal lymph node, medial suprainguinal lymph node, obturator lymph node, internal iliac lymph node, lateral sacral lymph node, and cardinal ligamentous lymph node. If it is needed, para-aortic lymph node is removed.

Ligation of the Uterine Artery

When the umbilical ligament is pulled outward, the uterine artery is exposed in the pararectal space. When the uterine artery is identified, it should be cleared of fat with a vacuum device. The uterine artery is clamped laterally at the distal from the internal iliac artery (see Figs. 98.6, 98.7, and 98.8).

Separation of the Ureter

The ureter is separated from the posterior layer of the broad ligament using an electric scalpel, separating the ureter to near the point where it intersects with the uterine artery (see Figs. 98.9 and 98.10). In this case it is simple to separate and lift up the uterine side stump of the uterine artery that was disconnected earlier. In the case of oophorectomy, after separating the ureter the ligation of the infundibulo-pelvic ligament is performed (see Figs. 98.11 and 98.12). The opposite side is also performed in the same manner.

In the Wertheim procedure the ureter passes through the tunnel of the cardinal ligament, but in the Okabayashi procedure the cardinal tunnel does not exist.

Douglas Fossa

The uterus is pulled in the posterior direction of the pubic symphysis, pulling the rectum to the cranial side. Thereupon, tension is created in the uterosacral ligaments and the Douglas fossa is clear. First, incise the Douglas fossa with an electric scalpel, and then also dissect the surface of the uterosacral ligaments with an electric scalpel (see Figs. 98.13 and 98.14).

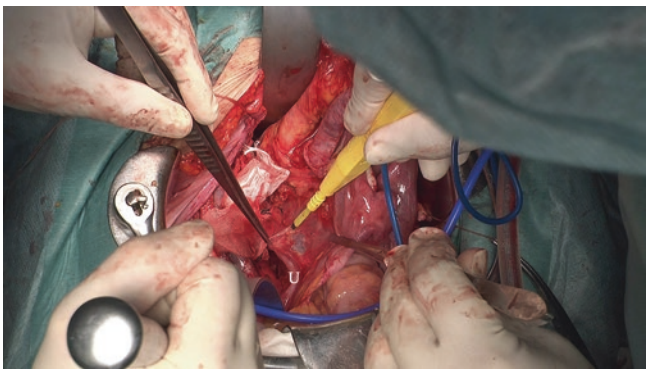

Fig. 98.9 Separation of the ureter. The ureter (*U*) is detached from the broad ligament with electronic scalpel to the point where the uterine artery crosses over the ureter

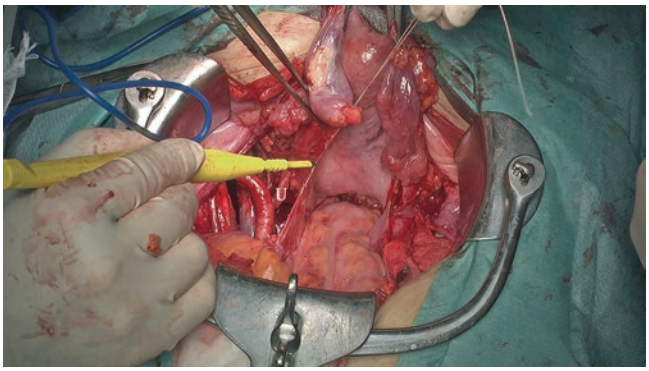

Fig. 98.12 Dissection of the broad ligament. After lifting the cut edge of the infundibulopelvic ligament, the broad ligament is incised toward the uterosacral ligament

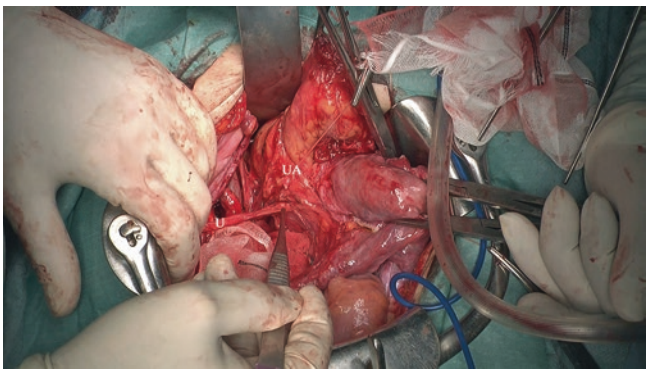

Fig. 98.10 Dissection of the ureter. These ureteral branches of the uterine artery (*UA*) are cut with a Harmonic Focus

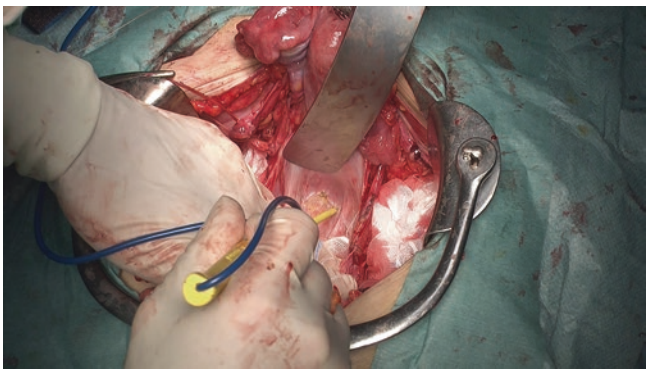

Fig. 98.13 Incision of the Douglas' fossa. When the rectum is pulled in the cranial side and the uterus is pulled to the opposite side, the Douglas' pouch is visible between the two uterosacral ligaments. The peritoneum of Douglas' pouch is cut, and the rectum is separated from the vagina

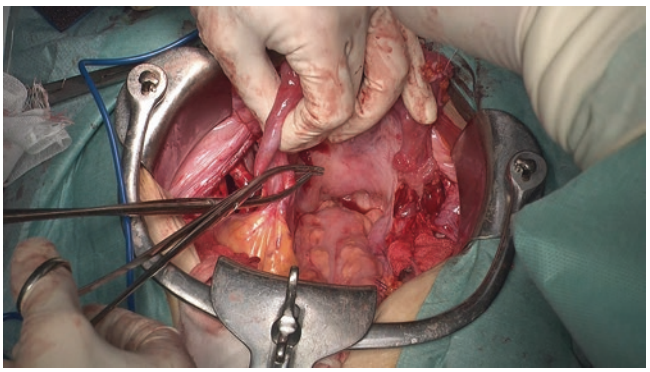

Fig. 98.11 The dissection and ligation of the Infundibulopelvic Ligament. The infundibulopelvic ligament is clamped, cut, and doubly suture-ligated

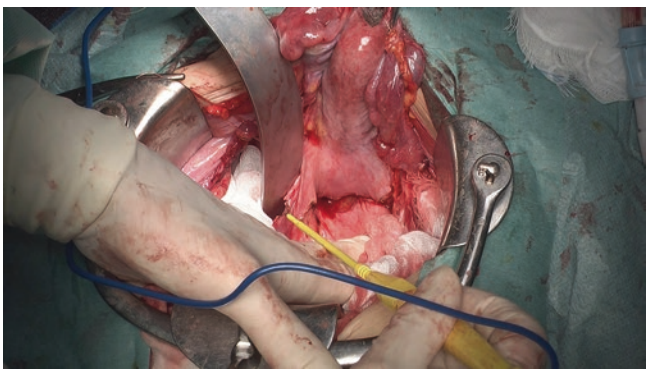

Fig. 98.14 Dissection of the uterosacral ligament. The uterosacral ligament is cut, and the incision connects to the cut membrane of the peritoneum of Douglas' pouch

Uterosacral Ligaments and the Rectovaginal Ligaments

In the rectum marginal line, incise and ligate the left and right uterosacral ligaments. When separating the uterosacral ligaments, the uterus is lifted up and this tends to put tension on the ligaments. Although the uterosacral ligaments lead to the rectovaginal ligaments (see Fig. 98.15), the boundary between the two can be difficult to discern. However, care must be taken not to cut into the rectovaginal ligaments.

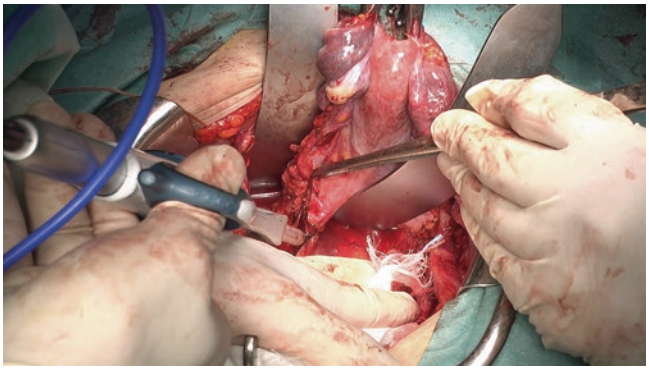

Fig. 98.15 Separation of the left rectovaginal ligament. The rectovaginal ligament behind the uterosacral ligament is dissected with a sealing device

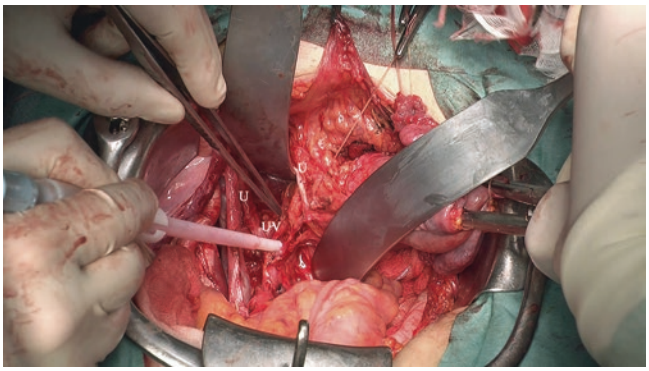

Fig. 98.17 Exposure of the deep uterine vein. The fatty tissue is dissected out of the cardinal ligament by a vacuum device and then the deep uterine vein (*UV*) is exposed. Ureter (*U*)

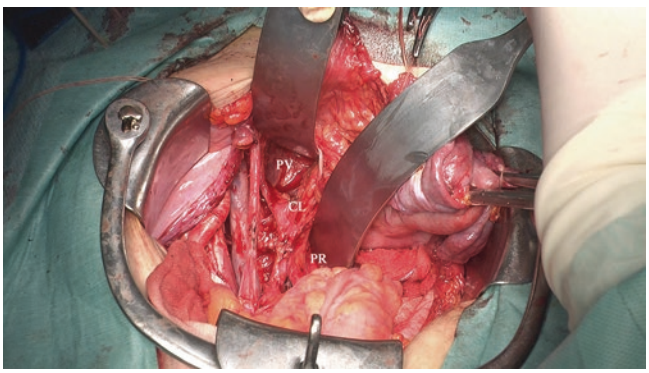

Fig. 98.16 Exposure of the cardinal ligament. After pulling the uterus, two retractors are placed in the paravesical (*PV*) and pararectal (*PR*) spaces and then the cardinal ligament (*CL*) is exposed between the two retractors

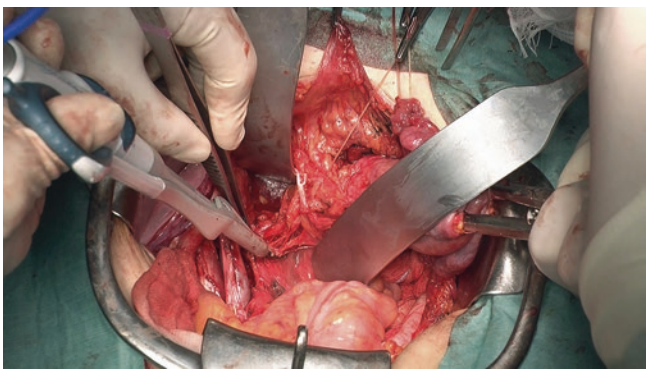

Fig. 98.18 Treatment of the cardinal ligament. The small vessels in the cardinal ligament are cut with a sealing device, and then the deep uterine vein is exposed. Ureter (*U*)

Dissection of the Cardinal Ligaments

Pulling the uterus upward, if two retractors are inserted in the pararectal and paravesical spaces, the cardinal ligaments will become apparent between the two spaces (see Fig. 98.16). The deep uterine vein and pelvic splanchnic nerve are included in the cardinal ligament. Beneath the deep uterine vein is the splanchnic nerve, when the entire cardinal ligament is cut this connects the pararectal space and paravesical space (see Figs. 98.17, 98.18, 98.19, 98.20, 98.21, and 98.22). Under the pararectal space is the sacral region. One must avoid scrapping this region with the retractor as it may cause major hemorrhaging and hemostasis is difficult. In the original Okabayashi method, the cardinal ligaments were cut, thus the deep uterine vein and pelvic splanchnic nerve were ligated together. Therefore it is possible to cut the pelvic splanchnic nerve in the Okabayashi procedure. In recent years, we have tried to avoid severing the nerve plexus when possible.
