In Fig. 98.22, with the original Okabayashi method, the cardinal ligament collectively with the nerves and blood vessels were cut, but in this case the cardinal ligament is not cut. This is because we wish to spare the nerves as much as possible. However, in Figs. 98.36 and 98.37, ultimately it has been found

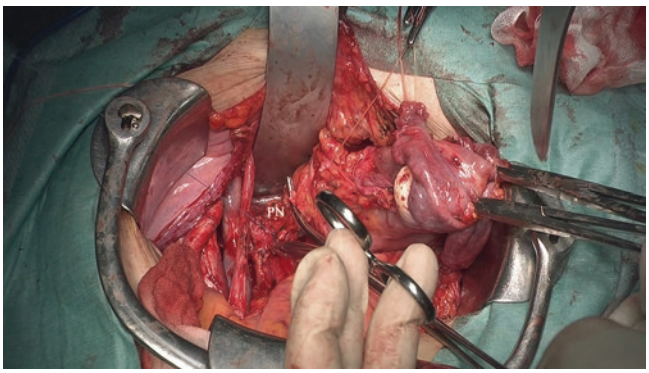

Fig. 98.20 Exposure of the cardinal ligaments nerve section. By lifting the cut end of the deep uterine vein, the pelvic splanchnic nerve (*PN*) becomes visible beneath the deep uterine vein

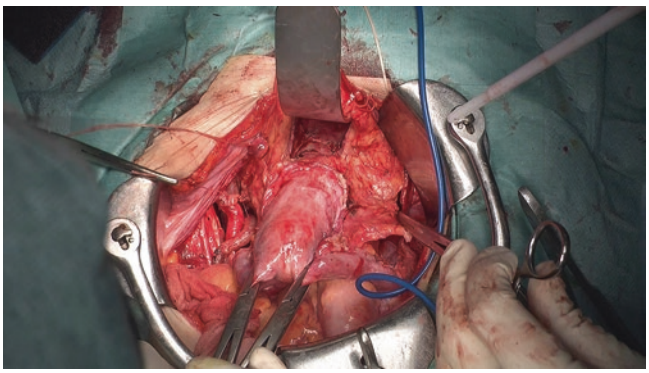

Fig. 98.23 Separation of the bladder. The bladder is separated from the vaginal wall until it is 2 cm beneath the cutting line

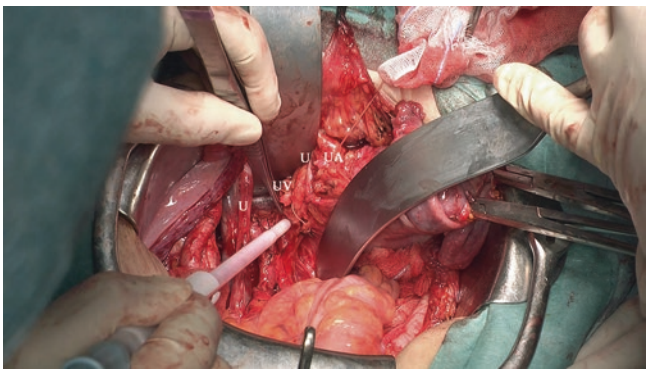

Fig. 98.21 Treatment of the cardinal ligament. Fat and connective tissue is removed from the cardinal ligament with a vacuum device. Deep uterine vein (*UV*), Uterine artery (*UA*), Ureter (*U*)

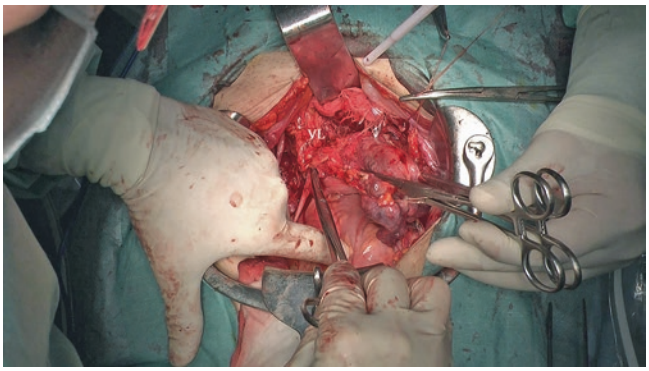

Fig. 98.24 The ureter tunnel. The ureter is located over the cardinal ligament and passes through its' tunnel through the vesicouterine ligament (*VL*). The roof of the ureter tunnel is the anterior leaf of vesicouterine ligament, and the floor of the ureter tunnel is the posterior leaf of vesicouterine ligament. After lifting up the uterine artery, curved Kelly forceps are inserted along the ureter from the entrance of the ureter tunnel. The ureter tunnel is then expanded with these forceps. Great care must be taken not to damage or scratch the vessels within the vesicouterine ligament because they hemorrhage easily and so require great care and skill

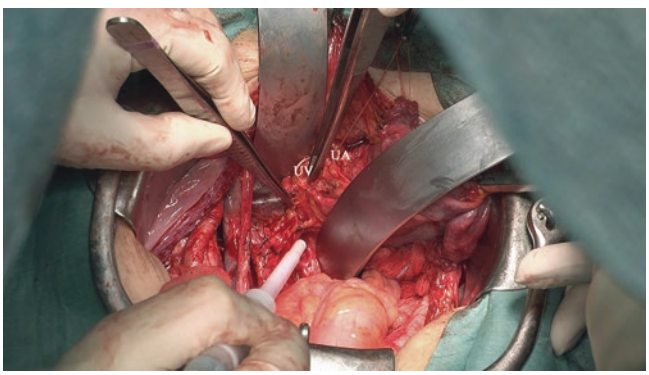

Fig. 98.22 Cardinal ligament nerve section. Fat and lymph nodes have been dissected from the cardinal ligament, and the pelvic splanchnic nerve can then be clearly seen. In the original Okabayashi procedure, the pelvic splanchnic nerve of this cardinal ligament is cut at this point. However, in this case, the cardinal ligament is not cut now, because there exists the possibility that the nerve can be preserved. Deep uterine vein (*UV*), Uterine artery (*UA*)

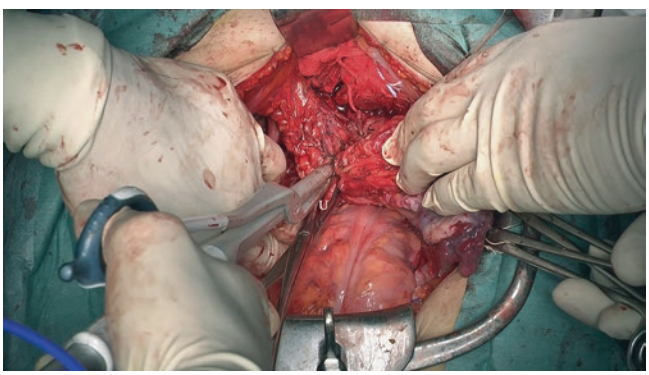

Fig. 98.25 Dissection of the anterior leaf of the vesicouterine ligament. When the ureter is clearly free from the roof of the ureter tunnel, the anterior leaf of the vesicouterine ligament is separated with a sealing device. Ureter (*U*)

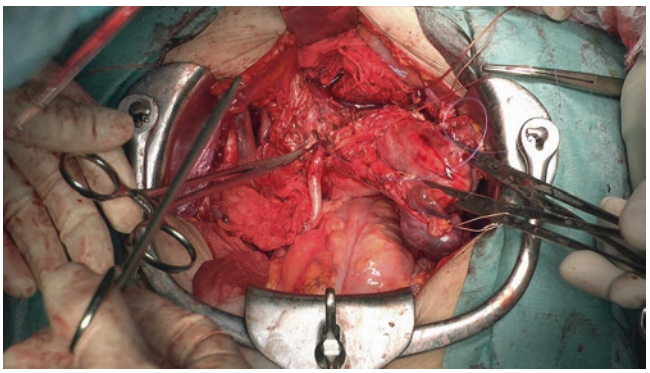

Fig. 98.26 Dissection of the anterior leaf of the vesicouterine ligament. If the ureter is near from the cutting margins, Kelly forceps may be used to clamp the anterior leaf of the vesicouterine ligament as shown in the photo

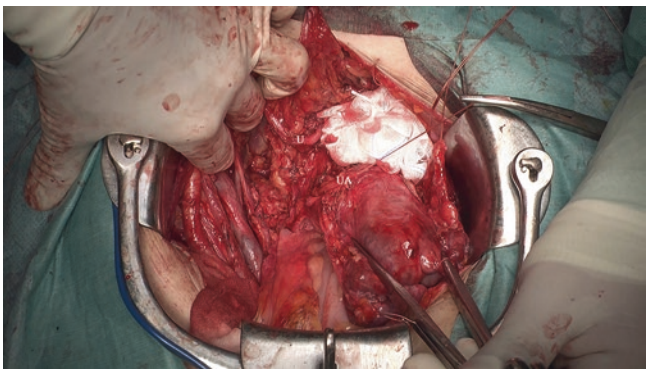

Fig. 98.29 Completion of the treatment of the anterior leaf of the vesicouterine ligament. The division of the anterior leaf of vesicouterine ligament has been completed. The entire course of the left ureter is shown above the posterior leaf of vesicouterine ligament. Uterine artery (*UA*), Ureter (*U*)

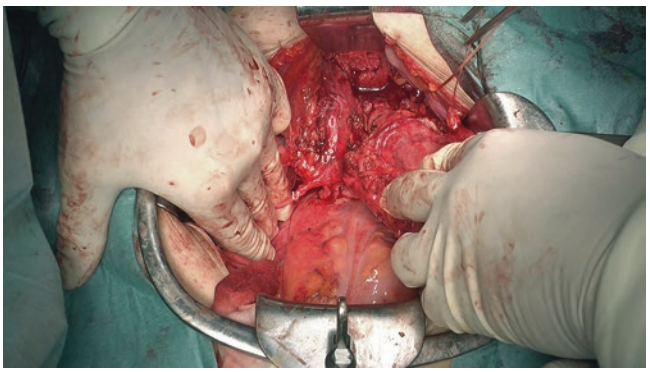

Fig. 98.27 Dissection of the anterior leaf of the vesicouterine ligament. Once the roof of ureter tunnel has been separated, the entire ureter (*U*) within the vesicouterine ligament is exposed

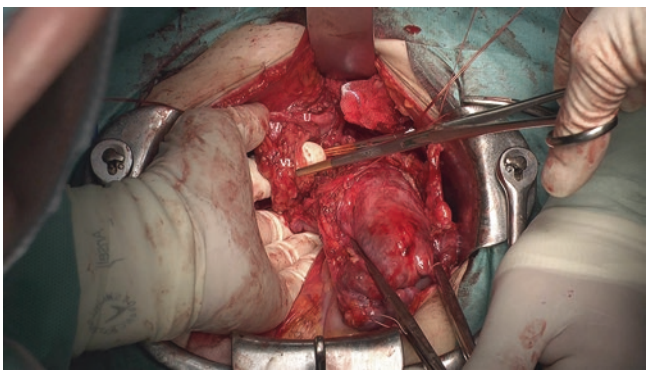

Fig. 98.30 Treatment of the posterior leaf of the vesicouterine ligament. The area located between the posterior leaf of the vesicouterine ligament and the paracolpium is non vascular adipose tissue. Professor Okabayashi referred to this space as the paravaginal space. In this photograph, the index finger of the operator has been inserted in the paravaginal space and is holding the posterior leaf of vesicouterine ligament (*VL*). Ureter (*U*)

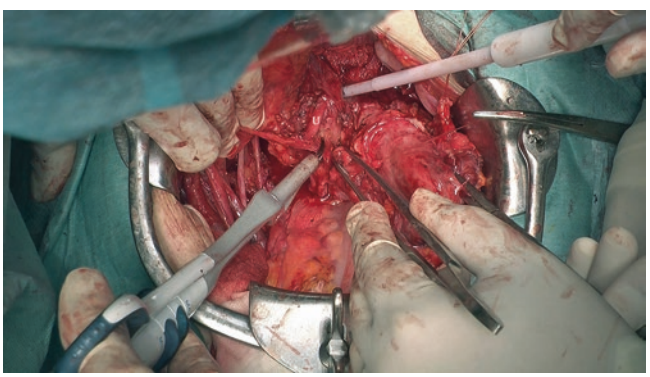

Fig. 98.28 Treatment of loose connective tissue around the ureter. The layer of loose connective tissue which is located on the cranial side from the ureter is divided with the sealing device, and then the ureter is pushed in the caudal direction

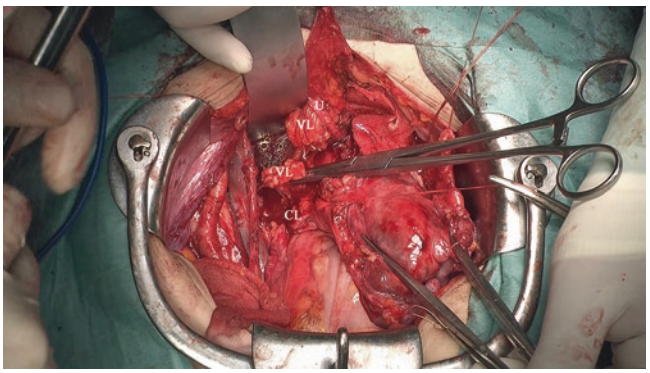

Fig. 98.32 Dissection of the posterior leaf of the vesicouterine ligament. The posterior leaf of vesicouterine ligament (*VL*) has been cut. The cardinal ligament (*CL*) is located behind the cut edge of the vesicouterine ligament on the uterine side. Ureter (*U*)

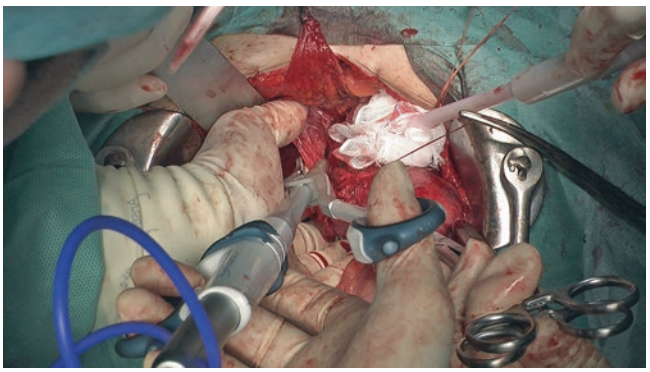

Fig. 98.33 Dissection of the vesicovaginal ligament. The posterior leaf of vesicouterine ligament is connected to the vesicovaginal ligament. If the vesicovaginal ligament remains, it is separated with a sealing device

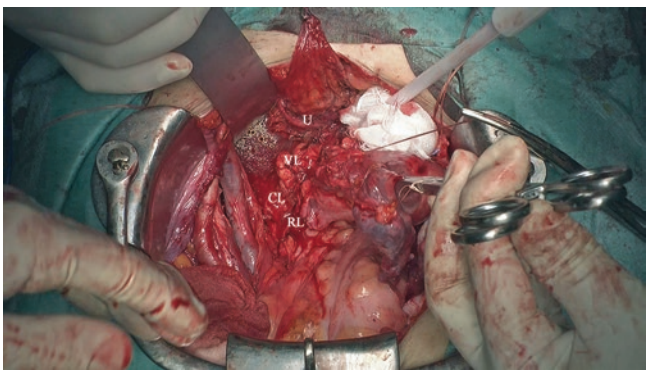

Fig. 98.34 Completion of the dissection of the anterior and posterior vesicouterine ligaments. The posterior leaf of vesicouterine ligament is dissected, and then the vesicouterine ligament (*VL*) is completely divided from the bladder. Ureter (*U*), Cardinal ligament (*CL*), Rectovaginal ligament (*RL*)

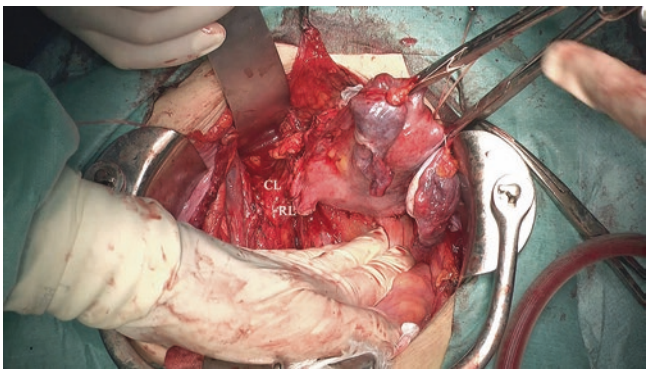

Fig. 98.35 Treatment of the rectovaginal ligament. When the rectum is pulled in the cranial direction and the uterus is pulled in the caudal direction, both the cardinal (*CL*) and rectovaginal ligament (*RL*) are stretched

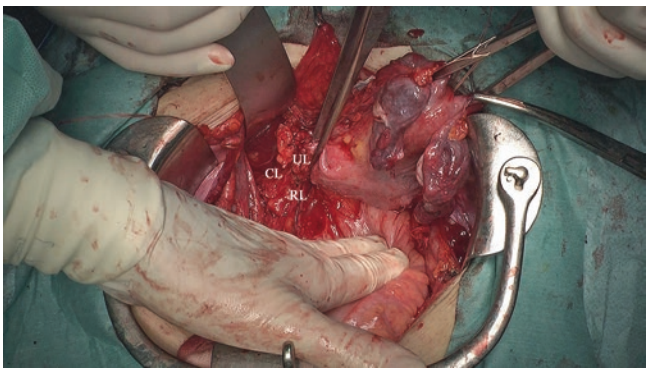

Fig. 98.36 Treatment of the rectovaginal ligament. By lifting the cut edge of uterosacral ligament with (*UL*) the forceps, the rectovaginal ligament (RL) connected to the cardinal ligament (*CL*) is identified. If the cardinal ligament had been dissected like the original Okabayashi's method, the rectovaginal ligament is more visible

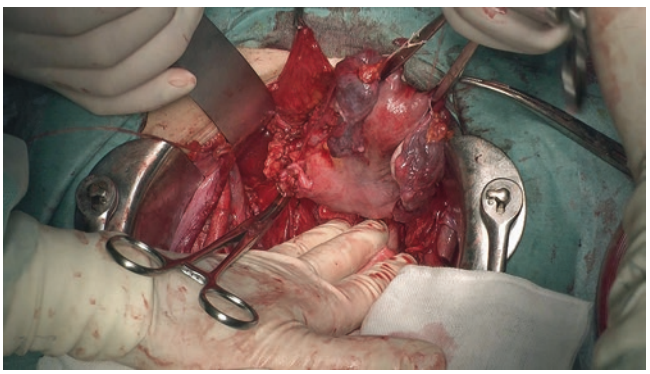

Fig. 98.37 Treatment of the rectovaginal ligament. The rectovaginal ligament is clamped, cut and ligated

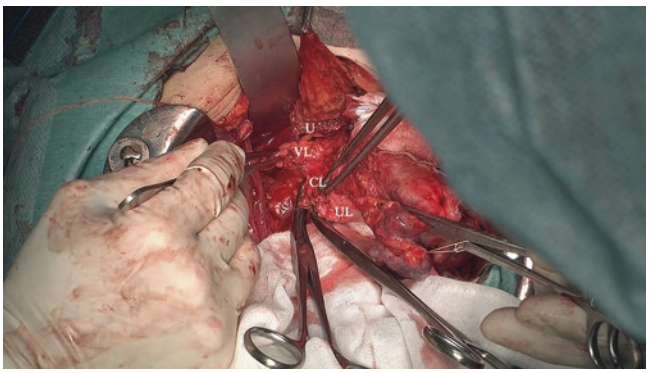

Fig. 98.38 Clamping of the cardinal ligament. In this case, due to tumor invasion of the cardinal ligament (*CL*), it is difficult to perform a nerve sparing procedure, thus the cardinal ligament is clamped. Vesicouterine ligament (*VL*), Uterosacral ligament (*UL*), Ureter (*U*)

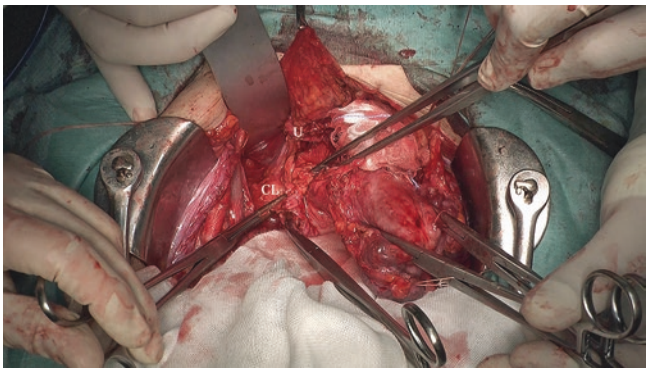

Fig. 98.39 Clamping of the cardinal ligament on the uterine side. The cardinal ligament (*CL*) of the uterine side is clamped

that nerve sparing is difficult when the rectovaginal ligament is cut and tumors are observed in the parametrium. Therefore, in Fig. 98.38, the cardinal ligament is clamped and cut.

Separation of the Bladder from the Vagina

The uterus is pulled to the cranial side while the bladder is pulled with a retractor to the caudal side, then the uterus is separated between the bladder and vagina with an electric scalpel (see Fig. 98.23). The separation is then performed from the central area.

Treatment of the Anterior Leaf of the Vesicouterine Ligaments

The vesicouterine ligaments are thinned as much as possible. However, as in this case, it is often difficult to thin the vesicouterine ligaments.

The uterus is pulled to the cranial side, the bladder retracted with a retractor to the caudal side and the uterine

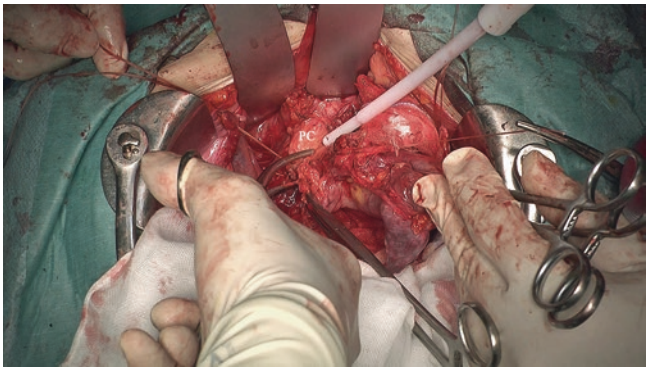

Fig. 98.40 Clamping of the paracolpium. The paracolpium (*PC*) is clamped

artery is also kept raised. Insert Cayley forceps along the urinary tract and create a ureteral tunnel (see Fig. 98.24). The first layer of the vesicouterine ligaments are separated with sealing device such as a Harmonic Focus® (see Fig. 98.25), or dissection ligation (see Fig. 98.26). After separating the superficial layer of the vesicouterine ligaments, for a urinary tract that is covered with loose connective tissue, push the ureter to the caudal side exposing the posterior leaf of the vesicouterine ligament (see Figs. 98.27, 98.28, and 98.29).

Treatment of the Posterior Leaf of the Vesicouterine Ligament

Thin between the posterior leaf of the vesicouterine ligament and paracolpium and clamp the posterior leaf of the vesicouterine ligament with forceps (see Figs. 98.30, 98.31, and 98.32). After it is confirmed with forceps to be far enough away from the ureter, sever the posterior leaf of the vesicouterine ligament and ligate. If any part of the posterior leaf remains cut it with a Harmonic Focus (see Figs. 98.33 and 98.34).

Cardinal Ligament and Rectovaginal Ligament Dissection.

The cardinal ligament and rectovaginal ligament are createded by the surgeon. In this case I do not cut the cardinal ligament till after cutting the rectovaginal ligament. Generally if a strong infiltration of cancer is observed the nerve plexus does not remain uncut. Figure 98.38 summarizes the clamping, disconnection and ligation of the rectovaginal and cardinal ligaments together (see Figs. 98.35, 98.36, 98.37, 98.38, and 98.39).

Paracolpium Disection

The paracolpium is clamped, cut and ligated (see Figs. 98.40, 98.41, 98.42, and 98.43).

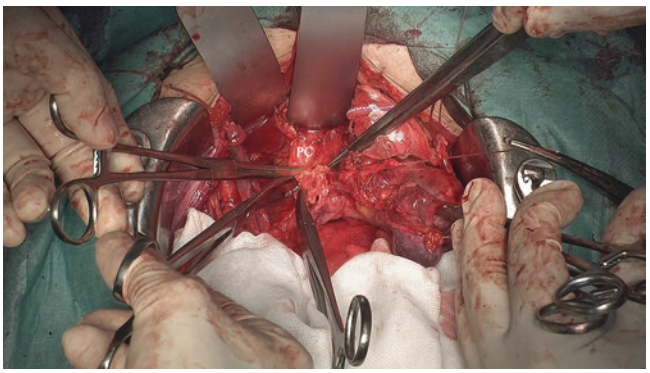

Fig. 98.41 Clamping of the paracolpium. After cutting the cardinal ligament, the paravaginal tissue remains on the lateral wall of the vagina. This is paracolpium (*PC*) and it is grasped with Sanritu fine serration forceps

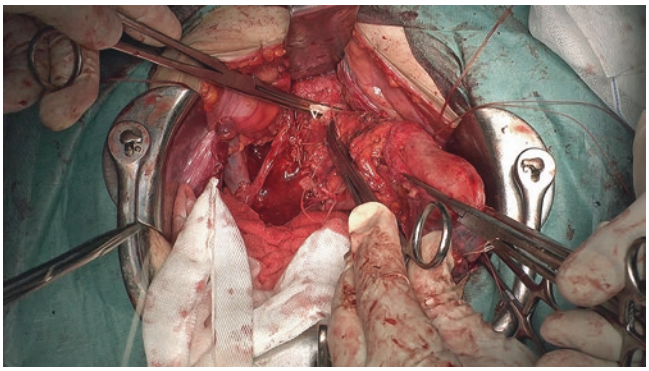

Fig. 98.44 Dissection of vaginal wall. The vagina (*V*) is clamped, and is cut. The edge of the vagina is closed with 1-0 Vicryl

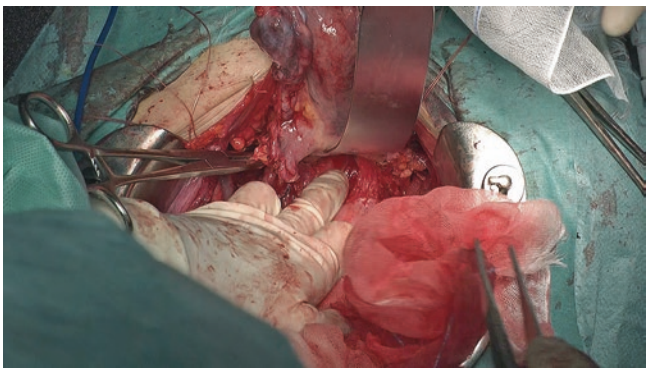

Fig. 98.42 Checking the rectum. After clamping the paracolpium, check to confirm that the rectum has not been clamped

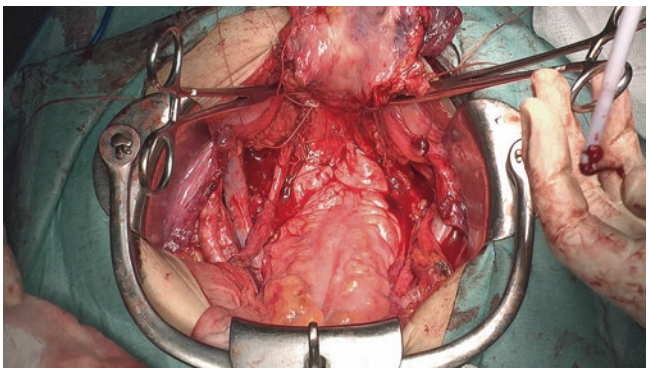

Fig. 98.45 Confirmation of the vaginal wall margin. From the posterior view, confirm that the rectum has not been damaged

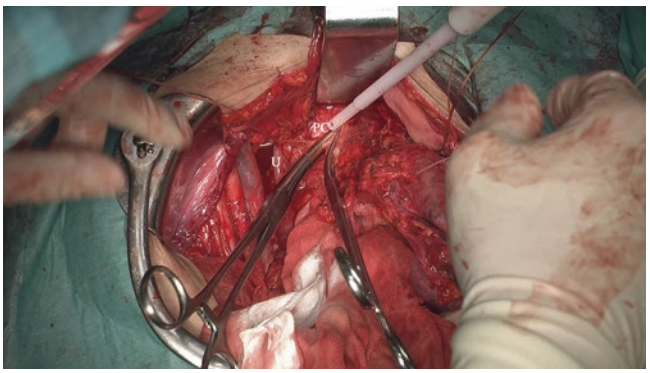

Fig. 98.43 Clamping of the paracolpium. The paracolpium is cut and ligated with 1-0 Vicryl. Ureter (*U*)

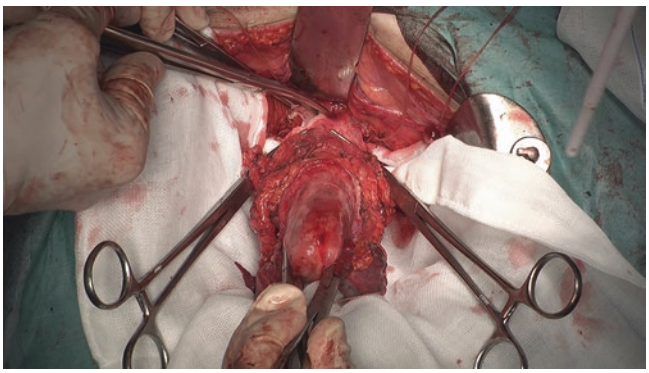

Fig. 98.46 Vaginal wall dissection. The vaginal wall is cut with Mayo scissors and the uterus is amputated from the vagina

Vaginal Tract Dissection

The vaginal tract is clamped laterally and dissection, as well as ligation, is then performed within the vaginal tract (see Figs. 98.44, 98.45, 98.46, 98.47, 98.48, and 98.49).

While most of the original Okabayashi procedure remains the same today, new adaptations to the original such as the development of the retroperitoneal space and performing a lymphadenectomy have made the procedure more convenient. After creating the retroperitoneal space and performing the

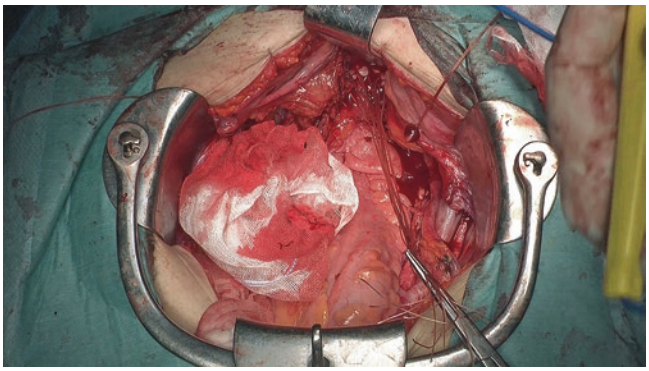

Fig. 98.47 Vaginal wall suture. The vaginal wall is closed with 1-0 Vicryl

Fig. 98.48 Extracted formalin fixed uterus. In the anterior view of the formalin fixed uterus, the 8 cm tumor is located in the cervix. Adequate vaginal tissue is removed

lymphadenectomy the surgeon can clearly see the structure of the ligaments. In addition, to the benefit of the patient, we now perform nerve sparing radical hysterectomy whenever possible, something that was not done in the original procedure.

Fig. 98.49 Posterior view of the formalin fixed uterus. In the posterior view of the formalin fixed uterus, the parametrial tissues are widely excised. The excised specimen includes the cardinal ligament, uterosacral ligament, vesicouterine ligaments, and adequate parametrial and paravaginal tissue

Radical Abdominal Hysterectomy with Electrosurgical Bipolar Vessel Sealing

99

Satoru Kyo

During each radical hysterectomy, a number of large vessels must be dissected, and firm hemostasis is absolutely required throughout the operative procedure. Therefore, reliable suture ligation is generally used to secure vascular pedicles in this operation; however, suturing involves clamping, cutting, and ligation, which together require considerable time and result in prolonged operative time and substantial blood loss. To resolve these operative issues, a variety of vessel sealing systems have been developed and used for this operation; these systems include LigaSure™ (Covident, Inc.), ENSEALR G2 Tissue Sealers Ethicon Endo-Surgery, Inc., Gyrus PlasmaKinetic Superpulse System (Gyrus, Inc.), and ERBE BiClamp™ Open (ERBE USA, Inc.). Several studies have compared the efficacy of these devices in a variety of fields [1].

We have used the LigaSure™ vessel sealing system, which is a hemostatic system involving a combination of pressure and bipolar electrical energy that can seal vessels up to 7 mm in diameter [2]. The device delivers a controlled high-power current at low voltage to melt and fuse the collagen and elastin within vessel walls. The seals created with LigaSure™ can withstand a minimum of three-times normal systolic pressure, resulting in a distinctive permanent translucent seal zone. In a study that compared the LigaSure™ system to three other approaches (ultrasonic coagulation, bipolar coagulation, or surgical clips and sutures), the LigaSure™ system created seals stronger than those created by the other energy-based ligation methods and comparable in strength with those created by mechanical ligation techniques [2]. Notably, this vessel sealing mechanism produces significantly less thermal spread than bipolar instruments because the energy automatically switches off when tissue impedance reaches a critical level [2]. Furthermore, the current delivered to achieve hemostasis takes between 2 and 4 s, which is faster than suture ligation. These technical merits prompted us to apply this vessel sealing system to radical hysterectomy. In our previous study [3], 85 consecutive cases involving radical abdominal hysterectomy (RAH) with pelvic lymphadenectomy for cervical cancer or endometrial cancer were analyzed; in 18 cases the LigaSure™ system was used to secure the vascular pedicles; in the remaining 67 cases, clamps were used, and the pedicles suture were ligated. Compared to the conventional suture group, the LigaSure group had a significantly and substantially shorter mean operation time (mean, LigaSure 242.8 ± 36.1 vs. conventional 349.1 ± 82.6 min, $P < 0.001$) (Fig. 99.1) and significantly less blood loss (mean, 583.1 ± 287.6 vs. 999.0 ± 524.2 ml, $P < 0.005$) (Fig. 99.2). Only one (0.06 %) of the 18 patients in the LigaSure group was transfused; in contrast, 27 (40.2 %) of the 67 patients in the conventional suture group were transfused. These findings indicated that the LigaSure vessel sealing system is useful for reducing blood loss in and shortening operating times of RAHs. In this chapter, I introduce our operative procedures and how to use vessel sealing system for RAH with a focus on sparing nerves.

The first step toward sparing the autonomic nerve is to isolate the hypogastric nerve and laterally translocate it before the dissection of the sacrouterine and rectouterine ligaments. To isolate the hypogastric nerve, we usually develop Okabayashi's pararectal space [4] by sharp dissection of broad ligament just above the ureter, making a shallow dimple that can be developed bluntly (Fig. 99.3). Using forceps, we isolate in a lateral direction a thin and loose lateral part of the broad ligament that sits directly underneath the ureter; this segment of the ligament is called the mesoureter or ureteral leaf and it contains the hypogastric nerve. This procedure exposes a firm medial part of the ligament that consists of the uterosacral fibers. Eventually, the hypogastric nerve is translocated laterally by this maneuver. Then, the medial part of the broad ligament that consists of the sacrouterine fibers is resected, while the hypogastric nerve is far from the line of resection and is safely preserved. The

hypogastric nerve can be fully isolated from the mesoureter and be marked by taping (Fig. 99.4).

Among the most suitable targets for this vessel sealing system in RAH are the cardinal ligaments, which include the deep uterine veins and middle vesical veins; these vessels are particularly suitable targets because they are situated most deeply in the pelvic cavity and are often hard to handle. We preferentially use LigaSure Impact™ (Fig. 99.5a) on this site because this system has an ideal blade size and a ligation strength that is suited to the broad ligaments and large vessels. Furthermore, we prefer the shape of the blade because of the gentle curve, which is preferable for ligaments located in the deep layer of the pelvic cavity. Figure 99.6 shows the three major vessels of the left cardinal ligament (the deep uterine vein, middle and inferior vesical veins); all three veins converge into the internal iliac vein. These vessels are most clearly exposed by complete dissection of the cardinal lymph nodes with ultrasonic surgical aspirators. Of these three vessels, only the deep uterine vein should be dissected; the other two usually remain untreated. The distal-most cut line depends upon the judgment of the surgeons, and this judgment is informed by clinicopathological findings of cancer. In some cases, the deep uterine vein swells to greater than 5 mm in a diameter; notably, we have successfully treated deep uterine veins that were 7–8 mm in a diameter. To guarantee secure and complete seals, we prefer to repeatedly seal one site when completing the first sealing. Because the area of the pelvic splanchnic nerves and plexus is anatomically separated from these vessels at the cardinal ligament [5], this dissection does not affect the function of the splanchnic nerves. Thereafter, the uterine-side edge of the deep uterine vein is ventrally elevated by detaching the surrounding membranes over the upper border of the hypogastric nerve tract; this maneuver results in complete separation of the deep uterine vein from the pelvic nerve plexus (Fig. 99.7) [6]. The bladder branch of the pelvic nerves arises from the pelvic plexus at the same level with the hypogastric nerve tract; consequently, the subsequent resection of the rectovaginal ligament above this level guarantees the preservation of the bladder branches of the pelvic nerves, while the deep uterine vein can be fully resected.

Other prime sites for the use of vessel sealing are the anterior and posterior layers of the vesicouterine ligaments that encircle the ureter. Making a "ureter tunnel" in the space just inside the ureter is the initial step in stratifying the anterior and posterior layers of this ligament. After making the tunnel, the ureter is laterally translocated with forceps; the space between the ureter and the cervix in the anterior layer of vesicouterine ligament is then carefully sealed up to the vesicoureteral junction; a secure seal in this layer usually requires three to four consecutive sealing processes. This layer contains two or three vesicocervical veins. Although these vessels are small, establishing hemostasis at these vessels is sometimes difficult because the ureter is very close and surgical carelessness can result in ureter injury. We preferentially use the LigaSure Small Jaw™ (Fig. 99.5b) at this site; this tool is probably best choice for the sealing of this site because of the size and the shape of the blade (Fig. 99.8). To reduce costs by avoiding using two

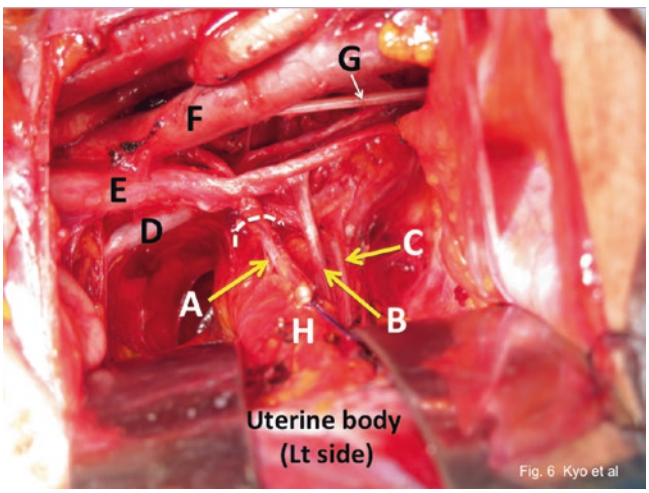

Fig. 99.6 Left-side view of the uterus and pelvic cavity. The three major vessels associated with the left cardinal ligament are shown; (*A*) Deep uterine vein. (*B*) Middle vesical vein. (*C*) Middle rectal vein. These vessels were fully exposed after complete dissection of cardinal lymph nodes with ultrasonic surgical aspirators. (*D*) Internal iliac vein. (*E*) Internal iliac artery. (*F*) External iliac vein. (*G*) Obturator nerve. (*H*) Uterine-side edge of dissected uterine artery. *Dotted lines* indicate possible vessel sealing system cut line for the deep uterine vein

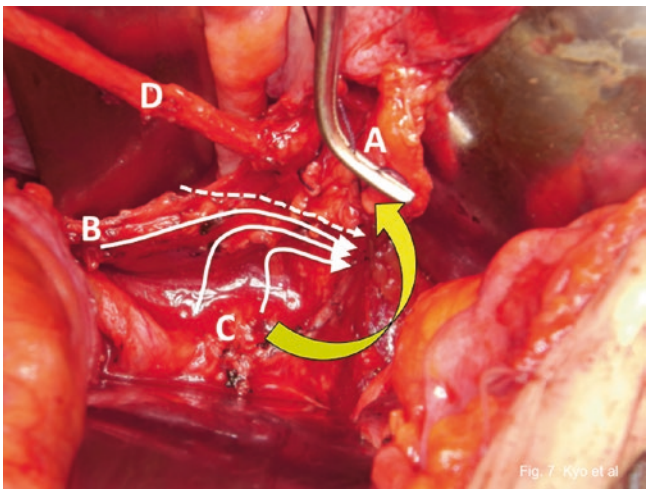

Fig. 99.7 Separation of deep uterine veins from the pelvic nerve plexus. The uterine-side edge of the deep uterine vein (*A*) is ventrally elevated by detaching the surrounding membranes over the upper border of the hypogastric nerve tract, resulting in complete separation of the deep uterine vein from the pelvic nerve plexus. *Solid lines* and arrowheads show the hypogastric nerve (*B*) and splanchnic nerve tracts (*C*), which together comprise the pelvic nerve plexus. Since the bladder branch of the pelvic nerves arises from the pelvic nerve plexus at the same level with the hypogastric nerve tract, the subsequent resection of the rectovaginal ligament above this level (shown as *dotted line*) guarantees the preservation of the bladder branches of the pelvic nerves, while the deep uterine vein can be fully resected. (*D*) Ureter

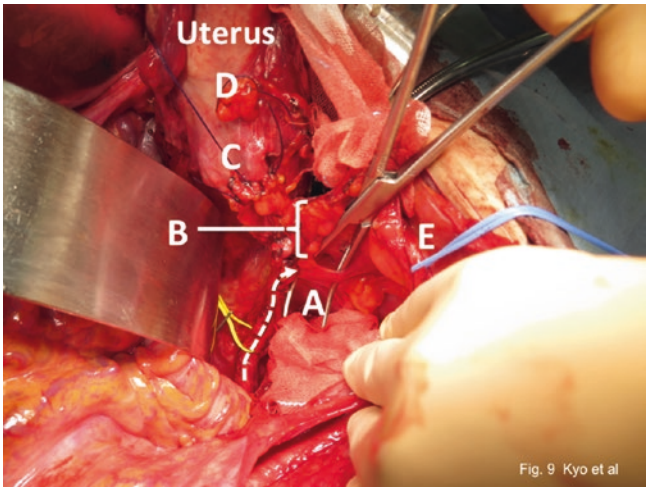

Fig. 99.9 Isolation or prediction of vesical nerve tracts in the posterior layers of vesicouterine ligaments. Lateral view of the right pelvic cavity. The tracts of vesical branches of pelvic nerves (*A*) are exposed by the forceps, which are continuous with the hypogastric nerves (shown in a *dotted line*). (*B*) Posterior layers of vesicouterine ligament. (*C*) Uterine-side edge of dissected deep uterine vein. (*D*) Uterine-side edge of dissected uterine artery. (*E*) Ureter

different sealing devices, the LigaSure Impact™ might be used for both the vesicouterine and cardinalvesicouterine ligaments; however, the blade seems slightly large for manipulating the vesicouterine ligament. Conversely, the LigaSure Small Jaw™ might be used for both ligaments; however, this tool appears to be insufficient in size to seal the larger vessels. Either way, the important point when using these devices in pelvic cavity, especially for the vesicouterine ligament, is to avoid heat injury of the ureter. Sufficient lateral translocation of the ureter with forceps is essential for avoiding such injury (Fig. 99.8).

The use of these devices for the posterior layers as well as subsequently for the paracolpium raises another concern. These tissues include autonomic nerves, called "vesical branches", and these nerves arise from the pelvic nerve plexus. Heat injury or directly cutting of these nerves causes post-operative urinary dysfunction. Although it is not always successful, we often attempt to visualize the bladder branches that run along these sites and to isolate these branches with tape (Fig. 99.9). Even when these branches cannot be visualized, it is optimal to predict the course of these nerve tracts in these tissues. Anatomically, the tracts of the vesical branches of pelvic nerves are continuous with the hypogastric nerves; however, the latter joins the pelvic splanchnic nerves from the sacral nerves (S2, 3, and 4) from which the vesical branches arise. Therefore, we mark the hypogastric nerve, which is easily identified between the rectouterine ligament and the mesoureter (Fig. 99.4). The posterior layer of the vesicouterine ligament can be dissected with either LigaSure Impact™ or LigaSure Small Jaw™ when special care is taken to keep sufficient distance between the sealing lines and the nerve

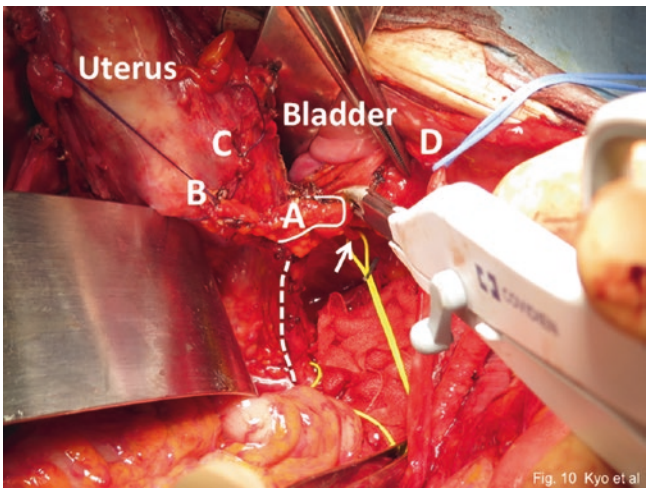

Fig. 99.10 Dissection of the posterior layer of the vesicouterine ligament with the LigaSure™ Small Jaw. The posterior layer of the vesicouterine ligament (*A*) should be dissected without cutting these nerves. When these nerves are hard to visualize, the surgeon should carefully predict the tract of the nerves by recognizing that they are continuous and in line with the hypogastric nerves (shown as *dotted line*). The arrow indicates the bladder branches of the pelvic nerves, which are isolated and marked with tape. The *solid line* indicates the line to be dissected; the lateral edge of this line should be completely out of the line of the vesical branches of pelvic nerves. (*B*) Uterine-side edge of dissected deep uterine vein. (*C*) Uterine-side edge of dissected uterine artery. (*D*) Ureter

tract in these sites; such distance is essential to preventing intra- and postoperative complications in urinary function (Fig. 99.10).

The selection of devices for each site may be challenging for surgeons. Very recently, a new device (LigaSure Maryland 23™) that can resolve this issue has become available (Fig. 99.5c). This device has an intermediate blade size that is suitable for both the cardinal ligament and the vesicouterine ligaments. Furthermore, this new device has a longer shaft than the LigaSure Small Jaw™; this additional length facilitates sealing the ligaments in deeper positions, such as the rectovaginal ligaments. I believe that LigaSure Maryland 23 ™ can be used at every site for nerve-sparing RAH and that this multi-functionality should reduce surgical costs.

Finally, I will briefly address the use of these devices at other sites, such as the upper ligaments of the uterus or infundibulopelvic ligaments. These other sites are very amenable to mechanical suturing, and I think that use of LigaSure devices is not necessary for these other sites and that it is more important to avoid exhausting the devices and optimizing LigaSure-mediated sealing at the less tractable sites.

ARH as a Nerve-Sparing Procedure

100

Tomoyasu Kato

Pelvic organ function is organized by both central and peripheral nerve system. For instance, the lower urinary tract is innervated by 3 sets of peripheral nerves involving the parasympathetic, sympathetic, and somatic nervous systems. Pelvic parasympathetic nerves arise at the sacral level of the spinal cord, excite the bladder, and relax the urethra. Lumbar sympathetic nerves inhibit the bladder body and excite the bladder base and urethra. Pudendal nerves excite the external urethral sphincter. These nerves contain afferent sensory as well as efferent motor axons. These autonomic nerves are running and distributed as shown in Fig. 100.1.

Autonomic nerve damage during surgery is thought to play a crucial role in the etiology of bladder dysfunction, sexual dysfunction and colorectal motility disorders that are seen in patients after radical hysterectomy [1]. Bladder dysfunction is present in 70–85 % of patients for up to 12 months postoperatively, including urinary or anal incontinence or retention [1]. In order to prevent these complications, Japanese gynecologists introduced a surgical technique with preservation of the pelvic autonomic nerves in 1961 [2]. Thereafter Japanese doctors had learned and modified this procedure. In the twentieth century there were few articles reported in English [3, 4]. It is only recently that nerve-sparing radical hysterectomy has been introduced to Western [5] as well as to Asian countries [6]. As the postoperative QOL was noted, studies on precise neuroanatomical studies [1, 7] as well as the technique of nerve-sparing radical hysterectomy were reported [8]. Nowadays the concept of preservation of autonomic nerves during radical hysterectomy has become standard in many gynecological cancer centers in the world [9].

These autonomic nerves related to bladder function can be dissected during the different phases of radical hysterectomy. A level of nerve preservation is classified into 4 levels: non-touch, exposure, partial preservation and dissection. From a point of view on nerve preservation, non-touch preservation provides high quality of life. Simple and modified radical hysterectomy can archive non-touch preservation of autonomic nerves, however, they compromise radicality for invasive cervical cancer. To achieve a good balance between radicality and retaining pelvic function, we conducted to perform exposure or partial preservation of these autonomic nerves. Our procedures based on the previous anatomical study are noted as follows [7]:

1. Opening of retroperitoneal spaces (Figs. 100.2, 100.3, 100.4, and 100.5)
2. Identification of the hypogastric nerves during developing the pararectal space (Figs. 100.6, 100.7, 100.8, and 100.9):

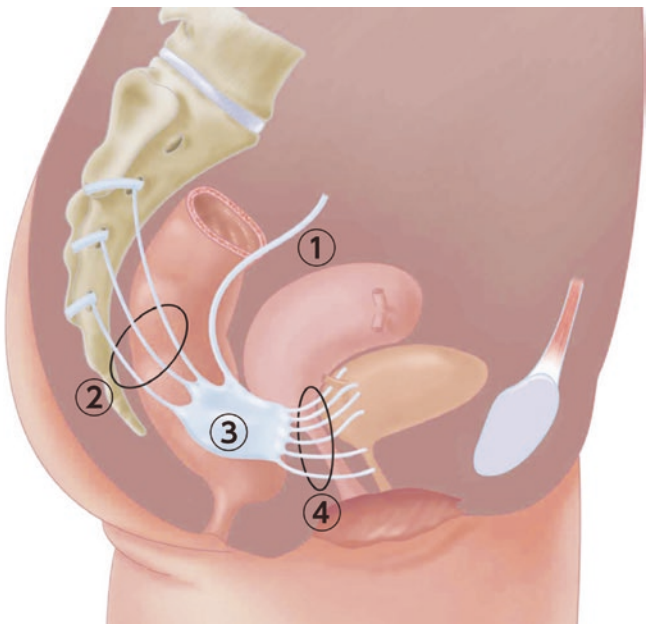

Fig. 100.1 Illustration of running of autonomic nerves in the pelvis (right lateral view) *1*: Hypogastric nerves, *2*: Pelvic splanchnic nerves (S2 – 4), *3*: Pelvic plexus, *4*: Vesical branches

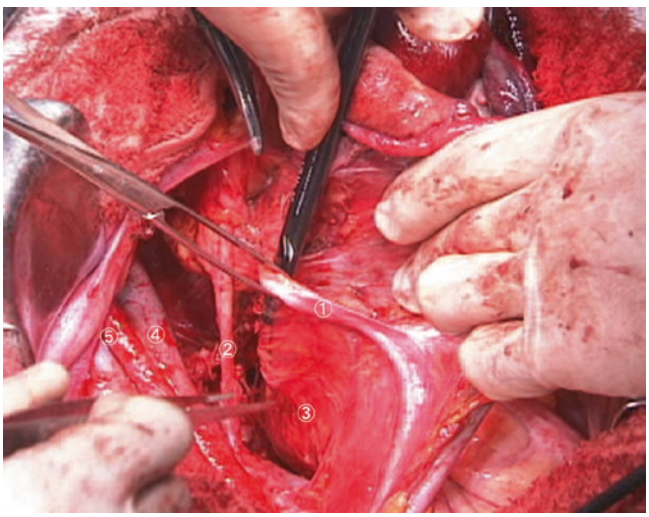

Fig. 100.6 Separation of the ureterohypogastric fascia from the posterior leaf of the broad ligament. The ureterohypogastric fascia including ureter is separated from the posterior leaf of the broad ligament. This isolation progresses in a downward direction. *1*: Ureter; *2*: Internal iliac artery, *3*: Hypogastric nerves, *4*: External iliac vein, *5*: External iliac artery

Developing the pararectal space between the ureter and the internal iliac vessels, the hypogastric nerves (HGN) running along the rectum is to be identified. The ureter is separated from the retroperitoneum and this tissue plane is kept facing downwards. The ureter should not be free from the posterior layer of the broad ligament. HGN are found to be running in parall under 3–4 cm of the ureter. This tissue plane is corresponded to the ureterohypogastric fascia (UHF), which includes the HGN and the pelvic plexus.

3. Pelvic lymphadenectomy (Figs.100.10, 100.11, 100.12, and 100.13)

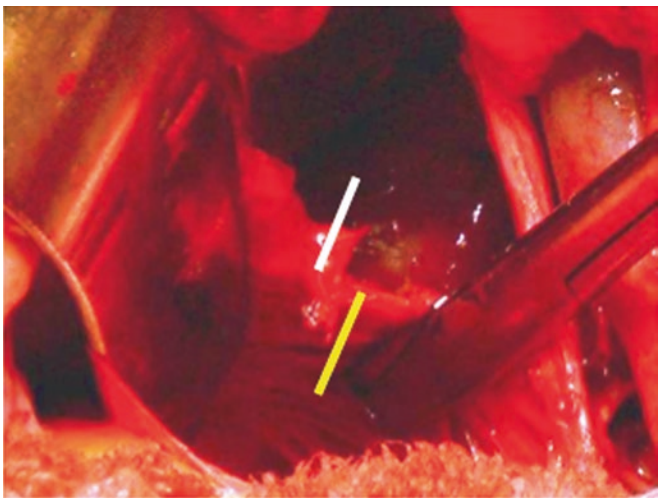

Fig. 100.14 Division of the cardinal ligaments according to the original procedure. According to the original procedure [2], the cardinal ligament is divided into two parts. The superficial vascular part (*white line*) is dissected, while the deep neural part (*yellow line*) that contains the pelvic splanchnic nerves is preserved

4. Preserving the pelvic splanchnic nerves during dividing of the cardinal ligament (Figs. 100.14, 100.15, 100.16, and 100.17):

According to the original procedure [2, 3], the cardinal ligament (CL) is divided into two parts. The superficial vascular part is dissected, while the deep neural part that contains the PSN is preserved. Because the surgical margin of the CL might compromise radicality, the indication of this method is limited to cervical cancer with early stage. In order to raise radicality of nerve-sparing radical hysterectomy we demonstrated that the pelvic splanchnic nerves (PSN) arise from the dorsomedial portion of the neural part of the CL, based on operative findings as well as fresh cadaver studies [7].

The CL is dissected immediately above the middle rectal artery as close as possible to the pelvic sidewall. The PSN originating from S3 run to the pelvic plexus dorsal to the middle rectal artery. The landmark of middle rectal artery is vessels that run under 1–2 cm of the deep uterine vein and pierce the pelvic plexus.

5. Developing the rectovaginal space (Figs. 100.18, 100.19, 100.20, 100.21, and 100.22)

To connect both ends of posterior layer of the broad ligament, the peritoneum of cul-de-sac is dissected. As the rectum being pulled cranially with gauze, the rectovaginal space is developed.

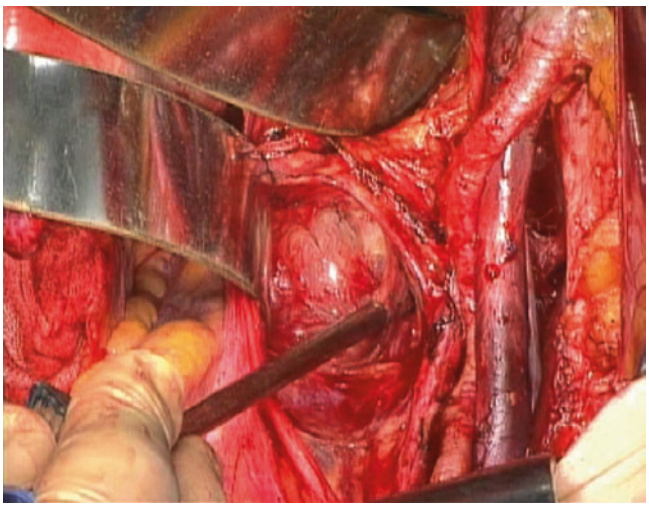

Fig. 100.15 Developing of the paravesical and the pararectal spaces. The cardinal ligaments are exposed

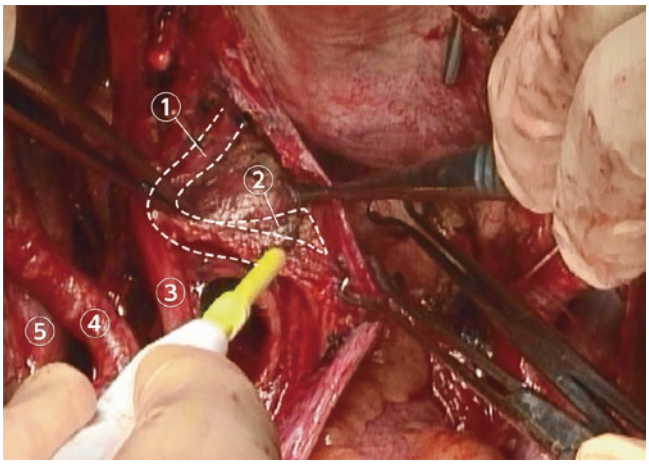

Fig. 100.19 Separation of the ureter and ureterohypogastric fascia from the broad ligament. The ureter and ureterohypogastric fascia is further separated from the peritoneum until the entrance of the ureteric tunnel. *1*: Ureter; *2*: Ureterohypogastric fascia, *3*: Internal iliac artery, *4*: External iliac artery, *5*: External iliac vein

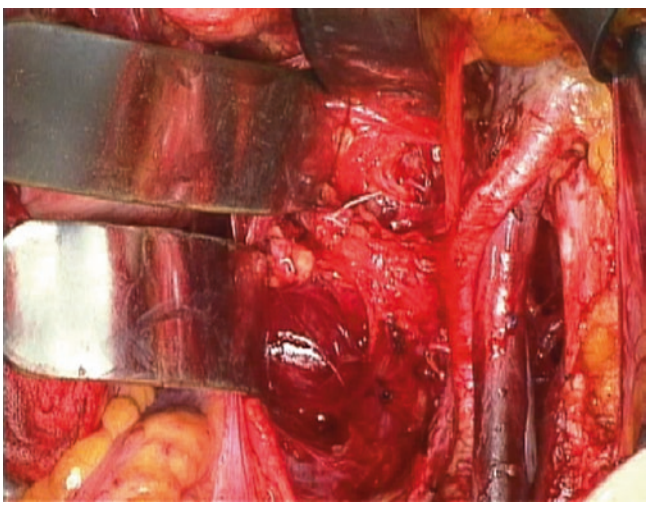

Fig. 100.17 Final view of division of the cardinal ligament. The PSN from S3 is running beneath the middle rectal artery

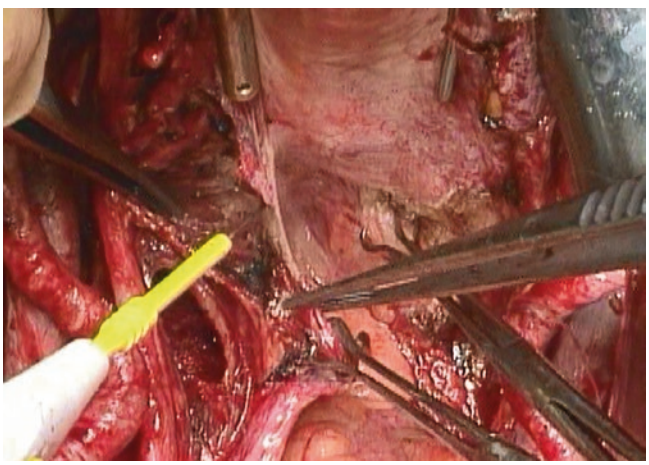

Fig. 100.20 Incision of the posterior leaf of the broad ligament. The posterior leaf of the broad ligament is incised to mobilize ureter laterally

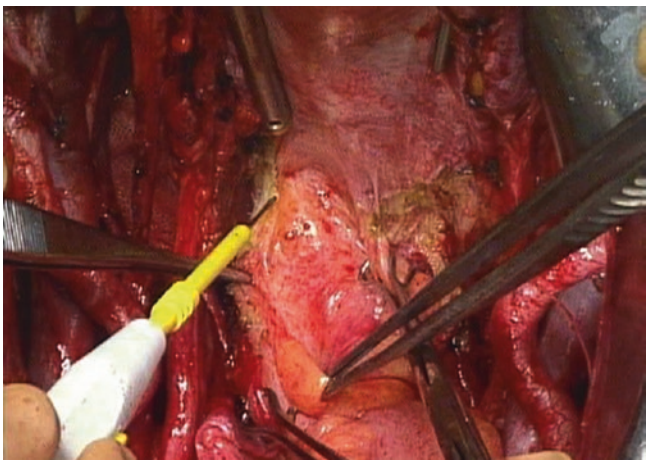

Fig. 100.21 Incision of peritoneum of the cul-de-sac. To connect both ends of posterior layer of the broad ligament, the peritoneum of the cul-de-sac is incised

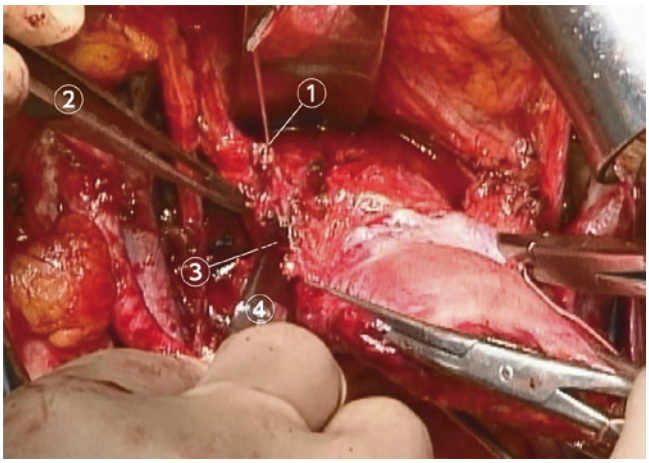

Fig. 100.23 Division of the anterior layer of the vesicouterine ligament. The ureteral tunnel is deroofed, allowing exposure of the ureters. *1*: Stump of uterine artery *2*: Superior vesical vein, *3*: Ureter, *4*: Ureteric tunnel (behind the sccissors)

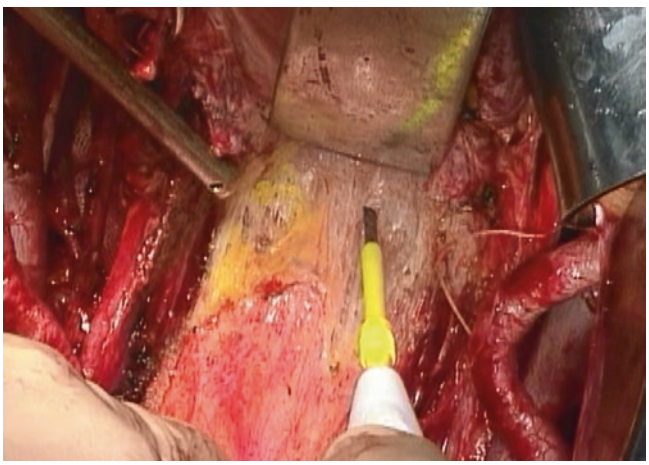

Fig. 100.22 Developing the rectovaginal space. The rectum is dissected sharply down 3 to 4 cm from its attachment to the vagina

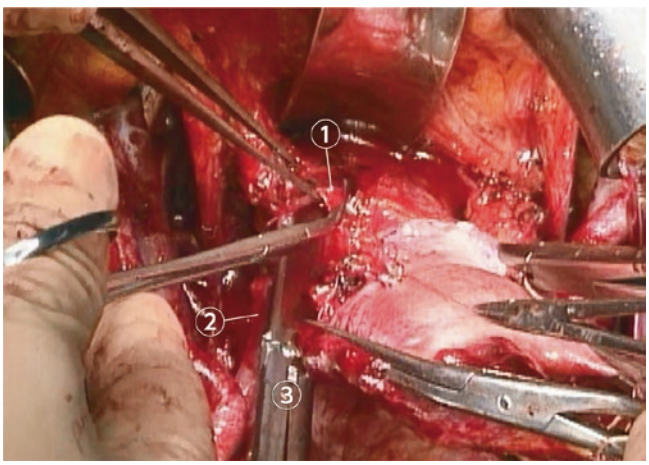

Fig. 100.24 Division of cervicovesical vessels. Division of cervicovesical vessels leads to roll ureter downward and laterally. The bladder is further dissected laterally to expose the paracolpium. *1*: Cervicovesical vessels, *2*: Ureter, *3*: Ureteric tunnel

6. Dissection of the anterior layer of vesicouterine ligaments with keeping the ureterohypogastric fascia (Figs. 100.23 and 100.24)
7. Preserving the pelvic plexus during dissection of the uterosacral ligaments (Figs. 100.25, 100.26, 100.27, and 100.28):

The UHF is incised at midline between the HGN and the ureter. The HGN entered the pelvic plexus at the anterosuperior corner. Deep uterine vein is located below the HGN. The HGN and the pelvic plexus were frequently damaged during dissection of the uterosacral ligaments (USL). To diminish these nerve injuries, the medial stump of the CL should be fully mobilized above the HGN before dissecting the USL. In the case of the tumor with deep myometrial or parametrial invasion, we dissect the USL just below the medial stump of the CL. Then the pelvic plexus is preserved partially.

8. Preserving the bladder branches during the dissection of the rectovaginal ligaments (Figs. 100.29 and 100.30):

The ventral half of bladder branches to the ureter are more likely to be injured in dissection of the posterior leaf of the vesicouterine ligament for wide resection of the paracolpium and the vagina. In order to maximize preservation of the dorsal half of bladder branches, the rectovaginal ligaments should be clamped using right angle forceps not to involve them.

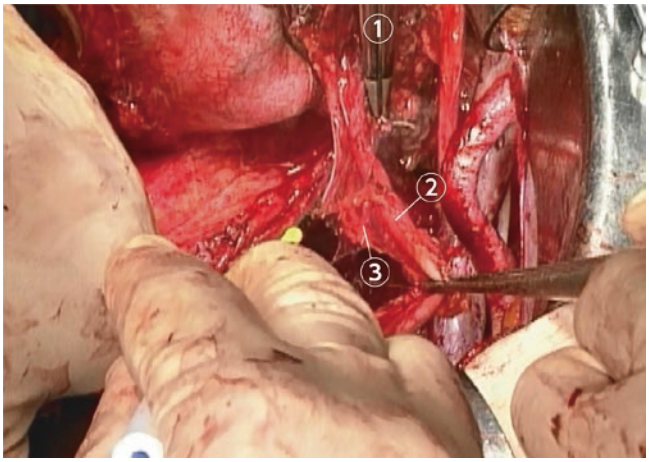

Fig. 100.25 Incision of the ureterohypogastric fascia. Right ureterohypogastric fascia is incised at midline between the ureter and hypogastric nerves. *1*: Medial stump of the cardinal ligaments *2*: Ureter, *3*: Ureterohypogastric fascia

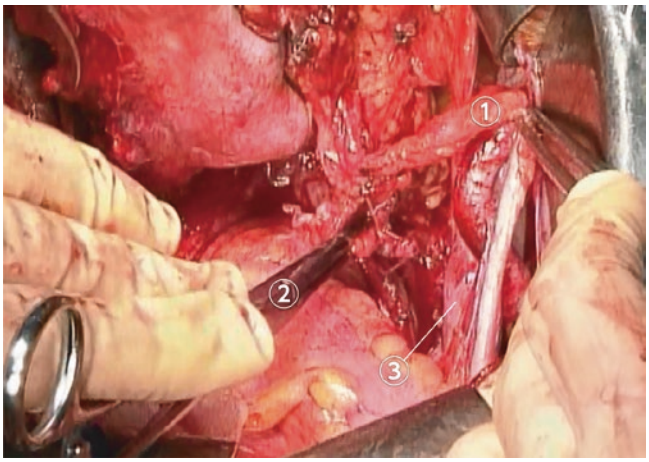

Fig. 100.26 Re-clamping of the medial stump of the cardinal ligaments. The medial stump of the cardinal ligament is re-clamped from the inside of the ureterohypogastric fascia. *1*: Ureter *2*: Medial stump of the cardinal ligaments, *3*: Ureterohypogastric fascia

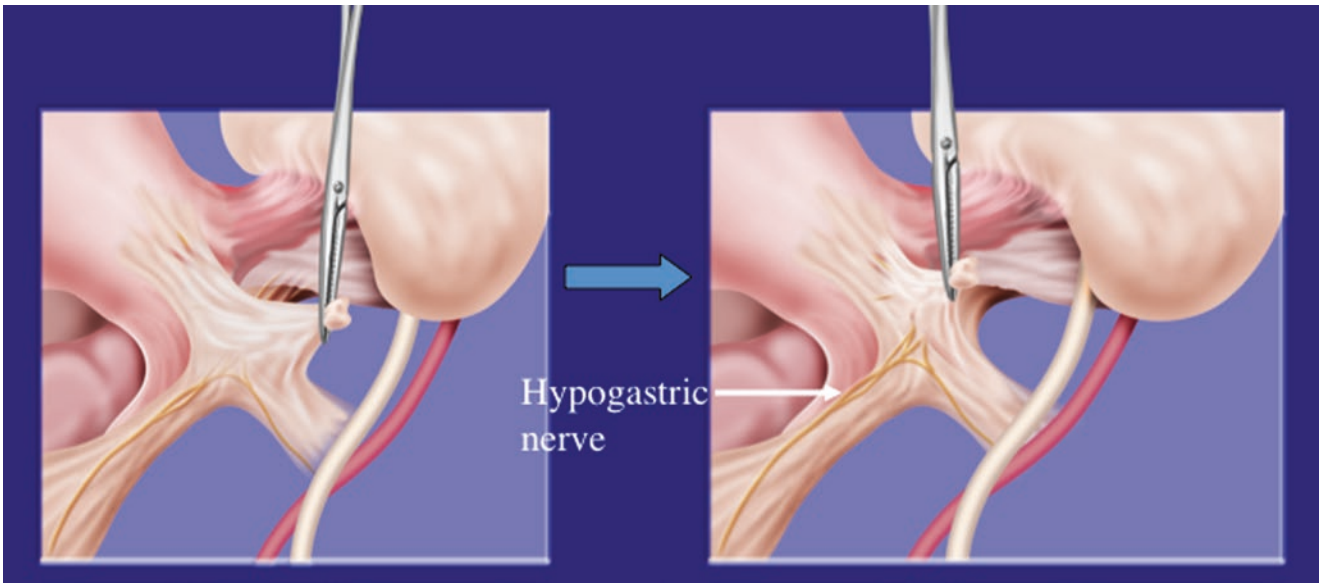

Fig. 100.27 Mobilization of medial stump of cardinal ligaments. The bottom of medial stump of the cardinal ligaments usually located beneth the hypogastric nerves. To diminish these nerve injuries during dissecting the uterosacral ligaments, the medial stump of the cardinal ligament should be mobilized above the hypogastric nerves in advance

9. Dissection of the posterior layer of vesicouterine ligaments (Figs. 100.31, 100.32, 100.33, and 100.34):

Further rolling the ureter allows the clearance of the boundary between the posterior layer of the vesicouterine ligaments and the paracolpium. Forceps are inserted into this boundary.

10. Dividing the paracolpium and the vagina (Figs. 100.35, 100.36, 100.37, and 100.38)

Separating the paracolpium from the posterior layer of the vesicouterine ligament to extend the resection field of the paracolpium is an original point of Okabayashi hysterectomy [10, 11]. This procedure allows us wider and longer resection of paracolpium and vagina.

11. The level of preservation of autonomic nerves after nerve-sparing radical hysterectomy (Figs. 100.39, 100.40, 100.41, 100.42, 100.43, and 100.44):

Dissection line of autonomic nerves by our procedures is indicated by red line in Fig. 100.43. According to our method, the HGN are found to preserved in exposure, the PSN in non-touch or exposure, pelvic plexus in exposure or partial, and

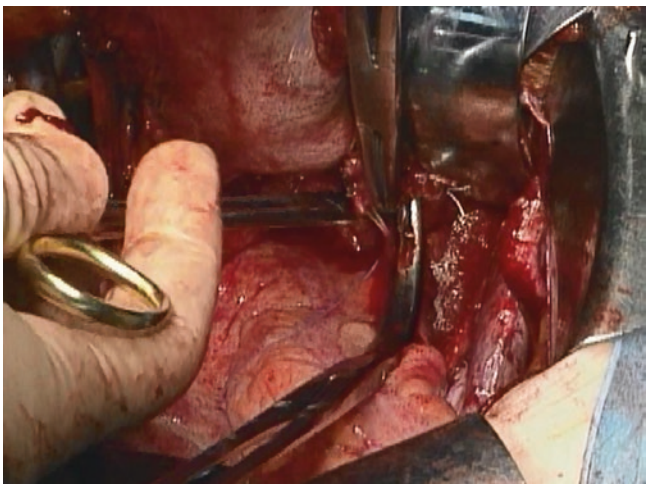

Fig. 100.28 Division of the sacrouterine ligaments. The uterosacral ligaments are divided immediately the hypogastric nerves

Total and Peritoneal Mesometrial Resection

101

Benjamin E. Wolf and Nadja Dornhöfer

Principles of Conventional Radical Hysterectomy and Their Shortcomings

Since the introduction of radical hysterectomy as the main surgical approach to the treatment of cervical cancer about 100 years ago, only minor modifications of the procedure as proposed by Wertheim have been made (Wertheim 1912). Endoscopy and robotically assisted surgery as well as nerve sparing surgical techniques have reduced postoperative morbidity and sequelae significantly [6, 24]. In essence, traditional radical hysterectomy is based on the principle of wide excision, which is considered to be the basis of curative cancer resection. This principle has not changed over more than 100 years.

The concept of wide excision rests on two assumptions which are regarded hallmarks of malignant tumors: that cancer growth is isotropic, dissipating peritumoral tissues potentially in all directions following paths of least mechanical resistance, and that the macroscopic and microscopic tumor fronts can be preceded by the spread of occult tumor cells. Thus, all tumors should be resected with a metrically defined radial margin of microscopically healthy tissue (Fig. 101.1a–d).

The width of resection margins is considered the most important quality parameter of wide excision which may necessitate the resection of functionally important healthy adjacent tissue increasing procedure related morbidity. However, the association between margin width and probability of local tumor recurrence is not robust and results of different studies examining the benefit of wider excision margins have reported conflicting results [16].

Nevertheless, if such empirically defined tumor-free margins cannot be achieved surgically as determined by histological examination, adjuvant chemo-radiotherapy is considered standard of care [23, 26, 28]. Less frequently, targeted additional tissue resection can be considered in some situations.

Although adjuvant radiotherapy leads to a significant reduction in local tumor recurrence in cervical and endometrial cancer, it is associated with additional morbidity without improving overall survival [25]. According to data from Landoni and colleagues, adjuvant radiotherapy is required in up to 54 % of patients treated for cervical cancer [20]. Finally, local tumor control fails in up to 50 % of cervical cancer patients treated with surgery alone and in 10–20 % of patients receiving adjuvant radiotherapy [8].

Depending on tumor characteristics and stage, regional lymph node dissection is an integral part of operative tumor staging and in the case of metastasis part of tumor debulking surgery in cervical cancer. If histological analysis reveals lymph node metastasis, patients are usually referred for adjuvant radiation, frequently combined with chemotherapy as well [26, 28].

In endometrial cancer, the benefit of adjuvant radiation is unclear, as is the role of lymph node dissection with both treatments adding significantly to treatment related morbidity [10]. Traditional radical hysterectomy including bilateral salpingo-ovarectomy combined with adjuvant radiation (if indicated) leads to a good overall survival of about 90 % for patients with stage I endometrial cancer and a favorable histological risk factor profile. However, 5-year overall survival for stage I endometrial cancer patients can fall below 50 % depending on histologic risk factors. In patients who do not receive adjuvant radiation, 45–65 % of recurrences occur primarily in the pelvis while most patients die of distant metastasis [1]. Pelvic recurrence indicates that tumor foci are left in place during initial surgical treatment. Adjuvant radiotherapy fails to eliminate these residual tumor foci since adjacent pelvic structures frequently limit maximal radiation dose and volume and thus cannot reach all potential areas of residual tumor [7]. Not surprisingly, the PORTEC-1 study of

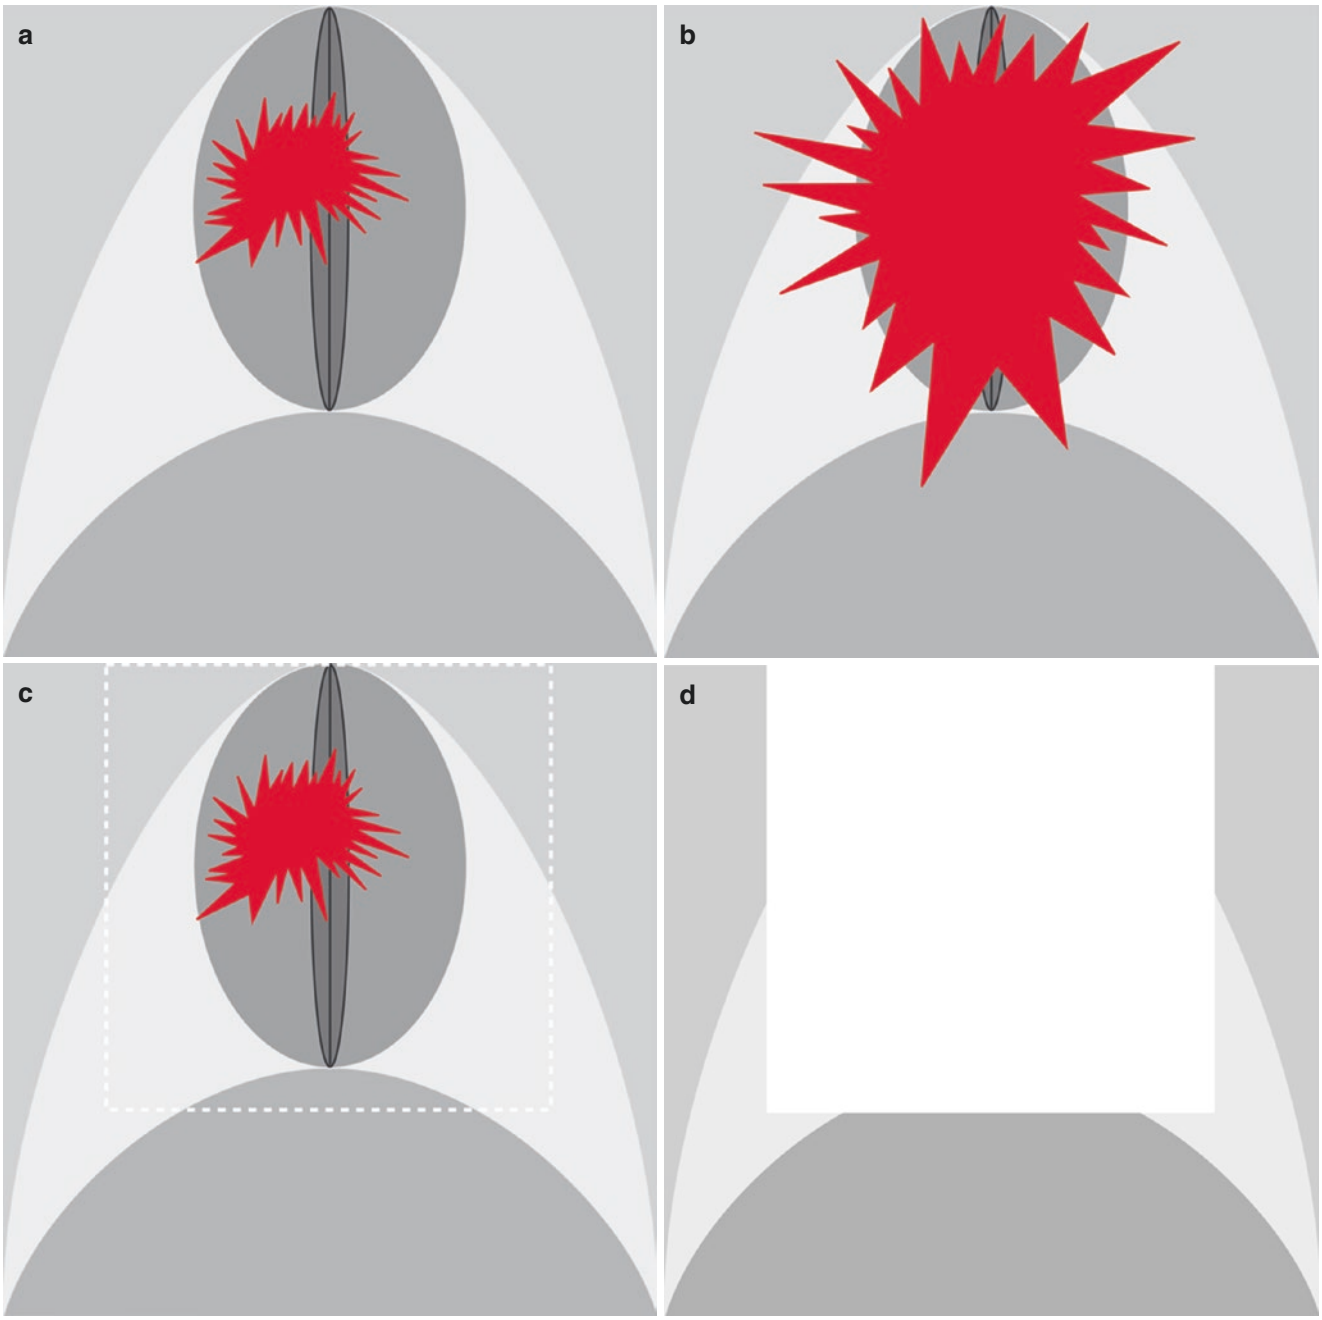

Fig. 101.1 Traditional theory of tumor spread. Traditional theories of tumor spread assume isotropic tumor permeation of all surrounding tissues (**a**, **b**). Surgical tumor resection aims to achieve metrically defined clear margins at all sides (**c**, **d**) (Courtesy of Prof. Michael Höckel. Modified from Höckel [14] (Reproduced with permission by Future Medicine Ltd))

stage I endometrial cancer found a significantly improved reduction in loco-regional recurrence but no improvement in overall survival [4, 27]. The 10-year locoregional recurrence rates were 5 % in patients receiving adjuvant radiation and 14 % (p<0,0001) in the observation group while 10-year overall survival was 66 % and 73 % respectively (*P*=0.09). The most common site of relapse was isolated vaginal recurrence (73 %).

Local recurrence of endometrial cancer in patients who did not receive adjuvant radiotherapy initially can frequently be treated successively by salvage surgery while most recurrences after adjuvant or primary radiotherapy are not amenable to surgical treatment. This was also shown in the PORTEC- trial for vaginal recurrence: 70 % of patients who did not receive adjuvant radiation were treated successfully by salvage surgery while this was only the case in 38 % of patients with adjuvant radiation [27].

15-year follow-up data of this trial published in 2011 confirmed that survival after vaginal relapse was 51 % in patients who did not receive adjuvant radiation while it was 25 % in irradiated patients. Survival-rates for pelvic relapse were 18 % and 0 % respectively. There was a trend towards an increased incidence of second cancer in irradiated patients [5]. Also, in the ASTEC/EN5 combined trial analysis [3], no overall survival benefit of adjuvant external beam radiation following surgery for medium and high risk stage I endometrial cancer was found.

This probably explains the fact, that a reduction in pelvic recurrence in patients who receive adjuvant radiotherapy does not translate into an overall survival benefit [10].

Especially for patients with a high risk for recurrence as determined by histological factors, there is urgent need for an improved surgical strategy without the need for adjuvant radiation. Studies examining the therapeutic role of lymph node dissection have revealed conflicting results (ASTEC and [2]; Panici et al. 2008; [29]). This can be explained by the inconsistency with regard to extend and quality of lymph node dissection across different studies with many not taking into account the possible routes of lymphatic spread and performing only pelvic lymph node dissection. As such, only pelvic lymphonodectomy was performed consistently in the ASTEC and the Italian trial reported by Panici et al. even though it has been clearly shown that the risk for isolated paraaortic lymph node metastasis in patients with tumor free pelvic lymph nodes can be as high as 16 % [22]. This could explain why there was a therapeutic benefit for patients treated with systematic pelvic and paraaortic lymph node dissection in the retrospective SEPAL study [29].

In summary, the established gynecological cancer operations are based on functional anatomy and on a model of radial progressive tumor permeation. They aim to resect tumors with a metrically defined radial margin of tumor-free, healthy tissue accepting a hereby caused higher morbidity. Nevertheless, this treatment strategy often needs additional adjuvant (chemo)radiation which further increases treatment-related morbidity and relapses still occur. Therefore, new strategies with a better therapeutic index were needed to improve oncologic outcome and lower morbidity.

The Ontogenetic Theory of Cancer Fields: New Strategies for Gynecologic Oncology

During the last two decades, a new paradigm of radical oncological surgery based on considerations derived from ontogenetic anatomy has been pioneered by Michael Höckel.

During embryonic morphogenesis, tissue domains with increasing specificity and differentiation develop. In this process, definite compartments and finally subcompartments evolve from early and late developmental metacompartments. This process is thought to be driven by the sequential activation of genetically encoded developmental programs which are silenced successively until a state of morphostasis is reached in adult organisms [18]. According to the ontogenetic theory of cancer fields, malignant progression of cancer is caused by a retrograde activation of these developmental programs. Reactivation of these programs occurs in a fixed sequence and thus cancerous morpholysis follows a predictable way. During malignant progression, a tumor arising in an ontogenetic subcompartment sequentially infiltrates the surrounding compartment and then successively the late and early metacompartments. Transgression from one developmental domain to the next is the phenotypic correlation of malignant progression. Thus, at a certain tumor stage, malignant cells are confined to a clearly demarcated, ontogenetically defined field of potential tumor growth (cancer field), the borders of which have intrinsically tumor suppressive properties. It should be noted that tumors grow isotropically *within* a given ontogenetic domain (Fig. 101.2a, b).

Based on these observations, a novel ontogenetic tumor staging system has been proposed and developed for cervical cancer which is shown in Table 101.1 [17]. The extent of the respective ontogenetic domains is highlighted in (Fig. 101.3a–f).

Taking this into account, locoregional tumor control can be achieved surgically by complete resection of the developmental domain of potential cancer spread according to ontogenetic tumor stage (Fig. 101.2c,d). When the entire ontogenetic domain of potential tumor spread is removed, there is an exceedingly small risk of local recurrence, even if the cancer reaches the resection margins (without transgressing it).

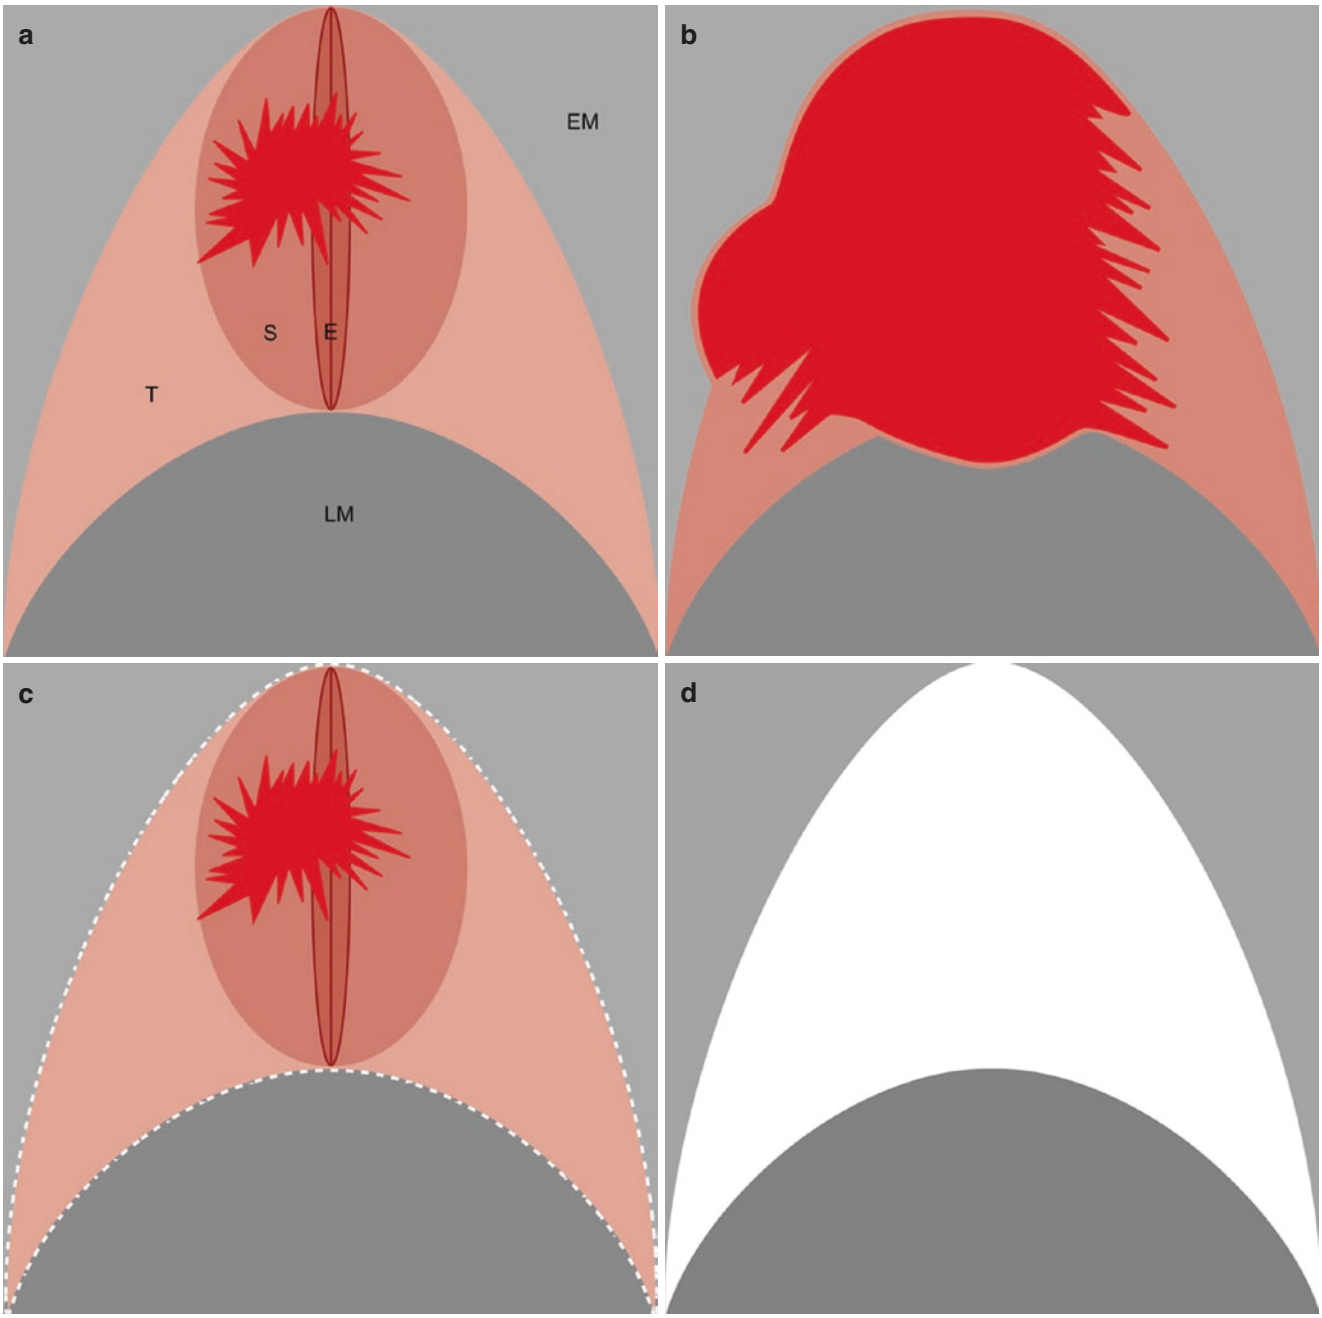

Fig. 101.2 Ontogenetic theory of cancer fields. The ontogenetic compartment (*shades of red*) contains an epithelial subcompartment (E), functional stroma (S) and tissue without apparent function (T) which are all derived from one embryonic precursor (anlage). The ontogenetic theory of cancer fields assumes that malignant tumors grow isotropically only within this compartment (**a**). The borders of a given cancer field have intrinsically tumor suppressive function and thus inhibit infiltration of the adjacent tissue (**b**) until malignant progression permits infiltration of the early and then the late metacompartment. The tumors in (**a**) and (**b**) can both be treated by complete resection of the compartment (**c** and **d**). All tumors which are contained inside the compartment (e.g. Müllerian compartment) are by definition staged as oT2-Tumors. *E* Epithelium, *SC* Subcompartment, *C* Compartment, *EM* Early Metacompartment, *LM* Late Metacompartment (Courtesy of Prof. Michael Höckel. Modified from Höckel [14] (Reproduced with permission by Future Medicine Ltd))

Table 101.1 Ontogenetic domains, tumor stages and tailored surgeries for respective domain resection

Ontogenetic Domain	Anatomical Structures	Ontogenetic Tumor Stage	Surgical Procedure
Subcompartment	Cervical stroma	oT1	LLETZ+first-line LND/ TMMR
Compartment (Müllerian)	Cervical stroma + uterine corpus, Fallopian tubes, mesosalpinx, proximal 2/3 of vagina and paracolpos	oT2	TMMR
Late (genital) Metacompartment	Müllerian + ovaries, infundibulopelvic, ovarian and round ligaments, dorsal bladder wall, medial bladder mesentary, distal vagina and dorsal urethra	oT3	EMMR/LEER
Early (urogenital ridge) Metacompartment	Late Metacompartment + peritoneum, retroperitoneum, urogenital mesentery, ureters and kidneys, bladder and urethra, rectovaginal septum, rectum and mesorectum	oT4	LEER in selected cases

LLETZ large loop excision of the transformational zone, *TMMR* total mesometrial resection, *EMMR* extended mesometrial resection, *LEER* laterally extended endopelvic resection, *LND* lymph node dissection

Surgical Procedures

As stated before, local tumor control according to the concept of the ontogenetic cancer field theory can be achieved by complete resection of the respective cancer field. Different surgical procedures have been designed at our institution for different gynecological cancers. In line with the book title, this text is concerned with different types of hysterectomy according to ontogenetic principles. The TMMR as a novel treatment approach to cervical cancer has been evaluated most extensively and will be described in detail. For endometrial cancer, a variant of this procedure termed peritoneal mesometrial resection (PMMR) has been developed and will be described briefly. A prospective proof of principal study for PMMR is currently underway.

Other surgical procedures based on the ontogenetic theory of cancer fields are extended mesometrial resection (EMMR) and laterally extended endopelvic resection (LEER) for treatment of oT3 cervical cancer, and LEER for oT4 disease (in form of primary or recurrent cancers). Vulva field resection (VFR) has been developed for surgical treatment of vulvar cancer. These procedures will not be discussed here, the interested reader should refer to the respective publications [12, 15].

Evidence and Benefits

The benefits of this surgical strategy have been clearly demonstrated in a series of 367 cervical cancer patients who were treated with operations tailored to ontogenetic tumor stage, i.e. TMMR/EMMR and LEER [17]: 217 patients had oT1- , 101 oT2-, 38 oT3- and 11 oT4-disease. Traditional tumor stages for the same collective ranged from pT1 to pT4. 88 % of the patients received TMMR, 6 % EMMR and 6 % LEER.

Microscopically free margin resection could be achieved in 99 % of patients irrespective of pathologic tumor stage.

Sustained locoregional tumor control over 5 years was achieved 94 % of patients who received surgery alone. Local tumor control during the same period was maintained in 96 % of patients. Close free margin resection (<5 mm) was not an independent risk factor for tumor recurrence, lending proof to our concept of compartment resection.

5-year overall survival for patients with oT1 tumors was 97 %, for oT2 tumors it was 94 %. In contrast, it was 64 % for patients with compartment transgressing oT4 disease.

Of note, none of the patients was treated with adjuvant radiotherapy. This represents an obvious advantage for patients since radiotherapy adds significantly to overall morbidity. Accordingly, moderate to severe procedure-related perioperative morbidity in patients treated with TMMR (grade 2–4 according to the Franco-Italian glossary) was 15 % [11] which is much lower than the morbidity reported with radical hysterectomy combined with adjuvant radiation [19].

Taken together, TMMR presents a surgical option for the treatment of cervical cancer which achieves better locoregional tumor control than traditional radical hysterectomy without the need of adjuvant radiation, thus decreasing treatment related morbidity significantly.

PMMR is currently being evaluated in an ongoing prospective observational study at our institution.

Relevant Ontogenetic Anatomy: The Müllerian Compartment

The anatomical structures of the adult female belonging to the Müllerian compartment have been defined [9, 13] and are outlined in Fig. 101.4. Its borders can be visualized using

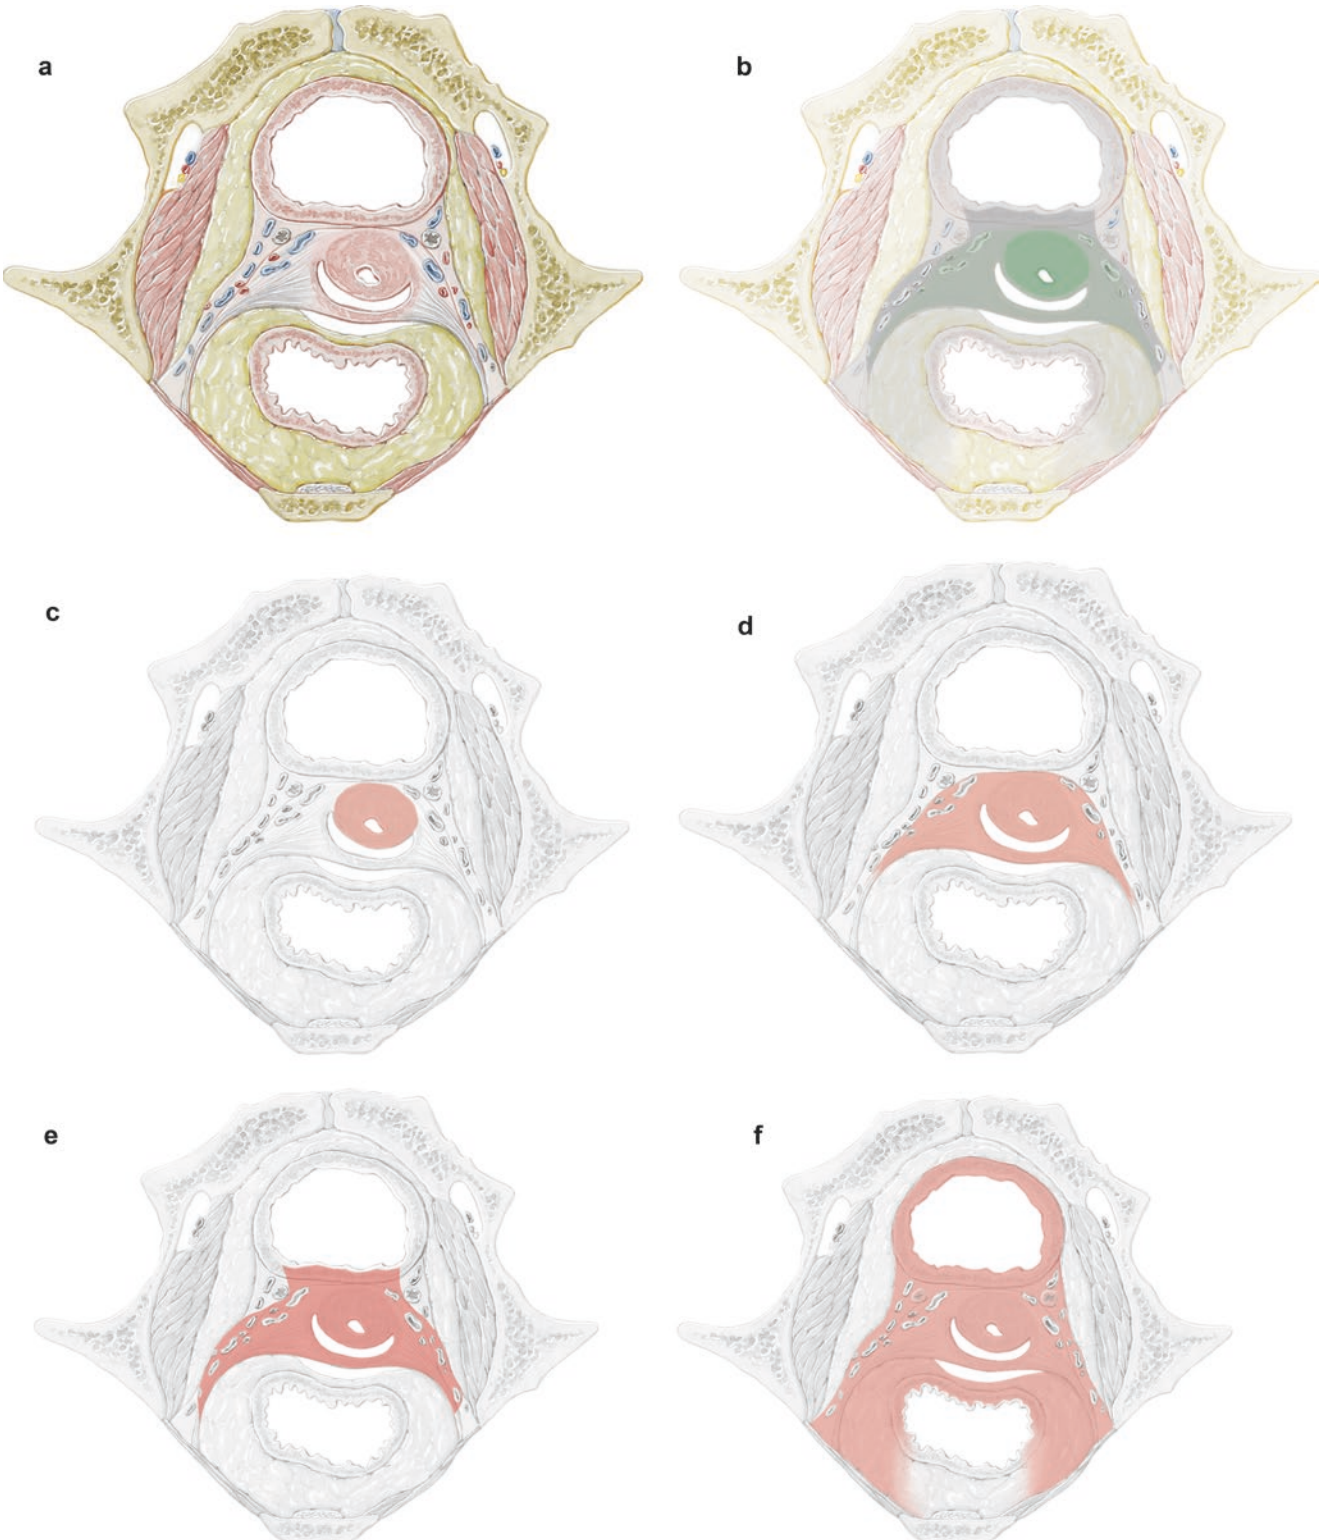

Fig. 101.3 Adult anatomic structures of possible tumor spread at different ontogenetic tumor stages. Transsectional anatomy of the pelvis (**a**). The Müllerian compartment (*green*) and the late genital metacompartment (*darker green*) (**b**). The tumor first grows in the uterine cervix (oT1, C), infiltrates during its malignant progression the structures belonging to the Müllerian compartment (oT2, D), the genital metacompartment (oT3, E) and the urogenital ridge metacompartment (oT4, F) (From Höckel et al. [17], Copyright 2014 with permission from Elsevier)

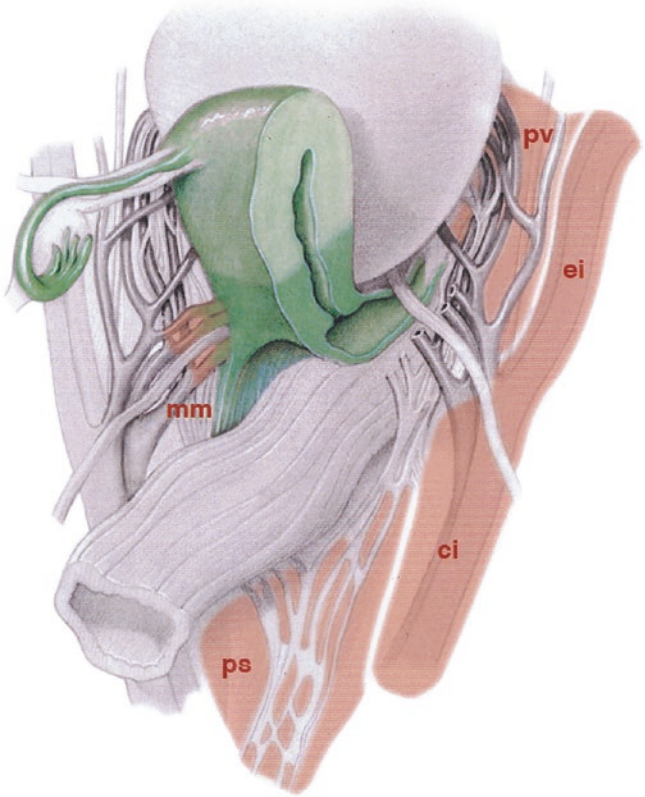

Fig. 101.4 Anatomy of the Müllerian compartment and its lymphatic drainage basins. The anatomic structures belonging to the Müllerian compartment are marked green, first-line lymph node stations dark red and second-line lymph node basins bright red. *mm* mesometrial, *pv* paravisceral, *ei* external iliac, *ci* common iliac, *ps* presacral (Reprinted from Höckel et al. [11], Copyright 2009, with permission from Elsevier

high resolution 3.5 Tesla MR-Imaging. Cranially, the compartment is located intraperitoneally and includes the fimbriae, fallopian tubes, mesosalpinx, uterine corpus and broad ligaments. The caudal part extends retro- and subperitoneally and is comprised of the uterine cervix, the proximal two thirds of the vagina and the enveloping tissue termed parakolpos and paracervix. The subperitoneal part of the Müllerian compartment is a closed vessel system covered by a continuous tissue lamella, multiple venous connections to the neighboring bladder compartment exist however.

The mesometrium can be divided into two ontogenetically and functionally distinct parts, the vascular and the ligamentous mesometrium. The vascular mesometrium extends dorsolaterally and contains the uterine and vaginal vessels as well as the lymphatic drainage system including important intercalated lymph nodes. The vascular mesometrium is adherent to the bladder mesentery and is traversed by the ureters. The ligamentous mesometrium is directed dorsally, is attached to the mesorectum and may also harbor intercalated lymph nodes draining the Müllerian compartment. By conventional terminology it is composed of parts of the broad ligament, the rectouterine and rectovaginal ligaments as well as the rectovaginal septum. The inferior hypogastric plexus marks the lateral border of the ligamentous mesometrium, dorsally and inferiorly it is continuous with the endopelvic fascia of the pelvic wall and floor. It should be noted, that the mesometrium is not part of the Müllerian compartment but of the genital (late) metacompartment.

TMMR and TLND

The objective of TMMR is the resection of the Müllerian compartment, the mesometria and the pelvic and paraaortic lymphnodes (where indicated) to achieve optimal local and regional tumor control without compromising adjacent structures (e.g. bladder meso, inferior hypogastric plexus) and without the need for adjuvant radiation. With the exception of the vagina, the compartment should be resected completely along the borders described before. For the purpose of maintaining a functional vaginal stump, the vaginal resection is performed intracompartimental in form of a wide excision with a resection margin of 2 cm. We believe this compromise in radicalness to be justified considering the rarity of vaginal recurrence (2 % according to our data) and the large benefit of maintaining vaginal integrity.

It should be stressed that therapeutic lymph node dissection as outlined in the step by step surgical description below is an integral part of TMMR. Without therapeutic lymph node dissection regional tumor control cannot be achieved.

Current treatment strategies incorporate lymph node dissection for staging purposes to determine the need for adjuvant radiation. As outlined before, in addition to patients with lymph node metastasis, patients which are considered at high risk for tumor recurrence on the basis of histological findings are subjected to adjuvant radiation of the pelvis. Meticulous pelvic (and paraaortic) lymph node dissection using the adventitia stripping technique can achieve excellent locoregional tumor control without the need for adjuvant radiation as was shown in the TMMR trials [11, 17]. Taking this into account lymph node dissection in the context of TMMR is therapeutic rather than diagnostic.

There is a fixed anatomic relation between lymph nodes and their tributary tissues through the afferent lymphatic vessels. With increasing ontogenetic tumor stage an increasing number of first-line lymph node drainage basins become potential stations for metastasis [17]. According to data from our institution, lymph node metastasis in cervical cancer occurs most frequently in the external iliac and paravisceral lymph node basins (Fig. 101.4). Together with

intercalated lymph nodes in the vascular mesometrium, these lymph nodes are considered first-line lymph nodes and should always be dissected and subjected to intraoperative frozen section examination. In clinical stage IB1 tumors of less than 2 cm in size, it is sufficient to remove the first-line lymph nodes. Second-line lymph nodes consisting of the common iliac and presacral lymph nodes must be removed in all other tumors or if first-line lymph nodes carry metastasis. If the latter is the case, ascending lymph node dissection up to the origin of the lower mesenteric artery should also be performed since preliminary data suggests, that direct metastasis from first-line pelvic lymph node stations to the aortic bifurcation can occur. Importantly, in the case of tumor infiltration of the uterine corpus, complete infrarenal paraaortic lymph node dissection is essential since metastasis can occur via the lymphatic drainage system of the uterine corpus along the infundibulopelvic ligaments. In this situation, infrarenal paraaortic lymph nodes become first-line lymph nodes. The algorithm for therapeutic lymph node dissection which we use is outlined in Fig. 101.5.

Ovariectomy should be performed in all oT3-Tumors since the ovaries are part of the genital (late) metacompartment. This is the case when there is evidence for mesometrial tumor infiltration as determined by intraoperative frozen section examination. Also, according to empirical data from our institution, the likelihood for subclinical oT3 disease increases significantly when more than two first-line lymph nodes carry metastasis. In these circumstances, the ovaries should be resected. Adjuvant radiotherapy is not indicated.

PMMR and TLND

PMMR includes surgical removal of the Müllerian compartment (except the distal vagina) including the genital peritoneum and the gonadal compartment. It is indicated for oT1 endometrial cancer which corresponds to FIGO stage I. The surgical technique is the same as for TMMR with the exception that the ovaries including the meso are always resected as well as the infundibulopelvic ligament which contains intercalated lymph nodes along the lymphatic drainage vessels from the corporal subcompartment analogous to the intercalated lymph nodes of the cervical subcompartment in the mesometria. In contrast to TMMR, the distal ligamentous mesometrium is left in place. This means that when performing a PMMR, preparation of the mesometrium stops just below the uterine artery while in TMMR the paracervical ligamentous mesometrium is dissected all the way down to the vaginal fold to include all paracervical drainage tissue. Since the inferior hypogastric plexus is separated from the distal ligamentous mesometrium in TMMR, the incidence of bladder function disturbances is much lower with PMMR than with TMMR.

If there is pre-operative suspicion for Stage II disease (cervical involvement), TMMR is indicated.

At our institution, we use the Mayo Clinic criteria to determine risk of lymphatic spread with G3-grading, extrauterine disease, non-endometrioid cancer and myometrial invasion depth of more than 50 % indicating high risk of lymph node metastasis [21]. If there is risk for lymphatic tumor spread, TLND needs to include all lymphatic drainage

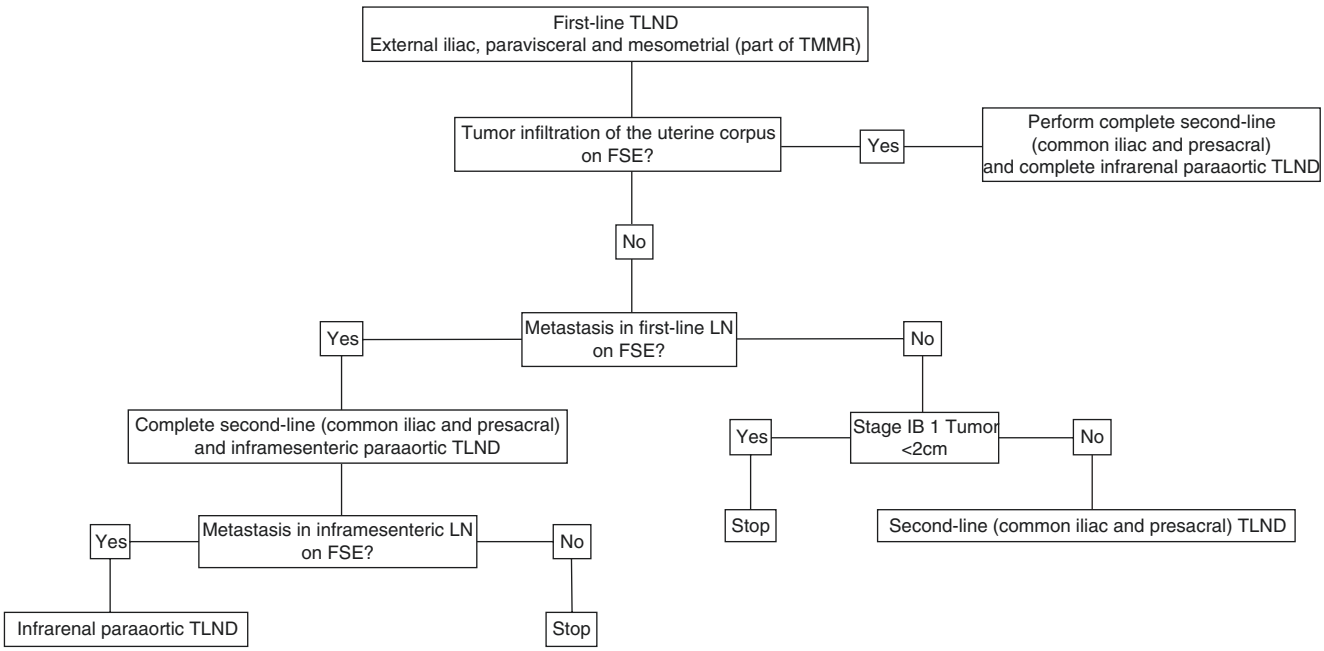

Fig. 101.5 Flowchart showing the successive steps of comprehensive therapeutic lymph node dissection in cervical cancer. *TLND* therapeutic lymph node dissection, *LN* lymph nodes, *FSE* frozen section examination

regions of the uterine corpus. Lymphatic drainage occurs directly to the internal iliac lymph nodes and along the ovarian vessels via the infundibulopelvic ligament into the infrarenal paraaortic region. TLND in this region is carried out as in cervical cancer cases with tumor infiltration into the uterine corpus. Adjuvant radiation is not indicated.

We acknowledge that there is a collective of patients with low to intermediate risk for lymphatic tumor spread (e.g. G2-grading). In these cases we recommend performing only first-line TLND including external iliac, paravisceral and infrarenal paraaortic lymph node basins. If intraoperative frozen-section examination reveals lymph node metastasis in first-line regions, TLND of all pelvic and paraaortic regions is indicated. If there should be *preoperative* evidence of significant cervical tumor infiltration (i.e. stage II tumors), TMMR is indicated.

TMMR: Surgical Management

Indication

Management protocol for the treatment of cervical cancer stage FIGO IB1-IIA and some cases of IIB (oT1 and oT2 tumors).

Surgical Treatment Oals

1. Local tumor control through complete resection of the Müllerian compartment with a wide tumor-free vaginal margin (intracompartimental resection margin)
2. Regional tumor control through resection of the mesometria and therapeutic lymph node dissection as outlined in Fig. 101.5.
3. Ovarectomy in oT3 tumors (i.e. mesometrial tumor infiltration, more than 2 lymph node metastases on frozen section examination)

Presurgical Diagnostics and Management

- History and general clinical investigation
- High resolution pelvic MRI (at least sagittal and transverse T2-weighted scans) presented during the examination under anesthesia
- Clinical evaluation under anesthesia by an experienced gynecologic oncologist
- Tumor biopsy and biopsies of clinically suspicious tissues within the Müllerian compartment
- Staging applying the FIGO criteria
- cT cN cM summarizing all diagnostic information, including maximum tumor size
- oT-Staging if clinically possible
- PET/CT when distant metastasis is suspected
- Symptom-guided additional investigations to estimate the risks associated with surgical treatment
- Preoperative bowel preparation
- Perioperative single shot antibiotic prophylaxis

Surgical Strategy

1. Exposition of the relevant tissue structures based on ontogenetic anatomy as depicted in Figs. 101.6, 101.7, 101.8 and 101.9. After the usual mobilization of the intestinal mesentary, the key step is the mobilization of the ureters and their meso from the ligamentous mesometrium and perirectal peritoneum medially. Expose their crossing of the vascular mesometrium caudally and separate them from the iliac vessel system laterally. At this point, the ureter and its meso should be completely separated from the surrounding structures as it demarcates the lateral border of the genital metacompartment (see Fig. 101.10a, b of the step-by-step description below). All tissue lateral of the ureter will be left in place.
2. First-line pelvic TLND (Figs. 101.11, 101.12, and 101.13, send to frozen section examination immediately)
3. TMMR (Figs. 101.14, 101.15, 101.16, 101.17, 101.18, 101.19 and 101.20, surgical specimen is sent to frozen section examination for evaluation of resection margins, mesometrial infiltration and tumor spread into the uterine corpus.
4. Second-line pelvic TLND (common iliac vessels and presacral space, see Figs. 101.21 and 101.22), this step can be omitted in stage IB1 tumors of less than 2 cm size and negative first-line pelvic lymph nodes on intraoperative frozen section examination.

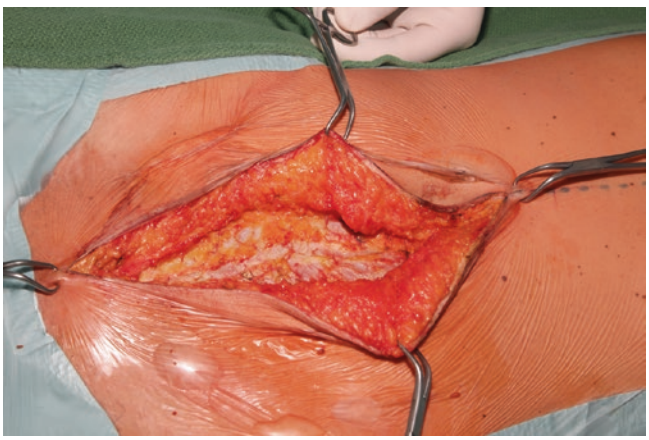

Fig. 101.6 Hypogastric midline laparotomy with left circumcision of the umbilicus. If periaortic lymph node dissection is required or in very obese patients, epigastric advancement of the laparotomy may be necessary

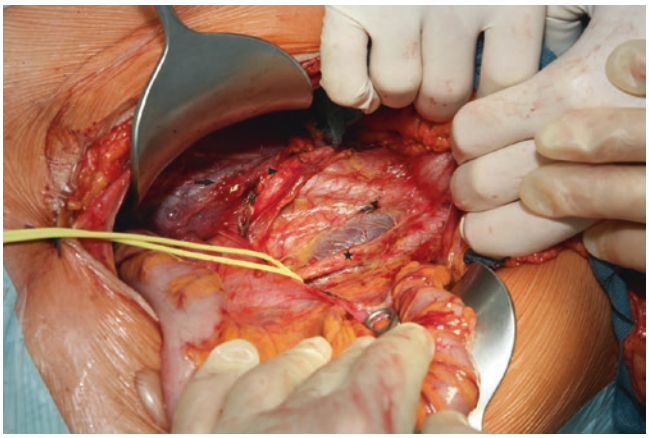

Fig. 101.7 Get retroperitoneal access through bilateral paracolic incisions and incision at the radix mesenterii. Expose ligamenta infundibulopelvica (*arrow*), ureters (*arrow head*) and plexus hypogastricus superior (*star*)

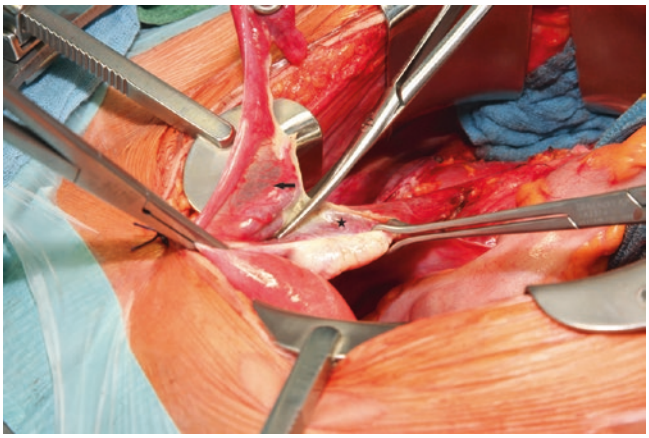

Fig. 101.9 Separate mesosalpinx (*arrow*) from mesovary (*star*), sever ligamentum rotundum, ligamentum latum, ligamentum ovarii proprium. Mobilize ovary attached to ligamentum infundibulopelvicum cranialward

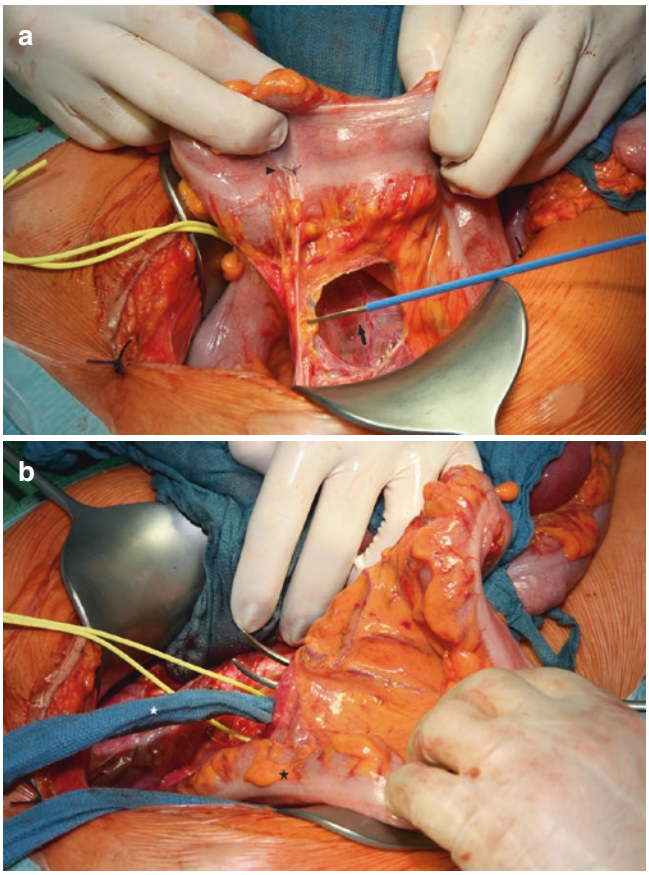

Fig. 101.8 (**a**) Lyse connatal peritoneal adhesions of the sigmoid colon (*black star*) to the left abdominal wall. Mark the site of colon sigmoid fixation (*arrow head*), mobilize caecum, duodenum and sigmoid colon cranialward. (**b**) Undermine the mesosigma (*arrow*) with two tissue stripes (*white star*) for optimal dynamic retraction of the mobilized colon rectosigmoideum

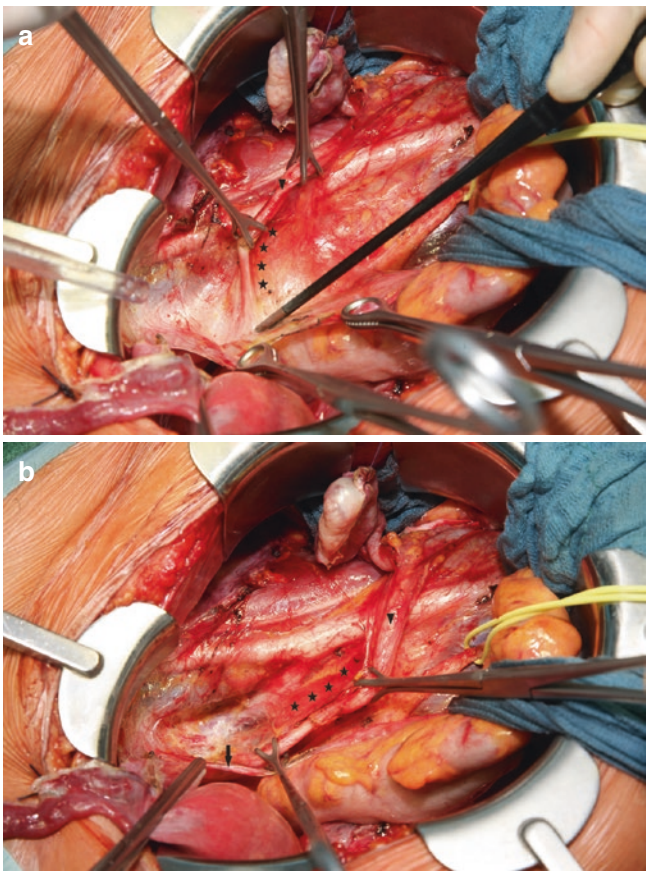

Fig. 101.10 (**a**) Mobilize pelvic ureter (*arrowhead*) with complete meso-ureter (*stars*) medially from perirectal peritoneum, ligamentous mesometrium (*arrow*) and plexus hypogastricus inferior (*yellow loop*). (**b**) Mobilize the ureter laterally from iliac vessels and lymphatic fatty tissue. Caudally expose the ureter up to the crossing vascular mesometrium. Be aware of keeping the meso-ureter intact

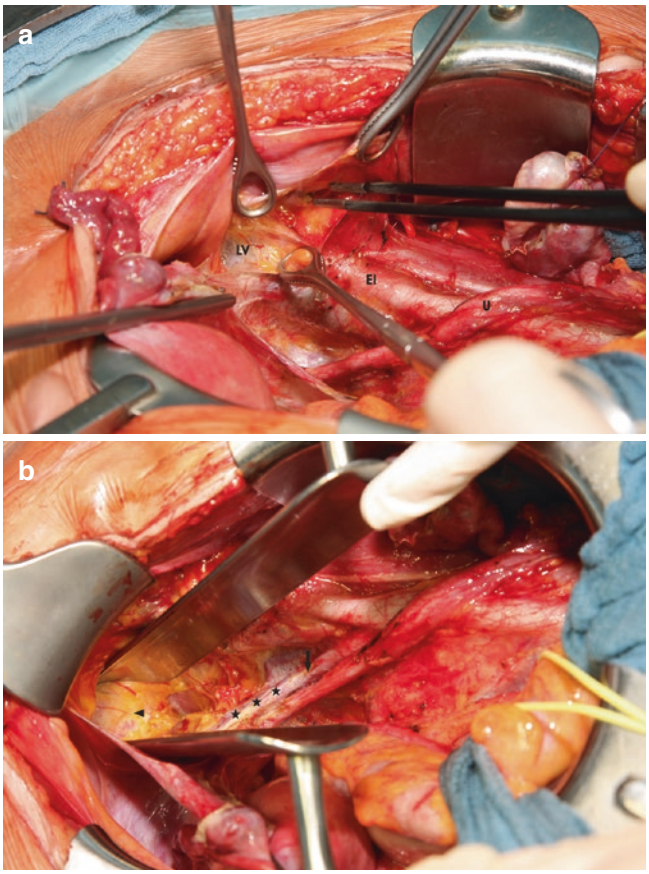

Fig. 101.11 (**a**) Dissect fatty tissue to expose the retroinguinal lacuna vasorum (LV) and the obliterated umbilical artery (*stars*) which should be visible from its origin at the internal iliac artery (*arrow*) up to the formation of the medial umbilical peritoneal fold. (**b**) Develop the complete paravisceral space by separation of the urogenital mesentery from the parietal paravisceral fat pad down to the levator ani muscle (*arrowhead*). *U* ureter, *EI* external iliac artery

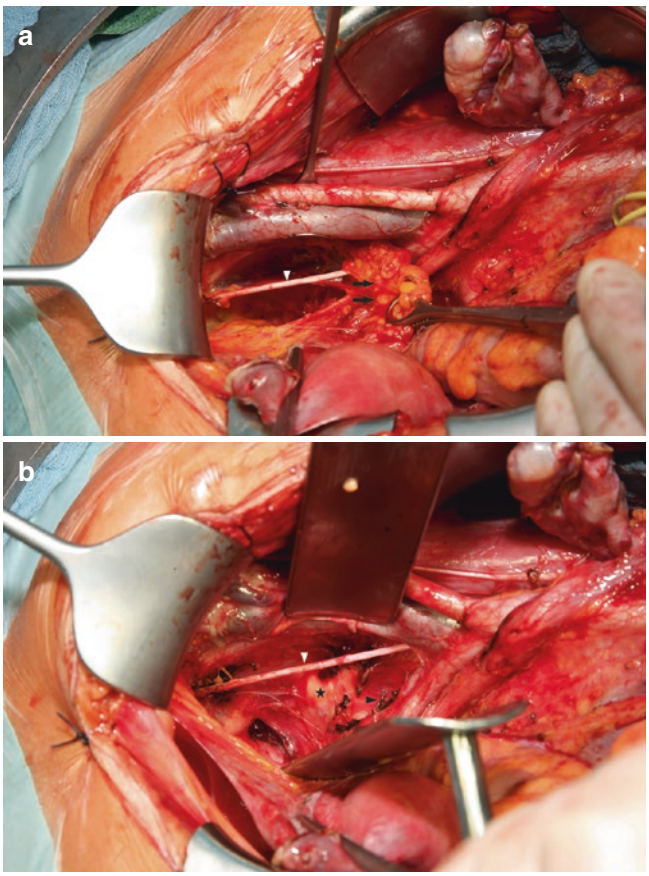

Fig. 101.13 (**a**) Remove the complete paravisceral fat pad (*black arrows*) and expose the obturator nerve (*white arrowhead*) and the proximal sciatic nerve (*black star*) along with its lumbar and first sacral trunci. Seal and dissect parietal branches of the internal iliac venous system (*black arrowhead*). (**b**) Expose the obturator muscle, levator ani muscle and its arci tendinei and the endopelvic aspect of the sciatic spine

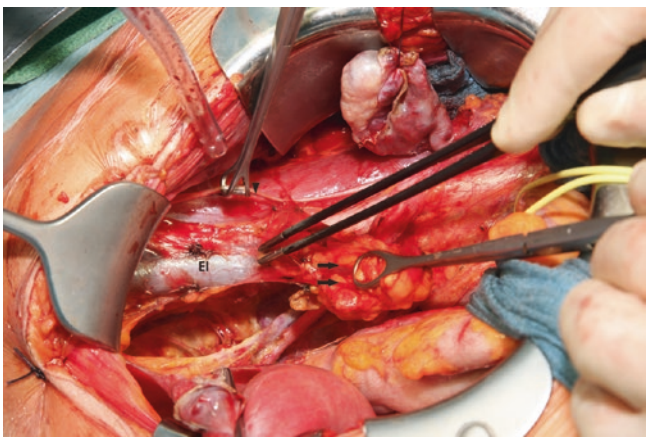

Fig. 101.12 Harvest the external iliac lymphoid tissue (*arrows*) by adventitia stripping taking care to preserve the genitofemoral nerve (*arrowhead*). *EI* external iliac vein

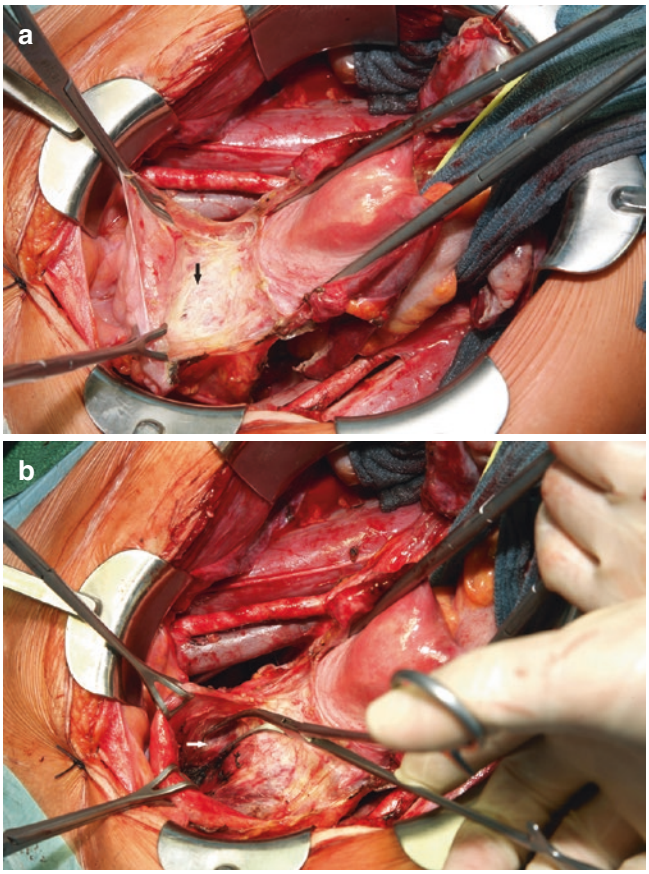

Fig. 101.14 (**a**) Incise the vesicouterine peritoneal fold (*black arrow*) and separate the bladder from the anterior cervix and proximal vagina. (**b**) Expose the medial uterovesical junctions (*white arrow*)

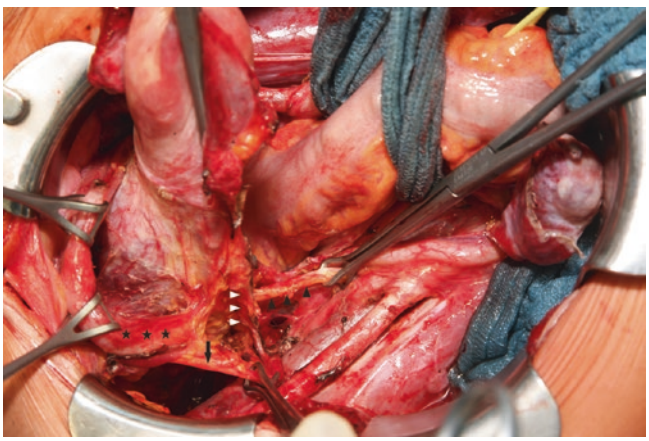

Fig. 101.15 Separate the vascular mesometrium (*white arrowheads*) from the superior bladder mesentery (*black stars*) anteriorly and the mesureter (*black arrow-heads*) posteriorly. The obliterared umbilical artery is marked by the *black arrow*

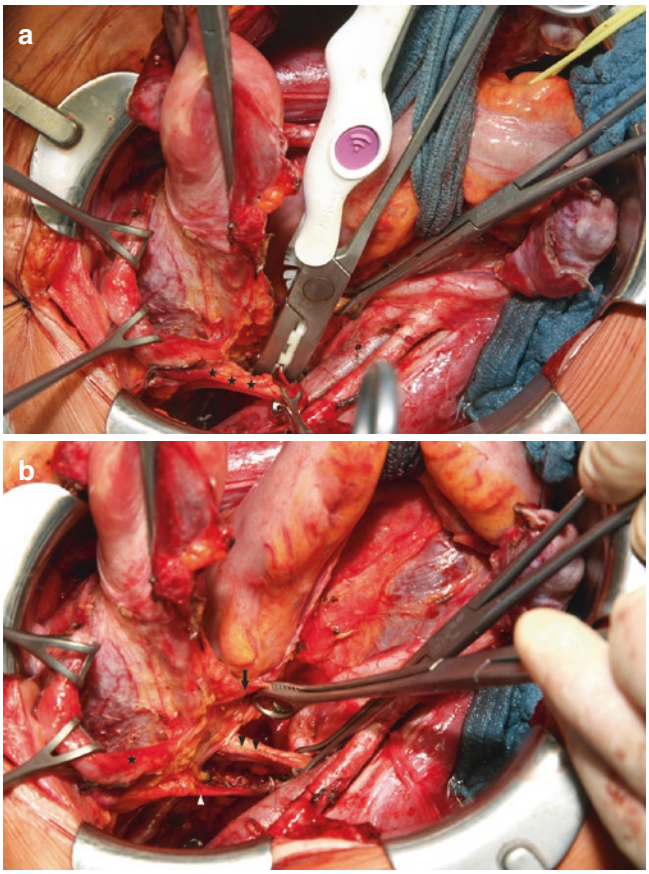

Fig. 101.16 (**a**) Seal and sever the vascular mesometrium (*black arrow*) containing the uterine artery at its origin from the hypogastric vessels. (**b**) Flip the vascular mesometrium medially over the ureter (*black arrowheads*). The bladder mesentary containing the obliterated umbilical artery (*white arrowhead*) is marked by black stars

5. When lymph node metastasis on first-line lymph nodes is present, ascending paraaortic lymph node dissection up to the inferior mesenteric artery is performed and lymph nodes are sent for frozen section examination (Fig. 101.23a, b). If there is metastasis, infrarenal lymph node dissection is performed.
6. When tumor involvement of the uterine corpus is present, infrarenal paraaortic TLND is indicated.
7. Ovariopexy when ovaries are preserved and closing procedures (Figs. 101.24 and 101.25).

Surgical Procedures (Step-By-Step)

The photographic pictures illustrating each step of the procedure are taken exclusively from the view of the surgeon

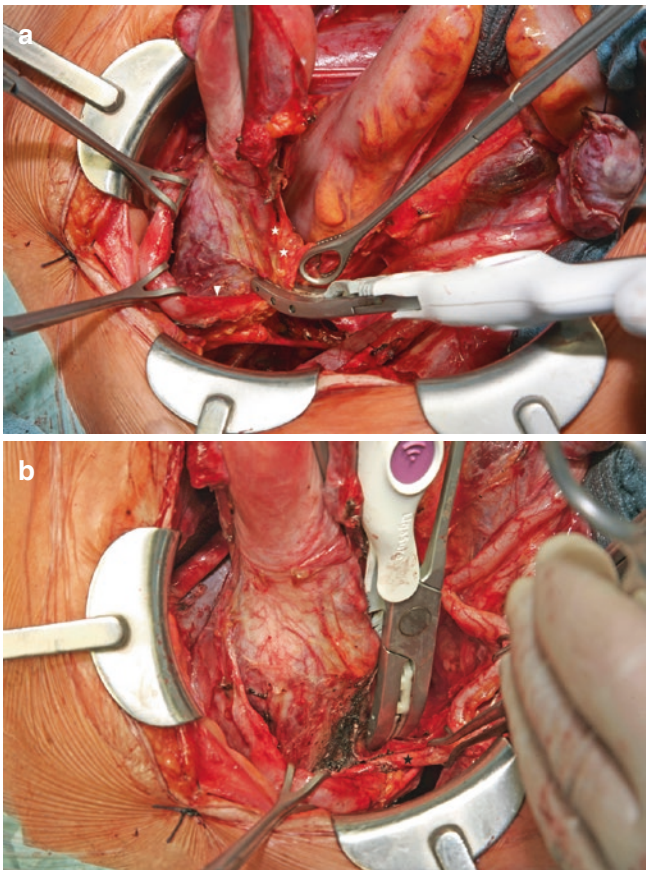

Fig. 101.17 (**a**) Seal and sever the vesicouterine vessel connections (*white arrowheads*) above the ureter and the vesicovaginal vessel connections below the ureter (**b**) taking care not to violate the ureter (*black star*) and mesureter containing the feeding vessels from the superior and inferior vesical artery. The bladder mesentary is marked by the *white arrowhead*

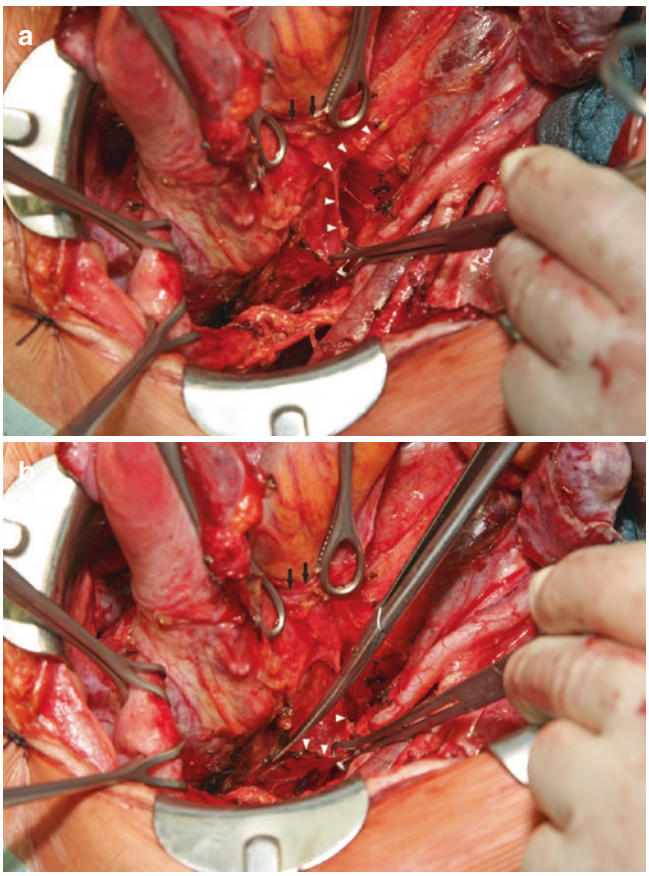

Fig. 101.18 (**a**) Separate the inferior hypogastric plexus (*white arrowheads*) from the ligamentous mesometrium (*black arrows*). (**b**) dissect its uterine braches

positioned at the patient's left side. Where applicable, all procedures are carried out on the contralateral side as well. A picture of the final surgical TMMR specimen is provided in Fig. 101.26.

PMMR: Surgical Management

Indication

Management protocol for the treatment of endometrial cancer FIGO IA and IB.

Surgical Treatment Goals

1. Local tumor control through resection of the Müllerian compartment (except the middle vagina) and the gonadal compartment.
2. Regional tumor control through therapeutic pelvic and paraaortic lymph node dissection including the infundibulopelvic ligaments (intercalated lymph nodes).

Presurgical Diagnostics and Management

- History and general clinical investigation
- Gynecologic ultrasound imaging
- Dilatation and curettage for pathologic diagnosis and tumor grading
- In advanced disease PET/CT to exclude distant metastasis
- Staging applying the FIGO criteria
- cT cN cM summarizing all diagnostic information, including maximum tumor size
- oT-Staging if clinically possible
- Determination of risk of lymphatic spread according to the Mayo Clinic criteria if possible (e.g. grading)

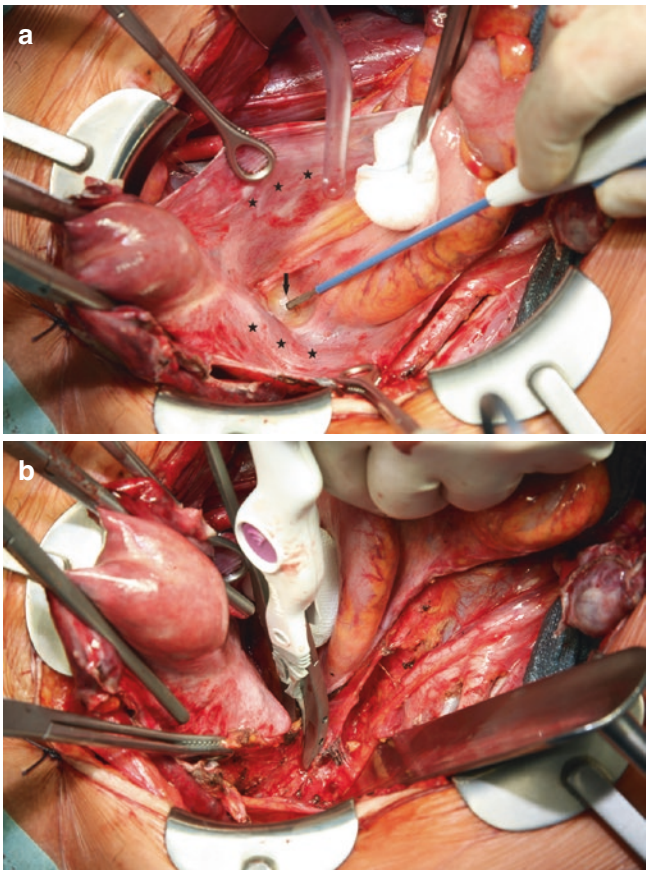

Fig. 101.19 (**a**) Exert tension on the pouch of Douglas and incise the peritoneum at its lowest level (*black arrow*). (**b**) Seal and sever the bilateral ligamentous mesometria (*black stars*) and the rectovaginal fibrofatty tissue at the anterior mesorectal surface keeping the inferior hypogastric plexus lateral

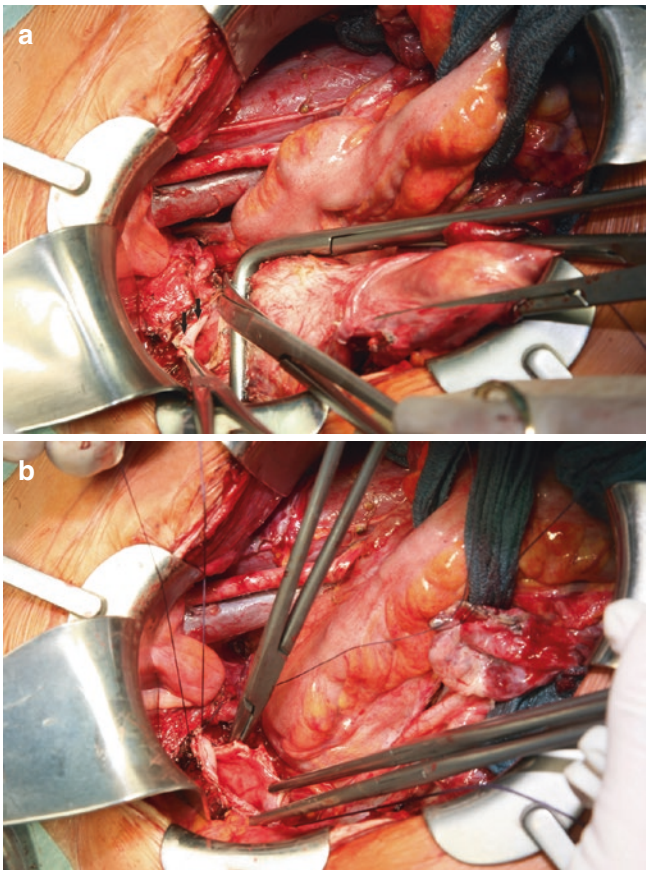

Fig. 101.20 (**a**) After clamping the proximal vagina perform a stab incision in its anterior wall followed by a circumferential colpotomy (*black arrows*). (**b**) Close the vaginal stump by a running everting suture

- Symptom-guided additional investigations to estimate the risks associated with surgical treatment
- Preoperative bowel preparation
- Perioperative single shot antibiotic prophylaxis

Surgical Strategy

1. Exposition of the relevant tissue structures based on ontogenetic anatomy (see Figs. 101.27, 101.28, 101.29, 101.30 and 101.31).
2. PMMR including ovaries, mesovary and infundibulopelvic ligaments (Figs. 101.32, 101.33, 101.34, 101.35, 101.36 and 101.37 send to frozen section examination to determine risk of lymphatic spread (i.e. myometrial tumor infiltration depth, grading etc.) and evaluation of resection margins.
3. When frozen section examination reveals an intermediate risk for lymphatic tumor spread (e.g. G2-grading), perform first-line TLND including infrarenal paraaortic, external iliac and internal iliac lymph node basins (see Figs. 101.11, 101.12 and 101.13, send to frozen section examination). The infundibulopelvic ligament is resected as well.
4. When there is lymph node metastasis in the first-line stations, complete therapeutic pelvic lymph node dissection including common iliac, presacral and inframesenteric lymph node basins is indicated. In high risk situations comprehensive TLND including all lymph node stations is performed irrespective of the presence of first-line lymph-node metastasis.
5. In case of serous-papillary or clear cell carcinoma perform peritoneal sampling biopsies.
6. Closing procedures (Figs. 101.38, 101.39 and 101.40).

PMMR Surgical Procedures (Step by Step)

The photographic pictures illustrating each step of the procedure are taken exclusively from the view of the surgeon positioned at the patient's left side.

For a description of the technique for lymph node dissection please refer to the TMMR step by step protocol.

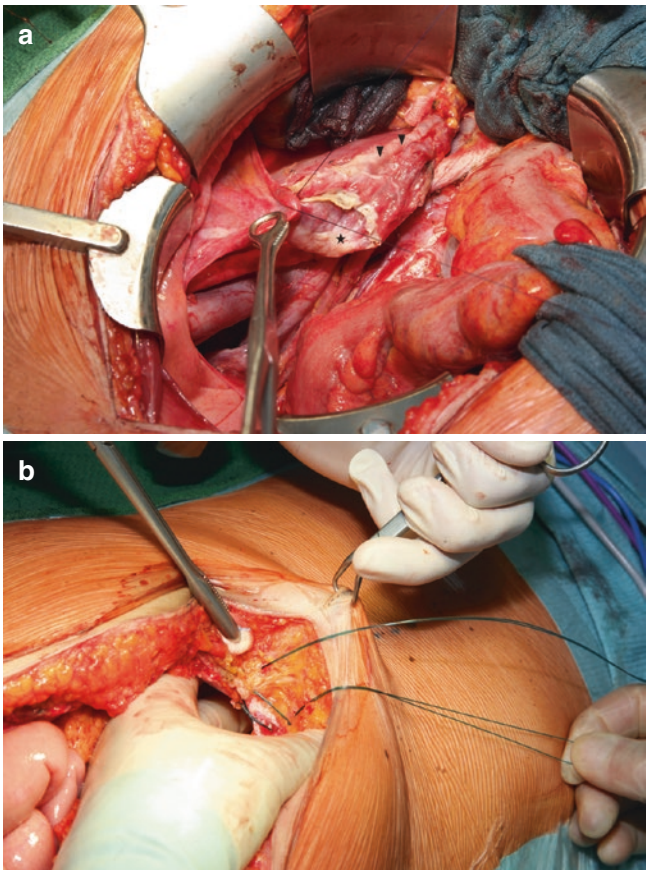

Fig. 101.25 (**a**) Fix the ovaries (*star*) to the incision margin of the parietal peritoneum. (**b**) Close the laparotomy. The *black arrowheads* mark the infundibulopelvic ligament. Depending on patient's choice suprapubic cystostomy and placement of a suprapubic catheter for future bladder training. Alternatively, a transuretheral catheter is inserted

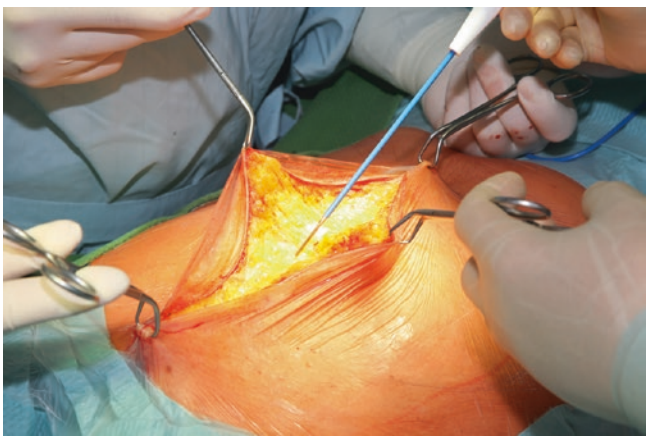

Fig. 101.27 Hypogastric midline laparotomy. If a high risk situation for lymphatic tumor spread is established pre-operatively, the laparotomy is extended cranially for infrarenal lymph node dissection

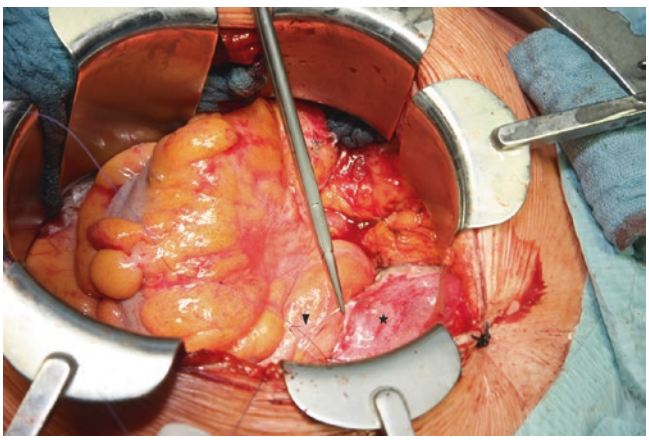

Fig. 101.39 Peritoneal reconstruction. The peritoneum of the bladder ist marked by the *asterix*, the rectal peritoneum by the *arrowhead*. Picture taken from the right side

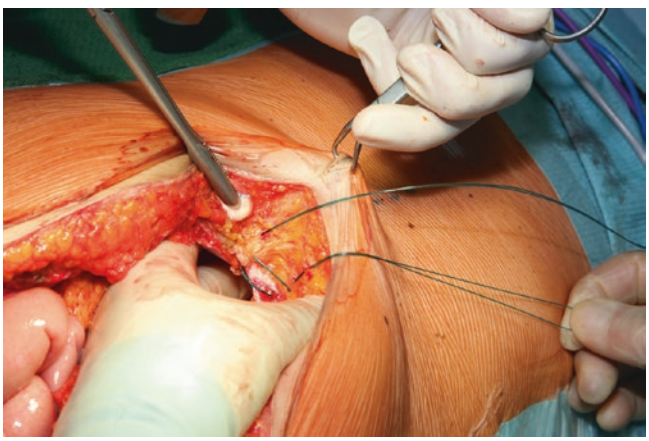

Fig. 101.40 Closing the laparotomy

Postoperative Management

Mobilization is possible immediately after surgery.

Purgatives are given on the third postoperative day if no stool has been passed spontaneously (we generally use sorbitol 30–40 ml).

Until the 5th postoperative day a suprapubic or transurethral catheter is continuously left open to avoid overextension of the bladder (does not apply for PMMR).

On day 5 training of bladder function with intermittent self-catheterization via transurethral or suprapubic catheter is commenced and continued until post-voiding residual urine is less than 50 ml on two successive measurements (does not apply for PMMR).

Skin staples are removed on days 10 and 14.

Radical Abdominal Trachelectomy

102

Rene Pareja and Pedro Ramirez

Introduction

The standard recommendation for the treatment of patients with early-stage cervical cancer (stages IA2–IB1) interested in fertility preservation is radical trachelectomy [1]. In 1994, Dargent et al. [2] reported on the safety and feasibility of vaginal radical trachelectomy (VRT) with laparoscopic lymph node dissection for the treatment of early-stage cervical cancer. However, one of the major concerns with regard to the vaginal approach when considering radical trachelectomy is the fact that it requires surgeon expertise in radical vaginal surgery and also in advanced laparoscopic procedures. In 1997, Smith et al. published the first report of abdominal radical trachelectomy (ART) [3]. The advantages of ART include the reproducibility of the technique, the fact that the procedure can be performed without training in radical vaginal surgery, that it requires no laparoscopic equipment, and a wider parametrial resection can be achieved with this approach.

Radical trachelectomy has also been reported through a minimally invasive approach. The laparoscopic approach offers the benefits of minimally invasive surgery; however, it is also associated with the fact that it is a challenging technique requiring the expertise of a well-trained surgeon in radical laparoscopic pelvic surgery [4, 5]. Others have published on the robotic-assisted approach [6, 7]. However, the number of published data on these minimally invasive approaches is limited and the follow-up times are short thus limiting the information on long-term oncologic outcomes.

This chapter will describe the surgical technique, and the oncological and obstetric outcomes after radical trachelectomy. We will also provide details on the most common complications associated with this procedure.

Surgical Technique

The initial entry into the abdominal and pelvic cavity is performed through either a low transverse (Pfannenstiel, Cherney, Maylard) or median incision. The main advantage of the median incision is the broader space that it provides. Careful inspection of the pelvic and peritoneal surfaces is performed in order to rule out any metastatic disease. To gain access into the retroperitoneum one may begin by transecting the round ligament and making an incision along the lateral aspect of the infundibulo-pelvic ligament. The round ligaments may also be preserved depending on the surgeon preference. However, as an alternative, one may also begin by opening the pouch of Douglas by making an incision between both uterosacral ligaments (Fig. 102.1). The paravesical (limited laterally by the iliac vessels, medially by the obliterated umbilical artery, caudally by the deep uterine vein, posteriorly by internal iliac artery and anteriorly by the pubic bone) and pararectal spaces (limited laterally by internal iliac artery, medially by the hypogastric nerve, anteriorly by the uterine artery and posteriorly by the sacral fascia) are developed (Figs. 102.2 and 102.3). Upon inspection of the retroperitoneum, if there is any evidence of obvious nodal disease, surgeons should consider sending the lymph node for frozen section evaluation to determine the status of the lymph node. If there is evidence of disease in the lymph node, the ART should be aborted and definitive chemotherapy and radiation recommended.

A complete pelvic lymphadenectomy is performed from the level of the bifurcation of the common iliac vessels proximally to the circumflex iliac vein distally. This dissection includes the external iliac nodes, internal iliac nodes, and obturator nodes (Fig. 102.4). There is no utility of sending normal appearing nodes to frozen section. As an alternative, sentinel node mapping can be performed, with

good performance regarding, detection rate , sensitivity and specificity [8].

The uterus is gently grasped with a Somer uterine elevating forceps (Aesculap Surgical Instruments, Tuttlingen, Germany) (Fig. 102.5). After exposing the paravesical and pararectal spaces bilaterally, the ureters must be identified bilaterally before proceeding with any pelvic dissection. Care must be taken to assure that the infundibulopelvic ligaments with the ovarian vessels are intact. In addition, special attention must be paid to assure that there is no injury to the fallopian tubes or the utero-ovarian ligament. Therefore, surgeons must place special emphasis to assure that fallopian tubes are not grasped during the surgery. The dissection continues by placing upward traction on the uterus and developing of peritoneal bladder fold. The bladder must be mobilized inferiorly to assure that at least a 1–2 cm margin of upper vagina is secured. The ureters are separated from the peritoneum medially starting the pelvic brim and continuing distally until the point where they course under the uterine vessels. .(Figs. 102.6, 102.7 and 102.8) Often one can also visualize the ureters entering the bladder in the Yabuki's space. (Figs. 102.9 and 102.10) The uterine arteries are then ligated at their origin.

There is some debate regarding preservation of the uterine vessels. According to Tang et al. [9] among 16 patients who had preserved uterine arteries, only two (12.5 %) showed identifiable bilateral uterine arteries, seven (43.6 %) showed unilateral uterine artery occlusion and seven (43.6 %) exhibited bilateral occlusion. The authors concluded that the uterine arteries, when dissected and pre-

served, have an 87.4 % chance of obstruction in the postoperative period, thus the authors do not recommend uterine artery preservation when performing an abdominal radical trachelectomy.

Once the ureters have been properly mobilized bilaterally to the level of insertion into the bladder, surgeons must proceed with medial mobilization of the parametrial tissue bilaterally. This is done by assuring to mobilize the ureters inferiorly and laterally. In addition, surgeons must be certain to transect the vesico uterine ligament to further mobilize the bladder inferiorly. The uterosacral ligaments are then identified and transected bilaterally in medial-most third (Fig. 102.11). The parametrial tissue should be dissected so that there is a lateral margin of resection of approximately 3–5 cm (Fig. 102.12). A colpotomy is then performed circumferentially (Figs. 102.13 and 102.14). At this time, the cervix, parametrial tissue, and upper vagina are amputated from the uterus (Fig. 102.15). The landmark used to help guide with the amputation of the cervix is located approximately 0.5 or 1 cm below the internal uterine os, and the cut is preferably done with cold knife, in order to assure that there is no cauterized tissue that would potentially hinder the pathologic interpretation. The specimen is then sent for frozen section evaluation to assure that at least a 5-mm margin free of tumor (Figs. 102.16 and 102.17).

At this point, surgeons must determine whether they will place a cerclage at the same time of the procedure or do so when the patient becomes pregnant at a later time. In our institution, we prefer to place a cerclage at the time of the radical trachelectomy. The documented advantages of a cerclage are that it is important to reduce undesired obstetric complications such cervical incompetence, second trimester losses, premature rupture of membranes or preterm labor. The potential disadvantages are that it may cause cervical steno-

sis, chronic vaginal discharge, or it may potentially erode through the vagina. In a recent literature review, the investigators showed that the average rate of stenosis rate after radical trachelectomy was 10.5 % (0–73.3 %). The rates of cervical stenosis was 8.6 % when a cerclage was placed and 3.0 % when none was placed. In our institution, we do routinely place a cerclage at the time of radical trachelectomy.

When placing a cerclage, several suture may be used. We prefer to use 0-Ethibond suture(Johnsons & Johnsons, New Jersey, USA). The cerclage is placed approximately 2 cm superior to the lower edge of the uterus in order to decrease the likelihood of cerclage erosion into the vagina as a consequence of placing the cerclage too close to the uterine vaginal anastomosis. The suture of the cerclage should also be placed posteriorly to avoid erosion of the cerclage into the bladder. The abdominal wall is then closed in a routine fashion.

Another area of controversy is whether to place a uterine cannula to prevent the occurrence of future amenorrea after radical trachelectomy. A number of tools have been used such as pediatric Foley catheter or a Smitt sleeve (Elekta AB, Stockholm, Sweden) When placing the Smitt sleeve, it is important to suture the Smitt sleeve to the uterus using 4–0 Chromic suture. Among those in whom a cannula was placed the rate of stenosis was 4.6 % compared to 12.7 % when none was used ($P < 0.001$) [12]. In a recent study by Vieira el at. [10], the investigators used a pediatric Foley in 57 (62 %) of 92 patients versus a Smitt sleeve (Elekta AB, Stockholm, Sweden) in 23 (25 %) of 92 patients or none in 12 patients (13 %). In the Foley catheter group, six (10.5 %) developed cervical stenosis, compared with one (4.3 %) patient who developed stenosis in the Smitt sleeve group and one (8.3 %) patient with no catheter placement. Additionally, Nick et al. showed that the rate of cervical stenosis after radical trachelectomy prior to use of the Smitt sleeve was 14 % and 0 % after implementating its use in every case [11]. When a Smitt sleeve is secured to the uterus, it is then removed 3–4 weeks after the radical trachelectomy.

At this point, the uterus draws its blood supply from the utero-ovarian ligaments that in turn derive their blood supply from the ovarian vessels bilaterally (Fig. 102.18). The uterus is then anastomosed to the vagina using interrupted 2–0 Vicryl sutures. Sutures may be placed continuously or interrupted (Fig. 102.19). Alternatively, one may use a barbed suture, such as a V-loc suture (Covidien, London, UK).

Results

As of August 2015, there were a total of 663 intended ART's published in the literature [13–29]. The procedure was performed as planned in 608 patients, whereas in the remaining 55 patients a conversion to a radical hysterectomy was required. Conversions to radical hysterectomies were done for close margins or nodal involvement. The most common histology was squamous cell carcinoma (76 %), and the most frequent stage was IB1 (75 %). Lymphovascular space involvement was present in 21.5 % of cases (Table 102.1). The surgical time ranged from 100 to 611 minutes and the blood loss ranged from 50 to 4300 ml. The transfusion rate among those who reported this information was 42 % (102/238) (Table 102.2).

Intraoperative complications other than bleeding necessiting transfusion are rare, or not reported in most studies. The most common postoperative complication described is cervical stenosis occurring in 9.5 % of patients, followed by infection or abscess in 38 8.6 %, and lymphocyst in 5.9 % of patients [9] (Table 102.3). The global pregnancy rate after ART was 17.9 % which is very similar to 16.2 % described in a recent literature review [9]. Pregnancy rate was calculated as follows: total pregnancies/patients with

fertility preservation. It is important to highlight that not all authors report the number of patients seeking to get pregnant, but among those reporting this information, the percentages fluctuate between 16.9 % [11] and 60 % [25]. Obtetrical outcomes show that there were 109 pregnancies out of a total 658 patients who maintained their fertility, with 25 miscarriages (14 first trimester and 9 s trimester). A total of 14 patients had an ongoing pregnancy at the time of report. There were 71 deliveries, 24 of them at term, 28 preterm, and 19 without information on delivery time. Table 102.4 summarizes the obstetrical results.

Given the current data on abdominal radical trachelectomy, it seems that this procedure is safe and feasible and offers patients with early-stage cervical cancer a very reasonable option for fertility preservation with excellent oncologic outcomes. In the future, perhaps less radical approaches, such as simple conization or simple hysterectomy, will be feasible for select patients with low-risk criteria.

Radical Abdominal Hysterectomy with Anterior and Posterior Exenteration: Gynecological Perspectives

103

Ana-Maria Schmidt and Daniel Fink

Introduction

Alexander Brunschwig was the first surgeon to publish his preliminary experience with pelvic exenterations in 1948. The procedure included the en bloc resection of the internal and external reproductive organs, the bladder with the urethra, the pelvic ureter, anus, rectum and colon sigmoideum, including the perineum. There was no reconstruction, and the ureters were implanted in the colon [1]. The morbidity and mortality rates were very high because of the empty pelvis and the combined stoma. The new method involving an ileal conduit presented by Bricker in 1956 helped lower the number of renal complications, although at the price of an additional stoma [2, 3].

Today, new surgical techniques for resection and reconstruction and greatly enhanced postoperative care have improved patient outcomes significantly. Primary and palliative exenterations have also gained acceptance.

Classification and Indications

Pelvic exenterations are mostly performed with a curative aim; nevertheless, indications for palliative exenterations are possible in special cases. The exenteration is considered curative when no distant metastases are found on the preoperative imaging or intraabdominal survey during the operation and the pathological findings show clear margins. Tumor perforations into the pouch of Douglas, positive margins or peritoneal lavage or distant metastasis change the aim from curative to palliative.

e-mail: ana-maria.schmidt@usz.ch; daniel.fink@usz.ch

An anterior exenteration is defined as the removal of the reproductive tract and the bladder with the pelvic ureters and the urethra. A posterior exenteration includes the removal of the reproductive tract with the rectosigmoid colon. A total exenteration is the combination of both procedures.

Whenever possible a complete reconstruction is carried out, which includes the building of a continent bladder (often out of the ileocecal segment) and the formation of an omental flap, a neovagina and a colorectal anastomosis. These steps fill the empty pelvis, reducing complications such as ileus, and have a positive impact on the postoperative quality of life of the patients.

Indications for primary exenteration are uterine tumors infiltrating the bladder and/or rectum and tumor-induced fistulae between the bladder and/or rectum and vagina. Indications for secondary exenteration are tumor recurrences after surgery or irradiation with infiltration of the bladder and/or rectum. Large fistulae after radiotherapy or cloacae can also be an indication for exenteration, even in the absence of tumor.

Occasionally, additional interventions such as nephrectomy, vulvectomy or resection of the anus should be considered.

The most common genital tumor treated through exenteration is carcinoma of the cervix, followed by carcinomas of the uterine corpus, vagina and vulva.

Before undergoing an exenteration, all patients should have examinations under general or spinal anesthesia, including cystoscopy and rectoscopy, to evaluate their operability and to histologically verify the tumor. Positron emission tomography (PET) scans of the thorax and the abdomen and other examinations needed to evaluate the patient's operability should also be part of the preoperative evaluation (Fig. 103.1 and Table 103.1).

Surgical Technique

The exenteration procedure comprises first a destructive and afterwards a reconstructive part.

The abdomen is opened through a longitudinal incision from the symphysis to the upper abdomen. The height of the incision depends on the weight of the patient and/or the necessity of performing a paraaortic lymphonodectomy.

After the insertion of the retractor system, a systematic inspection of the abdominal cavity is undertaken to exclude tumor spread. A lavage of the cavity for cytological examination is indicated.

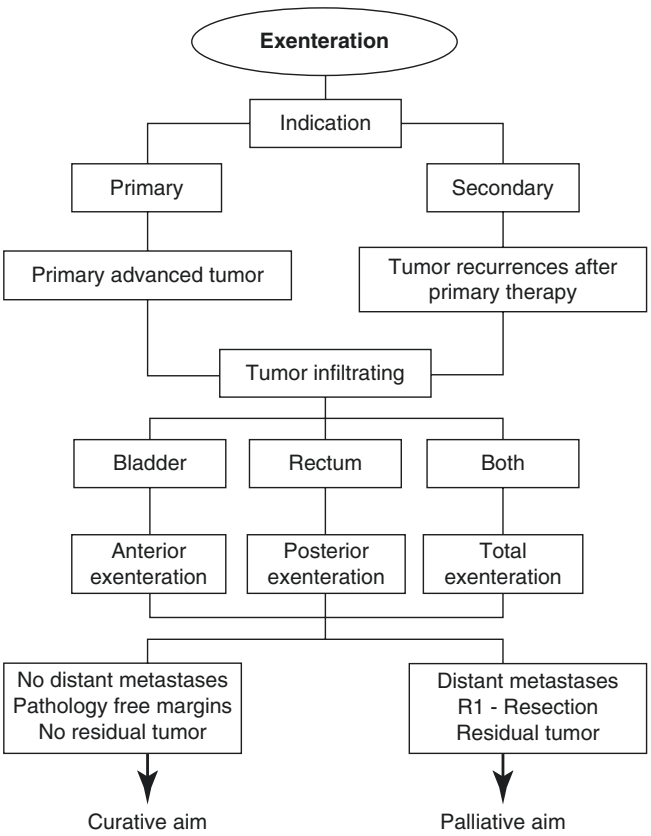

Fig. 103.1 Exenteration flow chart: indications and aims

If a lymphonodectomy has to be undertaken, the corresponding incisions are made in the peritoneum to expose both the descending aorta and the vena cava for a paraaortic lymphonodectomy or the bifurcations of the great vessels for a pelvic lymphonodectomy.

In cases with no indication for lymphonodectomy but with expected high blood loss, preemptive exposure of the internal iliac vessels should be considered. This step may save time later if ligation becomes necessary (Fig. 103.2).

The destructive part of a primary exenteration begins with dissection of the round ligament on the right side after straight grips have been applied to the uterus and tightened. The gap in the peritoneum is then enlarged with scissors, first in a cranial and then slightly medial direction (Fig. 103.3). Traction is applied to the medial part of the peritoneum so that the ureter can be exposed and lateralized. In the direction towards the tumor, the lateralization should end at a safe distance, which is at least 2 cm above the tumor. The lumbosacral plexus and the infundibulopelvic ligament should now be visible (Fig. 103.4).The ureters can now be dissected out followed by catheter insertion. The catheters are directed into reservoirs at the sides of the patient so that the urine does not flow into the abdomen (Fig. 103.5). If needed, the infundibulopelvic ligament can now be dissected.

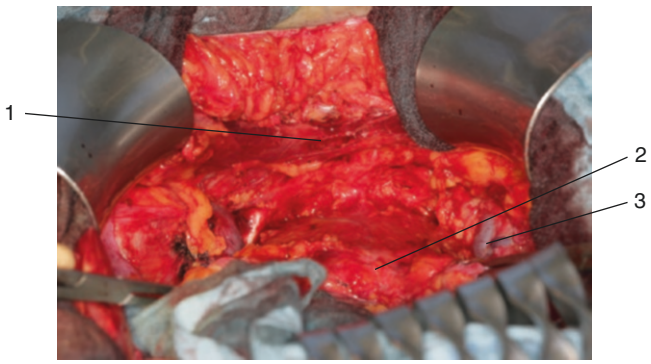

Fig. 103.6 Anterior pelvic space. *1* Posterior wall of the symphysis, *2* Anterior bladder wall, *3* External iliac vessels

If an anterior or a total exenteration is planned, the peritoneum is also dissected in a caudal and medial direction, following the curve of the dorsal face of the symphysis to expose the ventral surface of the bladder.

These steps are repeated on the other side of the pelvis. Now, the ventral surface of the bladder can easily be separated from the dorsal face of the symphysis (Fig. 103.6). Blunt separation may be used, and if small vessels are exposed, they can be coagulated and then dissected. For a posterior exenteration, the dissection of the peritoneum should occur immediately above the vesico-uterine fold. Then, the posterior wall of the bladder can be separated from the anterior uterine and cervical faces.

For a posterior or a total exenteration, the sigmoid colon is detached from the left pelvic wall, and the retroperitoneal space is opened. The round ligament and the infundibulopelvic ligament are then dissected after lateralization of the ureter. The ureter is then also dissected, if needed. Particularly, if a sub-total exenteration is the aim, the lumbosacral plexus should be preserved. The plexus is visible bilaterally to the medial peritoneum. After the peritoneum has been retracted, the plexuses can be easily moved aside. The plexus will then cover the sacral os like a fine net (Figs. 103.7 and 103.8). Now, the sigmoid colon is mobile, so the resection plane can be determined. The plane should be chosen at least 5 cm above the tumor level. It should not be so low that it would compromise the margins and not so high that more colon than needed is removed. The mesosigmoid is now bluntly mobilized from the anterior wall of the sacral os. The small vessels that occasionally appear can be dissected after coagulation (Fig. 103.8). In cases with very aggressive tumors, positive paracolic lymph nodes are found so that a complete resection of the mesosigmoid is recommended. The colon-tube is separated with a fine clamp from its mesentery, and then the mesentery is divided (Fig. 103.9). Afterwards, the intestine is divided as well, and a stapler is used to close both ends. For an anterior exenteration, the peritoneum in the

pouch of Douglas is opened, and the posterior vaginal wall is separated from the rectum.

Next, the specimen, consisting of the uterus, bladder and/or rectum (Figs. 103.10 and 103.11) is grasped with blunt clamps that have been tightened and retracted to the left side so that the right pelvic wall and the broad ligament with the uterine vessels are clearly shown (Figs. 103.12 and 103.13). If a pelvic lymphonodectomy has been performed, the iliac vessels (common, internal and external) and the obturator nerve come into view (Figs. 103.14 and 103.15). The lateral

bladder wall can now, mostly bluntly, be separated from the pelvic wall. There are sometimes some small vessels to be coagulated. Now, the specimen can be better retracted. The lateral umbilical ligament and the uterine artery thus come into view better (Fig. 103.16) so that the dissection of the upper part of the broad ligament can take place under direct visualization. Afterwards, the lower part will be visible (Fig. 103.17) and can also be dissected. Further retraction of the increasingly mobile specimen displays the paracolpic tissue (Figs. 103.18 and 103.19). Repeating this procedure on the left side displays the tissue connecting the urethra to the symphysis (Fig. 103.20), which can be now be divided. Using only the hand, one can now raise the specimen by lifting the dorsal part of the specimen out of the lower pelvis to display the anterior wall of the sacral os (Fig. 103.21). Afterwards, the posterior wall of the symphysis can also be totally displayed (Fig. 103.22). By the end of this procedure,

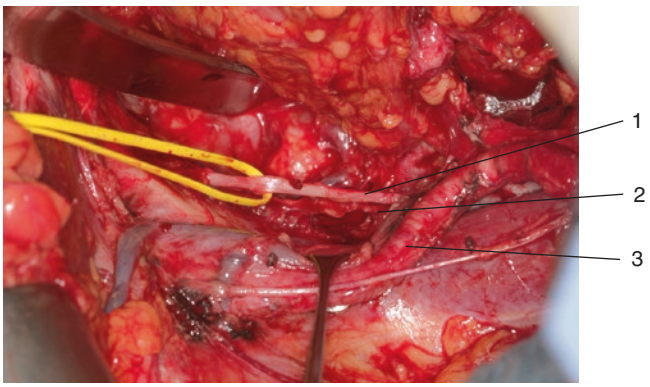

Fig. 103.18 Left pelvic wall. *1* Obturator nerv, *2* Paracolpic tissue, *3* External iliac vessels

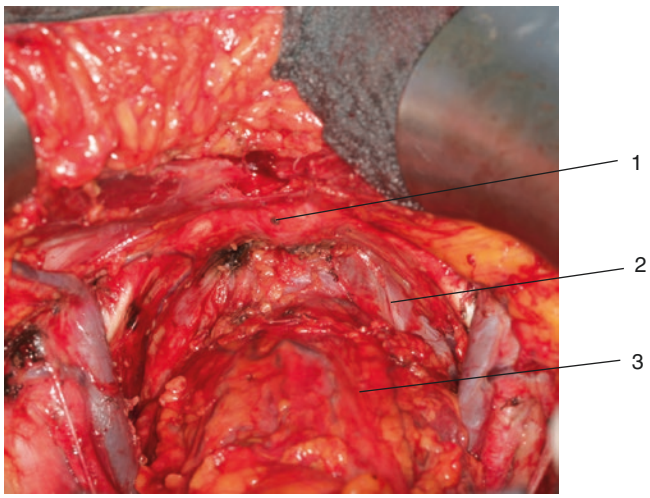

Fig. 103.22 Posterior wall of the symphysis with tendinous arch. *1* Symphysis, *2* Tendinous arch, *3* Anterior bladder wall

the tendinous arch of the pelvic will come into view laterally (Fig. 103.23). The abdominal procedure can now be completed by liberating the specimen from all remaining connections to the pelvis as much as possible, and the exenteration is then continued toward the vagina after positioning the patient in the lithotomy position.

It is recommended that the lower back of the patient be positioned a few centimeters over the lower edge of the operating table. This position provides better access to the rectum, especially when a rectum amputation is planned. In other cases, rectal digital control during the separation of the dorsal wall of the vagina from the rectum is mandatory.

If there is tumor debris protruding out of the vagina or rectum, it is recommended to place several alcohol-soaked cotton swabs inside to prevent tumor cells from being carried over to the remaining tissue.

Depending on the aim of the exenteration, the resection field is determined to include the urethral meatus and/or the anus and eventually the vulva, as well (Figs. 103.24 and

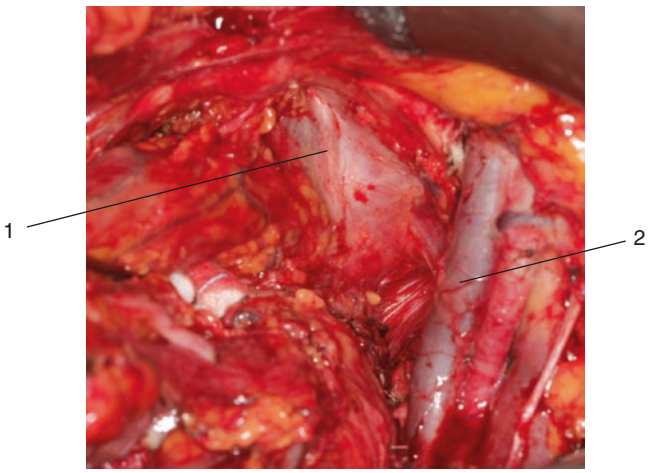

Fig. 103.23 Anterior/lateral/distal pelvic space. *1* Tendinous arch, *2* External iliac vessels

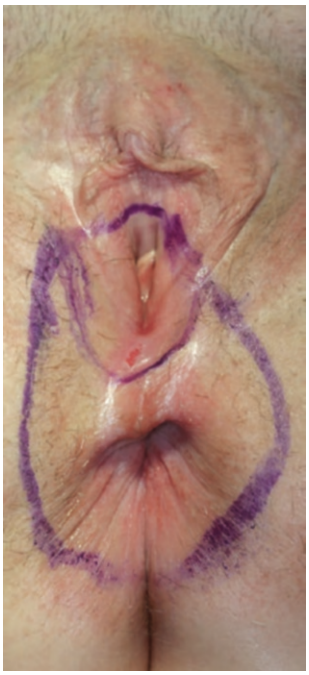

Fig. 103.24 Perineal excision

103.25). The vaginal incision is made just below the hymen, paying great attention to preserving the urethra or rectum if needed (Figs. 103.26 and 103.27). For an anterior or total exenteration, the dissection is continued alongside the posterior wall of the symphysis, both bluntly and sharply. Eventually, the connection to the abdominal operating field is completed after only a few steps. Then, the dorsal connection alongside the anterior rectal wall can be completed if an anterior exenteration is planned. This step will facilitate the lateral preparation. For a posterior or total exenteration, the level of preparation should be defined depending on the tumor position. Clear margins are most important, but a rectal stump of at least 6 cm is preferred. Now, the paracolpic tissue can be

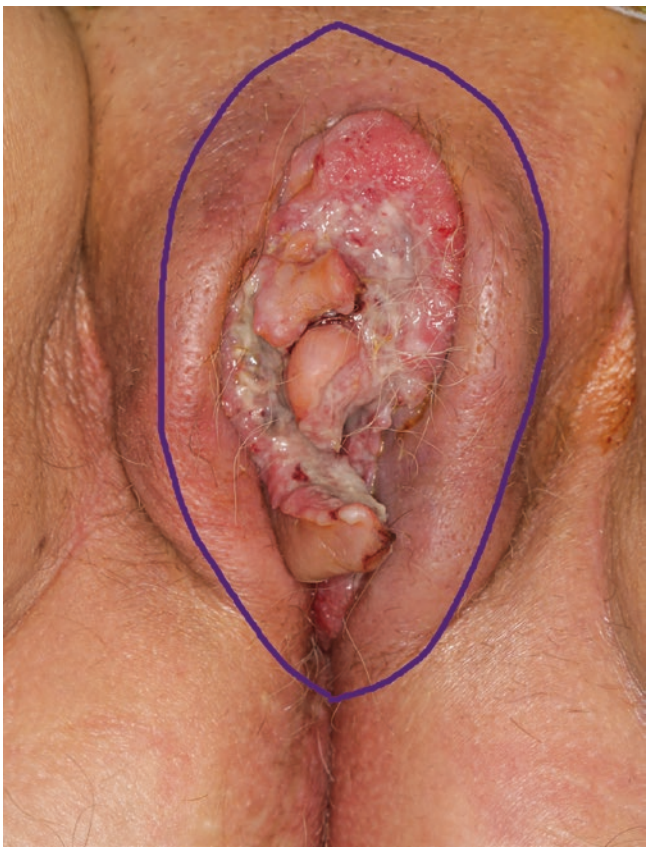

Fig. 103.25 Perineal excision with vulvectomy

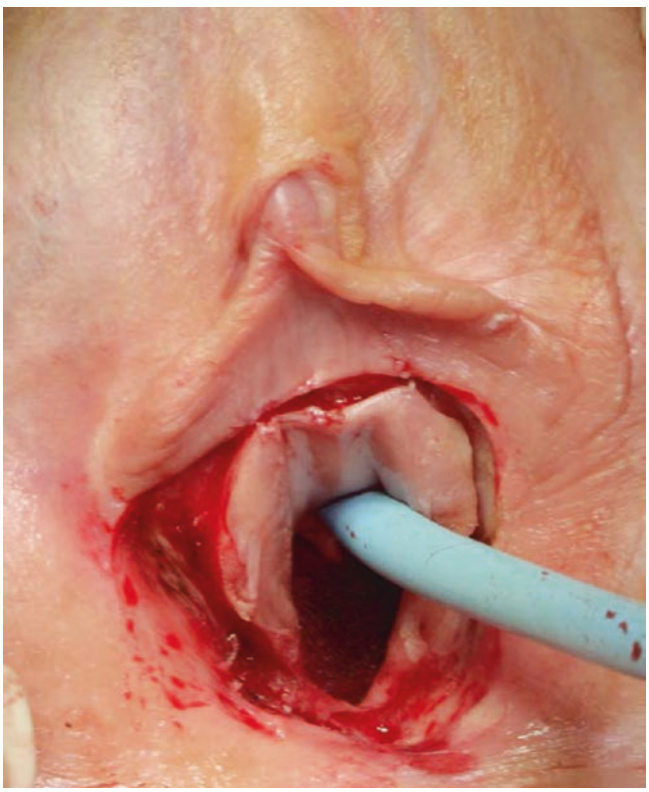

Fig. 103.26 Vaginal incision

displayed with Preisky blades and dissected so that the connection to the abdominal resection field is also completed. The specimen will now only be connected to the part of the rectum that is to be removed. The operational field is now again changed to an abdominal procedure.

Gently, the ventral part of the specimen is now upturned, paying attention not to spill tumor debris and not to avulse the caudal part of the tumor. The caudal rectal tube is now freed from the connecting tissue containing its blood supply and then divided using a stapler. Therewith, the resection of the specimen is completed (Fig. 103.28). After a total exenteration, the pelvis is now empty (Fig. 103.29).

It is recommended that the specimen should be pinned with the correct anatomical positioning on a cork disk (Figs. 103.30 and 103.31).

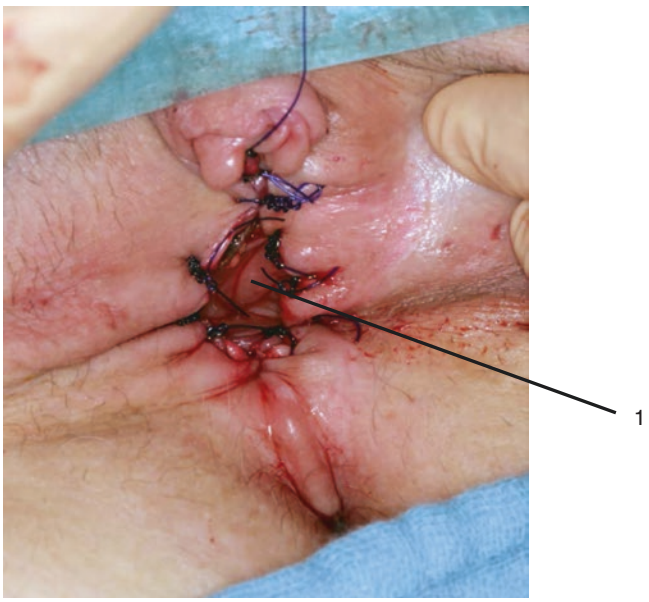

Fig. 103.32 1180° colonic neo – vagina

After rinsing all the operating fields with warm isotonic fluid and coagulating any bleeding vessels, the pelvis is packed with laparotomy sponges, and then the perineal wound is closed in 2–3 layers (Fig. 103.32), leaving a 3 cm gap for a neovagina, if needed. In cases involving an additional vulvectomy, skin grafts are eventually needed. In most cases, grafts are harvested from the inner thighs and rotated to cover the defect.

A secondary exenteration is a more challenging procedure due to the preceding treatment. These patients have undergone prior operations, irradiation or both. Depending on the prior treatment, adhesions and/or diffuse tissue induration can occur.

Reconstruction

A reconstruction that is as complete as possible is very important to the quality of life of the patients and also reduces the number of postoperative complications such as bowel obstruction.

To reconstruct the bladder, the two most frequently used options are an ileal conduit or a continent pouch. The first option is easier and faster to accomplish and needs only a small bowel anastomosis. However, it does involve a wet stoma and the necessity of wearing a collection bag. The building of the continent pouch, mostly out of the ileocecal segment of the bowel, takes 1–2 h longer and requires a colon anastomosis. If the appendix has not already been removed, it can serve as a neourethra. Once implanted at the bottom of the umbilicus, it is barely visible. The patient empties the pouch using a non-sterile catheter. If the prolongation of the operating time can be tolerated well by the patient and the patient can manage to regularly take care of the pouch, this should be the preferred option, especially in young patients.

The building of a neovagina can be a great psychological help, not only for younger patients. A neovagina also has the important function of filling the empty pelvis. When a posterior or total exenteration is undertaken, the caudal 10 cm of the remaining colon are separated, keeping the same blood supply, and then rotated 180°. The former cranial end is fixed at the introitus (Fig. 103.31). To prevent prolapse, the neovagina can be attached via a polypropylene mesh to the sacral os (180° colonic neovagina) [4].

The building of an omental flap is also highly recommended. The flap should retain its blood supply on the left side and should be placed ventrally to cover the colon anastomosis. It can prevent the formation of fistulae, and it also fills the empty pelvis. If the omentum is too small or has previously been resected, a polypropylene mesh can be attached to the pelvic side wall to prevent the small bowel from falling into the empty pelvis.

The colon anastomosis completes the reconstruction and should be carried out just before fixing the neovagina to the introitus. If the patient has previously undergone

irradiation or if the caudal rectum stump is shorter than 6 cm, a protective ileostoma should be performed for 6 weeks.

Even after an additional vulvectomy and/or anal extirpation, primary closure of the wound should be possible (Figs. 103.32, 103.33 and 103.34). If it is not, skin grafts from one or both thighs can be removed and rotated to cover the defect.

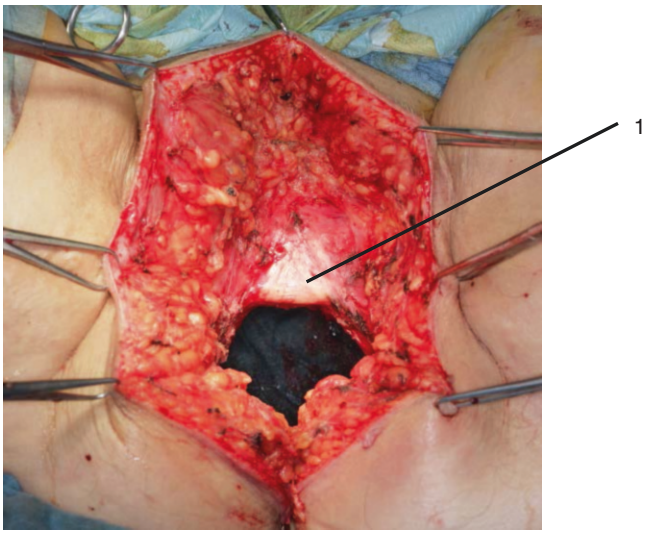

Fig. 103.33 Perineal sight after exenteration with vulvectomy and resection of the anus. *1* Symphysis

Fig. 103.34 Primary closure

Postoperative Care

Intensified care is usually needed for the first 1–2 postoperative days; afterwards the postoperative care should remain in the usual frame for patients undergoing large operations. Daily blood tests and clinical evaluation are needed. Prophylactic antimicrobial treatment is recommended for 5 days. Drains should be inspected twice daily for the color and appearance of their output. The critical period for an insufficiency of the colo-anal anastomosis is 3–5 days postoperatively. Physical training with the help of specialized personnel is recommended.

Complications

The most feared complications are septicemia, pulmonary embolism and those related to insufficiencies of the sutures in the bowel or neobladder. Eventually, relaparotomy is needed. The perioperative mortality is approximately 5 % [4-9].

Although the perioperative morbidity and mortality are not negligible, long-term survival in a considerable proportion of women with advanced or recurred gynecological cancer is possible. Due to modern reconstruction techniques, these patients can have a good quality of life.

Radical Abdominal Hysterectomy with Anterior Exenteration: Urological Perspectives

104

Siamak Daneshmand

Introduction

Radical abdominal hysterectomy with anterior exenteration (radical cystectomy) is most commonly performed by the urologist in the context of bladder cancer. In the United States, urothelial carcinoma of the bladder is the second most common malignancy of the genitourinary tract, and the second most common cause of death among all genitourinary tumors. An estimated 74,690 new cases of bladder cancer and 15,210 deaths from bladder cancer were expected in 2014 in the United States [1]. In women bladder cancer ranks as the 17th most common malignancy worldwide however it ranks 9th in developed countries [2]. Men are 2.7-times more likely to develop urothelial carcinoma in their lifetime [3]. The gender disparity may be due to differences in smoking and occupational risk factors although hormonal influences may also play a role [4]. Data is conflicting whether gender specific hormonal differences may influence UC development and prognosis [5, 6]. In general women tend to present with more advanced stage at diagnosis and have worse survival when compared to men, although recent data suggests the prognosis is similar to men in a large matched cohort [4, 7–9]. The difference in prognosis does not appear to be explained by differential under treatment or choice of therapy between sexes [10, 11].

Although about 70 % of patients with primary urothelial carcinoma of the bladder present with non-muscle-invasive tumors, up to 30 % will either present with or progress to high-grade, muscle-invasive disease. These cancers are highly lethal and are the cause of death in the vast majority of patients within 2 years of diagnosis without aggressive treatment. Approximately 70 % of patients present with localized disease, while 33 % have regional spread and 5 % have distant metastasis at the time of diagnosis [1]. Radical cystectomy with or without neoadjuvant chemotherapy is still considered the gold standard therapy for high-grade, muscle-invasive bladder cancer and high-grade non-muscle-invasive cancers deemed to be at high risk for progression or non responsive to intravesical therapy. In addition, radical cystectomy with a thorough, meticulous lymph node dissection provides accurate pathologic staging, and provides optimal outcomes in terms of survival and preventing local pelvic recurrence. Pelvic recurrence rates in patients undergoing an extended pelvic lymph node dissection range from 15 to 32 % in large institutional series [12–14].

Over the past several decades, improvements in anesthesia, surgical technique, and perioperative management have led to a decrease in perioperative morbidity and mortality. Nevertheless, radical cystectomy with pelvic lymphadenectomy remains a formidable surgery with significant early and late complications. Mortality rates, however, have decreased significantly to 2–3 % in contemporary series from centers of excellence [15]. In addition, radical cystectomy with a meticulous and thorough pelvic lymphadenectomy provides optimal local control of the tumor. Bladder substitution with an orthotopic ileal neobladder in general has excellent functional outcomes in experienced centers and may allow some patients and surgeons to consider radical cystectomy earlier in the disease process when it has the best chance of cure. Currently, most women with preserved pelvic floor function can safely undergo orthotopic lower urinary tract reconstruction to the native urethra following cystectomy [16, 17].

There have been significant refinements in the surgical technique of radical cystectomy over the past decade, particularly with respect to blood loss and preservation of the urethral rhabdosphincter and the neurovascular bundles without any compromise in oncologic principles. The surgical technique is critical in minimizing local recurrence and positive surgical margins and to maximize cancer-specific survival. Positive surgical margins and/or tumor spill during surgery put the patients at exceedingly high risk for local

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_104

recurrence and should be avoided at all costs. Local pelvic recurrence is a lethal event in the vast majority of patients, and salvage therapies are currently ineffective [12].

There has been significant debate regarding the ideal limits of pelvic lymphadenectomy for bladder cancer over the last few decades. There is universal agreement that all patients should undergo at least a bilateral pelvic lymphadenectomy to include at least the external, internal, and obturator lymph nodes. There are abundant retrospective data suggesting that an extended pelvic and iliac lymphadenectomy including bilateral pelvic, common iliac, pre-sciatic (Fossa of Marcilles), and pre-sacral nodes increases the number of nodes identified by the pathologist and identifies more metastatic nodes in node-positive patients. At some centers the proximal limit of the dissection is further extended to include the para-caval and para-aortic nodes up to the inferior mesenteric artery.

In women, radical cystectomy is often called anterior pelvic exenteration which includes en bloc removal of the uterus, cervix, fallopian tubes, ovaries and the anterior vaginal wall [18]. A distal ureteral margin is usually sent for frozen section to ensure the absence of dysplasia or frank carcinoma although its relation to outcome is controversial [19]. The reproductive organs are removed in order to achieve negative margins and maximize oncologic control, although risk of involvement in female patients who undergo anterior pelvic exenteration for urothelial carcinoma of the bladder is less than 10 % with the vagina the most commonly involved site [20]. Patients with lower stage disease and no evidence of disease involving the anterior vaginal wall on bimanual examination preoperatively can be considered for vaginal sparing techniques, which can potentially offer better preservation of sexual function [21]. This may be in part due to preservation of the neurovascular tissue along the anterolateral vaginal wall. In addition, some studies have shown improved voiding patterns with an orthotopic urinary diversion when the vagina and uterus are spared during cystectomy, although randomized studies are lacking [22, 23]. However, most women undergoing radical cystectomy are elderly and not sexually active and performing organ preserving surgery must be weighed against the risk of compromising oncologic control. In unselected patients undergoing anterior pelvic exenteration for bladder cancer, the incidence of local invasion of the gynecological organs at the time of RC ranges from 2.6 to 7.5 % [24]. In our experience, the vagina is the most commonly involved with an incidence of 5 %, and is commonly associated with urothelial carcinoma present at the bladder base [20]. Concomitant gynecological malignancy is, however, much less common. In a large series of 609 patients undergoing anterior exenteration, none of the patients had a synchronous primary gynecological malignancy [25]. The long-term risk of cervical, uterine and ovarian cancer remains in this population and requires appropriate follow up. It should also be noted that in some women, preservation and transposition of the ovaries leads to cystic changes that may require eventual re-operation for oophorectomy [26]. Reproductive organ preserving cystectomy is best suited for younger women desiring preservation of sexual function and/or fertility and should be considered only after meticulous pre-operative staging and proper counseling.

Anatomy

The vascular anatomy of the urinary bladder is generally consistent and uniform. The primary blood supply is derived from the anterior division of the internal iliac (hypogastric) artery which in turn gives rise to the superior and inferior vesical arteries. When dissecting the ureters, preservation of the longitudinal blood supply within the peri-ureteral tissue is imperative in order to prevent uretero-intestinal anastomotic strictures. Colleselli et al., described the innervation of the urethral sphincteric mechanism in the female [27] Fibers from the pelvic nerve course along the lateral vaginal wall just posterior to the bladder to innervate the bladder neck, and fibers from the internal pudendal nerve travel underneath the endopelvic fascia to innervate the distal two-thirds of the urethra, and the rhabdoid sphincteric mechanism. If orthotopic urinary diversion (neobladder) is to be considered, it is imperative that these structures including the endopelvic fascia are preserved in order to maintain continence.

Lymph Node Drainage

The primary lymphatic drainage of the bladder is to the nodes in the true pelvis, which include the obturator, internal, and external iliac nodes. The secondary and tertiary lymphatic drainage is to the common iliac, para-caval and para-aortic nodes, respectively. The pre-sacral nodes also receive direct drainage from the trigone and posterior bladder wall and, although rare, nodal metastasis in this region may occur in the absence of disease distal to the common iliac bifurcation.

Lymph node metastases from bladder cancer tend to track to the ipsilateral nodes associated with the invasive cancer. However, node metastases contralateral to the primary site of the tumor are common and thus mandate a bilateral node dissection [28]. Up to 12 % of nodes found along the external iliac and distal common iliac vessels are located in the Fossa of Marcilles (also referred to as the pre-sciatic fossa). Complete skeletonization of the common iliac vessels and dissection in this area is important in order to remove all of the potential nodal tissue. Metastasis to common iliac and more proximal nodes in the absence of

pelvic nodal metastasis is uncommon but can occur via the posterior lymphatic collecting ducts which may drain directly to the common iliac nodes [29, 30].

Small perivesical lymph nodes lie within the perivesical fascia and intercalate within the lymphatic ductal network, organized around the trigone, anterior and posterior bladder walls. These nodes may be the only site of node metastasis, have been associated with aggressive tumor biology, and have an independent association with worse overall and disease-specific survival [31, 32].

Pre-operative Evaluation

Pre-operative evaluation includes the standard detailed history including gynecological health focusing on menopausal status, abnormal spotting, last pap smear and past gynecological procedures. We do not advocate routine cervical pap smear and transvaginal ultrasound prior to surgery given the low rates of concomitant gynecological malignancies in this population [33]. Sexual function and desire for future fertility should be documented although the vast majority of women undergoing cystectomy are beyond child-bearing ages. Staging should performed by transurethral resection of the tumor with adequate sampling of muscularis propria with specific focus on the bladder base, trigone and bladder neck. During this procedure, a bimanual examination under anesthesia must be performed, ideally before and after transurethral resection to aid in the clinical staging and identify concomitant gynecological pathology such as pelvic organ prolapse. A palpable tumor would designate clinical T3 disease and strong consideration should be made for neoadjuvant therapy in this setting. Imaging should include a CT scan of the chest, abdomen and pelvis with IV contrast whenever possible to rule out metastatic disease. It should be noted that clinical understaging remains a significant issue in bladder cancer management. Various clinico-histopathologic features such as lymphovascular invasion, presence of hydronephrosis, variant histology, and deep muscularis propria invasion substantially increase the risk of upstaging. Laboratory evaluation should include routine blood counts and comprehensive metabolic panels to include liver function tests and serum alkaline phosphatase. There are no specific tumor markers for bladder cancer although carbonic anhydrase 19–9 has been shown to have independent prognostic value when elevated [34]. Bone scintigraphy is not routinely used to screen for bone metastases unless there is an elevation of alkaline phosphatase or presence of bone pain [35]. Positron emission tomography combined with CT is not routine used although it may identify patients with locally advanced bladder cancer and identify occult metastases [36–38]. False positives and the excretion of the FDG tracer into the urinary tract limit its utility however.

Perioperative Management

Many patients undergoing cystectomy have significant comorbidities often related to long-term tobacco use. Preoperative evaluation and optimization of cardiac and pulmonary function are crucial in risk assessment and reducing post-operative complications. Cardiac clearance is obtained for most patients with a cardiac history with appropriate stress testing. Pulmonary function testing is not routinely performed unless a decision has to be made regarding the suitability of the patient for the surgery. Mechanical and antibiotic bowel preparations have been traditionally recommended in order to cleanse the bowel for urinary diversion, however this practice may lead to dehydration, alteration of normal bowel flora, and electrolyte disturbances. Retrospective studies have shown that the elimination of bowel preparation prior to radical cystectomy shows no difference in perioperative outcomes, including gastrointestinal complications [39, 40]. In addition, a meta-analysis performed to investigate the effect of bowel preparation in reducing the incidence of post-operative complications in patients undergoing elective colorectal procedures showed no differences in the rates of mortality, reoperation, peritonitis, and wound infection [41].

Nasogastric (NG) decompression is also commonly used post-operatively following cystectomy in an attempt to decompress the stomach, prevent emesis and aspiration, and to minimize the risk of bowel anastomotic leak or dehiscence. However, data suggest that NG tube decompression is unnecessary and may, in fact, *increase* complication rates [42]. Donat et al. described an overnight-only NG tube (NGT) with use of metoclopramide, demonstrating the benefits of an early return of bowel function and reduced pulmonary complications [43]. In a study including 430 patients, Inman et al. demonstrated prolonged NGT decompression was associated with prolonged time to GI recovery. Omission of NGT in these patients was associated with a shorter time to return of flatus and a reduced length of stay [44]. Numerous other studies including general surgery cases in addition to radical cystectomy have shown that bowel resection can be safely performed without the use of post-operative NGT decompression [45, 46]. A meta-analysis involving 26 trials including nearly 4000 patients established the non-necessity of routine NGT decompression by demonstrating a higher incidence of pulmonary complications with no clinical benefits such as reduction in gastrointestinal complications or length of stay [47].

Fasting and adherence to a clear liquid diet prior to surgery has long been the dogmatic approach to a patient undergoing surgery requiring bowel resection. In response to fasting, however, insulin resistance can develop and, in fact, increase post-operative complications. Pre-operative carbohydrate loading has been shown to play an important

role in decreasing hospital stay and in recovery after elective bowel surgery. Pre-operative administration of oral carbohydrate energy-containing fluids can help reduce insulin resistance and has been associated with a reduced length of stay following elective surgery [48].

Use of perioperative opioids for pain control is a significant contributor to post-operative ileus. Opioid receptors are distributed throughout the gastrointestinal tract, and most opiates have mu receptor activity that inhibits gastric motility and delays emptying [49]. Alvimopan is a mu-opioid receptor antagonist that has been shown in multiple randomized trials to accelerate the return of bowel function following bowel resection. Results from five multi-center, double-blind randomized placebo-controlled trials including 1877 patients, as well as a meta-analysis of three of the trials including a pooled modified intention-to-treat population of 1388 patients have documented the benefits of Alvimopan in reducing time to bowel recovery and hospital discharge in patients undergoing abdominal surgery [50]. A recent phase IV double-blind, placebo-controlled study involving the use of Alvimopan in patients undergoing radical cystectomy for bladder cancer confirmed the benefits by demonstrating quicker bowel recovery and shorter hospital stays compared with those who received placebo. There were significantly fewer episodes of post-operative ileus in the Alvimopan group (8.4 vs 29.1 %; $p<0.001$) with no increase in adverse effects [51].

We have adopted an evidence-based multimodal care pathway (commonly referred to as ERAS-enhanced recovery after surgery) aimed at providing optimal perioperative care for all patients undergoing radical cystectomy (Fig. 104.1). The goal of this protocol is to minimize perioperative gastrointestinal complications and reduce hospital stay while improving the perioperative experience. We have demonstrated a significant decrease in length of hospital stay with this protocol from a median of 8 days down to 4 days [52]. Given the evidence against the use of bowel preparation, and the potential for increasing complications, we have omitted all bowel preparation prior to surgery unless there is a preoperative plan for using the colon for continent cutaneous diversion. A high-protein, high-carbohydrate liquid drink is recommended for a few days prior to surgery, without any recommendation for withholding intake the day prior to surgery, i.e. a regular diet is maintained up to the night prior to

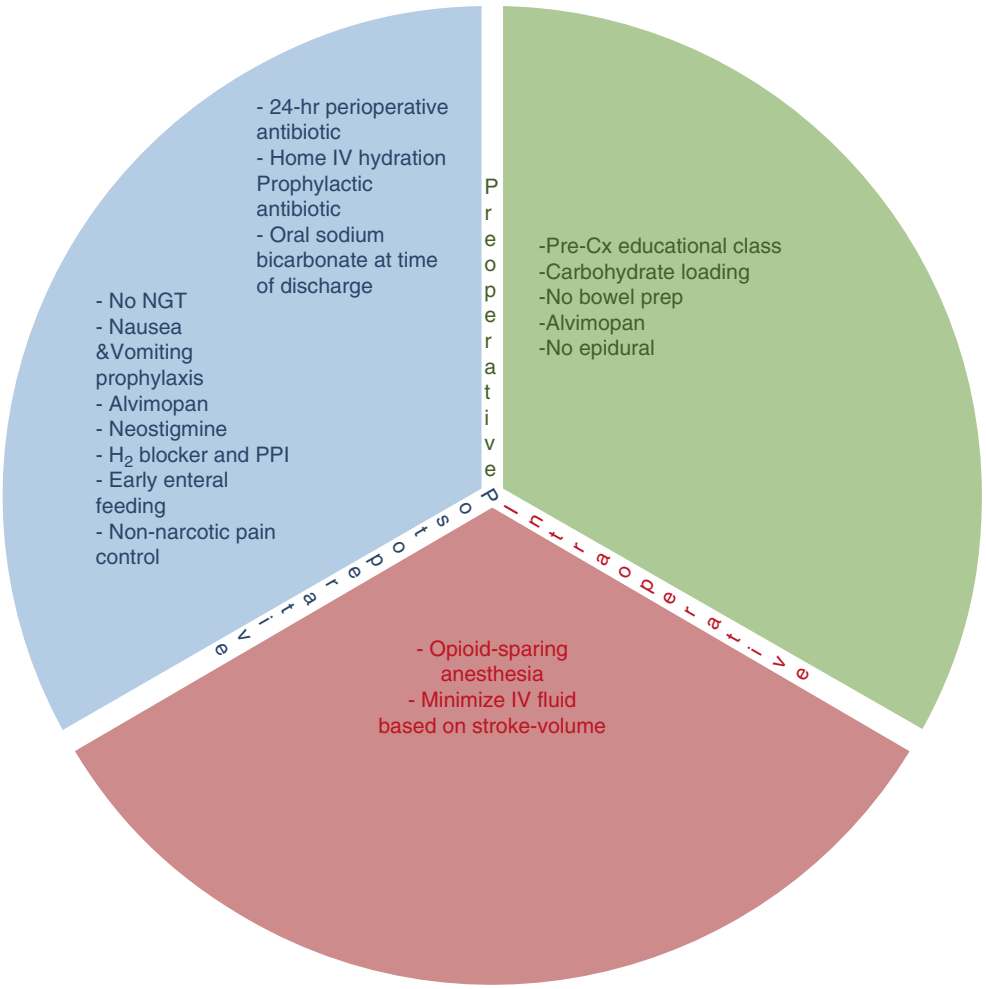

Fig. 104.1 Peri-operative management protocol for patients who undergo radical cystectomy and urinary diversion reconstruction for bladder cancer

surgery. A pre-operative counseling session as well as educational classes aimed at detecting psychosocial barriers that may impede early recovery can help improve outcomes with this surgery. Standardized pre-operative educational classes may also provide a platform for improvement of patient compliance and understanding of the post-operative milestones required prior to discharge. Alvimopan is given in the pre-operative holding area 30–60 min prior to the operation. Subcutaneous heparin is given in the pre-operative holding area for thromboprophylaxis. Our enterostomal therapy nurse marks all patients for a stoma in cases of cutaneous incontinent diversion.

Intraoperatively, blood loss and bowel manipulation are kept to a minimum. Fluid intake is minimized while the ureters are clipped. Intravenous acetaminophen acetate and ketorolac are started intraoperatively if there are no contraindications, and opioid use is kept to a minimum. An orogastric tube (if used) is removed at the conclusion of surgery and the patient is then transferred to the ward on telemetry unless there is any indication for admission to ICU.

Patient Positioning

Patients are placed in a frog leg position to allow access to the vagina intraoperatively. The patient is hyperextended to allow better exposure to the pelvis, with care being taken to protect the arms and adequately pad all sensitive areas. The patient is placed in a reverse Trendelenburg position to level the abdominal wall parallel to the floor, which helps keep some of the small bowel contents within the abdominal cavity. Arterial and central lines are placed as necessary and an orogastric tube is placed which is removed at the conclusion of the case. The patient is prepped per routine guidelines and the vagina is fully prepped. After draping, a Foley catheter is placed in the bladder and left to gravity drainage. A right-handed surgeon usually stands on the patient's left-hand side of the operating table.

Incision and Intra-abdominal Exposure

The pelvic organs are generally accessed through an infraumbilical midline incision. The anterior rectus fascia is incised and the rectus muscles are retracted laterally. The posterior rectus fascia is incised, the peritoneal cavity is entered and self-retaining retractors are placed. Manual palpation of the pelvis and retroperitoneum is performed to look for palpable lymphadenopathy and to make sure the bladder is not fixed to the pelvic sidewalls. Next, the posterior peritoneum is incised, taking down the peritoneal attachments to the small bowel mesentery. The right colon is not mobilized, unless a continent cutaneous reservoir using the colon is planned. It may be necessary to mobilize the mesentery of the terminal ilium in order to allow maximal mobility for neobladder reconstruction. The rectosigmoid is mobilized along the avascular line of Toldt and its mesentery is elevated off the sacral promontory up to the level of the inferior mesenteric artery (IMA) in order to allow the left ureter to pass easily to the right side and to expose the lower retroperitoneum for the extended lymphadenectomy. The ureters are dissected into the deep pelvis where they are clipped and divided with the distal circumferential tip sent for frozen sections analysis. Next, the small bowel is packed into the abdomen using lap pads and retractors.

Pelvic Lymphadenectomy

As previously mentioned, a meticulous pelvic lymph node dissection is a critical part of the procedure. It should be noted that this is not a lymph node 'sampling' procedure but rather an extensive removal of all lymphatic bearing tissues around the vessels which should be skeletonized whenever possible. The extended pelvic lymph node dissection is initiated approximately 3 cm above the aortic bifurcation at the level of the inferior mesenteric artery (superior limit of dissection). The dissection extends laterally over the aorta and vena cava to the genitofemoral nerve on either side, which represents the lateral limits of dissection. The para-aortic and para-caval nodal tissue is removed and the proximal tissue is clipped, with care being taken not to dissect too deeply in the interaortocaval area. Frequently, small anterior tributary veins originate from the vena cava just above the bifurcation, which should be clipped and divided. Hemoclips are generally used at the superior, inferior and lateral limits of the dissection while the rest of the vessels are circumferentially skeletonized. The infundibulopelvic ligament containing the ovarian vessels are ligated and divided in order to include the ovaries with the specimen.

Next, all fibroareolar and lymphatic tissue is peeled off the common iliac arteries with the dissection extending out laterally to the genitofemoral nerve and then sweeping medially down over the sacral promontory into the hollow of the sacrum. The genitofemoral nerve is preserved although small branches that course more medially that are intimately associated with the iliac arteries are excised. Care must be taken to avoid injury to the left common iliac vein, which courses directly posterior to the right common iliac artery. The sacral promontory is skeletonized and the presacral nodes are removed. The left median sacral vein drains into the left common iliac vein and must be recognized and often clipped to avoid avulsion during removal of the pre-sacral nodes.

Once the proximal portion of the lymph node dissection is completed, a finger is passed under the peritoneum proximally over the external iliac artery and vein distally to

the femoral canal. The opposite hand is used to connect with the proximal dissection from above and the peritoneum is divided lateral to the infundibulo-pelvic ligament and the round ligament is clipped and divided. The external iliac artery and vein are then circumferentially mobilized, freeing up all of the lymph node bearing tissue to join up with the proximal limits of dissection over the common iliac vessels. Care must be taken to recognize and ligate an accessory obturator vein, which originates from the inferomedial aspect of the external iliac vein in approximately 40 % of patients. There is often a psoas branch arising from the lateral aspect of the proximal external iliac artery, which must be clipped and divided. The distal limits of the dissection are the circumflex iliac vein crossing anterior to the external iliac artery distally, the genitofemoral nerve laterally, and the lymph node of Cloquet situated on Cooper's ligament medially. The lymph node of Cloquet (also known as node of Rosenmüller) is removed and the iliac vessels are carefully retracted medially in order to clear the obturator fossa. This can be facilitated by passing a small gauze sponge lateral to the vessels along the pelvic sidewall taking care to stay anterior to the internal iliac vein. The external iliac vessels can then be retracted laterally and the sponge is brought medially and removed. Care however must be taken not to avulse deep venous branches, which can be the source of significant bleeding. Small tributary vessels and lymphatics from the sidewall are clipped and the hypogastric artery is skeletonized while the obturator/internal iliac nodes are removed. The obturator vessels are generally not divided and are dissected proximally to the internal iliac vessels. Finally the fossa of Marcille (lateral to the common iliac vessels) is dissected and the lumbosacral branch of the sciatic nerve is identified. The lymphatic tissue is sent as separate packets and includes the para-aortic, para-caval, the common iliacs, presacral nodes, external iliacs, the pre-sciatic nodes (fossa of Marcilles) and the obturator/internal iliac nodes (Fig. 104.2a, b).

The Lateral and Posterior Bladder Pedicles

After skeletonizing the proximal internal iliac artery and vein, the lateral vascular pedicle of the bladder and uterus is stretched, clipped and divided down to the area of the

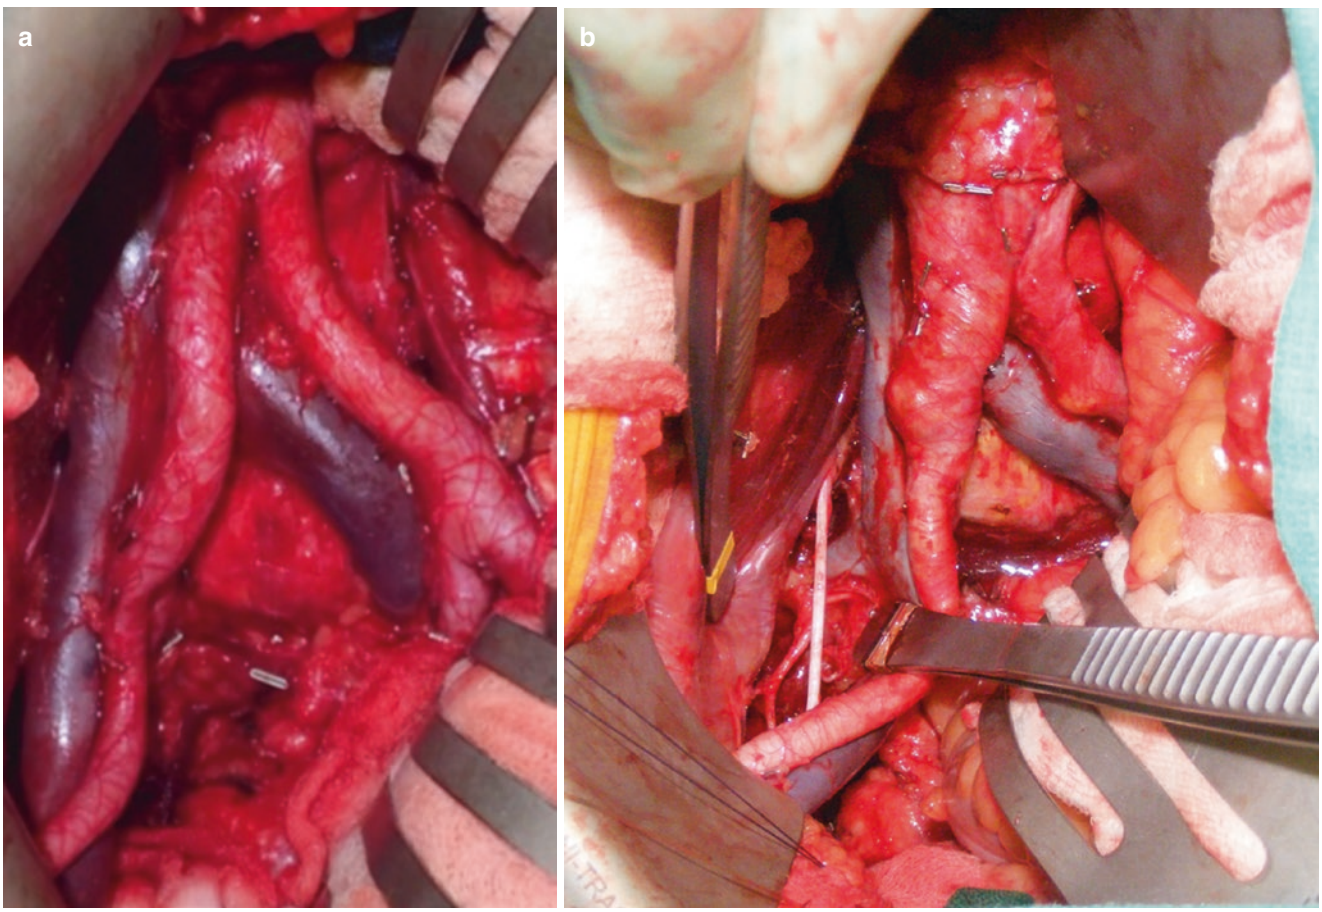

Fig. 104.2 Completion of an extended pelvic lymph node dissection for bladder cancer (**a**) Nodal packet includes the para-aortic, para-caval, common iliac, external iliac, internal iliac/obturator fossa, presacral as well as pre-sciatic nodes (within the Fossa of Marcille, **b**)

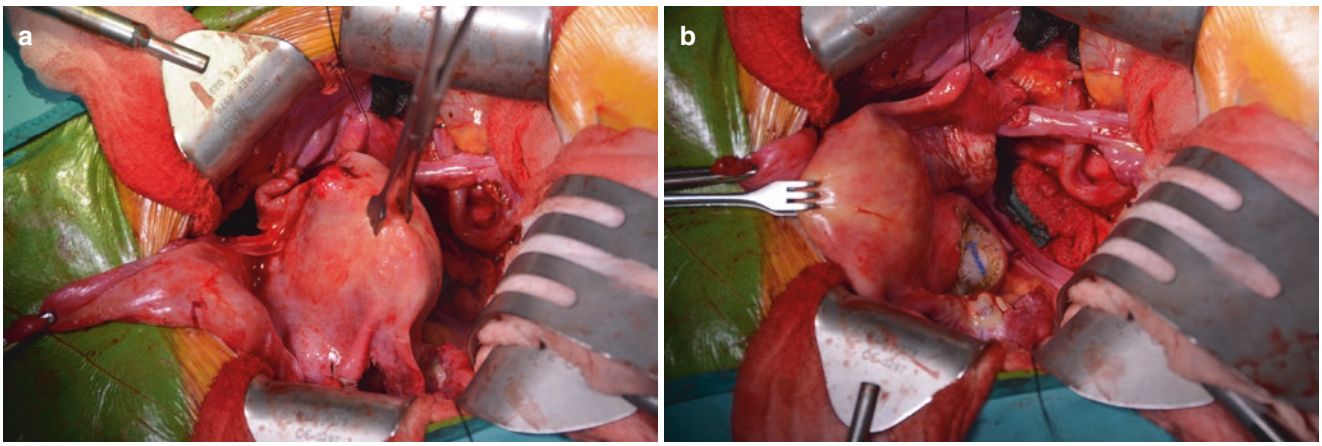

Fig. 104.3 (**a**) The uterus is grasped with forceps and lifted anteriorly. (**b**) A lubricated sponge stick is placed in the vagina and directed cephalad to allow precise identification of the apex of the vagina which can now be incised

endopelvic fascia. The uterus is grasped with a tenaculum and lifted anteriorly along with the bladder in order to align the lateral pedicle with identification of individual branches off the anterior branch of the internal iliac artery (Fig. 104.3a). The first branch to the bladder (the superior vesical artery) is clipped and divided which the rest of the branches of the lateral pedicle including the uterine artery and vaginal artery can be ligated using a tissue sealant device.

Posterior Dissection

A lubricated sponge stick is placed in the vagina and directed cephalad to allow precise identification of the apex of the vagina. The incision is made at the apex of the vagina just distal to the cervix (Fig. 104.3b) The cardinal ligaments are taken down and the vaginal wall is then circumferentially incised and the cervix, along with the uterus, fallopian tubes and ovaries are included in the specimen (Fig. 104.4). The tissue sealant device is then used to divide the anterior vaginal wall which is included in the specimen unless a vaginal-sparing technique is being performed (Fig. 104.5). If the bladder tumor is not located posteriorly or at the trigone, a vaginal sparing approach may be performed by developing the plane between the anterior vaginal wall and the posterior bladder. It is critical to avoid entry into the bladder or end up with a positive margin during this maneuver since there is no natural fascial plane between the bladder and the vagina. If there is copious fat lateral to the vagina, this can first be ligated with the tissue sealant device. This aids with the precise identification of the lateral wall of the vagina and also significantly reduces blood loss. However, if a nerve sparing technique is to be performed, then care must be taken to preserve that neurovascular bundle that course on the lateral aspect of the vaginal wall. A meticulous dissection along the lateral vaginal walls, bladder neck and proximal urethra is necessary to preserve these nerves and the use of electrocautery should be minimized. Nerve-sparing techniques typically go hand in hand with a vaginal sparing cystectomy. The dissection is carried just distal to the vesicourethral junction. Palpation of the Foley catheter balloon assists in identifying the bladder neck/urethral junction (Fig. 104.6) In the case of orthotopic diversion the plane between the anterior vaginal wall and the urethra is bluntly developed. The distal urethra is left intact along with the endopelvic fascia and the urethral support mechanism (Fig. 104.7a) The catheter can at this point be removed and the bladder neck clamped and divided. A total of 8–10 urethral sutures are placed circumferentially around the urethra for later neobladder anastomosis. The vaginal cuff is closed in 2 layers using 2-0 Vicryl and then pexed to the sacral promontory (sacrocolpopexy) using a soft prolene mesh using permanent suture to prevent an enterocele (Fig. 104.7b). In case of a posterior tumor, the anterior vagina is divided using the tissue sealant device and included en bloc with the specimen (Fig. 104.8). The urethra can still be preserved in these cases and orthotopic diversion is possible as long as the rhabdosphincter complex is kept intact. In these cases, the vagina is usually reconstructed by a clam shell or side to sided technique with absorbable sutures. A well-vascularized omental pedicle graft is mobilized off the colon based on the left gastroepiploic artery and secured anterior to the reconstructed vagina to prevent fistulization (Fig. 104.9). If a continent cutaneous diversion or ileal conduit is planned, the urethra can be removed en bloc by dividing the pubourethral ligaments and taking down the endopelvic fascia. The anterior vaginal wall is dissected further distally and incised around the urethral meatus. The vaginal cuff is closed as previously described. Alternatively the urethra can be dissected transvaginally to meet up with the dissection from the pelvis. In rare cases of concomitant bilateral upper tract involvement or previous renal transplant, the entire genitourinary tract can be removed en bloc (Fig. 104.10).

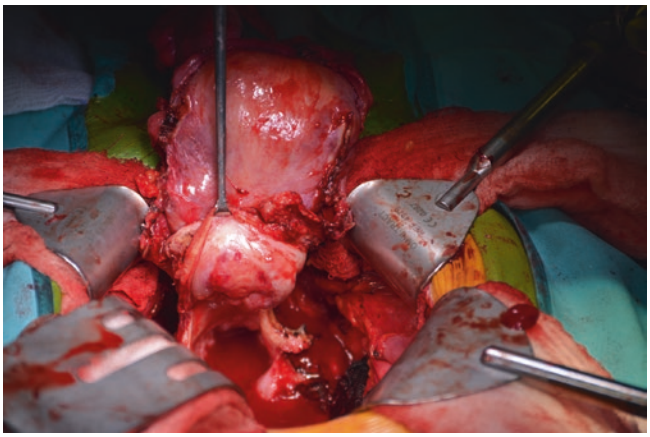

Fig. 104.4 The incision is made at the apex of the vagina just distal to the cervix. A tissue sealant device can now be used laterally to include the anterior vaginal wall with the specimen

Urethra

A concomitant urethrectomy is typically performed with the anterior pelvic exenteration unless an orthotopic diversion is planned. In the past it was believed that the retained female urethra was insufficient to maintain continence and there were concerns about possible urethral recurrence. However ongoing anatomic and clinical evidence proved that excellent functional results can in fact be achieved with preservation of the urethra and the surrounding support structures [53].

Two important pathologic studies were critical to understanding of urethral preservation in female patients undergoing anterior exenteration for urothelial carcinoma. In a

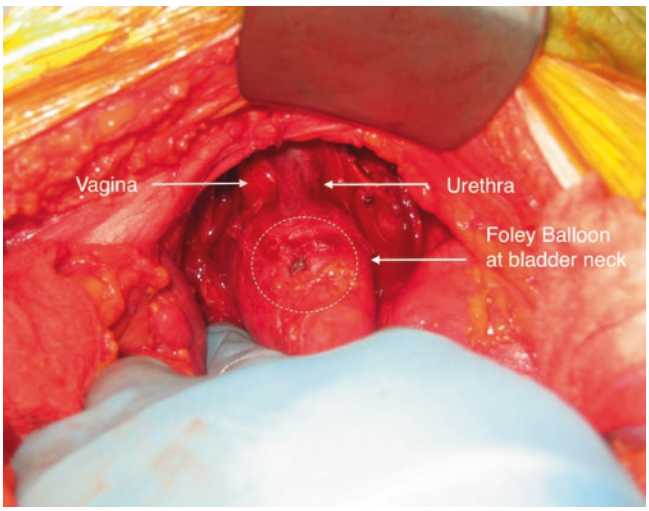

Fig. 104.6 Figure showing the anatomic relationship at the bladder neck. Precise identification of the bladder neck/urethral margin is critical in preservation of the sphincter mechanism in case of orthotopic urinary diversion

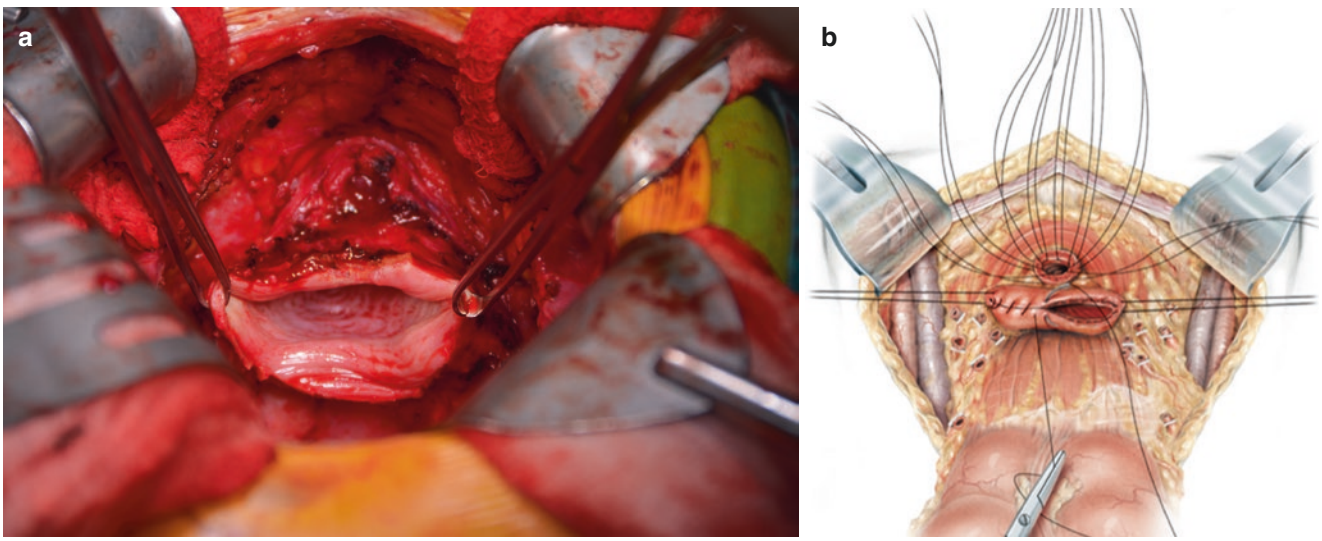

Fig. 104.7 (**a**) Urethral and vaginal sparing anterior pelvic exenteration in preparation for orthotopic ileal neobladder reconstruction. (**b**) Once the specimen is removed, the vaginal cuff is closed in two layers using 2-0 Vicryl and 8–10 urethral anastomotic sutures are placed. The vaginal cuff is then anchored to the sacral promontory (sacrocolpopexy) using a piece of soft Prolene mesh to prevent prolapse (From Stein and Skinner [67], with permission)

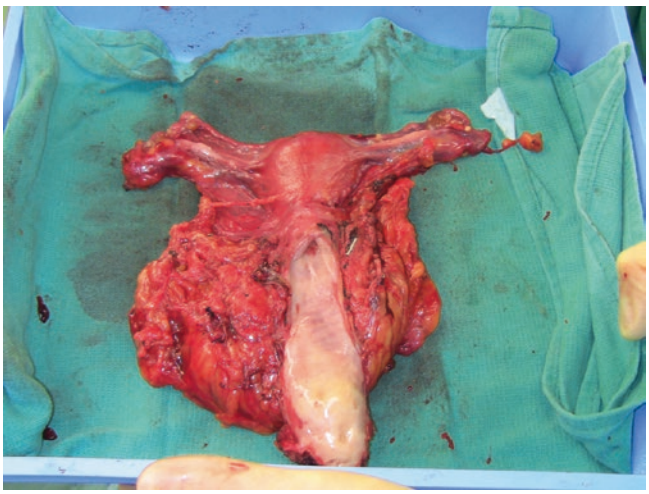

Fig. 104.8 En bloc anterior pelvic exenteration with anterior vaginectomy in a patient with tumor at the posterior bladder wall

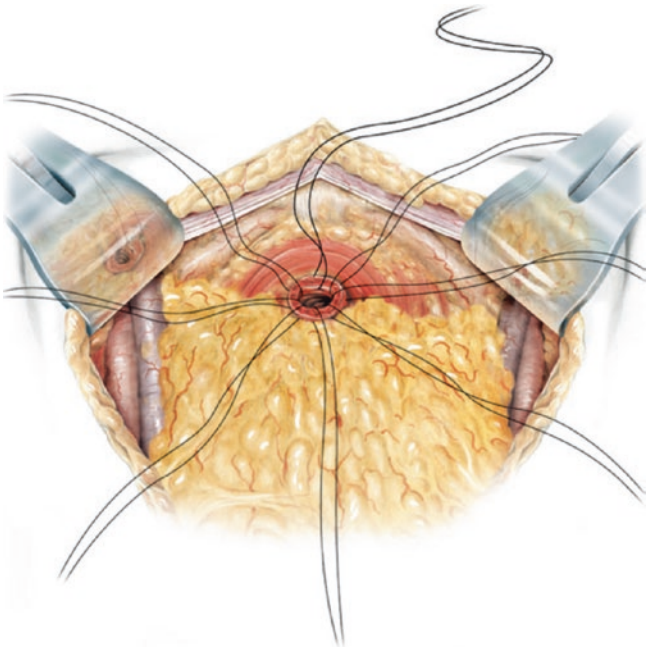

Fig. 104.9 In case of orthotopic urinary diversion the omentum is mobilized based on the left gastroepiploic pedicle and placed over the reconstructed vagina and secured to surrounding tissue in order to prevent a neobladder-vaginal fistula (From Stein and Skinner [67]. With permission)

series of 67 female patients undergoing cystectomy with urethrectomy for bladder cancer, Stein et al. re-evaluated the primary pathologic specimens and found 17 (25 %) had involvement of the bladder neck while 9 (13 %) of them had urethral involvement. All patients who did not have bladder neck involvement also had no urethral involvement whereas approximately 50 % of patients with a bladder neck tumor had concomitant urethral tumor involvement. The major risk favor for the presence of urethral tumor was found to be

Fig. 104.10 En bloc resection of the genitourinary tract in patient with urothelial carcinoma of bilateral upper tracts and the bladder. Specimen includes both kidneys, ureters, uterus, fallopian tubes, ovaries, bladder, anterior vagina and urethra

vaginal wall involvement, albeit rare (1 %) [53]. The presence of vaginal wall invasion is best evaluated on bimanual examination under anesthesia, either at transurethral resection or at cystectomy. Stenzl and colleagues also studied the risk of synchronous or secondary urethral tumors with long-term follow-up in 356 women with bladder cancer of all stages. Urethral involvement was only found in 2 % of the patients, and it was always associated with bladder neck involvement. Of the patients with cT2–T4 localized disease only 1 % had urethral involvement. The conclusion from these studies was that the urethra can be safely preserved in patients who have no involvement of the bladder neck [54].

In a prospective study aimed to identify appropriate female candidates for orthotopic urinary diversion, Stein et al. examined the final pathologic analysis of the bladder neck and proximal urethra and compared it with the intraoperative frozen-section analysis of the proximal urethral margin. Tumor involvement at the bladder neck and proximal urethra was found in 14 (19 %) and 5 (7 %) cystectomy specimens, respectively. All patients with urethral tumor also had concomitant bladder neck tumor as previously seen.

Bladder neck tumor involvement was again found to be the most significant risk factor for tumor involving the urethra. However, approximately half of patients with bladder neck tumors had a normal proximal urethra and none of the patients with normal bladder neck pathology had urethral involvement. In all cases, intraoperative frozen-section analysis of the proximal urethra correlated with and was correctly confirmed by final permanent section [55]. These results confirmed that intraoperative frozen section analysis of the proximal urethra can rule out urethral involvement and determine the eligibility for orthotopic diversion.

In the study examining the clinical follow-up data of the first 88 women undergoing orthotopic diversion at University of Southern California, there were no urethral recurrences observed with a median follow-up of 30 months [56]. In a similar study Ali el Dein et al. prospectively evaluated 145 women undergoing cystectomy and orthotopic diversion. Two patients developed urethral recurrence. One had a primary squamous cell cancer of the bladder, and the other had urothelial carcinoma with carcinoma in situ of the trigone [25, 57]. In a recently published multi-institutional study of 297 women undergoing radical cystectomy with ileal neobladder for bladder cancer at four centers, solitary urethral recurrence was seen in only 2 patients (0.6 %). Urethral recurrence was associated with a positive final urethral margin whereas no significant associations were found for carcinoma in situ, pathologic tumor and nodal stage, and bladder trigone involvement [58].

Detailed understanding of the urethral and pelvic anatomy is critical to preservation of sphincteric function if orthotopic diversion is planned. Knowledge of the rhabdosphincter complex was derived from elegant neuroanatomic studies of the female urethra. Colleselli and colleagues performed extensive microneuroanatomic dissections, histologic examination, and three-dimensional reconstructive imaging to better define the urethral sphincteric and rhabdosphincteric anatomy in women. The female urethral sphincter system consists of smooth muscle innervated by the autonomic nervous system and striated muscle supplied by somatic nerves. The autonomic nerves that emerge from the pelvic plexus course along the lateral aspect of the rectum and vagina to innervate the bladder neck and proximal urethra, however these nerves do not appear to play a significant role in the innervation of the actual rhabdosphincter that is responsible for the continence mechanism [27]. Most investigators agree that the rhabdosphincter is supplied primarily by the branches of the pudendal nerve [27, 59].

Complications

Many of the complications following anterior pelvic exenteration with urinary diversion are related to bowel complications. Each form of diversion carries a unique set of complications but all share similar changes in bowel habits such as chronic constipation and chance of bowel obstruction. Sexual dysfunction is common following anterior exenteration and includes diminished ability or inability to achieve orgasm, decreased lubrication, decreased sexual desire, and dyspareunia. Only half of the patients report being able to have successful vaginal intercourse with 52 % reporting decreased satisfaction with overall sexual function [60]. This is most likely a result of damage to the neurovascular bundles that course along the lateral vaginal wall [61]. Nerve sparing and reproductive organ sparing techniques however aim to preserve sexual function and satisfaction [21]. Sexual dysfunction however can be multi-factorial and choice of urinary diversion following anterior exenteration can have a significant impact on health related quality of life. Some studies demonstrate improved sexual function following orthotopic urinary diversion while others have shown no difference [62, 63].

Other complications include bowel vaginal fistulas particularly with neobladders where there could be overlapping suture lines. Rates of neobladder vaginal fistulas range from 3 to 5 % and may be diminished by placement of a pedicalized omental flap between the neobladder and vagina [64]. Preservation of the anterior vaginal wall and pubo-urethral ligaments also likely decreases the likelihood of anterior vaginal wall descent [65]. Concomitant fixation of the posterior vaginal wall to the sacrum (sacrocolpopexy) using mesh may further decrease the chance of prolapse and enterocele [66]. Other more rare complications include ureterovaginal fistulas and vaginal mesh erosion.

Conclusion

Anterior pelvic exenteration with a thorough pelvic lymph node dissection and subsequent urinary diversion remains a challenging operation with considerable morbidity. Surgical technique along with surgeon and hospital experience is critical in optimizing clinical outcomes. The surgery still provides the best survival rate with the lowest chance of local recurrence for high-grade invasive bladder cancer. Further refinement in identification of candidates for female organ preserving surgery may reduce complication rates and improve health related quality of life.

Radical Abdominal Hysterectomy (RAH) with Anterior and Posterior Exenteration: Surgical Perspectives

105

Manol B. Sokolov

Introduction

The pelvic exenteration is defined as a surgical intervention, including: removal of rectum, distal colon, urinary bladder, distal segments of ureters, internal genital organs, lymph nodes, which drain these organs, and pelvic peritoneum.

In terms of history we have to mention Brunschwig, who first published in 1948 a series of 22 patients, who underwent pelvic exenteration by marking perioperative mortality of 23 %. Bricker introduced in 1950 the use of ileal segment and forming of skin ureteroileostomy. Pomel et al. published in 2003 a report about the first laparoscopic total pelvic exenteration.

Factors that accentuate the expansive growth of tumor are:

- sites at which different and more numerous systems are in very close contact
- limited space at which tumors may expand
- hystological pathology and differentiation

Definition of Locally Advanced Pelvic Carcinoma

Making of a definition of locally advanced stage of the disease is required with the purpose of theoretical and practical clarity, concerning relatively big percentage of patients with colorectal carcinoma or malignant tumor of internal female genital organs, i.e. carcinoma with pelvic localization, including also carcinoma of urinary bladder and ureter. Some patients with pelvic carcinoma present with different form and grade of locally advanced primary or relapsed tumor process, but in stage of non-metastatic disease, which, despite the absence of generalization, cannot be resected. The criteria for non-resectability are variable and are not clearly defined. For example, the definitions for locally advanced colorectal cancer vary with different authors. Several authors determine it as one, visualized by means of endorectal ultrasound diagnostics as T3/4 and N1 tumor, or one that is also clinically diagnosed by a tumor mass found upon palpation during physical examination, but with no presence of distant metastases [1, 2].

American Joint Committee on Cancer Staging Scheme classifies them as T4 lesion [3].

The term "advanced cancer" was suggested in clinical and pathological sense for the first time by William Stewart Halsted (1852–1922), who established the foundations of modern surgical treatment of carcinoma of mammary gland. This notable surgeon added to that category the tumors with significant size, involving the underlying structures of thoracic wall or with presence of metastases in the regional lymph nodes, considered as direct tumor growth. Halsted noted some rules for extended resection of mammary gland as a prerequisite for radical treatment of early and advanced stages, and he accepted the advanced local growth of the tumor outside of organ borders as a main hindering factor for operative removal of the tumor or predetermining factor of poor prognosis after non-radical surgical operation. He did not assume that the distant metastases are related and originate from the primary tumor, and assessed them as other neoplastic diseases [4]. Stephen Paget circumstantially studied in 1921 the metastatic process of carcinomas of breast and lung, and made a well-grounded suggestion that the cancer cells disseminate by means of blood circulation, but may settle and grow only in certain organs, developing the "seed and soil" theory. Later, based on the studies of Virchow from 1885–1892, and his own observations and studies of synchronous metastatic process, Paget underlined the role of the lymph system as a main road for occurrence of secondary (metastatic) foci and generalization of neoplastic disease. He determined as advanced carcinoma the one which had presence of secondary lesions originating from the primary tumor [4].

According to our opinion, a suitable working definition of locally advanced colorectal tumor, and generally of malignant tumor of lesser pelvis, is such that the final assessment by a multidisciplinary medical team for management of patient, represented by surgeons, pathologists, radiologists and medical oncologists, gastroenterologists and specialists in medical imaging is namely that standard single-organ resection could not be performed (without the major probability for remaining in the tissues surrounding the specimen and spaces of microscopically or macroscopically found residual disease due to the adhesion or the fixation of the tumor to the surrounding anatomical structures). Locally advanced lesion may vary from having apparently intimate adhesion to the surrounding tissues, i.e. marginally, "borderline" resectable tumor to one, which directly, macroscopically, involves the adjacent critical structures (for example main blood vessels, pelvic bones, lateral or anterior abdominal wall, other portions of large and small intestine or their mesenteria, internal genital organs or organs of urinary bladder, nerve plexuses, etc.). The sigmoid colon cancer may invade inside the urinary bladder, ovaries, and uterus. The preoperative medical imaging methods in many cases cannot ensure precise information about the malignant invasion. In this particular situation the intraoperative making of decision about performing of multivisceral resection is difficult. The tumor mass is usually very voluminous for adequate determination of the tumor borders. The data from the literature indicate that the surrounding anatomical structures and organs are involved in the context of primary localization of the tumor in the sigmoid colon and rectum – 66–89 % of the cases. The reasons for that are the big frequency of localization of carcinoma in these portions, mobility of sigmoid colon, and narrow spatial distances of structures in the lesser pelvis [5–7]. The determination of locally advanced stage of the disease depends on whether clinical assessment of the resectability is done preoperatively or intraoperatively. In some cases the inoperable tumor, assessed as such upon clinical or imaging radiographic examination, may consequently, upon intraoperative exploration, turn to one susceptible to radical resection [1].

From 5 to 22 % of all colorectal carcinomas present as "locally advanced" tumors [8, 9]. The absence of local tumor control, especially in locally advanced colorectal cancer, has disastrous consequences as intestinal or urinary obstruction, bleeding from the lower intestinal tract, and morphological and functional disorders of the remaining surrounding organs, fistulizations, and considerable pain. The successful eradication of locally advanced tumor would ensure better survival and better quality of life. Many investigators have reported the possibility of en bloc-resection in series of cases [10–15] and some have demonstrated significantly better long-term prognosis and actual survival. Nakafusa Y. et al. reported in 2004 53 patients with multivisceral resection, among 323 with elective surgery for pT3/pT4 without any distant metastases. They took into consideration that the en bloc-resections were significantly related to the tumor size, depth of invasion, surgical blood loss and hemotransfusions, as well as surgery time ($p < 0.0001$). The morbidity after en bloc-resections was higher compared to the standard – 49.1 % vs. 17.8 % ($p < 0.0001$) – without any intraoperative and early postoperative mortality in the two groups, while the perioperative and early postoperative mortality were 0 % in both groups. The level of survival had no significant difference (5-year 76.6 % vs. 79.5 %, $p = 0.9347$). The lymph node metastases (hazard ratio, 2.519; 95 % confidence interval, 1.460–4.315; $P = 0.0009$) and hemotransfusions (hazard ratio, 2.353; 95 % confidence interval, 1.185–4.651; $P = 0.0145$) were taken into consideration as independently associated with the survival [16]. Park S, Lee Y.S. [17], who studied in 2011 the short-term and long-term results of 54 patients with macroscopically found locally advanced tumor among a total of 266 patients with curative resection (2000–2007) for T3 and T4 colorectal carcinoma, found histological infiltration in 44.4 % of the en bloc-resections, and at the same time their results demonstrated increased postoperative morbidity in multivisceral resections (35.2 % compared to 17.5 % in standard resections), but long-term survival without any statistical difference to the one in standard single-organ resections (5-year survival: 61 % vs. 58 %; $p = 0.36$). Cho S. et al. demonstrated in 2009 similar results in 36 patients with en bloc-resections from a total of 476 patients with locally advanced colon cancer [18]. Hoffmann M. et al. published in 2012 the analyses of 78 patients with multivisceral resections from a total of 123 patients with T4-locally advanced colorectal carcinoma (2002–2008), who had as a main significant prognostic factor in multivariation analysis ($p < 0.0001$) the consideration of the possibility of achievement of R0-resection with 5-year survival in 55 % without any significant difference in the non-multivisceral resections ($p = 0.608$), without any significant difference for the tumor origin–colon or rectum ($p = 0.839$), in laparoscopic or open procedures ($p = 0.610$) and in emergency compared to elective procedures ($p = 0.674$). They found that the presence of lymph node metastases in their study was not a predictive factor for survival, not taking into consideration the difference in patient with or without N+ ($p = 0.658$) [19]. Gezen C. et al. published in 2012 an analysis of 90 patients with clinical T4 colorectal carcinoma from a total of 354 patients (2001–2010), and multivisceral resection in 91.1 % (82 of them), and at the same time in 34.4 % of the clinical T4 they found actual histological invasion in the surrounding anatomical structures–pT4, more rarely in men ($p < 0.05$). pT4 cancer was more frequent when the clinical T4 (cT4) was localized in colon (48.8 % vs. 21.3 %; $p < 0.01$), the laparoscopic method was used rarely and the risk of conversion was higher in the T4 tumors ($p < 0.05$), the number of

sphincter-saving procedures did not demonstrate any difference compared to the non-en bloc-resections, but the surgery time, intraoperative blood loss, and amount of blood transfused had considerable increase, when en bloc-resection was required ($p < 0.05$). There was no significant difference in the hospital stay, complications, and 30-day mortality. Identical level of 5-year survival was noted ($p > 0.05$) [20].

Types of Pelvic Exenteration

The types of pelvic exenteration are:

- Anterior pelvic exenteration (Fig. 105.1)
- Posterior pelvic exenteration(Fig. 105.2)
- Total pelvic exenteration
  - Supralevator
  - Infralevator (Fig. 105.3)

As a part of the pelvic exenteration, in the context of tumor involvemennt of the lower rectal portion and/or anal canal, the modern conception for performing of abdomino-perineal extirpation (APE) comprises three types of extent of resection–inter-sphincter APE; extra-levators APE (ELAPE); ischio-anal APE (Figs. 105.4 and 105.5).

- Extended exenteration, which includes abdomino-sacral resection (Figs. 105.6, 105.7, 105.8, 105.9, 105.10 and 105.11)

Approximately about 85–95 % of patients with advanced malignant disease of pelvis, subjected to pelvic exenteration, are expected to survive the surgical intervention. Initially designed as a palliative procedure in advanced malignant diseases of pelvis, today the 5-year survival of patients after pelvic exenteration due to relapsed pelvic tumor has improved and varied between 20 and 60 %.

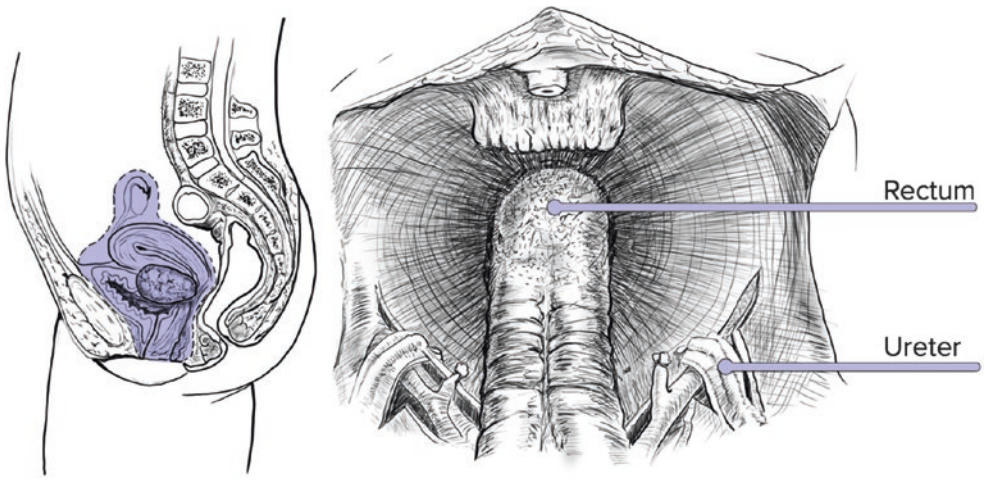

Fig. 105.1 Anterior pelvic exenteration

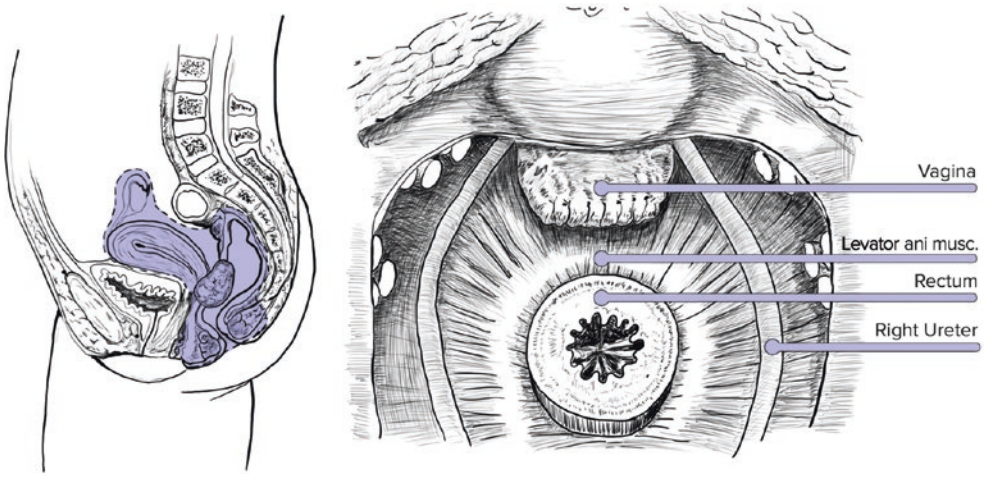

Fig. 105.2 Posterior pelvic exenteration

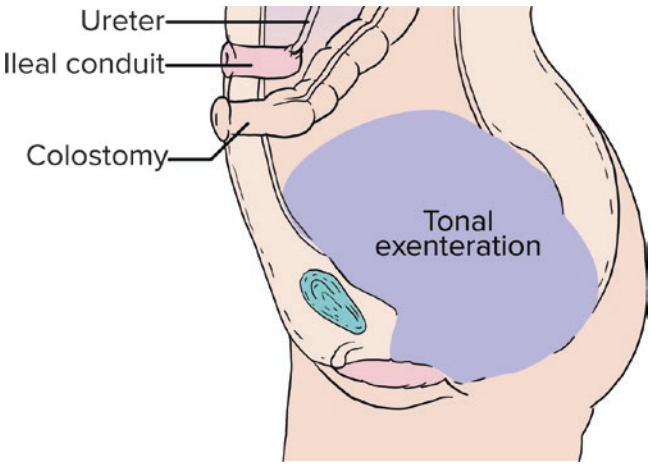

Fig. 105.3 Total pelvic exenteration

For many patients with massive, locally advanced primary or relapsed malignant pelvic disease, the aggressive pelvic exenteration is the best option for their treatment.

With the improvement of the surgical equipment and devices, and of perioperative care, the mortality and morbidity, related to the pelvic exenterations, significantly decreased.

Nevertheless, in the different modern series the frequency of serious complications varies between 36 and 46 %. When it is indicated, the pelvic exenteration for the treatment of locally advanced pelvic malignant diseases must by considered as a standard surgical intervention in the major surgical centers.

Indications for Pelvic Exenteration

- Carcinoma of urinary bladder–primary or relapsed
- Carcinoma of prostate–palliative treatment
- Carcinoma of rectum or sigmoid colon–primary or relapsed
- Squamous cell carcinoma of anus–relapsed
- Carcinoma of uterine cervix–primary or relapsed
- Carcinoma of uterine cervix–relapsed after radiotherapy
- Endometrial carcinoma–primary or relapsed
- Cervical carcinoma–palliative treatment
- Vaginal carcinoma–primary or relapsed
- Squamous cell carcinoma of vulva–relapsed
- Post-radiation lesser pelvis fibrosis, necrosis, or fistula

The main indications are cancer of uterine cervix, rectal carcinoma, and relapsed carcinoma of rectum.

Cancer of Uterine Cervix

The most frequent disease, treated by total pelvic exenteration is the central pelvic relapsed carcinoma of uterine cervix. Landoni et al. noted that among patients treated for IB and IIA stage of cancer of uterine cervix, not less than 25 % developed a relapse after the treatment [27]. Most of patients with non-treated cervical carcinoma died from locally advanced carcinoma, which might cause obstructive uropathy or peritonitis. Only 25 % of patients with non-treated cervical carcinoma have distant metastases.

The radiotherapy is considered in locally advanced disease, but the possibility of healing by radiotherapy in case of advanced carcinomas of uterine cervix is much lesser than in less advanced stages of the disease. The higher is the total dose of radiation, the higher is the morbidity related to it.

Rectal Carcinoma

Newer studies (Mercury study) [21] demonstrate that about 50–64 % of the primary rectal carcinomas are locally advanced (T4a,b at the time of admission), without any metastases found during the exploration or suitable for local radical surgery. The preoperative examinations, especially the endorectal intracavitary ultrasonography and magnetic resonance imaging currently visualize with high precision the infiltration in an adjacent organ (T4b), which excludes the performing of only the conventional resection strategy. The problems related to the locally advanced tumors localized in the pelvis are such, that the real tumor infiltration is hard to be intraoperatively distinguished from the peritumor inflammatory adhesions.

In earlier historical periods of the treatment of locally advanced colorectal carcinomas, the rule for performing of miltiorgan resection was adopted only, when there presented macroscopic infiltration, while upon possible separation of the adhered organ through “blunt dissection”, standard resection was performed. This, on its part, results in more than 35 % local relapses for the first postoperative year and 5-year survival–less than 30 % [22].

The dissection and disturbance of the integrity of tumor upon standard resections, even assessed as R0, is related to approximately 69 % locally advanced relapses and 5-year survival of 17 %, while in multiorgan resections, the frequency of relapses is 18 %, and the 5-year survival – 49 % [23, 24].

Although many tumors form adhesions to the adjacent anatomical structures, it would not be true to say that all of them present malignant infiltration. The frequency of these malignant adhesions varies between 40 and 85 %. Nevertheless, in these patients withholding from performance of radical en bloc-resection increases the number of local relapses and compromises the postoperative survival. In a clinical study (J. Hunter), the 5-year survival after en bloc-resection was 61 %, but it decreases to 23 %, when the tumor is only anatomized up to the organ, at which it had adhered [13]. In a similar clinical study (H. Jensen) 36 % had local relapse after en bloc-resection, compared to 77 %, when there was performed only anatomization of the tumors [25, 29].

Relapsed Carcinoma of Rectum

Despite the aggressive resection of primary rectal carcinoma, including also total mesorectal excision, the local relapses of rectal carcinoma vary from 5 to 15 % and require an approach as with primary T4 rectal carcinomas. In a study by Cass, the frequency of local relapses is related to the stage of the primary tumor, while for tumor of B1 stage according to Dukes staging system, it is 15 %, and for tumor of C2 stage – 52 % [30]. In patients, who have a relapse after low anterior resection, it is more probable to occur non-fixed, surgically resectable relapsed tumor than in patients, who had a relapse after abdomino-perineal resection. About 50 % of the local relapses are limited in the lesser pelvis and are associated with potentially operable oligometastatic disease, while thus they are candidates for curative radical repeated operation [36–38]. The surgical principal bases of these aggressive therapeutic measures require the surgical approach to be strictly individualized for the different patients and determined by the localization of the relapsed tumor and the involved anatomical structures. According to the anatomical region, the relapsed tumor is classified as:

- Central–the tumor is limited to the pelvic organs without any invasion of bone structures or pelvic walls
- Sacral–the tumor takes the presacral space and involves the sacrum
- To the lateral pelvic walls–laterally parietal lesser pelvis relapse (sidewall)–the tumor involves one of the lateral pelvic walls with or without extension through the greater sciatic foramen and/or piriformis muscle and gluteal region
- Combined–combined sacral and lateral pelvic walls relapse

In compliance with the latter, Mirnezami A. and Sagar P. divided the surgical procedures to radical and extensively radical resections [41, 42]. In radical resections removal of the relapsed tumor formation is achieved with no need for resection of the adjacent parts or whole pelvic organs. The extensively radical surgical procedures are characterized with resection of at least one involved pelvic organ (partially or totally), bone structure (e.g. sacrum), or main blood vessels (e.g. iliac artery or vein). Mirnezami A. and Sagar P. also accentuated on the multidisciplinary detailed consideration of patient in the preoperative period through the co-ordinated efforts of a medical team, consisting of a colorectal surgeon, urologist, vascular surgeon, plastic surgeon, neurosurgeon, orthopedic surgeon, and, frequently, gynecologist. The medical specialists in the latter team are sellected and co-ordinated by a coloproctological surgeon according to their experience in the resection and/or reconstruction of abdominopelvic anatomical structures.

Selection of Patients Suitable for Pelvic Exenteration

The locally advanced pelvic tumors may infiltrate adjacent organs as: urinary bladder, prostate galnd, seminal vesicles, urethra, ureter, uterus, adnexa, posterior vaginal wall, sacrum. Direct invasion of these structures may be susceptible to radical exenterative surgery and lead to healing in well-selected patients. Every case of locally advanced pelvic tumor must be assessed individually and by a multi-profile medical team (MDT – multidisciplinary team).

The main task of that assessment is performing of examination of the clinical, pathologo-anatomical, and radiological findings in order to be accomplished evaluation of the suitability of patient for potentially curative pelvic resection. The suitability of patient for major exenterative surgery is of first-rate significance for achievement of optimal postoperative results. Cardiopulmonary test loadings, Karnofsky Performance Scale Index, ASA classification, etc. were recently and most frequently used for that evaluation.

Preoperative Examination

Upon making a decision of the suitability of patient to be subjected to multivisceral resection, multimodal approach is necessary, including: physical examination (digital rectal examination, and examination of rectum and vagina under anesthesia), endoscopic examination, radiologic examination (magnetic resonance imaging with high resolution, endorectal sonography of local lesions, computed tomography of thoracic cage, abdomen, and pelvis), positron emission tomography-computed tomography (PET-CT) for searching of distant metastases and pathologo-anatomical examination (Figs. 105.12 and 105.13).

Only the experienced hand of a specialist in surgery may assess the tumor as mobile, withdrawn or fixed, or to determine its distance from the anorectal and anocutaneous lines, and the possibility for restorative or non-restorative procedure.

The endoscopic examination is helpful in assessment of tumors, which cannot be examined digitally, and it provides information about the size and degree of obstruction of an opening (this is important when undertaking of neoadjuvant therapy). The histological result confirms the diagnosis, and it also allows rejection of squamous cell carcinoma of anus. The local status of tumor is best assessed by magnetic resonance imaging of high resolution, using a protocol of examination for rectal carcinoma. The magnetic resonance imaging demonstrates with high sensibility and specificity the degree of tumor invasion in the surrounding anatomical structures. Additionally, it provides a precise

Fig. 105.12 X-ray of female patients with locally advanced rectal carcinoma with infiltration into the uterus and vagina. There are metachronous metastases–right chest wall–basal on average

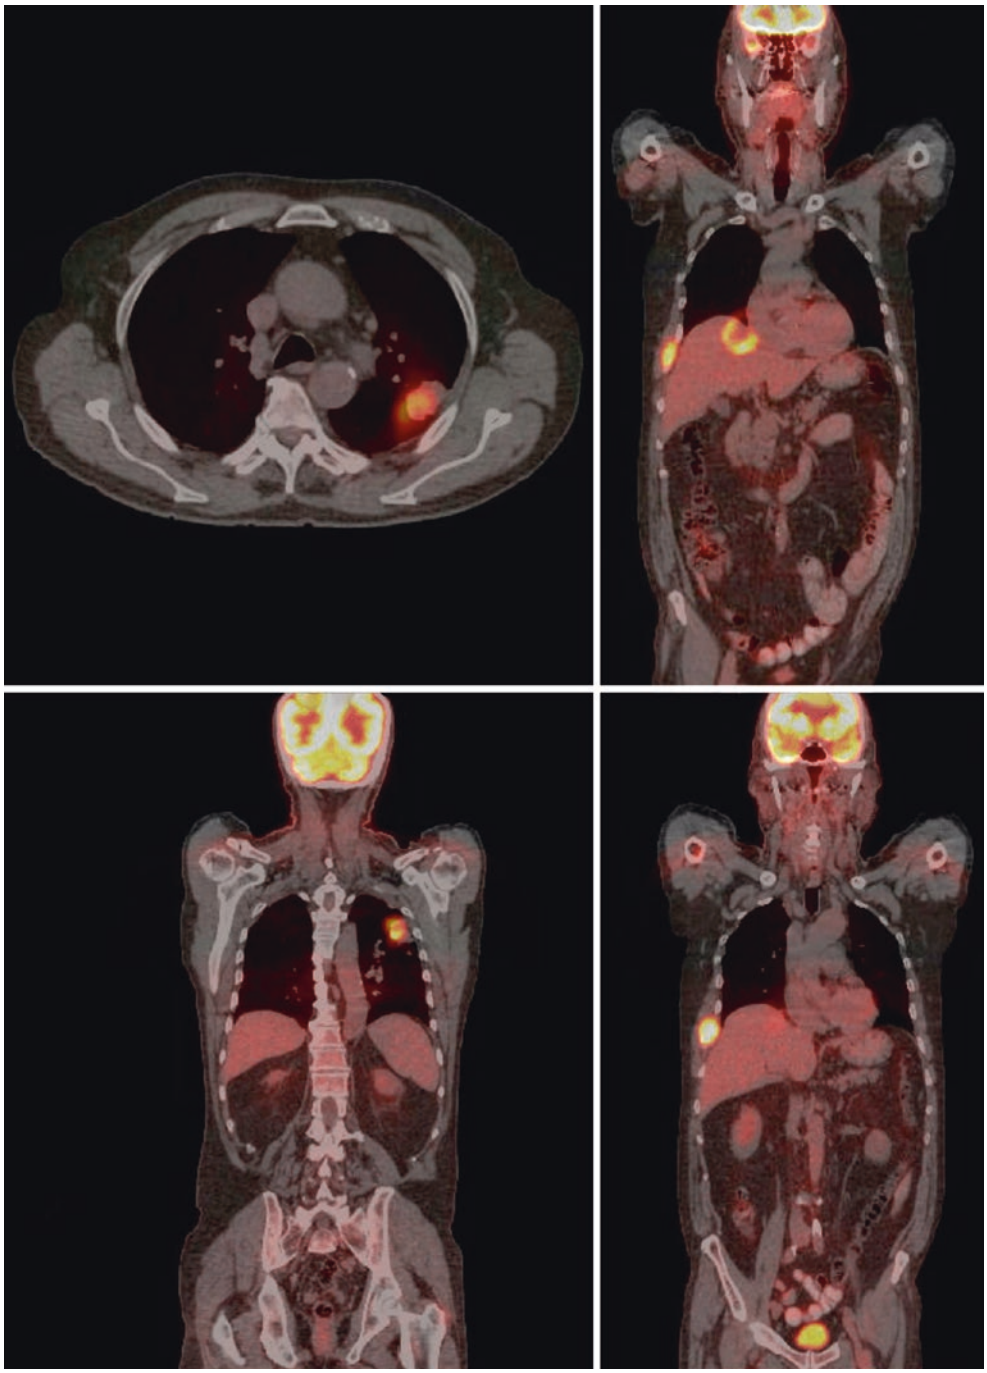

Fig. 105.13 PET CT scans + reconstruction after posterior pelvic exenteration with local recurrence. Enhanced signal intensity (bright yellow zones) of accumulation of the radiopharmaceutical substance indicating metachronous metastatic lesions in the right liver lobe, left lung and right chest wall. MDT assessed inability to achieve oncological radicalism–contraindicated for reoperation

assessment of the lymph node status of the tumor; it also provides with high grade of probability an assessment of the operability or inoperability; and it best aids the surgical team in the planning of the surgical intervention. The preciseness of magnetic resonance imaging decreases in tumors of the lower third of rectum, where endorectal sonography is preferred whenever an experienced sonographist is available. The presence of localized metastases in the liver and lung, which are assessed as resectable, according to the current guidelines, does not exclude performing of pelvic exenteration.

The clinical assessment allows the experienced clinician to correlate the results from the device examinations with their clinical signs and symptoms, and this provides an option for better evaluation of the ratio tumor/surrounnding tissues.

Contraindications for Potentially Curative Pelvic Exenteration

Absolute Contraindications

- Distant metastases
- Metastases in the paraaortic lymph nodes
- Massive infiltration in the pelvic wall (infiltration in the common or external iliac artery; venous or lymph obstruction)
- Infiltration in sacrum, proximally from S2/S3
- Transient R2-resection

Relative Contraindications

- Obstruction of ureter
- Presence of pronounced edema of lower extremity subsequent to lymph or venous obstruction
- Propagation of the tumor through greater sciatic foramen
- Tumor encircling of more than 180° of the external iliac blood vessels
- Relative contraindication due to concomitant disease (ASA physical status IV/V)
- Relative contraindication due to inability to care for a stoma or advanced age

All potentially operable candidates are considered when they pass through pedantic preoperative assessment process. The aim of the performed preoperative examinations is precise staging of the disease, identification of all contraindications for surgery, assessment of the comorbidity and finding of eventual, non-resectable metastases, covered by Mirnezami A. and Sagar P. The typical staging examinations include: computed tomography (CT) of thoracic cage, abdomen, and pelvis: magnetic resonance imaging (MRI) of pelvis and/or liver; and 18F–fluorodeoxyglucose positron emission tomography (FDG-PET), recently combined with computed tomography–PET/CT scan. The cystoscopy comes into consideration upon suspected involvement of urinary bladder, while the transcystoscopic stenting of ureters is related both to excluding of their eventual involvement by the tumor, and as a preventive measure against intraoperative iatrogenic lesions.

Lack of presentation of patients suspected for advanced disease to specialized oncology committee (MDT–multidisciplinary team) before surgery represents a gross "blunder of the medical art". This often leads to inadequate preoperative planning of the type and volume of intervention (potentially curative, i.e. radical surgery or palliative surgery) when it is discussed only in clinical board consisting mostly of general or coloproctology surgeons but often without participation of imaging diagnostics, pathologists, urologists, gynecologists and plastic surgeons as well as a specialist in anesthesiology and intensive care. As a result, the decision on the type and volume of operation is taken essentially by the operating surgeon during the intraoperative assessment of the tumor situs without supporting data from imaging studies and the poin of views of other particular specialists. We, therefore, allow ourselves to offer the following diagnostic algorithm in order to emphasize on preoperative suspicion of locally advanced tumor of the colon and rectum with a presumption of possible infiltration into neighboring pelvic structures. That would be which is necessary to carry out a particular type of pelvic exenteration (Fig. 105.14):

Following this algorithm, all suspected cases of locally advanced tumor with probability of infiltration of pelvic organs and structures should be submitted in advance for a comprehensive discussion to preoperative MDT.

In patients, who did not undergo prior radiotherapy, a long-term course of chemoradiotherapy is performed and after 6–8 weeks waiting for repeated complete staging before eventual repeated operation. Although by this method the disease can significantly transform in lower T-size (downsizing), all authors recommend the following surgical treatment to be complied with the involvement of the anatomical structures before the neoadjuvant–regarding the repeated operation–chemoradiotherapy [42]. Increasingly more newly found patients with locoregional relapses already receive neoadjuvant therapy before their first operation. Although most of them will not undergo a following radiotherapy, there are publications that in certain patients performing of additional hyperfractioned chemoradiotherapy with no significant toxicity is acceptable and with a proven result [43].

When there is a probability of the repeated resection to include in its dimensions portions of the large intestine that are non-excluded from function or previously formed neorectum of colon or ileal conduit, performing of complete preoperative mechanical or osmotic large intestinal preparation is necessary. Upon planning of resection only of non-functioning anorectum or neorectum, single cleansing enema is completely sufficient. As preoperative manipulations, assisting the dissection and resection, preoperative stenting of one or both ureters, or tattooing are performed–as a way of marking the level of forthcoming sacral resection. The early postoperative monitoring, and complete surgical and medical care of patient, is foreseen in a Specialized Clinic of Intensive Follow-up Observation and Care, especially after high risk procedures as resection of sacrum or lateral pelvic vascular dissection. Most of the procedures are performed by abdominal approach, but certain cases require only posterior or perineal access. In transabdominal or perineal accesses,

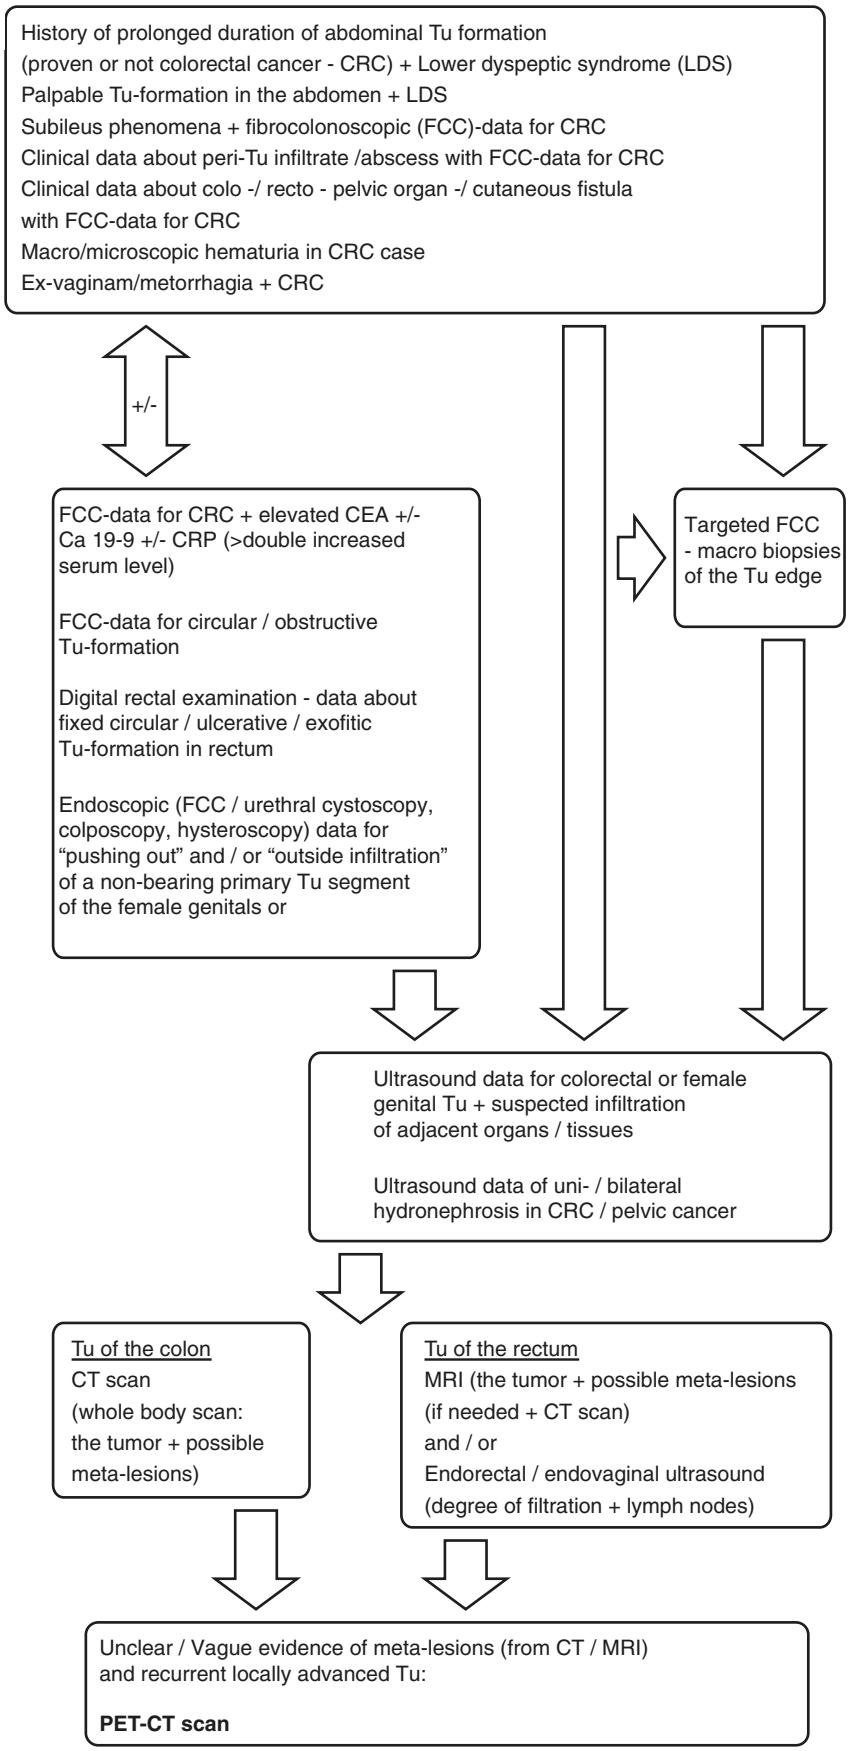

Fig. 105.14 Algorithm in diagnosis of locally advanced colorectal cancer

patients are placed on the operating table in Lloyd-Davies position, while in posterior access supine position is suitable, with bending of the table at the level of waist–"prone jack-knife position" [42].

Surgical Technique

- The aim of surgeon is R0-resection, including negative circumferent border, highly qualitative, verified total mesorectal excision (TME), negative proximal and distal resection line.
- This approach ensures 5-year survival to patients after pelvic exenteration for advanced primary rectal carcinoma from 32 to 66 %, and for the relapsed one–from 22 to 42 % [26].
- R0-resection is acquired after development of three main surgical planes, corresponding to different stages of the intervention:
  - ventral plane, with borders urinary bladder and internal genital organs;
  - ventrolateral plane, consisting of obturatory neurovascular structures, ureter, internal iliac blood vessels and their branches, passing through the suspensory net of rectum and intrapelvic part of internal obturatory muscle;
  - dorsal and dorsolateral plane, consisting of levator ani muscle, intrapelvic attachment of piriform muscle, sacral nerves and vascular plexuses, and sacrum.

In abdominal access, median laparotomy is applied with subsequent total adhesiolysis–"débridement generale" with the aim of overview of the peritoneal cavity for excluding of occult intraabdomial metastases. The discovery of non-diagnosed, preoperative, peritoneal or visceral metastases is a poor prognostic indicator and, with the exception of the cases when the metastases are single and/or resectable, it is a contraindication for definitive selective surgery. The aim of the surgical treatment is achievement of R0-resection, which requires resection of the tumor and of the involved by the tumor adjacent anatomical structures and organs to be performed "en bloc". Not rarely, however, it is possible to exist an uncertainty as regards the exactness of achievement of "clean" resection lines, especially upon presence of radio-induced fibrosis. In this case it is obligatory to be considered the introduction of the rapid intraoperative histological examination–frozen section procedure, for analysis and verification of the sections suspect for infiltration.

Ventral Plane

- Ventral plane is formed when preserving of the urinary bladder is planned.

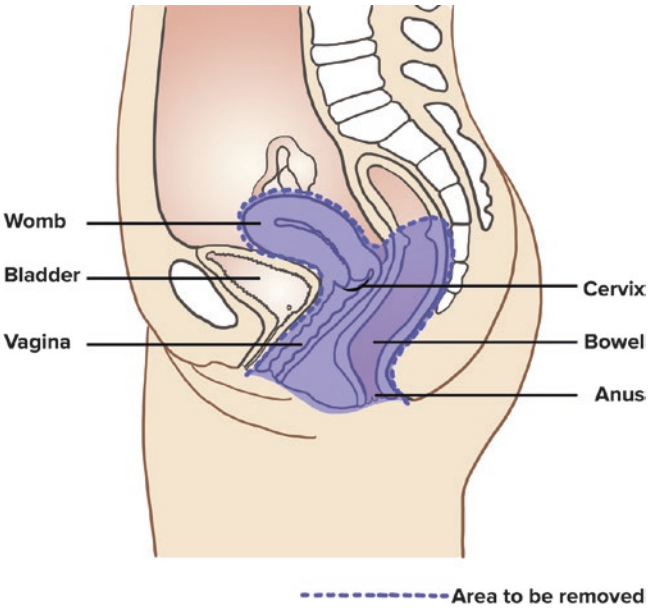

Fig. 105.15 Ventral plane in posterior pelvic exenteration

- The female genital organs are an easy for resection buffer, while in men the tumor infiltration in the genital organs often means, that the ventral plane cannot be elaborated.
- Upon tumor infiltration of dorsolateral position, it is possible a ventral plane to be formed in front of peritoneo-perineal fascia (Denonvilliers' fascia).
- The infiltration of the anterior fornix of vagina does not exclude the formation of ventral plane.
- In tumors with ventrolateral infiltration the transection of the ureters facilitated the achievment of clean lateral circumferent border.
- The repeated implantation of ureters, if they are not infiltrated, can be performed after mobilization of urinary bladder and its adjustment to the adjacent greater psoas muscle (Figs. 105.15 and 105.16).

In terms of the dimensions of resection in posterior exenteration, the following organs and structures need to be removed: recto-sigmoid colon; lymph nodes; uterus with ovaries; vagina; adjacent pelvic fat, and connective tissue; perineal structures (Figs. 105.17, 105.18 and 105.19).

Bilateral ligation of internal iliac artery is a significant critical turning point to continue the operation–to proceed with pelvic exenteration [28]. It may be used as palliation. This procedure results in decrease of operative blood loss and respectively decreases surgery time. It also facilitates finding and ligating of uterine and bladder arteries. It is important to certain extent for the iliac lymph node dissection. It is also possible to ligate internal iliac vein. It is possible even to resect internal iliac artery and vein–in cases when it is necessary to extract an obturatory fossa mass, penetrating the internal iliac blood vessels (Figs. 105.20, 105.21, and 105.22).

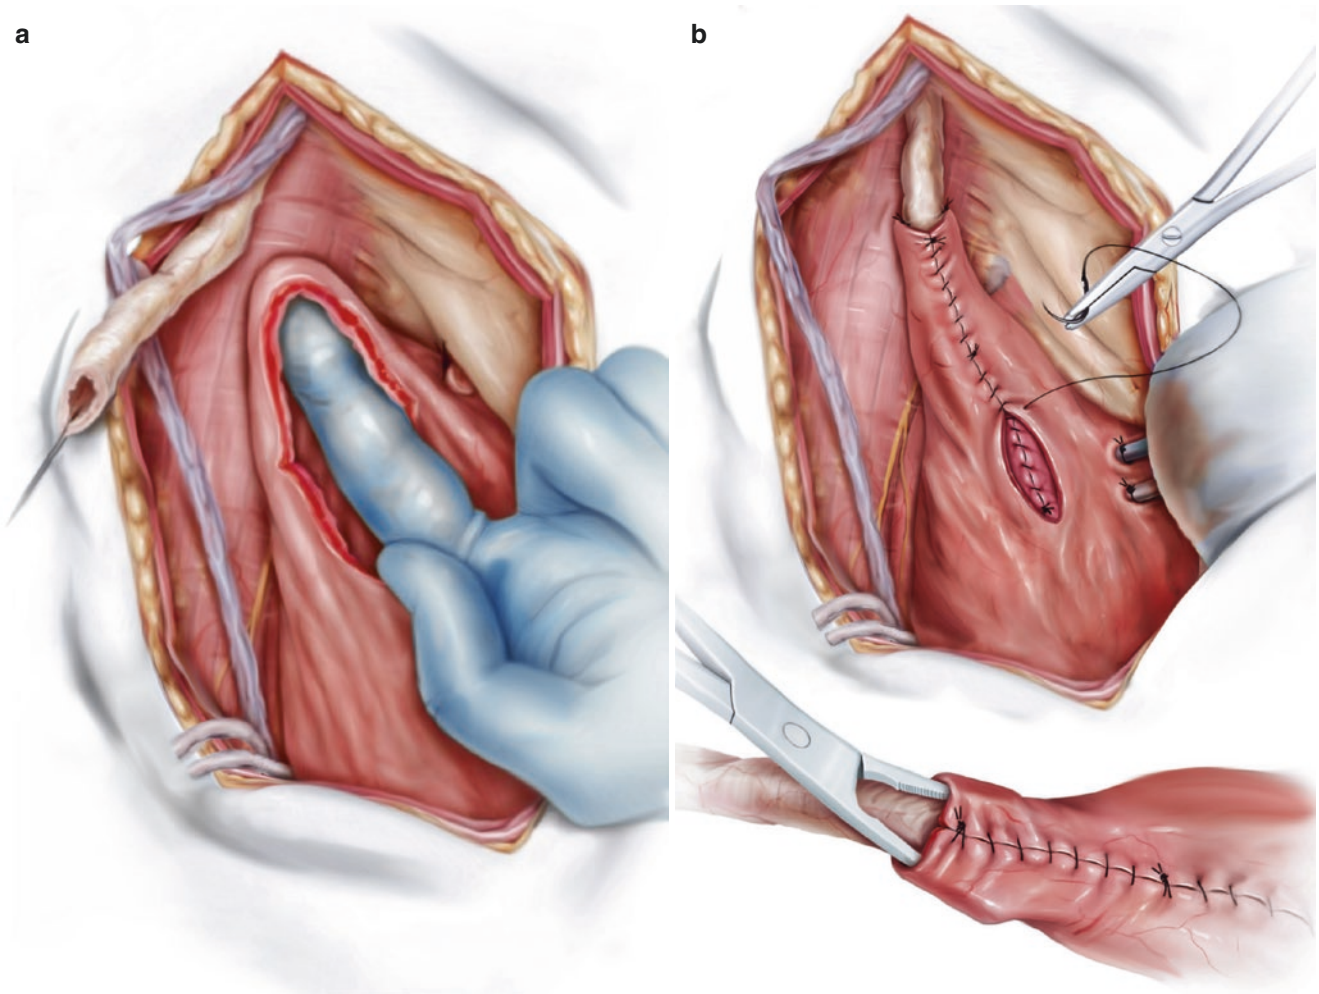

Fig. 105.16 (**a**, **b**) Repeated implantation of ureters in the wall of urinary bladder

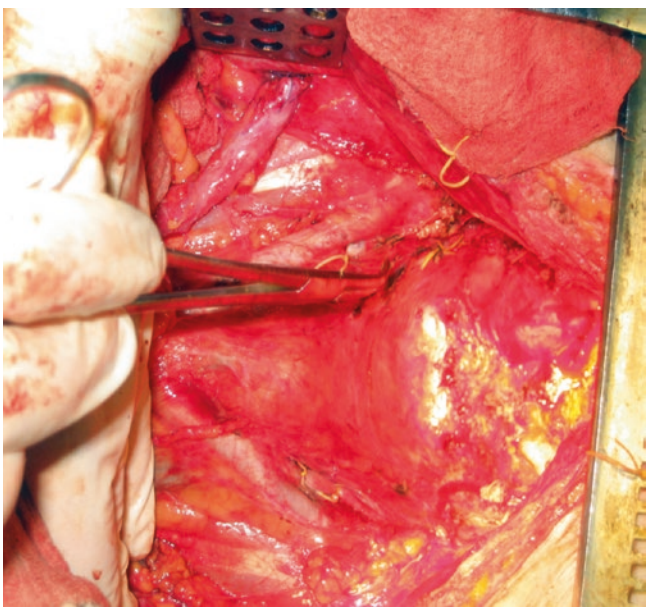

Fig. 105.18 Intraoperative ligation of the internal iliac arteries of both sides

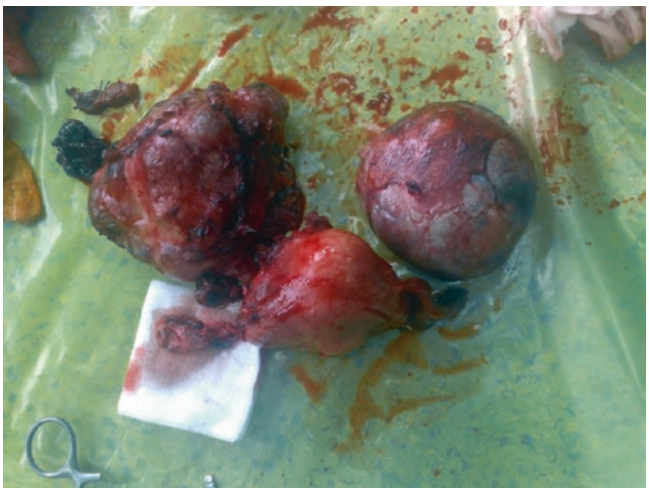

Fig. 105.19 Operative specimen of block anterior resection of the rectum and uterus + adnexes because of suspected malignant infiltration (pathologically proved postoperatively + metastasis in the left ovary of the same cancer)

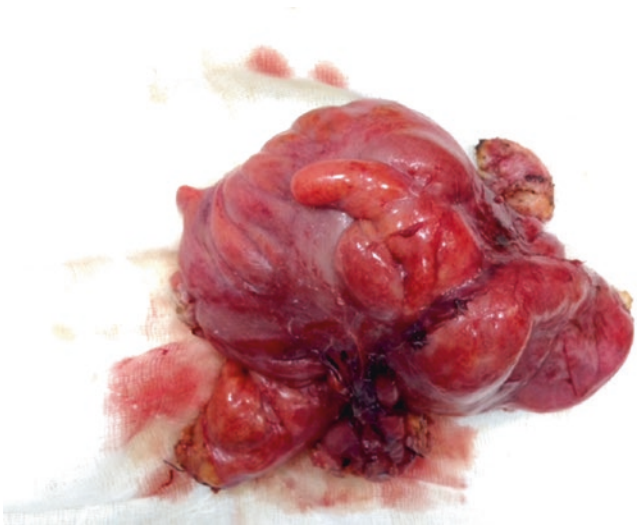

Fig. 105.21 Surgical specimen of en block-resection of sygma/rectum + mesorectum (partial mesorectal Excision – PME) + uterus

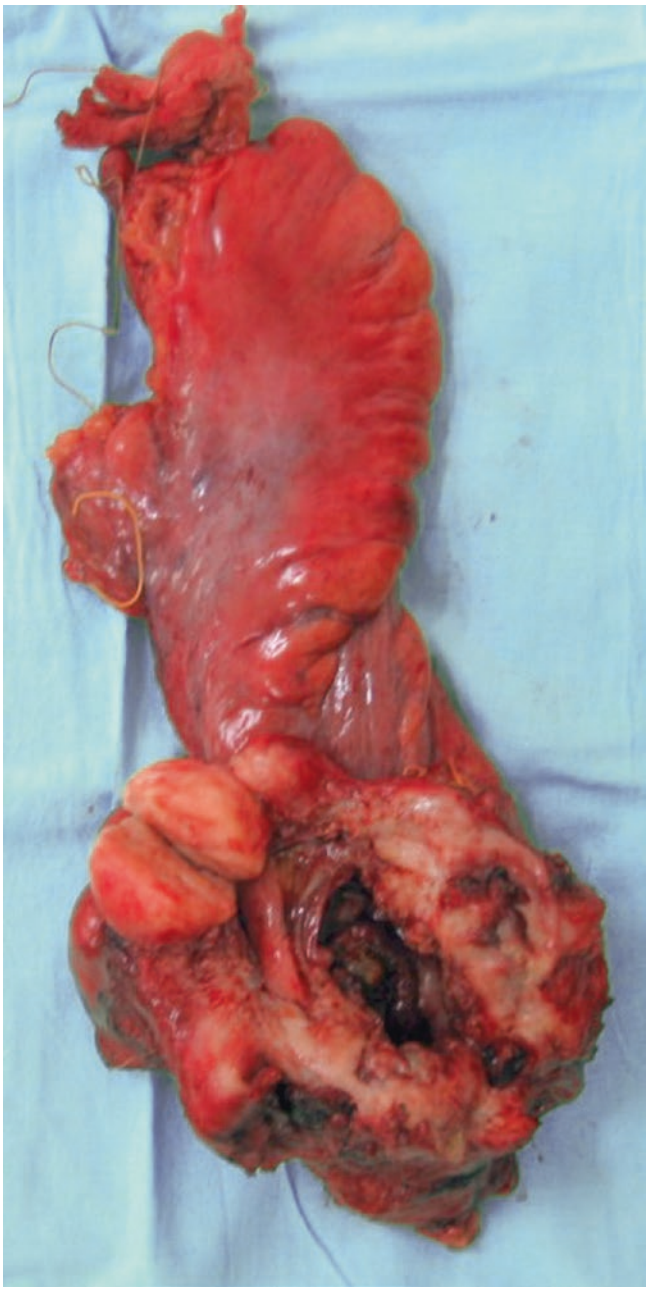

Fig. 105.20 Surgical specimen of en block-resection of rectum + mesorectum (Total Mesorectal Excision – TME) + uterus

An especially important milestone in the mobilization of rectum and performing of total mesorectal excision by the method of Heald in single-organ resection and posterior exenteration with no sacral resection is avoiding "blind" dissection performing in dorsal plane, which with a great probability would lead to damage of the sympathetic innervation–superior hypogastric plexus and forming in distal direction of left and right hypogastric nerve. This, of course, is of no importance in total exenteration, because innervated organs are removed (Fig. 105.23).

In a case of massive tumor infiltration of urinary bladder, negative ventral circumferent border cannot be achieved. These patients are suitable only for total pelvic exenteration.

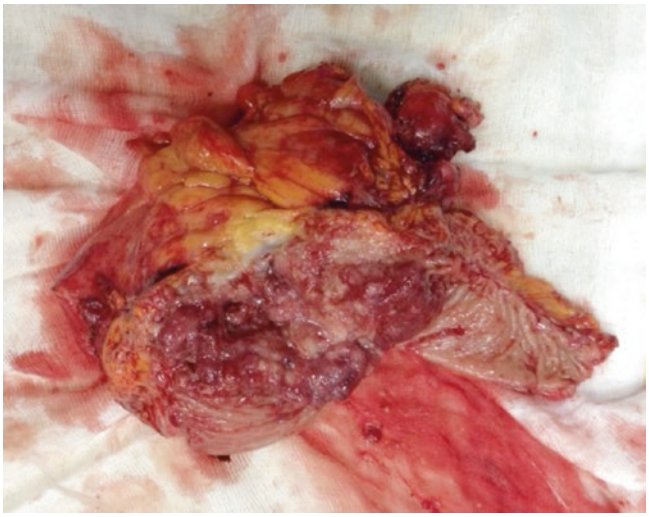

Fig. 105.22 Surgical specimen of en block-resection of coecum – right colectomy (with Complete Mesocolic Excision – CME) + uterus

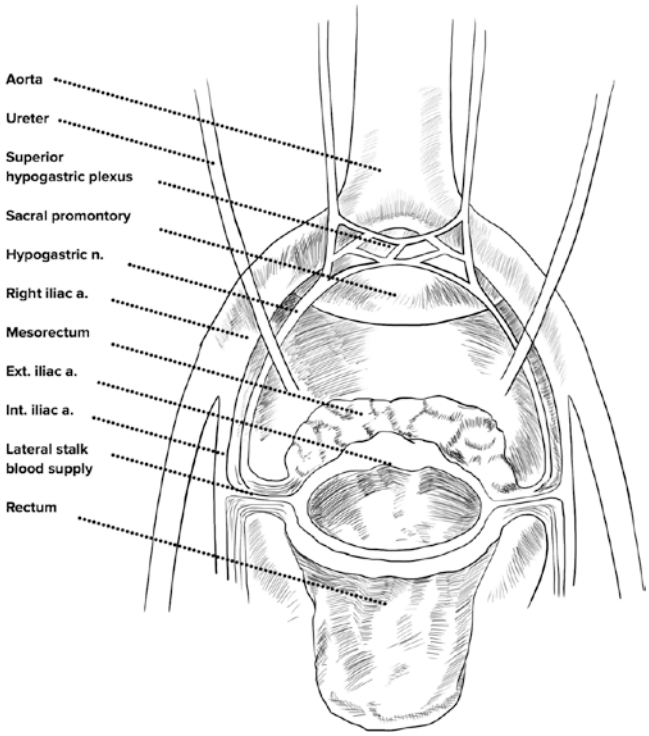

Fig. 105.23 Autonomic pelvic nerves and their positions amongst other pelvic structures

Total Pelvic Exenteration

The following organs and structures are to be removed: recto-sigmoid colon; lymph nodes; urinary bladder; urethra; uterus with ovaries; vagina; vulva; adjacent pelvic fat and connective tissue.

Locally Advanced Pelvic Carcinoma or Central Relapse

Several scenarios are possible in median, axial relapse depending on the gender and eventual involvement of urogenital structures, everyone of which requires different surgical approach. In all cases generally acquired oncological principle is that the resection of a relapse must be extended to a degree of preventing of positive resection lines, analogically with the resections in sarcomas.

In isolated perineal relapses, usually after abdominoperineal excision/extirpation of rectum (amputation) (APER), the transperineal access is sufficiently adequate, although sometimes it must be combined with posterior access, including the distal sacrum.

As it has been already explained, the involvement of visceral structures requires en bloc-resection. For example, the infiltration of the body/cupula of urinary bladder requires partial cystectomy, while the involvement of trigone of bladder is an indication for total pelvic exenteration. In women the involvement of vagina or uterus requires performing of hysterectomy with partial or total vaginectomy. The preoperative stenting of ureters supports their visualization in order iatrogenic lesions to be avoided.

In cases of central relapses, not involving urogenital structures, the operative strategy depends on whether the prior surgical operation had the dimensions of anterior resection or of abdominoperineal extirpation. In both cases the resection must be performed in a plane wider than the prior dissection with the purpose of preventing residual tumor sections. In the presence of "high" anastomosis at the prior operation, it is possible to be performed repeated anastomosis between the transverse or descending colon, and rectal section after ablastic tumor removal. Frequently, however, the technical difficulties in the context of adhesions from the first operation and radio-induced fibrosis require performing of ultra-low Hartmann procedure or abdominoperineal procedure–Miles-extirpation. The present prior anastomosis turns to be a critically "weak" place in cases with relapses and extensive traction of neorectum, and the anastomosis is a dangerous activity as regards the intestinal or tumor rupture, which must be avoided by suitable mobilizing practices. If Denonvilliers' fascia is well-presented and not involved by the tumor process and radiotherapy, a ventral plane from that structure is a choice in anterior dissection. In prior abdominoperineal extirpation with poor peritonization frequently in lesser pelvis, in a repeated surgical operation, multiple adhered small intestinal loops were found, not rarely infiltrated by a relapsed tumor, which requires their combined en bloc-resection with the main tumor mass [40].

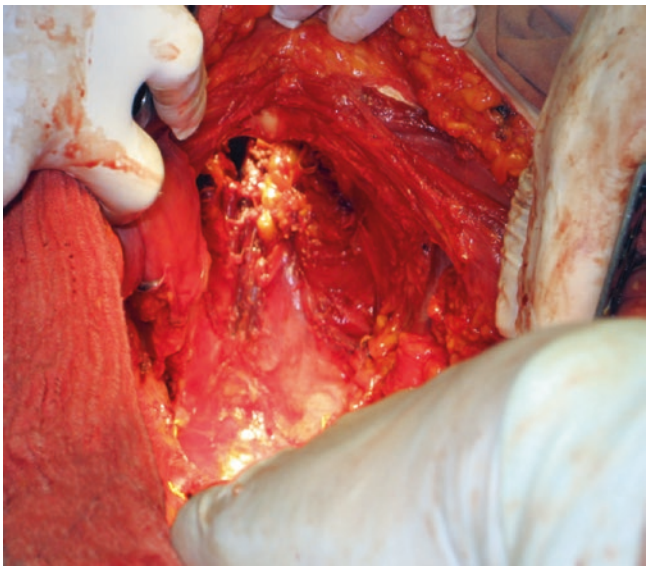

Fig. 105.24 Intraoperative view of the pelvis

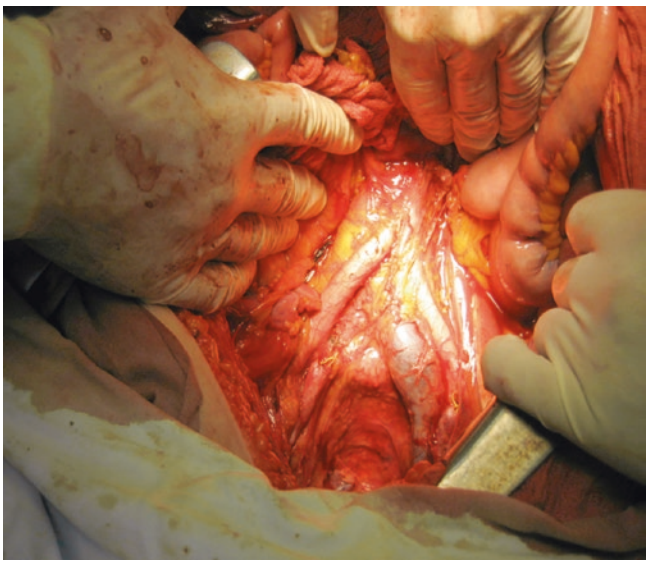

Fig. 105.25 Ligation of both internal iliac arteries is shown

The question about the dimensions of lymph node dissection in multivisceral resection of relapsed rectal carcinoma is important and not explicitly solved. Theoretically the invasion in other organs opens new lymph draining systems for the disease, because of which they have to be included in the dimensions of repeated resection in order to be prevented a new relapse or carcinomatous generalization in distant locations. There is still no consensus on this matter with a few present literature data. In the modern practice most surgeons, and we as well, keep close to the therapeutic measures of Mirnezami A. and Sagar P. for not performing of radical

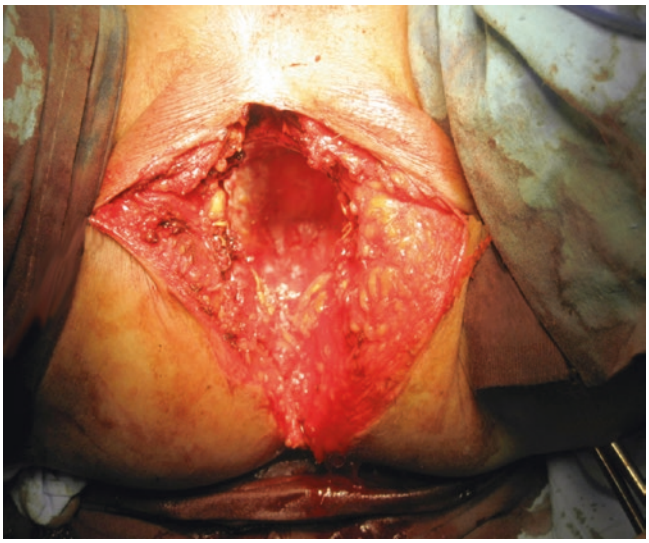

Fig. 105.26 Perineal view after total pelvic exenteration

pelvic lymphadenectomy due to the accompanying high morbidity, caused by that procedure, as well as the absence of specific proofs for the benefits–as regards the survival–of that method [44] (Figs. 105.24, 105.25 and 105.26).

Abdominosacral Resection

If the tumor invasion disseminates dorsally to the sacrum, lateral pelvic wall, or muscles of pelvic fundus, and wide dorsal access is necessary with a view to improvement of the operative field and easing the resection of the tumor within healthy tissues, performing of abdominosacral resection is required (Fig. 105.27).

Transsacral Resection

- patient is turned from supine position in prone jack-knife position (Fig. 105.28)

This position has the following *advantages*:

- improved visibility
- easier retraction by assistant
- reduced perforation
- reduced circumferential resection margin (CRM) positivity

and the following *disadvantages*:

- long surgery time as patient position needs to be changed

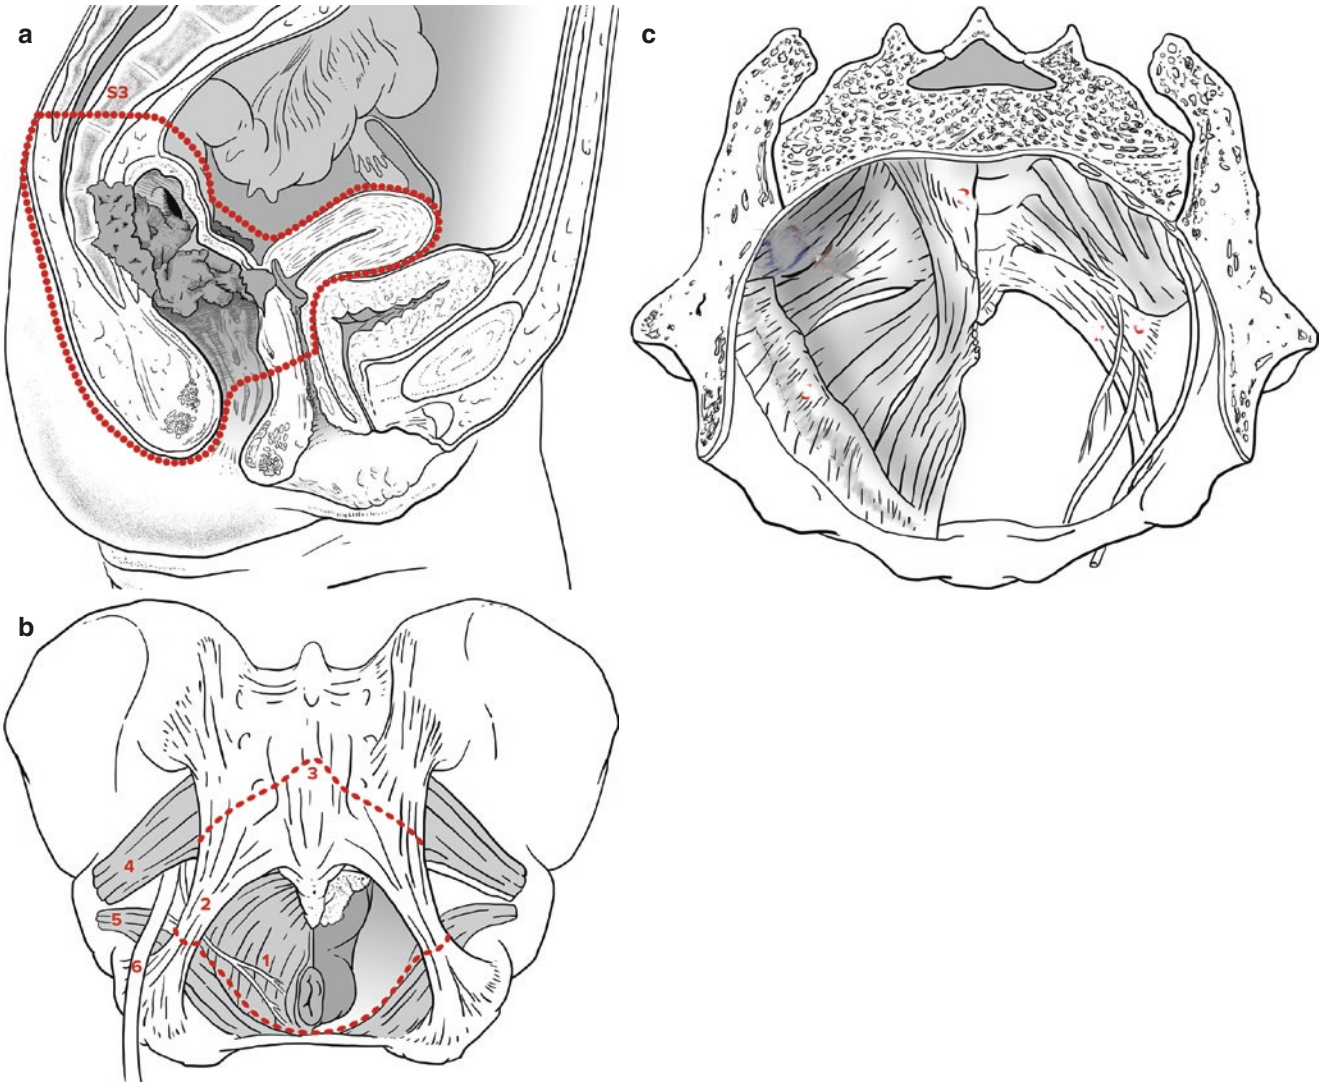

Fig. 105.27 (**a**–**c**) Abdomino-sacral resection in pelvic exenteration

- inability to perform rectus or gracilis transformation

The functional result after transsacral resection depends on the degree of resection. Transection of sacrum at level S3 for tumors with low position essentially is connected with normal function of urinary bladder, if the latter is preserved. The proximal transectional incision at level S1 is a more traumatic procedure frequently for more considerable or voluminous, and highly localized lesions. The stability of the pelvic ring may be maintained with no requirement of plastic reconstruction, if the lumbosacral facet surfaces are preserved at bilateral base and there is no pronounced neuromuscular locomotor deficit. The transection of levels S1, S2, and S3 compromises the functions of urinary bladder due to bladder denervation. Although the emptying can be managed by the method of Crede, the use of alpha agonists or the current catheterization requires permanent attention and care by the attending physician and–as a whole–aggravates the quality of life.

It seems that there is a consensus that the infiltration tissues involved in the tumor must be removed by resection within macroscopic borders of 2 cm. Although it is advisable, with no solid evidence for that 2 cm border, the rule is not always applied. If that rule is strictly observed, that means the resection of sacrum and/or piriform muscles with a part of the nerve sacral plexus must be performed in most of patients. The operation is difficult due to the absence of plan for dissection around the relapsed tumor mass. That is so especially after prior total mesorectal excision. “Guidance document”, published by National Health System / Department of Health in England, outlines a frame, based on the evidence, and recommends that such an operation must be performed only by a specialist with experience in that kind of surgery [24].

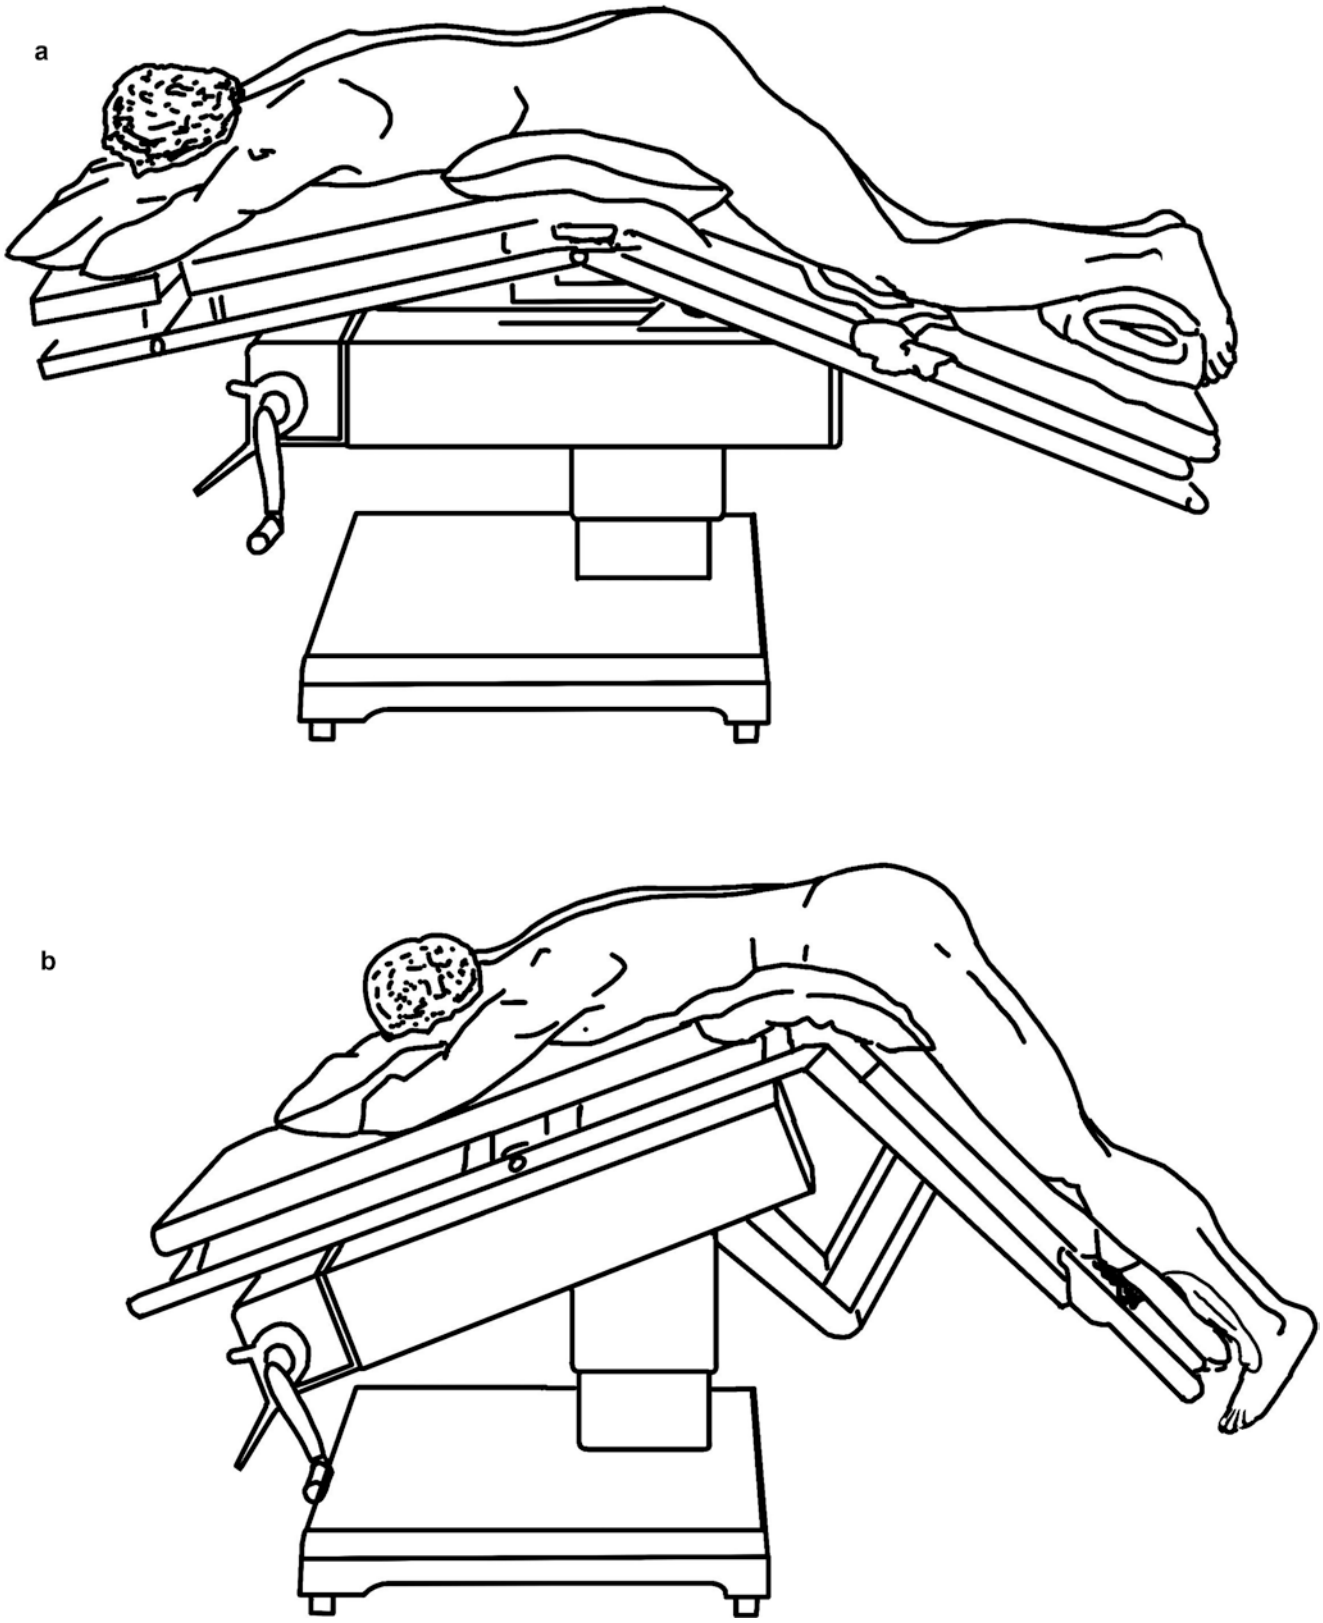

Fig. 105.28 (**a**, **b**) Prone jack-knife position

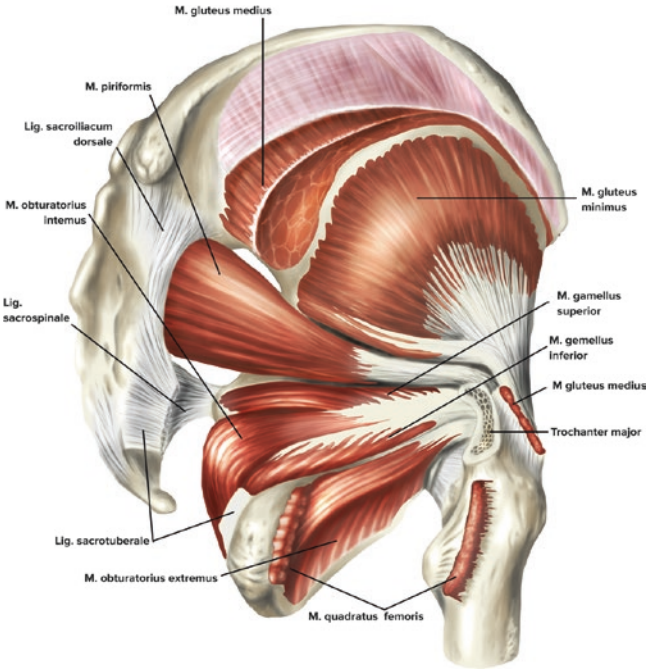

Fig. 105.29 Musculo-aponeurotic view in a stage of transsacral resection (Adopted by http://wellinhealth.com/sports-tissue-trauma/)

Fig. 105.30 Digital maneuver in mobilizing and grip of the sacrum

Dorsal longitudinal median sacral incision–from L5 to the perineum, and around anus or anal surgical scar–is performed. Myocutaneous flaps are formed bilaterally, including gluteus maximus muscle and gluteus minimus muscle, which are cut from their origins and elevated bilaterally (Fig. 105.29).

All visceral sections infiltrated by the tumor are removed en bloc, e.g. small intestinal loops, ovaries, etc. After the tumor mass remains fixed only in posterior direction, a stoma is brought out and ideal conduit is elaborated, draining tubes are implanted and lesser pelvis is "filled with an inlay" of omentum–omentoplastic surgery of lesser pelvis before closing of abdominal wall. A change in the position of patient follows–prone jack-knife position for the posterior stage of operation. This position allows sufficient exposition for the wide en bloc-resection, however, the control on the main blood vessels is insufficient and the danger of massive hemorrhage must be recorded by the medical team.

Dorsal longitudinal incision over the sacrum is performed at the level of fifth lumbar vertebra up to the perineal scar or anus–depending on the type of prior surgical operation. The incision is deepened up to the sacral bone, and the gluteal muscles are retracted laterally. The sacrotuberous and sacrospinous ligaments are cut laterally from the sacrum, which allows intervention inside the cavity of lesser pelvis, followed by digital revision of the presacral space in order to be verified the level of forthcoming sacral resection. In this case intraoperative radiographic scopy may also be used for precise determination of the level of resection. The osteotomy of sacrum is performed by the means of spinal elevator of Cobb and osteotomic forceps. The epidural adipose tissue, contained in the sacral canal is explored for presence of components from the dural canal, and if these are found, they have to be thoroughly ligated with non-resorbable sutures. All residual fascial and ligamentary infiltrative areas are dissected by electrocauter before completing of the sacrectomy and removal of the specimen en bloc. Different combinations of omentum, absorbing a prosthetic leaflets or pedicularized flaps could be used for reconstruction of the remaining defect and for prevention of prolapse of small intestinal loops in the lesser pelvis. The abdominal stage of surgical operation could be performed also laparoscopically, as described by some authors (Fig. 105.30).

Lateral Parietal Pelvis Relapse: Sidewall

The parietal relapse is related to poorer prognosis and involves lesser probability for achievement of R0 resection. The tumor frequently infiltrates critical structures as ureters, iliac blood vessels, sciatic nerve or the mass of side pelvic bones, and most of authors share the opinion that the wide parietal infiltration from a relapsed tumor is a relative contraindication for surgery. If a decision is made for performing of operation, the preoperative stenting of ureters is obligatory in order to the excluded their infiltration and for better identification upon the dissection. During the operation permanent control on the key structures is necessary

and obligatory, proximally and distally from the tumor area. After en bloc-resection of the tumor and structures infiltrated by it, reconstruction of the essential blood vessels and repeated implantation of ureters is performed, if necessary.

The dissection begins from the pelvic ring with identification and isolation of holder portions of ureters and common iliac blood vessels. The ureters are followed up to their running into urinary bladder, and dissection continues along the internal and external iliac arteries and veins. The ligation and cutting of internal iliac artery provides access to the underlying internal iliac vein, which can also be ligated and resected upon its involvement by the tumor process. These blood vessels may be ligated and cut bilaterally, if it is required for achievement of R0-resection. Whenever it is possible, the internal iliac artery is ligated distally from its first branch, as was already mentioned. Iliolumbar, superior gluteal, and lateral sacral branches successively separate from the first branch of the artery, and avoiding of the mentioned blood vessels from damage reduces and prevents from perineal and posterior wound complications in the postoperative period. The blood vessels, and their branches and tributaries are clasped individually, and are ligated with successive free and quilting ligatures, or are coagulated and cut with bipolar current from modern devices–Harmonic Scalpel ACE (Ethicon Endo-Surgery Inc., Cincinnati, OH; Johnson & Johnson, Arlington, TX). After control over the internal iliac blood vessels is achieved and they are cut, the removal of the relapsed tumor mass is made significantly easier, and subsequently multivisceral resections, excision of parts of pelvic fundus, and distal sacrectomy are performed with no technical difficulties. Some authors report also of a more aggressive approach with dissection in a plane between the bones of pelvis and parietal pelvic muscles, with reported 69 % survival achieved upon average period of follow-up of 19 months [41].

Paraaortic Lymphadenectomy

This procedure–although currently with controversial result in primary and relapsed colorectal carcinomas as regards the distant prognosis–has practical curative significance by removing present or future sites of metastases by ovarian, rectal, and cervical cancer. It is performed proximally to the left renal vein (Fig. 105.31).

Reconstructive Phase: Urine Derivation

The surgeon must be acquainted with the different technical aspects of the pelvic exenterations, but also with the different modifications of the procedure. Lateral pelvic lymph dissection, including the obturatory lymph nodes, is performed in combination with cystoprostatectomy.

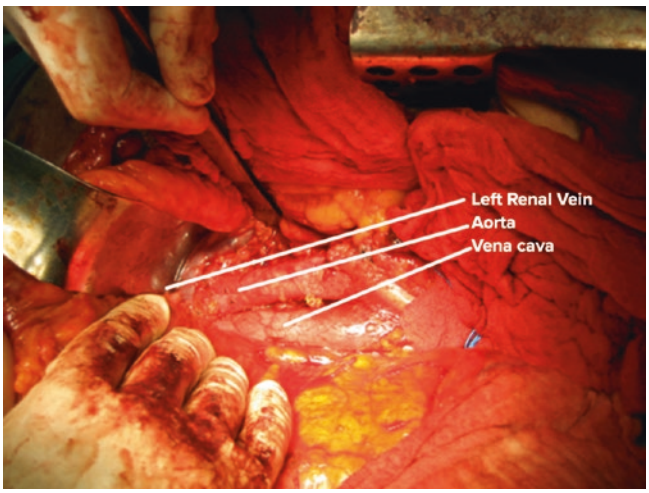

Fig. 105.31 The aorta, inferior vena cava, and left renal vein are shown

The knowledge and management of the different possibilities for urine derivation, and also for reconstruction of the pelvic fundus are especially significant. The reconstruction of the urinary tract, following performed multivisceral resection, most frequently is performed by forming of ileal or colon conduit. There are very little data from the literature, which differentiate the two methods, and the comparative studia do not demonstrate any existing advantages of one or the other method as regards urinary infection, reduction of glomerular filtration, stenosis, or other complications of uretero-intestinal anastomosis. Practically convenient is the model with creating of ileal conduit, and in the cases, when the trigone of urinary bladder is not involved, and partial cystectomy is possible, the plastic surgery of urinary bladder is performed with isolated and detubularized intestinal segment (in a good condition, with no signs of post-radiation ileitis along it) (Table 105.1) (Fig. 105.32).

Reconstructive Phase: Forming of Colostoma or Ileostoma

- Brooke technique
  - 3-point technique
  - full thickness of bowel – 2–3 mm (must include serous membrane)
  - serous muscular bite of the wall approximately 4 cm from the opening of bowel
  - deep dermal
  - absorbable suture–usually 3–0 or 4–0 Vicryl/Polysorb (Fig. 105.33)

- Pseudo-loop technique

Table 105.1 Algorithm in reconstruction of urine derivation after pelvic exenteration

Partial cystectomy ↓	Radical cystectomy ↓
Residual urinary bladder with sufficient capacity → Primary closure	Continuous urinary derivation → Ileal neovesica (orthotopic) → Ileocecal reservoir
Insufficient capacity → Augmentation with small intestinal segment	Non-continuous urinary derivation → Ileal conduit → Colon conduit

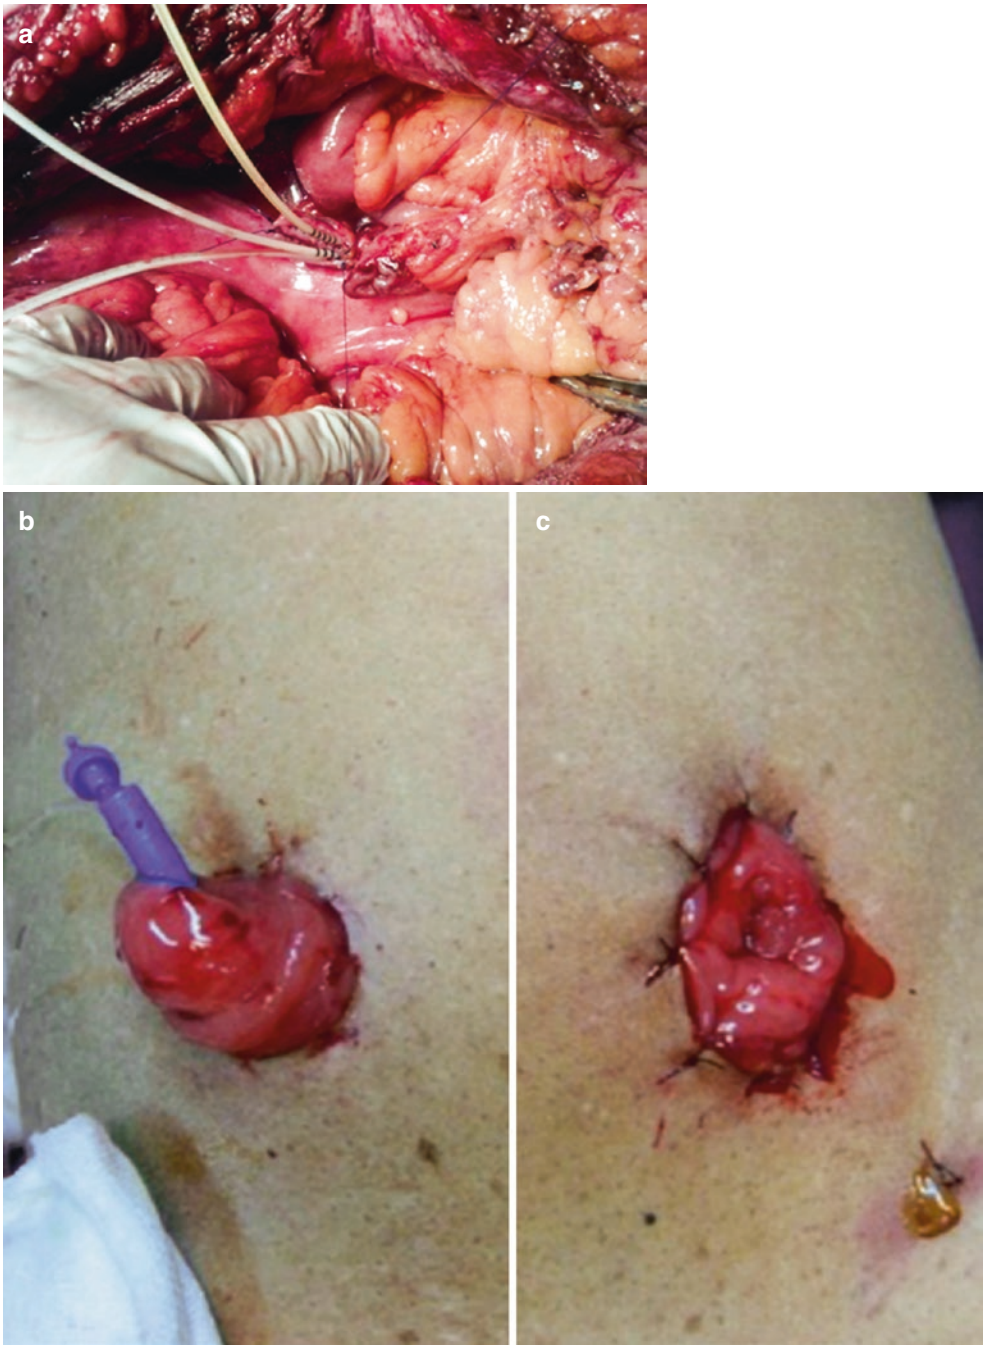

Fig. 105.32 Urine derivation with ileal conduit (**a**, **b**), and colostoma (**c**)

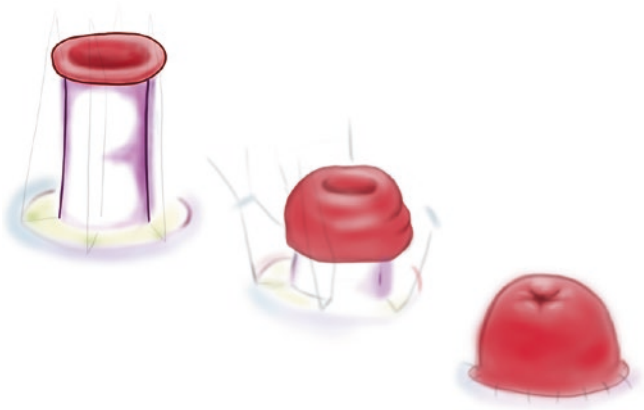

Fig. 105.33 Brooke technique of formation of stoma

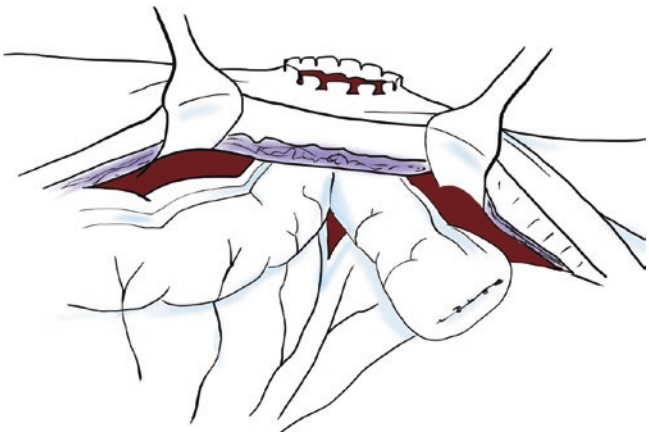

Fig. 105.34 Pseudo-loop technique

  - maturation of antimesenteric border of colon
  - no use of Brooke technique–often ends up at skin level, or retracted
  - emergencies only–only when no other stoma will reach (Fig. 105.34)

Appropriate Lengths for Stoma

- Ileostomy
  - Total bowel length above skin – 6–8 cm
  - Loop – 3 cm at mesenteric apex
  - Height of spout after Brooke ileostomy creation of more than 20 mm decreases skin/wound issues
- Colostomy
  - Total bowel length above skin – 2–4 cm
  - Height of stoma after colostomy maturation should be more than 5 mm

Stoma Complications

- Technical
  - Surgeon factors: judgement; technique; stoma type
  - Patient factors: indication for stoma creation; baseline functional status; postoperative care

- Physiological
  - electrolyte abnormalities
  - fluid balance
  - nutritional deficiencies
  - cholelithiasis
  - psychosocial issues.

The most frequent complications are:

Vascular Compromise of the Stoma due to

- technical error
- venous congestion
- disruption of segmental arterial supply
- too tight abdominal wall
- if inferior mesenteric artery is ligated, the ascending branch of left colic arter must be retained

Stenosis/Stricture (About 2–14 %)

- late sequela of vascular compromise
- it may present with bowel obstruction at level of fascia
- it is often successfully treated with finger tip dilation
- if there is unacceptable result, revision may be required
- if early on, it may be due to a small aperture through fascia

Dusky Stoma

- 2–17 % of stomas
- superficial
- full thickness

(If superficial–it can be watched and treated conservatively; if intraperitoneal–it needs laparotomy and revision) (Figs. 105.35 and 105.36).

Stomal Prolapse It is usually a late occurrence, and includes approximately 7 % of all stomas and up to 30 % of transverse

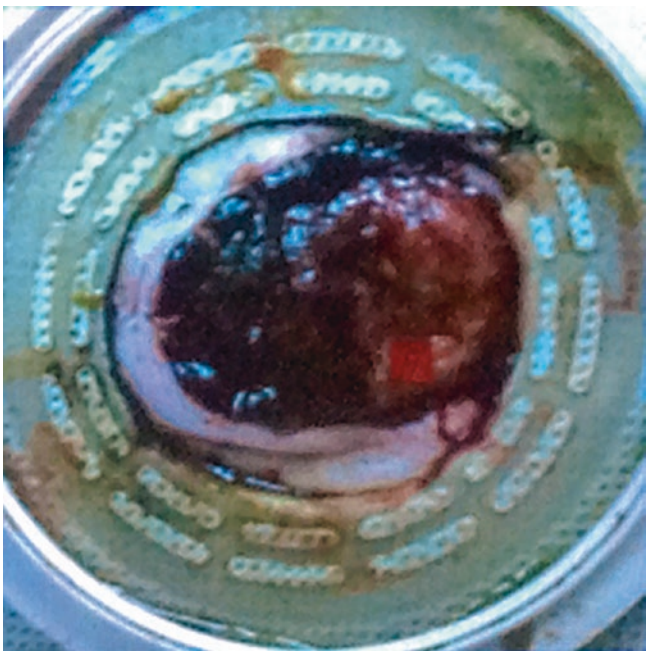

Fig. 105.35 Dusky stoma

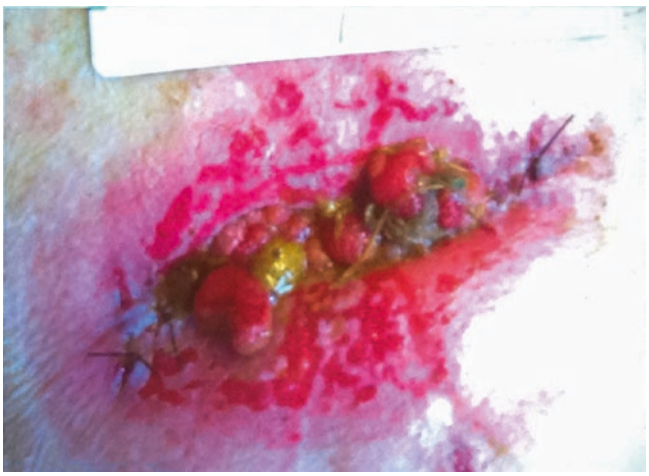

Fig. 105.36 Retraction of the stoma after vascular compromise

loop colostomies; it is controversial whether suturing bowel to fascia will prevent this (Figs. 105.37 and 105.38).

In case of chronic prolapse, the surgical options include:

- modified Altmeier or Delorme procedures (dissection of mucocutaneous junction; resection of either only mucose (Delorme procedure), or full thickness (Altmeier procedure)), and repeated Brooke stoma for creation of a new mucocutaneous border
- relocation of stoma with resection of extra length
- Burton modification of Thirsch Wire technique

Fig. 105.37 Stromal prolapse

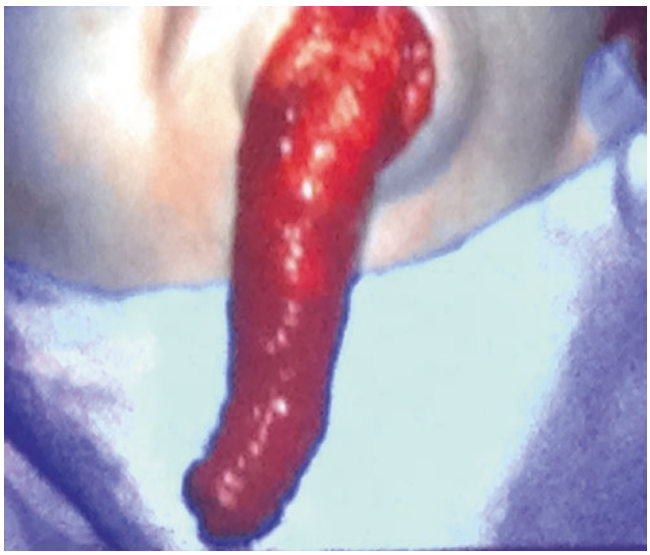

Fig. 105.38 Acute prolapse with necrosis of the bowel segment

Parastomal Hernia

- incidence is unknown due to underreporting and difficult detection
- estimated to be 20–80 %
- more frequent with colostomy than ileostomy
- early (presents with acute pain, mass, obstruction; less than 30 days from stoma creation).

It is due to technical failure; too large of an aperture in fascia.

- late ("inevitable"–according to many authors; it presents with slow growing mass, abnormal contour of tissues around stoma; consequence of increasing intraabdominal tension)

Difficult Stomas to Create

- inflamed, thickened, foreshortened mesentery (prior operation or inflammatory changes)
- obesity (thick abdominal wall and/or poor tissue quality)
- distended colon
- epiploic appendages (Fig. 105.39)

The strategy for success in those cases includes excision of the total inflamed sigmoid colon–the segment used for stoma must be free of inflammation.

Obesity stoma creation features with increased depth of skin creases, which causes pouching difficulties, even when properly constructed, and well-located ostomies; it is difficult to identify the rectus mucles preoperatively; obese patients cannot see their lower abdomen; thickened abdominal wall adipose tissue requires increased amount of length for mobilisation (Fig. 105.40).

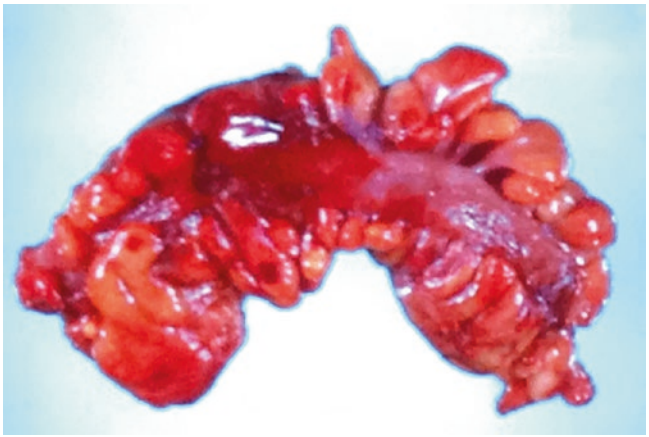

Fig. 105.39 Inflamed and full of epiploic appendages sigmoid colon–inappropriately for stoma creation segment–it must be resected

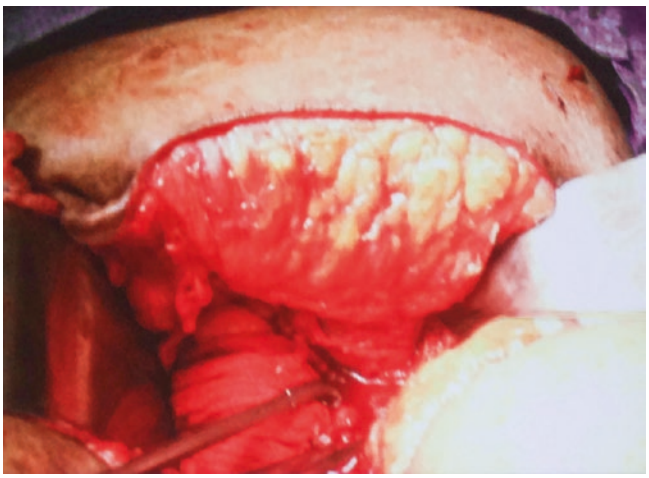

Fig. 105.40 Creation of colostoma in obese patient – BMI = 48.7

Tactics in Management and Reconstructions of Perineal Wound. Filling of the Pelvic "Dead Space" (Empty Space): Vaginal Reconstruction

The surgical removal of relapsed rectal tumor, especially in local advance of process and performed multivisceral and/or bone resections, results in formation of wide soft tissue defect and frequently requires also reconstruction of the urogenital tract. Additionally to the latter, the wound healing can be seriously affected by prior chemoradiotherapy, which involves significant risk of complications as infection, dehiscence, and delayed wound repair. The optimal healing and outcome can be achieved with the use of pedicularized cutaneous and muscular flaps.

In women with anterior pelvic exenteration, the vaginal reconstruction is performed with pedicularized flap–most frequently myocutaneous flap from rectus muscle of abdomen. This flap has the advantage of being constructed with a long pedicle, and it may fill the lesser pelvis, as well as be used for plastic surgery of vagina and perineum. The flap passes transpelvically and is rotated in order to cover the perineum. The nutrition of the flap is realized by the deep inferior epigastric blood vessels, with the use of the right muscle and skin area, because definitive colostoma is created most frequently on the left side of anterior abdominal wall. The authors, who use the method, do not report of any complications on the part of the donor portion of anterior abdominal wall. Only one out of five women have some complications subsequent to vaginal plastic surgery of that method and although most do not have any post-surgery sexual intercourses, almost all women prefer such plastic recovery [33].

The perineal and sacral defect after multivisceral surgical operation for rectal relapse may be wide with different options described for their plastic recovery. The closure of the defect may be achieved by means of biologic cloths (e.g. Pharmacol) or absorbable prosthetic cloths, or pedicularized flaps. Except for the transpelvic vertical myocutaneous flaps from the anterior right rectus muscle of abdomen, gluteal and femoral muscles are also used, as well as free myocutaneous flaps. In patients who had underwent preoperative radiotherapy, a myocutaneous flap with the use of rectus muscle of abdomen is preferred against the gluteal donor area. It is also used in patients with distal sacrectomy, when the first branch of the internal iliac blood

vessels is not preserved. Myocutenous flaps, according to many authors, are preferred to the omentoplastic surgery or primary provisionary closure with excellent results in several series [34]. A myocutaneous flap with the use of gracilis muscle is related to more complications and covers smaller portion, and therefore the authors do not recommend it [35].

The adding of surgical procedure of omentoplasty to the referred plasty methods allows reduction of the dead space in the lesser pelvis, decrease of the period of draining, as well as improvement of the healing of perineal wound. The omentoplasty takes little time and is performed by downward pulling in the lesser pelvis (antecolically or retrocolically) of the omentum priorly mobilized from the side of the greater curvature of stomach during the abdominal surgery time. During the perineal or sacral phase of operation, the omentum is finally drawn out and fixed at place (Figs. 105.41, 105.42, 105.43, 105.44, 105.45, 105.46, 105.47, 105.48 and 105.49).

Palliative Treatment

Although the pelvic exenteration was initially designed as a palliative procedure, its use for palliative treatment remains controversial. Due to the high morbidity and perioperative mortality, related to the procedure, some authors do not recommend it as palliative. Other authors consider that with pelvic exenteration the quality of life of patients with advanced stage of the disease can improve and that is why it is indicated for palliative treatment.

The pelvic exenteration is used as palliative treatment in cases of uncontrallable pains in the pelvis, tumor abscess, relapsing hemorrhages, intestinal obstruction, enterourinary and genitourinary fistulas, etc.

A wide variety of palliative locally destructive and other palliative techniques come into consideration in cases of locally advanced unresectable primary pelvic tumor or unresectable locoregional recurrence in pelvis . Those are: bypass anastomoses; disruption of the intestinal passage (anus preter without definitive resection of the tumor-bearing section); intermittent providing the mechanical intestinal conductivity–tunnelization (like Cryodestruction or stenting), cytoreductive surgery (includind Cryodestruction)–reduce cancer intoxication, palliative ligation of large blood vessels in order to prevent life-threatening bleeding; other methods – termoablation of metastasis, locoregional chemotherapy for liver metastasis by implantation a catheter through a. gastroduodenalis into *a. hepatica* propria–Port-A-Cath, hyperthermic intraperitoneal chemotherapy (HIPEC)–in cases of diffuse metastatic peritoneal spread (Figs. 105.50 and 105.51).

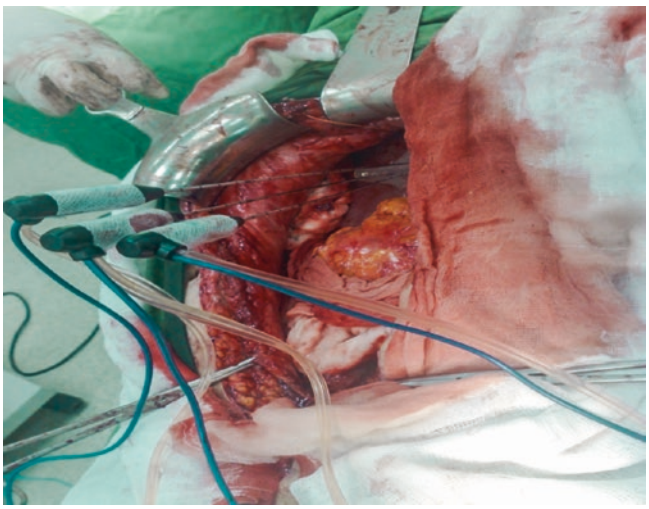

Fig. 105.51 Termoablation of unresectable liver metastasis

Potential Complications of Pelvic Exenteration

1. *Gastrointestinal complications*
   Intestinal obstruction
   Enteroperineal fistula
   Perineal hernia
   Peristomal hernia
   Bleeding

2. *Urine conduit*
   Insufficiency
   Stricture of the anastomosis
   Calculi
   Urinary sepsis or pyelonephritis
   Enterourethral fistula

3. *Pelvic*
   Abscess
   Fistula
   Wound infection

4. *General*
   Myocutaneous necrosis of the flap
   Pneumonia
   Deep venous thrombosis
   Depression
   Difficult social adaptation

Management of the Complications

Bleeding

The intraoperative hemorrhagia during surgery for advanced pelvic primary or relapsed tumor can be serious and life-threatening, and it requires methodical approach for its stopping. Most frequently the bleeding has as a source the presacral venous plexus or the internal iliac veins, and it could quickly result in the need for massive replacement hemotransfusion with subsequent fatal coagulopathy. In this case it is especially important to keep calm, and compression to be provided–a hot wet compress on the bleeding section, additional and sufficient light, and width of the field to be ensured by widening of the incision, if possible. The anesthesiologist must be informed of the quantity and intensity of blood loss, as well as about the planned units of blood and plasma. Frequently the "packing" is achieved by massive compression for 10 min. There is a dramatical effect, which results in hemostasis. The removal of compress requires careful manipulation with it in order not to be extracted the created vascular obturators and to prevent renewal of bleeding. If these occur, the following algorithm comes into consideration:

Persistent bleeding from the presacral veins → Mechanical hemostasis (1. Vascular ligation with non-resorbable sutures; 2. Clasps) → High-energy devices (1. Powerful diathermia (spray regimen); 2. Argon plasma coagulator; 3. Harmonic scalpel) → Hemostatic agents (1. Surgical; 2. FloSeal; 3. Fibrin-glue) → Packing (tamponade) for 36 h → Dissection along the sacrum and resection of the Waldeyer's fascia → Ligation of the dorsal veins → Clamping / ligation of the internal blood vessels → Looking for co-operation by a vascular surgeon.

Wound Complications

The wound complications are among the most frequent ones, accompanying the pelvic exenteration, and at the same time they frequently delay and prolong significantly the period of postoperative morbidity. Risk factors are the neoplastic disease itself with its reflection on the organism, preoperative radiotherapy, poor antiseptics and aseptics, coarse manipulation with the tissues and poor choice of surgical tactics for recovery of soft tissue defects. Approximately 43 % of patients, who underwent abdominoperineal resection, develop wound complications (Fig. 105.52).

In the presence of infection at the operative site, the adequate draining and necrectomy are the first important conditions for its overcoming. As a result a big open defect is created, in some cases this would be through performing of a laparotomy which is difficult for everyday care (Fig. 105.53). A good therapeutic variant in these cases is the Negative Pressure Wound Therapy (NPWT) with its necessary devices and consumables, which facilitate and accelerate the therapeutic process by preventing of multiple daily change of dressings, malodorous secretions from the wound, stimulation of repair of tissues and shortening of hospital stay, which represents financial benefit as well. System Info VAC® (KCI®) is excellent for such cases. After each surgery the wound defect is left under V.A.S. operational bandage to reduce contamination, drainage of wound secretions and stimulation of granulation. The most frequently used pressure is high level vacuum (−125 mmHg)

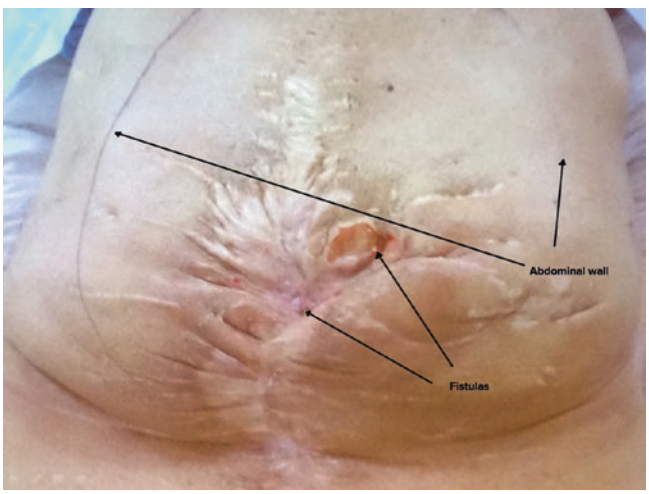

Fig. 105.52 Enterocutaneous fistulas after surgical side infection

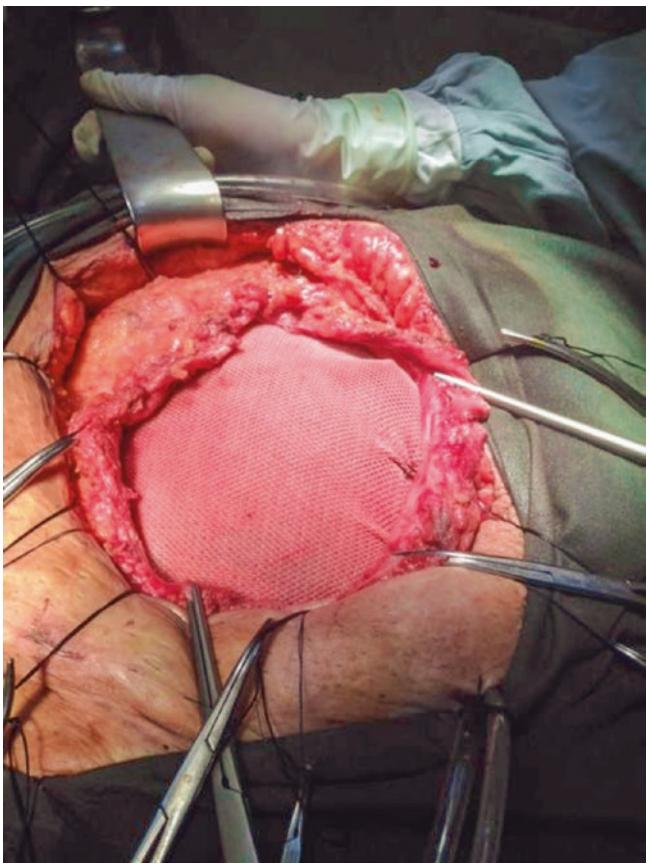

Fig. 105.53 Laparostoma covered with prosthetic mesh

and dressing type VAC Granu Foam® (KCI®) (Fig. 105.54). The frequency of replacement is 48 h. During the replacement of the dressing there should be carried out debridement with jet irrigation or lavage with saline according to the condition of the wound. It is often used also a modified vacuum assisted laparostoma consisting of three layers: an inner–silicone (nylon) canvas, intermediate–mesh (ampoksen shed, prolene, Miculitz compress) and outside–coverslip foil. The mesh is sutured to the fascia with absorbable suture – 2/0. Between the mesh and the cover sheet are placed gauze compresses and aspiration drain, providing negative pressure. Surgical wound and the whole abdomen are covered with surgical foil (e.g. Joban-2, 3 M). Drainages should be placed of permanent soft aspiration (50–125 mmHg) forming a vacuum that constantly cleans the wound. That negative pressure evacuates surgical wound secretions and also stimulates granulation on the wound surface.

Separation of the abdominal wall – Component separation technique by Oscar Ramirez, is a method of choice in impossible conventional secondary closing of the laparostoma defect after overcoming of the abdominal sepsis (Fig. 105.55a, b). The plan of dissection is comprised between the separate layers of the anterior abdominal wall as well as it is mandatory being especially careful to preserve the perforant branches of the lower and upper epigastric vessels to the rectus abdominis muscles and also prevent the development of abdominal compartment syndrome.

Fig. 105.54 A vacuum system for maintaining a negative pressure in the wound

Neoadjuvant Chemoradiotherapy and Adjuvant Chemotherapy in Cases of Rectal Cancer

- It has been proved that the preoperative radiotherapy improves the resectability of not less than 50–75 % of patients with non-resectable rectal tumors and it is more effective than the postoperative radiotherapy (L. Pahlman) [31].
- The use of chemotherapy in combination with radiotherapy may increase the effectiveness of radiotherapy as regards the transformation into lower stage of initially non-resectable tumors.
- Minsky et al. reported that the intake of 5-Fluorouracil + Leukovorin with additional 50.4 Gy preoperative radiation on the pelvis result in higher grade of response and less regional lymph nodes with metastases upon the resection, than the radiotherapy itself [32].
- Neoadjuvant chemoradiotherapy in case of rectal cancer:
  - It is applied in locally advanced cancer and is combined with radiotherapy 50–54 Gy + 5-Fluorouracil + Leukovorin.
- Adjuvant chemotherapy
  - It is applied after surgical treatment of locally advanced cancer. Preliminary histological examination of the tumor for the marker K-ras is recommended.
    (i) Leukovorin + 5-Fluorouracil
    (ii) Oxaliplatin + Leukovorin
    (iii) Capecitabine

In terms of evidence-based approach in pelvic exenteration, it would be useful to demonstrate a comparison as regards the survival of groups of patients with potentially curative pelvic exenteration, palliative pelvic exenteration, and palliative non-resectable procedure [39]. According to Zarkov et al. the 5-year survival for radical pelvic exenteration is about 22 %, whereas survival for the palliative pelvic exenteration does not exceed 18–30 months and explorative laparotomies and palliative procedures have reached only 2–9 months survival [28]. Those data eloquently emphasize significantly more prolonged period of overall survival in the group of potentially curative pelvic exenterations.

Conclusion

The pelvic exenterations have their place in the treatment of advanced pelvic tumors. Irrespective of the severe surgical trauma and the comparatively high frequency of postoperative complications, in well-selected patients, carefully precized surgical tactics, and adequate perioperative cares, the procedure provides an opportunity for improvement of the survival and it has explicit indications.

Nevertheless, the pelvic exenteration continues to be a very traumatic intervention with potential of severe complications in the early and late postoperative period.

There is a lot of evidence that the pelvic exenteration in patients with primary rectal cancer and cancer of uterine cervix may result in significant increase of their

5-year survival; however, the prognosis after pelvic exenteration in patients with relapsed rectal carcinoma still is not so good.

The pelvic exenteration keeps on having an important role in the multimodal approach in the treatment of patients with advanced pelvic tumors. Conditions for improvement of the surgical technique and lowering of the frequency of complications are established with the acquiring of bigger experience in the field of that pathology.

Pelvic and Para-aortic Lymph Node Dissection

106

Florian Heitz, Andreas du Bois, and Philipp Harter

General Surgical Approach of Systematic Abdominal LNE

Open surgery is the standard in ovarian malignancies and still indicated in some patients with uterine malignancies despite the advances of endoscopic surgery. If pelvic and paraaortic lymphadenectomy is indicated for surgical staging in women with malignant uterine disease and the laparoscopic approach is contraindicated or rejected by the patient, abdominal LNE should be performed. Minor bleedings are coagulated with the bipolar forceps immediately by the first assistant. The lymph vessels and the surrounding tissue at the cranial border at the renal vein and at the caudal border at the annulus inguinal internus should be cut horizontally with a vessel sealing device, to minimize the risk of lymphatic drainage postoperatively and the development of lymphoceles. In addition, a conventional ligature or clip should be placed to further reduce the risk. If the application of sponges to the resection site immersed with thrombin and coagulation factor 1 is of further benefit is currently under investigation.

Technical Requirements

To conduct abdominal systematic pelvic lymphadenectomy bipolar scissors, bipolar forceps and a monopolar needle should be available as well as vessel sealing instruments, clips and ligatures to minimize lymphatic spillage after excision of the lymph nodes. To obtain an optimal exposure of the surgical area a sufficient retractor must be available (in here, shown our most frequently used Muenster retractor, Fig. 106.1).

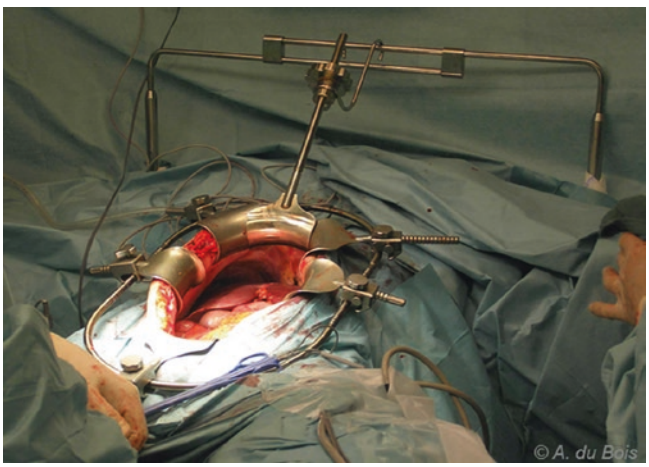

Fig. 106.1 A number of different retractors are commercially available. The retractor system shown here is a combination of the body-placed Münster retractor to obtain lateral and to a lesser degree vertical retraction combined with the Gnauert bracket for further vertical but also ventral retraction. If there is no tumor suspected in the upper abdomen, the midline incision must not be conducted as far as shown here, but probably 5 cm less

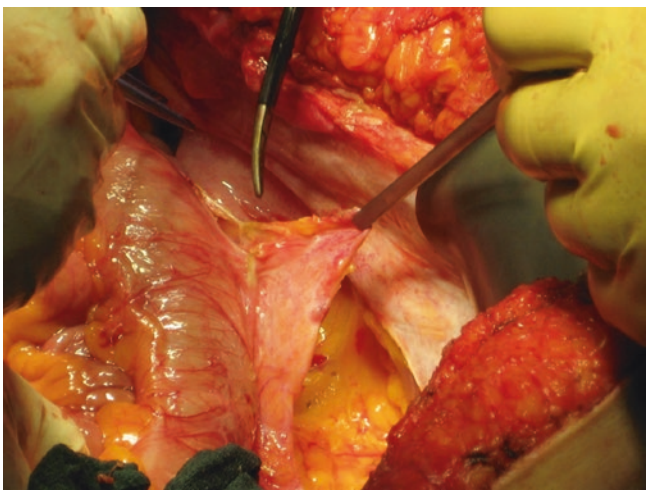
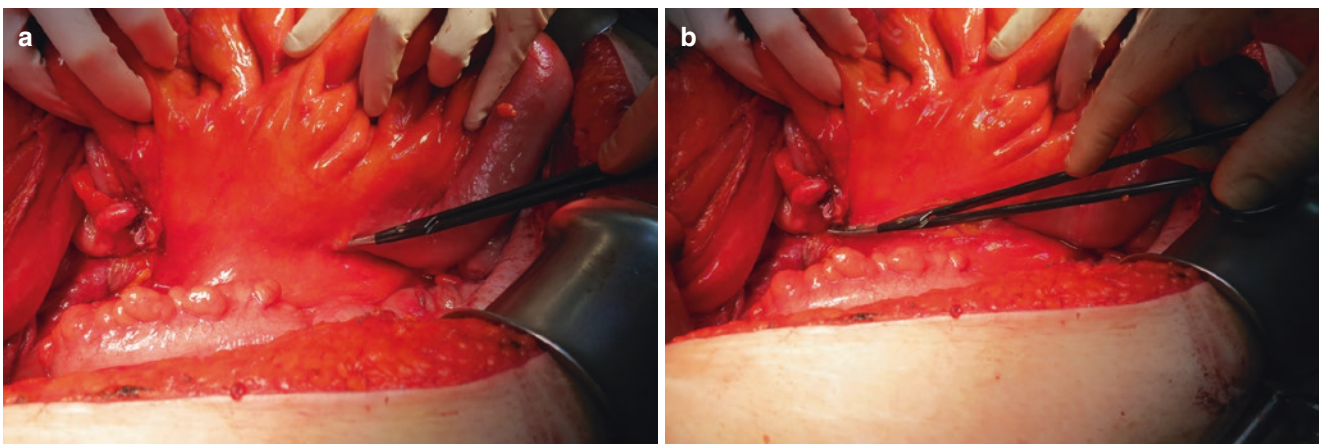
Preparations

The patient is settled down on a vacuum mattress in lithotomy position and the lower legs and feet are placed into cushioned surgical shoes. The patient wears antithrombotic stockings. The hip and the knees are slightly (20–30°) inflected to prevent compartment syndromes and other lesion due to wrong positioning. The patient receives cefuroxim and metronidazol as antibiotic prophylaxis. The first surgeon needs assistance by at least one surgical assistant (superiorly by two, one on the other side and one between the legs) and an assisting nurse.

Median laparotomy is conducted with an incision from the pubic bone to the xiphoid with a scalpel and the layers of the abdominal wall are incised separately with bipolar scissors. After getting into the abdominal cavity, the fascia of the upper right incision is crabbed by two Mikulicz retractors. The abdominal wall is lifted by the second assistant to present the falciforme ligament. It is consecutively removed with bipolar scissors or vessel sealing instruments from the abdominal wall and from the liver surface via bipolar scissors. The teres ligament, which is the caudal end of the falciform ligament is removed over an Overholt forceps and this is replaced by ligature. The Münster retractor with the Gnauert bracket is getting installed (Fig. 106.1). The peritoneum of the paracolic gutter is incised longitudinally of the ascending and descending colon at the white line of Toldt and the peritoneum is separated laterally (Fig. 106.2). To mobilize the colon properly the phrenicocolic ligaments and the spenocolic ligament on the left side have to be incised. As the kidneys might be attached in the connecting tissue of the colon with the anterior lamella of the renal fascia, those should be separated by cutting down the connecting tissue with bipolar scissors, without opening the fascia. Thereafter, the mesocolon sigmoideum is separated from the dorsal connecting tissue up to the suspensory muscle of duodenum (ligament of Treitz) (Figs. 106.3, 106.4, 106.5, 106.6, and 106.7) and the bowl is placed on and covered with wet rags on the chest.





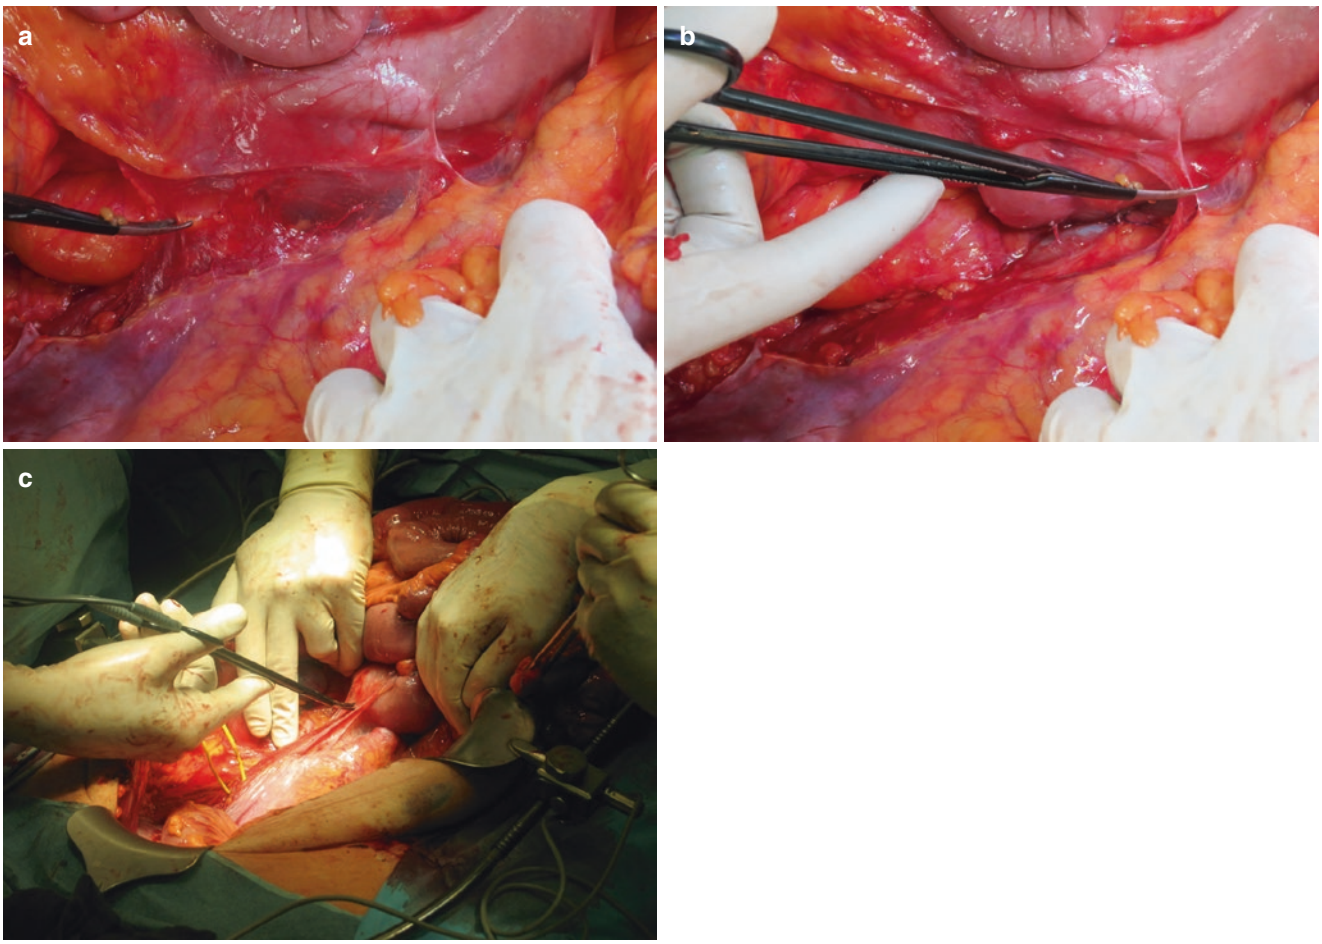


Fig. 106.2 The peritoneum of the paracolic gutter is incised longitudinally of the ascending and descending colon at the white line of Toldt and the peritoneum is separated laterally

In the next step the ureters are located. In case of adnexectomy, the infundibulopelvic ligaments should be identified ventrally and be branched off by Overholt forceps. After incision, the cranial portion is separated out of the connecting tissue being aware that the ureter is just a little dorsolateral. The kidney is pushed laterally with a swab. The infundibulopelvic ligaments will be cut over Overholt forceps at the inferior vena cava on the right side (Fig. 106.8a) and at the left renal vein (Fig. 106.8b). Before, or thereafter, the ureters are elevated and vessel loops might be attached, to minimize direct and traumatic traction (Fig. 106.9). The dorsal attachment to the connecting tissue is cut with bipolar scissors to move the ureters laterally. In case of the

Figs. 106.3 and 106.4 Thereafter, the mesocolon sigmoideum is separated from the dorsal connecting tissue up to the suspensory muscle of duodenum (ligament of Treitz). Therefore, the meso of the small intestine is mounted ventrally and it is incised horizontally

Figs. 106.5, 106.6 and 106.7 The connecting tissue is then cut in a stepwise fashion while mounting the small and large intestine cranially/ventrally

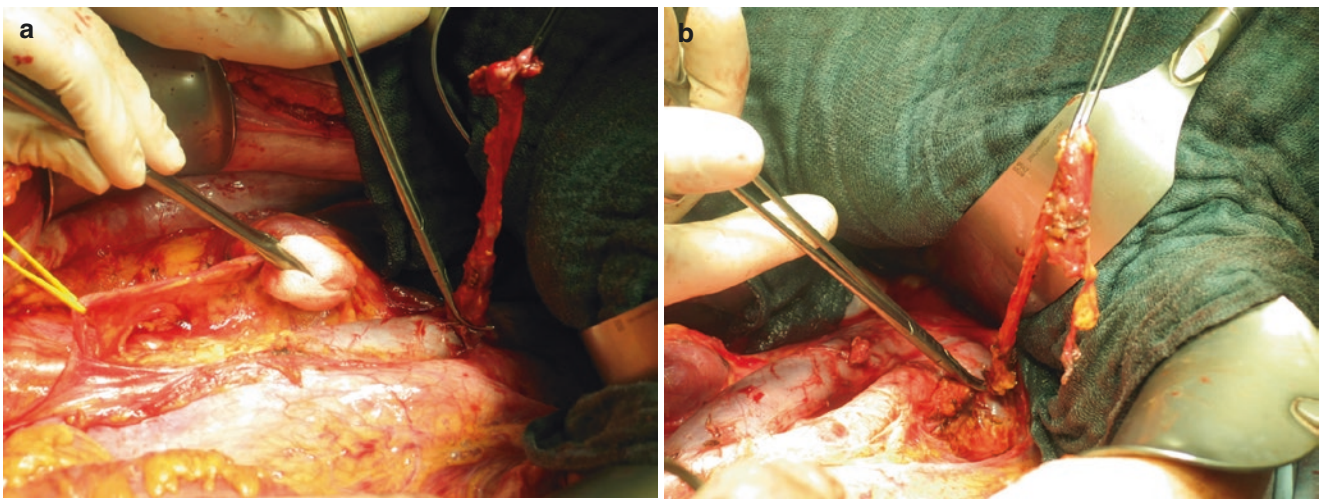

Fig. 106.8 The infundibulopelvic ligaments will be cut over Overholt forceps at the inferior vena cava on the right side (**a**) and at the left renal vein (**b**)

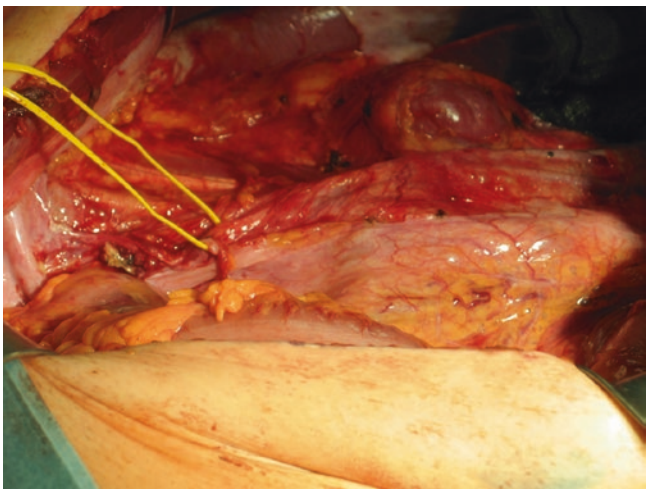

Fig. 106.9 Before, or thereafter, the ureters are elevated and vessel loops might be attached, to minimize direct and traumatic traction

preservation of the adnexa the infundibulopelvic ligaments have to be carefully separated from ureters on the entire lengths between the crossing of the ureters with the common iliac vessels and the insertion of the ureters in the pararenal fat tissue with bipolar scissors.

Surgical Approach of Systematic Abdominal Paraaortic LNE

Surgical Workflow

Basically, we dissect four compartments during systematic paraaortic lymphadenectomy, however, other approaches and subdivisions are possible. (1) paracaval: lateral and dorsal of the inferior vena cava, (2) inter-aortocaval: medial and dorsal of the inferior vena cava and medial and dorsal the aorta abdominalis, (3) low paraaortic: lateral and dorsal the aorta between the common iliac artery and the IMA and (4) high paraaortic: lateral and dorsal of the abdominal aorta and between the IMA and the renal vessels.

The paraaortic lymphadenectomy is started caudally at the bifurcatio aortae and the parietal peritoneum is vertically cut approximately 1 cm cranially of the aortic bifurcation, to avoid injuries of the common iliac arteries, mainly if the diameter of the vessel is small. Figure 106.10 displays all areas in which lymphadenectomy is conducted. The first area for lymphadenectomy is the paracaval space. Therefor the second assistant between the legs takes a large swab in the left hand to push the kidney and the ureter laterally and a wet small swab to push the inferior vena cava medially. . Alternatively, the inferior vena cava is pulled with two small hooks. The assistant should place the swab

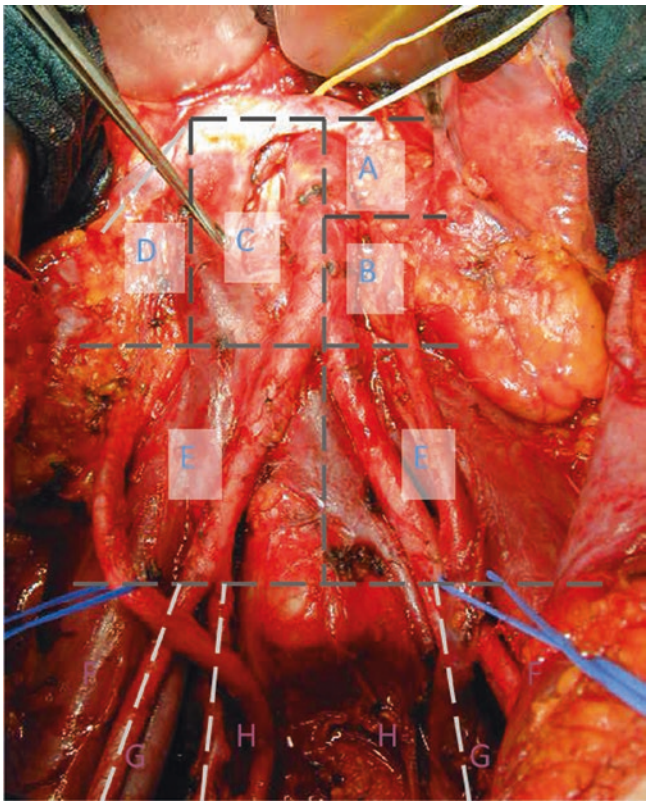

Fig. 106.10 Definitions of regions how we conduct para aortic lymphadenectomy: *A* high para-aortic: medial aorta abdominalis, left V. renalis, caudally A. mesenterica inferior, dorsally spine and right laterally fat for the kidney; *B* low para-aortic: medial Aorta abdominalis, cranially A. mesenterica inferior, caudally bifucatio aortae, dorsally spine, laterally M. psoas; *C* interaorto-caval: medial V. cava inferior, medial Aorta abdominalis, cranially left V. renalis, dorsally spine, caudally bifurcatio aortae; *D* para-caval: medial V. cava inferior, cranially right V. renalis, caudally bifurcatio aortae, laterally fat of the kidney/ M. psoas

on the vena cava in a position that the dorsolateral border of the vessel is visible, even during pushing the cava medially (Fig. 106.11). The paracaval tissue is dissected horizontally with bipolar scissors up to the renal vein. The lymph vessels and the surrounding tissue at the cranial border at the renal vein should be cut horizontally with a vessel sealing device. In case of bleeding, bipolar forceps should be used immediately. In case of larger injuries sewing the wall of the vena cava should be conducted with non-absorbable monofil suture. In the next step, the interaortic fraction of the lymphatic tissue is harvested. To remove the ventral portion of the tissue no traction on the vessels is needed (Fig. 106.12). To reach the dorsal portion the second assistant between the legs takes a wet small swab to push the inferior vena cava laterally and inverted large forceps to push the aorta laterally. Removing the lymphatic tissue in the low paraaortic region (inferior of the inferior mesenteric artery (IMA)) and the high paraaortic region (cranial of the

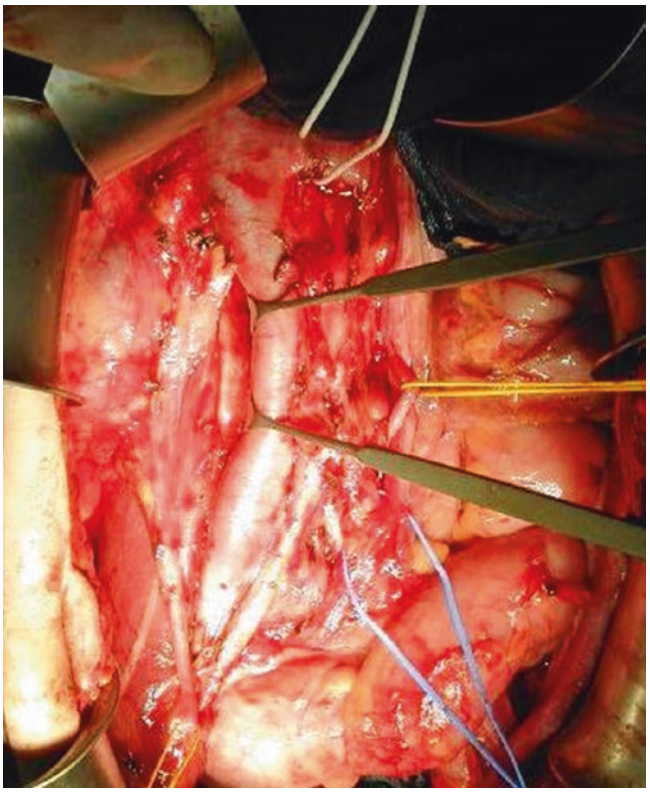

Fig. 106.11 Resection of the paracaval portion

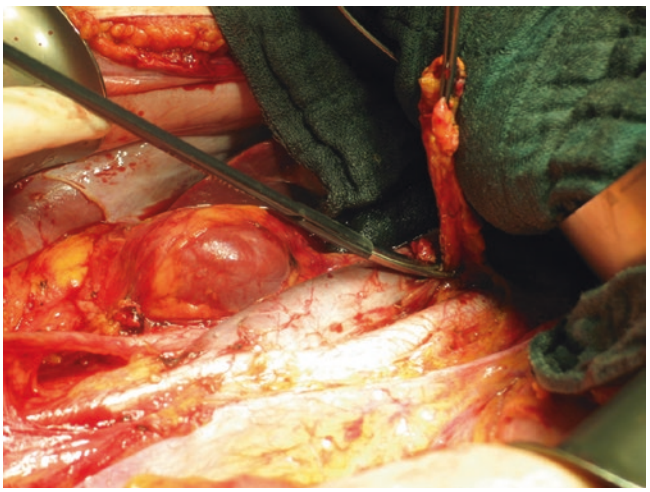

Fig. 106.12 To remove the ventral portion of the tissue, no traction on the vessels is needed

IMA) harbors the highest technical demand, as the meso of the descending colon is attached at the IMA and left the ureter takes course laterally very near, but is hidden by the meso. Sometimes it might be helpful to see-saw the descending colon with the meso to be sure to remove all lymphatic tissue, without injuring the ureter or the IMA (Fig. 106.13). Consecutively, the second assistant gets a large swab in the right hand to move the left kidney and the ureter laterally and an inverted large forceps to push the aorta medially. The paraaortic tissue is dissected vertically with bipolar scissors, primary between the common iliac artery and the IMA and in a second step between the IMA and the renal vein. The lymph vessels and the surrounding tissue at the cranial margin at the renal vein should be again cut horizontally with a vessel sealing device (Fig. 106.14).

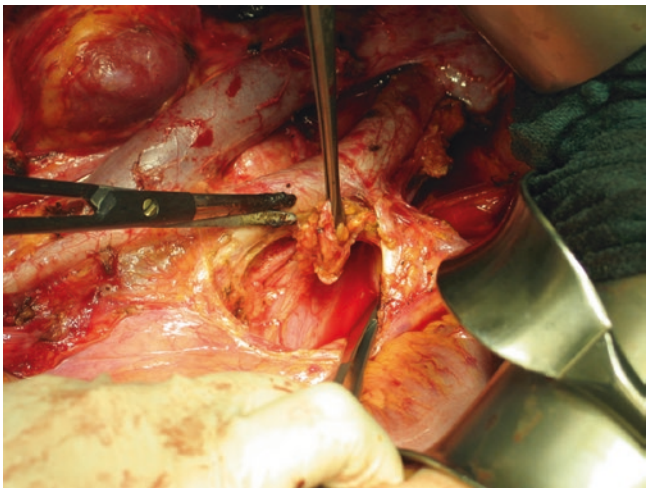

Fig. 106.13 The second assistant gets a large swab in the right hand to move the left kidney and the ureter laterally and an inverted large forceps to push the aorta medially

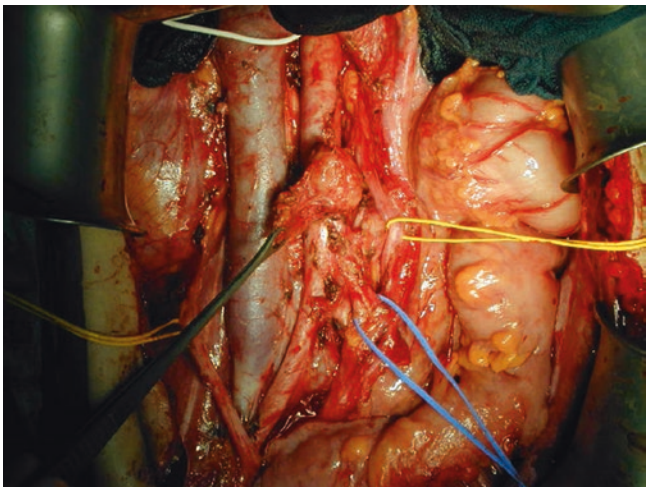

Fig. 106.14 The paraaortic tissue is dissected vertically with bipolar scissors, primary between the common iliac artery and the IMA and in a second step between the IMA and the renal vein

A thorough inspection of the key structures should take place and a sufficient hemostasis must be ensured before ceasing the operation. Drainage at the surgical field of pelvic lymphadenectomy is usually not necessary (Fig. 106.15).

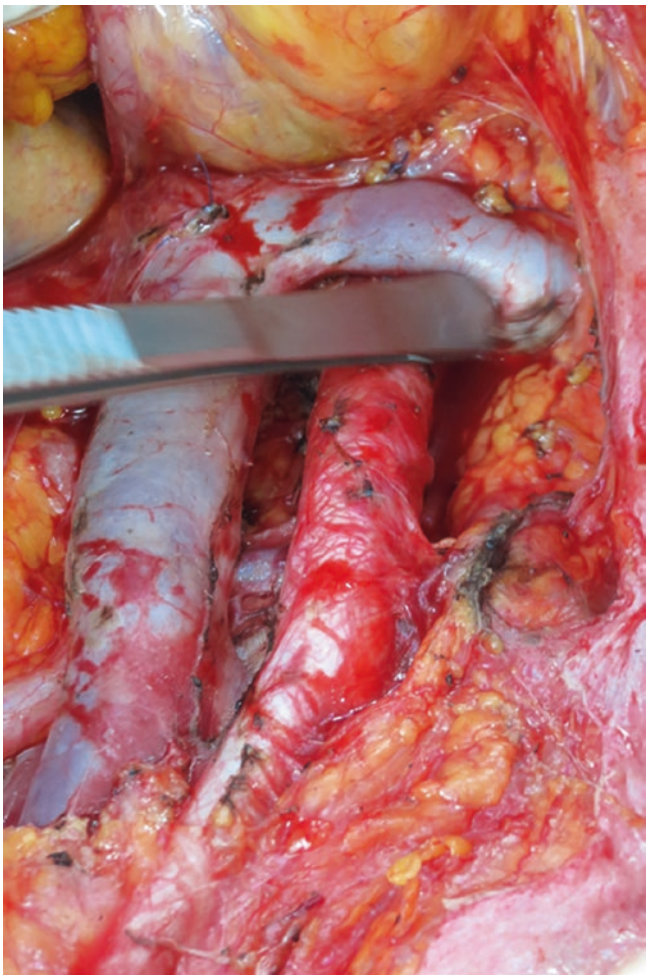

Fig. 106.15 It is not always indicated to remove all tissue from the ventral portion of the aorta and the ventral portion of the V. renalis sinistra. However, the insertion of the V. ovarica sinistra is shown explicitly

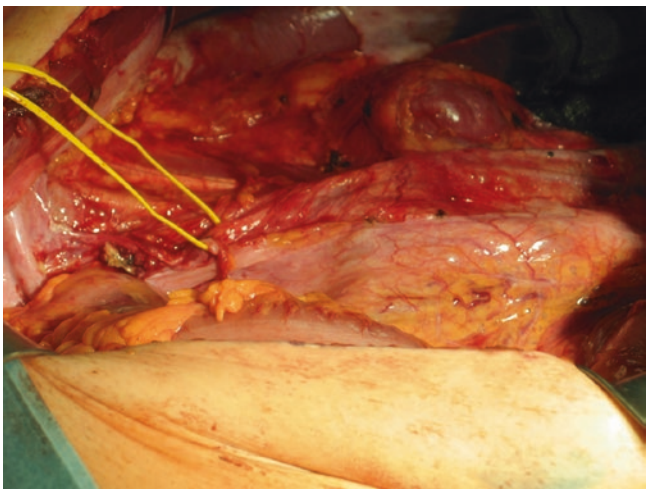

Fig. 106.16 The ureter is elevated and a vessel loop might be attached, to minimize direct and traumatic traction

Surgical Approach of Systematic Abdominal Pelvic LNE

Surgical Workflow

If there is no doubt that abdominal systematic pelvic lymphadenectomy will not be combined with abdominal systematic paraaortic lymphadenectomy or other staging procedures, a Pfannenstiel incision might be used. Otherwise, a complete median laparotomy should be conducted as described above.

The retroperitoneal space is opened laterally of the round ligament and is incised cranially on the ileopsoas muscle. The infundibulopelvic ligament is identified cranio-medially and the ureter is located dorsally. In case of adnexectomy, the infundibulopelvic ligament should be identified ventrally of the ureter and branched off by Overholt forceps. The infundibulopelvic ligament is cut between Overholt forceps and it is ligated. Thereafter, the ureter is elevated and a vessel loop might be attached, to minimize direct and traumatic traction (Fig. 106.16). The dorsal attachment to the connecting tissue is cut with bipolar scissors to move the ureters laterally.

In case of the preservation of the adnexa/ ovary but hysterectomy the fallopian tube and the utero- ovarian ligament is cut between clamps and the clamps are substituted by ligature. The mesovar and the mesosalpinx are cut with the bipolar scissors in mesenteric direction, cranially. Some cm cranially of the location of the ovary, the peritoneum is pulled ventrally-medially and the ureter is found dorsally at the crossing of the common iliac vessels. After identification of the ureter, the ventral portion including the ovary, the utero-ovarian ligament, the mesovar, the fallopian tube and the mesosalpinx are dissected from the peritoneum and the lateral connecting tissue and might be primary placed in the median abdominal cavity, before fixation at the lateral abdominal wall at the end of the surgery. At the beginning or end of this procedure we would perform a salpingectomy. Thereafter, the ureter is elevated and a vessel loop might be attached, to minimize direct and traumatic traction. The dorsal attachment of the ureter to the connecting tissue is cut with bipolar scissors to move the ureters laterally (Fig. 106.17).

Four compartments are going to be dissected for systematic pelvic lymphadenectomy: (1) the tissue surrounding the common iliac vessels, (2) the tissue surrounding the external iliac vessels, (3) the tissue surrounding the internal iliac vessels and (4) the tissue in the obturatoric fossa. The pelvic lymphadenectomy is started cranially at the bifurcatio aortae and the ventral portion of the perivascular tissue of the common iliac artery is cut with bipolar scissors. If no paraaortic LNE is conducted, the cranial resection should take place with a vessel sealing instrument to reduce the risk of lymphatic spillage and lympoceles. The superficial tissue is removed laterally to the genitofemoral nerve and medio-dorsal under the external common iliac vein (Fig. 106.18). The

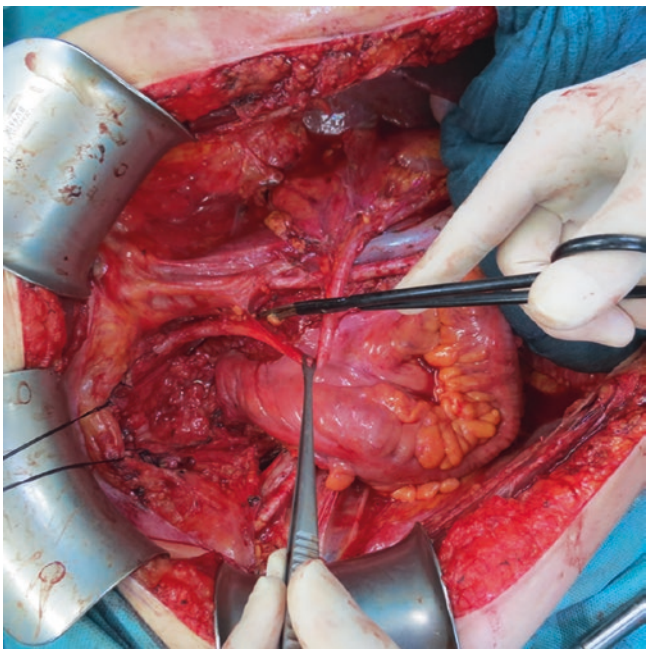

Fig. 106.17 The dorsal attachment of the ureter to the connecting tissue is cut with bipolar scissors to move the ureters laterally

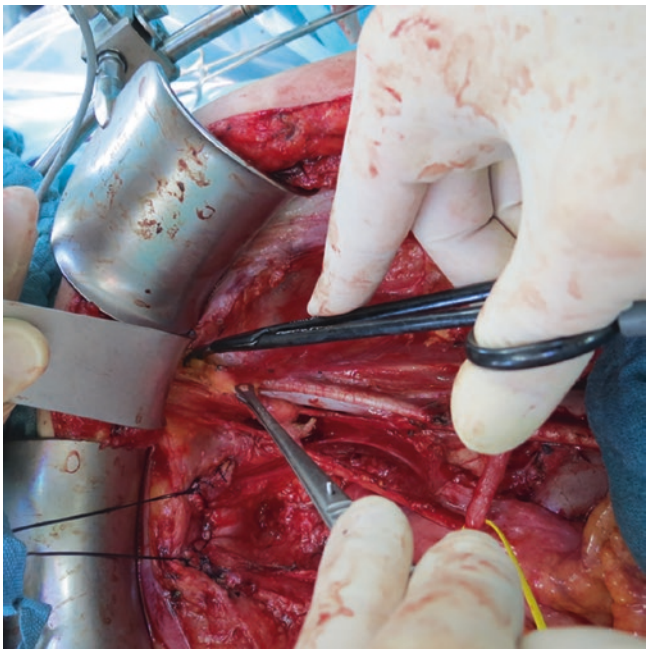

Fig. 106.19 To obtain a good insight into the abdominal inguinal ring, the abdominal fat tissue and abdominal wall is lifted with a Roux retractor

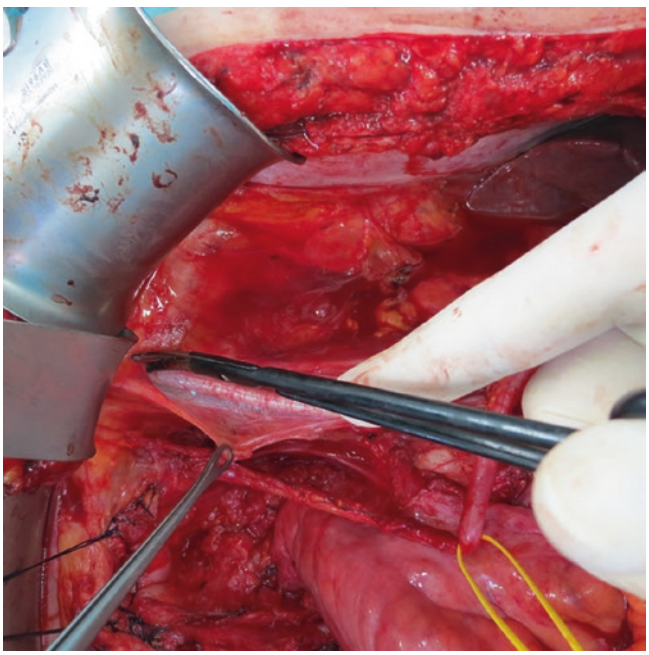

Fig. 106.18 The superficial tissue is removed laterally to the genitofemoral nerve and medio-dorsal under the external common iliac vein

medially located hypogastric plexus should be preserved. At the bifurcation of the common iliac vessels the common iliac portion of the pelvic lymphadenectomy is cut and the removal of the tissue surrounding the external vessels is conducted. The presacral space is only opened in the case of palpable lymphnodes. To obtain a good insight into the abdominal inguinal ring, the abdominal fat tissue and abdominal wall is lifted with a Roux retractor (Fig. 106.19). The caudal resectionmargin is the Rosenmuller node. At this stage the ramus pubicus of the inferior epigastric artery must be carefully prepared to avoid bleeding, which is often rather difficult to stop. The obturator fossa is opened with cutting the fascia of the psoas muscle along the vessel direction and the connecting tissue between the external iliac artery and the psoas fascia, respectively. Sometimes it helps to dilate the space in the obturator fossa with the index finger, tenderly. Traction to open the obturator fossa should be given with a large Breisky retractor to push the psoas muscle laterally and a small Breisky retractor to push the external vessels medially (Fig. 106.20). The caudo-dorsal margin is the obturator nerve and the cranial margin the crossing of the ureter (Fig. 106.21). The resection cranially and caudally should be conducted with a vessel sealing device. Before starting the preparation of the lymphatic tissue surrounding the internal iliac artery the ureter should be mobilized adequately medially and caudally near to the insertion of the obturator vessels and nerve to the obturator foramen. Thereafter, the dissection of the perivascular tissue containing the lymph nodes along the vessel direction is conducted with bipolar scissors (Fig. 106.22). The caudal resection should be conducted again with vessel sealing device.

A thorough inspection of the key structures should take place and a sufficient hemostasis must be ensured before ceasing the operation. A drainage at the surgical field of paraaortic lymphadenectomy is usually inserted.

Omentectomy

107

Katherine A. Nixon and Christina Fotopoulou

Anatomical Landmarks and Aims of Omentectomy

The large omentum constitutes a double layer of peritoneum covered by fatty tissue and consists mostly of fibroblasts and mesothelial cells. It hangs from the large curvature of the stomach, attaches to the transverse colon and covers parts of the small bowel. Embryologically the omentum develops from the posterior part of the Dorsal Mesogastrium: the stomach undertakes a 90° rotation, which produces a duplication of peritoneum, this will later represent the omentum. The vascular supply of the large omentum consists of an anastomosis between the right gastroomental artery (which originates from the Gastroduodenal artery, a branch of the Common Hepatic artery) and the left gastroomental artery (arising from the splenic artery).

The lesser omentum also develops from the peritoneal layers and lies between the stomach, proximal duodenum and porta hepatis and represents the anterior border of the omental bursa (lesser sac). It can be divided into two parts: the hepatogastric and the hepatoduodenal ligaments.

The omentectomy is a significant part of surgical staging for malignant ovarian tumors. In cases of advanced disease, tumour involving the omentum builds an "omental cake", therefore omentectomy is part of the cytoreductive procedure aiming at total macroscopic clearance of the malignant disease. Omentectomy in the case of epithelial ovarian cancer should be infragastric and extend to the inferior splenic pole. Depending on the extent of the disease the vascular arcade on the large gastric curvature will either be resected or preserved. In early borderline ovarian tumours, in the absence of peritoneal implants, an infracolic omentectomy is sufficient for staging; whereas in epithelial ovarian cancer, especially in the presence of an omental cake omentectomy should be performed at the level of the large curvature.

The correct timing for the omentectomy, during an operation that involves hysterectomy, depends on the tumour dissemination pattern and intraoperative findings. In the case of an extensive "omental cake" it would be advisable to proceed to the omentectomy in the beginning of the operation in order to clear the field, stop the bleeding from the omental tumour plaque and be able to work with better conditions in the pelvis.

Surgical Steps for the Omentectomy

The omentectomy should start by freeing any potential adhesions to neighbouring structures like bowel loops, especially in the case of extensive disease. It would then be advisable to free any connections to the splenic pole to avoid any tearing and bleeding of the splenic capsule. To facilitate this, the left colic flexure needs to be completely mobilized by dividing the Lienocolic ligament between the inferior splenic pole and the left colic flexure. In order to further avoid tearing and bleeding of the splenic capsule it may be helpful to carefully place a swab behind the spleen to provide a posterior support. In the case of a splenic tear with bleeding, haemostasis can be achieved by bipolar coagulation ± the use of haemostatic agents like Floseal® or Tachosyl®. Often compression alone is enough to achieve control of bleeding. However, if the bleeding does not stop despite all attempts then one should proceed to splenectomy to avoid further haemorrhage. Emergency splenectomy has a higher risk of pancreatic injuries.

The next step is the mobilization of the omentum from the right colic flexure; this is usually easier compared to the left side, unless the patient has undergone previous liver or gall bladder surgery, in which case adhesions and/or infection

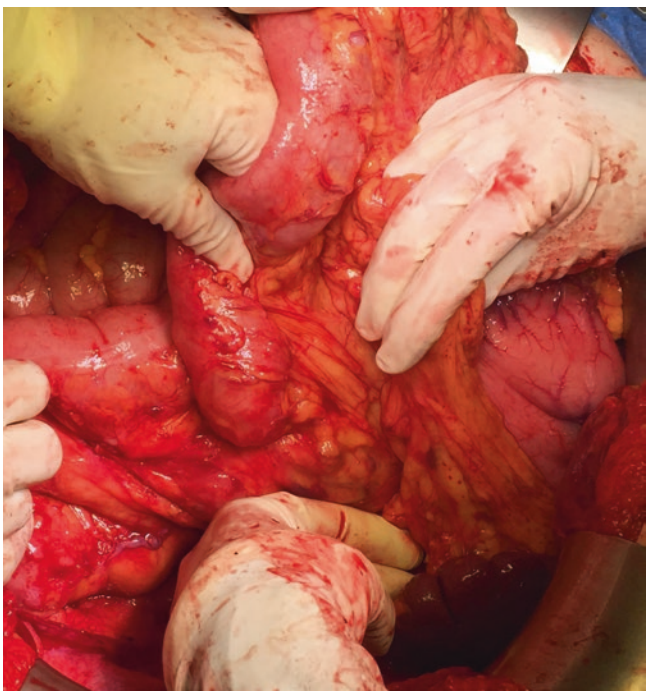

Fig. 107.3 Dissection of the greater omentum from the inferior splenic pole

may impede dissection. In this case it might be necessary to mobilize the omentum from the duodenum, gallbladder or porta hepatis. Here one needs to pay attention to avoid accidental injury to the pancreatic head and the biliary duct (Figs. 107.1, 107.2, 107.3, 107.4, and 107.5).

Proceed with the dissection of the omentum off the transverse colon. This can be achieved through use of diathermy or with sharp dissection with Mcindoe scissors by dividing the physiologic avascular adhesion layer between the omentum and transverse colon. The dissection should occur exactly in the avascular space to avoid bleeding and injuries of the transverse mesentery (Figs. 107.1 and 107.5). If diathermy instruments are used to perform the dissection one should be careful to avoid unintended thermic injuries to the bowel serosa and/or mesentery which may lead to a bowel perforation in the postoperative period. Any bowel serosal injuries should be repaired immediately with PDS 4.0 or 5.0, as, especially in smaller lesions, it might be difficult to identify them again later.

After sharp dissection of this physiologic adhesion layer a blunt approach can be taken to dissect the gastrocolic ligament from the dorsal side of the transverse mesentery. Via this method one opens the omental bursa and can identify

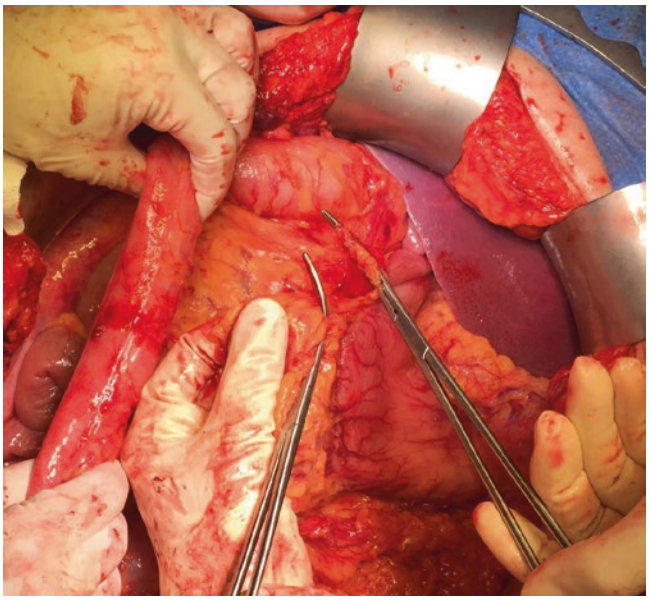

Fig. 107.4 Dissection of the greater omentum from the large curvature of the stomach

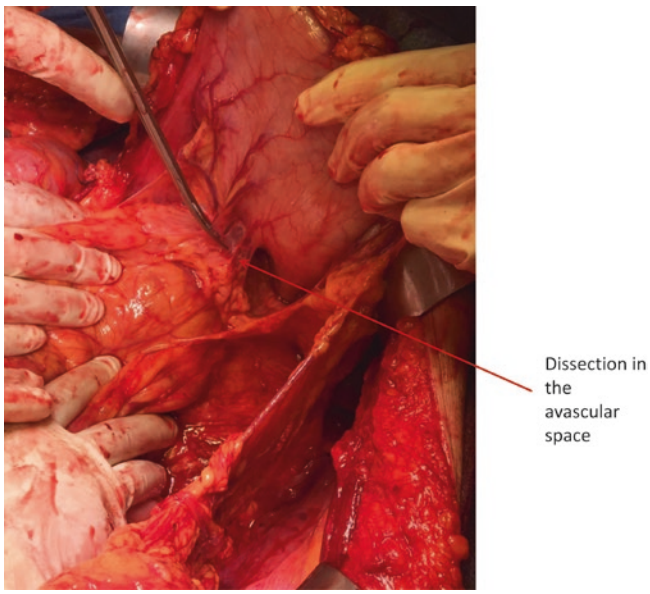

Fig. 107.5 Dissection of the physiological adhesions of the posterior gastric wall in the omental bursa for better sight in the entire omental bursa

and inspect the pancreas. At this step one should be careful not to enter the wrong layer and injure the transverse mesentery and its vessels, especially branches of the middle colic artery. During the dissection at the level of the mesenteric root is it important not to injure the superior mesenteric vessels which will impair the vascular supply from the distal duodenum to the left colic flexure. An injury of the Middle colic artery, which comes from the superior mesenteric artery, can result in prolonged or segmental necrosis of the transverse colon.

The omentum is now completely freed up from all sides and can be safely dissected off the large curvature of the stomach. This can be performed either with clamps and ligations or with special coagulation and cutting devices. In cases of extensive tumor involvement the gastroepiploicae vessels along the large curvature of the stomach may have to be resected, paying attention not to cause ischemic injuries to the gastric wall. By resecting the gastropepiploical vessels the vasculature of the stomach is not impaired, since the stomach is sufficiently supplied via the Right and Left Gastric arteries and the Short Gastric artery from the Splenic artery. During the dissection of the Gastrosplenic artery, which connects the large curvature of the stomach with the spleen and along which runs the Left Gastroomental artery, one should pay particular attention to avoid injuries of the pancreatic capsule and the pancreatic tail.

Resection of the Lesser Omentum

This is not part of the routine staging but may be necessary in cases of tumour infiltration along the small curvature of the stomach/omental bursa. The resection of the lesser omentum can occur either by resecting or preserving the vessels along the small curvature, depending on the extent of the disease. Even if both the gastric and gastroepiploic vessels need to be resected the stomach still has sufficient supply from the Short Gastric artery; which however needs to be preserved otherwise there will be ischemic damage to the stomach. If a splenectomy is additionally performed then at least one of the other two ways of vascular supply (gastroepiploic vessels vs gastric vessels) need to be preserved.

The resection of the lesser omentum is not part of the staging and should occur only if there is tumor involvement. In this case only the cancerous part should be removed paying attention to the preserve the vessels in the upper rand of the pancreas, the liver and the stomach.

Abdominal Closure at Longitudinal and Horizontal Abdominal Incisions

108

Markus C. Fleisch and Philip M. Hepp

Introduction

Most surgical procedures in gynecology including most hysterectomies are nowadays performed using minimally invasive techniques. One of the major advantages of the laparoscopic approach is the use of smaller incision avoiding major incision-related complications. These include minor or major wound infections, incisional hernias or abdominal bursts, cosmetically undesirable hypertrophic scarring or nerve transection or entrapment.

However, in some cases a longitudinal ("midline") or horizontal ("Pfannenstiel-") incision might still be necessary. The utilization of a conventional access by laparotomy can be owed to a lack of surgeons experience with laparoscopic techniques, to technical reasons (e.g. size of the uterus/specimen to be removed) or to oncologic concerns.

Open surgery raises the question of the optimal way of abdominal closure. In general, interrupted or continuous sutures, using various commercially available braided or monofilament suture material, which might be antibacterially coated or not, layer by layer or as a mass closure are at hand (Table 108.1). The ideal way of closure should provide reliable mechanical stability of the abdominal wall to prevent incisional hernia or abdominal bursts, a desirable cosmetic result and should be time saving and cost effective.

Potential Wound Complications

There are various potential wound related complications which might occur early or late during postoperative course [1]. The most frequent type of wound failure is a superficial brake down. Superficial separation is frequently preceded by a hematoma or seroma with or without bacterial infection. This should be distinguished from (partial) fascial dehiscence or complete fascial brake down. The most severe form of wound brake down is a burst abdomen with abdominal contents protruding through the fascial and skin defect. This severe complication is still afflicted with a significant morbidity and mortality. If skin stays intact fascial defects may cause symptomatic or asymptomatic hernias.

It is believed that transverse incisions have a lower fascial dehiscence rate than midline, however, some speculate that this is not true when cases are controlled for infection, as postoperative wound infection appears to foster fascial dehiscence [2, 3].

Wound infections are the most frequent type of nosocomial infection in surgical patients. Therefore one must employ medicinal as well as surgical means in order to reduce their incidence. As for prevention by application of antibiotics timing seems to play a pivotal role. In a study comprising 2874 patients undergoing surgery it could be demonstrated that Infection rates are the lowest if prophylactic antibiosis is given up to 2 h before incision. Any other timing increases the odds for wound infection (Table 108.2) [4].

Table 108.1 Technical principles and materials for (fascial) closure

Surgical technique	Suture material
Interrupted vs. continuous	Braided vs. monofilament
Layered vs. mass closure	Antibacterially coated vs. not
	Rapidly vs. delayed vs. non-absorbable

Table 108.2 Relation of timing between antibiotic prophylaxis and wound infection [4]

Time of administration	% of infection	Odds ratio (95 % CI)
24 till 2 h before incision	3.8	4.3 (1.8–10.4)
Less than 2 h before incision	0.6	
Within 3 h after incision	1.4	2.1 (0.6–7.4)
3 up to 24 h after incision	3.3	5.8 (2.4–13.8)

It is controversial which antibiotic agent to use as resistance patterns and predominant microbiotic strains vary from country to country and even from region to region. In general the antibiotic of choice should cover skin flora like streptococci and staphylococci. Cefazolin is the antibiotic agent most widely used for infection prophylaxis in the setting of abdominal incisions. Beside its efficacy against skin germs it is also inexpensive and has a favorable side-effect profile except for rare allergic reactions. In uncomplicated hysterectomy the use of anaerobic bacteria targeting agents like metronidazole seems dispensable.

Good surgical technique during closure can also add to reduced wound complications. In general measures for reduction of "dead" tissue and prevention of fluid accumulation are advisable. Furthermore obese patients seem to benefit from closure of subcutaneous dead space by subcutaneous suture as explained further below [5].

Considerations When Choosing Closure Technique

Peritoneum

Closure of the peritoneum does not contribute to the strength of closure. Furthermore peritoneum is capable of defect closure by growth from the wound rims within 72 h after incision. In review of the evidence at hand for longitudinal as well as transversal incision for various indications there is no advantage in performing a peritoneal closure [6]. In addition convincing evidence exists from the obstetric setting, that closure of peritoneum by suture has detrimental effects in terms of adhesion formation and postoperative fever. The Cochrane analysis thereto, "Closure versus non-closure of the peritoneum at caesarean section", concludes that "There is at present no evidence to justify the time taken and cost of peritoneal closure" [7].

Fascia

Closure of the fascia is the crucial point when it comes to abdominal closure and yet daily practice shows a variety of different approaches mostly driven by personal experience. However there is a growing body of evidence about techniques best suited to reduce the impressingly high reported complication rates especially incisional hernias. Pfannenstiel laparotomy obviously has a low incisional hernia rate ranging between 0 and 2.1 % [8]. Evidence regarding best way of fascial closure for midline incisions is somewhat contradictory and many of the studies published so far suffer from bias. Diener et al. published a remarkable metaanalysis reporting on 7711 patients with abdominal incision (6752 midline). They saw a significantly higher incidence of incisional hernia in the interrupted compared with continuous closure group (12.6 versus 8.4 %) regardless of the type of suture material used [9].

Table 108.3 Comparison of interrupted vs. continuous slowly absorbable sutures for closure of midline abdominal incisions

Method	Interrupted	Continuous with elasticity	Continuous without elasticity
Hernias after 1 year	15.9 %	8.4 %	12.5 %
Wound infection	12.7 %	19.4 %	16.3 %
Burst abdomen	2.0 %	3.0 %	4.0 %
Mortality	7.9 %	5.5 %	7.9 %
Time for closure[a]	17.5 min	14.5 min	12.9 min

[a]Sig; according to [10]

Recently a multicenter trial investigated the optimal way of fascial closure randomizing 625 patients undergoing non-emergency surgery via midline incision [10]. Primary endpoint was the frequency of incisional hernias measured clinically and verified by ultrasound 1 year after the scheduled surgery. Other complications and safety were secondary endpoints. Surgeons were trained in standardized abdominal closure procedure and patients were randomized in three treatment arms according to the way of fascial closure: (a) an "interrupted suture" group using braided absorbable material, and two "continuous suture" groups with slowly absorbable monofilament material (b) one with longitudinal elasticity and (c) one without. As a surprising result the overall incisional hernia rate was 12 % and therefore higher than expected despite a standardized training protocol. Comparison of the three arms revealed no significant differences regarding hernia, burst abdomen wound infection rate or other investigated complications between treatment groups. Table 108.3 gives an overview about the study results [10]. These results were confirmed in a prospective study where 191 patients undergoing midline laparotomy for gynecologic cancers were randomized in three different arms regarding abdominal closure [11]. With the primary endpoint occurrence of incisional hernia and the secondary endpoint infection and wound dehiscence neither running nor interrupted suturing nor different suturing materials showed a significant benefit [11].

Regarding the stiches size and intervals to be used with continuous sutures there is consistent proof, that a "suture length" to "wound length" ratio (SL:WL) of >=4:1 has a significantly smaller risk of hernia formation compared with <4:1 (Fig. 108.1) [12]. Based on that work, there is data indicating a detrimental effect of very high SL:WL in obese patients. This statement has been challenged by Millbourn et al. [13]. Their data showed decreasing rates of incisional hernias with increasing SL:WL even for exceptional high SL:WL up to 16:1. In contrast to antecedent studies they

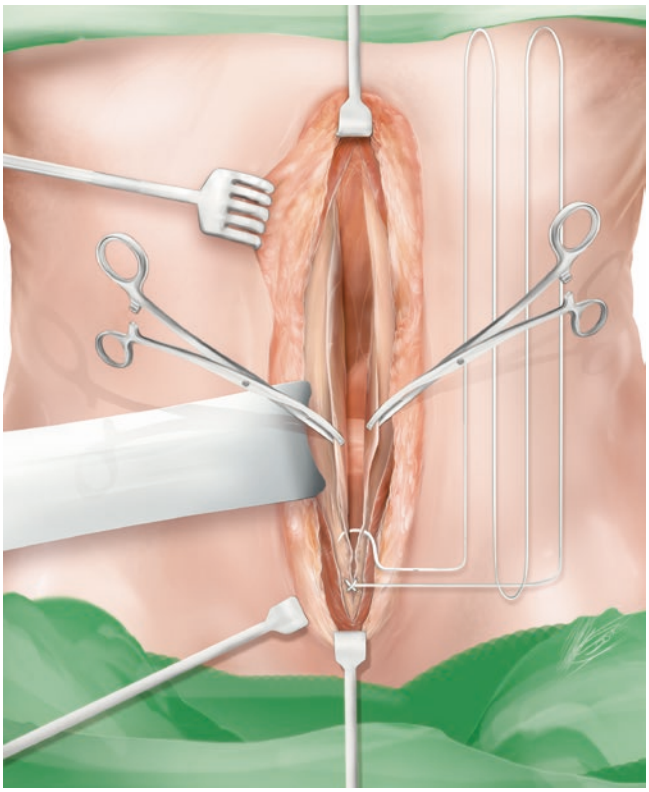

Fig. 108.1 Closure of the abdominal wall in consideration of wound-to-thread ratio

also controlled for stitch interval as well as stich length (meaning the size of the bite of fascia taken by every single stich), therefore preventing an increase in SL:WL mere by bigger bites containing more soft subcutaneous, fatty tissue which is prone to compression effects than by shortened intervals. With this approach they failed to show higher complication rates in obese patients using high and very high SL:WL [13]. This is in line with results from a pig study examining the effect of small interval /small bites (0.5/0.5 cm) stiches vs large interval/large bites stiches (1/1 cm) [13, 14].

In summary there is a growing body of evidence supporting the use of continuous, slowly absorbable monofilament material with small bites (0.5–1 cm) and intervals (0.5–1 cm).

Subcutaneous Tissue

Although application of subcutaneous sutures is a routine practice in many institutions there is little evidence about it. A Cochrane review reported on 815 patients out of six trials. All of these trials were prone to bias. In the metaanalysis there were no significant advantages or disadvantages by the application of subcutaneous sutures. Therefore no change of practice can be advised based on this data [15]. Nevertheless there is evidence that obese patients undergoing hysterectomy may profit from subcutaneous closure. One prospective study found less wound complications after subcutaneous closure in patients with more than 2.5 cm subcutaneous tissue than without closure [5].

Skin

Several options exist for skin closure. Beside the mere medical aspect of wound closure it is pivotal for a satisfying cosmetic result of the procedure. In general transverse incisions heal well due to the lack of skin tension. Skin closure may be performed with steel staples, subcuticular suture, subcuticular absorbable staples, surgical tape, or wound adhesive glue.

Staples provide a very fast way of skin closure which is also is the main advantage. In contrast to continuous sutures they also allow for opening of small portions of the wound, for example in order to drain a seroma. Nevertheless their cosmetic result seems inferior compared to all other alternatives available due to the traumatic penetration of skin [16], and there is also more wound pain [17]. In addition the steel staples need to be removed in the course of healing. In contrast to that self-resolving thread can be used in subcuticular sutures. In addition it is less costly and more comfortable to the patient [16]. Subcuticular absorbable staples on the other hand seem to combine the advantages of staples and subcuticular sutures since they can be applied in a fast manner without the staples typically appearance of the skin. Alternatively adhesive tapes or tissue glue may be employed.

Kolt performed a literature review to compare skin closure with adhesive tapes, subcuticular suturing and the combination of both [18]. Taped closure alone has advantages of lower wound infection rates and greater wound tensile strength, but disadvantages of epidermal reaction, skin edge inversion, doubtful safety and time required for meticulous surgical technique. The use of the continuous absorbable subcuticular suture allows accurate skin edge approximation, which increases the safety margin. The combination closure has a slightly superior cosmetic result to sutureless techniques but no study has been performed so far comparing the results of combined subcuticular suture and tape vs. tape or subcuticular suture alone [18].

Tissue glue may be time saving and have wound infection rates and cosmetic results that are equivalent to subcuticular sutures. However tissue glue may be associated with a slightly higher rate of wound dehiscence than observed with other techniques [19].

Drainages

The placement of prophylactic drains remains controversial. Possible complications comprise hernia, infection and bleeding. Therefore thorough evaluation of possible advantages of

drain placement needs to be practiced. Usually intraabdominal drains have no added benefit for patients undergoing hysterectomy for benign conditions. In radical hysterectomy with or without lymph node sampling on the other hand drainages could be of added value to control for postoperative bleeding and drainage of lymphatic fluids and therefore preventing formation of lymphocele [20]. Recently a large systematic review and metaanalysis has been published investigating the effect of a subcutaneous vs. no drainage in 52 studies with a total of 6930 operations [21]. Placement of a prophylactic subcutaneous drainage offered a statistically significant advantage only for (a) prevention of hematomas in breast biopsy procedures and (b) prevention of seromas in axillary node dissections. In all other procedures studied, drainage did not offer any advantage.

Dressings

Except for tissue glue a sterile dressing is mandatory after wound closure to avoid bacterial colonisation of the wound in the first 24–48 h and absorption of wound liquids. Traditionally dry sterile compresses or plasters are used for wound coverage. Nevertheless it can be reasonable to use semi occlusive dressings since a moist environment seems to foster wound healing [22].

Abdominal Hysterectomy: Postoperative Care

109

Erich Franz Solomayer, Julia Caroline Radosa, Ingolf Juhasz-Böss, and Russalina Mavrova

Postoperative Care

Optimal postoperative care is an important step of surgical treatment, especially after open surgery as in case of abdominal hysterectomy, which is associated with various postoperative complications; for example more postoperative infections; a higher rate of incisional hernia, a higher rate of thromboembolic complications and higher blood loss and a three times higher morbidity and mortality rate compared to vaginal or laparoscopic hysterectomy [1, 2].

Routine postoperative care includes monitoring of a patient's hemodynamic and fluid status, pain control and resumption of normal diet and activity. A standardized management is recommended to minimize postoperative complications and avoid a prolonged hospitalization of the patient. Table 109.1 show an overview of the postoperative care recommendations, which are explained in detail below.

Postoperative Monitoring After general anesthesia a monitoring of hemodynamic and fluid status is recommended during the first three to four postoperative hours at an intermediate care station when available.

Blood check and postoperative bleeding At least one postoperative hemoglobin check should be performed after 12–24 h depending on the intraoperative blood loss and the patient's condition. Detailed laboratory blood tests are optional and depend on the patient's symptoms. In case of a postoperative hemoglobin drop <10 g/dl (normal hemoglobin levels for wome: 12–16 g/dl) and an iron deficiency anemia patients can be treated with iron replacement products orally or intravenously. In case of an excessive blood loss with hemoglobin <8 g/dl or symptoms of dizziness blood transfusion should be considered. Furthermore the bleeding source should be identified by checking the amount and texture of the fluid in the drainages and using intravaginal and abdominal ultrasound to exclude an abdominal hematoma. If there is a reasonable suspicion of a postoperative bleeding with excessive blood loss a laparoscopy or re-laparotomy should be also taken into account.

Wound management Wounds bandages should be renewed daily and an inspection of the wound should be performed by the surgeon. If signs of a wound infection (as redness, hyperthermia, swelling and pain) are observed, a microbiological wound swab should be performed. The swab should be taken from the bottom of the wound or abscess and not superficially

Table 109.1 Recommendations for postoperative care management

Monitoring of the hemodynamic and fluid status during the first 3 to 4 postoperative hours at an intermediate care station when available
At least one postoperative hemoglobin check after 12–24 h depending on the intraoperative blood loss
Detailed laboratory blood tests are optional
Inspection of the wounds and wounds bandages should be renewed daily
A standardized pain control regime helps in the daily routine
Obstipation prophylaxis and antiemetics are optional
Removing of the bladder catheter during the first 24 h
Removing of drainages after 24–48 h depending on the amount of fluid flowing off
Early feeding and no special diet
Thromboembolic prophylaxis with low-molecular-weight heparin under frequent control of the thrombocytes
Fast mobilization
Gynecologic examination, transvaginal ultrasound and ultrasound of the kidneys before discharge
Discharge instructions (avoiding heavy lifting (> 5 kg), exercises and vaginal intercourse for 6–8 weeks)
follow-up visit 2 weeks after surgery
Removing of skin stitches or staples 10–14 days after surgery

from the surface of the dermis where microbes occupying the dermis are found physiologically. A calculated antibiotic therapy should be started for example with a combination of a cephalosporin (e.g. Cefuroxim 3 × 1,5 g i.v.) and metronidazole (e.g. Clont 2 × 500 mg i.v.). After microbiological analysis the antibiotic therapy can be adjusted according to the pathogenic agent and its resistances. The therapy should be given for at least 5–7 days. Infections are distinguished in superficial infections of the dermis and subcutaneous abscesses. In case of subcutaneous abscess an incision of the abscess capsule is necessary.

Prevention of postoperative infections A calculated postoperative treatment with antibiotics is not recommended in routine cases. In case of clinical suspicion of a postoperative infection (fever, shivering) blood samples should be drawn and inflammatory markers should be assessed. A calculated antibiotic therapy should be started and inflammatory markers should be checked regularly. Furthermore an infected abdominal hematoma should be excluded using intravaginal ultrasound. A bowel injury can be excluded by performing a computer tomography with application of oral contrast agent. In case of persistent suspicion of a bowel injury or signs of peritonitis a laparoscopy or re-laparotomy should be performed.

Postoperative pain management Management of postoperative pain decreases suffering and leads to earlier mobilization. This leads to a shorter hospital stay, reduced hospital costs and increases patients` satisfaction. Pain control regimes can be used standardized. Although it is postulated to tailor the medication to the needs of the individual patient, a standardized pain control regime helps in the daily routine and can be easily adapted to the patient's needs if the standardized protocol is not adequate. A multimodal attempt is recommended, for example a combination of an opioid based drug (e.g. Oxycodone hydrochloride and Naloxone hydrochloride 10/5 mg 2 × 1 p.o. per day), Metamizole (3 × 1 g p.o. per day) and non-steroidal anti-inflammatory drugs (NSAID) (e.g. Ibuprofen 400 mg 3 × 1 p.o. per day) can be used. An obstipation prophylaxis is obligatory when opioids are prescribed. Antiemetics can be helpful in cases of nausea.

Bladder catheter and drainage management The bladder catheter can be removed during the first 24 h postoperatively to reduce the risk of an urinary tract infection. An intraoperatively placed drainage (e.g. Robinson or Penrose drainage) can be removed after 24–48 h depending on the amount of fluid measured and the fluid's texture.

Postoperative diet A special postoperative diet is not necessary after an abdominal hysterectomy, except in cases of bowel injury during the surgery. An early feeding (oral intake within 24 h) and fast mobilization stimulate the bowel and prevent stasis and postoperative paralytic ileus [3, 4, 5]. Diet protocols for patients undergoing bowel surgery depend on the localization and extent of the removed bowel and the recommendation of the surgeon. Usually it is possible to start with small amounts of oral intake of fluids within 24 h after surgery, a soup or yoghurt ca also be chosen. After return of bowel function (e.g. presence of bowel sounds or flatus) oral intake of foods can be started with mashed potatoes or white bread and be adapted to normal food depending on patient's well-being.

Intestinal paralysis and postoperative ileus The intestinal motility is often reduced after open surgery [6, 7]. This can lead to an ileus. Ileus is a blockage of the intestines caused by a lack of peristaltic (paralytic ileus) or the bowel movement is inhibited due to a mechanical blockage (mechanical ileus). In case of paralytic ileus, muscle or nerve problems disrupt the normal coordinated muscle contractions of the intestines, slowing or stopping the movement of food and fluid through the digestive system. A paralytic ileus is often caused by trauma (e.g. abdominal surgery), lack of activity, or as a side effect of certain pain medications, such as morphine. A mechanical ileus is often caused by postoperative adhesions, inflammation, tumor or volvulus (twisted colon). The most common symptoms of ileus are discomfort in the abdomen due to cramping, bloating, diarrhea, or obstipation related symptoms. Nausea and vomiting are also common symptoms. Ileus is considered a serious medical emergency and should be treated as such. If symptoms appear, further investigations should be initiated immediately. Medical anamnesis and physical examination are needed to diagnose an ileus. The presence of bowel sounds should be checked consecutively via auscultation. Furthermore a X-ray or a computer tomography using oral contrast agents can be performed to exclude a mechanical ileus. Therapeutic treatment varies according to these different types of ileus with different patho-mechanisms [8, 9]. In case of paralytic ileus a nasogastric tube can be placed and the patient should obtain drugs stimulating the intestinal motility (e.g. Neostigmine, Metoclopramide, laxatives and suppositories). In case of mechanical ileus surgical removal of the intestinal blockage should be performed. If left untreated, ileus could lead to death of tissue or cause peritonitis. This infection can be serious and potentially life-threatening.

Thromboembolic prophylaxis Thromboembolic prophylaxis with low-molecular-weight heparin (e.g. Enoxaparine 40 mg, s.c. once a day) under frequent control of the thrombocytes is fundamental. In case of a benign uterine pathology it should be continued for 5–7 days, in case of malignancy for 4–5 weeks [10]. Without thromboembolic prophylaxis

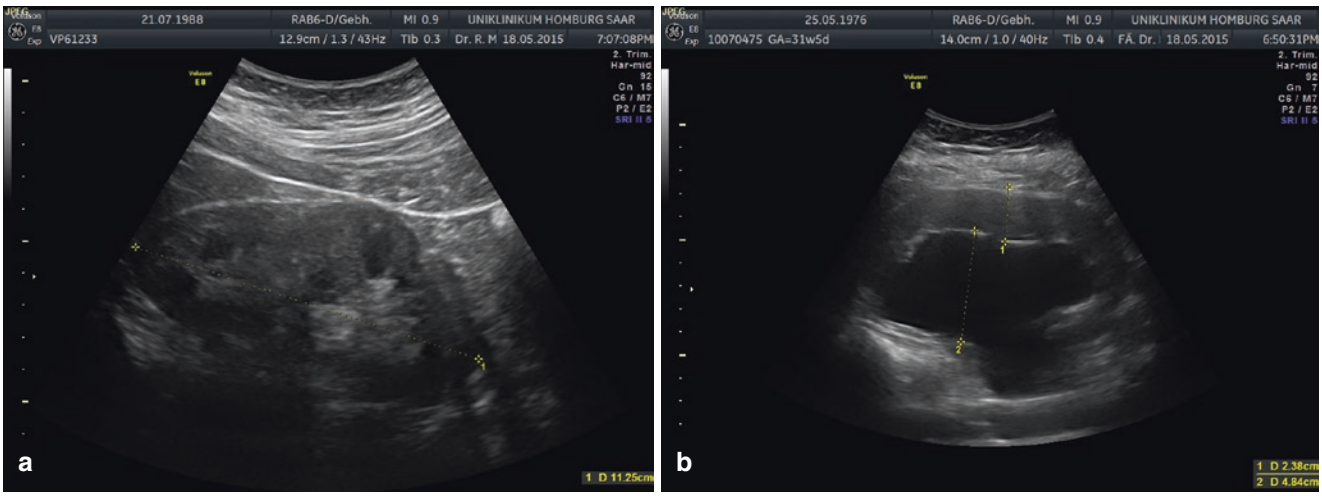

Fig. 109.1 (**a**) Ultrasound of a normal kidney, (**b**) Ultrasound of a kidney with grade III renal calyx reflux

the risk of deep vein thrombosis in patients after major general or gynecologic surgery is 15–30 %; the risk of lethal pulmonary embolism is 0.2–0.9 % [11].

Mobilization A fast mobilization is important for the postoperative outcome, a physiotherapist can be involved and help the patient with mobilization instructions.

Postoperative adhesions Postoperative adhesions have important consequences for patients, surgeons and the health system. Abdominal hysterectomy is a surgical procedure with a high risk of adhesion-related complications. Postoperative adhesions have been observed in up to 94 % of patients after laparotomy [12]. Ellis et al. reported of 34.6 % patients who underwent open abdominal or pelvic surgery were readmitted a median 2.1 times over 10 years for a disorder directly or possibly related to adhesions [13]. Pelvic adhesions can be the result of inflammation or surgical trauma. Several measures to prevent adhesion, for example placing of barrier agents between the pelvic structures [14, 15], have been proposed, but up to now none has been successful enough to find widespread acceptance. Laparoscopic lysis of adhesions is proposed for patients who have failed conservative measures [16].

Hospital stay The length of hospital stay after abdominal hysterectomy depends on the patient's mobility and is in average 3–5 days.

Examinations All patients should undergo gynecologic examination, transvaginal ultrasound and ultrasound of the kidneys before being discharged to exclude a vaginal cuff dehiscence, a renal calyx reflux and a postoperative abdominal hematoma. Figure 109.1a shows an example of a normal kidney, and Fig. 109.1b shows an example of a grade III renal calyx reflux which is pathologic. A vaginal cuff dehiscence is a rare complication of total hysterectomy (0.24–0.31 %) [17, 18]. Possible sites of origin can be poor wound healing, excessive intra-abdominal pressure at the vaginal incision site or pelvic floor defects. Prompt surgical and medical intervention is required to avoid bowel evisceration and sequelae including peritonitis, bowel injury, necrosis and sepsis. It is important to know that this is a complication which occurs mostly few weeks after surgery. Patients should be advised to avoid vaginal intercourse for 6–8 weeks. An iatrogenic ureter injury is generally asymptomatic and can lead to a renal calyx reflux after weeks, which is associated with consistent pain. An ultrasound of the kidney or an urography may help to identify this complication, prevent renal damage and is also important forensically. A postoperative abdominal hematoma or pelvic fluid accumulation can also occur as postoperative complications. A small hematoma or a small amount of pelvic fluid accumulation do not need further surgical intervention, but should be observed via sonography. In case of distinct hematoma a laparoscopy or re-laparotomy should be considered.

Discharge instructions Patients should avoid heavy lifting (> 5 kg) and exercises for 6–8 weeks to minimize traction on the fascia and prevent an abdominal hernia. Vaginal intercourse should be avoided for 6–8 weeks to prevent vaginal cuff infections and allow the vaginal cuff to heal completely.

In 2011, a panel of 12 experts used the modified Delphi method and literature review to develop multidisciplinary recommendations for graded resumption of activity after laparoscopic, vaginal and abdominal hysterectomies and adnexal surgery (Vonk Noordegraaf et al. [19]). The panel considered 65 activities and judged 38 to be relevant for convalescence

recommendations. The recommendations were then judged as feasible by 63 physicians. Examples of recommendations after vaginal hysterectomy include avoiding lifting or carrying over 10 kg, bicycle riding and vacuum cleaning for 3 weeks, and avoiding lifting or carrying over 15 kg and "standing and walking during the entire working day" for 4 weeks.

Restrictions for the same sets of activities were changed to 3–4 weeks and 6 weeks, respectively, after abdominal hysterectomy, and to 2–3 weeks, respectively, after laparoscopic supracervical hysterectomy. The Dutch authors point out that the optimum lengths of inability to work after laparoscopic, vaginal and abdominal hysterectomy are 4, 4 and 6 weeks, respectively for sedentary work and 10, 10 and 12 weeks, respectively, for physically demanding jobs.

Follow-up An ambulant follow-up visit is recommended 2 weeks after surgery in gynecologic out-patient practice. The follow-up visit should include an evaluation for potential complications (e.g. wound healing problems, postoperative abdominal hematoma, vaginal cuff dehiscence or a renal calyx reflux) and an examination of the abdomen, wound and vaginal cuff in case of a total hysterectomy. Skin stitches or staples should be removed 10–14 days after surgery. As the patients are often discharged before the arrival of histopathological results, the gynecologist should give the patient a review of the histo-pathologic results. In case of a malignant pathology further treatment should be initiated.

Long-term outcome Hysterectomy can be associated with an earlier onset of menopause [20, 21, 22]. Patients should be informed about the risk of osteoporosis and the options of prevention such as vitamin D and calcium substitution.

On the other hand, there are reports of improved overall sexual functioning after hysterectomy [23, 24]. These effects can be explained by postoperative symptom relief.

Several studies report an association of urinary incontinence following hysterectomy irrespective of the surgical technique. Due to this fact the risk for subsequent uro-gynecological surgery is increased, a fact which should be mentioned in the preoperative counselling of the patients [25, 26].

Conflict of Interest Statement The authors organize laparoscopic training workshops and take part in presentations supported by Storz, Erbe, Johnson & Johnson and Takeda (category A).

Part XI

Vaginal Hysterectomy and Extended Procedures for Benign and Malignant Indications

Indications and Contraindications of Vaginal Hysterectomy

110

Shalini Rajaram and Bindiya Gupta

Introduction

Hysterectomy remains the most common gynaecological surgery performed in women worldwide with rates ranging from 180/100,000 woman years to 540/100,000 woman years in the western world [1–3]. The choice of hysterectomy as a therapeutic procedure depends on the patient's age and most importantly the indication. Medical therapy or conservative surgery is possible in most cases of abnormal uterine bleeding due to non -structural causes. Structural abnormalities like fibroids, polyps and adenomyosis may respond to conservative therapy but hysterectomy may be required in many women. The most common benign indications for hysterectomy are uterine fibroids (40–55 %), abnormal uterine bleeding (25 %), endometriosis (17.7 %) and uterine prolapse (15 %) [1, 3, 4].

Safety and cost effectiveness are the two important determinants while choosing the route of hysterectomy. In a recent analysis of trends in routes of hysterectomy, rates of abdominal hysterectomy have reduced while vaginal hysterectomy rates have increased from 15/100,000 to 75/100,000 woman years and the rates of laparoscopic hysterectomy have increased from 10/100,000 woman years to 36/100,000 woman years [1]. There has also been an increase in the rates of robotic hysterectomy for benign indications from 0.5 to 9.5 % in USA [5].

Evidence states that vaginal hysterectomy should be the first choice of surgical approach for most benign indications for hysterectomy [6, 7]. There are well documented health and economic benefits such as reduced morbidity, fewer postoperative complications like unspecified infections and febrile episodes, shorter duration of hospital stay and shorter recovery time as compared to abdominal hysterectomy [8]. Vaginal hysterectomy also has a shorter operating time when compared to laparoscopic hysterectomy [9]. The American College of Obstetricians and Gynecologists "has identified the preferred method for hysterectomies to be vaginal whenever feasible" [8, 10]. A leading insurance company United Healthcare quoted the college as stating that "evidence demonstrates that in general, vaginal hysterectomy is associated with better outcomes and fewer complications than laparoscopic or abdominal hysterectomies. United Healthcare will now require prior authorization for all hysterectomies except those performed vaginally on an outpatient basis beginning April 2015 [11]. In April 2014, the FDA recommended that surgeons no longer use laparoscopic power morcellators for hysterectomy or myomectomy in most women with uterine fibroids because of the risk of disseminating occult cancer [12]. FDA estimated that every 1 in 350 women undergoing power morcellation to remove fibroids has an unsuspected uterine sarcoma such as leiomyosarcoma. Therefore it becomes imperative that gynaecologists are trained to perform vaginal hysterectomies for most benign conditions and understand indications and contraindications for the procedure.

Factors to Be Considered While Choosing Vaginal Hysterectomy

Uterine Size, Mobility and Descent

According to ACOG, vaginal hysterectomy is indicated in upto 12 weeks size (< 280 gm) mobile uterus [13]. Preoperative measurement of uterine size in grams can be determined with the radiologic measurements of uterus (length, width, anteroposterior diameter at fundus × 0.52) (Fig. 110.1) [14].

However, reduction techniques such as coring, corporeal bisection and wedge morcellation facilitate the removal of bigger size uteri upto 20 weeks vaginally (Fig. 110.2) [15].

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_110

More than the size, mobility of uterus, degree of descent, position of the uterus and the amount of lateral bulk are important. Mobility of the uterus should be assessed antero-posteriorly and laterally to assess parauterine space. Descent of the uterus should be reassessed under anaesthesia using the "traction test" (Fig. 110.3). Some surgeons feel nulliparity to be a deterrent for vaginal hysterectomy, but it must be understood that under anesthesia and after transection of the utero-sacral ligaments, the uterus descends, facilitating completion of the procedure. Thus nulliparity alone is not a contraindication to surgery. Success of vaginal hysterectomy in nulliparous females ranges from 92–97 % [16, 17].

Vaginal Parameters

A vagina narrower than two fingerbreadths, especially at apex and a narrow pubic arch are not contraindications to vaginal hysterectomy but may increase the level of difficulty of the procedure [13]. Vaginal narrowing in postmenopausal women especially at the vault and a cervix flushed with the vagina must be kept in mind while deciding on the route of surgery for this group of women as surgery may prove difficult.

Extrauterine Disease and Previous Abdomino-Pelvic Surgery

In case of extrauterine involvement on preoperative workup, laparoscopic evaluation should be done before proceeding to vaginal hysterectomy. In patients with previous surgery, it is essential to ascertain the nature of surgery and postoperative complications if any [13]. Various methods like sharp dissection have been advocated for safe dissection of vesico-uterine space and bladder mobilization in those with previous

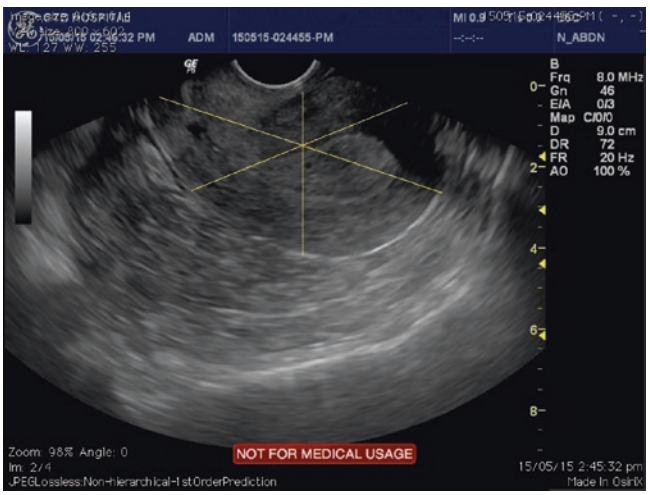

Fig. 110.1 Estimation of uterine volume on transvaginal ultrasound

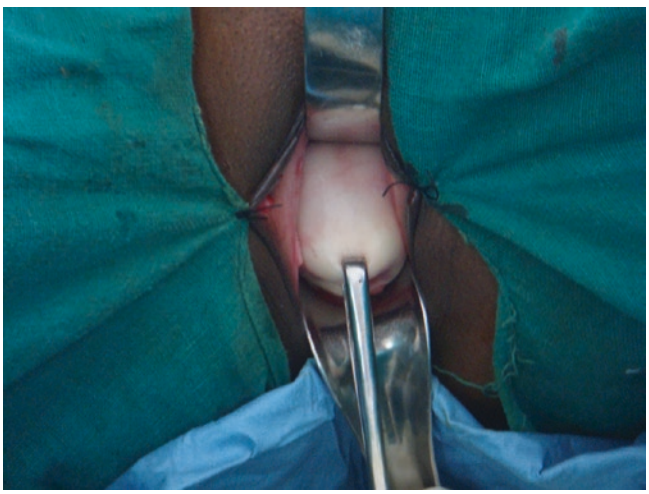

Fig. 110.3 Traction test

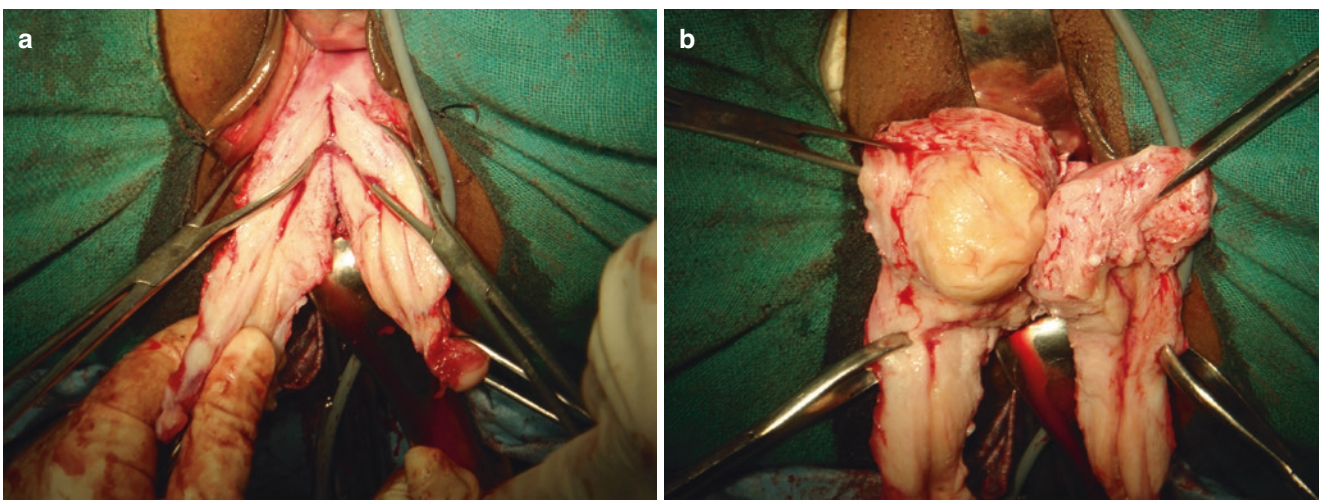

Fig. 110.2 Uterine volume reduction techniques. (**a**) Bisection; (**b**) Myomectomy

caesarean sections. The lateral window approach as described by Sheth SS is a good technique in cases of previous caesarean [18]. In case of extensive adhesions or endometriosis, laparoscopic ablation of implants and adhesiolysis may be done before vaginal hysterectomy Thus laparoscopy is complementary to vaginal surgery especially in endometriosis and previous surgeries. In endometriosis, division of infundibulo-pelvic ligaments after visualizing and isolating the ureters is probably the safest technique to adopt before proceeding with the vaginal approach.

Need for Concurrent Procedures

In a few cases mobile ovarian cysts such as simple cysts and dermoids can be removed vaginally during a vaginal hysterectomy. Most ovaries are readily accessible at the time of vaginal hysterectomy and bilateral salpingo-oophorectomy can be safely performed, provided the ovaries can be brought down beyond the ischial spines by applying moderate traction. This is assessed after division of the round ligaments laterally and gaining access to the avascular window in the broad ligament (Fig. 110.4). In case descent is inadequate, laparoscopic division of infundibular pelvic ligaments can be done. Grading of ovarian descent is done according to the position of the ovary in relation to the long axis of vagina after stretching the infundibulopelvic ligament (Table 110.1) [19]. Fallopian tubes are readily accessible at the time of vaginal hysterectomy and prophylactic salpingectomy is recommended for prevention of high grade serous ovarian tumors [20].

Surgeon's Expertise

The surgeon's list of indications not only reveals his attitude towards the operation but also the confidence or lack of it. The learning curve consists of a step ladder pattern of learning. We have tentatively divided the indications of non descent vaginal hysterectomy into four levels of learning according to the feasibility of the procedure, positive attitude, experience and confidence of the surgeon and patient consent. The levels are as follows:

Level 1: The uterine size ranges from normal size to 10 weeks. The surgeon should do at least 5–10 cases to be able to remove this size of uterus.

Level 2: The uterine size is upto 12–14 weeks' with or without nulliparity/ obesity. The surgeon usually becomes accomplished after carrying out 5–10 procedures. This size may be accomplished by bisection of the uterus or enucleation or slicing of the bulky myometrium to facilitate access to the lateral uterine structures.

Level 3: The uterine size is over 14–16 weeks' and/or previous abdominal surgeries like cesarean, myomectomy, hysterotomy or surgery on tubes and ovary. In this

Table 110.1 Grading of ovarian descent [19] (With permission)

Grade 0	No descent. Infundibulopelvic ligament has little or no stretchability, ovaries are positioned at lateral pelvic wall or above the ischial spines and cannot be pulled into the long axis of vagina with traction
Grade 1	The infundibulopelvic ligament is stretchable, and the ovaries can be brought into the long axis of vagina, with traction, halfway between the ischial spines and midvagina
Grade 2	Ovaries can be brought into the long axis of vagina, with traction between the midportion of the vagina and the hymenal ring
Grade III	The infundibulopelvic ligament is highly stretchable, the ovaries can be brought into the long axis of vagina with traction, past the hymenal ring

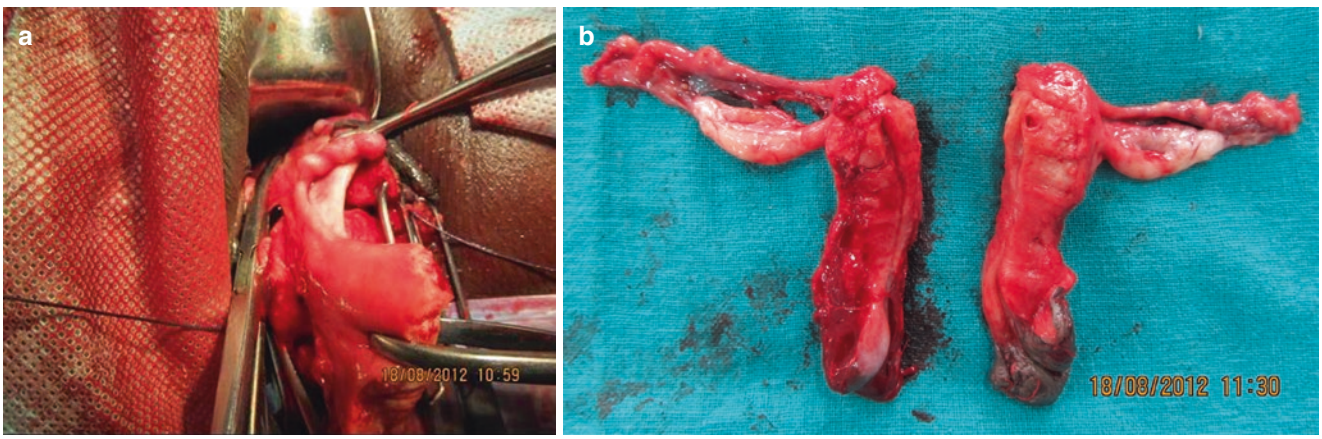

Fig. 110.4 Vaginal salpingo-oophorectomy. (**a**) Technique: clamping the infundibulopelvic ligament through a lateral window in the round ligament. (**b**) Vaginal hysterectomy with salpingo-oophorectomy specimen

category the surgeon may expect to convert to a laparoscopic or abdominal route.

Level 4: The uterine size can be any (upper limit cannot be defined) and/or previous 2–3 cesareans, vaginal surgeries like Fothergill's, sling operation, anterior or posterior colporrhaphy, with or without concomitant oophorectomy.

Patient Preference and Hospital Infrastructure

These are also important aspects to be considered in selecting the route of hysterectomy. In developing countries with a long waiting list for surgeries and insufficient laparoscopic facilities, vaginal hysterectomy is probably better in terms of cost, hospital stay, ease of surgery and safety. ACOG also re-iterates that vaginal hysterectomy is the preferred method of hysterectomy [8].

Indications of Vaginal Hysterectomy

Vaginal hysterectomy should be the technique of choice in routine practice for the management of women with non-malignant pelvic disease involving the uterus. Even early stage cervical and endometrial malignancy is not a contra-indication to vaginal hysterectomy [21, 22]. The indications should however be selected carefully on a case-to-case basis. The vaginal route is particularly useful as a good cuff of vagina is best removed vaginally. Trans-abdominal approach should be only left for those cases where vaginal hysterectomy is either contraindicated, in cases of advanced malignancy or when it may be technically impossible to perform a hysterectomy vaginally. As surgical skill improves, the indications of hysterectomy by vaginal route increase. Vaginal hysterectomy can be easily done under regional anesthesia which is very useful in women with medical illness, contraindications to general anesthesia, morbid obesity and older patients [23]. With this background knowledge and several studies supporting the feasibility of choosing vaginal route for all indications of hysterectomy unless absolutely contraindicated, the indications are as follows.

Abnormal Uterine Bleeding (AUB)

It accounts for 30–50 % of all the indications. Indications for hysterectomy for AUB have decreased in the recent past because a number of safe, easy, effective conservative methods such as hormone therapy, intrauterine device (Mirena), thermal balloon or radiofrequency ablation are now available [24]. However, when hysterectomy is required due to failure of conservative management, vaginal route is the choice because the uterus is usually < 10 weeks' size, mobile, gross adnexal pathology is rare and oophorectomy is not routinely warranted as most women are in the reproductive age group.

Adenomyosis

Adenomyosis is usually less responsive to conservative treatment and is a common indication for hysterectomy. Uterus is firm in consistency, uniformly enlarged, globular, usually not exceeding 12–14 weeks' size and volume of <300 cm^3 on ultrasound. The uterus is hard and scirrhous because of an increased fibrous component brought about by intramyometrial bleeds [25]. This will cause difficulty in debulking procedures such as coring and morcellation as the fibrous myometrium offers resistance to cutting.

Fibroid Uterus

Fibroids that cause symptoms need to be operated upon unless patient is nearing menopause with benign endometrial histopathology. Evidence advocates vaginal hysterectomy for myoma upto 12 weeks' size and uterine volume of 250–300 ml [8, 13, 26]. With experience, size can be increased and in the literature vaginal hysterectomy has been done for bigger uteri [27, 28]. In the author's experience, 18–20 weeks size uterii can be successfully removed vaginally. Apart from size, the location and accessibility of fibroids, access to pouch of Douglas, cervical descent on traction and available lateral parauterine space to free vascular pedicles are important [29]. Usually a three dimensional assessment on ultrasound should be done in cases of large uteri, and the distance of the largest fibroid from the endometrium and internal os should be determined [30]. Intramural, submucus, single fibroid present in posterior wall are dealt with ease. Fibroids increasing transverse diameter of fundus and body of uterus to more than 10 cm, anterior and distal fibroids, large degenerated fibroids, or those present in broad ligament or in cervix making uterine artery ligation difficult are problematic [15]. Vaginal morcellation techniques (with scalpel and not power morcellators) and vaginal myomectomy can be used for debulking taking care to remove each piece vaginally without entering peritoneal cavity. Multiple small fibroids can be safely removed by lateral tunneling i.e. removal from inside the uterus unless there is a presence of an obvious external bulge [15].

In case of fibroid polyps, vaginal hysterectomy can be done after removal of the fibroid polyp. Small posterior wall cervical fibroids are amenable to vaginal hysterectomy after vaginal myomectomy. The most important aspect in cervical fibroids is to determine the ease of access to uterine vessels.

Uterine Prolapse

The major indication for vaginal hysterectomy in India is utero-vaginal prolapse. Traditionally, treatment of uterovaginal prolapse is accompanied by a concomitant hysterectomy

as most women are postmenopausal and anterior and posterior colporrhaphy can be accomplished at the same sitting. Vaginal hysterectomy can also be offered to premenopausal women beyond 40 years if there is a concomitant uterine or cervical pathology and marked cervical elongation [31]. The ease of surgery and short hospital stay are other advantages. Vaginal hysterectomy with descent is technically easy and is the initial step to learn the technique. Uterus sparing techniques like sacrohysteropexy, sacrospinous hysteropexy and uterosacral hysteropexy have been advocated in women who desire uterine preservation. However, these are reserved for younger women, there is more recurrence and is limited by lack of evidence [32, 33].

Preneoplastic Conditions

Vaginal hysterectomy with concomitant bilateral oophorectomy is ideal for complex hyperplasia with atypia of the endometrium. An attempt should be made to avoid debulking techniques. Hysterectomy can be done vaginally in cases of cervical intraepithelial neoplasia grade 3, in older women not desirous of preserving uterus, provided a detailed colposcopic examination has been done of the cervix and vagina.

Neoplasia

Cervical Malignancy

Carcinoma in situ can be managed with vaginal hysterectomy. This route has the advantage of removing a cuff of the vagina especially if disease extends onto the vagina as seen on colposcopy. For microinvasive cervical cancer (stage 1 A1) with no lymphovascular space invasion, vaginal hysterectomy with partial removal of vagina can be done post conization [34]. In a woman who has undergone conization, the bulk of the cervix which is normally available for traction is lost and dissection especially of the bladder anteriorly must be done carefully. Inadvertant cystotomy has occurred in the authors' experience at the time of bladder dissection as there is only a thin cervix on which the bladder rests.

Newer minimally invasive techniques like Laparoscopically assisted vaginal radical vaginal hysterectomy (LAVRH) and laparoscopic lymphadenectomy in combination with radical vaginal hysterectomy are gaining popularity for cervical cancer stage Ib1 and select cases of Ib2 and IIa [35].

Endometrial Cancer

Vaginal hysterectomy with laparoscopic lymphadenectomy can be done in stage 1, grade 1 & 2 well differentiated endometrioid adenocarcinoma [22]. This route is especially useful in women with impaired cardiorespiratory efforts, morbid obesity, hypertensive and diabetic woman or in those with concomitant vaginal prolapse. Vaginal hysterectomy with bilateral salpingo-oophorectomy has shown to have equivalent results to abdominal route in select cases with well differentiated or moderately differentiated carcinoma confined to endometrium [36].

Table 110.2 Indications of vaginal hysterectomy

Abnormal uterine bleeding
Fibroid uterus, adenomyosis
Cervical polyp or fibroid
Chronic pelvic pain, chronic uterine inversion
Postmenopausal bleeding, pyometra
Cervical dysplasia, microinvasive cervical cancer (Stage Ia1)
Complex hyperplasia with atypia, Stage 1a G1 & 2 well differentiated endometrial cancer
Prolapse uterus

Other Indications

Other indications include chronic pelvic pain, chronic uterine inversion and recurrent post menopausal bleeding. Vaginal route is advisable in patients with morbid obesity, medical high risk cases like poor cardiac status and impaired pulmonary function and after ventral incisional hernia repair [37, 38]. The indications have been summarized in Table 110.2.

Contraindications

Absolute contraindications of vaginal hysterectomy are as follows:

1. Uterus more than 20 weeks' size: Although ACOG recommends vaginal hysterectomy up to 12 weeks uterine size [8], but size as a limitation depends on surgical skill.
2. Very limited vaginal space: vaginal hysterectomy is difficult if vagina is narrow especially at the apex.
3. Cervix completely flushed with uterus.
4. Severely restricted uterine mobility: Uterine mobility can be a limiting factor in cases with grade 4 endometriosis, post cesarean cases, previous abdominal surgeries and pelvic inflammatory disease. These conditions have the highest rate of conversion to abdominal route [39].
5. Previous vesico-vaginal or recto-vaginal fistula repair
6. Previous rectosigmoid resection with low anastomosis
7. Genital malignancies: In high grade, clear cell and papillary serous or advanced endometrial cancer vaginal route is not recommended. Cervical cancer more than stage Ia_1 upto IIa is not an indication for radical vaginal hysterectomy.
8. Gross adnexal pathology or suspected malignancy

The relative contraindications are mainly based on surgeon's experience and expertise.

1. *Uterine size >12 weeks (>280 cc volume):* In case of a uniformly enlarged large uterus, if all the three dimensions are ≥10 cm and the angle between the lateral border of the uterus and the cervix is ≥ 90°, it is a contraindication to vaginal route [30, 40].
2. *Short cervix*: In post menopausal women the cervix is flushed with vagina. Following cervical amputation and conization, there is difficulty in holding the cervix. In these cases traction can be given with Allis tissue forceps and careful sharp dissection of the vesico-uterine pouch should be done.
3. *Broad ligament fibroid*: These are usually not amenable to vaginal removal. It is suggested that if the surgeon can reach the infundibulopelvic ligament, he can access the medially placed broad ligament fibroid [26]. This is because the lateral limit of broad ligament is restricted by bony pelvis and the medial extent is similar to the distance of ovary from uterus. Difficulty in delineating the ureter is a major drawback with the vaginal route for accessing broad ligament fibroids.
4. *Endometriosis*: The level of difficulty, as mentioned above depends on disease severity. In cases of endometrioma, vaginal aspiration can be done before attempting salpingo-oophorectomy.
5. *Benign adnexal disease*: The contents of the cyst can be aspirated before salpingo-oophorectomy. Laparoscopic removal of the adenexa can also be done followed by vaginal hysterectomy.

To conclude, vaginal hysterectomy is a gynecologist's domain and the approach of choice for benign pathology and early cervical and endometrial cancers. The indications are many and contraindications few.

Preparation for Vaginal Hysterectomy: History, Preoperative Assessment, Operative Set-up, Table, Antibiotics

111

Bindiya Gupta and Shalini Rajaram

Introduction

Optimising surgical outcome is a surgeon's priority and careful patient selection, systematic preoperative preparation and work up is the key to a good outcome, along with fine surgical skills and technique. Surgical intervention should always be the last resort and done when all other conservative methods fail. For instance in cases with abnormal uterine bleeding conservative options like levonorgesterl intrauterine system or endometrial ablation should be tried before considering surgery. The patient should be explained in detail the benefits, risks and complications associated with surgery. A thorough patient evaluation with investigations is imperative to accurate diagnosis of the underlying pathology and helps in appropriate selection of surgical procedure. The various components of preoperative care and evaluation for vaginal hysterectomy will be discussed in the chapter.

Consent

It is the most crucial component before planning any surgical procedure. The woman should have a clear understanding of the surgical procedure and its associated risks. For consent to be valid, patient must be competent to make treatment decisions on her own behalf. She should have received appropriate information to make the choice and decision must be voluntary without coercion [1]. It is usually given by adults over the age of 18 years, before the proposed procedure and before any sedation is given.

The components of an informed written consent form besides patient particulars should include specific sections for documentation i.e. the name of the procedure and brief details of the procedure like incisions, extent of surgery, expected outcome, impact on fertility, any necessary concomitant extra procedures, use of prophylactic antibiotics and thromboembolic prophylaxis. [2] The other components include intended benefits, serious and frequent risks of the procedure, implications of no treatment, type of anaesthesia and availability of alternative treatments [2].

Consent should be obtained by person capable of performing the procedures themselves or who have received specialist training in advising patients about the procedure [1]. It is usually obtained by the doctor who is the operating surgeon or by his junior associate.

Preoperative Evaluation and Planning

Once the surgical intervention is decided and the woman gives consent, a detailed surgical planning should be instituted. The goals of preoperative evaluation are to reduce surgical morbidity, minimize expensive delays and cancellations, evaluate and optimize patient's health status and fitness for surgery, detect anticipated complications and prepare to tackle them, facilitate the planning of anesthesia and perioperative care and reduce patient anxiety [3].

The components of preoperative evaluation include assessment of patient's health, evaluate factors that can influence the operative outcome, and decide the route and type of surgery best suited for the problem [4]. It includes a complete history and thorough physical examination, laboratory testing and imaging procedures as well as consultations to promote optimal outcomes.

History

The entire history must be reviewed and re-evaluated in detail before finally deciding the surgical intervention. Key components include a review of symptomatology, detailed

Table 111.1 Preoperative history taking

History
Symptomatology
Menstrual history (amount and duration of flow, cyclicity, last menstrual period)
Obstetric history
Acute or chronic medical illness, previous history of surgery
Family history
Personal history: smoking and other addictions, dietary history and socio economic status

menstrual and obstetric history, associated medical and surgical conditions and family history. An insight into personal history of smoking and other addictions, dietary history and socio economic status must be taken as it has a significant impact on post operative recovery. The key points in history taking are summarized in Table 111.1.

Examination

A systematic physical examination must be done to assess well being, anaesthesia fitness and nutritional status of the patient. A detailed preoperative gynaecologic examination is carried out keeping in mind indications and contraindications of vaginal hysterectomy.

The following points should be noted while doing a pelvic examination:

(a) Local examination of vulva and perineum should be done to exclude local pathology and infections like warts and fungal infections. Assess levator ani tone and perineal body especially in cases of uterine prolapse.
(b) Assess size and mobility of the uterus. The descent of the cervix should be assessed without traction and then by giving traction using a vulsellum (Traction test). The length of the portio vaginalis portion of the cervix should also be noted. The depth of the fornices, subpubic angle and intertuberous diameter also need assessment.
(c) Assess width of vagina, especially at the fornix and it should accommodate at least two fingers. Mobility of vagina is evaluated by applying upward and downward traction on cervix with vulsellum and looking for any puckering of vaginal mucosa which may indicate underlying adhesions. Displacing the bladder sulcus with a moistened sponge on a holder also helps in assessing mobility of vaginal mucosa.
(d) A cervix that is flushed with the vagina is a contraindication to vaginal hysterectomy
(e) In case of fibroids the number, location, position and lateral bulk of the uterus is assessed.
(f) The uterine free pelvic space around the uterus is palpated and assessed.

Table 111.2 Perooperative score under anesthesia for vaginal hysterectomy [7]

Score	0	1	2
Size of uterus	<8 weeks	8–10 weeks	>10 weeks
Mobility of uterus	Good	Fair	Poor
Inter tuberous distance	>4 knuckles	4 Knuckles	<4 Knuckles
Sub pubic arch	>90°	90°	<90°
Digital exam of vagina	3 finger loose	3 finger tight	2 finger tight
Mobility of vaginal mucosa	Good	Fair	Poor
Fornix depth	>1 finger crease	1 finger crease	<1 finger crease
Descent with volsellum	>1°	1°	<1°
Surgeons experience	>10 years	5–10 years	<5 years
History of previous surgery	Nil	One	>one

Score classification: very easy (0–5), easy (6–10), difficult (11–15), and very difficult (>16)

(g) In cases of previous surgery, non descent of the cervix below the ischial spine on applying traction is a contraindication for vaginal surgery.
(h) Seth's cervicofundal sign: When the cervix is not visualised on introducing a large full length speculum and only visualised when anterior vaginal wall retractor is used along with a pulled up posterior wall indicates adhesions between the uterus, cervix and lower abdominal wall. A positive sign is a contraindication to vaginal hysterectomy [5, 6].

The preoperative score for non descent vaginal hysterectomy can be calculated as shown in Table 111.2 [7]. The score ranges from 0 to 20 and higher the score, the difficulty level of surgery increases. It is classified as very easy (0–5), easy (6–10), difficult (11–15), and very difficult (>16).

Investigations (specific)

Examination can be supplemented by detailed assessment of the uterus by ultrasound. Other imaging modalities like computed tomography (CT)/ Magnetic resonance imaging (MRI) are rarely required. An assessment of uterine volume, size, location and size of fibroids, endometrial thickness and adnexal pathology are a few parameters to be noted. Endometrial sampling should be done in all women with abnormal uterine bleeding or abnormal endometrial imaging using a Piplle or Vabra aspirator, or a Karman's cannula. Screening for cervical cancer should be done in all women.

Anesthesia Evaluation and Preoperative Investigations

The anaesthetic risk assessment of patient's preoperative physical status for all surgeries is established by the American Society of Anesthesiologists. It is a subjective assessment of patient's overall health and is divided into six classes (Table 111.3) [8]. The ASA category has been closely related with surgical outcomes, operating time, complications, blood transfusions, and overall morbidity and mortality [9–11]. Patients for an elective procedure with an ASA grade 3 or 4 need consultation with a senior anesthetist [8].

The purpose of laboratory tests is to detect a medical disease or defect that could adversely affect anaesthetic and surgical outcome. Initially, these tests were done in all patients, irrespective of age or concurrent medical or surgical pathologies which were not cost effective, and led to unnecessary interventions. Evidence indicates that, 60–70 % of laboratory tests ordered preoperatively are not required based on a review of the history and/or physical examination and only 1 % or less of routinely performed preoperative tests reveal abnormalities that might influence perioperative management [12, 13]. Thus, universal use of "routine" preoperative tests is not beneficial in terms of good and cost effective patient care and does not offer any legal protection [14, 15]. Focal and selective preoperative testing is more useful and laboratory tests should be individualised based on patient's age, history, examination, review of medical records and the type and extent of surgery. [16]In asymptomatic healthy women, hemoglobin or hematocrit must be measured in all patients over the age of 6 months; an electrocardiograph on all women over the age of 40 years; and a blood urea nitrogen test and a glucose test in all women over the age of 65 years. Additionally, a pregnancy test should be done in all reproductive age women who are at risk of early pregnancy [17]. In our hospital we do a minimal investigative work-up which includes blood glucose and kidney function tests apart from haemoglobin, blood grouping and cross-matching, electrocardiograph (ECG) and X-ray Chest. We also screen all women undergoing surgery for HIV, Hepatitis B and Hepatitis C.

In women who are symptomatic and/or have other medical or surgical pathologies, preoperative tests should be done to determine the current status of medical or surgical co morbidities and determine their effect on the outcome of the proposed surgery. This would also help perform necessary medical interventions to minimize adverse outcomes. Recommendations for selective preoperative laboratory testing are summarized in Table 111.4 [16, 17].

Table 111.3 Classification of physical status, established by the American Society of Anesthesiologists 1962, amended 1980 [8]

Class	Description
ASA PS1	Normal healthy and fit patient
ASA PS2	Patient has mild systemic disease
ASA PS3	Patient with severe systemic disease not incapacitating
ASA PS4	Patient with severe incapacitating systemic disease that is a constant threat to life
ASA PS5	Moribund patient who is not expected to survive 24 h with or without surgery
ASA PS6	Declared brain dead patient whose organs are being removed for donor purposes
E	Emergency surgery, suffixed after ASAPS

Medical/Gynecologic Management

Preoperative planning also includes any medical or gynecological management in the months preceding the surgical procedure to help achieve maximum physical status, optimal surgical outcome and minimize complications. Examples

Table 111.4 Preoperative testing in special situations [16, 17]

Preoperative test	Medical condition
ECG	Cardiac disease, hypertension, COPD[a], Central Nervous System disorder, Thyroid and parathyroid disorder, morbid obesity, diabetes, poor nutrition, digoxin therapy, males>45 years, females> 55 years
X ray chest	Congestive heart failure, hypertension, valvular heart disease, COPD[a], Morbid obesity, heavy smoker, radiation therapy, aortic aneurysm, cardiomegaly
Complete blood counts	Major surgery, neonates, males>70 years, females>45 years, chronic renal, liver and lung disease, anemia and other hematological disorders, coagulopathies, CNS disorders (stroke, seizures, tumor), malignancy, cushing's syndrome, addison's disease, poor nutrition, steroids, chemotherapy
Electrolytes	Hypertension (on diuretics), diabetes, heart disease, renal disease, stroke, seizures, thyroid disease, cushing's disease, addison's disease, hyperparathyroidism, poor nutrition, diuretics use, digoxin therapy, steroids, chemotherapy
Renal profile	Hypertension, diabetes, renal disease, poor nutrition, diuretics
Glucose	Diabetes, family history of diabetes, stroke, seizures, cushing's and addison's disease, marked obesity, poor nutrition, steroid therapy
Coagulation profile	Hepatic disease, family history of coagulopathy, anticoagulant therapy, renal dysfunction
Liver function test	Liver disease
Calcium levels	Hyperthyroid, parathyroid disease

[a]*COPD* chronic obstructive pulmonary disease

include use of preoperative vaginal estrogen cream for 4–6 weeks before surgery for increasing vaginal mucosal thickness in postmenopausal women. This facilitates dissection, post-operative repair of tissues, reduces urinary tract infection and postoperative morbidity.

Another important aspect is the regulation of medications taken by the patients prior to the surgery. For example, modification of insulin dose in the diabetic women, appropriate timing of surgery in women taking anticoagulants or continuation/discontinuation of oral contraceptive pills. Warfarin should be stopped 5–6 days prior to surgery if the pre procedure International normalised ration (INR) is 2.0–4.5. Repeat INR within 24 h of surgery to ensure that it is less than 1.5 or lower and patient should be started on unfractionated heparin. [18, 19, 20] In case the cardiovascular risk is high or moderate, aspirin can be continued before and during surgery, but in case the risk is low aspirin is stopped 7–10 days prior to surgery [19, 20]. Estrogen containing oral contraceptive pills or hormone therapy should be discontinued 4 weeks prior to surgery [21]. In cases of emergency surgery in patients on estrogen containing pills, use of intravenous heparin, graduated compression stockings and early mobilization is recommended [21].

Preoperative Care

Antibiotic Prophylaxis

Postoperative infections remain a major source of morbidity and a potential cause of mortality in surgical patients. All major gynecological surgeries, either vaginal or abdominal carry a significant risk of infectious morbidity (20 %) [22].Infections after hysterectomy include operative site infections, vaginal cuff cellulitis, pelvic cellulitis, pelvic abscess, urinary tract infections and generalised sepsis [23]. These prolong hospital stay and increase health care costs. Risk factors for infection after hysterectomy include older age, diabetes, obesity, peripheral vascular disease, coagulation disorder, anemia, poor nutritional state, past h/o surgical infection, presence of malignancy, prior radiotherapy, long duration of surgery and presence of indwelling catheters [24].

Operative-site infections after a hysterectomy result from the ascending spread of microorganisms from the upper vagina and endocervix to the vaginal cuff and paravaginal tissues dissected during the procedure. Postoperative infections following vaginal hysterectomy are polymicrobial, with enterococci, aerobic gram-negative bacilli, and *Bacteroides* species isolated most frequently. [25] Bacterial vaginosis, a complex alteration of vaginal flora resulting in an increased concentration of potentially pathogenic anaerobic bacteria, is associated with an increased risk of posthysterectomy cuff cellulitis [26]. However, there is a lack of data showing that pre-treatment for bacterial vaginosis before hysterectomy reduces the rate of postoperative cuff cellulitis.

The most critical factors in the prevention of postoperative infections, although difficult to quantify, are the sound judgment and proper technique of the surgeon and the surgical team, as well as the general health and disease state of the patient. Antibiotic prophylaxis is increasingly used to augment host defence mechanism and reduce infectious complications in patients by almost 50 % [22]. A meta-analysis found that the rate of postoperative infection (surgical and pelvic sites) in women undergoing vaginal hysterectomy who received placebo or no prophylactic antimicrobial ranged from 14 to 57 %, which was significantly higher than the 10 % rate reported with antimicrobials [27].

Principle of Antimicrobial Prophylaxis

The principle of antibiotic prophylaxis is to reduce the colonization of microorganisms to the extent that the patient's natural immune-defence mechanisms are able to overcome the bacterial load in the wound. [28] Only a narrow window of antimicrobial efficacy is available, requiring the administration of antibiotics either shortly before or at the time of bacterial inoculation (e.g., when the incision is made, viscus entered, or pedicles clamped); i.e. at least 15–60 mins before skin incision [29]. A delay of only 3–4 h can result in ineffective prophylaxis. The induction of anesthesia represents a convenient time for initiating antibiotic prophylaxis such that serum and tissue levels are adequate before the incision is made, the levels are maintained during surgery and few hours after the incision is closed [30, 31]. For lengthy procedures (>3 h) and for procedures with increased blood loss (>1500 ml), a second intraoperative dose of antibiotic can be repeated at intervals of one or two times the half-life of the drug (3–4 h after first dose) to maintain adequate levels throughout surgery [29, 30].

Antimicrobial of Choice

The administration and the choice of antibiotic depend on wound classification. Vaginal hysterectomy is classified as "clean-contaminated" wound and prophylactic antibiotics have reduced the incidence of febrile morbidity from 40–50 to 5–20 % [28, 31, 32]. First or second generation cephalosporin's have emerged as the drugs of choice for the vast majority of operative procedures because of their broad antimicrobial spectrum and low incidence of allergy and side effects [24, 29]. The recommended regimen is a single dose of cefazolin (1 or 2 g single dose IV), but alternative agents

such as Cefoxitin, cefotetan, or ampicillin–sulbactam may also be used. [24]In case the patient is allergic to β lactams, either of the following regimens can be used [23, 24, 29].

1. Clindamycin or vancomycin plus an aminoglycoside (or aztreonam, or a fluoroquinolone)
2. Metronidazole plus an aminoglycoside (or fluoroquinolone)
3. Clindamycin monotherapy.

Screening for bacterial vaginosis is not recommended prior to surgery. However, treatment of bacterial vaginosis using metronidazole 4 days prior to vaginal hysterectomy did reduce the incidence of vaginal cuff cellulitis from 59 to 27 % in one study [33].The recommendations are similar for surgery for prolapse and stress urinary incontinence.

Patients who have specific cardiac conditions should be offered infective endocarditis prophylaxis [30]. Postoperative respiratory infections can be reduced by optimization of lung functions by medication and physiotherapy, cessation of smoking and early mobilization with good pain control. To reduce urinary tract infections, indications for the use and duration of indwelling catheters may be optimised.

Adjunctive Techniques to Prevent Postoperative Infections

Preoperative shaving of pubic and abdominal hair prior to gynaecological surgery is not recommended; in fact preoperative shaving is associated with a significantly higher surgical site infection rate, particularly when completed the night before surgery. When hair removal is required, hair clipping is recommended at the time of surgery [31].

Surgical site antisepsis is a crucial step to prevent post operative surgical site infections. The only recommended solution is povidone iodine (PVP-I) for vaginal cleaning before surgery [34]. It is a non irritant and has less reported sensitivity reactions. However, iodophors are inactivated in presence of blood and may cause hypersensitivity reactions in patients allergic to iodine [28, 34]. In known cases of PVP-I allergy, 4 % solution of chlorhexidine gluconate is a safe and effective alternative. Chlorhexidine gluconate causes destruction of bacterial cell membranes, has a greater residual effect than iodine and does not get inactivated in presence of blood. [35] The chlorhexidine solution with 70 % alcohol concentration used for abdominal skin preparation is contraindicated for vaginal use as it causes excessive mucosal irritation [34].

A shower with antiseptic soap in the evening before surgery remains a helpful adjunct to infection prevention [31]. Vaginal douching the night before surgery has been shown to be less effective than thorough cleansing of vagina with a povidone iodine solution immediately prior to surgery in the operation theatre. Most vaginal procedures do not require a rigorous bowel preparation; however, it is useful in pelvic surgery to try to ensure that a loaded colon does not limit access. A proctoclysis enema or two rectal suppositories are given the night before surgery.

The recommendations for prevention of surgical site infections (SSI) and health care associated infections have been developed and updated by National Institute of Health and Care excellence in 2008 and Centre of disease Control (CDC) in 2012 respectively (Table 111.5). [31, 36].

Thromboembolism Prophylaxis

Most of the gynecological surgeries are associated with a moderate risk of thromboembolism. In absence of prophylaxis, the risk is 7 % after vaginal hysterectomy, 14 % after abdominal hysterectomy, 38 % after Wertheim's hysterectomy and there is upto 0.4 % risk of fatal pulmonary embolism. [37] Risk factors include older age, obesity, malignancy, previous venous thrombolembolism, estrogen treatment, previous chemotherapy or radiotherapy and complex and increased duration of the procedure [38]. All patients should be individually assessed for risk of thromboembolism and treated appropriately. Low risk patients do not require specific prophylaxis other than early ambulation, while moderate and high risk gynecologic surgery candidates should be offered thromboprophylaxis [39–41]. The recommendations are summarised in Table 111.6. Evidence suggests that unfractionated heparin and low molecular weight heparin are equally effective in preventing venous thrombosis [41].

Operative Set up

Optimal positioning and illumination of the surgical field is essential to obtain optimal exposure in order to ensure a safe and effortless surgery. Every surgeon must have basic knowledge regarding operating tables and light fittings in the operating theatre.

Operating Table

An operating table consists of a table top supported by the column which in turn is attached to the base. The table top is a rectangular metal top usually made up of stainless steel or aluminium, while the column contains lifting mechanisms which can be hydraulic or electro-hydraulic. The base and column are also usually covered with stainless steel fittings for hygiene and durability. The table top is X-ray translucent and is covered by self-adhering, sectional and conductive rubber mattresses.

Table 111.5 Guidelines to prevent infections after surgery

Top CDC recommendations to prevent healthcare associated infections (HAI)36
Before surgery
Administer antimicrobial prophylaxis in accordance with evidence-based standards and guidelines
Treat remote infections-whenever possible before elective operations
Avoid hair removal at the operative site unless it will interfere with the operation; do not use razors
Use appropriate antiseptic agent and technique for skin preparation
During surgery
Keep OR doors closed during surgery except as needed for passage of equipment, personnel, and the patient
After surgery
Maintain immediate postoperative normothermia
Protect primary closure incisions with sterile dressing
Control blood glucose level during the immediate post-operative period (cardiac)
Discontinue antibiotics according to evidence-based standards and guidelines
Also consider
Before surgery
Screen preoperative blood glucose levels and maintain tight glucose control
During surgery
Redose antibiotic at the 3 h. interval in procedures with duration >3 h
Adjust antimicrobial prophylaxis dose for obese patients (body mass index >30)
Use at least 50 % fraction of inspired oxygen intraoperatively and immediately postoperatively in select procedure(s)
To prevent catheter associated Urinary tract infections
Insert catheters only for appropriate indications using aseptic technique and sterile equipment
Leave catheters in place only as long as needed
Ensure that only properly trained persons insert and maintain catheters
Maintain a closed drainage system and maintain unobstructed urine flow
Comply with CDC hand hygiene recommendations and Standard Precautions
Also consider
Alternatives to indwelling urinary catheterization
Use of portable ultrasound devices for assessing urine volume to reduce unnecessary catheterizations
Use of antimicrobial/antiseptic-impregnated catheters
NICE guidelines for Prevention and treatment of surgical site infection 2008 31
Preoperative phase
Advise patients to shower or have a bath using soap, either the day before, or on the day of, surgery
Do not use hair removal routinely to reduce the risk of surgical site infection. If hair has to be removed, use electric clippers with a single-use head on the day of surgery. Do not use razors for hair removal
Give patients specific theatre wear that is appropriate for the procedure and clinical setting, and that provides easy access to the operative site and areas for placing devices, such as intravenous cannulas. Consider also the patient's comfort and dignity
All staff should wear specific non-sterile theatre wear in all areas where operations are undertaken
Staff wearing non-sterile theatre wear should keep their movements in and out of the operating area to a minimum
Do not use nasal decontamination with topical antimicrobial agents aimed at eliminating *Staphylococcus aureus* routinely to reduce the risk of surgical site infection
Do not use mechanical bowel preparation routinely to reduce the risk of surgical site infection
The operating team should remove hand jewellery, artificial nails and nail polish before operations
Antibiotic prophylaxis
Give antibiotic prophylaxis to patients before clean surgery involving the placement of a prosthesis or implant, clean-contaminated surgery, contaminated surgery. Do not use antibiotic prophylaxis routinely for clean non-prosthetic uncomplicated surgery
Use the local antibiotic formulary and always consider potential adverse effects when choosing specific antibiotics for prophylaxis.
Consider giving a single dose of antibiotic prophylaxis intravenously on starting anaesthesia. However, give prophylaxis earlier for operations in which a tourniquet is used
Before giving antibiotic prophylaxis, consider the timing and pharmacokinetics (for example, the serum half-life) and necessary infusion time of the antibiotic. Give a repeat dose of antibiotic prophylaxis when the operation is longer than the half-life of the antibiotic given
Give antibiotic treatment (in addition to prophylaxis) to patients having surgery on a dirty or infected wound
Inform patients before the operation, whenever possible, if they will need antibiotic prophylaxis, and afterwards if they have been given antibiotics during their operation

Table 111.5 (continued)

Intraoperative phase
Hand decontamination
The operating team should wash their hands prior to the first operation on the list using an aqueous antiseptic surgical solution, with a single-use brush or pick for the nails, and ensure that hands and nails are visibly clean
Before subsequent operations, hands should be washed using either an alcoholic hand rub or an antiseptic surgical solution. If hands are soiled then they should be washed again with an antiseptic surgical solution
Maintaining patient homeostasis
Maintain patient temperature intraoperatively, avoid hypothermia
Maintain optimal oxygenation during surgery. In particular, give patients sufficient oxygen during major surgery and in the recovery period to ensure that a haemoglobin saturation of more than 95 % is maintained
Maintain adequate perfusion during surgery
Do not give insulin routinely to patients who do not have diabetes to optimise blood glucose postoperatively as a means of reducing the risk of surgical site infection
Others
Do not use non-iodophor-impregnated incise drapes routinely for surgery as they may increase the risk of surgical site infection
If an incise drape is required, use an iodophor-impregnated drape unless the patient has an iodine allergy.
The operating team should wear sterile gowns in the operating theatre during the operation
Consider wearing two pairs of sterile gloves when there is a high risk of glove perforation and the consequences of contamination may be serious
Prepare the skin at the surgical site immediately before incision using an antiseptic (aqueous or alcohol-based) preparation: povidone-iodine or chlorhexidine are most suitable
If diathermy is to be used, ensure that antiseptic skin preparations are dried by evaporation and pooling of alcohol-based preparations is avoided
Do not use diathermy for surgical incision to reduce the risk of surgical site infection
Do not use wound irrigation to reduce the risk of surgical site infection
Do not use intracavity lavage to reduce the risk of surgical site infection
Do not use intraoperative skin re-disinfection or topical cefotaxime in abdominal surgery to reduce the risk of surgical site infection
Cover surgical incisions with an appropriate interactive dressing at the end of the operation
Postoperative phase
Use an aseptic non-touch technique for changing or removing surgical wound dressings
Use sterile saline for wound cleansing up to 48 h after surgery
Advise patients that they may shower safely 48 h after surgery
Do not use topical antimicrobial agents for surgical wounds that are healing by primary intention to reduce the risk of surgical site infection

Table 111.6 Classification of risk and prophylaxis for thromboembolism in patients for gynecologic Surgery

Risk category	Patient and surgery characteristics	Prophylaxis
Low risk group	Minor surgery (<30 min), no risk factor other than age Major surgery (>30 min). Age <40 years, no other risk factor, Minor trauma or surgical illness	Early ambulation
Moderate risk group	Major surgery, age ≥40 years or other risk factors Major medical illness; heart or lung disease, cancer, Inflammatory Bowel disease Minor surgery, trauma, illness in patients with previous thromboembolism or thrombophilia	[a](a) Thigh-high graduated compression stockings/ Pneumatic compression or/and (b) Unfractionated heparin (5000 U) administered 2 h before surgery and continued postoperatively every 8 h until discharge Or Low-molecular-weight heparin (dalteparin, 2500 U, or enoxaparin, 40 mg) administered 12 h before surgery and once a day postoperatively until discharge (c) Fondaparinux
[b]High risk group	Major pelvic or abdominal surgery for cancers Major surgery, trauma, illness in patients with previous thromboembolism or thrombophilia, Lower Limb Paralysis	[a]Pneumatic compression Unfractionated heparin (5000 U) administered 8 h before surgery and continued postoperatively until 4 weeks Or Dalteparin (5000 U)/ Enoxaparin (40 mg) administered 12 h before surgery and then once a day thereafter × 4 weeks

[a]Placed intraoperatively and continued until the patient is fully ambulatory
[b]A combination of mechanical and pharmacologic methods is used

The table top consists of three or more hinged parts namely, head, body (trunk) and leg sections which can be flexed or extended to achieve the desired position [42]. These joints can also be detached (breaking the table) or the entire table can be raised, lowered, laterally tilted or positioned in Trendelenburg or reverse Trendelenburg positions. Operating tables also have accessories such as arm rest, stirrups, leg supports/padded knee crutches, bowls etc. Arms should be placed with palm up and should never be abducted beyond an angle of 90° from shoulder to prevent stretching of ulnar nerve and brachial plexus. The hands must never be placed under the body to avoid compression. To make a lithotomy position, metal stirrups are fixed in holders on both sides of the operating table. Leg supports with clamps are available which are padded and have Velcro straps and a ball joint or occasionally the feet are supported by sling stirrups.

The Yellofins® stirrup enables safe and easy positioning while providing better surgical site access. Yellofins Stirrups allow for easy adjustment of abduction and lithotomy in patients up to 500 lbs. (227 kg) while maintaining the sterile field. The boot is extended along its lateral side (referred to as a "lateral fin") and is padded on the interior. The purpose of this fin is to cover and protect the head of the fibula and the peroneal nerve. The boot is self-adjusting to minimize pressure on the calf when moving the stirrup and the pad completely covers the foot. These stirrups also feature lift assist technology to provide easy movement of the leg into the desired position.

All operating tables have control mechanisms to achieve desired positions by manipulating different parts. Some are manually controlled (hydraulic mechanism), whereas movements of others are electrically controlled by remote hand or foot control switches (control unit). All operating tables are movable and can be locked for stabilization by a brake or floor lock.

Positions

Lithotomy

This position is the most favourable for vaginal surgeries as it facilitates surgical access to the perineum as the patient lies supine and the knees and hips are flexed, and the hips are abducted. The buttocks lie at the edge and knees are flexed and the feet are placed in canvas slings of the stirrups or in the leg supports and strapped (Fig. 111.1). Movement of both the limbs must be simultaneous and excessive abduction or external rotation of limbs is avoided. Femoral neuropathy or compartment syndrome has been reported following prolonged surgery in lithotomy position due to compression of blood supply of femoral nerve leading to local ischemia and decreased perfusion pressure of nerve

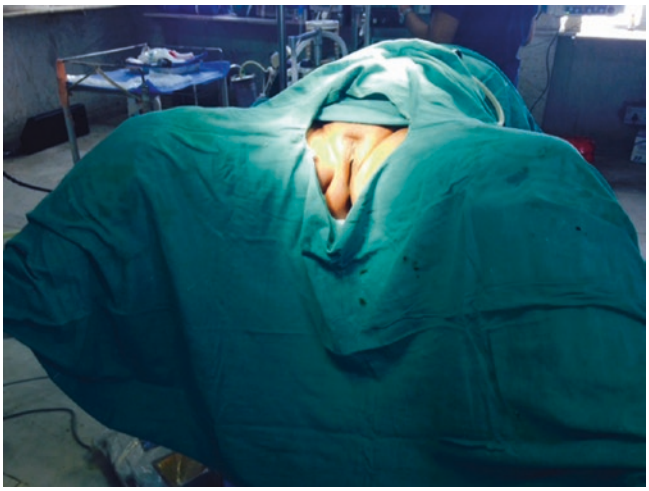

Fig. 111.1 Low lithotomy position for vaginal hysterectomy

trunk. [43] Nerve damage can also occur due to improper positioning and due to undue pressure on patient's legs especially if the duration is more than 2 h [44]. Common peroneal nerve damage can occur due to compression between the head of the fibula and lithotomy pole, use of the yellowfins stirrups prevents this injury In patients who require additional general anesthesia due to ineffective regional anesthesia, risk of regurgitation and thus aspiration is increased in lithotomy position due to increased intra-abdominal pressure. In such cases the position should be preferably changed to supine. As the vital capacity is decreased in lithotomy, respiration should be carefully monitored in sedated, spontaneously breathing patients [45]. The preload to the heart is increased due to limb elevation. Hence, in case of significant surgical bleeding, when legs are lowered at the end of surgery, depending on degree of vasodilatation, 500–800 ml of blood may drain back into lower limbs causing sudden hypotension. [46].

Other Positions

For procedures, like laparoscopic gynecological procedures, the preferred position is modified lithotomy with a considerable degree of head-down tilt (Trendelenburg) with the patient's buttocks overhanging the end of the operating table, also known as the Lloyd-Davies position). Other positions commonly used for vescico-vaginal fistula repair are knee-chest position and reverse lithotomy with head-up tilt.

Operative Field Lighting

Adequate lighting is essential for a safe and easy surgery. There should be even illumination of the room using white fluorescent ceiling lights and the ratio of intensity of general room lighting to that at the surgical site should not exceed

1:5 to minimise eye fatigue [47]. Illumination of the surgical site depends upon balance between the quality of light from an overhead source and reflection from drapes and tissues. Usually the operating lights have halogen bulbs which emit light with a pale bluish cast which is very intense but causes less eye fatigue, have an adequate colour temperature and are safe to be used near tissues as more of the energy is released as light than as heat [48]. Lamps should produce less than 25,000 μW/cm^2 of radiant energy. Most lights focus on a central point which is surrounded by a wider, less intense area and to avoid shadows, the beams of light should be produced from a various angles or multiple light sources or reflectors can be used.

To conclude, a proper preoperative evaluation and planning for appropriate surgery as well as indicated and appropriate use of prophylactic measures to prevent surgical complications like sepsis and thromboembolism go a long way to achieve the successful outcome of gynecological surgical procedures. Preoperative care is as important as intraoperative management and postoperative care and should be carried out thoroughly and completely for optimal results. Besides a basic knowledge of the operating room set up including its table, lights and surgical positions are crucial for a successful surgical outcome.

Vaginal Hysterectomy: Instrumentation and Apparatuses

112

Carl W. Zimmerman

Introduction

Successful vaginal surgery is dependent on several factors including the skills and experience of the surgeon, adequate surgical assistance, lighting, proper anesthesia, and medical care of the patient pre-, intra-, and postoperatively. Even when all of these factors are optimized, surgical instrumentation can significantly facilitate completion of a challenging operation and, if properly chosen, can extend the skills and efficiency of the surgeon to the benefit of the patient. Instruments used in vaginal hysterectomy are exceptionally important because the size of the operating field is determined by the patient's anatomy, not by the size of an incision that is made by the surgeon. The caliber, depth, and axis of the vagina are of primary importance in defining the operative field. Instrumentation used in abdominal or endoscopic hysterectomy may or may not be useful when adapted to vaginal work; however, an innovative surgeon is not hesitant to use instruments that have previously been developed for other operative approaches or for use by other specialties elsewhere in the body. In this chapter, discussion will be developed for basic instrumentation for the routine hysterectomy and more specialized instrumentation will be discussed for more difficult or unique cases [1].

Basic and Advanced Instrumentation for Vaginal Hysterectomy

Successful performance of a vaginal hysterectomy includes retraction, lighting, incision, transection of surrounding structures, and removal of the organ. Each of these components of surgery will be considered separately.

Retraction

A variety of instruments can be used for retraction. The most widely used retractors are hand held. Heaney retractors are widely available, ergonomic due their right angle design, and are available in different sizes (Fig. 112.1). Briesky-Navratil retractors are preferred by many surgeons because of the variety of sizes, depths, widths. The angulation of the handle is oriented so that the assistant's hand is well away from the operative field (Fig. 112.2). In the posterior colpotomy, a weighted Steiner-Auvard retractor is often used, so that the blade of the instrument is inserted into the peritoneal cavity through the incision and exposes the posterior wall of the uterus and cul de sac, while holding the anorectum safely out of harm's way (Fig. 112.3a, b). Two examples of self-retaining tools are illustrated. The Martin's arm attaches to the side of the operating table and allows the surgeon to attach a retractor, usually anteriorly to retract the bladder out of the operative field. The retractor is held in place passively, under constant tension, and without tiring an assistant (Fig. 112.4). Variations on the popular Bookwalter® retractor system that is commonly used abdominally are available for the vaginal approach to hysterectomy. Magrina-Bookwalter ™ (Symmetry Medical, Antioch, TN) and Jordon-Simpson™ (Marina Medical, Sunrise, FL) are two examples with the latter being illustrated without implying preference (Fig. 112.5). Experts in the use of all these systems report that the learning curve for each of them is shortened by frequent use. The utility of these self-retaining systems is that once in place, a variety of attached retractors available in differing sizes can virtually eliminate the need for assistants. There is a learning curve for efficient placement with these self-retaining retractors; however, the rewards can be significant especially when there is a need to minimize the number of assistants. The cost is greater than more simple devices; however, if used repeatedly, the cost factor can be attenuated.

Lighting

Light and visibility of the operative field are often at a premium in vaginal surgery. Surgeons are familiar with headlights which are useful for directing light into a deep operative field (examples are not pictured here). In addition, two other products may be useful. Versalight® (Cura Surgical, Geneva, IL) is a combination fiber optic (cool) light, suction, and retraction instrument that is useful in delivery of light combined with the other two functions from the hand of an assistant. High density plastic construction of this instrument is strong enough to allow the instrument to function as a retractor without damage, and the suction function replaces the commonly used Yankauer suction tip (Fig. 112.6). Also available are flat light transmitting pads, Lightmat® (Cura Surgical, Geneva, IL), that can be applied directly to retraction instruments to deliver a constant source of lighting when the retractor is in place without occupying any significant space in the operative field (Fig. 112.7).

Fig. 112.7 Light Mat™, a light transmitting pad (With permission of Cura Surgical)

Incision

An incision may be made with either a scalpel, scissors, or electrocautery at the preference of the surgeon and with respect to the specifics of the case. Whatever approach is used, the full thickness of the vaginal epithelium should be incised at the proper level of the cervix in order to gain access to the required structures for extirpation of the uterus. No special instruments are needed for cervical incision unless the cervix is high in the vagina or its position is distorted by a fibroid. In that circumstance, an extended length electrocautery, curved Jorgensen or Dean scissors, or an angled knife may be helpful. I tend to use the extended cautery unless a specific clinical circumstance, e.g. limited vision, prohibits safe application of that technique.

Fig. 112.6 Versalight™ is a lighting, suction, irrigating and retracting device that has maximum function and minimal intrusition within the vaginal operative field (With permission of Cura Surgical)

Transection of Surrounding Structures

The key to successful removal of the uterus is transection of the ligamentous structures of the paracolpium (uterosacral, cardinal, and pubocervical ligaments), ligation of the uterine blood supply, and, finally, successful and secure transection of the adnexal connection to the uterus. Traditionally surgical clamps have been used, and they remain the most widely used, available, and versatile method of performing vaginal hysterectomy used today. N. Sproat Heaney was a pioneer vaginal hysterectomist who developed several useful instruments that are still available today (see Fig. 112.1 as an example). Heaney hysterectomy clamps are more useful abdominally than vaginally. While adequate and subsequently improved by people like Ballentine, their gripping capacity can be tested in difficult vaginal cases. Typically the instruments are available in one length, with only straight and slightly curved alternatives. The cross-hatching is shallow, and if cross cleats are present, they are sometimes not adequate to hold tissue under the tensions that may be necessary in vaginal hysterectomy (Fig. 112.8). Atraumatic Hysterectomy Clamps, available from several manufacturers, were originally based on thoracic surgery instruments and are available in several lengths and

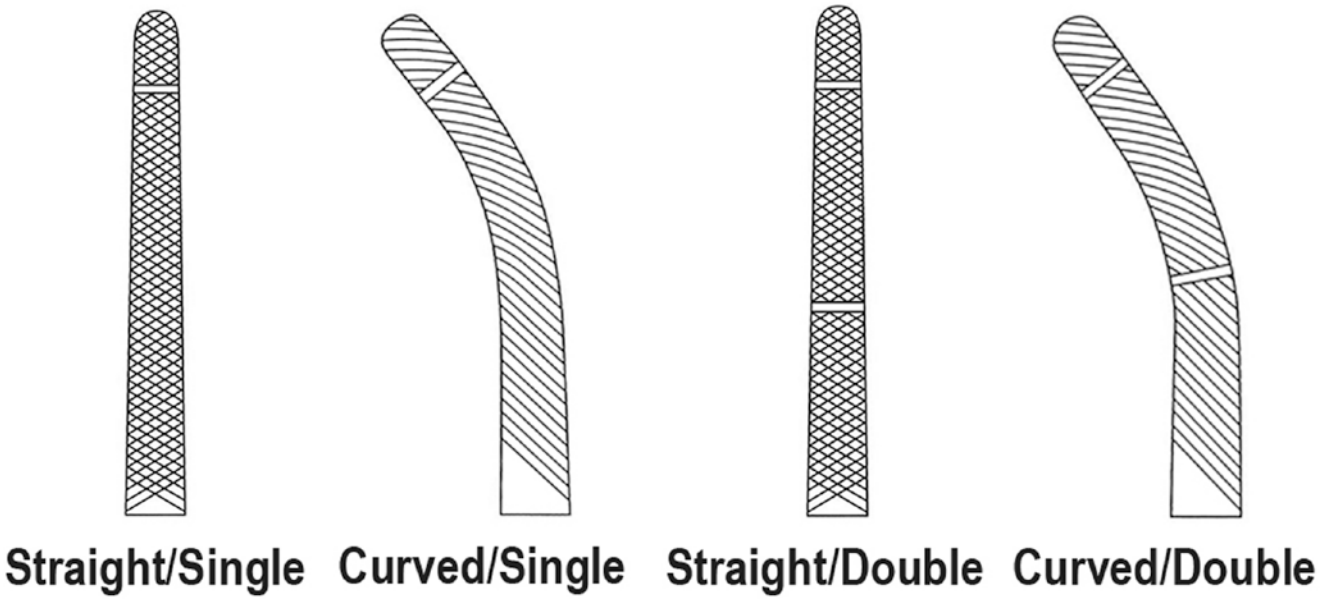

Fig. 112.8 Heany Hysterectomy Clamp™ with detail (With permission of Marina Medical, Sunrise, OH)

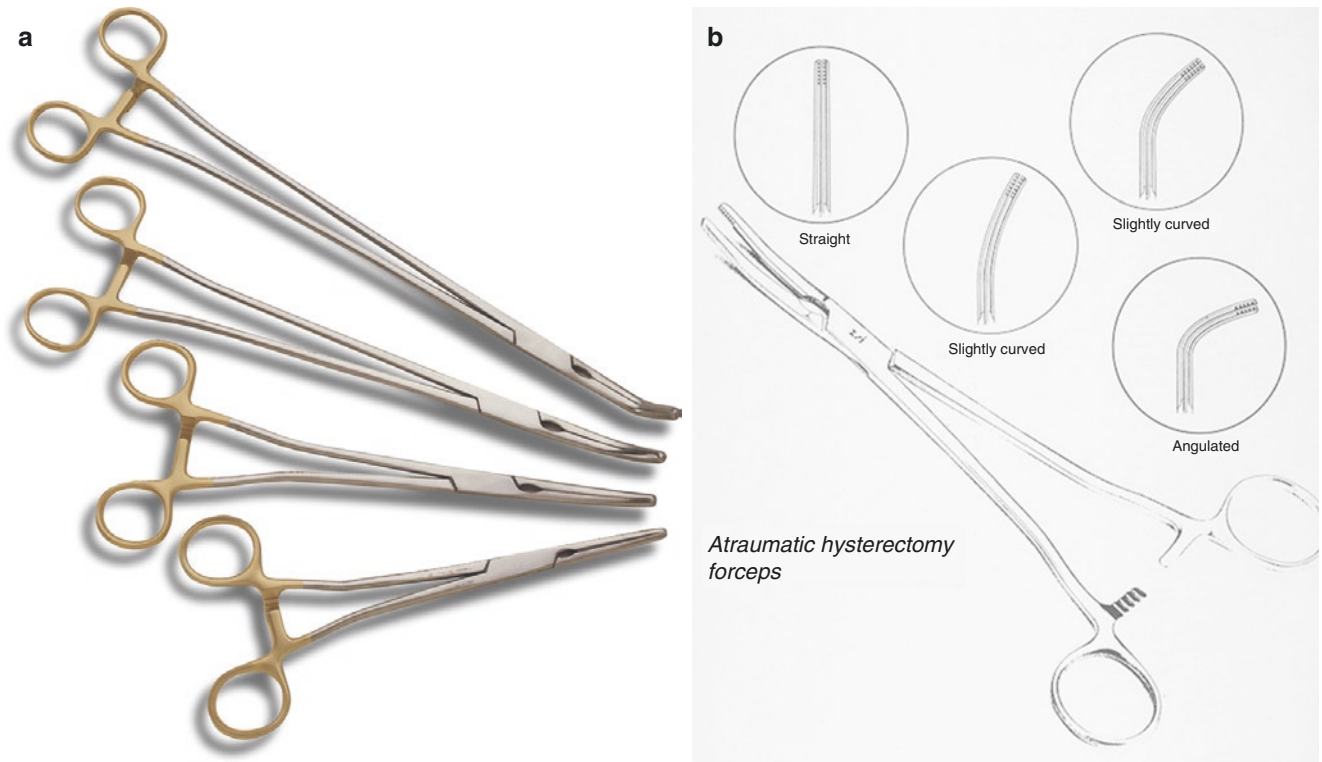

Fig. 112.9 (**a**) Atraumatic Hysterectomy Clamps; note the various lengths and curvatures available; (**b**) Detail of the grip pattern and available curvatures (With permission of Marine Medical, Sunrise, FL)

curvatures that make them very useful and safe for vaginal hysterectomy (Fig. 112.9a). The longitudinal deep grips are designed to minimize trauma to tissue, and the cleats located at the end of the grip help to prevent tissue slippage out of the clamp, a feature that is very useful and reassuring in vaginal hysterectomy (Fig. 112.9b). The Atraumatic Hysterectomy Clamps are also bulky enough that, in the usual circumstance, no lateral retraction is needed when securing a pedicle with these instruments. When rotated outward, they create sufficient exposure for safe and secure pedicle ligation.

Ligament and vessel bipolar sealing devices, while costly, can shorten operating time and facilitate completion of a vaginal hysterectomy. These devices are particularly useful when speed is important, as, for example, in a medically-compromised patient. They are also useful to secure pedicles in the absence of prolapse, or in the presence of obesity, and especially hyperobesity, where visibility and access are typically compromised. Normally, in vaginal hysterectomy, the uterosacral pedicles are suture ligated so they may be incorporated into the cuff at the time of repair. Thermal sealing of the uterosacral is not contraindicated; however, a suture would simply need to be added at the end of the case for reincorporation of suspensory function of those ligaments into the incisional cuff prior to closure (colpopexy). In addition, the adnexal pedicle at the fundus of the uterus is often not completely visible, and the potential for thermal injury to bowel and other structures is a possibility at that level of hysterectomy. For that reason, bipolar thermal sealing devices should be used with caution at that level of the uterine adnexal attachment. The technology used in these devices was developed initially for endoscopic and abdominal work and many devices are available.

Removal of the Uterus

With a normal sized uterus and a normal amount of vertical mobility, simply clamping the adnexal pedicle and transecting medially releases the organ from its last attachments and permits removal. With enlargement from either leiomyomata or andenomyosis, special instrumentation and techniques can be used to advantage. Uteroreductive techniques include cervicectomy, coring, myomectomy, and morcellation. Except in unusual circumstances, e.g., a large cervical myoma or other dominant myoma blocking access to the structures surrounding the uterus, these maneuvers should only be used after the pericolpium and uterine blood supply have been secured and after entry into the peritoneal cavity has unequivocally been demonstrated. Cervicectomy is useful when the cervix blocks the operative field. Generally performed at the level of the isthmus, a scalpel or electrocautery is sufficient for removal of the cervix. Coring may be performed after the above-mentioned criteria are met for uteroreductive techniques. The technique is described by Kovac [2], and simply employs a long handle scalpel with a #10 or other suitable large scalpel blade. No other special instrumentation is used. The processes of vaginal myomectomy and morcellation are safe and effectve if the above mentioned surgical criteria are met before beginning the process. Of course, a malignant tumor should not be morcellated. Reducing the overall size of the uterus permits removal of much larger uteri that the size of the vaginal canal would normally permit. Typically the cervix is grasped with Lahey thyroid clamps and the cervix is incised vertically along the path of the endocervical canal. Downward traction is maintained on the cervix in order to minimize blood loss; however, if the uterine vessels are ligated, bleeding is commonly not a problem during morcellation. As the fundus is approached, myomata are exposed (Fig. 112.10). Depending on the number, size, and location of myomata, various techniques can be used. Vulsellum clamps, e.g., a Gordon or Zimmerman myoma grasper™ (Marina Medical, Sunrise, FL), both longer than a Lahey, are useful for grasping and securing fibroids that are deep within the operative field (Fig. 112.11). Zimmerman myotomes™ (Marina Medical, Sunrise, FL) are instruments derived from the Cobb and Langenbeck periosteal elevators (Figs. 112.12, 112.13, and 112.14). Periosteal elevators are usually used to separate the periosteum from the surface of flat or long bones. These instruments were developed for use in orthopedics and neurosurgery; however they have been modified by adding a handle that is more ergonomic and easily manipulated for the gynecologic surgeon. As a result, they are useful when removing fibroids because the tip is designed to dissect without cutting. That ability to dissect without cutting makes the design of myotomes ideal for enucleating myomas while not risking injury to deeper structures. After a myoma has been identified and grasped with a vulsellum clamp, the myotomes can be used to separate the tumor along the cleavage plane of its capsule with relative ease and with minimal blood loss. Enucleation can then be accomplished if the myoma is small enough (Fig. 112.15). If a myoma is too

large to easily enucleate, another useful orthopedic instrument is the Martin Cartilage Scissors (Marina Medical, Sunrise, FL) (Fig. 112.16). The tip is pointed and sharp so that it can be thrust into a myoma, even one that is calcified. The cutting edges of these scissors are serrated and designed to be strong enough to transect cartilage, similar to the texture of a typical fibroid. They can be used to wedge resect the bulk of a dominant myoma with the process continuing until extraction is possible (Fig. 112.17). A long handle scalpel may also be used to reduce larger myomata by wedge resection. Care should be taken to avoid injuring deeper structures such as bowel if a scalpel is used.

Removal of the Adnexa

The indications for removal of the adnexa should not change regardless of the approach used for hysterectomy. Typically the atraumatic hysterectomy clamps mentioned earlier in this chapter are sufficient to secure release of the adnexal structures (Fig. 112.9). Especially useful are the 30 and 45° curvatures at the level of the infundibulopelvic ligaments. The ability of these clamps to secure tissue without slippage is exceptionally important during this portion of a hysterectomy. A specially-designed Kovac (Marina Medical, Sunrise, FL) or Sheth clamp (Cooper Surgical®, Trumbull, CT) is also useful because of its curved design which allows the clamp to rotate laterally so that manipulation of the adnexa within the clamp becomes easier [3] (Fig. 112.18). A particularly challenging maneuver in removal of the adnexa is securing the infundibulopelvic ligament containing the ovarian artery and veins. The Endoloop® (Ethicon, Cincinnati, OH), developed for endoscopic work is ideal for this stage of the case especially when the infundibulopelvic ligament is isolated and a large bulky pedicle is avoided. It easily slips into place with equal upward push and downward traction so that the pedicle is secured with no tension, often deep within the operative field.

Conclusion

Instrumentation is a key resource in completion of vaginal hysterectomy. Often, innovative use of instruments developed for use in other fields can be useful in completing vaginal hysterectomy efficiently and safely. Use of the proper instruments allows the surgeon to expand her or his skill set, and allow patients who need hysterectomy to have the minimally invasive vaginal approach. The utilization of the vaginal approach to hysterectomy is currently being emphasized in the United States by our national organizations. The cost of endoscopic and robotic approaches has come to the attention of insurers. There are signs that the vaginal approach will be incentivized, if so, the technique of vaginal hysterectomy will be poised to assume its rightful place as the primary approach for benign hysterectomies not only in practice, but also in training programs. Properly emphasized, the vaginal approach will then hopefully attract the same type of attention to innovations that the more invasive endoscopic approaches have attracted.

Set-Up

Good exposure sets the surgeon up for success. A combination of optimal factors including patient positioning, assistance, retraction, and lighting can improve the exposure and make even a complex appearing case feasible. If one has to pick one factor which influences the success the most during vaginal hysterectomy, it is the surgical positioning. The procedure should not begin until the patient's lower extremities are safely positioned to provide comfortable space for two assistants and the surgeon between the patient's legs. Similarly, patient's buttocks should extend 2–3 cm over the edge of the table for a successful vaginal hysterectomy. Stirrups supporting the entire leg or candy cane stirrups, which hold the foot up with straps, are both appropriate as long as the minimum angle between thigh and torso is 60°, and 90° at the knee. Trendelenburg position should not be exaggerated (Fig. 113.1).

Retractors should not be in the surgeon's way. Self-retaining ring retractor sets may be advantageous for gynecologists who have limited access to assistants. We prefer fluid movement of retractors by assistants accommodating the surgeon's needs. The right angle shape of a Heaney retractor, which was originally designed to deflect the posterior vaginal wall, is not ideal for retraction of the bladder because it is not well-suited for the curvature of anterior pelvic compartment and can result in bladder injury in the hands of inexperienced assistants. The versatility of malleable ribbon retractors have made them our retractors of choice as it is possible to change their curve, angle, and retracting depth according to the anatomy of each specific patient. If they are not available or fail to retract collapsing tissue, Breitsky-Navratil retractors of various sizes may also be used (Fig. 113.2).

Not every weighted speculum is appropriate for all patients. The length and angle of the speculum has to fit the patient's anatomy. For instance, a suitable size Sims retractor may be preferred in a woman with prolapse. A Steiner-Auvard weighted speculum with its longer, curved blade which fits the sacral hallow is essential and should always be used after, but never before, posterior colpotomy to deflect the rectum and expose the uterosacral ligaments (Fig. 113.2). If the weighted speculum is too long, it will push away the apex and make colpotomy difficult. In fact, with correct positioning and optimal exposure, long instruments for suturing, clamping and cutting will hardly be necessary.

The bladder is drained partially with an indwelling catheter before the procedure. The catheter is then clamped to allow bladder to fill spontaneously. We deliberately do not empty the bladder completely as this may enable immediate recognition of accidental cystotomy. The catheter is unclamped intermittently during the procedure to monitor urinary output.

Optimum illumination of the surgical field is paramount to the successful vaginal surgeon. This may be by means of a variety of tools such as a lighted suction irrigation device, headlight, light attachment to a retractor or by simply holding a cystoscopy fiber optic light cable with a Babcock clamp as needed.

Injection into the cervical stroma with Vasopressin or Lidocaine including Epinephrine for initial incision may be a good step when teaching, however; it is not necessary for an experienced surgeon especially if this incision is made with electrocautery. The bleeding from this incision will stop with the swift placement of the first clamps on each side.

Colpotomy

The conventional approach to colpotomy is a circumferential incision on the cervix. In our institution, we prefer an entry from the posterior aspect before making the circumferential incision.

First, a weighted speculum is inserted in the vagina. It should not be too long but has to be long enough to deflect the entire posterior vagina. After the speculum is inserted, the surgical drape on each side of can be clamped together over the weighted portion to prevent it from slipping out. A malleable retractor is bent approximately at a 5 cm distance from one end with about a 90° angle to expose the entire cervix. The cervix is grasped with two short Lahey tenacula at its anterior and posterior portions. It is important to hold both portions with a good grip. The cervix is pulled up to expose the posterior fornix and then moved up and down and in and out to visualize the creases forming in this area. This delineates exact location of the bilateral uterosacral ligaments as well as the dimple forming immediately at the edge of posterior cervix (Fig. 113.3). This area represents the part of the cul-de-sac where the only structures separating the vaginal and abdominal cavities are the peritoneum and the vaginal wall. If there is no previous history of a pelvic infection or severe endometriosis, the thickness of vaginal wall and the peritoneum together is about 3–4 mm. Location of this free area can also be confirmed by palpation of this the posterior fornix or pressing a blunt surgical instrument against the posterior cervix and moving it down and visualizing a drop-off effect where the cervix ends. The full thickness vaginal wall is held with a longer Allis clamp at approximately 2 cm from the demarcation signifying where the cervix ends. If grasped appropriately, the peritoneum is also included in this grip. Using traction and counter-traction between the Allis clamp and the tenacula holding the cervix, a vertical line is formed in the most apical portion of the posterior fornix. Mayo scissors are then used to cut the full thickness vaginal wall firmly in the middle of and perpendicular to this line. This typically allows direct entry into the cul-de-sac between the uterosacral ligaments (Fig. 113.4). We switch to a longer Steiner-Ouvard weighted speculum after the entry into the cul-de-sac. Even though bleeding

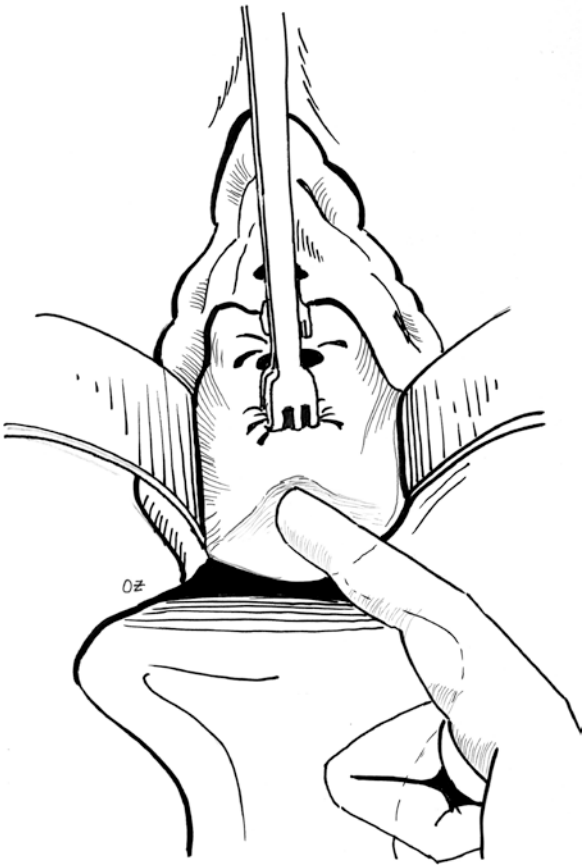

Fig. 113.3 The cervix is moved up and down and in and out. Creases and dimple forming in the posterior fornix during this maneuver delineates exact location of the uterosacral ligaments and the edge of posterior cervix

from the cut edge of the posterior cuff is typically not significant, some surgeons choose to suture this edge with a running suture at this time.

A rectal injury with this approach is extremely unlikely as the rectum and vagina are not adjoining in the proximal 3–4 cm of the posterior vaginal wall (Fig. 113.4). In cases when this free area cannot safely be identified or peritoneum is spared from this initial cut with Mayo scissors, we choose to use the conventional layer-by-layer technique in which a scalpel is used to incise the full thickness vaginal wall and then the peritoneum is found and elevated with a well-grasping forceps or Allis clamp and then peritoneal cavity is entered sharply with Metzenbaum scissors.

Possible technical difficulty with this approach is being unable to cut the peritoneum at the first attempt. It often happens with the fear of a novice cutting too close to the cervix and getting into the visceral peritoneum/serosa of the cervix. When that happens, the peritoneum can be grasped with the technique described above and entered sharply. If the peritoneum is pushed away by a novice, it is ok to start clamping the uterosacral and cardinal ligaments extraperitoneally. Usually the peritoneal cavity will be entered effortlessly and spontaneously with this latter approach.

When posterior entry is presumed to be difficult, an alternative approach can be attempted. First the posterior cervix is held with two tenacula on each side. Then it is infiltrated with a diluted vasoconstrictive solution and bisected until cul-de-sac peritoneum is entered (Fig. 113.5).

Location of the anterior colpotomy incision is important. It should not be too close to either the bladder or the cervical os.

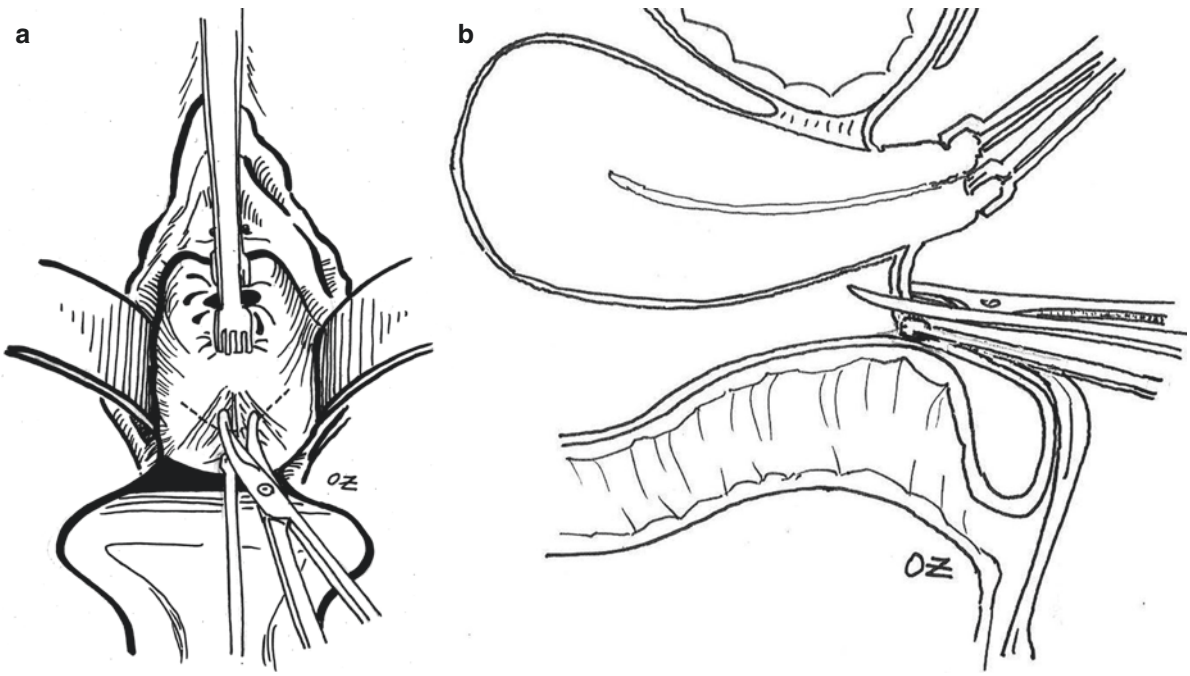

Fig. 113.4 Posterior colpotomy. (**a**) Using traction and countertraction between the Allis clamp and the tenacula holding the cervix, a vertical line is formed. Mayo scissors are held firmly and perpendicular to the midpoint of this line. A full thickness cut typically allows direct entry into the cul-de-sac. (**b**) A rectal injury with this approach is extremely unlikely as the rectum and vagina are not adjoining in the proximal 3–4 cm of the posterior vaginal wall

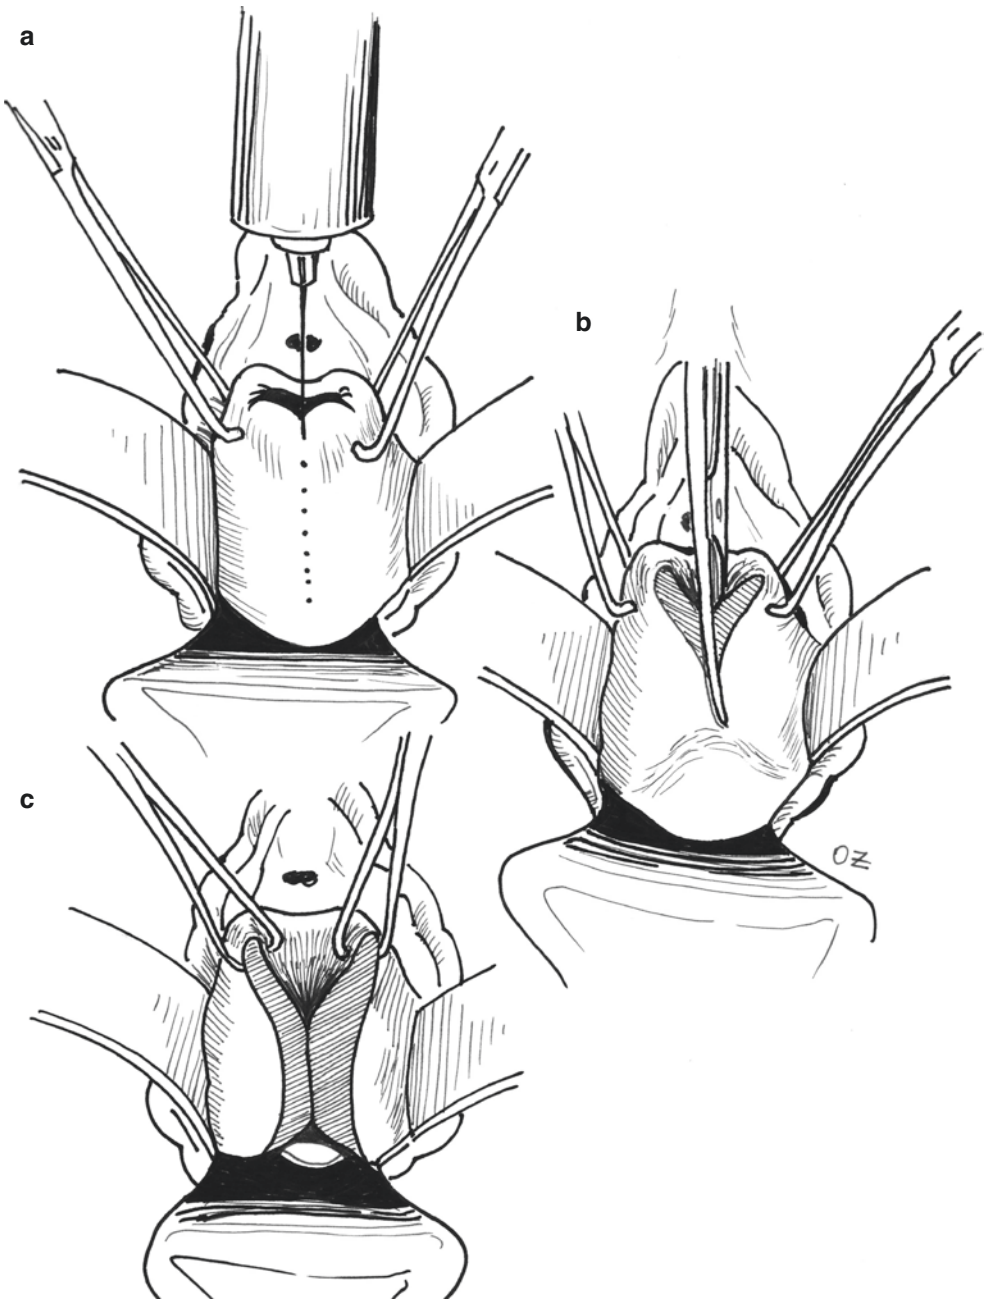

Fig. 113.5 Alternative approach to posterior colpotomy: (**a**) First the posterior cervix is held with two tenacula on each side. (**b**) Then it is infiltrated with a diluted vasoconstrictive solution and (**c**) bisected until cul-de-sac peritoneum is entered

The bladder location can be determined by the appearance of the rugae in the anterior vagina (Fig. 113.6). The anterior incision can be made exactly where the rugae end. We typically make our anterior incision with pure cutting function of the electrocautery on the smooth surface of the anterior cervix paying particular attention to stay outside the transformation zone. It typically happens to be about 5–8 mm away from the tenaculum on the anterior cervical lip. In our experience, we have realized that accurate identification of the bladder reflection takes some time. When teaching beginners, we simply instruct them to make the incision about 5 mm cephalad to the anterior cervical tenaculum (Fig. 113.7). This approach is more reproducible for a novice who is yet to develop familiarity with vaginal tissue planes. It is important to cut down to the vesicouterine separation plane between 10 and 2 o'clock but the rest of the incision on the sides should be more superficial. The correct plane almost always shows itself by the "falling away" of the bladder. This incision is extended along each side more superficially and connected to posterior colpotomy incision. Then the vaginal side of this incision is held with an Allis clamp and elevated while Mayo scissors are used to develop this plane further. It is critical to hold the scissors parallel to the cervical axis and press them against the firm surface of the cervix and lower uterine segment (Fig. 113.8). After the so-called "vesicouterine septum", a 1.5–2 cm connective tissue band which firmly attaches the bladder to the lower uterine segment, is divided, the avascular vesicouterine space opens leaving only a thin sheet of peritoneum

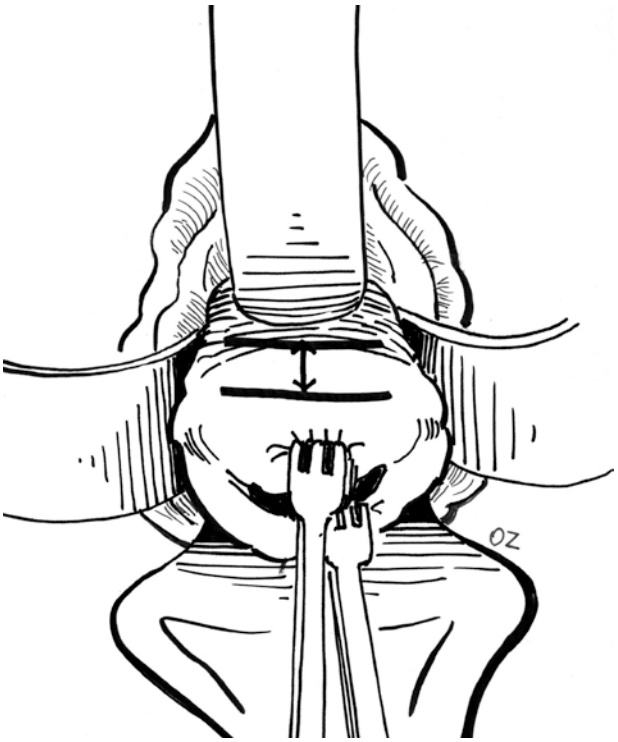

Fig. 113.6 Anterior colpotomy. Location of the anterior colpotomy incision is important. It should not be too close to either the bladder or the cervical os. The bladder location can be determined by the appearance of the rugae in the anterior vagina.

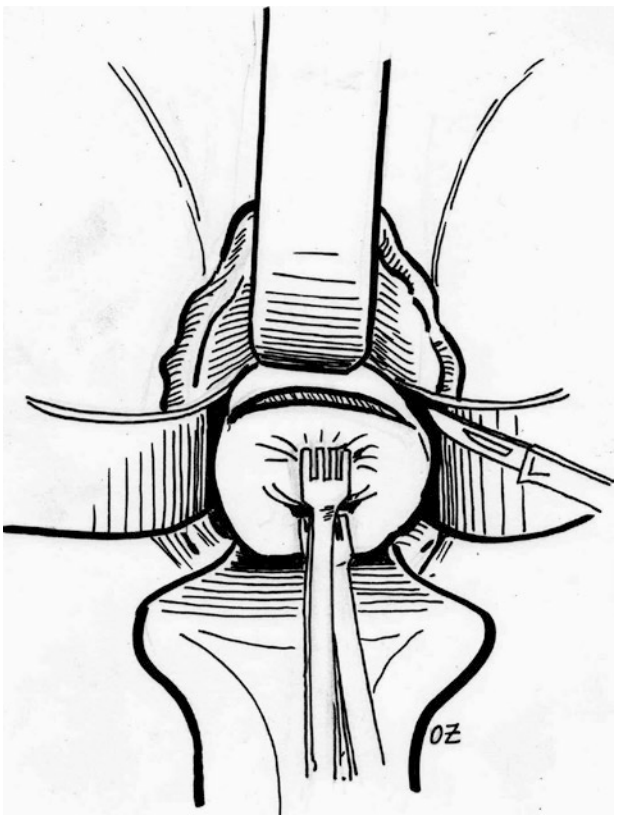

Fig. 113.7 In our experience, we have realized that accurate identification of the bladder reflection takes some time. When teaching beginners, we simply instruct them to make the incision about 5 mm cephalad to the anterior cervical tenaculum

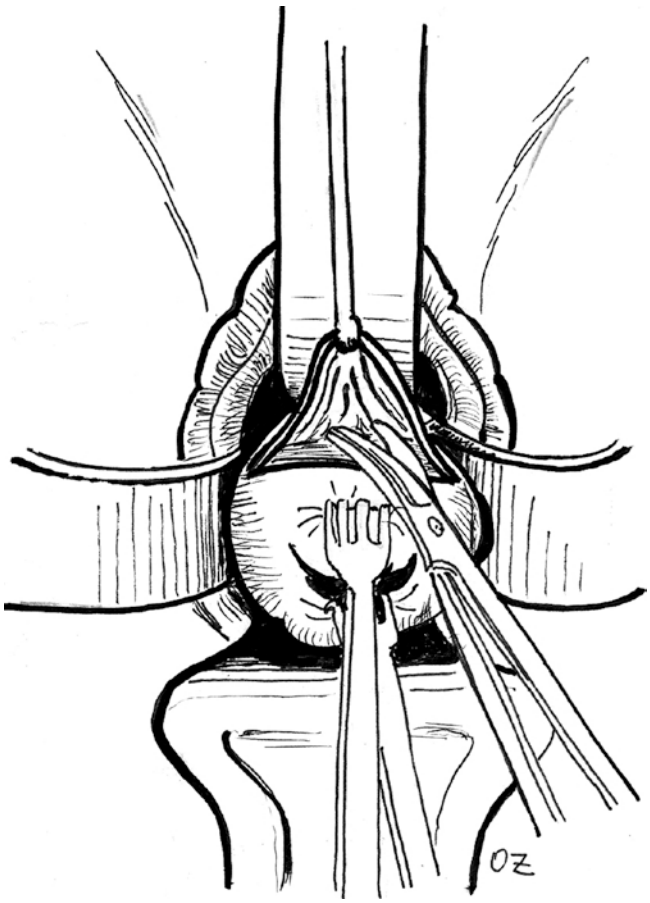

Fig. 113.8 It is critical to hold the Mayo scissors parallel to the cervical axis and press them against the firm surface of the cervix and lower uterine segment when developing the vesicovaginal plane

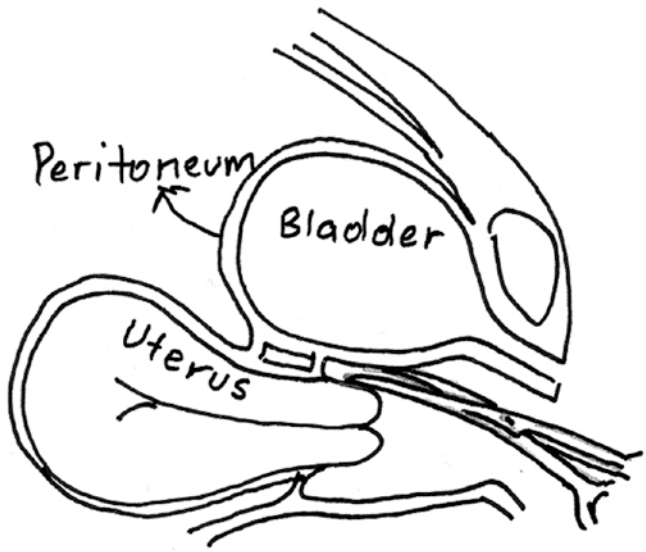

Fig. 113.9 After the so-called "vesicouterine septum", a 1.5–2 cm connective tissue band which firmly attaches the bladder to the lower uterine segment, is divided, the avascular vesicouterine space opens leaving only a thin sheet of peritoneum intact

intact (Fig. 113.9). This space is the same as the so-called "bladder flap" area during an abdominal procedure such as Cesarean delivery. An expert vaginal surgeon may be able to

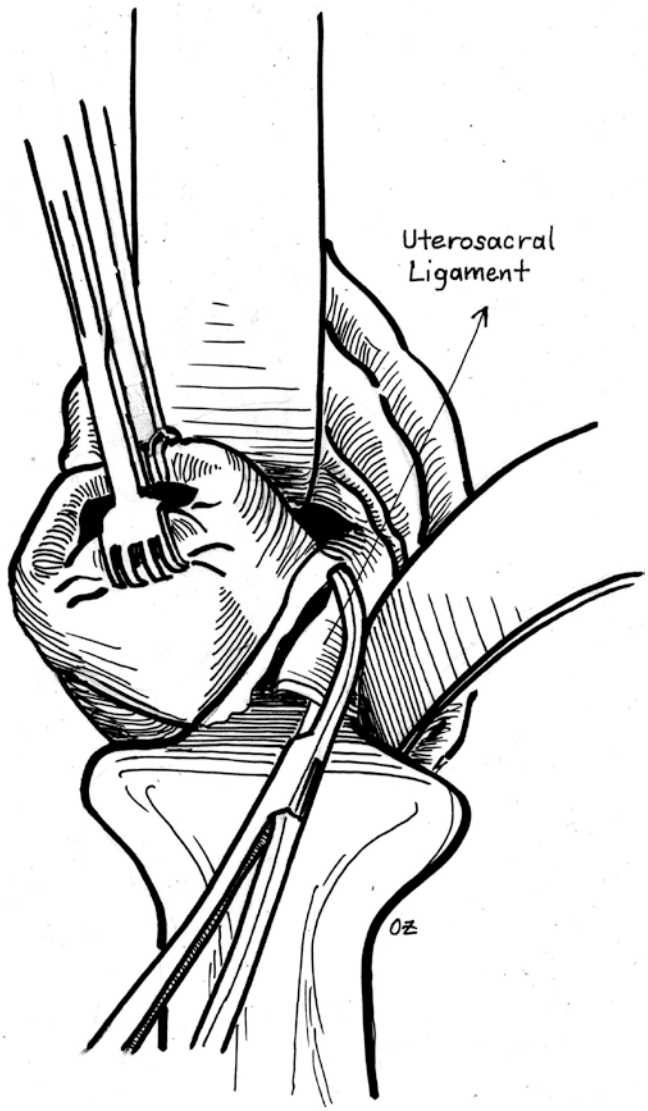

Fig. 113.10 After entry into the avascular vesicovaginal space, even when the peritoneum is still intact, it is safe to start clamping the uterosacral and cardinal ligaments as long as a retractor is placed appropriately deflecting the bladder and down and outward traction is applied to the cervix with the tenacula

determine the vesicouterine plane precisely and may prefer to complete the anterior colpotomy by identifying the peritoneum floating freely over the lower uterine segment although this is not necessary as it is safe to start clamping the uterosacral and cardinal ligaments as long as a retractor is placed appropriately deflecting the bladder and down and outward traction is applied to the cervix with the tenacula (Fig. 113.10). In many cases, we have deferred anterior entry into the peritoneal cavity until after the division and ligation of the uterosacral and cardinal ligaments. If the size of the uterus allows, the fundus is delivered posteriorly and the surgeon's index finger can be advanced behind the uterine fundus toward the anterior compartment and bring the peritoneal sheet into view for safe entry (Fig. 113.11).

Some vaginal surgeons just make an incision anteriorly and posteriorly but leave the area in between intact. After

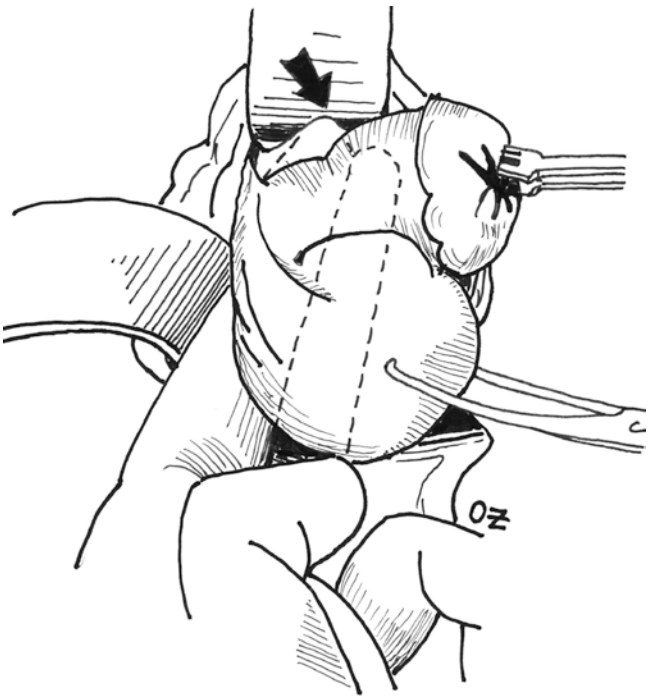

Fig. 113.11 If the size of the uterus allows, the fundus is delivered posteriorly and the surgeon's index finger can be advanced behind the uterine fundus toward the anterior compartment and bring the peritoneal sheet into view for safe entry

deflecting the rectum and bladder away through these incisions, they simply incorporate these lateral intact epithelial surfaces between the anterior and posterior incisions within their uterosacral ligament clamps and cut them together (Fig. 113.12).

Anterior entry is potentially more complicated in women with previous cesarean deliveries. Even though the bladder border can be identified with a transurethrally inserted rigid metal instrument such as a uterine sound or a metal urinary catheter or by retro-filling the bladder, these steps are rarely necessary as long as one does not deviate from using sharp technique with the tips of the scissors against the cervix and lower uterus and the body of the scissors always pressing down.

A novice may also err on the uterine side too much and enter into myometrium and even the uterine cavity with this technique. Even though it is better to invade into the uterine tissue rather than the bladder wall, this may be avoided by advancing the sharp dissection parallel to the cervico-uterine axis.

Closure

Optimal closure of the colpotomy incision is important to prevent cuff dehiscence and pelvic organ prolapse. Vaginal cuff dehiscence is hardly ever a concern after a vaginal hysterectomy. However, this dramatic complication has become a legitimate concern with the increasing popularity of laparoscopic

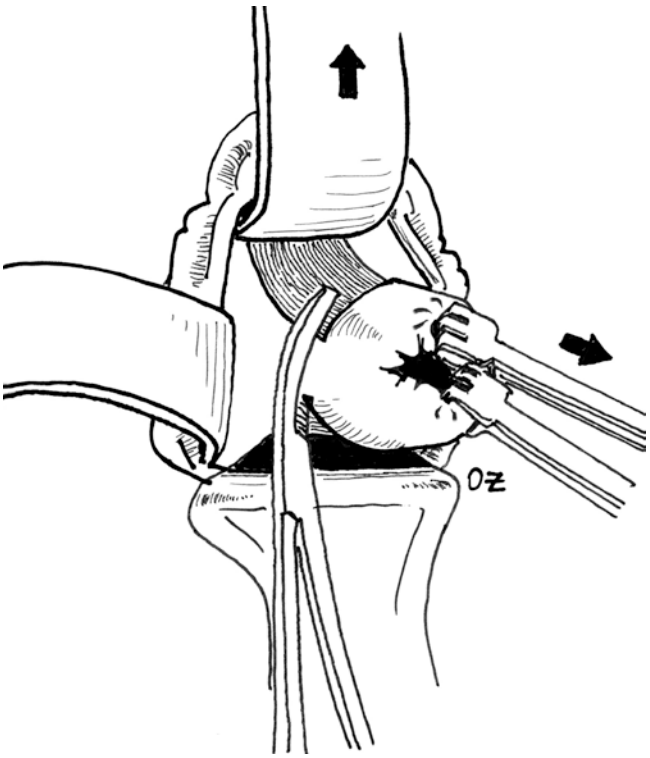

Fig. 113.12 Some vaginal surgeons just make an incision anteriorly and posteriorly but leave the area in between intact. After deflecting the rectum and bladder away through these incisions, they simply incorporate these lateral intact epithelial surfaces between the anterior and posterior incisions within their uterosacral ligament clamps and cut them together

and robotic gynecologic surgery. A group in Italy has demonstrated that transvaginal cuff closure after laparoscopic hysterectomy can significantly reduce the dehiscence risk.

Many different cuff closure techniques have been proposed. The only absolute consensus of these techniques is the emphasis on reattaching the cuff to the natural suspensory mechanisms of the vaginal apex, the uterosacral ligaments. Everything else including peritoneal closure, leaving the cuff partially open, and the sagittal versus transverse direction of closure are still debatable.

A cuff closure method described by McCall is commonly considered the most appropriate choice when apical support is not optimal. The goal of this approach is to obliterate the cul-de-sac for prevention of future enteroceles, plication of the uterosacral ligaments, and connecting the cuff to the uterosacral ligaments for a secure apical support. In a traditional McCall Culdoplasty, the uterosacral ligaments and intervening peritoneal surfaces are sutured together intraperitoneally with two running permanent sutures. A third suture is placed through the ligament intraperitoneally and then brought out through the posterior vaginal cuff edge and tied outside after the rest of the cuff is closed horizontally (Fig. 113.13).

In some closure techniques, after the peritoneum is closed and all the pedicles are exteriorized, the cuff is not closed in the middle, the edges of this 1–2 cm opening is run with a suture for hemostasis only. Some gynecologists place a drain through this opening. For example, in an approach described in a German textbook by Reiffenstuhl, Platzer and Knapstein, the peritoneum is closed with a purse string absorbable suture which also brings the uterosacral, cardinal and adnexal pedicles together in the midline. Sutures are placed on the posterior cuff edge for hemostasis. They note that this is optional on the anterior cuff edge. This closure technique leaves the cuff open but closes the peritoneal cavity.

The following outlines our closure technique for women who have adequate apical support: Before closure, all pedicles should be carefully inspected for hemostasis with a systematic approach (Fig. 113.14). First the area between the uterosacral and utero-ovarian pedicles must be hemostatic. This area on each side is where sutures have been placed to ligate the cardinal ligaments, and the ascending branch of the uterine vessels within the lower end of the broad ligament. With one retractor in the anterior compartment deflecting the bladder, and another one retracting the vaginal sidewall, the utero-ovarian and uterosacral pedicles are held on gentle traction. We routinely leave the suture ligatures of these pedicles longer and label them. To avoid any inadvertent slippage, the vascular utero-ovarian pedicles are double ligated and only the distal ligature is labelled. Once hemostasis of the pedicles and the intervening surfaces is ensured, the rest of the bleeding should typically be from the cuff edge and will be controlled with cuff closure.

We have stopped closing the peritoneum in simple vaginal hysterectomies for several reasons. First, it is a time-consuming and difficult skill to acquire and safely perform in the early learning curve. It may potentially risk ureteral occlusion and bleeding. Additionally, a randomized study, though underpowered, did not show any difference in complications or dyspareunia after peritoneal closure. We came to the conclusion that if peritoneal closure is not essential during open or laparoscopic transabdominal approaches, it should not be so for vaginal hysterectomy either. By eliminating it, we feel that vaginal hysterectomy has become less intimidating for the beginners without any apparent increase in morbidity.

We close the cuff vertically using two continuous delayed absorbable zero sutures (Fig. 113.15). To start the closure, we hold the midpoint of the posterior cuff edge and the posterior peritoneum together with an Allis clamp. We then continuously suture the full thickness cuff edge and the peritoneum on each side of this Allis together. Before alternating to the other side, we also include the intervening peritoneum of the cul-de-sac with each bite. After three to four of these bites, we tie this running suture at the uterosacral ligaments ensuring that they are also incorporated in the closure (Fig. 113.15). This technique obliterates the cul-de-sac,

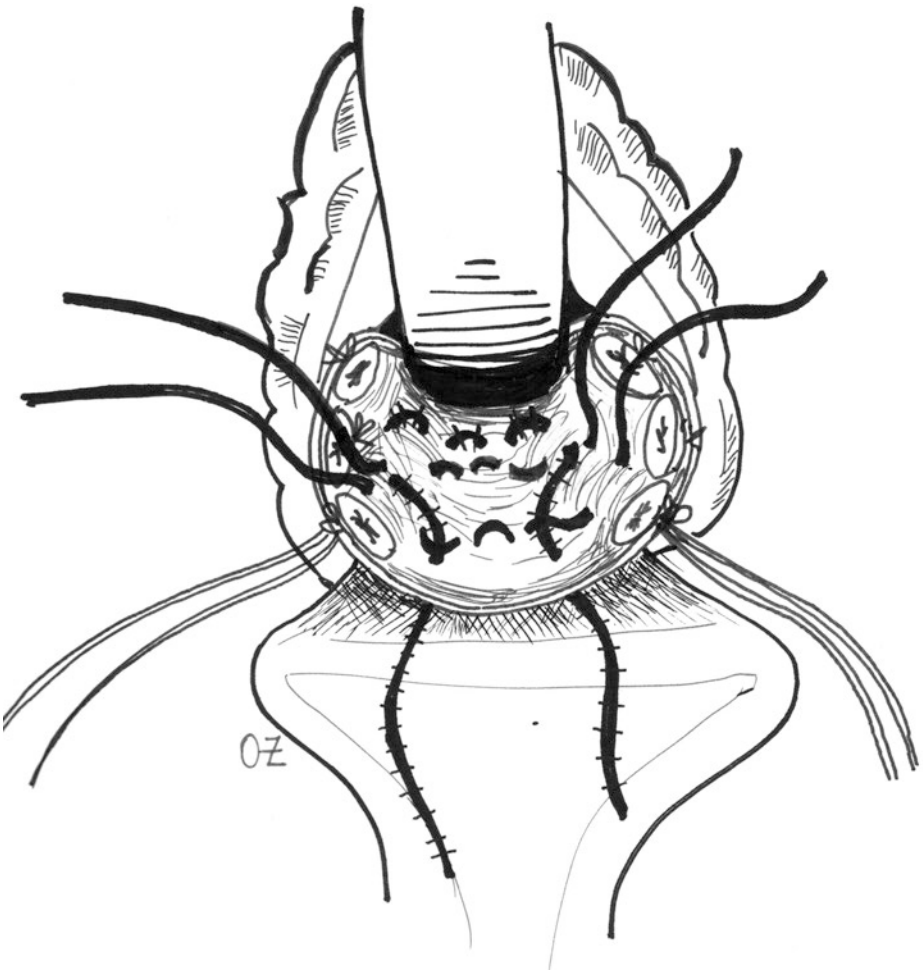

Fig. 113.13 McCall culdoplasty. This method is commonly considered when apical support is not optimal. The goal of this approach is to obliterate the cul-de-sac for prevention of future enteroceles, plication of the uterosacral ligaments, and connecting the cuff to the uterosacral ligaments for a secure apical support. In a traditional McCall Culdoplasty, the uterosacral ligaments and intervening peritoneal surfaces are sutured together intraperitoneally with two running permanent sutures. A third suture (*marked with cross lines*) is placed through the ligament intraperitoneally and then brought out through the posterior vaginal cuff edge and tied outside after the rest of the cuff is closed horizontally

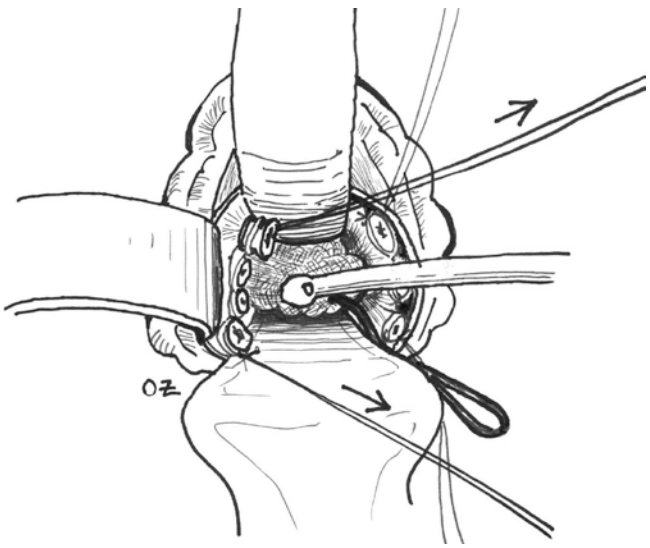

Fig. 113.14 Hemostasis check. Before closure, all pedicles should be carefully inspected for hemostasis with a systematic approach

brings the uterosacral ligaments together in the midline, and attaches the cuff to the uterosacral ligaments similar to the McCall culdoplasty. The rest of the cuff is closed starting from the midpoint of the anterior cuff edge with full thickness purchases from each side and completed at the uterosacral ligaments. If there is an anterior compartment defect, we begin the anterior compartment repair from the anterior cuff and close it at the end. If there is apical prolapse, we add an apical suspension procedure such as high uterosacral ligament suspension or sacrospinous ligament fixation. It is important to rule out a posterior apical vaginal defect causing an enterocele. When this exists, posterior compartment should be opened as in a posterior vaginal repair and attach the torn apical edge of the posterior vaginal muscularis layer to the uterosacral ligaments as well.

At the end of the procedure, we place an indwelling bladder catheter, though not always necessary, but do not use vaginal packing unless a vaginal prolapse repair is also performed.

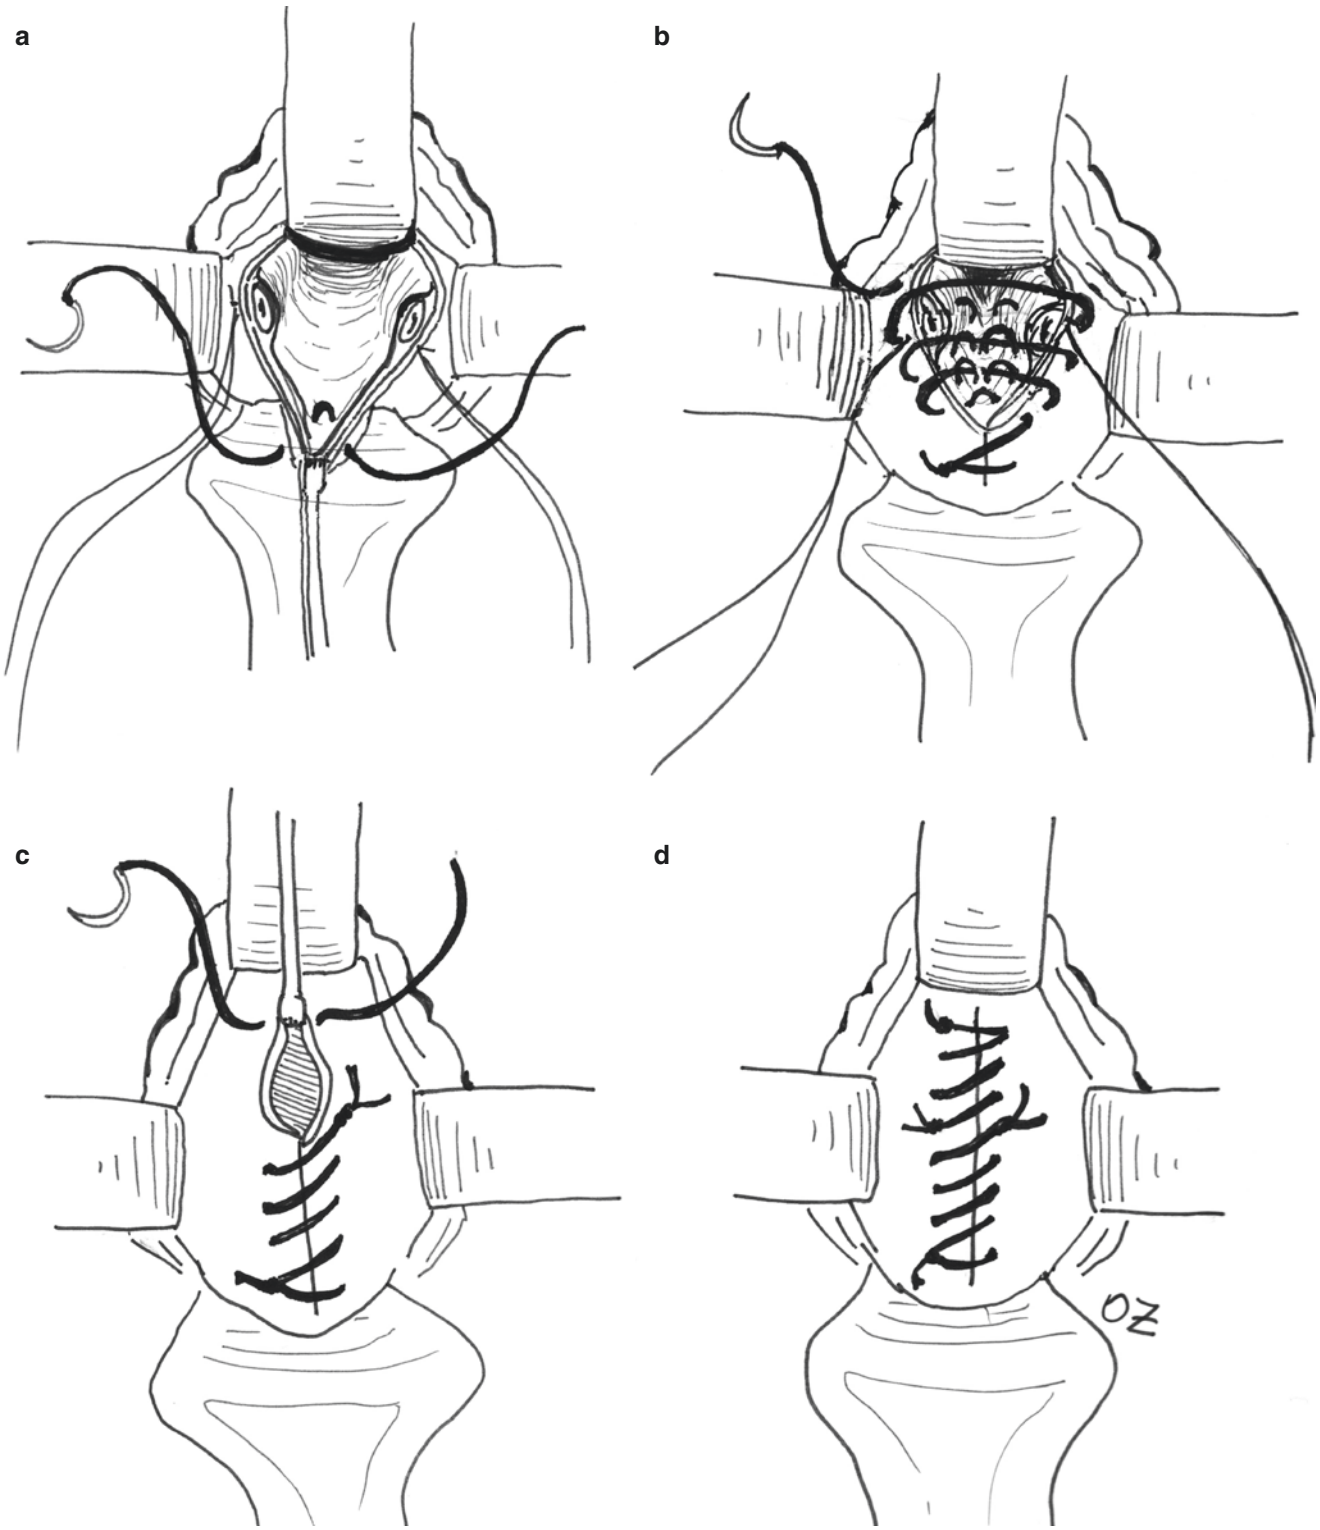

Fig. 113.15 We close the cuff vertically using two continuous delayed absorbable 0 sutures. To start the closure, (**a**) we hold the midpoint of the posterior cuff edge and the posterior peritoneum together with an Allis clamp. (**b**) We then continuously suture the full thickness cuff edge and the peritoneum on each side of this Allis together. Before alternating to the other side, we also include the intervening peritoneum of the cul-de-sac with each bite. After 3–4 of these bites, we tie this running suture at the uterosacral ligaments ensuring that they are also incorporated in the closure. (**c**)The rest of the cuff is closed starting from the midpoint of the anterior cuff edge with full thickness purchases from each side and (**d**) completed at the uterosacral ligaments

Adhesions

114

Shirish S. Sheth

Introduction

If you want to grow roses, you also have to water the thorns!

Adhesions bind tissues and organs to each other. They can make the organ to be dealt with – uterus, and/or its appendages attached to one another and the adherent area can easily get traumatized. For adheseolysis, the principle of treatment is always to proceed from the non- adherent site to the adherent site and then to carefully start separating the adhesions.

Adhesions present a similar problem during vaginal surgery as they do during abdominal surgery and should be managed in the same fashion, as safely as possible. Routinely, one finds gynecologists deal with them laparoscopically and/or abdominally but almost always remain away from it vaginally. Adhesions, particularly flimsy ones may spring a surprise during surgery and often "suspected adhesions" are totally absent. Small ovarian endometriotic cysts can often be without adhesions, just as not all the women with history of caesarean delivery in the past, have a bladder adherent to the uterocervical surface. The surgeon must learn to deal with it vaginally, keeping women's safety and his operative capabilities in mind [1].

Unexpected tuboovarian pathologies, pelvic inflammatory disease, benign ovarian cyst, or endometriomas, hydrosalpinx and tubo-ovarian mass can cause concern and difficulty in treatment. Sonography will not pick up all adhesions and are not always reliable as it is a combination of man-n-machine. Reliable preoperative sonography, and a highly reliable sonologist are essential, particularly, when the pelvic findings are not normal. Sonography findings get confirmed at every surgery which is performed. An examination under anesthesia before the start of surgery can make the surgeon suspect the possibility of adhesions and even cause a change in route and/or technique. However, if in doubt, instead of changing the route, it may be preferable to perform a laparoscopic evaluation to make a definitive decision. Once the route chosen is vaginal hysterectomy, adhesions are likely to hamper or interfere: (1) while getting an access to the anterior and/or posterior peritoneum or pouch or cul-de-sac and /or the, Anterior uterocervical surface with bladder or posterior cervico uterine surface with rectum; (2) flimsy adhesions around the fundus or upper uterine body; (3) a strong or firm band from the lateral posterior uterine surface; (4) Between the fundus or upper uterine body with intestines and/or omentum; (5) uterus with tube and/or ovary; (6) tube and ovary with each other and/ or with surrounding structures; Careful blunt dissection will facilitate salpingectomy or oophorectomy.

Sharp dissection must be carefully performed only under direct vision. However, if the surgeon thinks that it will not be possible to excise the pathologic mass or separate the adhesions safely per vaginam, he or she should have no hesitation in taking the abdominal route, preferably laparoscopically than by laparotomy as lesser invasion is the prime consideration. After a failed vaginal, the abdominal surgery becomes remarkably easy, as most of the lateral pedicles have already been secured during the vaginal attempt.

Uterine Mobility

Clinically, the uterus is mobile in four directions. Restriction of uterine mobility raises the suspicion of adhesions. Testing the anatero-posterior mobility and side-to-side mobility gives an idea about the available uterus-free pelvic space. This estimation, along with the degree of descent or ascent with an upward push, is a better guideline than the distance between the ischial tuberosities which Nichols [2] recommends. The latter can be as fallacious as external pelvimetry in obstetrics [3].

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_114

At an abdominal hysterectomy, there are occasions when we have to separate loops of bowel from the abdominal wall, from one another, from omentum, and finally if required, from the uterus. However, when one reaches the uterus it is often surprising how easily the uterus delivers or enters the abdominal cavity from the pelvis leaving all the adhesions higher up [1, 4, 5].

Often, the mere history of some abdominal or pelvic surgery makes the operator think twice or even deters him from undertaking the vaginal route for hysterectomy. Previous pelvic surgery per se is not a contraindication to vaginal hysterectomy as the nature of the previous operations is the deciding factor. Most operations in past, abdominal or vaginal, are unlikely to cause disturbing adhesions [3].

Previous Abdominal Surgery

These operations can be broadly divided into four categories as in Table 114.1:

1. Operations performed on the uterus are caesarean section, hysterotomy and myomectomy. They are common, important to deal with and do not constitute a contraindication (Table 114.2) [6]. Ventrofixation, contraindicates vaginal hysterectomy, but by experienced gynecologist it can be successfully performed without resorting to the abdominal access. No doubt it demands extra care and effort. At present, laparoscopic adheseolysis to assist VH will solve the problem and spare abdominal opening [6–8].
2. Sling operations for prolapse also make vaginal hysterectomy difficult. Needs back up of experience to perform and spare the abdominal access.
3. Operations performed on the tubes, ovaries and broad ligament tissues in past can give a few flimsy adhesions. They are easily separable as one reaches close to upper pedicle. They should never contraindicate vaginal route, as often done in situations which can be easily dealt with vaginally.
4. Operations performed beyond the genital tract, as appendix, intestines, gall bladder, urinary tract (except bladder) should not hinder or deter and be given undue importance as they are miles away from contraindication.

Encountering any adhesion that holds the uterus inseparably or fear of traumatizing a hollow organ should serve as a contraindication for the vaginal route, an indication to abandon the vaginal route, and to complete the operation with abdominal access.

Previous Vaginal Operations

History of vaginal operation in past is not a contraindication to vaginal hysterectomy. It warrants the surgeon to take extra care. Vaginal operations are (Table 114.1):

1. On the vaginal epithelium and around it, e.g. anterior colporrhaphy, vaginal wall cyst.
2. Cervical amputation. Needs skill and gentleness for accessing anterior and posterior cul-de-sac. It can contraindicate vaginal route for hysterectomy.
3. Fothergill's operation: Past surgery almost makes cervix look like 'nothing on earth' and contraindicates vaginal hysterectomy
4. Operations wherein the peritoneum is entered, e.g. on the tube and/or ovary or myomectomy etc.; need extra care to access and open anterior or posterior peritoneum.
5. Sites slightly away from the site of hysterectomy, e.g. posterior colpoperineorrhaphy, Bartholin's cyst etc.

Though uncommon, bladder or rectal repair done in the past can contraindicate the vaginal route for hysterectomy.

Cervical amputation distorts the anatomy considerably and thus to attempt vaginal hysterectomy after a previous Fothergill's operation is to invite bladder and/or rectal injury. Therefore it can contraindicate the vaginal route for hysterectomy. The other categories only merit special or extra attention.

In day to day practice, situations which hinder the decision to undertake VH are: (1) History of caesarean delivery(ies) / section(s) in past; (2) Ovarian cyst, particularly endometriotic cyst and (3) select surgeries abdominal and/or vaginal performed in the past.

Favourable Pelvic Findings Under Anaesthesia

1. Absence of contraindication to the vaginal route for hysterectomy
2. Mobility of the uterus in all planes
3. Physiologic uterine descent particularly, under anaesthesia, irrespective of parity.
4. Adequate uterus-free pelvic space around the uterus
5. Free vaginal mucosa around the site of both pouches
6. Normal cervical length of portio vaginalis with deep fornices.

Unfavourable Findings Under Anaestehsia Because of Adhesions

1. Restricted uterine mobility in one or more directions
2. Palpable adnexal pathology
3. Cervix flush with the vaginal mucosa
4. Short cervix and shallow fornices; bladder and/or rectum almost on the cervical lip
5. Loss of mobility of the vaginal skin or obvious restriction at the site to get access to the anterior or posterior pouches.

If there is adhesion between the uterus – fundus or body with bowel and/or omentum, it can be easily and

safely separated and pushed away with blunt or sharp dissection.

For enthusiastic to advance vaginal surgical skill, it is a great opportunity to plunge forward and deal with it but within parameters of safety. This will be a step in the right direction. Careful blunt-n-sharp dissection will lyse the adhesions and make the surgery possible.

Blunt dissection with tip of the finger using tactile sensation provides the safest method of entering the right plane of cleavage, allowing separation of adherent structures. Feeling a bit of ovary and then ovarian surface with finger and finger(s) continuing on that surface easily frees most of the adherent ovary. Sharp dissection must be performed carefully only under vision, which can separate the adherent ovary [3, 5, 7].

Cesarean Section Adhesions

Women who have had caesarean section(s) may develop adhesions. They may be flimsy, around the operated area of the lower uterine segment with bladder, omentum and/or intestine(s) or with tube and/or ovary. However, one specific area that bugs the surgeon is in the vesico-uterine area when doing a hysterectomy on a woman with cesarean section(s) in past. For getting an access to the vesico-uterine peritoneum or anterior peritoneum or anterior pouch (cul-de-sac), the bladder needs to be safely separated from the uterocervical surface and this causes anxiety in the surgeon's mind when hysterectomy is considered via the vaginal route [6, 8–13].

No less an advocate of vaginal hysterectomy than Heaney [14] believed that a history of previous pelvic surgery precluded removal of the uterus through the vagina. Coulam and Pratt [15] mention that the chief concern in such cases is the risk of injury to the bladder and difficulty in gaining entry through the scarred anterior cul-de-sac. Carpenter and Silva [16] compared vaginal and abdominal hysterectomies after previous pelvic surgery and concluded: 'vaginal hysterectomy following pelvic operation is technically easy and without an increase in morbidity'. Kovac et al. [17] have discussed the role of LAVH in women with caesarean delivery in past. However there is no doubt that LAVH is more invasive than vaginal hysterectomy [12, 18].

On the basis of observations in women with history of caesarean delivery(ies) in past, it can be said that (1) if the bladder is adherent, it is always in the central 3/5ths and not the lateral 1/5th, and (2) magnetic resonance imaging (MRI) studies at the isthmic level through different planes show a distinct vacant space medial to the line joining the maximally bulging uterus above and the cervix below, with its continuity medially between the uterocervical surface and the bladder, until they come extremely close to each other in the midline and continue laterally between the two leaves of the broad ligament (Figs. 114.1 and 114.2) [3, 9, 10, 12, 19]. Separation is from

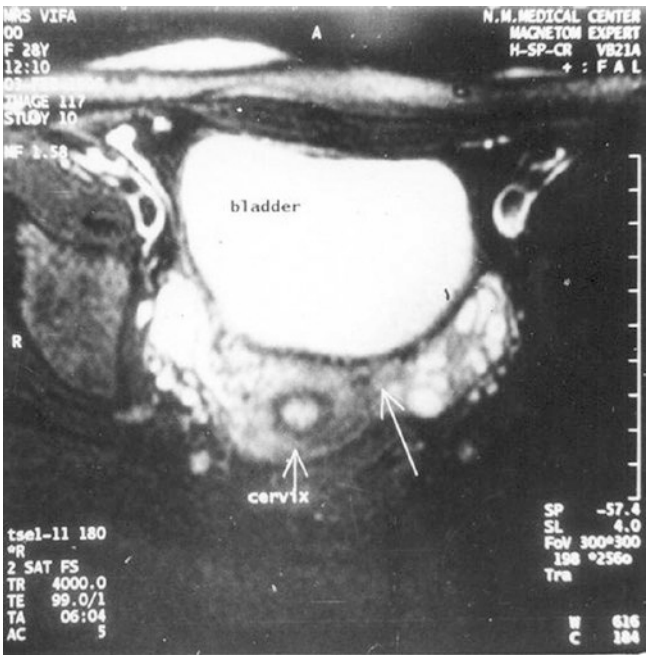

Fig. 114.1 Magnetic resonance imaging (MRI) study showing distinctly the presence of free space laterally between bladder and uterocervical surface (Sheth [10])

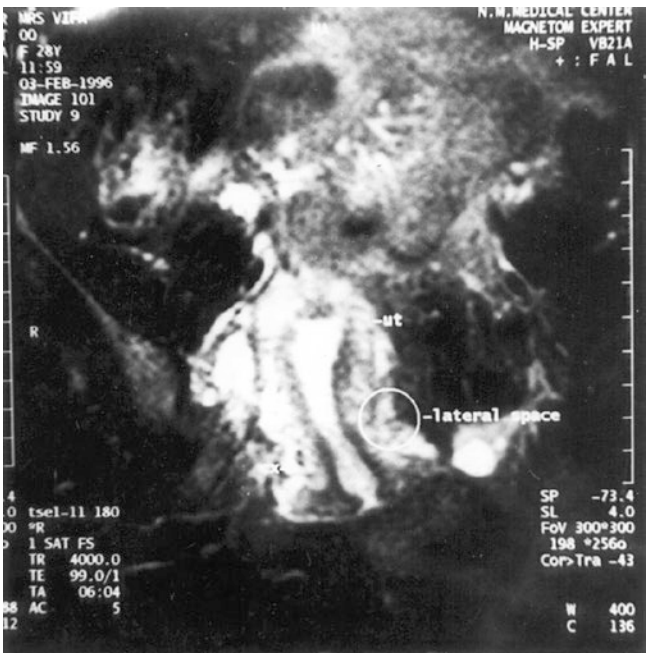

Fig. 114.2 Magnetic resonance imaging (MRI) study confirming the presence of free space surgical window laterally between bladder and uterocervical surface (uterocervical-broad ligament space) (Sheth [10])

non adherent lateral to adherent medial adhesions, and the, occasionally depressed adherent scarred surface guides the operator to the correct site. Familiarity with this and the normal uterine serosal surface is helpful [9, 10, 12] (Fig. 114.3).

John M. Monaghan, an eminent gynaecological oncologist from UK (personal communication) writes' I find Sheth's

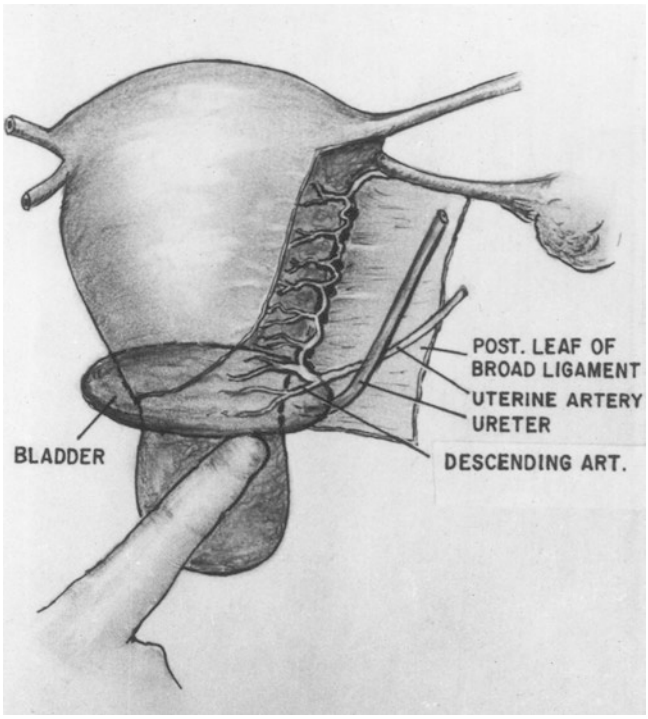

Fig. 114.3 The finger is on the normal uterocervical surface, the site of dissection between the bladder anteriorly and the uterocervical surface posteriorly, finger guides the dissection. The distally placed ureter is also seen (Sheth [10])

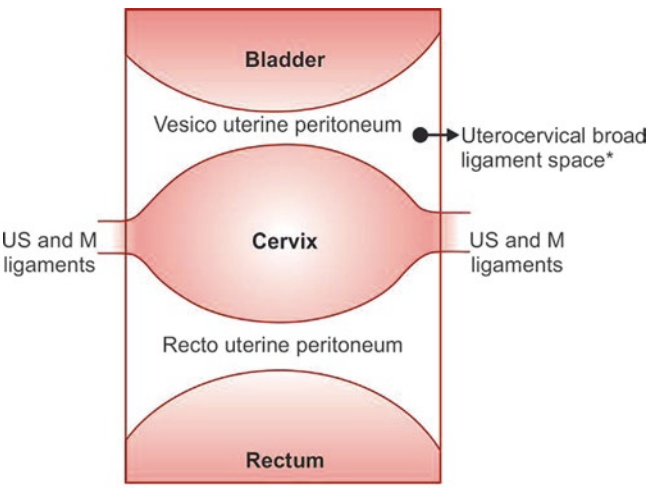

Fig. 114.4 Distinctly shows the space between bladder and cervix or cervicouterine surface, which is much more under lateral one fifth of bladder when compared with central three fifths of bladder (Sheth [19])

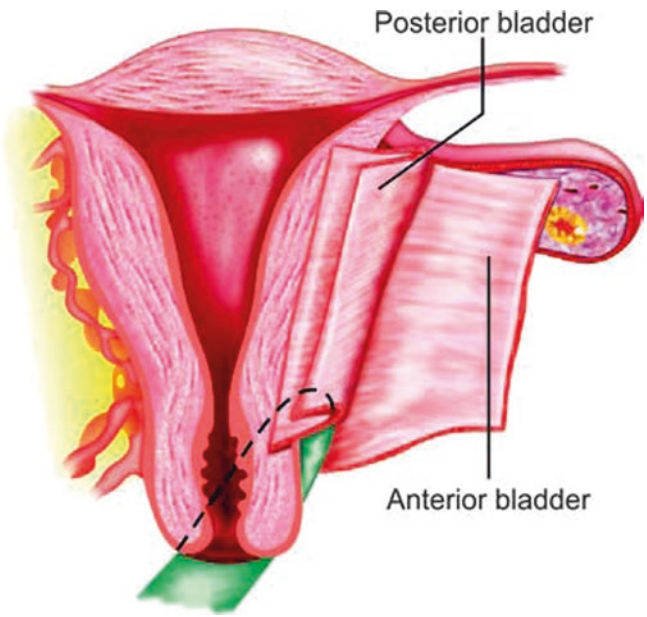

Fig. 114.5 Sagittal section of uterus seen from behind. The leader lines indicate the site of the uterocervical broad ligament space or surgical window going laterally between two leaves of broad ligament (Allahbadia and Sheth [7])

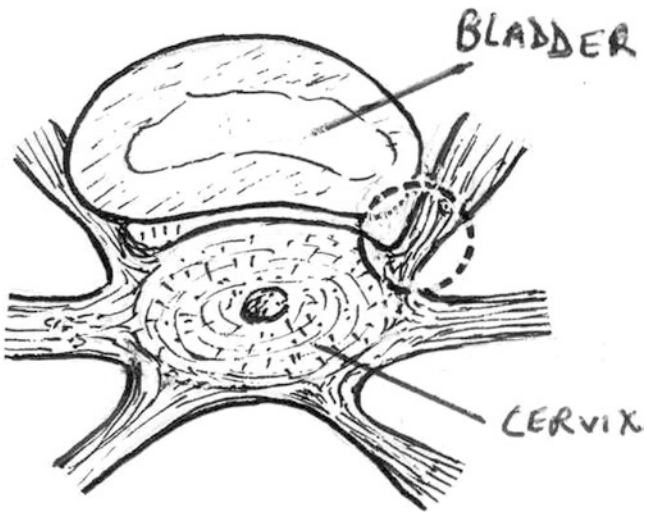

Fig. 114.6 At the lateral angle of the uterovesical junction there is more room, a window or uterocervico broad ligament space (*circle of dotted lines*), to enter the uterovesical space and begin the bladder separation from uterocervical surface (Sheth [3])

space useful for accessing the vesico-uterine peritoneum. At VH in a patient with history of cesarean(s) in the past, Khung chooses to separate the lateral non-adherent portion of the bladder through a surgical window lateral to the midline on the anterior cervix or Sheth's uterocervical broad ligament space (Figs. 114.4, 114.5, 114.6, and 114.7) [3, 6, 10, 19, 20] and the same space is utilized at the time of laparoscopic hysterectomy or abdominal hysterectomy when separation of the bladder in its central portion is difficult or risky by Sizzi and Rossetti [21] who write that "a safer approach is from the lateral, the surgical window described by Sheth which allows a safe, sharp dissection also through laparoscopy, starting from both sides going medially towards the medial portion of the vesico-uterine space". Methylene blue is injected in the described space (Fig. 114.8). Finding the access point from the central area where the bladder is more likely to be adherent in women who have had previous caesarean sections (deliveries) will only increase the risk of traumatizing the bladder as it

is more likely to be adherent in the central 3/5th. All gynecologists who genuinely want to learn and progress can initially choose to practice such sound anatomical access in five to 10 vaginal hysterectomies in women who have had no uterine, particularly previous caesarean sections or caesarean deliveries in the past and therefore are without such adhesions.

The author has routinely used this surgical window for more than 20 years to obtain access to the vesico-uterine space during vaginal hysterectomy in women with a previous history of cesarean section, including many with multiple previous cesarean sections and/or myomectomy in the past including women with a history of uterine rupture following caesarean deliveries [12, 22].

Intra-operatively, when bladder separation is difficult, despite that an attempt must be made to dissect the bladder angle and the uterocervical space as described and if uterine descent and space permit, the index and middle fingers of the left hand can be inserted through the posterior cul-de-sac and brought to the front (preferably near cornual area) or utero-vesical reflection so as to permit an incision of the thin peritoneum as it rests on the fingers under direct vision, followed by severance of the upper pedicles (Fig. 114.9) [6, 19, 22].

The decision to carry out vaginal hysterectomy in women who have had previous caesarean sections should be guided by two questions: 'with the same pelvic findings in a woman, in the absence of caesarean section in the past would I attempt vaginal hysterectomy?' If the response is yes, than the second question is 'will I be able to access the vesico-uterine peritoneum?' Gynaecologists need to remember that previous caesarean sections per se should never contraindicate

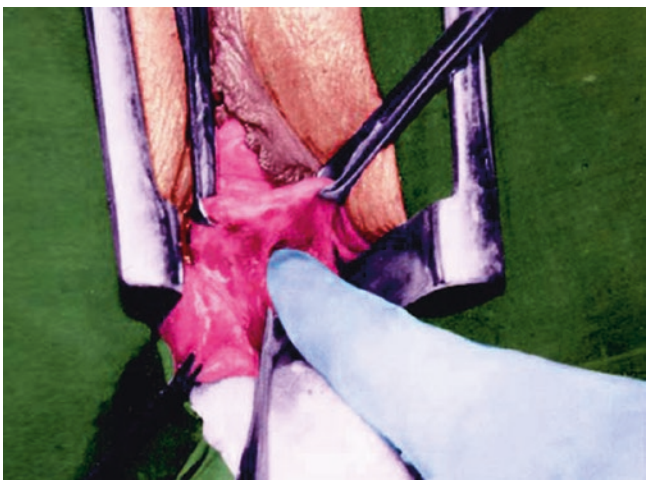

Fig. 114.7 The uterocervical-broad ligament space. The tip of the finger remains on the uterocervical surface, with the bladder anteromedially, as it insinuates further laterally between the two leaves of the broad ligament (Sheth [10])

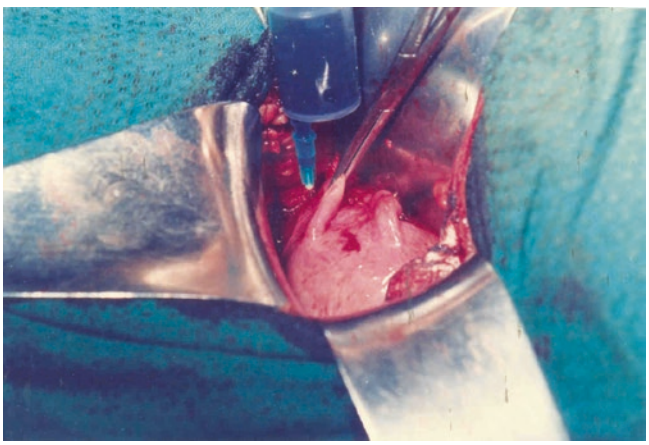

Fig. 114.8 With laparotomy, uterus is seen with its round ligament held by the artery forceps and methylene blue being injected through uterocervical broad ligament space to picturise or demonstrate the same plus its continuity between bladder and uterocervical surface

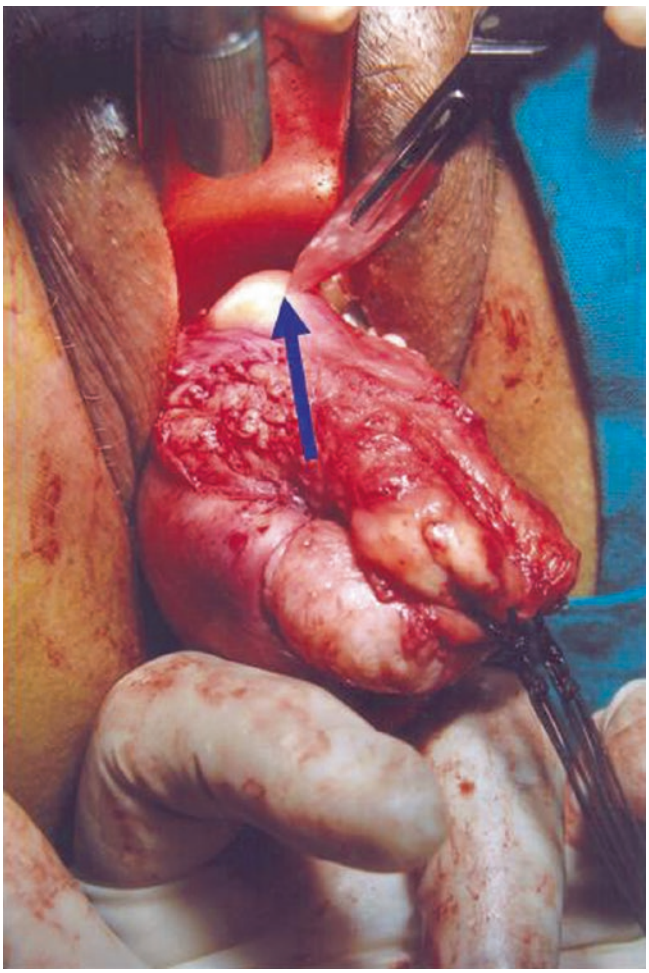

Fig. 114.9 Access to the vesicouterine peritoneum via posterior. After the uterine vessels are secured and the uterine fundus is brought out of the pouch of Douglas (POD) or posterior cul-de-sac and pulled as anteriorly as possible. Finger almost reaches the round ligament laterally, then passes through the POD and exits near the right cornual area. Finally, the finger covered by thin peritoneum insinuates itself and appears anteriorly, near right cornual area. The peritoneum is then incised to allow the finger to pass through it (Figure reproduced with permission granted by FIGO from: Sheth [22])

hysterectomy via the vaginal route. Quite often the adhesions are in the operator's mind and not in patient's pelvis [10, 23].

Surgical technique to access the vesicouterine peritoneum (VUP) in women with history of two or more c deliveries (sections) in the past [13, 19, 22]:

The Technique consists of four operative steps. They are as follows: (1) To enter the cervicouterine surface from both the uterocervical broad ligament spaces; (2) for uteri not enlarged beyond 8–10 weeks, after creating a larger bare cervicouterine surface, access to the VUP is achieved by reaching the lateral uterine serosal surface; (3) when the fundus is reachable and access is still not achieved, an approach is made from EITHER (A) the pouch of Douglas through one of the two techniques given below. This approach is made to achieve bladder separation either by bringing the uterine fundus out from the posterior cul-de-sac anteriorly. A Drooping bladder facilitates separation of the VUP, preferably close to the cornual area and thus leads to the required access (Fig. 114.10) [19], OR the finger is passed from the POD laterally in one of the cornual areas and with the help of tactile sensation emerges anteriorly and the moving finger covered by thin VUP is now incised. The Access so obtained permits placing the bladder retractor and keep the bladder away. Guidance comes from the distance at which the fundus is OR (B) by separating the centrally adherent bladder that is already made free laterally and shows folds and the plane of cleavage. If required, debulking can bring the fundus proximally and (4) when above steps fail the cervix is bisected upward to get a plane of cleavage and access [13, 19, 22].

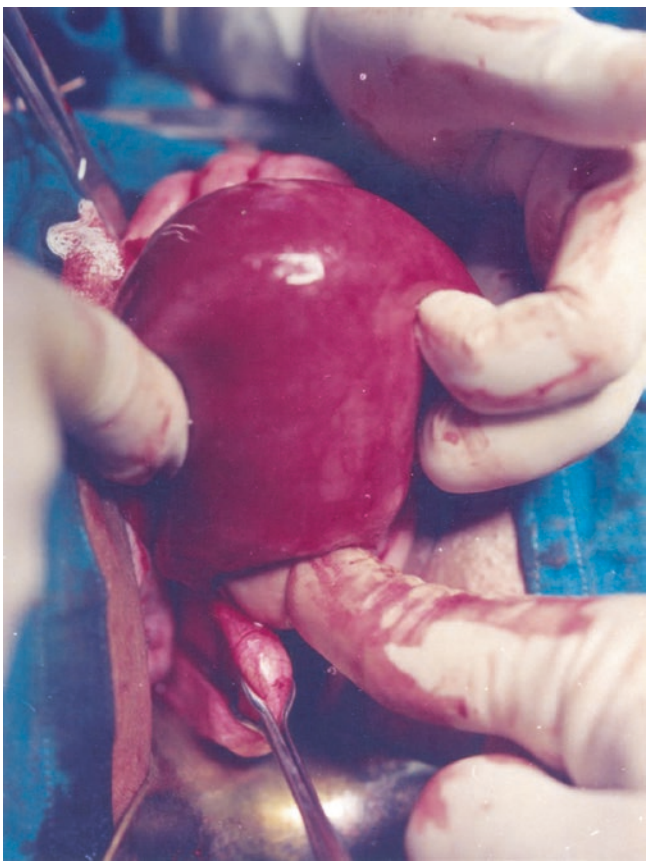

Fig. 114.10 Uterine fundus is delivered from the pouch of Douglas or posterior cul-de-sac and pulled in front. Babcock's forceps clearly show the bladder and site of vesicouterine peritoneum to be accessed – the reverse of what is done at the abdominal hysterectomy for similar access (Allahbadia and Sheth [7])

Adhesions: Pouch of Douglas

Opening the pouch of Douglas or getting access to it is simple and straight-forward (Fig. 114.11). The posterior cul-de-sac is explored with the index finger to exclude adhesions or any other pathology. As a rule, rectal trauma is much less likely than bladder trauma at vaginal hysterectomy. However, when the site is not normal, and when access is difficult, tactile sensation and anatomical planes should be used more carefully to access the pouch of Douglas.

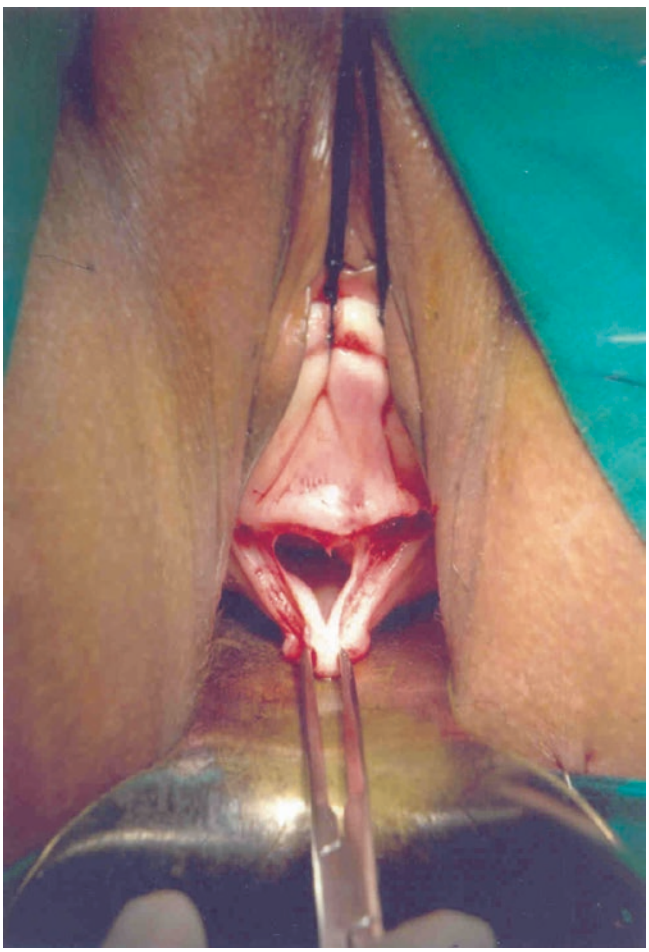

Fig. 114.11 Opening the pouch of Douglas or posterior cul-de-sac is simple and straightforward. Once the peritoneal cavity is reached, speculum is inserted to facilitate further instrumentation and required surgery

In cases of previous pelvic inflammatory disease (PID) or subclinical PID, if a firm band is felt posterolateral to the uterus, cutting it immediately provides 'give' with the required descent. On reaching the highest pedicle in the absence of uterine enlargement, if the uterus does not descend at all, the probable reasons are intestino-omental adhesions with the uterus or sling or previous surgery for prolapse or suspension or band from the abdominal wall to the uterocervical surface. This needs gentle perseverance and if not favourable, a serious consideration be given for changing the technique to either an LAVH or to laparotomy [18].

Posterior uterocervical broadligament space—a surgical space: This is to get an access to obliterated posterior cul-de-sac for VH and perform concomitant salpingo-oophorectomy at VH for ovarian endometriotic cyst.

The safest and most effective approach in these cases is subcervical extraperitoneal tunneling, a tunnel beneath the posterior cervical surface towards the uterine serosa using digital palpation, until the affected area has been passed. It is vital to keep pressure on the posterior cervico-uterine surface and push the soft tissue, if any, away to avoid rectal trauma and mobilize the obliterated area, facilitating dissection until free peritoneal space is encountered. If required, rectal examination is a good guide in these cases. To feel bare the posterior cervico uterine surface is reassuring. Occasionally, even the uterine arteries need to be ligated extraperitoneally as long as they are close to the utero-cervical border. A drop of peritoneal fluid or chocolate-like material should delight the operator as it means access to the peritoneal cavity is obtained. Insertion of a finger or artery forcep through the same opening will then provide further access. Colpotomy performed through the vagina may actually have a lesser potential for morbidity than colpotomy through an abdominal or laparoscopic approach.

Unexpected tubo-ovarian pathological conditions may be recognized while attempting to opening the pouch of douglas; pelvic inflammatory disease, benign ovarian cyst, or ovarian endometriosis, with or without adhesions, can lead to difficulty in surgery [5].

Patients with endometriosis, previous genital tuberculosis, pelvic inflammatory disease, or previous surgery like tubal sterilization, ovarian cystectomy, or oophorectomy via the pouch of Douglas are often found to have distorted or obliterated cul-de-sac. Under these conditions, the distortion of normal anatomical planes increases the risk of standard techniques of colpotomy. Experience through perseverance in contraindicated cases showed that an open space existed in women with a retroverted, retroflexed uterus and space, (described by the author as a posterior uterocervical broad ligament space) for experienced colleagues to attempt a relatively safe and effective approach [13, 19, 24] (Figs. 114.12 and 114.13). Such cases are suitable for LAVH or abdominal hysterectomy, when vaginal route is assessed as difficult or contraindicated.

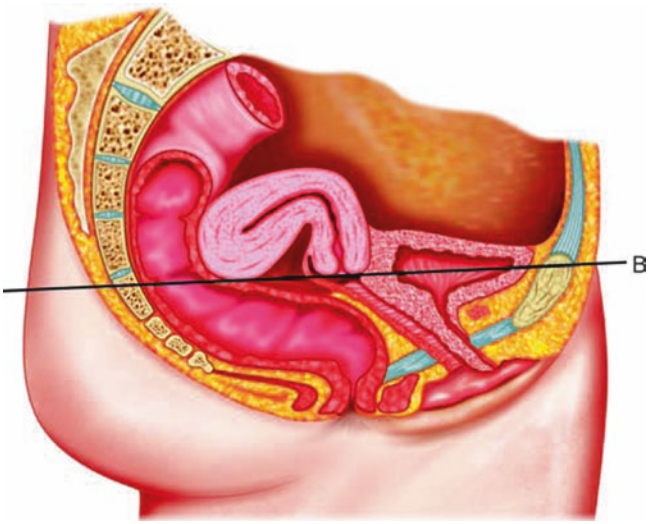

Fig. 114.12 A marked retroversion with retroflexion creates a space between the uterocervical junction and the B line. (Prepared by surgeon, Dr. RD Prabhu, Shimoga, Karnataka India.) (Figure reproduced with permission granted by FIGO from: Sheth [24])

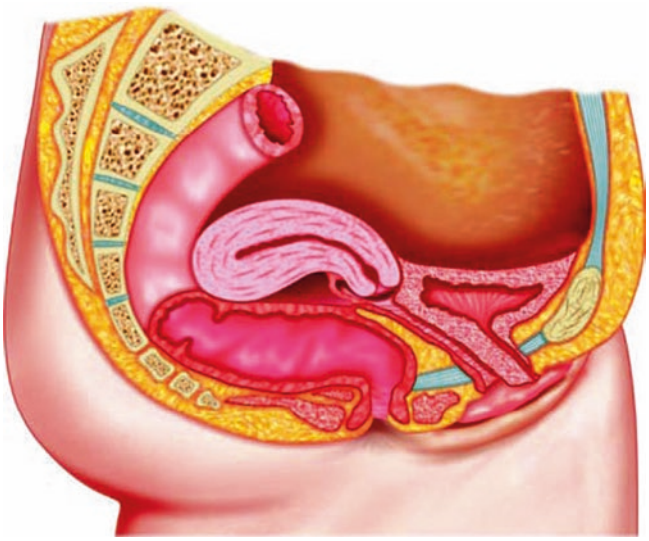

Fig. 114.13 Adherent mass in the posterior uterocervical-broad ligament space. (Prepared by surgeon, Dr. RD Prabhu, Shimoga, Karnataka, India.) (Figure reproduced with permission granted by FIGO from: Sheth [24])

In our experience, adhesions separate easily from below upwards than going from above downwards and allows surgery to be carried out. Entry in an obliterated POD can be obtained by sub-tunnelling and with the use of the posterior surgical window (posterior uterocervical broad ligament space) to separate adhesions above and below , and to gain access to the Pouch of Douglas [24]. The author has utilized the vaginal approach when an endometrial cyst is of 5 cm or

less. Confidence was gained from the past experience of concomitant bilateral salpingo-oophorectomy for mobile, benign adnexal pathology at vaginal hysterectomy and finding many endometrial cysts without any adhesions and/or cysts so small in size that they gave no difficulty in performing salpingo-oophorectomy [12, 24].

Transcervical Access

It is utilized in those cases when the access is risky or impossible by the above methods. The cervix is pulled anteriorly with firm traction. With stout scissors, the surgeon initiates a full-thickness division of the posterior cervical wall in the midline, with one blade inserted in the cervical canal, cutting from canal to external wall, keeping the rectum away until the peritoneum of the cul-de-sac is entered [11, 13, 24].

In some cases of pelvic endometriosis, involving one or both ovaries, there is retraction of the posterior vaginal wall adjacent to the pouch of Douglas. This is demonstrable as a 'Dimple sign', dimpling when the cervix is pulled up with a tenaculum. From the central dimple, the vaginal wall fans out for 1 cm or more in diameter, feels thickened and irregular, and adheres to underlying tissues; beyond this, it assumes its normal free and supple nature. The presence of a dimple in the posterior vaginal wall, adjacent to the pouch of Douglas denotes adhesions due to ovarian endometriosis. Such cases need second thoughts even for the experienced vaginal surgeon. Vaginal hysterectomy is contraindicated in patients with a positive 'Dimple sign' [25]. Attempts to open the pouch of Douglas are attended by a great deal of difficulty because there is no free space and no plane of cleavage; such attempts can result either in the release of chocolate-coloured material OR trauma to the rectum [13, 18, 24].

Adhesions may cover the vaginal mucosa overlapping the anterior or posterior cervical lip and this should not discourage the surgeon, as it needs only a small dissection close to the respective lip to find the space and reach the peritoneum. Rectal examination is a useful guide when the vaginal mucosa overlaps the posterior cervical lip.

Utero Abdominal Wall Adhesions

Uncommonly, caesarean delivery(ies) in past, can result in specific dense adhesions between lower abdominal wall and uterocervical surface (Fig. 114.14), which are diagnosable clinically and sonographically [11, 26]. This contraindicates the vaginal route for hysterectomy even for experienced vaginal surgeons.

Clinical diagnosis comes from the described 'cervico fundal sign' [11, 26] (Fig. 114.15), wherein speculum and bimanual examination findings give (1) the stretched posterior vaginal wall pulled upward in its upper half and inability to clearly visualize the cervix even after the use of an anterior vaginal wall retractor and/or vulsellum, and (2) the cervix is high and almost behind, or close to, the pubic symphysis facing the upper vaginal wall. Traction on the cervix, if possible, pulls the lower abdominal wall inwards, almost dimpling it or tucking it in on speculum examination. It is not possible to palpate the uterus and a highly placed fundus.

Fig. 114.14 Abdomen is opened by infra umbilical right paramedian incision upto pubic symphysis. In the small opened part, peritoneum is held to show the site of uterine fundus. Fundus of the normal uterus is seen placed too high because of adhesions

A positive clinical sign guides the examining gynecologist to suspect dense adhesions, which are classically between the uterocervical surface and the overlying urinary bladder with the surface of lower anterior abdominal wall, with an obliterated uterovesical pouch of the peritoneum (Fig. 114.16) [26]. Consequently, the uterocervical surface almost becomes one with the lower abdominal wall, with a resultant altered anatomy, which is not easily understood even on laparoscopy.

On abdominopelvic sonography in women with suspected intraperitoneal adhesions, altered sonography findings were (1) an elongated, pulled up cervix, (2) easy to identify, a long

Fig. 114.15 Speculum examination in a woman with cesarean sections in past shows a stretched and pulled up posterior vaginal wall and unseen cervix, high up behind pubic symphysis.(Sheth [11])

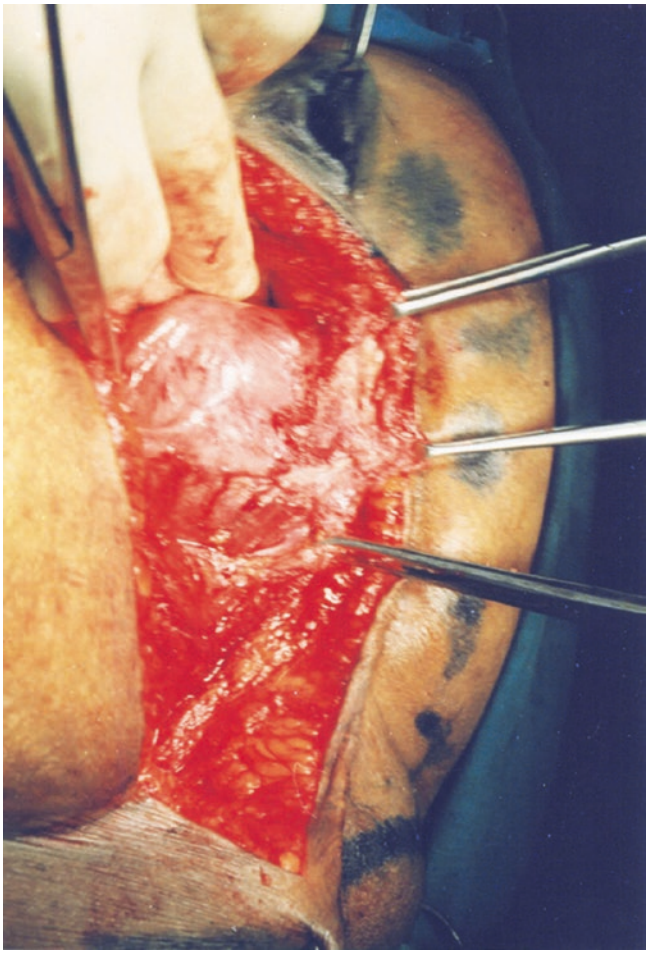

Fig. 114.16 Classic adhesions following cesarean section seen at laparotomy. Deaver's retractor and Allis forceps on the skin marking at the umbilical level close to the upper end of the right paramedian incision. The uterine fundus of normal uterus shown by fingers is well above half way between the symphysis pubis and the umbilicus (Sheth et al. [26])

cervix classically raises the suspicion of adhesions (Fig. 114.17) [27], (3) even a full or overdistended bladder does not appear between the fundus of the uterus and anterior abdominal wall (Fig. 114.18) [27], and (4) the uterus may tend to show retroflexion, forming an angle with the distended urinary bladder [27]. However, still rarer adhesions may manifest with a band binding the same uterocervical surface to the lower abdominal wall and not the uterocervical surface glued to lower abdominal wall surface. The above clinical sign, for glued surfaces, is absent when surfaces are not glued to each other but only a band binds them. Sonography findings will be: Attempt to move the uterus at sonography on releasing probe pressure gives restricted anteroposterior movement, as if it is adherent. Normally after applying probe pressure on the uterus and then releasing it, the uterus moves away from the abdominal wall surface, which is not observed when a band is binding the two.

Figure 114.19 [26] shows that the uterus (5.8 × 5.2 × 6.3 cm), close to 6 weeks size with the fundus located at the L4–5 intervertebral disc level, 14 cm above the symphysis pubis, and about midway between the symphysis pubis and the umbilicus. The anterior wall of the uterus is adherent to the anterior abdominal wall, as evidenced by obliteration of the fat plane on MRI study.

Diagnosis of the adhesions described above has the following advantages: (1) it explains the cause of pain; (2) acts as a warning for laparoscopy particularly the insertion of the Verres needle and trocar; (3) contraindicates VH; (4) it explains the difficulty in performing hysteroscopy and/or curettage; and (5) spares the patient from trauma to the bladder etc.

It should become a routine for every gynecologist who examines a patient with history of cesarean section(s) in the past, to have a careful speculum examination to exclude the 'cervico fundal sign' and the existence of described adhesions. Similarly, the sonologist should make it a routine (1) for every woman with a history of cesarean section

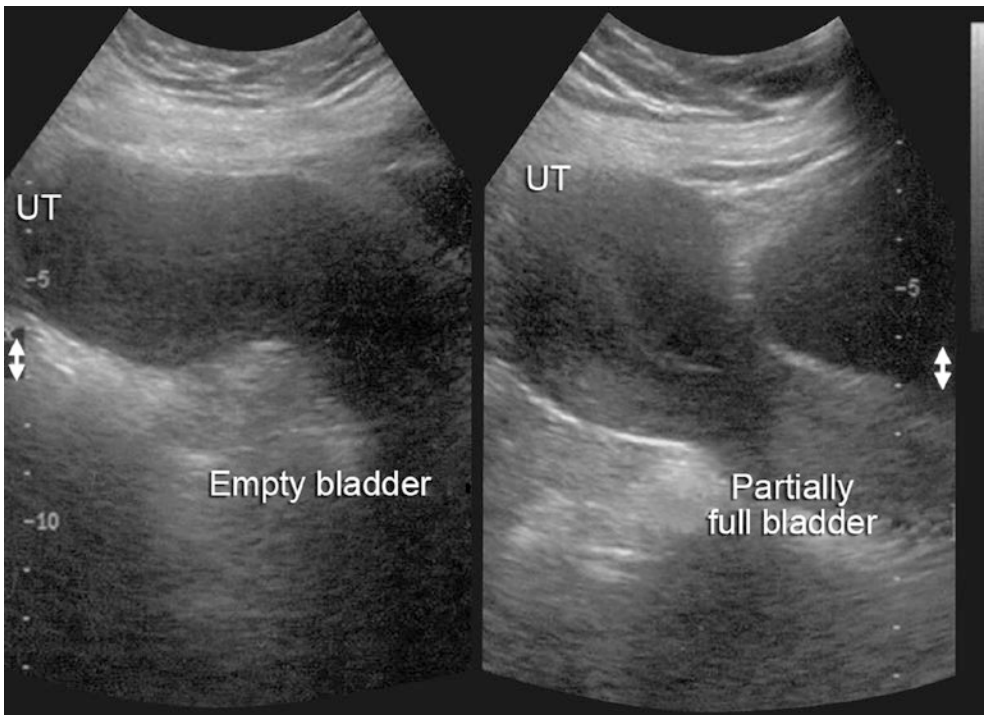

Fig. 114.17 Transabdominal pelvic sonography with empty bladder and partially full bladder in a patient with cesarean section(s) in past shows effect of elongated cervix (Sheth et al. [27])

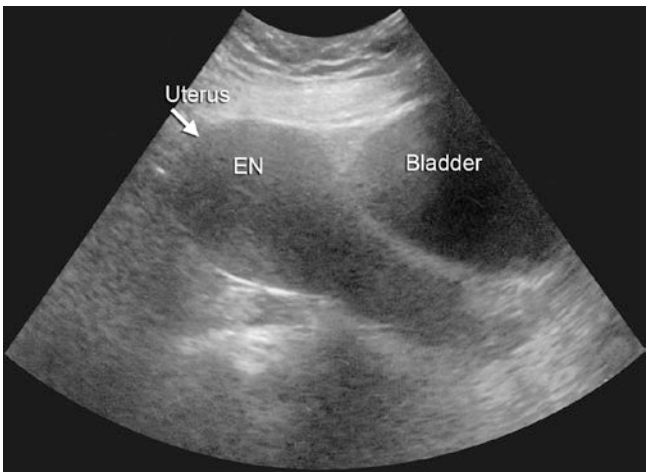

Fig. 114.18 Transabdominal pelvic sonography with full bladder in a patient with prior casarean sections. There is absence of a distended urinary bladder between the fundus of the uterus and the anterior lower abdominal wall (Sheth et al. [27])

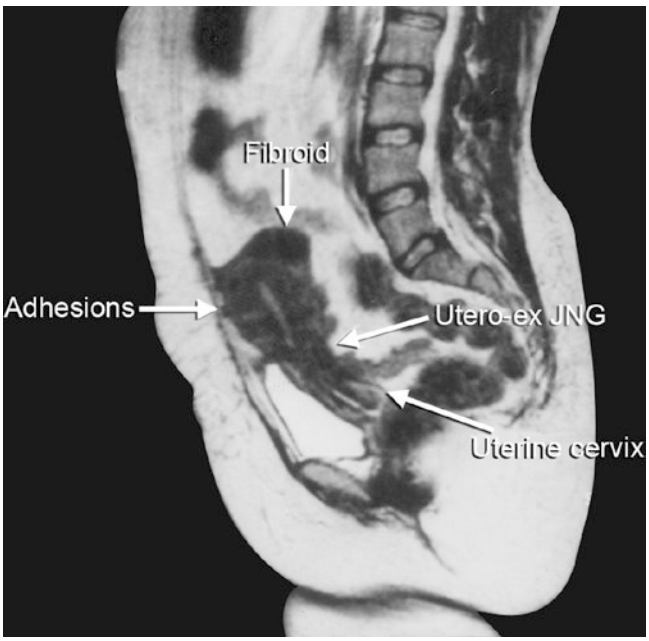

Fig. 114.19 Magnetic resonance imaging (MRI) shows elongated, displacedcervix behind the symphysis pubis facing the upper third of the vaginal wall and adhesions between the bladder and cervical surfaces (Sheth et al. [26])

in the past to look for altered sonography findings and (2) if present, report the possibility of adhesions between surface and surface to the gynecologist including sonography pictures showing an elongated cervix OR restricted antero-posterior movement on releasing probe pressure and the uterus not moving away from the abdominal wall, with absence of clinical cervico fundal sign. Elongated cervix in absence of prolapse, should inspire sonologists to look for each possibility.

The clinical sign and diagnosis are something akin to prenatal diagnosis of placenta percreta with the aid of sonography, based totally on the presence of placenta previa in a woman and a history of one or more cesareans in the past [27, 28].

Adnexal Mass: Adhesions

For benign adnexal pathology, concomitant adnexectomy at VH can be attempted and performed.

Today, the surgical scenario has changed drastically with the availability of a wide range of antibiotics, highly advanced surgical and anesthesia technology, and accurate definition of parameters from the laboratory and imaging sciences. This is adequate reason to consider strongly, reevaluate and even reject old contraindications, if an adnexal mass qualifies for removal vaginally and the pelvic examination findings endorse such a removal; adnexectomy for such pathology should be looked on as a current surgical advance. Thus, presence of an adnexal mass should not be a contraindication to VH but is to be managed vaginally when possible without invasion from a laparoscope.

Benign, mobile adnexal pathology will usually not deter the experienced surgeon who is likely to complete the excision vaginally with patience and perseverance. Suspicion of malignancy or the possibility of tuberculosis will be a contraindication. Success is very satisfying because surgery is with minimal access and is the least invasive. The presence of any adhesion that makes the uterus inseparable or risks traumatizing a hollow organ should be an indication to abandon the 'TRIAL VH' or 'TRIAL vaginal route' and complete the operation with abdominal access, laparoscopic or laparotomy [29].

If a benign adnexal mass is present and the gynecologist chooses to remove it concomitantly at VH, certain prerequisites should be met with. This starts with, case being taken as 'TRIAL VAGINAL ROUTE'.

- Preoperative investigations such as ultrasonography, Doppler studies, and blood CA-125 to indicate the benign nature of the mass.
- Accessibility and free mobility of the mass, which can bring the mass medially into the operative field when held with a Babcock's and/or Ellis' forceps.
- Visibly benign pathology.
- Facilities for frozen histopathology, laparoscopic assistance, and/or laparotomy are available.
- The surgeon has back up experience of vaginal surgery, particularly concomitant salpingo-oophorectomy at VH.
- The woman and her family have been adequately counseled and informed consent taken for a "Trial vaginal route" [30].

For a tubo-ovarian mass, in case of doubt and/or litigious surroundings, counseling, informed consent, and facility for frozen HP are mandatory. The author's experience of VH with concomitant bilateral salpingo-oophorectomy for a twisted gangrenous ovarian cyst in a nullipara was inspirational and should encourage colleagues to plunge more into this challenging sphere [31–34]. When treatment includes hysterectomy and if this is possible via the vaginal route, then let the anxiety and fright of dealing with a twisted ovarian cyst to perform salpingo-oophorectomy via the vaginal route [35] not be a contraindication or an obstacle. Backup experience of BSO at VH as well as dealing with benign adnexal pathology like teratoma or serous cystadenoma concomitantly at VH tilts the balance in favor of the present approach – TRIAL VAGINAL ROUTE – even for such a complicated condition. However, all the enumerated prerequisites must be fulfilled.

Carrying out the entire procedure of hysterectomy with concomitant BSO via the vaginal route, without laparoscopic assistance or laparotomy, would be of great advantage due to reduced morbidity, faster recovery, and shorter hospitalization, besides minimizing invasion and cost. There is no iota of doubt about the superiority of VH over its alternatives, when it can be safely performed [11, 30, 36, 37].

Place of Laparoscopy

An informed consent is obtained for evaluatory or diagnostic laparoscopy or for laparoscopic surgery or laparotomy; hence the patient should be fit for general anaesthesia. Under anaesthesia, a bimanual examination is done and the mobility of the uterus is assessed with and without traction with a vulsellum. If adhesions are expected and present, they are assessed laparoscopically and lysed if required, to make the vaginal surgery easier.

When an experienced vaginal surgeon plans to excise a benign, mobile, adnexal mass vaginally at vaginal hysterectomy, laparoscopy if needed, will confirm the earlier findings, exclude malignancy and tuberculosis, and enhance the possible removal via the vaginal route. A laparoscopic evaluation needs to be differentiated from laparoscopic surgical assistance in carrying out a vaginal hysterectomy. Laparoscopic evaluation is diagnostic and provides information to encourage the surgeon to use the vaginal route or to choose alternatives such as trial vaginal route, LAVH, or laparotomy [13, 18, 23].

Much can be learned from the experience of Kovac, who assessed all his patients scheduled for abdominal hysterectomy by performing a laparoscopy before opening the abdomen and interestingly changed the route to vaginal in large number, thereafter [17].

Place of LAVH

In the USA, a country where litigation is common, the American College of Obstetricians and Gynecologists (ACOG) recommends the following indications to use

the laparoscope to assist vaginal hysterectomy, i.e. by LAVH [38]:

- Lysis of adhesions
- Treatment of pelvic endometriosis
- Difficult oophorectomy
- Fibroid that complicates VH
- Evaluation of abdominal/pelvic cavity.

However, it must be noted that laparoscopic surgery comes into the picture only when oophorectomy is difficult. Let us not make every oophorectomy difficult but instead reduce their number to a minimum and feel satisfied.

Vaginal Assisted Laparoscopic Hysterectomy (VALH)

In select situations, there are times when part of laparoscopic hysterectomy needs to be assisted vaginally to ease and complete the hysterectomy [39].

Role of Anaesthesiologist

Peritoneal traction during salpingo-oophorectomy occasionally induces reflex straining and vomiting because of peritoneal irritation and visceral pain. It is essential that the pelvic structures be well relaxed during this step to provide maximal exposure, and the anesthetist's vigilance and help are of utmost importance in these circumstances. Because of them, for the vaginal surgeon, contraindications get reduced and become interesting indications to innovate and advance the realms of simplified surgery. Success in "difficult situations" leads to a second look at contraindications and helps in the advancement of surgical techniques [1, 13, 23].

Comorbidities Associated with Vaginal Hysterectomy

115

Laila Najjari

The patients selected for vaginal hysterectomy (VH) often have similar concomitants which include Pelvic Organ Prolapse and an overall weakness of the connective tissue as well as adhesions and endometriosis. Further, there are general concomitants such as metabolic syndrome, age, smoking and thromboembolism.

Pelvic Organ Prolapse

One of the main indications of vaginal hysterectomy is Pelvic organ Prolapse (POP). The overall incidence to develop postoperative POP is 4.4 %; the risk to redevelop POP after VH is 11.6 % [1]. Risk factors for recurrent POP include age <60 years and more advanced prolapses [2].

We can differentiate different forms of prolapses depending on the respective location. A common location for a prolapse arising after VH is the anterior vaginal wall. The resultant cystocele can be divided into lateral and central defects (Fig. 115.1). Equally the posterior vaginal wall can be affected, thus causing a rectocele (Fig. 115.2). Enteroceles are quite rare in this context, the incindence is around 1 %.

Finally, vaginal vault prolapses can occur, especially when the vault has not been appropiatley fixed to the uterosacral and cardinal ligaments. In order to prevent a prolapse, studies have shown that suspension of the vaginal apex to the uterosacral ligaments (McCall culdoplasty) or to the sacrospinous ligaments at the time of vaginal hysterectomy is efficient [3].

Urinary Incontinence

Women selected for VH often already suffer preoperatively from urinary incontinence. These women, mostly complaining of urge incontinence, often find that their symptoms improve after the operation due to the absence of the uterus which was formerly applying pressure onto the bladder. Other patients however, experience symptoms of stress incontinence after the operation. These can evolve for two different reasons: either the urinary stress incontinence was

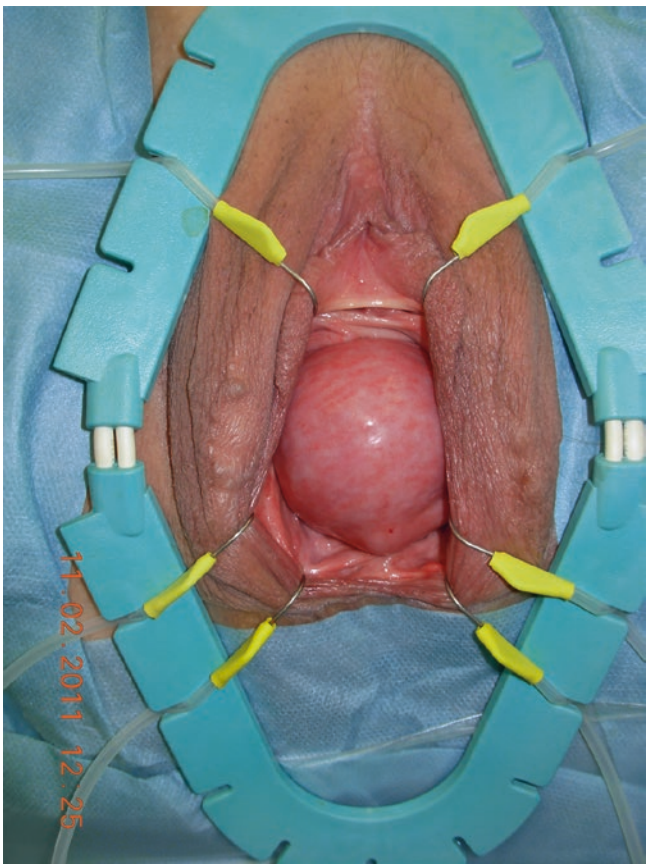

Fig. 115.1 Cystocele, central defect (4.88 × 6.79 cm)

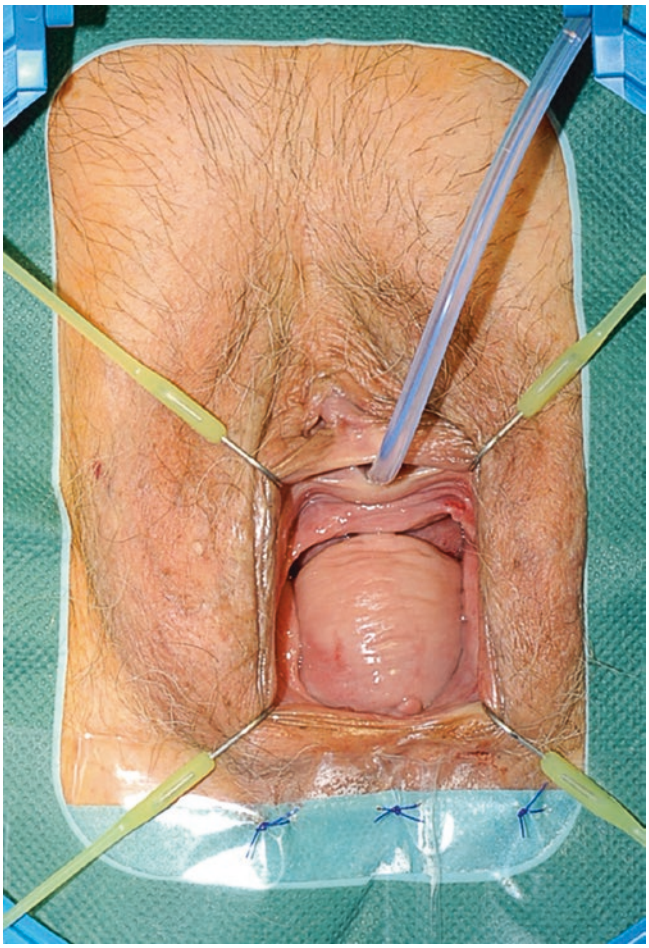

Fig. 115.2 Rectocele (4.88 × 6.79 cm)

there beforehand, this would be a masked incontinence which became symptomatic after the operation, or a de novo stress incontinence which developed due to VH.

Further voiding disorders appearing after VH include dysuria, nycturia and frequent urination.

Vesicovaginal Fistula

Vesicovaginal fistulas are rare with an incidence between 0–0.2 %. They can result from any damage caused to the bladder during the operation. Complaints normally arise around 5–10 days later and can be detected by vaginal inspection or imaging methods such as Cystoscopy, CT, MRT. Treatment normally consists of an early operational closure of the fistula. Depending on its diameter, flaps e.g. from the deep fatty tissue of the labias can be necessary.

Granulation Tissue

Granulation tissue at the end of the vaginal cuff develops quite frequently after vaginal hysterectomy. It is a harmless wound healing disorder and occurs in over 50 % if the vaginal cuff is left open, rarely however if the cuff is closed. The usual treatment is cauterization with silver nitrate. Studies have shown however, that lesions smaller than five millimeters rarely have to be treated as most regress spontaneousley [4]. A rare differential diagnosis is a prolapse of the tubes.

Cysts

Cysts can develop from vaginal epithelium in the vaginal cuff.

Dyspareunia

Dyspareunia can arise from a short, scarred vagina, or a deviation of the vagina, resulting from the closure of the vaginal cuff.

Post-hysterectomy Syndrome

This syndrome shows effects like psychosexual problems and depressions but also symptoms like hot flushes, headaches, dizziness and extreme postoperative tiredness. Most of these symptoms are attributed to a dysfunction of the ovaries but are influenced by psychological, social and cultural factors. To prevent this syndrome a thorough preoperational discussion is essential. Early studies (Richards 1974) have described post-hysterectomy syndrome in up to 70 % of patients. More recent prospective studies however, have found that the postoperative general mood has improved [5].

Dysfunction of the Ovaries

Damage of the ovaries during the operation (e.g. by too much traction) can result in dysfunction. An early menopause can arise from this as well as changes in the lipid and bone metabolism. A topic that is discussed very controversially in this context is the question if removement of the tubes can also cause ovarial dysfunction. Specialists supporting this thesis fear that by removing the tubes the blood supply could be

impaired and thus cause a dysfunction of the ovaries. On the other hand, there is also the opinion that if the right technique is applied, blood supply shouldn't be reduced [6].

Chronic Pelvic Floor Pain

This is defined as vague pain in the lesser pelvis which lasts longer than 6 months. It is rarely treatable.

Pelvic Infection

Vaginal hysterectomy is generally associated with fewer infections than abdominal hysterectomy or laparoscopic hysterectomy. Pelvic infection however, occurs more often in connection with VH than with AH or LH [7].

Removement of Fallopian Tubes

As normally the adnexa are not removed during vaginal hysterectomy, an opportunistic salpingectomy for cancer prevention is not possible. Currently, there is no significant data to say if removal of the fallopian tubes has a protective effect against the development of ovarian or endometrial cancers, so it is not clear if vaginal hysterectomy goes hand in hand with higher risk for cancer [8].

Morcellation

Because morcellation is associated with the spreading of cellular material, it is essential to rule out any malign tumors before morcellation. It has been shown that intra-abdominal morcellation of an unseen leimyosarcoma can correlate with a higher recurrence rate and worse prognosis [9]. The international consensus (SGO [10], FDA [11], ACOG [12], AAGL [13], ESGE [14]) is firstly, that the patient should be thoroughly informed about morcellation, the advantages of this technique, the potential risk of spreading cellular material and any alternatives and secondly, that any uterus with suspicion of malignity should not be morcellated.

Vaginal Total Hysterectomy in Benign Indications: Hysterectomy Techniques in the Normal-Sized Uterus

116

Michael Stark and Dragan Belci

Introduction

Vaginal hysterectomy was introduced already by Langenbeck in 1813 [1], and over the years many different methods were described, such as the Heaney [2], Porges [3], Falk [4], von Theobald [5], Joel-Cohen [6] methods, and the Chicago technique [7], which is a variation of the Heaney method. Each of these methods became the origin of many variations, and in certain hospitals local traditions prevailed.

Vaginal hysterectomy was developed prior to the introduction of antibiotics, and it became very popular in German-speaking countries. With accumulated experience, surgeons became able to remove uteri without prolapse and with large size [8].

For many years, different rates of abdominal or vaginal hysterectomies were performed in different institutions according to local experience and developing traditions. All this changed when endoscopy was introduced and with it the laparoscopic trend of hysterectomy [9].

These days, less vaginal hysterectomies are performed, and in countries with limited resources, where endoscopy has not yet been introduced, hysterectomies are mostly done abdominally.

Many comparisons are made between vaginal and abdominal hysterectomy. In many studies, the outcomes of both methods are compared, but mostly without detailed description of the operative steps.

Obviously, outcomes of surgeries performed by different surgeons and in different hospitals cannot be compared to each other unless the clinical profiles of the study groups (age, weight, size of the uterus, indication etc.) are similar and exactly the same techniques are used by surgeons with a similar level of experience [10].

In each operation, even minor variations can be reflected in big outcome differences. This includes the use of prophylactic antibiotics, the types of anaesthesia and analgesics, suturing or non-suturing of the peritoneum, etc.

Therefore, each step in each operation should firstly be evaluated for its necessity and, if applicable, for its optimal way of performance.

In the last years, many methods were developed in order to reduce the necessity for hysterectomy. These are focused ultrasound [11], the use of GNRA analogues [12], cryomyolysis [13] and microwave treatment of the endometrium [14].

Also the use of abdominal hysterectomy in developed countries has been reduced since it was partially replaced by laparoscopically assisted vaginal hysterectomy. However, in a randomised prospective study, no difference between vaginal hysterectomy and laparoscopically assisted vaginal hysterectomy was found concerning estimated blood loss, postoperative complications and convalescence. The costs of laparoscopically assisted vaginal hysterectomy, however, are considerably higher [15].

Due to all these considerations, it is important to revisit the traditional vaginal hysterectomy in normal-size but also in fibroid uteri and in uteri with or without prolapse in order to find out if this operation can still be simplified and optimised. This chapter is dedicated to normal-sized uteri with or without prolapse, however the principles which are described apply for larger uteri as well.

The Ten-Step Vaginal Hysterectomy

In the line of the idea to find out which steps are essential, six different methods in use were analysed for their way of performance. It became obvious that the number of steps (14–20) as well as their sequence during the operation was different. Only 12 steps were common to all the methods, and therefore they were obviously the most essential. Two of

them, the separate handling of the sacro-uterine ligaments as well as the closure of the peritoneum, were considered unnecessary and were abandoned by us. The remaining ten steps were critically examined for their optimal way of performance, and the restructured operation, as will be described later, has been subject to prospective studies in Italy, Croatia and Bangladesh. In all these studies the Heaney method served as the point of reference for the sake of standardisation. In the Heaney method, after circumcision of the cervix or, in case of cystocele, an inverted c-incision is done and the excess vaginal wall is excised. The anterior peritoneum is opened (occasionally, when technical difficulties occur, the posterior one is opened first). The sacro-uterine ligaments are clamped and sutured and thereafter the lower part of the broad ligament. The uterine arteries are clamped, sutured and cut, followed by the handling of the upper part of the parametrium and the ovarian ligaments. After removal of the uterus, a suture is passed through the anterior vaginal cuff in order to pick up the anterior fold of the peritoneum. The peritoneum is closed and the sacro-uterine ligaments are fixed to the vaginal vault and then tied together to obliterate the cul-de-sac. The rest of the vaginal vault is closed with interrupted sutures.

All the studies comparing the ten-step vaginal hysterectomy to the Heaney method show that the ten-step vaginal hysterectomy results in shorter operation time with reduced need for analgesics and earlier mobilisation.

Method Description

The following description of the ten-step vaginal hysterectomy includes the logic behind the steps and the optimal way to perform them next to the instruments needed for each step.

In many institutions, vaginal hysterectomy is performed in presence of a certain degree of prolapse, and some surgeons prefer the vaginal route in absence of prolapse using the laparoscopically assisted vaginal hysterectomy (LAVH). The ten-step vaginal hysterectomy, however, is suitable for prolapsed as well as non-prolapsed uteri because every non-prolapsed uterus will become prolapsed after completion of step 4.

Positioning of the Patient and the Surgeon

Optimally, the surgeon performing vaginal hysterectomy sits in front of the patient while the assistant stands on his left side. The right-handed surgeon should have access with his right hand to the instrument tray, and the nurse should stand behind him on his right side. Some surgeons prefer working with two assistants, which is not really necessary but enables young gynaecologists to become more familiar with the operative method. The assistant's task is to enable good exposure (Fig. 116.1), help in haemostasis and pull the ligaments when necessary.

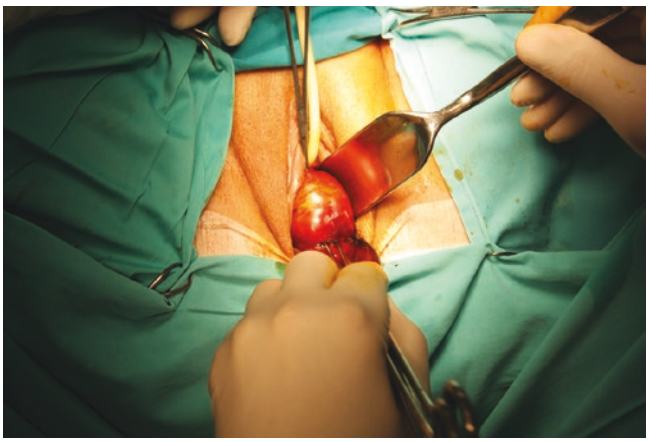

Fig. 116.1 The exposure of the cervix by the assistant

Step 1: Incision of the Vaginal Wall

In a Patient Without Prolapse

The cervix is grasped with two single-toothed tenaculi, and in case of a non-prolapse uterus, the left parametrium is massaged while pulling the tenaculi down in order to get better access. A circular incision is made around the cervix, a few millimetres above the external os. When the right cleavage is reached, the vaginal wall is separated from the cervix, just by pushing it up using a surgical forceps or a swab. The anatomical conditions among women can vary, and occasionally more vaginal retractors are needed in order to expose the cervix to the surgeon. This step should be done under optimal vision.

In a Patient with a Prolapse

Traditionally, most of the described methods begin with a circular incision around the cervix. Thereafter, the vaginal wall is incised vertically toward the orificium urethrae externum. Allis clamps or forceps grasp the edges of the vertical incision and gently the vaginal wall is separated from the bladder by lifting the vaginal wall up and pushing the bladder wall down using a swab on the finger, occasionally assisted by round-tip scissors. Thereafter, the redundant vaginal wall is cut away, leaving a free triangle with its basis on the cervix and its apex below the orificium urethrae externum. After making sure to be in the right cleavage, the scissors are pushed between the bladder and the vaginal wall, with their tips pointing toward the vaginal wall, and then the scissors are opened and pulled out. If performed in this way, this step is bloodless. The figures shown in this article represent a uterus with the prevalent grade II prolapse.

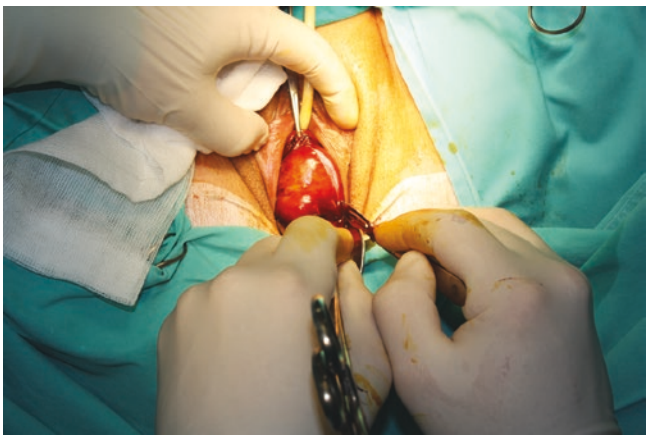

Fig. 116.2 A droplike incision of the vaginal wall starts under the external orifice of the urethra

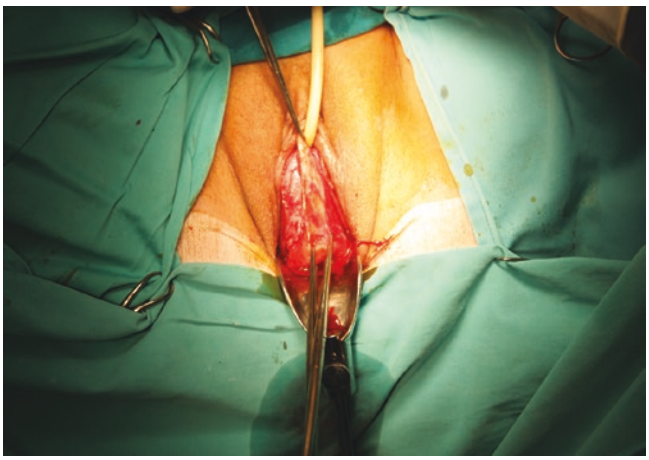

Fig. 116.4 Grasping and lifting the tip of the incised vaginal wall

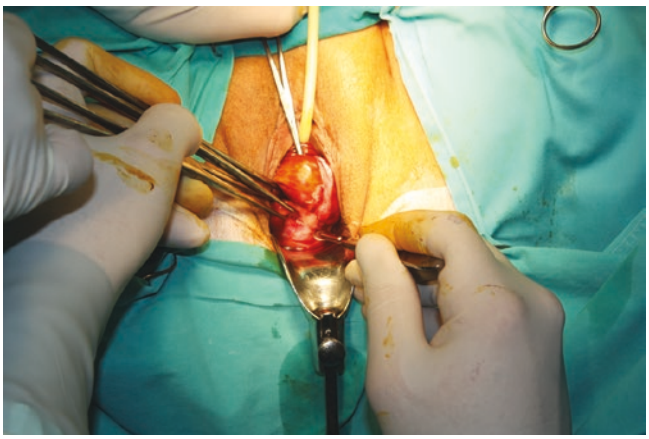

Fig. 116.3 Continuation of the droplike incision behind the cervix

Fig. 116.5 In case of adhesions, using Metzenbaum scissors is needed to separate the vaginal wall from the bladder

Other methods start the separation undermining the vaginal wall after the transverse incision before extending the incision cranially. All variations were analysed, and the simplest and easiest method is the one described by Joel Cohen [6]. In this method, the separation of the vaginal wall starts below the orificium urethrae externum (Fig. 116.2), continuing droplike lateral and caudal around the external os (Fig. 116.3), returning on the other side mediocranial until reaching the starting point.

This approach seems to be easy and logic, mainly in multiparae, where sometimes there are adhesions around the external os and entering the right cleavage when starting from above the cervix might be difficult and there is even a risk of penetrating the bladder.

Now the tip of the triangle is grasped (Fig. 116.4) and pulled toward the surgeon, exposing the lower part of the uterus. Sometimes, adhesions are found around the cervix, and Metzenbaum scissors are needed to separate the vaginal wall from the bladder (Fig. 116.5).

Instruments

Speculum, two single-tooth tenaculi, scalpel, surgical forceps.

Step 2: The Detachment of the Bladder from the Uterus

The border between the wall of the uterus and the bladder must be identified before starting to separate them. A cleavage exists between both structures, and pushing the bladder up without entering it might cause damage. When the right cleavage is identified, the bladder is pushed up with a swab (Fig. 116.6) will separate it from the uterus and also from the lateral vaginal walls. The bladder should be pushed until the anterior peritoneum is exposed. Opening the anterior peritoneum in this stage is not recommended, not just because this disturbs the dynamics of the operation but also because it might cause damage to the bladder when the inter-anatomical relations are not completely clear due to adhesions resulting from previous operations.

Instruments

Allis clamp, scalpel, occasionally scissors.

Step 3: Opening the Posterior Peritoneum

In prolapsed as well as in non-prolapsed uteri it is usually easy to identify the posterior peritoneum, as it is movable over the posterior aspect of the lower part of the uterus and therefore easily movable using surgical forceps. The tenaculi holding the uterus should be pulled up and after making sure that the posterior peritoneum has been correctly identified it should be opened with the tip of a pair of scissors (Fig. 116.7). It is recommended to use long scissors with curved tips like the Metzenbaum scissors, and after cutting the peritoneum the closed scissors should be inserted into the pouch of Douglas, while their tips point towards the uterus. The handles should be opened with two hands and pulled out while the assistant elevates the cervix. Doing so, the insertions of the sacro-uterine ligaments will be exposed. There is no risk of bleeding as there are no blood vessels in the vicinity.

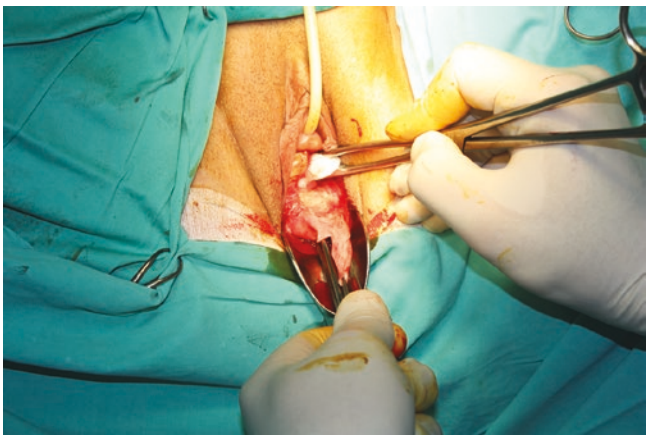

Fig. 116.6 Using a swab the surgeon pushes the bladder up, separating it from the anterior wall of the uterus

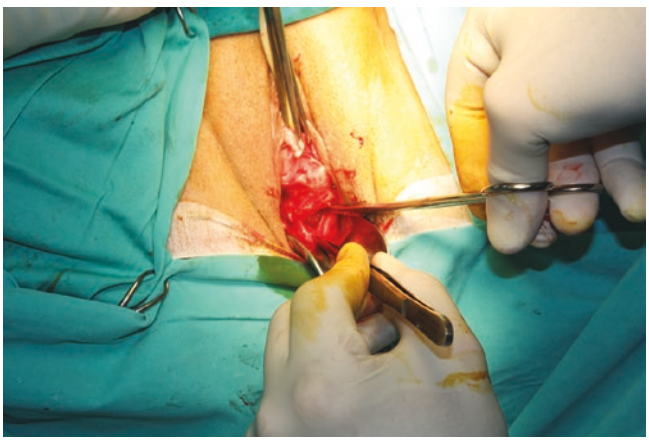

Fig. 116.7 Lifting the uterus up, grasping the peritoneum with surgical forceps and opening it

Instruments

Two tenaculi, cervical forceps, scissors.

Step 4: Dissection of the Lower Part of the Uterus

Conrad Langenbeck as well as his followers used an anatomy-based surgical approach. Therefore each anatomical structure during vaginal hysterectomy was dealt with separately. The sacro-uterine ligaments were firstly clamped, cut and sutured followed by clamping the lower paracervical tissues.

Our approach is functional. The sacro-uterine ligaments are not rich in blood vessels and, although in different anatomical plains, can be clamped together with the paracervical tissues (Fig. 116.8). This is done by a designed manoeuvre when one blade of an open Heaney clamp is placed beneath the insertion of the sacro-uterine ligament (lifting the clamp will assure the surgeon that he is in the right location), and the uterus, still held with the two tenaculi, is rotated toward the clamp while the clamp rotates toward the uterus; doing so, both structures are clamped together. The same is repeated on the other side (Fig. 116.9). A suture is placed as medial as possible, taking both structures, the sacrouterine ligament and the paracervical tissue together. The suturing material is kept long until the end of the operation (Fig. 116.10).

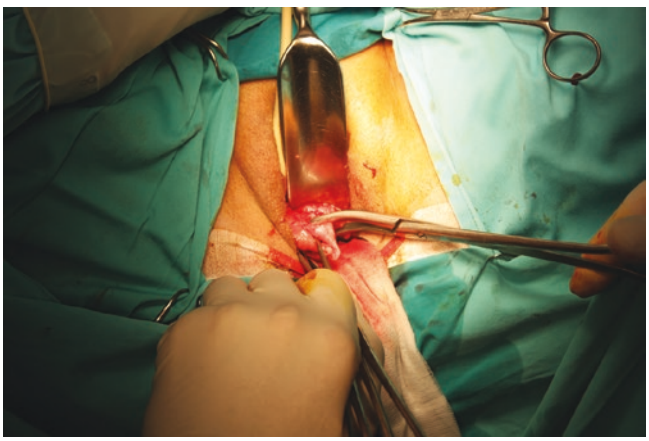

Fig. 116.8 Grasping both sacrouterine ligament and paracervical tissue with one instrument

Cutting both structures will transform any non-prolapsed uterus into a prolapsed one. After the ligation and removal of the Heaney clamp the uterus can be pulled gently to ascertain the access to the uterine arteries. Occasionally in nulliparae or in women with a long cervix an additional step should be made. From this stage and onward no significant difference between prolapsed and non-prolapsed uteri exists.

In the methods based on anatomical structures, anyhow the sacro-uterine ligaments and the parametrium will be sutured together at the end of the operation.

Instruments

Heaney clamp, needle holder, surgical forceps, scissors, two sutures.

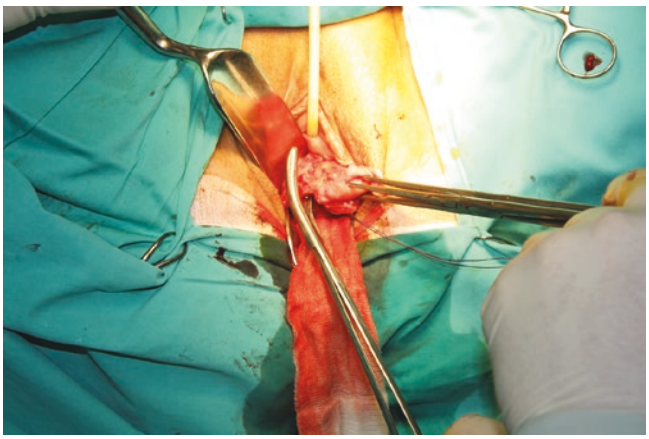

Fig. 116.9 While rotating the uterus toward the Heaney clamp, the sacrouterine ligament and the paracervical tissues of the right side are clamped together

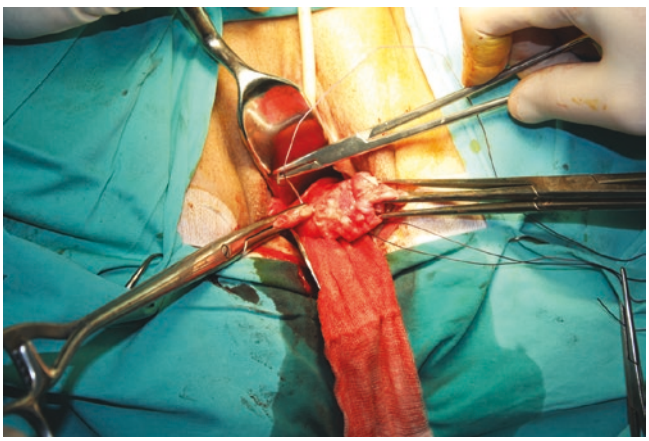

Fig. 116.10 Both structures, the sacrouterine ligament and the paracervical tissue, are sutered together; the thread is left long for the final stage

Step 5: Cutting and Ligating the Uterine Arteries

Pulling the uterus gently, both uterine arteries will be easily exposed. It is very important to identify them, and then to clamp, cut and double-ligate them (Fig. 116.11).

Instruments

Heaney clamp, needle holder, scissors, two sutures.

Step 6: Opening the Anterior Peritoneum

The uterus is pulled down while being slightly rotated. At that stage, with small uteri the fundus can easily be luxated posteriorly and the surgeon can introduce a finger of his left hand behind the fundus in order to lift the anterior peritoneum. It is important that he identifies the peritoneum and reassures himself about the position of the bladder. The peritoneum opens usually during this manoeuvre and under direct vision, and rarely scissors are necessary to cut it (Fig. 116.12). In any operation, each step should be done under direct vision. This applies also to the opening of the anterior peritoneum. Therefore, without or with adhesions which result from previous surgeries, this is the optimal and only method which should be used to open the anterior peritoneum.

This chapter deals with hysterectomy in normal-size uteri, but rotating the uterus and pulling it down can be very helpful also in bigger uteri. And with gained experience, morcellation of the uterus becomes unnecessary. In general, even bigger uteri should not be an absolute contraindication for vaginal hysterectomy.

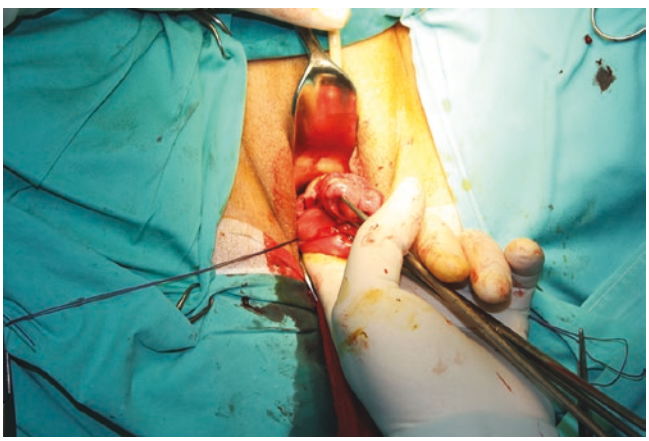

Fig. 116.11 After cutting the uterine arteries, a double suturing is done

Instruments

Scissors (occasionally).

Step 7: Dissection of the Upper Part of the Uterus

The round and ovarian ligaments are clamped together and ligated (Figs. 116.13 and 116.14), while the ligature is placed as lateral as possible from the clamp, leaving the ovarian ligaments as long as possible. While tying the ligature, the Heaney clamp should be gently opened and closed again. This will ensure that the blood vessels will be tied properly (Fig. 116.15). The uterus is now cut away from the ligaments medially from the instrument, and the stump is now transfixed laterally from the instrument and medially from the first ligature. This will prevent bleedings and the ligature guarantees no bleeding in case the transfixion loosens, and the needle should be inserted only after the ligature and after removal of the uterus in order to prevent occasional bleeding in the parametrium (Figs. 116.16, 116.17, and 116.18). The uterus can now be removed, and if oophorectomy is indicated, it can be followed by double clamping the ovarian arteries before removal of the ovary. Oophorectomy often needs more experience and should always be done under vision.

Instruments

Heaney clamp, scissors, needle holder, surgical forceps, four suture materials.

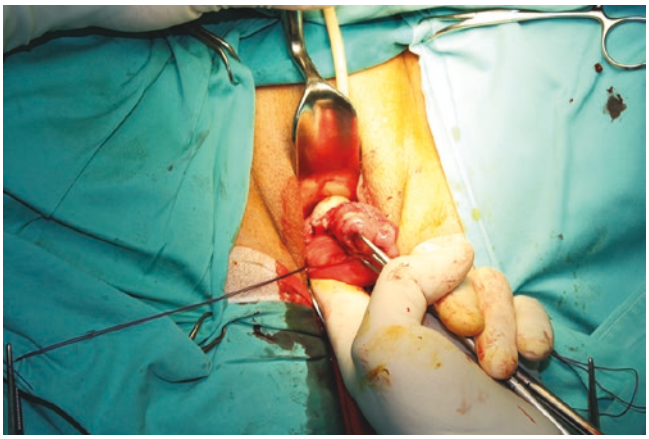

Fig. 116.12 The surgeon inserts his finger behind the uterus lifting the anterior peritoneum and penetrating it

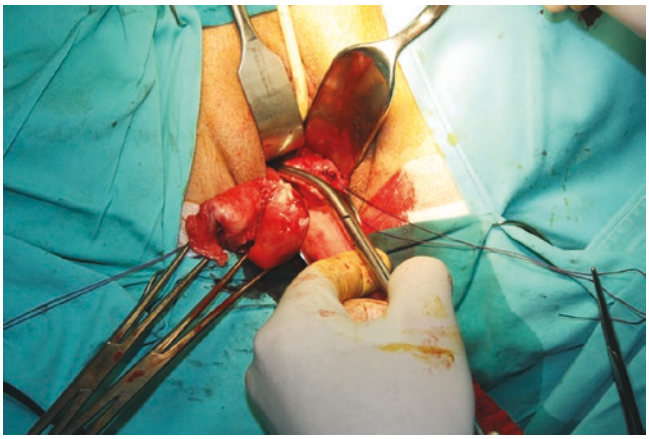

Fig. 116.14 The round and ovarian ligaments are cut and ligated

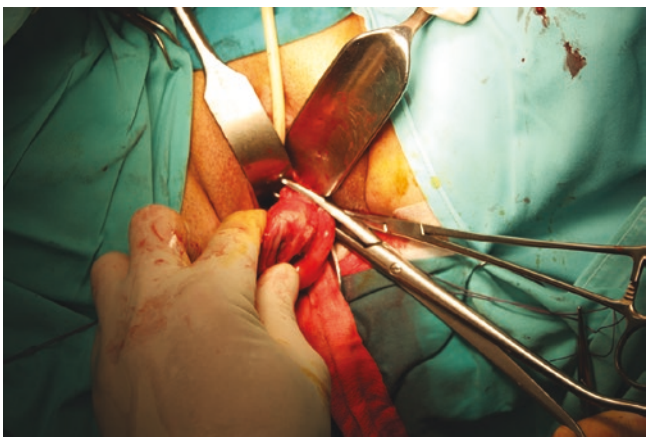

Fig. 116.13 The round and ovarian ligaments are clamped together and ligated

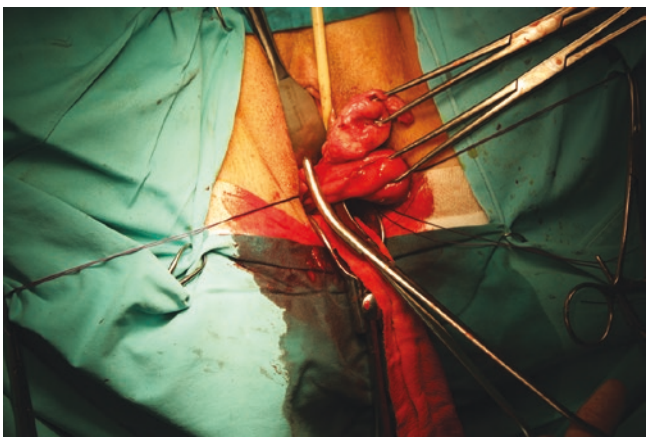

Fig. 116.15 A suture is made first around the ligaments in order to prevent bleeding

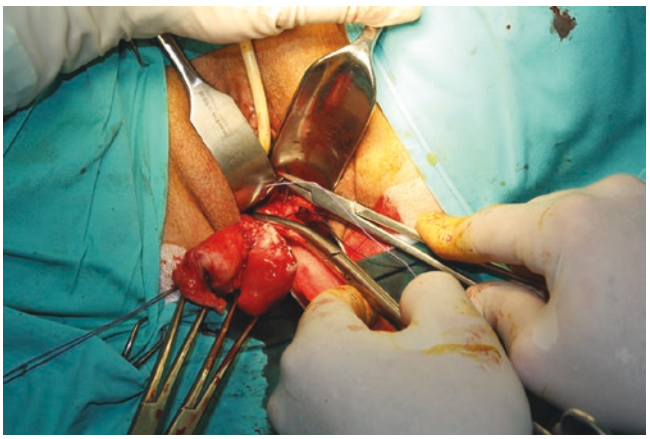

Fig. 116.16 The needle is inserted medially to the ligature in order to prevent haematoma in the parametrium

Fig. 116.17 After removing the uterus, the needle is inserted between the ligature and the Heaney clamp

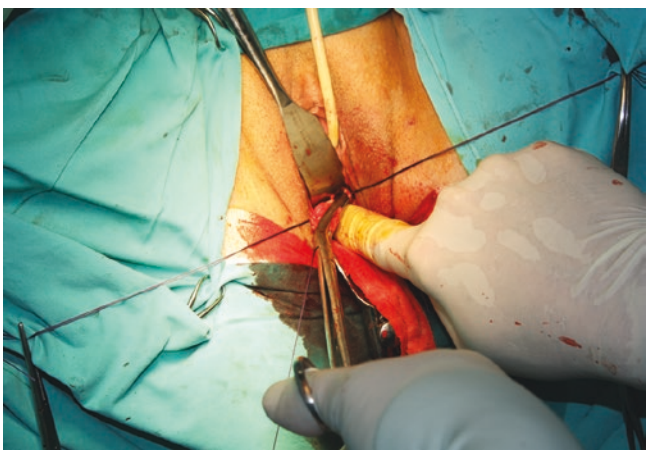

Fig. 116.18 Suturing both the round and ovarian ligaments leaving the suture long

Step 8: The "Non-stage": Leaving the Peritoneum Open and Correcting the Anatomy

In 1980, Harold Ellis suggested that closing the peritoneum is unnecessary. When left open, a new peritoneum will form within days from the coelum cells. Vascular bridges, when the peritoneum is sutured, are formed over sutures and are focus for ischemia and adhesions. In caesarean section, leaving the peritoneum open proved to result in less adhesions [16], and it was shown that its closure is not necessary in vaginal hysterectomy. The British Royal College of Obstetrics and Gynaecology recommended to leave the peritoneum open in its guideline no. 15 of July 2002 with evidence level Ib.

The pelvic parietal peritoneum follows and covers the pelvic ligaments. As will be seen later in step 9, at the end of the operation the ligaments are tied together bringing together the edges of the peritoneum. Leaving the peritoneum open is also an advantage for the free drainage into the peritoneal cavity, where blood can be absorbed by the peritoneum and the lymph channels.

Now is the time to reconstruct anatomy in case of the existence of enterocoele before the continuation of the operation [17].

Step 9: Reconstruction of the Pelvic Floor

The left and right sutures holding the sacro-uterine ligaments together with the paracervical tissues as well as the sutures of the ovarian ligaments are ligated to each other respectively (Figs. 116.19 and 116.20). Sometimes, according to individual anatomical conditions, an extra suture may be necessary to join the ligaments together.

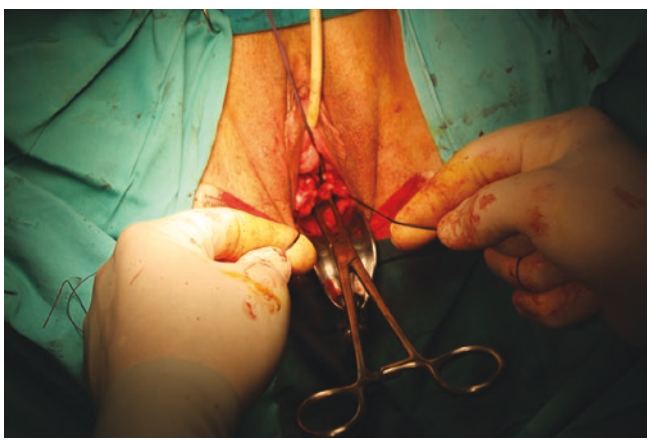

Fig. 116.19 The ovarian ligaments are sutured to each other

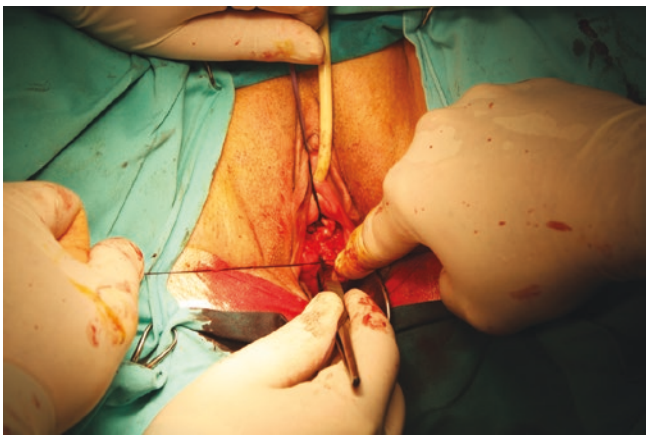

Fig. 116.20 The sacrouterine ligaments and the paracervical tissues are sutured to each other

Instruments

Scissors, needle holder, surgical forceps, one suture (optional).

Step 10: Closing the Vaginal Wall

The vaginal wall should be sutured continuously. In a sexually active woman, it is recommended to suture the vagina transversely. This might prevent dyspareunia, because the suture line will be placed on the upper side of the anterior wall.

Instruments

Allis clamp, needle holder, surgical forceps, scissors, one suture.

Discussion

Each new or modified surgical method should add value to existing ones. In an extensive literature research using Pubmed, there are studies comparing laparascopic and abdominal, or vaginal hysterectomies [18] but no single comparison between different techniques of vaginal hysterectomies was found, in contrast to other surgical methods like caesarean section, where the operation outcomes following different operative details like the way the uterus is opened are compared [19]. The reason is probably the insistence of some surgeons and institutions to adhere to local traditions. Sometimes many variations are made by different surgeons in one hospital. This is the reason why no valid comparison is possible, because results of different methods can only be compared when the surgical steps have been standardised [10].

In the time-honoured abdominal or endoscopic hysterectomy, the surgeon benefits from direct vision of the anatomical structures. The round ligaments, the plica of the bladder, the uterine arteries and the sacro-uterine ligaments are visible during the operation, and the surgeon can and should localise the course of the ureters, and in case of radical surgery be able to open the ureteric canals under vision.

In vaginal hysterectomy, however, a precise knowledge of the anatomy is of utmost importance. The anatomical structures should never be grasped, ligated or cut without being visualised first, but the surgeon must be aware of their location and know how to define them in normal-sized as well as in myomatous uteri, where the anatomy might be distorted.

Therefore, it is optimal that vaginal hysterectomy should be performed by surgeons who are already familiar with different methods of performing hysterectomy.

It is recommended that vaginal hysterectomy should not be part of the first stages of surgical training because the young surgeon has to become familiar at first with the topographic anatomy and its variation, but when he starts operating, it should be under guidance of an experienced surgeon. It is important to start with easy cases where the uterus is relatively mobile and with experience more difficult cases can be performed. The exposure of the surgical field is the key for good orientation and success. Paradoxically, sometimes it is easier to operate nulliparae than multigravidae, where the vaginal walls are relaxed and block the sight. An experienced assistant will be able to guarantee a good exposure.

Until the development of endoscopy, most gynaecologists were trained to do abdominal hysterectomy. Endoscopy opened a new era, firstly because today surgeons can be trained using simulators before starting to operate, and secondly, the tying and haemostasis are done completely differently, and therefore the skills acquired in training are different. Indeed, coagulation can be used also in open surgery, but suturing is done completely differently, and young surgeons that started their training with endoscopic operations do not have the same skills as older surgeons who started their career with open surgery. Indeed, some vaginal surgeons use similar equipment for vessel sealing, like LigaSure, and certain vaginal hysterectomy techniques were developed based on this equipment [20].

Optimally, vaginal hysterectomy should be performed using simple techniques which can be repeated in developed countries in well-equipped facilities as well as in countries with limited resources.

The vaginal hysterectomy for a normal-size uterus can be also used in combination with laparoscopic lymphadenectomy in the Schauta operation [21], can be done partially

using the laparoscopically assisted vaginal hysterectomy [22], but also when using this approach knowledge of the topographic anatomy is important.

One of the main problems are bleedings occurring during the surgery. During the circumcision of the cervix and/or separating the bladder from the body of the uterus, bleedings are not significant and can be easily controlled under direct vision. Bleedings from the uterine arteries after non-optimal ligature, however, are dangerous and difficult to control as the source of the bleeding is usually difficult to determine. It is therefore important that an experienced vaginal surgeon will perform the operation or assist a younger surgeon. Usually, the pulling down of the sacro-uterine ligament and the exposition of the anterior part of the uterus will help to locate the origin of the bleeding. An optimal technique to expose the origin of the bleeding is pulling back the sacro-uterine ligament and pushing up the ovarian ligament. Doing so, a distension of the parametrium occurs, and the stump of the artery becomes visible. Sometimes just the pulling will diminish or even stop the bleeding, which will resume when the tension is relieved. Therefore, the pulling should be done gently with optimal visibility and a good light source.

Re-suturing of the uterine arteries should be done very precisely, keeping in mind constantly the location of the ureter and avoiding the inclusion of any other structure. After separating the sacro-uterine ligament as well as the uterine arteries, together with the paracervical tissues, which include the parametrium, usually the uterus becomes mobile and can be pulled down easily by gently pulling while rotating the cervix.

Separating the sacro-uterine ligament and the paracervical tissues might be difficult for an unexperienced surgeon, but once it becomes customary, there is no obvious difference between prolapsed and non-prolapsed uteri and the ligation of the upper parts becomes easy in both cases.

Oophorectomy, when indicated, should be done by an experienced surgeon with long instruments, with the necessity to make secure suturing in the depth, which also implies the risk of including within the instrument other structures. It is very important to perform this stage only under good vision. It is not a shame to convert the operation to an endoscopic one even in this stage in case of an existing indication for oophorectomy but with technical difficulties to perform it.

When the first study was done comparing two standardised surgical methods for vaginal hysterectomy, the Heaney and the ten-step methods, the result was shorter operation time with reduced need for analgesics (Table 116.1). No variations were tolerated, and if they occurred they were excluded from the study. Due to its simplicity, the fact that only ten instruments and ten suture materials are needed makes this operation optimal also for countries with limited resources, as was shown by a prospective study which was carried out in Bangladesh (Table 116.2a, b). This method is now distributed in Africa, where it has been proven as a valid alternative to abdominal hysterectomy where endoscopy is not available, and even as an alternative for endoscopy where it is available.

One of the main advantages of this method is the ability to perform it using peridural rather than general anaesthesia. This is safer and simple to perform and reduces the need for analgesics in the first hours after surgery.

Table 116.1 Prospective, randomised comparison of vaginal hysterectomies performed by the Heaney and the ten-step vaginal hysterectomy methods [23]

	Heaney method *n* = 52 Median (25th–75th percentile)	Ten-step Vaginal hysterectomy *n* = 44 Median (25th–75th percentile)

[a]Statistically significant ($P < 0.05$)

A surgical method which has been found optimal, easy to learn, perform and teach should be used not just in countries with limited resources but practically everywhere. The New European Surgical Academy initiates surgical workshops concerning the ten-step vaginal hysterectomy in many countries. Recently, the method has been introduced to Croatia, Armenia, Senegal and Burkina Faso. FIGO and SAGO – the African society of gynaecology and obstetrics – are supporting these activities. The introduction of this method is suggested in any surgical service.

Although vaginal hysterectomy is occasionally done in presence of endometrial cancer [25], it is highly recommended to use this operation for benign conditions, and therefore no vaginal hysterectomy should be done unless the endometrium has been evaluated prior to the operation.

Hysterectomy Techniques for the Large Uterus

117

Stephen R. Kovac

Introduction

Fibroids are the most frequent benign growths of the uterus, and symptomatic fibroids are the most frequent indication for hysterectomy. Present treatment alternatives of fibroids for women who wish to preserve their fertility include management with oral contraceptives, GnRH agonists, or nonsteriodal antii-flammatory agents. Alternatives to traditional myomectomy include radiographic uterine artery embolization, laparoscopic uterine artery occlusion, and magnetic resonance imaging –guided high frequency ultrasound. Esmya, ulipristal acetate, has been used in Europe to reduce myomas size prior to myomsctomy. However, hysterectomy is the standard approach for symptomatic patients with large fibroid uteri who do not desire uterine preservation.

Uterine Size

The normal uterus weighs approximately 70–125 g. Most patients (80 %) undergoing hysterectomy do not have uteri that exceed the 280 g limit suggested by ACOG as an indication for abdominal removal, yet the most frequent indication for abdominal hysterectomy is leiomyomata or an "enlarged uterus" (Table 117.1).

What is considered an enlarged uterus must be accurately determined as many gynecologic surgeons consider that an "enlarged uterus" demand the abdominal approach. It is our experience when the uterus is weighed in the pathology lab that the presumed "enlarged uterus" may not be well documented. Currently the definition of an "enlarged uterus" is >280 g (12 week gestational size).

S.R. Kovac
Department Of Gynecology/Obstetrics,
Emory University School of Medicine,
Clifton Road, Atlanta, DeKalb/GA 30322, USA
e-mail: skovac@emory.edu

I believe it is more appropriate to measure and describe the size of the uterus in grams rather than by gestational size, which is really an obstetrical measurement. In the U.S. 80 % of all uteri removed for all indications were <280 g [1]. Thus, in contrast to the belief that many uteri are enlarged and require abdominal-type approaches for hysterectomy, have not really been proven. This chapter discusses the techniques for removal of uteri >280 g by the vaginal route. The only indications that make the uterus enlarged are fibroids and adenomyosis. In my personal study of 10,808 hysterectomies, 2593 were performed for leiomyomata with uterine weight/mean range was 255.8 g (90–2928 g), only 502 had uterine weights >280 g. For 308 cases of adenomyosis the uterine weight/mean range was 163.2 g (60–425 g) with only 11 cases exceeding 280 g. All other indications for uterine removal were <280 g (Table 117.2).

Uterine size reduction methods were only required when the uterus was >280 g.

Pelvic examination alone can frequently overestimate uterine size that is considered a contraindication to VH. Therefore, ultrasonic measurement of the uterus can accurately measure uterine size with 98 % accuracy and should be performed preoperatively before presuming a uterine size that is too enlarged and requires abdominal or laparoscopic-type approaches. In an article published in 1991, it was suggested that there were some inconsistencies in the preoperative assessment of uterine size [4]. The size

Table 117.1 Uterine weight and gestational size

Size of uterus	Weight (g)
Normal uterus	
Nulliparous	70
Multiparous	75–125
Enlarged uterus (Gestational size) (week)	
8	125–150
12	280–320
24	580–620
Term	1000–1100

HX history

or weight of the uterus in vivo often can be more accurately and objectively measured by preoperative ultrasonography. An algebraic formula is used to determine uterine size expressed in measurements and weights. By multiplying the three dimensions of the uterus in centimeters (length × width × anterioposterior diameter at the fundus) × 0.52, a more accurate assessment of preoperative estimate of uterine size can be obtained. ACOG and other investigators over the last 100 years assert that a vaginal hysterectomy is appropriately indicated in women with mobile uteri< 12 weeks of gestational size, thus suggesting that removal of uteri heavier than 280 g is appropriately performed by the abdominal route. However, uterine size may be frequently overestimated with pelvic examination and without more objective criteria, Because 80 % of uteri removed in the United States for various indications weigh<280 g [1] and many are removed by the abdominal route, because of the belief they are too enlarged for vaginal removal suggests that the abdominal approach is overutilized in many cases where the actual size of the uterus is really not a contraindication to the vaginal route (Do not delete!.). Accurate and objective evaluation of uterine size may allow surgeons to perform vaginal hysterectomy on uteri thought to be too enlarged when they are not, so they might gain experience with the vaginal method and may move on with confidence with to remove larger uteri vaginally as they gain experience with size reduction techniques. (Do not delete) Vaginal hysterectomy for the enlarged uterus is a concept of more than 100 years old, yet today is considered a difficult method to learn. In the nineteenth century, when laparotomy was dangerous because of suboptimal knowledge of anesthesia, blood transfusions and antibiotic therapy, this procedure was particularly relevant. Although considered a heroic procedure at the time, these techniques have greatly assisted to the development of vaginal surgery.

The pioneer surgeons in gynecology, especially in the days before aseptic techniques, found that they could remove major growths thru the vagina with greater safety than they could thru the abdominal wall. In the earliest days of gynecology, death regularly followed laparotomy. Recovery from vaginal self-removal of the uterus had been observed, so several of the early, braver gynecologists began their attempts to relieve those suffering women by planned vaginal hysterectomy. There was intense opposition to their efforts, but they persisted despite it. Soon, almost all types of serious pelvic disease, ranging from acute to chronic adnexal inflammation to large uterine and ovarian tumors, were being approached successfully through the vagina [4–7].

By the late nineteenth century vaginal hysterectomy had become a safe operation and was favored over the abdominal route because of the risk of laparotomy. Morcellation originated as a means for the removal of large, pedunculated, submucosal myomas.

Morcellation

Morcellation of the uterus was pioneered in the 1830s by Dupuytren and Velapeau, and by Anussat of France who removed a 440 g uterus in1840. Viennese surgeons Czerny, Billroth, Miller and others beginning in1879 published the first description of vaginal hysterectomy by hemisection in 1882. This was followed by Pean, Segond and Richelot of Paris, and by Jacobs of Brussels, between 1883 and 1890 [8]. A series of cases appeared in the 1860s and 1870s, and in 1881 Haiden reported 52 cases with a mortality of 32 %. By 1879 Czerny progressed to the point of standardized his own technique, and from then on the risks dropped rapidly to 5 % in his series reported in the 1890s. This procedure gained popularity among French gynecologists, and in 1895 Garceau reported more than 400 Vaginal hysterectomies with morcellation with a 1.7 % mortality rate [9]. Pean reported 60 cases of vaginal hysterectomy with large fibroids in 1886, and all patients survived the operation. This was in contrast to a study Pean published in 1881 of 51 women with large fibroids, treated by abdominal hysterectomy in which 18 died for a mortality rate of 35 %.

Siginicant contribution to morcellation techniques were made by Pryor of New York and Doyen of Paris in the 1890s [10]. Pryor popularized vaginal hysterectomy hemisection as an effective approached to the treatment of advanced pelvic inflammatory disease, achieving a remarkable 0.4 % mortality rate in 228 consecutive cases. Doyen described a very efficient method of morcellating enlarged, solid myomas with coring tubes [11]. Intramyometrial coring was introduced by Lash, of Chicago, in 1941 [12].

In the modern era, morcellation continues to be a useful approach for attacking increasingly larger uteri in skilled hands. The 1000 g mark has been surpassed by many, most notably by Kudo of Japan who reported 108 cases among 9230 vaginal hysterectomies between 1955 and 1987 [13], and by Pelosi who surpassed the 2000 g mark with the removal of a 2003 g fibroid uterus by total vaginal hysterectomy in 1996 [14], and by the author who removed a 2928 g fibroid uterus by vaginal hysterectomy in 1999 [15].

Indications for Morcellation

In the case of a slightly enlarged uterus larger than the adult fist in size, the need for size reduction techniques are dictated by clinical observation, during surgery. When it is deemed impossible to access the upper pedicles by simple traction or flipping the uterus through the posterior fornix. When the surgeon continues to place clamps above the uterine artery, the available space becomes more restricted and attempts to place sutures around the clamps become more difficult. Suturing of the broad ligament above the uterine is really unnecessary because of the few blood vessels within the leaves of the broad ligament do not require suturing. This unfortunate and incorrect misconception has been a major stumbling block for transvaginal removal of the uterus and a source of criticism of the vaginal approach to uterine removal. No clamping is needed above the uterine artery until the adnexal.

During abdominal hysterectomy the upper leaves of the broad ligament are infrequently clamped. This older technique of vaginal hysterectomy of sequential clamping the broad ligament should recognize why size reduction methods are successful. Regardless of the size of the uterus, the main blood supply come from the uterine vessels located at the level of the cervix and isthmic region, and accessible for ligation in the great majority of cases.

Sometimes a patient with a small uterus may present difficulty for removal of the uterus in to, either because of limited vaginal exposure or resistance of the uterine supporting structures. In cases such as this, efforts must concentrate on fragmenting the uterus in the midline by hemisection, anterior wedge resection, or coring instead of insisting on an inefficient and sometimes dangerous lateral approach or abandoning the vaginal approach.

Hemisection Technique

Hemisection consists of anterioposterior division of the uterus in two halves, and is a very efficient method for the removal of uteri containing fundal and/or midline fibroids (Fig. 117.1).

The cervix is grasped with clamps at the 3 and 9 o'clock position and traction is applied. A knife is preferable to heavy scissors for incising the cervix anteriorly, then posteriorly with retractors protecting the bladder and rectum. The incision is carried superiorly toward the fundus, always under direct vision, and always through the uterine cavity to assure anatomical orientation. The apex of the incision is pulled into view with clamps applied bilaterally to each edge and the process continued until the uterus is divided into two halves. Sometimes it is useful to place one half of the hemisectioned uterus back inside the pelvic cavity so that surgical exposure is improved, allowing clamping and cutting of the contralateral adnexal pedicle. The remaining half is exteriorized and then removed.

Hemisection also permits removal of relatively small uteri less than 280 g. For uteri > 280 g it may be necessary to combine other size reduction methods. When properly performed, blood loss is minimal during the procedure as a

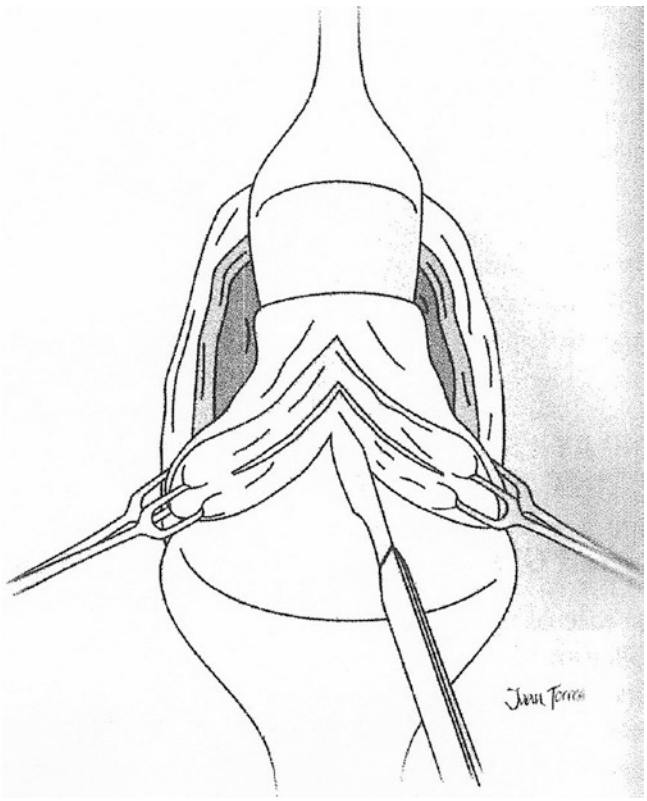

Fig. 117.1 Hemisection of the Uterus (From Kovac and Zimmerman [2, 3] Permission granted from Netto)

result of preliminary ligation of the uteri vessels and compression on the edges of the vaginal cuff by the enlarged uterus, as strong traction is applied. I have no such pictures.

Intramyometrial Coring

Abrahan Lash introduced this technique. Later, the author popularized this procedure in the United States in 1986. Coring is considered best suited of the moderately enlarged globular uterus, The author prefers this technique as the initial method to the start of any size reduction techniques which exposes the inner part of the uterus when the uterus is quite enlarged allowing resection of individual myomas to be grasped and removed or by wedge resection or hemisection (Fig. 117.2a–c).

The procedure begins at the level of the isthmus, below the peritoneal reflection. The myometrium is circularly incised with a scalpel, midway between the serosa and the uterine cavity, after the uterine vessels have been ligated. The drawings and description of the techniques clearly show that coring and hemisection are not similar at all. .As a result the anterioposterior and transverse diameters of the fundus acquires an elongated cylindrical shape. It is important to avoid multiple planes of the incision. As traction is placed on the cervix, the concentric incisions will eventually reach the fundus, and the uterus is progressively exteriorized thru the vagina. The advantages of this method is that the uterine cavity is not penetrated, so there is less chance of injury to adjacent organs, since the circular incisions in the myometrium do not reach the serosa of the uterus. Coring becomes easier once the corpus comes closer to the vaginal introitus. For small or medium size uteri that do descend well, intramyometrial coring can quickly result in delivering the uterus through the vagina and exposing the upper pedicles for clamping. Several examples of intramyometrial coring combined with wedge resection and enucleation of individual fibroids are presented for term-size uteri preoperatively determined to weigh in excess of 1000 g (Fig. 117.3).

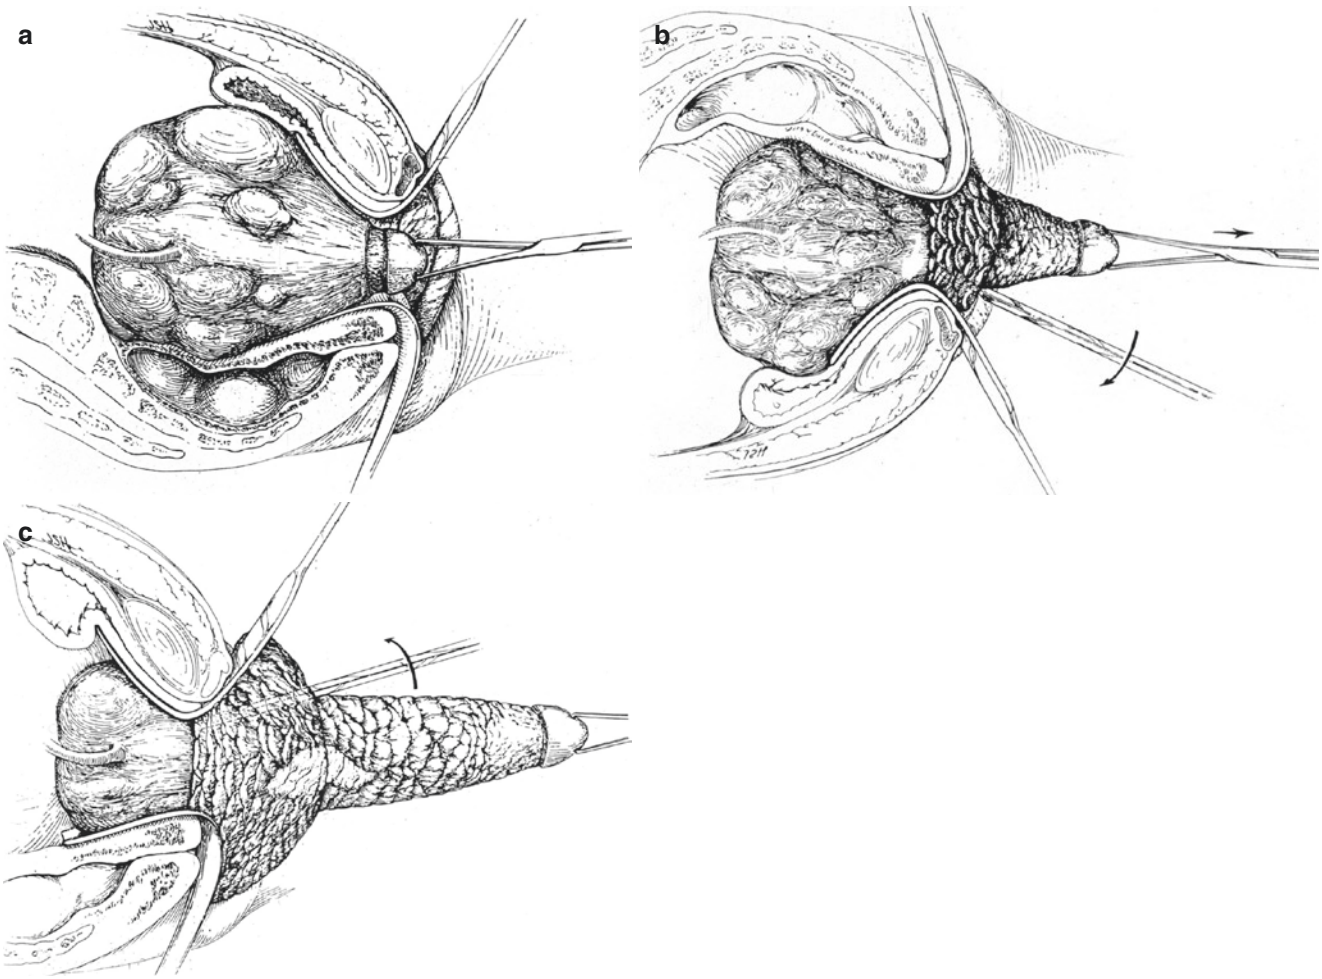

Fig. 117.2 (**a**) The cervix has been circumscribed through the full thickness of the vagina around the cervix, the anterior and posterior entered, and the uterosacral and cardinal ligaments secured. (**b**) After ligation of the uterine arteries, an incision is made in a circumferential fashion parallel to the endometrial cavity, and into the outer superficial myometrium in the same plane. Constant traction on the tenaculum while coring assists in developing the proper plane. (**c**) Continued coring and traction reduces the size of the uterus by exteriorizing the inside of the uterus with an intact endometrial cavity through the introitus. Intramyomural myomas are sometimes transected during the coring process (From Kovac [16])

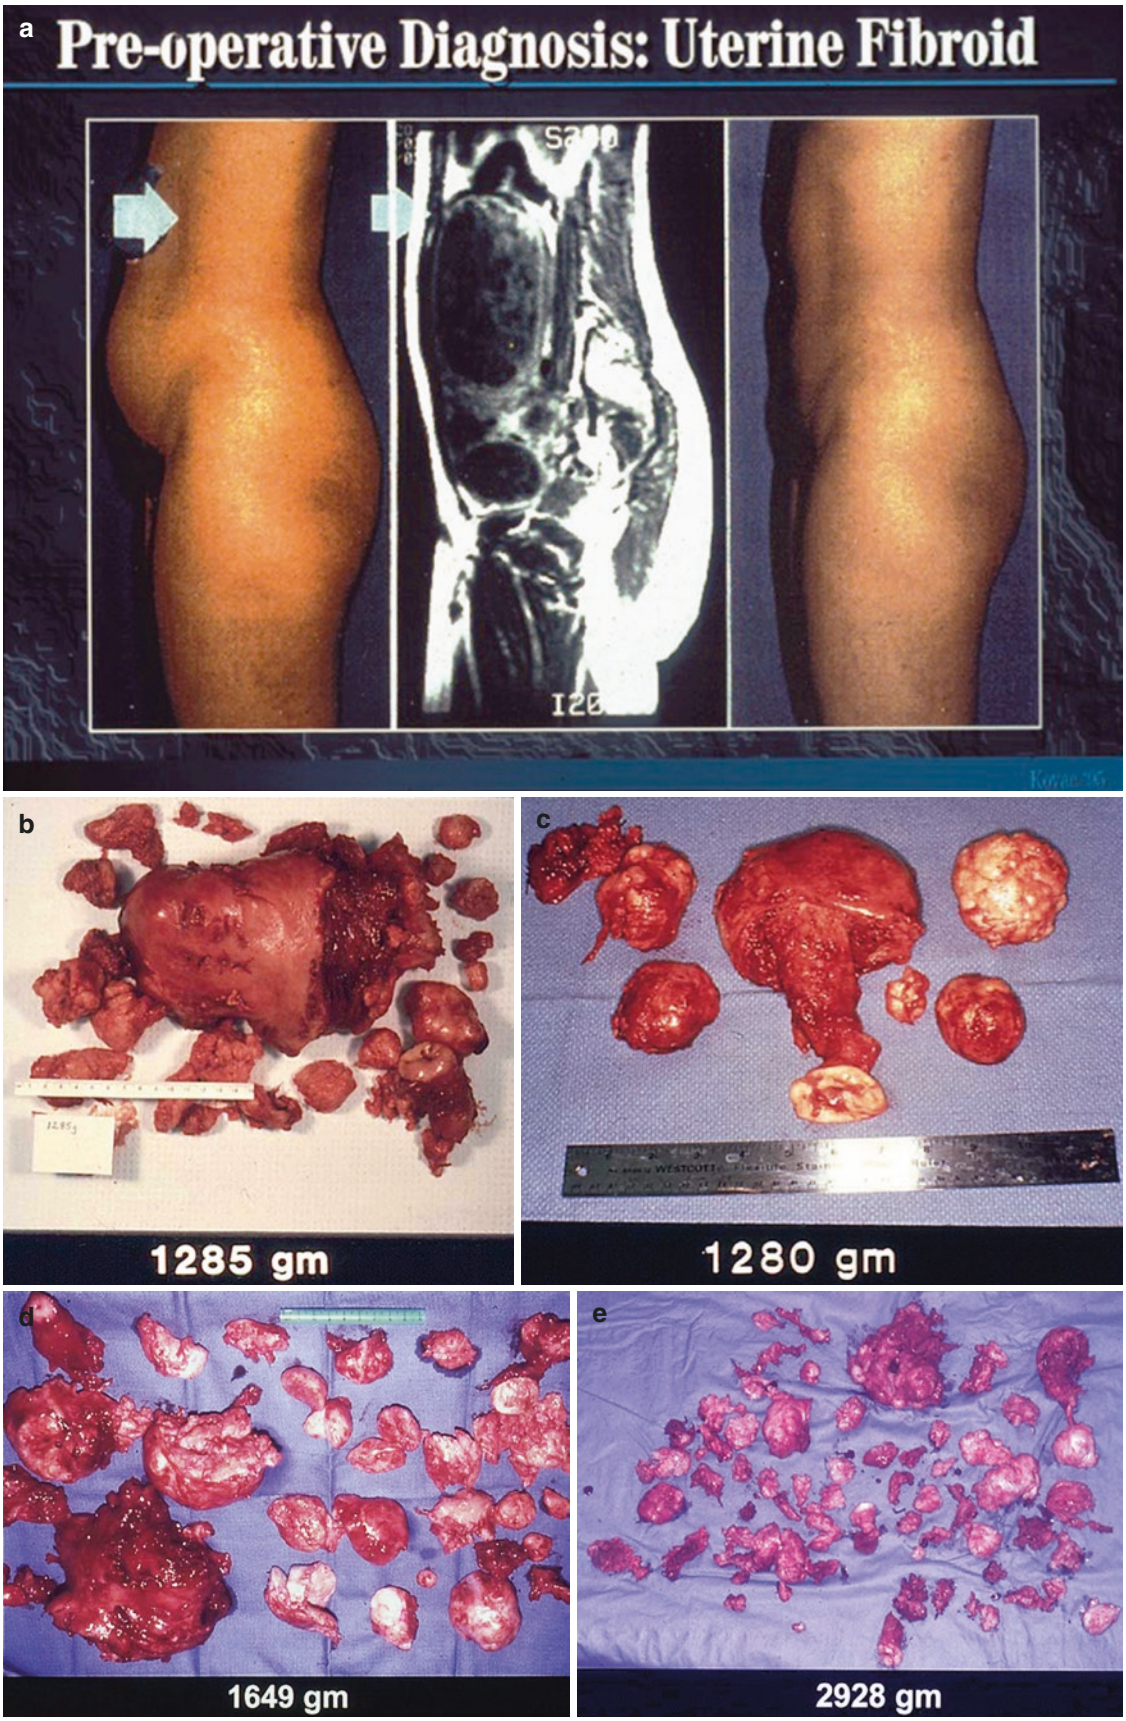

Fig. 117.3 (**a**) Pre and post operative photos after removal of the enlarged fibroid uterus seen on CAT Scan. Preoperative weight by ultrasonography was estimated to be 1200 g. (**b**) Photo of removed uterus from Fig. 117.5. Estimated weight and pathologic weight were quite similar (1285 g). (**c**) Removal of 1280 g uterus with Intrayometrial Coring. (**d**) Removal of 1649 g uterus with Coring and transection of intramural fibroids. (**e**) Removal of 2928 g uterus with coring a transection of many myometrial fibroids (Photo permission granted from Kovac, SR)

Wedge Resection

This is technique of choice for the grossly enlarged particularly when coring and simple hemisection have accomplished all that can do. It is a versatile method, but may require some experience before it is mastered. Wedge resection usually begins with a midline incision and progresses with the removal of small or large incisions of uterine tissue at the apex of these incisions. The central uterine mass is grasped with sturdy clamps or tenaculums and a long scalpel creates oval or triangular wedges of tissue that are removed in the midline (Fig. 117.4).

When the uterus is relatively soft, sometimes it is possible to extract larger pieces of tissue by using coring incisions from partially completed wedges. It is useful to effect bulking symmetrically in the midline of the uterus as this usually results in a rapid access to the adnexal pedicles by avoiding lateral deviation away from one adnexa. One needs to be patient during morcellation with wedge resection of large uteri removing sometimes-small wedges until the uterine mass becomes small enough to be exteriorized from the pelvic cavity. Re: comment:I have no such pictures or drawings.

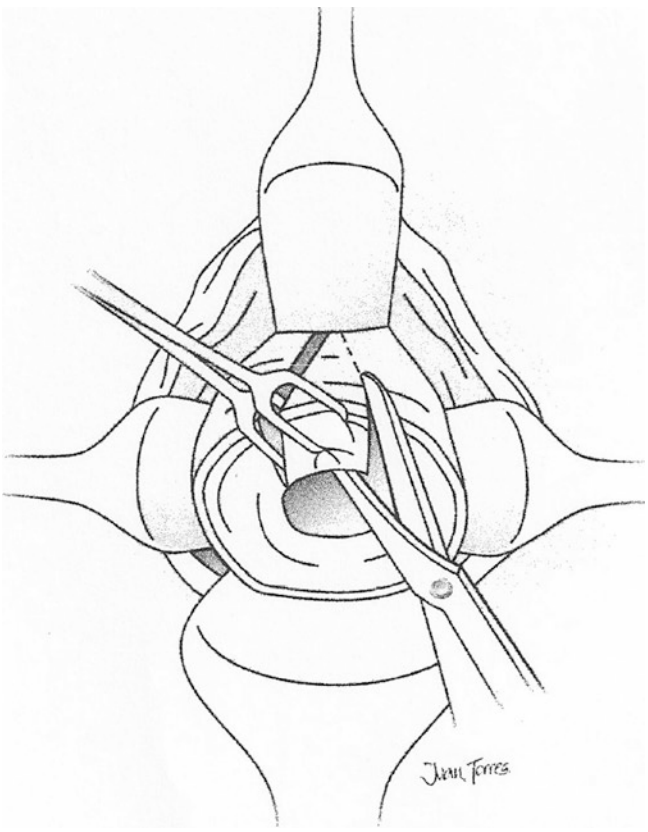

Fig. 117.4 Wedge resection of anterior uterine wall at the level of the isthmus (From Kovac and Zimmerman [2, 3] Permission granted from Netto)

Posterior Fundal Morcellation

This approach is useful after exteriorization of the posterior fundus that does not allow adequate space available for the application of clamps on the superior pedicles. A longituidinal wedge of myometrium can reduce a portion of the uterus containing a fibroid with the greatest volume that widens the space for the placement of clamps on the upper pedicles, and delivery of the remaining specimen (Fig. 117.5a, b).

Cervical Amputation and Myomectomy

In order to facilitate posterior rotation of the uterus, the cervix nay be amputated. Myomas are frequently encountered during the morcellation process regardless of the size reduction techniques employed. Large myomas require morcellation, while small or medium size may be enucleated increasing the mobility of the uterus.

Pryor's Technique

William Rice Pryor of New York described this technique in 1899 and is more of historical value infrequently performed today. This technique is performed, by flipping the uterus, anteriorly. Using this method the uterus is removed similar to the Doderlein-Kronig technique. After ligation of the uterine arteries, the bladder is retracted and the anterior uterine wall incised vertically in the midline. Starting at the level of the cervix, symmetrical pieces of myometrium are resected bilaterally from the midline incision as high as possible. Wedge-shaped pieces of uterine wall are cut bilaterally from the edges of the midline incision, as the everted edges are serialy grapsed and pulled downward, exposing more uterine tissue (Fig. 117.6).

What appears of the uterine tissue is again split in the midline from each side a wedge of tissue is symmetrically removed. Once the corneal regions are visualized, it is useful to excise an extensive wedge at the fundus exposing the adnexa. If anterior morcellation cannot be completed, the cervix is amputated and the posterior wall is morcelleted as for the anterior wall. The remaining uterine attachments are then transected and the uterus removed.

Doyen Method

This method was described by Doyen in 1920 consists of the removal of cylindrical columns of tissue from the myometrium and large fibroids, using a metallic tube with a cutting edge. The cutting portion of the tube is pressed against the central portion of tissue and with rotating

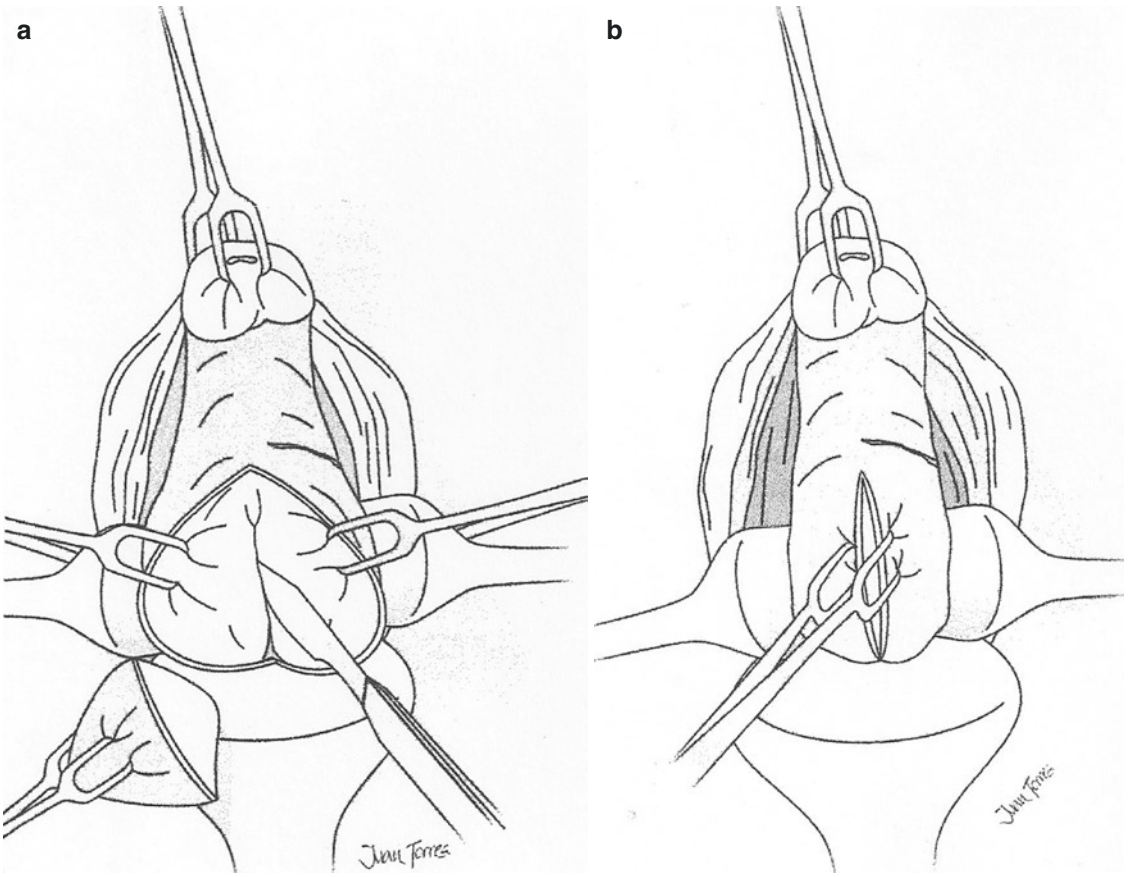

Fig. 117.5 (**a**) Uterus has been rotated posteriorly. If more room is required for rotation the cervix can be amputated. (**b**) After posterior rotation of the uterus, if more space is needed to clamp the upper pedicles, an incision into the posterior wall can remove any posterior wall fibroids restricting the space for upper pedicle clamping (From Kovac and Zimmerman [2, 3] Permission granted from Netto)

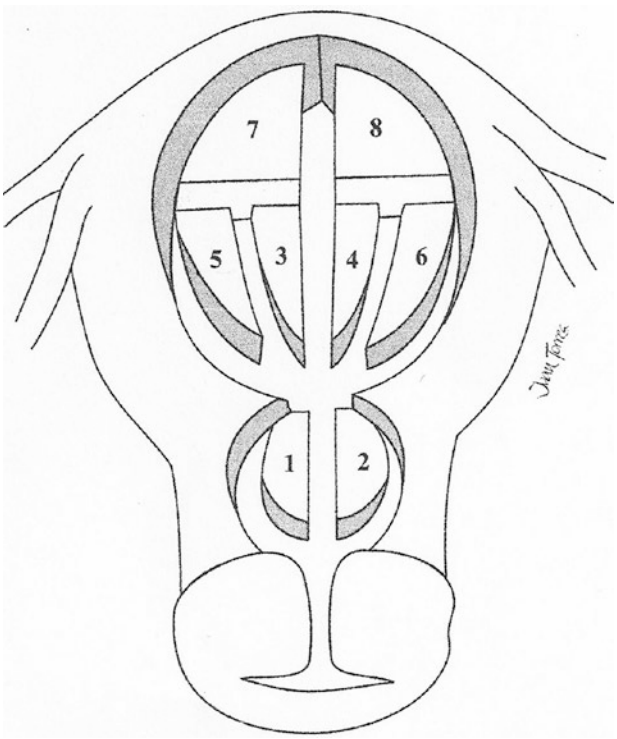

Fig. 117.6 Pryor Technique of uterine morcellation (From Kovac and Zimmerman [2, 3] Permission granted from Netto)

movements, it is advanced to a depth of 3–4 cm. Many columns of tissue can be removed in this fashion, reducing uterine volume through the creation of an artificial cavity (Fig. 117.7).

This method is also of historical value and is infrequently practiced today. The Doyen cylindrical morcellation tube is a tool rarely found for purchase by gynecologic instrumentation companies.

The overwhelming majority of well-selected cases are successfully performed and the confidence and experience of the surgical team increases accordingly. Sometimes a conversion of a vaginal hysterectomy to laparotomy should not be regarded as a complication, but as a demonstration of prudence and, above all, a focus on the patient's well being. Uncontrollable hemorrhage, a pelvic adhesion process of difficult dissection, an extremely enlarged uterus, or an unexpected adnexal tumor normally dictates a change to an abdominal approach. In my experience of 10,808 vaginal hysterectomies I had to convert to a laparotomy in eight cases (.07 %), not all because of an enlarged uterus. In fact a very small uterus because of fixation of the uterus to the anterior abdominal wall required conversion to a laparotomy. When change in approach is necessary, laparotomy should be performed without hesitation Excessive confidence, ostentation or

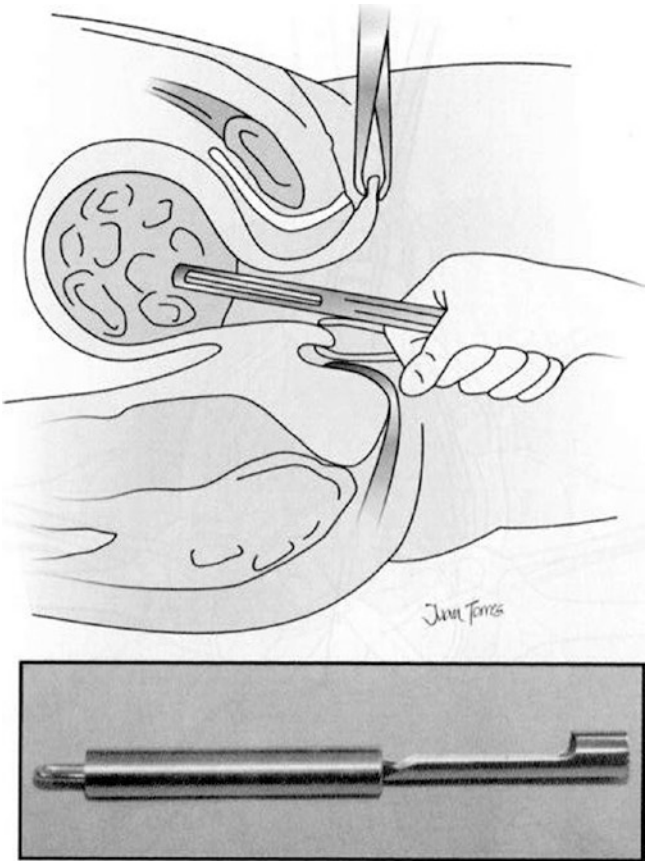

Fig. 117.7 Uterine morcellation using the Doyen Method (From Kovac and Zimmerman [2, 3] Permission granted from Netto)

pride have no place in this type of decision-making as additional problems for the patient may be created. The possibility of conversion to laparotomy should be a part of the informed consent process.

Vaginal Total Hysterectomy in Benign Indications: Hysterectomy Techniques with Bipolar Diathermy System

118

Sumita Mehta and Anshuja Singla

Hysterectomy for benign gynecological disease is one of the most common gynecological procedure and almost 30 % of women by the age of 60 years are hysterectomized. This surgery can be done through several routes; abdominal, vaginal, laparoscopic assisted and more recently robotically; however abdominal hysterectomy has been the preferred route by a 3:1 ratio compared to vaginal hysterectomy [1]. According to the Cochrane review for women undergoing hysterectomy for benign disease, vaginal route appears to be superior to abdominal or laparoscopic route as it is associated with benefits of shorter hospitalization, fewer complications and lower costs [2]. Vaginal hysterectomy has one major drawback of limited space for surgical access. Increased traction applied to the tissues during surgery leads to increased postoperative micturition symptoms and shortened vagina, vis-à-vis total laparoscopic intrafascial hysterectomy (TLIH) which encompasses the benefits of total and sub-total hysterectomy with few complications. Using a uterine manipulator and colpotomizer, the uterosacral ligaments are incised higher and the cervix is circumscribed while preserving the entire uterosacral ligaments and cardinal ligaments. This results in a longer vagina and excellent pelvic support [3, 4].

The number of oophorectomies done with hysterectomy has been increasing and 37 % of women below 45 years and 68 % of women over 45 years now have bilateral oophorectomy. Vaginal adnexectomy is often thought to be a difficult procedure because of restricted access and limited visibility of the Infundibulopelvic ligament but the need to perform salpingo-oophorectomy should not be considered a contraindication to vaginal hysterectomy [5].

With the advent of new hemostatic systems, total vaginal hysterectomy is now a more viable option. Overall success rate of oophorectomy at vaginal hysterectomy varies between 88 and 96 % and using various techniques, this rate can be increased to 97.5 % [6, 7, 8, 9]. Using coagulation techniques and now more recently vessel sealing systems, adnexectomy during vaginal hysterectomy has become easy and feasible. The new hemostatic systems which are safe alternatives to conventional suturing techniques include the high frequency electro-surgery, ultrasonic and laser. Monopolar, bipolar and laser are inherently risky to use because of considerable lateral thermal spread beyond area of treatment (up to 2 mm with electrocautery) and unreliable hemostasis (seen mainly with Laser) [10]. With electro-surgical bipolar vessel sealing (EBVS) system, the mean lateral thermal spread is 144.18 μm as compared to 215.79 μg with monopolar diathermy [11].

EBVS technique is an alternative method to conventional suturing and stapling techniques. By using this technique large caliber vessels can be secured using a single clamp which shortens the operative time as well as decreases the post- operative pain due to less traction on the tissues [12]. Mean arterial burst strength with vessel sealing systems has been shown to be similar to ligatures and higher than ultrasonic or bipolar sealed blood vessels [13].

The initial traditional electrosurgical generators used radio frequency electric current to heat and coagulate the blood vessels. But this method is adequate to seal vessels only up to 2 mm in diameter [14]. To seal blood vessels of larger caliber, advances in electrosurgical techniques have been specifically designed. The ideal vessel sealing device is the one which fulfills the following criteria:

(i) Consistency: Independent of user, the device must consistently perform the same way with every procedure.
(ii) Reliability: The device does not change its sealing capabilities for vessels up to 7 mm diameter with repetitive uses.

(iii) Efficiency: The treatment time needed to seal the tissue does not prolong the operation unnecessarily.
(iv) Safety: Lateral thermal spread is not excessive and does not exceed the recommended safety of >5 mm.

There are three important factors to achieve sealing of larger vessels. These have been incorporated in the EBVS system [15]. They are:

- Electro-surgical output- The bipolar current is higher compared with conventional electro-cautery.
- Electrosurgical generator- The vessel seal is achieved using a closed feedback loop to monitor the effect of current by measuring tissue impedance. Different generator models use different algorithms or tissue impedance values which may lead to some variability between different generator models and may affect the seal quality and thermal spread (Fig. 118.1).
- Forceps- An adequate seal depends upon optimal jaw pressure which in turn depends on the jaw distance. The forceps have stronger jaws and a welded positive electrode in the stationary jaw used in this system. The pressure with these forceps is higher and more evenly applied along the entire length than which is achieved using standard bipolar forceps [16] (Fig. 118.2).

Fig. 118.1 Electrosurgical generator

Fig. 118.2 Bipolar forceps

Variation in the design of any one of these factors can affect the surgical outcome. For example, the Triad feedback loop is faster and impedance calculations are performed in real time compared with the Ligasure which does retrospective calculations of the next energy pulse and has a slower sample rate [17].

Mechanism of Action

EBVS system delivers a high current (4 A) and very low voltage (<200 V) to the tissue. It monitors tissue impedance between jaws of the forceps and continuously adjusts delivery of energy. The system diagnoses the type of tissue in the jaws of the instrument and delivers the appropriate amount of energy needed to seal it. Collagen and elastin fibres in the vessel wall denature during the cool down phase and cross-linking which occurs creates a new solid wall of collagen and elastin tissue (Fig. 118.3). Algorithm in the generator determines the optimal energy and time required to seal vessels as large as 7 mm.

EBVS system is unique because of the fact that it works by applying a precise amount of pressure and energy to transform collagen and elastin fibers present in the vessel wall to create a permanent seal. Computer controlled bipolar diathermy system utilizes combination of pressure and bipolar energy incorporating impedance based feedback loops to modify energy. An acoustic signal informs the surgeon when the vessel obliteration is complete and its division possible. The obliterated lumen can be identified once the jaws of the forceps are released. This system does not

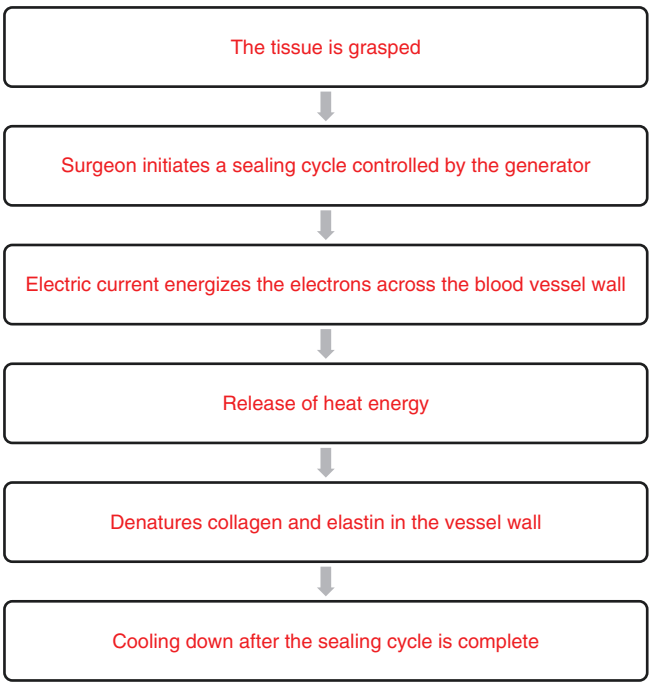

Fig. 118.3 Working of EBVS system

work consistently in tissues where the blood supply is predominantly through capillaries which have low collagen content. Also, while EBVS system may seal arteries up to 7 mm, the size limit for vein sealing is lower as their walls contain less collagen [17].

Operative Technique

The probability of adnexectomy by vaginal route can be graded pre-operatively using the scoring system given by Kovac et al. [18].

Grade 0: No descent of ovaries. Infundibulopelvic ligament has little or no stretchability. Ovaries are positioned at the lateral pelvic wall at or above the ischial spines and cannot be brought by traction into the long axis of the vagina.
Grade I: Ligament stretchability with traction brings the descent of the ovaries to the long axis of the vagina midway between the ischial spines and mid vagina.
Grade II: Traction brings the ovaries to midway between mid vagina and hymenal ring.
Grade III: Traction brings the ovaries beyond the hymenal ring.

Any ovary that is Grade I or more is generally accessible and visible for transvaginal removal.

Factors affecting the feasibility of adnexectomy during vaginal hysterectomy:

- Age: Relaxation of adnexae because of weakness of IP ligaments improves visibility and access of ovaries in such women.
- Obesity: Kammeran-Doak et al. found lower rates of successful oophorectomy in obese women [19].
- Stage of pelvic prolapse: Higher the grade of prolapse, the easier it is to carry out adnexectomy.
- Shorter cervical length: Karp et al. found cervical elongation >7 cm or exteriorized cervix to be associated with lower likelihood of salpingo-oophorectomy [20].

Position of Patient

Lithotomy position with both the hips and the knees being flexed is preferred for vaginal hysterectomy. The buttocks should be at the edge of the table to facilitate posterior vaginal wall retraction without hindrance to the instruments.

Step 1

The external genitalia, lower abdomen up to umbilicus, medial aspect of thigh, perineum and finally vagina and cervix are cleaned with betadine. Labial sutures are applied with silk to facilitate exposure. A metal catheter is used to empty the bladder. A careful pelvic examination is performed to confirm the pre-operative findings, find some unrecognized pelvic pathology and anticipate degree of operative difficulty.

The size, shape and mobility of the uterus is confirmed. Also, the position and depth of pouch of Douglas (POD), depth of vagina in resting position, length of uterosacrals and thickness of perineal body is noted.

Aqua Dissection: To decrease the intraoperative blood loss 30–40 ml of 1:200,000 epinephrine or 100–200 ml of

Fig. 118.4 Saline injection anteriorly

Fig. 118.5 Submucosal saline bleb

sterile saline may be injected submucosally around the cervix (Figs. 118.4, 118.5, 118.6, 118.7 and 118.8).

Advantages of aqua dissection (AD): Aqua dissection compresses the vascular plane and creates a fluid tourniquet in the injected area which prevents hemorrhage during surgery. Also various planes become easily separable which decreases the operative time [21].

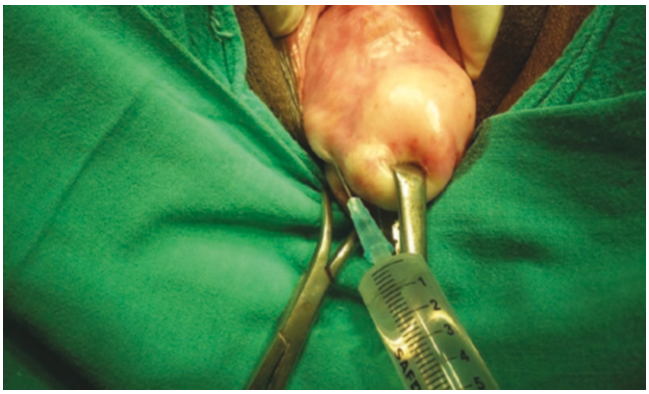

Fig. 118.6 Saline injection on left lateral side

Fig. 118.7 Saline injection on right lateral side

Step 2: Incision

The cervix is held with vulsellum and the lower limit of the bladder is identified, incision is made at the cervicovaginal junction using scalpel or scissors. Incision can be started either anteriorly or posteriorly (preferable as blood flow will not hinder vision in the operative area). The incision is deepened through the entire length with simultaneous traction on the cervix (Figs. 118.9 and 118.10). Vesicovaginal space is dissected and vaginal flaps are created on both sides (Figs. 118.11, 118.12 and 118.13).

Fig. 118.8 Saline injection posteriorly

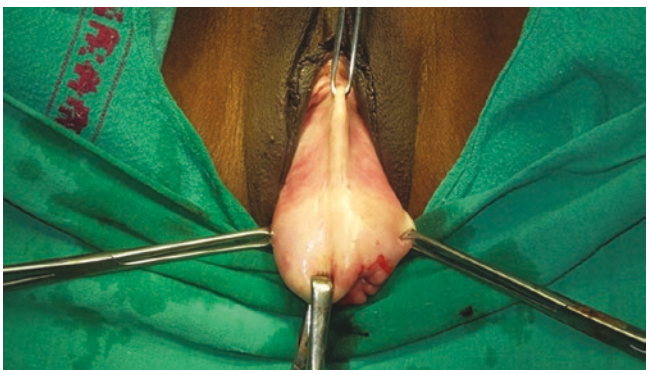

Fig. 118.9 Vaginal mucosa held at four cardinal points

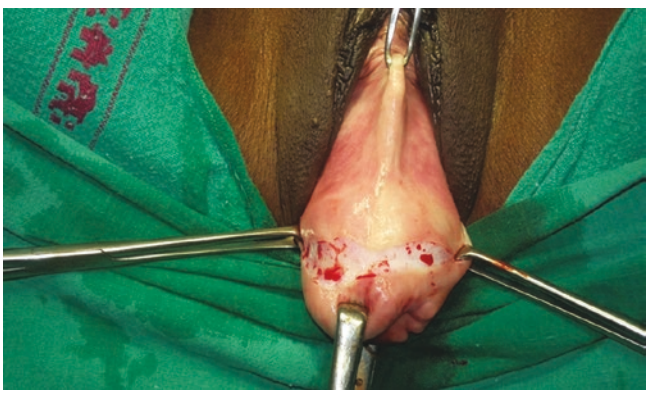

Fig. 118.10 Incision on anterior vaginal wall

Step 3: Opening the Anterior Pouch

While pulling down the cervix hold the anterior vaginal wall incision with Allies or toothed forceps. This will help to identify the vertical running fibres of vesico-cervical ligaments (also called bladder pillars). These are cut and ligated and the bladder can now be pushed up on the anterior surface of cervix using steady traction with a gauze or sponge on a holder till the shiny peritoneum of the uterovesical fold

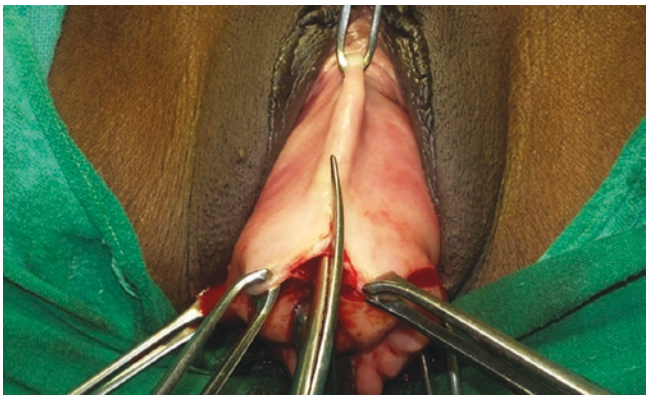

Fig. 118.11 Creation of anterior vaginal flap

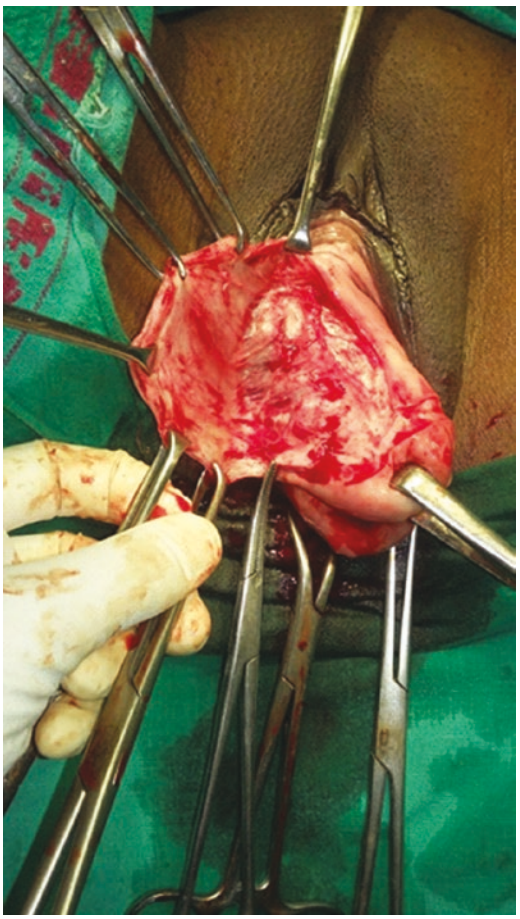

Fig. 118.12 Vesicovaginal dissection done on right side

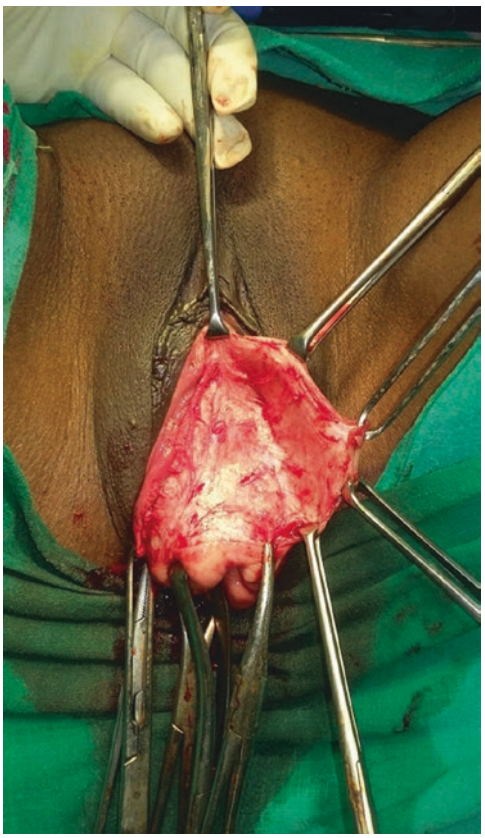

Fig. 118.13 Vesicovaginal dissection done on left side

Fig. 118.14 Anterior peritoneal reflection

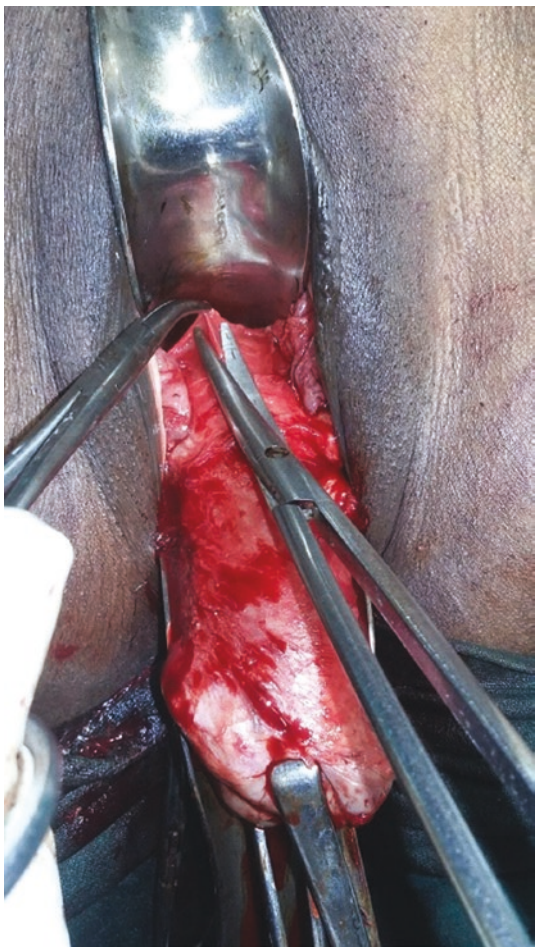

Fig. 118.15 Anterior peritoneum being cut

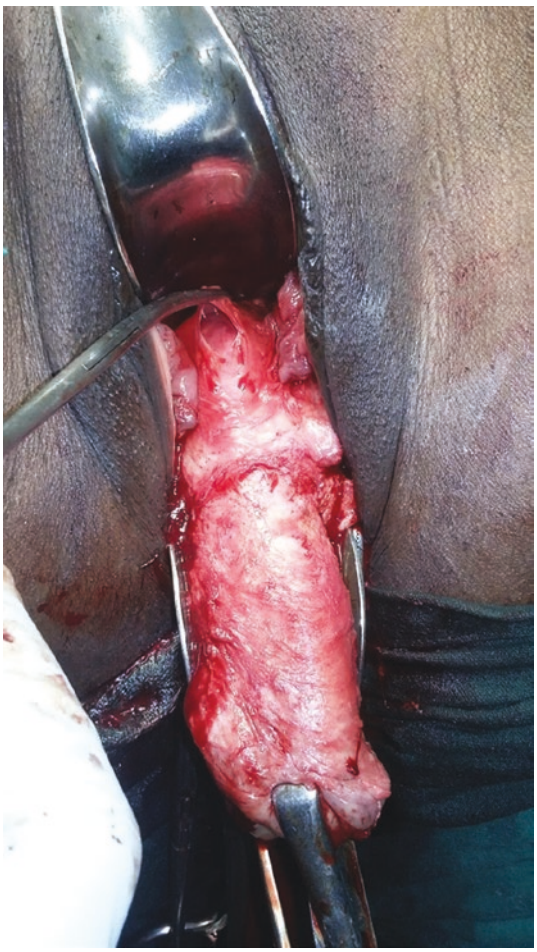

Fig. 118.16 Open anterior pouch

(UV fold) is seen (Fig. 118.14). When using scissors, be careful to direct the tip downwards to ensure that it does not injure the undersurface of bladder. Palpate with two fingers and peritoneum will feel slippery.

The peritoneum is held with artery forceps and cut with scissors (Figs. 118.15 and 118.16). The peritoneum should only be incised under vision. The bladder can then be elevated which would allow the ureters to be safely pushed upwards and outwards. In cases of difficulty in identifying the anterior pouch, the posterior pouch may be opened first. Introduce index and middle fingers through the posterior pouch into the anterior one, identify the peritoneum and then incise under vision. Once the peritoneum is incised, the incision is extended on either side and a Deaver's or Sim's speculum is introduced.

Step 4: Opening the Pouch of Douglas

Holding the posterior lip of the cervix, it is elevated and cut edge of posterior fornix is drawn using Allis forceps. A bold incision is given towards the back of the cervix in between the two uterosacral ligaments. Holding the vaginal edge, peritoneum is identified between the uterosacrals and posterior pouch is opened (Figs. 118.17 and 118.18).

Step 5: Division of Mackenrodt's and Uterosacral Ligaments

The Uterosacral-Mackenrodt's ligament complex is lifted with index finger and the electrodes on the hand piece are placed across the pedicle in such a way that the tissue is interposed between the jaws of the hand piece in the centre. The clamp is applied close to the uterus in the so called 'cheek to cheek surgery'(Figs. 118.19 and 118.20). Then close the handle in the tightest ratchet position and is pressed until a characteristic two-tone sound from the machine confirms complete coagulation of tissue. The handle of the handset is released and the electrode is removed.

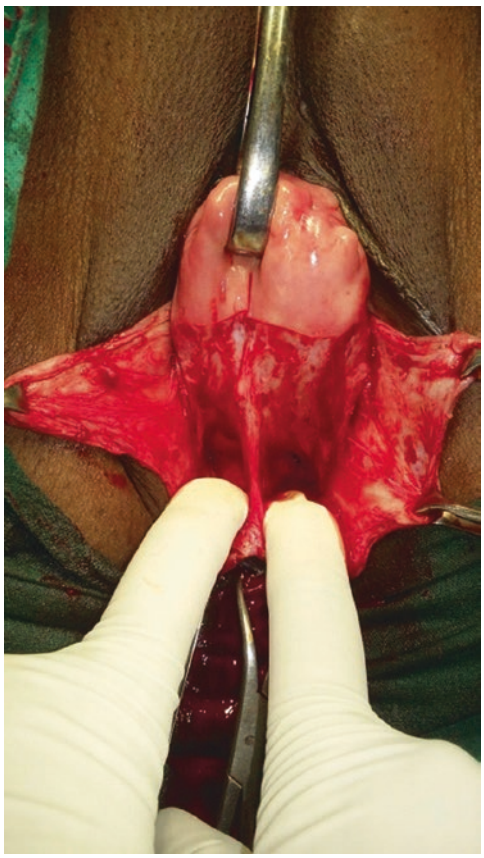

Fig. 118.17 Posterior peritoneal reflection

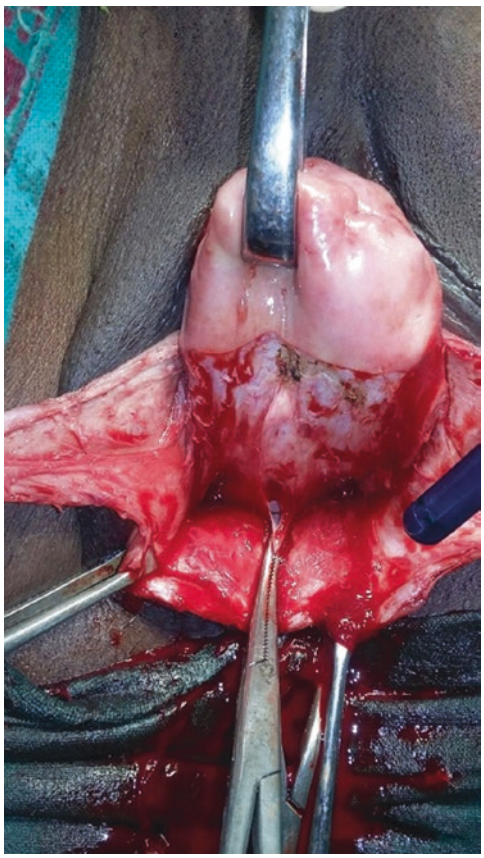

Fig. 118.18 Open posterior pouch

Step 6: Division of Uterine Vessels

The next step is to secure the uterine vessels and this pedicle contains the uterine artery, vein and anterior and posterior folds of the peritoneum (Fig. 118.21). The artery should be clamped medially to avoid thermal damage to the ureter (Figs. 118.22 and 118.23). The uterine vessels are coagulated twice, both applications placed close to each other. The coagulated area will turn white and is then cut close to the uterus.

Step 7: Division of Round Ligament

The clamp is applied to the round ligament and part of broad ligament inferior to it. The clamp is applied as lateral as possible (4–5 cm from the uterus) to prevent bunching of the fundal pedicles and better visualization of infundibulopelvic ligament (Figs. 118.24 and 118.25).

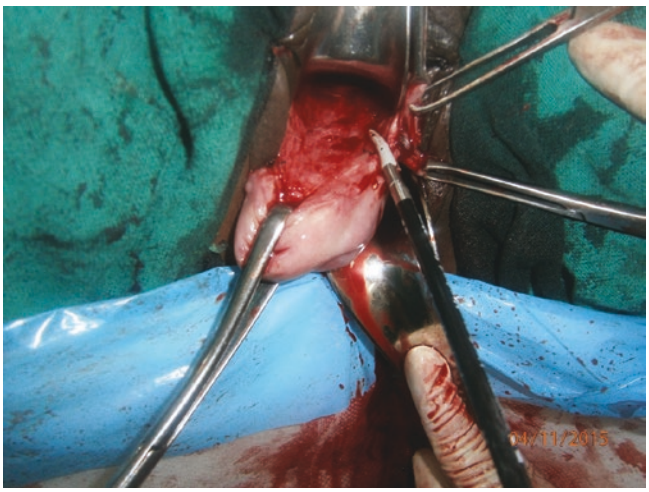

Fig. 118.19 Left Mackenrodt's ligament clamp on left

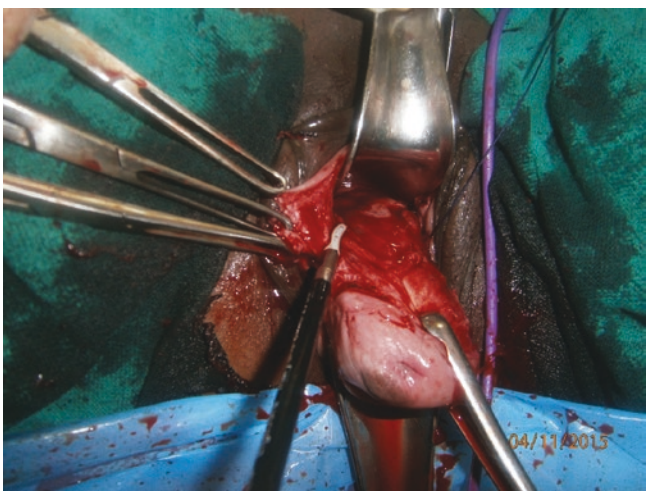

Fig. 118.20 Right Mackenrodt's ligament clamped

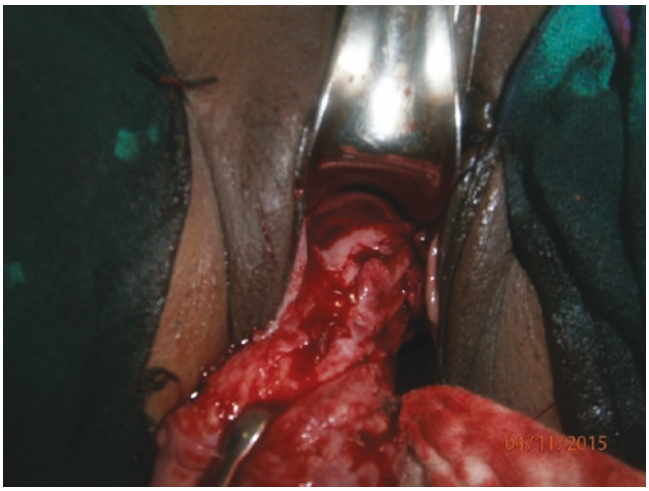

Fig. 118.21 Knuckle of uterine artery

Fig. 118.24 Clamp on right round ligament

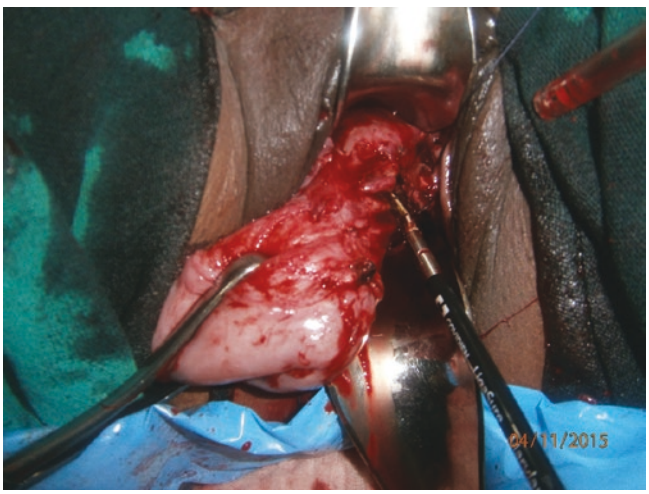

Fig. 118.22 Clamp on left uterine artery

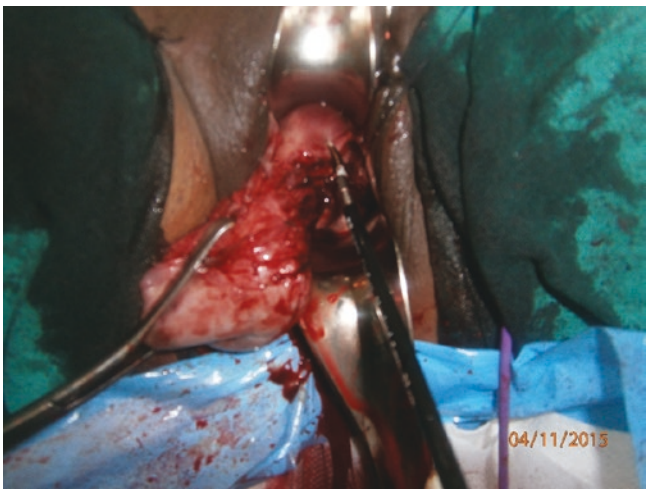

Fig. 118.25 Clamp on left round ligament

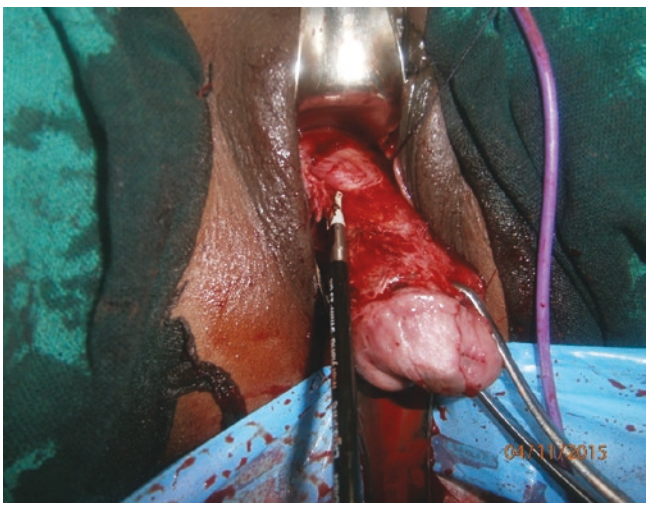

Fig. 118.23 Clamp on right uterine artery

Step 8: Division of Infundibulopelvic Ligament

Next the infundibulopelvic ligament is clamped. Downward traction is applied to the round ligament suture and the ovary is grasped in a sponge holder and gently pulled down. This will help in exposing the infundibupelvic ligament and the clamp can then be applied across it. Alternatively, traction on the uterine fundus delivers the fundus into the vagina and places tension on the IP ligament. A finger can then be inserted under the ligament and the clamp applied across it (Fig. 118.26). Always ensure that the end of the clamp is clearly visible and use a small sponge on holder to push away the intestinal loops coming in the operative area. Also, do not coagulate if the tissues are under traction as they can tear before complete hemostasis is achieved (Fig. 118.27).

If a salpingo-oophorectomy is difficult because of limited space or inaccessible IP ligament, only oophorectomy can be

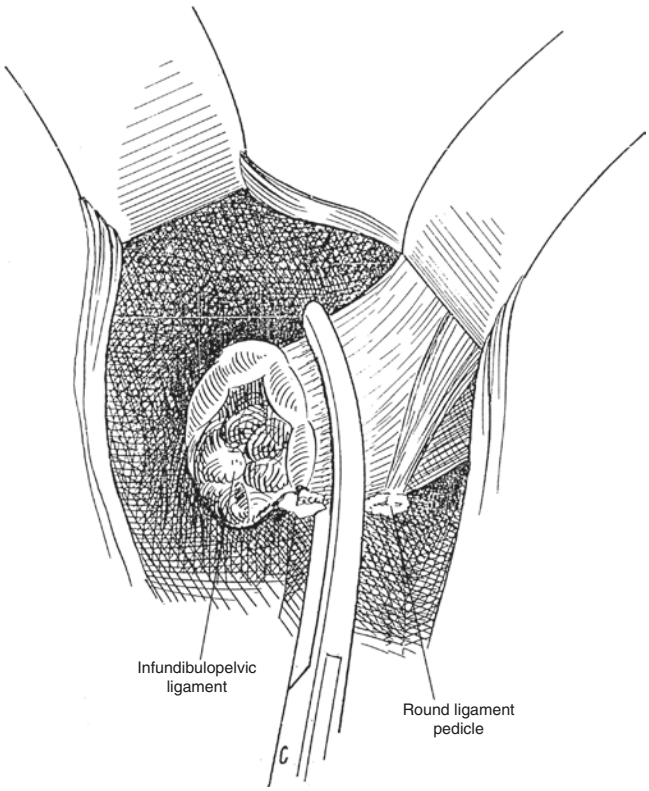

Fig. 118.26 Traction on the round ligament to facilitate clamping of the infundibulopelvic ligaments

Fig. 118.27 Clamp on right infundibulopelvic ligament

done. The ovary is gently pulled down with the help of Babcock's forceps and the diathermy clamp is applied on the mesovarium while keeping the fallopian tube away (Fig. 118.28).

Step 9: Reperitonization

The main goal of peritoneal closure following vaginal hysterectomy is to incorporate the strength of the sub-peritoneal

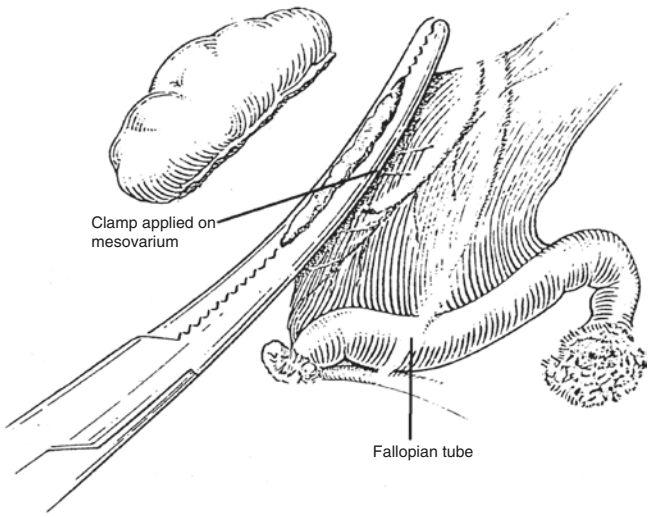

Fig. 118.28 Clamp on the mesovarium

connective tissue retinaculum into a firm scar at the bottom of the pelvis which resists increases in intra-abdominal pressure. A stitch is taken through the peritoneal side of left Uterosacral-Mackenrodt's ligament complex, the posterior peritoneum is reefed in a linear fashion in a series of bites till the same level on the right Uterosacral-Mackenrodt's ligament complex is reached. The suture is then passed through uterosacral ligament and adjacent peritoneum (Fig. 118.29). Then grasping the right adnexal pedicle, gentle traction is applied to bring round ligament into view and the stitch is passed through the round ligament proximal and medial to the previously placed pedicle ligature. The anterior peritoneum is reefed by series of bites which continue through the opposite round ligament. The purse string suture is then tightened and tied. The vaginal vault is then closed using continuous interlocking sutures in a longitudinal direction. Closing in this direction rather than from front to back provides an additional 2–3 cm of vaginal length.

Advantages of EBVS

Less Operative Hemorrhage

Levy B et al. compared procedure time and blood loss in 60 women undergoing vaginal hysterectomy with EBVS versus hysterectomy using sutures. They concluded that EBVS results in shorter procedure time as well as less blood loss (68.9 ml vs 126 ml; $p = 0.005$) [17]. Elhao et al. also found decreased blood loss in patients in whom vaginal hysterectomy was done using bipolar vessel sealing system (230 ml vs 360 ml; $p < 0.001$) [22]. Cronje et al. did not find any significant differences regarding blood loss (median blood loss 100 ml vs 160 ml) [23]. In a meta-analysis by Pergialiotis et al. which included eight randomized trials and 772 patients

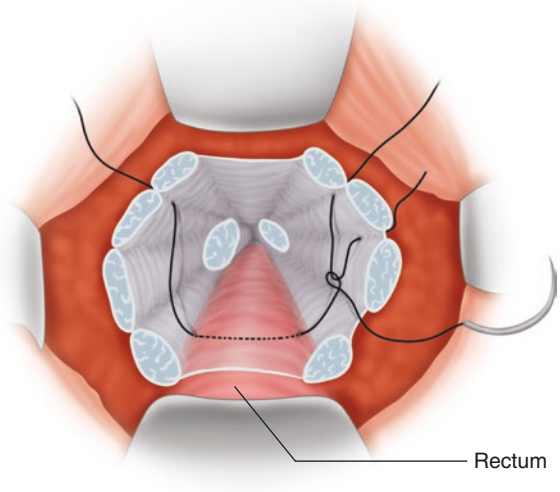

Fig. 118.29 Reperitonization

concluded that the intra-operative blood loss was significantly lower in the bipolar vessel sealing treated group (MD −49.4 versus 67.6). They did not find any significant difference in the operative duration or intra-operative complication rate [24].

Decrease in Operative Time

Vaginal hysterectomy using EBVS is associated with shorter operating time. Hefni et al. found the mean operating time to be 30 min in Ligasure group compared to 61 min in control group [25]. Silva-Filho Al et al. compared 45 women undergoing vaginal hysterectomy using EBVS with same number undergoing VH with conventional suture ligature. They found a significantly reduced operating time and operative blood loss (84 ml vs 136.4 ml; $p = 0.001$) [26]. Elhao et al. also found shorter surgery time (52.5 min vs 90 min; p<0.001) and less blood loss (230 ml vs 360 ml; $p < 0.001$) in participants undergoing vaginal hysterectomy using EBVS than those having conventional surgery [22]. Agrawal et al. also found significant reduction in operative time in the women who underwent VH using vessel sealing system as compared to the women in the conventional suturing technique. There was also a significant difference between the two groups in operative blood loss ($p = 0.0001$) and postoperative pain ($p = 0.0001$) [27]. None of the patients had any major surgical complications. Allam et al. compared total laparoscopic hysterectomy, vaginal and abdominal hysterectomy using vessel sealing technique in 90 women. They concluded that operative time for vaginal hysterectomy using this technique was shortened as compared to abdominal or laparoscopic hysterectomy (100.4 ± 35.8 min) [28].

Table 118.1 Operating time: comparative data from various studies

Author	VH using sutures (min)	VH using EBVS (min)	No. of hysterectomies in study (sutures: EBVS)
Agrawal et al.	70.03	57.34	60:65
Lakeman et al. [12]	76	60.5	50:50
Silva-Filho et al. [26]	75.2 ± 5	29.2 ± 2.1	45:45
Elhao et al. [22]	90	52	103
Cronje et al. [23]	40	32	31:37
Hefni et al. [25]	61	30	59:57
Levy et al. [17]	60	48	30:30

Significant reductions in operative time were found in various other studies also (Table 118.1).

Makes access easy EBVS system makes vaginal hysterectomy possible in situations of difficult access. In patients who are morbidly obese, have narrow vaginal canals or contracted pelvis can pose a surgical challenge. But as the space requirement is less while using this technique for vaginal hysterectomy, so it is the procedure of choice in such women.

Decrease in Post-operative Micturition Symptoms

In conventional vaginal hysterectomy traction is applied to the uterus to allow better visualization of tissues. This causes increased pain in the post- operative period and nerve damage which leads to micturition problems. While using bipolar sealing device the traction required on the uterus is less and also the tissues are cut closer to the uterus, which prevents innervational damage. This helps to decrease micturition symptoms in the post-operative period [3].

Decrease in Post-operative Pain

Gizzo et al. (2013) found EBVS to be significantly better than conventional vaginal hysterectomy in terms of intraoperative bleeding, number of sutures, surgical time and postoperative pain on day 1 and day 3 of surgery [29]. Lakeman MH et al. also reported significant less pain (5.7 versus 4.5 on scale of 0–10; $p = 0.03$) on first post-operative day but pain score were similar on subsequent days [15]. Vinita et al. also found significant reduction in post-operative pain in the group of patients who underwent vaginal hysterectomy using EBVS system [27].

Reduction in Thermal Spread

In spite of the high heat which is produced with its application, it produces minimal eschar and so minimizes the amount of lateral heat produced and hence the damage to surrounding tissue [30]. In a study by Kim et al., mean temperature of harmonic scalpel was 121.3 ± 97 ° C, LigaSure 76 ± 2.9 ° C (for liver). In the peritoneum, the Harmonic had a temperature of 195.9 ° C versus LigaSure which developed a mean temperature of 88.9 ° C [31]. The system also has no adverse influence on histology of margins of the resected tissue. Tissue adhesions are also rare with EBVS.

Learning Curve for Doing Vaginal Hysterectomy Using this Technique Is Easy

The forceps or the clamp of the EBVS system resembles the Heaney's hysterectomy clamp very closely. So, the vaginal surgeon needs no special training in the use of this instrument. Hefni et al. considered the use of EBVS as "operator independent" in contrast to suturing in vaginal hysterectomy which requires a high level of skill [25].

Facilitation of Oophorectomy at Vaginal Hysterectomy

As the vessel sealing achieved with EBVS system is reliable and the tissues more easily accessible, so the surgeon can do oophorectomy with more ease and confidence. Compared with women undergoing hysterectomy alone, those who underwent unilateral salpingo-oophorectomy had a hazard ratio for ovarian cancer of 0.58 and women who underwent bilateral salpingo-oophorectomy had a hazard ratio of 0.12 [32]. Also, prophylactic salpingectomy which is recommended for women at average risk for ovarian cancer is facilitated using EBVS technique [31].

Safe for Surgeon

It is also safe for the surgeon as it significantly reduces the risk of needle stick injury.

The Seal Achieved with EBVS Resists Dislodgement

The seal formed by the diathermy system is intrinsic to the vessel wall and so cannot be dislodged unlike the seals achieved with conventional suturing which can slip or dislodge.

Decrease in Hospital Stay

In the study by Silva et al. the hospital stay in women who underwent vaginal hysterectomy using the bipolar technique was significantly less (25.6 h versus 33.2 h; $p < 0.001$) [26]. Similar results were found in various other studies [33, 34]. Malinowski A et al. found the duration of hospital stay and complication rate similar in the women having vaginal hysterectomy via bipolar or conventional suturing technique [35]. Cronje et al. also found no significant differences regarding hospital stay in both the groups. (Median 2 days versus 2 days $p = 0.03$) [23]. Table 118.2 shows the comparative data regarding postoperative hospital stay.

In a meta-analysis done by Kroft J and Selk A which included seven studies and 662 women concluded that energy based vessel sealing devices decreased operative time by a mean of 17.2 min (seven studies, 662 patients; 95 % CI 7.5–27.0) and blood loss by a mean of 47.7 ml (five studies, 437 patients; 95 % CI 15.5–79.9) and postoperative hospital stay by 0.25 days(five studies, 554 patients; 95 %CI 0.13–0.37). They did not find any increase in the complication rate in their meta-analysis [36].

Complications of EBVS

Overall complication rate has been quoted as between 10–15 % in various studies [25, 36, 37].

Skin or mucosal burns: These are usually first degree thermal burns caused by prolonged contact of the forceps with the skin or vaginal wall. They can be prevented by keeping the forceps as close as possible to the uterus in the middle of the vagina and by taking greater care while maneuvering the instrument [38].

Table 118.2 Hospital Stay: comparative data from various studies

Author	VH using sutures (days)	VH using EBVS (days)	No. of hysterectomies in study (sutures: EBVS)
Silva-Filho Al et al. [26]	2	1	45:45
Cronje et al. [23]	2	2	31:37
Hefni et al. [25]	3	1.2	59:57
Zubke et al. [34]	7.1	5.8	40:40

Operative Hemorrhage

It can be prevented by not interrupting the flow of current too early. If necessary, coagulation must be repeated to ensure complete coagulation. The tissue after complete coagulation appears white, dry and parchment like. Also, too much traction should not be applied to the tissues because if coagulation is done on tissue which is already under tension, then it can tear before hemostasis is complete.

Post-operative Hemorrhage

Post-operative bleeding is seen in 1–2 % cases. The main causes [3] for this are:

Ignoring the "failed seal" tone given by the generator.

If the artery to be sealed is calcified.

Attempt to seal tissues with low amount of collagen such as veins.

Thermal Damage to Ureter

This can occur if uterine pedicle is clamped too laterally.

Thermal Damage to Bowel

These are caused if the tip of the clamp comes in contact with an intestinal loop or with wall of the colon during coagulation. This can be prevented by always keeping the tip of clamp under vision and keeping the bowel away with a mounted sponge during coagulation.

Tissue Sticking

This is a significant concern in electrosurgery as it increases the electrical resistance which inhibits energy delivery to the target tissue leading to ineffective hemostasis. Reduced sticking seen with EBVS system contributes to the consistent sealing seen with multiple firings also. Tissue sticking is generally seen in 1.39 % of vessels transected with ENSEAL and 13.3 % with Ligasure [39].

No Influence on Myoreduction Techniques

Techniques for myoreduction like morcellation, wedge resection, coring etc. may be required in vaginal hysterectomy to complete the surgery but they have not been shown to be influenced by the EBVS system.

The efficacy of vessel sealing system on atheromatous vessels is questionable. A normal artery consists of outermost layer called tunica externa which is composed of connective tissue made up of collagen fibres. Inside this is a tunica media of smooth muscles and elastin tissue. The innermost layer is tunica intima mainly made up of endothelial cells. However, in veins and atheromatous vessels the tunica media is thin because of less smooth muscles and elastin fibres, thereby decreasing the efficiency of EBVS on these vessels [40].

Conclusion

The use of energy based tissue sealing and cutting instruments is becoming popular in gynecological surgery. EBVS system is uniquely suited to vaginal surgery as it enables large caliber vessels to be sealed effectively and safely. The use of EBVS has enabled vaginal hysterectomy to be done in more complex cases. Its use during vaginal hysterectomy reduces the operative time and intra-operative blood loss without compromising on patient safety. EBVS is also associated with reduced post-operative pain and decreased hospital stay which translates into higher economic savings.

119 The Advantages in the Selection and Use of Bipolar Vessel Sealing Devices in Vaginal Hysterectomy, Dependent on the Different Degrees of Operative Difficulty

Mohamed Ellaithy and Wael Agur

In General, Vaginal Hysterectomy Is the Preferred Route for Hysterectomy

Current evidence demonstrates that vaginal hysterectomy (VH) is generally associated with fewer complications and better outcomes. A Cochrane review of 34 randomized trials of VH, abdominal hysterectomy, and, laparoscopic hysterectomy including 4495 women, concluded that among these three routes, VH has the best outcomes [1].

Compared to abdominal hysterectomy, VH is associated with quicker return to normal activities, fewer postoperative infections and febrile morbidities and a shorter hospital stay [1–3]. Compared to laparoscopic hysterectomies, vaginal hysterectomies are not lengthy operations and carry a less risk of bladder and ureteric injuries and a lower rate of substantial bleeding [1]. Based on its well-documented advantages and lower rates of complication, ACOG Committee on Gynecologic Practice recommended VH as the approach of choice [4].

The Challenging VH

VH constitutes only 23 % of the hysterectomies performed in the United States. Traditionally, so many gynecologists have avoided VH and used it only in carefully selected women [5]. Uterine enlargement, previous pelvic surgery, absence of uterine descent, a narrow pubic arch (<90°), limited vaginal and pelvic spaces, nulliparity, obesity, and the need for concomitant oophorectomy should no longer be considered as contraindications to VH [5–9].

Many women who have not given vaginal birth and many nulliparous women, have sufficient vaginal caliber to allow a successful completion of VH [10]. When the uterine descent is minimal, if the vagina allows access to divide the uterosacral and Mackenrodt's ligaments uterine mobility is improved enough to allow VH [6]. When the uterus is enlarged, VH often can be completed safely by using uterine debulking techniques (Figs. 119.1, 119.2, 119.3 and 119.4) [11]. The need for salpingoophorectomy is not a contraindication to perform VH as the success rate of performing a salpingoophorectomy during VH is reported to range from 65 to 97.5 % [12–15].

Of great importance for the vaginal surgeon is the ability to easily access, visualize, and ligate pedicles and maintain an

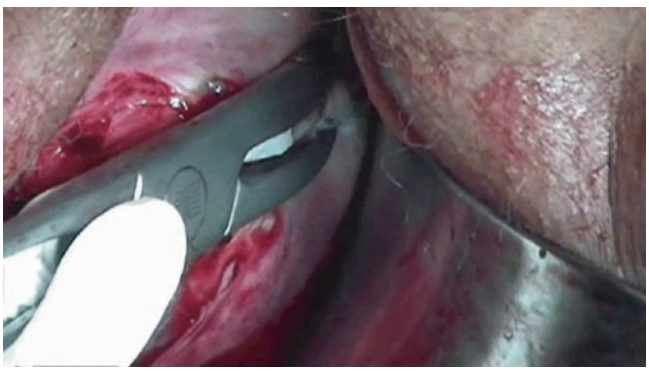

Fig. 119.5 Difficult access (bulky uterus and narrow space)

adequate hemostasis. During challenging VH, there is a limited space to access the vascular pedicles, specifically for suture ligation. The introduction of Electrobipolar vessel sealing (EBVS) systems, in VH, has facilitated the achievement of proper hemostasis in situations of difficult access (Figs. 119.5 and 119.6) into the pelvis, allowing vessels sealing with great ease and safety while reducing blood loss and operating time [16].

The Advantages of Using EBVS in VH with the Different Degrees of Operative Difficulty

VH solely using sutures is a challenging surgical technique and placing sutures on distant pedicles deep in the pelvis is problematic [17]. Hereby, the advantages of using EBVS in performing VH are thoroughly discussed:

- **EBVS is unique among the other hemostatic methods:**

Unlike the mechanical methods (suturing, clips, staples), EBVS does not introduce foreign bodies into the patient and is not cumbersome for the gynecologist faced with limited vaginal visibility and access. The bipolar current used in EBVS technology, eliminates the risk of capacitive coupling and unintentional injury to alternate sites that can occur with monopolar systems. As EBVS rapidly delivers a lower voltage electrical current, it is able to effectively seal the pedicles without sticking, tissue charring (Fig. 119.7) or significant thermal spread [16, 18].

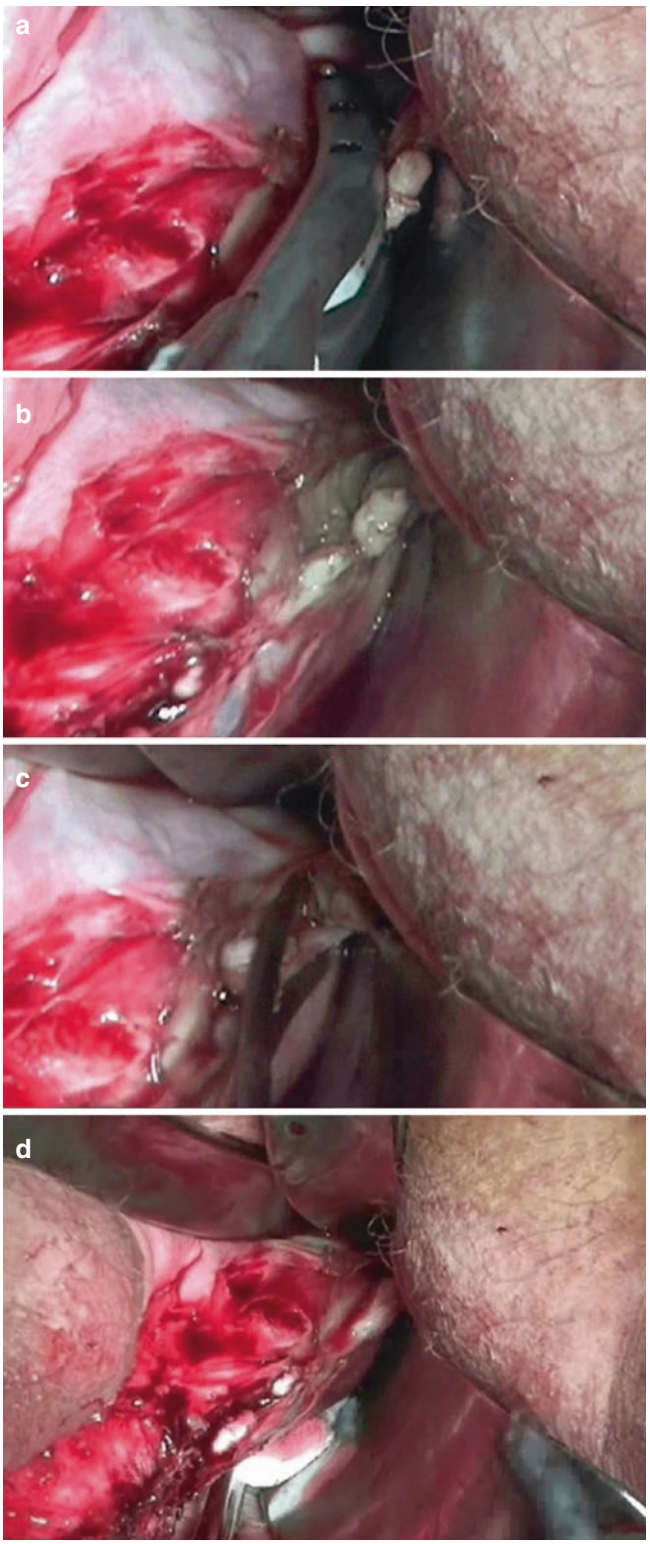

Fig. 119.6 EBVS is ideal in performing VH especially in situations of difficult access (**b**, **d**) (fewer instruments are used simultaneously (**a**, **c**))

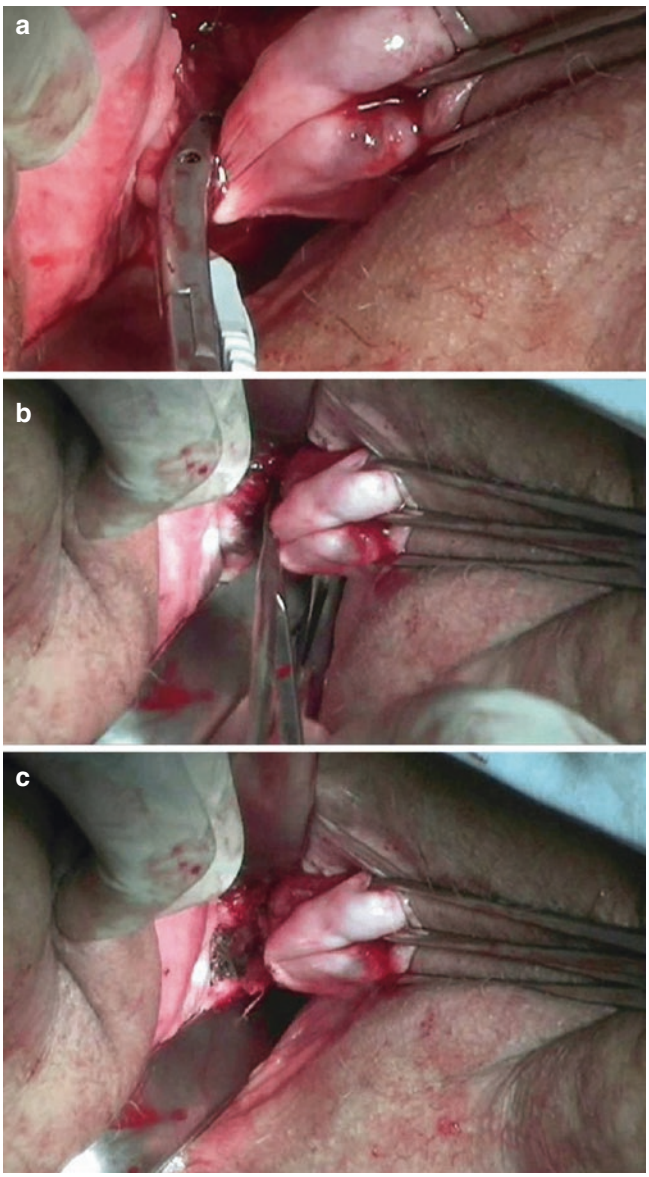

Fig. 119.7 Use of EBVS (**a**, **b**) is associated with minimal tissue charring (**c**)

- **EBVS can effectively secure all vascular pedicles during VH:**

The device can effectively seal all pedicles during VH including the transverse cervical ligament, the broad ligament containing the uterine arteries, the round ligament and the infundibulopelvic ligament [19]. EBVS is also effective on the bladder and rectal pillars, the transverse cervical ligament, and the paravaginal vascular bundles even without dissection. EBVS may occasionally fail to provide adequate hemostasis from the first attempt in structures with more connective tissue content such as the utero-ovarian and utero-sacral ligament and the vagina [20, 21].

- **EBVS saves operative time:**

Shorting of the pedicle dissection time could effectively decrease the total operative time during VH. In comparison to the traditional suture technique, EBVS could reduce the operating time by 8–37 min. This is particularly valuable when performing the challenging cases of VH with large, bulky uteri and/or a narrow pelvis [16, 19, 22–24]. From an economic point of view, the decrease in operating time can be utilized to increase the number of cases done on each theatre list.

- **EBVS decreases blood loss:**

As EBVS can rapidly and effectively secure the vascular pedicles during VH with significant shortening in the operative time, with subsequent significant reduction in the blood loss. The role of EBVS in reducing the operative blood loss was more pronounced in the difficult cases of VH [16, 19, 22].

- **EBVS has minimal lateral thermal damage and good safety profile:**

When compared with the traditional suturing technique, EBVS has been proven to be a safe and effective technique to perform VH. The complications rate was not significantly different between both techniques. Notably in the challenging cases of VH, EBVS decreases intra-operative conversion from vaginal to abdominal hysterectomy [24].

Thermal effects are usually limited to <1.5 mm beyond the grasped tissues [25]. This minimal lateral thermal spread enables the device to be safely used near important pelvic structures [19, 20]. However, positioning of the tip of the instrument near to forceps, metal clips or wet tissues (sponge) and fluid collections should be avoided, since heat may be transferred into tissues resulting in inadvertent organ injury [26]. During VH, the activated hand-piece, which is hot, should not contact the patient skin as it can lead to a labial burn [24]. As the steam from the EBVS devices (Fig. 119.8) may also cause burns; a suction device and a wet Ray Tec sponge must be used when the clamp is in close proximity to the vaginal sidewalls or labia.

- **EBVS produces strong seals:**

EBVS technology rapidly produces strong seals, using lower voltages and subsequently causes no significant sticking or tissue charring [27]. EBVS effectively seals vessels and maintains closure with one application at a level of pressure appropriate for clinical use. Validation in bench and animal models shows that EBVS systems can effectively seal blood vessels up to 7 mm in diameter. These seals can withstand a systolic blood pressure ≥360 mmHg for a minimum of 10 s. The pressure required to burst the sealed vessels is 1025 mmHg [28].

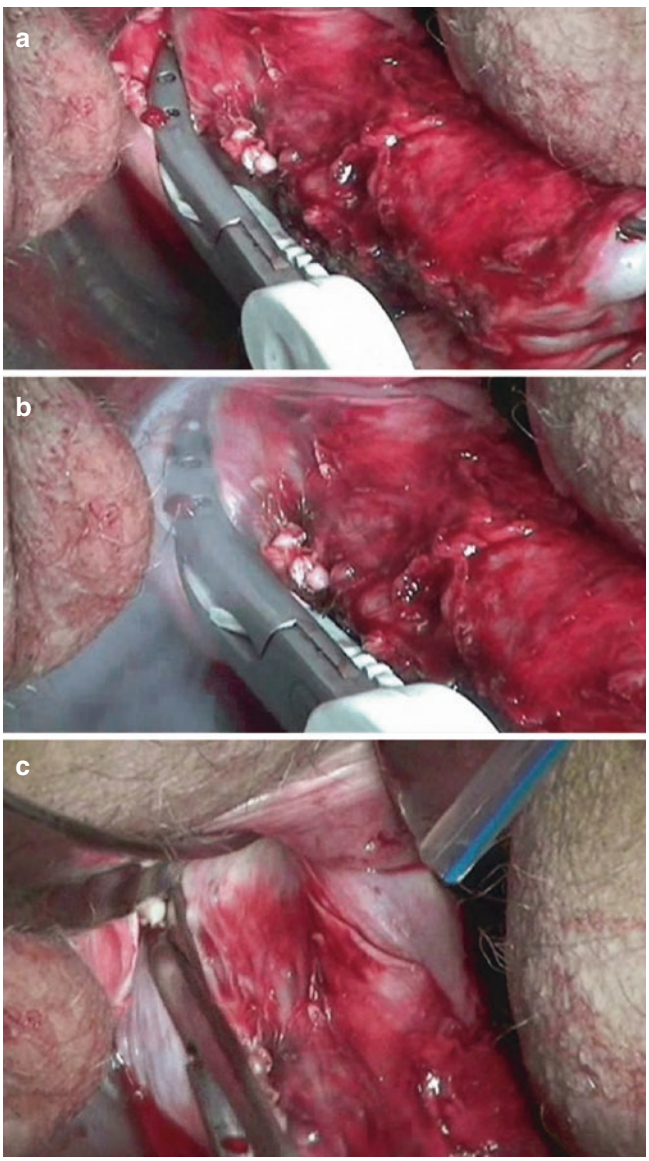

Fig. 119.8 Hot steam (**b**) is released from the EBVS devices (**a**) during VH, use of suction devices is recommended (**c**)

Recent studies, comparing EBVS with bipolar coagulation, ultrasonic coagulation, and surgical sutures and clips, demonstrated that EBVS creates seals stronger than other energy-based methods, and similar, in strength, to the mechanical techniques [25].

- **EBVS minimizes postoperative pain:**

EBVS reduces the pain perception during the immediate postoperative period. This can be attributed to: (a) Decreased intraoperative manipulation, compression and traction. (b) No foreign materials (e.g. clips or sutures) are left in the pelvic cavity. (c) No ischemic tissues are left distal to the suture or clip (including nerves) which can necrose post-operatively causing pain and infection [29].

- **EBVS reduces postoperative stay (outpatient VH)**

When using EBVS for VH, it is possible to reduce the hospital stay by 1 day, compared with using sutures alone. Furthermore, EBVS encourages gynecologists to switch to the vaginal route for hysterectomy with further reduction in the hospital stay by at least 2–3 days, compared with the abdominal route [30].

Nowadays, outpatient surgery is becoming one of the most important evolution axes of the surgery. The use of EBVS reduces the operative time and postoperative pain and makes outpatient VH possible. A recent French study, about outpatient VH, 36.7 % of women were very satisfied, 53.3 % were satisfied and 10 % were not much satisfied. Overall, 83.3 % of women agreed to repeat the procedure in the ambulatory care sector. The authors concluded that outpatient VH is a possible and a safe technique and is associated with a high patient's satisfaction [31].

In addition to the patient benefit, the reduction in the hospital stay can provide a financial incentive for using EBVS in hysterectomy.

- **EBVS facilitates difficult and challenging VH and facilitates the procedure for the less experienced surgeons:**

During VH, Space requirements are less for EBVS than when using traditional sutures (Figs. 119.5 and 119.6), because fewer instruments need to be used simultaneously. EBVS can also reduce bleeding and facilitate hemostasis especially at the sites of difficult access. This will be of great value especially while performing difficult cases of VH and also while training less experienced surgeons to perform VH. EBVS and the use of debulking techniques would enable many surgeons to complete the operation of VH in women with no uterine descent and bulky uteri [22].

- **EBVS facilitates Adnexectomy at time of VH:**

At the time of hysterectomy, the decision to perform prophylactic oophorectomy should be based solely on the patient's age and risk factors. VH should not be a barrier to remove the ovaries during hysterectomy (Fig. 119.9) [4]. EBVS can effectively facilitate oophorectomy at the time of VH even in less experienced hands. In one study salpingoophorectomy was performed successfully in 20 % cases either unilateral or bilateral, if needed, according to the clinical situation [22].

- **EBVS, is it cost effective?**

The initial EBVS generator investment cost and the ongoing annual consumable costs should be weighed against the potential cost savings from reducing the patient hospital stay and reducing the consumed suture materials. EBVS systems using reusable forceps (ERBE and Martin) have the lowest annual running cost, assuming that the reusable forceps needs to be replaced only after performing 50 cases. For the other systems, the increased cost spent in disposable forceps is usually cost effective if accompanied by reducing the patient's hospital stay. Some systems (ERBE, BOWA & Martin) use general purpose electrosurgical units with

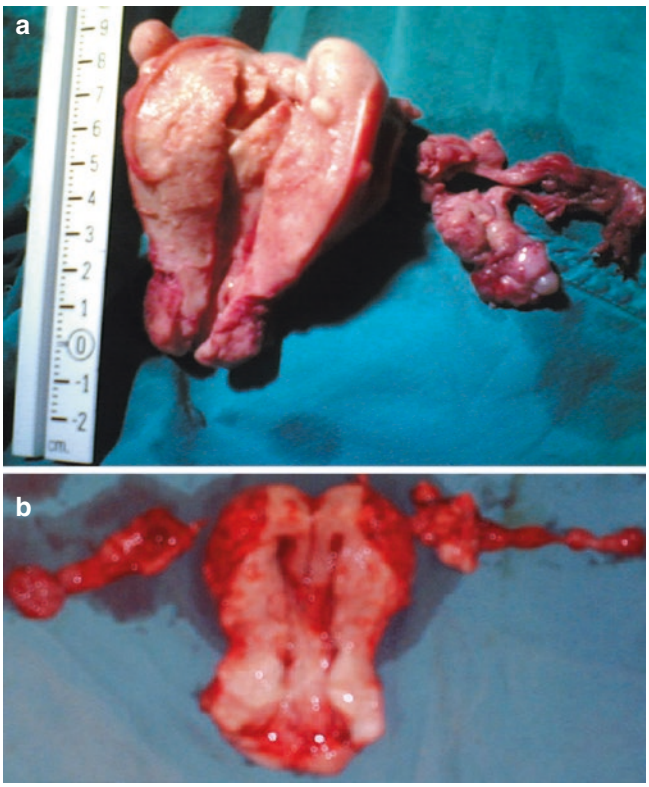

Fig. 119.9 Salpingoophorectomy can be easily performed during VH using EBVS [two cases (**a**) and (**b**)]

Fig. 119.10 VH using EBVS requires only one suture for vaginal cuff closure

specific modes designed for specialist vessel sealing instruments. Others (Valleylab LigaSure & Gyrus PK System) are based on specialist bipolar electrosurgical units [18].

Although there are great variations can exist regarding patient's hospital stay, according to the surgeon and patients expectations, EBVS can play a great role to minimize the duration of hospital stay after hysterectomy by 1–3 days [18]. EBVS patients require only one suture for closure of the vaginal vault (Fig. 119.10), with subsequent saving of ±6 sutures per case [19, 23].

Three additional factors can add to the cost effectiveness of using EBVS in performing VH. First, EBVS decreases intra-operative conversion from vaginal to abdominal hysterectomy [24], this is an important additional factor in the overall cost saving while performing VH using EBVS especially in the challenging cases [18] The same apply when using EBVS technology to preoperatively schedule these cases for VH rather than AH or LAVH. Second, EBVS consistently reduces operating time for VH, this can increase the number of cases scheduled in the OR list every day [18] Third, EBVS reduces pain in the immediate postoperative period resulting in reduced use of morphine [32, 33].

Preoperative Assessment for the Feasibility and Expected Difficulty of VH

- **Uterine size**, there is no universal agreement about the upper limit of uterine size suitable for VH, however some surgeons consider 16-week uterine size as a practical cut-off [34]. When vaginal access is adequate and the lower uterine segment is surgically accessible, VH can be accomplished for large uteri (up to 22-week size) using uterine debulking techniques (myomectomy, morcellation, bisection, and/or coring) by an appropriately skilled surgeon [3, 22].
- **Uterine accessibility**, some authors claims that the presence of narrow subpubic angle (<90°), narrow vagina, undescended uterus, and nulliparity are all solid contraindications for VH [4]. However, it is more wise to say that if the surgeon has an adequate space to divide the uterosacral and cardinal ligaments then the uterine mobility can be improved to allow completion of procedure [6].
- **Extrauterine pathology**, extrauterine diseases e.g. adnexal pathology, endometriosis, obliterated cul-de-sac or pelvic adhesions, may preclude VH. VH is not preferred when thorough examination of the abdomen is needed.
- **Prior cesarean delivery**, previous cesarean section is not a contraindication to VH. However, the presence of previous pelvic surgery with lower uterine segment scarring, can result in bladder trauma, excessive bleeding, and ultimate failure to perform the hysterectomy procedure vaginally.
- **Nulliparity**, VH is not contraindicated in case of nulliparity. Women who do not have vaginal deliveries and nulliparous women can undergo VH safely [35].
- **Obesity**, VH is not contraindicated in case of obesity [36].
- **Clinician and patient preferences**, the surgeon's preference and practice style can influence the choice of hysterectomy route. Additionally, an appropriately informed patient who is aware about the advantages and disadvantages of each type of hysterectomy can aid the surgeon to arrive at the best surgical route suitable for patient's disease and circumstances [37].
- **Preoperative investigation**, a preoperative ultrasonography is done to assess the size of the uterus, number, site and size of fibroid and any adnexal pathology. Preoperative hemoglobin, hematocrit and blood grouping are measured for every patient.

Intraoperative Assessment of the Feasibility and Expected Difficulty of VH

- **Examination under anaesthesia**, Examination under anaesthesia forms an integral part of assessment of feasibility of the hysterectomy by vaginal route. It confirms the preoperative findings and evaluates uterine size, mobility and descent to finalize the decision about route of hysterectomy and also about the expected degree of difficulty of VH if feasible. The size of the uterus is evaluated meticulously, mobility of uterus is also assessed both anteroposteriorly as well as laterally, to provide an accurate assessment of parauterine space. Descent of Cervix is an important factor in the feasibility of VH. If the cervix is visualized on introduction of the Sim's speculum it indicates good descent. Descent of cervix can also

Table 119.1 Modified Seth's score used for per-operative assessment of VH procedural difficulty

	0	1	2
Uterine size	≤8 weeks	9–10 weeks	≥12 weeks
Previous abdominal surgery (e.g. CS)	None	–	Present
Vaginal width	>3 fingers	3 fingers	<3 fingers
POPQ stage	2	1	0
Uterine mobility	Good	Fair	Poor
Subpubic angle	>90°	90°	<90°
Fornices depth	> 1 finger	1 finger	< 1 finger
Surgeon grade	Senior consultant	Junior consultant	Trainee
The score varies from a minimum of 0 to a maximum of 16			

assessed by the volsellum test (Volsellum is applied on the anterior lip under anaesthesia and cervix is pulled downwards). The length of the vaginal fornices is assessed by measuring the distance between the lateral fornix and the cervix at the level of the external os. Fibroids, if any, are assessed. Size, accessibility and position of the fibroid are evaluated meticulously. The breadth of the vagina is assessed with fingerbreadths at the fornix and the pelvis is evaluated by measuring the subpubic angle.

- **Per-operative Scoring**, Several clinical scoring systems have been evolved taking into consideration all factors responsible for the success of the surgery and its difficulty, Table 119.1 illustrates modified Seth's scoring system used for per-operative assessment of procedural difficulty. Procedures can classified into either: 'straightforward' or 'difficult'. A score of less than eight categorised the procedure as 'straightforward' [22].

Using EBVS in VH, Intraoperative Surgical Considerations

EBVS is an energy based technology that use an alternate electrosurgery form to denature the vessel wall content of collagen and elastin and subsequently convert these proteins into a hemostatic seal. This remodeling requires the combined application of mechanical energy (pressure) in conjunction with the electrical energy. During activation, the electrosurgical generator is designed to monitor tissue response through measuring the voltage and current. The resistive heating will change the tissue impedance and subsequently the voltage and current will vary. A cool cycle starts once the tissue impedance indicates a successful seal. After cooling, the generator will emit an audible tone to indicate cycle completion. On average, it takes approximately 5 s to complete one sealing/cooling cycle, during which the device position should be maintained in place [16].

The EBVS clamp is used in exactly the same fashion as standard hysterectomy clamps. Pedicles are clamped, sealed, and

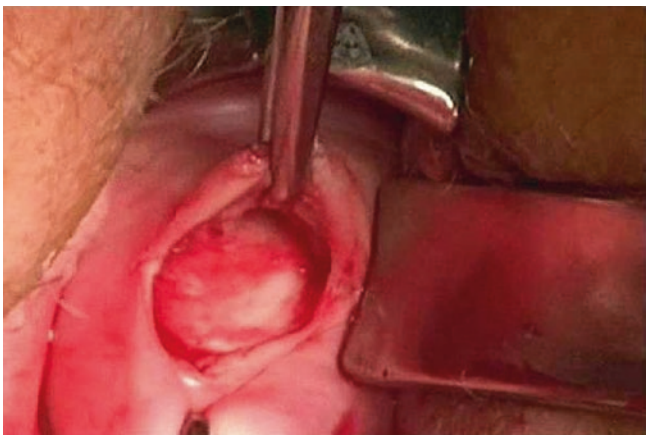

Fig. 119.11 Anterior colpotomy and creating the bladder flap. While doing a downward traction on the cervix, incision is made into the anterior vaginal mucosa at the level of the cervico-vaginal mucosa, this is followed by blunt and/or sharp dissection to push the urinary bladder away from the cervix. Later on during VH, the anterior peritoneal reflection will be identified and the anterior cul-de-sac (vesico-vaginal space) will be entered

then cut on the uterine side before the clamp is released and advanced to the next pedicle (another option is to release the clamp and divide the sealed tissue to avoid back bleeding from the uterine specimen). Traction on the cervix and any tissue traction should be avoided while sealing all pedicles as the surface of clamp in contact with the grasped tissue is smooth and can be easily slipped once the sealing cycle is activated. Supporting the EBVS clamp during the sealing cycle is also beneficial to ensure that the clamp is in contact with grasped pedicle and does not slip. The device can be used on all pedicles beginning with the cardinal ligament, the broad ligament including the uterine arteries, and the round and uteroovarian ligaments. After completing the colpotomy, creating the bladder flap (Fig. 119.11) and opening the Douglas pouch (Fig. 119.12), continue as the following:

1. Clamp, avoid tissue traction and support EBVS clamp, seal, and divide uterosacral ligaments and cardinal ligaments (Fig. 119.13).

2. Clamp, avoid tissue traction and support EBVS clamp, seal, and divide uterine vessels (Fig. 119.14).
3. Clamp, avoid tissue traction and support EBVS clamp, seal, and divide broad ligaments (Figs. 119.15, 119.16 and 119.17).
4. Clamp, avoid tissue traction and support EBVS clamp, seal, and divide utero-ovarian pedicles (Fig. 119.18).

After excision of the uterus (Fig. 119.19), the closure of the vaginal cuff is performed in a way identical to that of the classic VH (Fig. 119.20). Suturing the sealed parts of the uterosacral and cardinal ligaments into the vaginal apex, if feasible, would aid the support of vaginal vault.

Hysterectomy Techniques in Prolapse Situations

120

Stephen T. Jeffery

Introduction

Physicians have been obsessed by the cure of a prolapsed uterus since the second century BC, and for many years this "wandering womb" was considered to be the cause of hysteria in women [1]. Aretaeus is noted to have said: "In the middle of the flanks of women lies the womb, a female viscus, closely resembling an animal; for it is moved of itself hither and thither in the flanks, also upwards in a direct line to below the cartilage of the thorax, and also obliquely to the right or to the left, either to the liver or the spleen, and it likewise is subject to prolapsus downwards, and in a word, it is altogether erratic" [2]. In 120 AD Soranus of Ephesus was the first physician to perform a vaginal hysterectomy to cure a women of this problem of hysteria caused by a "wandering womb" [3].

Despite the wide array of modern options that are now available for uterine prolapse, including the laparoscopic and robotic approaches, a vaginal hysterectomy and vault repair remains one of the safest and most effective treatments for this condition. The technique is simple, has a relatively short learning curve, does not require any advanced equipment and is a relatively inexpensive compared to other approaches.

It is important to appreciate that a prolapsing uterus is always associated with distorted pelvic anatomy. The weakened pelvic support often results in concomitant prolapse of the bladder, rectum and small bowel and the location of important structures is therefore difficult to predict. As a result, there are significant risks of bladder and ureteric injury. As an example, the location of the ureters could be at any of the depicted locations in Figs. 120.1 and 120.2.

Safely performing a vaginal hysterectomy in women with advanced uterine prolapse requires a systematic, step by step approach. This includes safe entry into the anterior and posterior cul-de-sacs followed by hysterectomy using standard sequential pedicle ligation. Suspension of the vaginal vault then follows and finally the prolapse of the anterior and posterior compartments is addressed.

Surgical Options for Uterine Prolapse

In selecting an operative technique for uterine prolapse, we are faced with a broad range of options, from archaic interventions such as the Manchester Repair and colpocleisis, to modern, state-of-the-art robotic and mesh procedures. The first decision is whether a vaginal or abdominal approach is optimal. The surgeon will also need to decide if a hysterectomy should be performed or whether a uterine preservation and suspension technique should be utilised. If the operation is being done vaginally, some surgeons still make use of mesh in managing women with uterine prolapse and so a decision needs to be on the appropriateness of using one of these devices. There remains very little comparative data on the various techniques. The factors that may influence the approach include the severity of the prolapse, the age of the patient, the presence of co-morbidities and whether the woman is sexually active or not. Table 120.1 contextualises the vaginal hysterectomy relating to other options for uterine prolapse.

Despite the large number of options available to us for uterine prolapse, a vaginal hysterectomy and vault suspension remains one of the best options for even the most extensive prolapse. It is essential to remember that simply performing a hysterectomy for uterine prolapse is usually not enough and that the vaginal vault always needs to be supported.

Choosing Between an Abdominal and Vaginal Approach

For women with post-hysterectomy vaginal vault prolapse, sacrocolpopexy (SCP) has been shown to be better in terms of anatomical outcomes and sexual function. This conclusion was reached in the Cochrane review when comparing sacrospinous fixation (SSF) and SCP. In particular, the abdominal SCP was associated with a vaginal axis that more closely resembled the normal anatomy, and a better vaginal length to the vaginal SSF [4]. The superiority of the SCP for vault prolapse has prompted increasing interest in performing a sacrocolpopexy-type procedure for uterine prolapse.

Table 120.1 Surgical options for uterine prolapse

Vaginal approach	Abdominal /laparoscopic/robotic approach
High uterosacral ligament suspension (with or without hysterectomy) Sacrospinous fixation (with or without hysterectomy) Manchester repair Mesh kit procedure (e.g. Uphold, Elevate, Nuvia) Colpocleisis	Supra-cervical hysterectomy and sacrocolpopexy Total hysterectomy and sacrocolpopexy Sacrohysteropexy

The most popular approach is to perform either a total or subtotal hysterectomy followed by a mesh sacrocolpopexy. A uterine-sparing alternative is the mesh sacrohysteropexy.

There are relatively few data comparing the outcomes of the abdominal to the vaginal approach in women with uterine prolapse. Roovers et al. [5] randomized 84 women with uterine prolapse into an abdominal sacrohysteropexy or vaginal hysterectomy and uterosacral ligament suspension. Those women who had vaginal surgery had better outcomes in multiple domains on the quality of life questionnaires. The abdominal approach was also associated with a much higher re-operation rate (22 % vs 2 %). They concluded that vaginal hysterectomy with anterior and/or posterior colporraphy is preferable to abdominal sacrocolpopexy with preservation of the uterus as surgical correction in patients with uterine prolapse grades 2–4. De la Cruz et al. [6] compared the change from pre- to postoperative total vaginal length (TVL) in women who underwent either a total vaginal hysterectomy (TVH) with uterosacral ligament suspension or a robotic hysterectomy with SCP. Recurrent prolapse (defined as any prolapse at or beyond the hymen) was not different between groups. Vaginal length was decreased in the vaginal hysterectomy group compared with the robotic group but this did not make a difference to postoperative sexual or pelvic floor function between the groups.

Prolapse surgery is more of an art than a science and this remains true when managing women with uterine prolapse. Before embarking on a specific technique, a large number of factors should be considered. The abdominal approach is most suited to young, fit women who are sexually active. An abdominal or laparoscopic hysterectomy and sacrocolpopexy will however be much more difficult in women with a high BMI and previous abdominal surgery. The potential morbidity of sacrocolpopexy is significant. Patients should be counseled regarding the risk of bladder and bowel injury, severe haemorrhage from the sacral venous plexus and spondilodiscitis. These are all potentially life-changing events and also place the surgeon at risk for litigation if they do occur.

Many surgeons are not proficient at the abdominal approach to uterine prolapse. For these doctors, the current data would support the use of the vaginal approach, rather than embarking on potentially difficult surgery without adequate training and experience.

The rest of this chapter will focus on the most important practical steps in achieving a safe and durable result when performing a hysterectomy for uterine prolapse.

Practical Approach to Vaginal Hysterectomy in Prolapse Situations

Pre-operative Examination

There are two aspects that require assessment before embarking on a vaginal hysterectomy for uterine prolapse, including

ascertaining the severity of the prolapse and determining the uterine size.

Severity of Uterine Prolapse

In a woman with a large cystocele, it is often difficult to assess the extent of uterine prolapse. When observing a large cystocele as depicted in Fig. 120.3, it is often erroneously assumed that the main part of the prolapse is in the anterior compartment. As demonstrated in Fig. 120.4, by using two Simms speculae with the patient in the left lateral position, the cervix is easily visualised and the extent of uterine prolapse is determined by asking the patient to bear down. This maneuverer will allow the surgeon to assess the necessity of performing a hysterectomy in addition to repair of the anterior and posterior compartment. Remember, where there is substantial uterine prolapse and one is planning on repairing a cystocele or rectocele, performing a hysterectomy followed by a vault suspension procedure will ensure a better result than simply performing a prolapse procedure.

Fig. 120.3 Using a Sims speculum to visualise a cystocele that often accompanies uterine prolapse

Fig. 120.4 Using two Sims specula, it is possible to evaluate the extent of uterine prolapse

Assessing the Uterine Size

The prolapsed uterus is in most cases small and atrophic, however if it is enlarged and myomatous it will result in challenging surgery. Every surgeon should therefore ensure that an appropriate assessment has been made of the uterine size prior to commencing the operation. A clinical evaluation by bimanual examination (Fig. 120.5) is usually adequate, but if there is doubt, an ultrasound examination should be done. It remains an excellent habit to repeat the bimanual examination under anaesthesia in the operating room prior to commencing the surgery. An unexpected enlarged uterus is not a pleasant surprise for any vaginal surgeon!

Catheterisation of Bladder

A full prolapsed bladder will always make the surgery more difficult and it is therefore important to catheterise the patient and ensure the bladder is empty at the start of the surgery. In advanced prolapse, it is also a good idea to reduce the anterior vaginal wall using a vaginal retractor, to ensure that bladder emptying is complete. It is also useful to place a bag

Fig. 120.5 It is essential to do a Bimanual examination to evaulaute uterine size

on the catheter to allow it to drain and remain empty during the procedure. An indwelling catheter also allows the urine to be checked intermittently for haematuria, which is a useful early warning of a possible bladder injury. This is particularly important in the anterior dissection of women with a large uterine prolapse.

Placement of the Initial Clamps

In prolapse surgery, the surgical planes are most easily identified by applying traction and countertraction to the prolapsing structures. In order to provide adequate traction to the cervix, two Vulsella are placed on the cervix, one on the anterior lip and another on the posterior lip. In addition, an Allis or Littlewood clamp is placed at the apex of the tear-drop incision, which is shown in Fig. 120.6. It is also easier to do the tear-drop incision if two Allis clamps are positioned at 9 and 3 'o clock on the vagina, alongside the cervix.

Infiltration

Infiltration is performed using a dilute mixture of Bupivicaine and a vasoconstrictor agent, either Adrenaline, Vasopressin or Ornipressin. Inject the infiltration solution into the pericervical tissues going around the full circumference and ensure adequate infiltration of the anterior vaginal wall. It is important to inform the anaesthetist when this is done since the vasoconstrictor can result in changes in pulse and blood pressure (Figs. 120.7 and 120.8).

Fig. 120.6 The upside V- incision is a useful technique to commence the vaginal hysterectomy in prolapse situations

Initial Incision and Accessing the Vesico-Uterine Pouch and Peritoneal Cavity

Remember that injury to the bladder and ureter are avoided by meticulous dissection of the bladder from the entire length of the cervix and lower part of the uterus prior to placing any pedicle clamps. A non-descent vaginal hysterectomy is usually commenced by performing a circumferential incision of the cervix, but in women with advanced uterine prolapse, it may be wise to deviate from this since there is often profound anterior and posterior vaginal wall prolapse. A "tear-drop" shape vaginal incision is often useful in these circumstances (Figs. 120.9 and 120.10).

Where there is minimal anterior and posterior compartment prolapse as in the example provided in Fig. 120.11, then a simple circumcision of the cervix may remain a suitable option.

After performing the "tear-drop" incision, the anterior triangular flap of skin is dissected away from the bladder by starting at the apex of the triangle. A useful technique is to place an Allis or Littlewood clamp at the top point of this

Fig. 120.7 Injection of a dilute solution of a vasoconstrictor into the anterior compartment

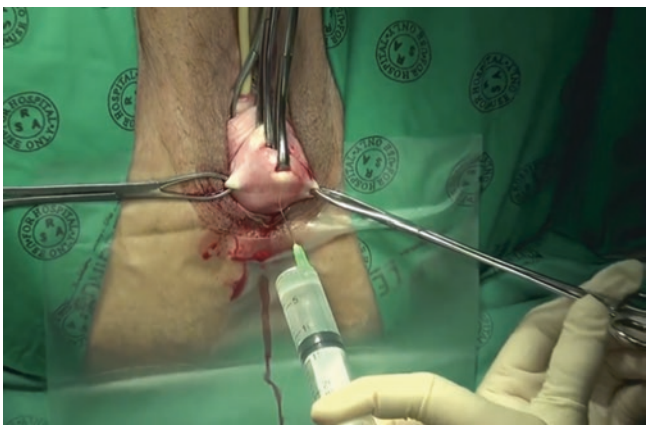

Fig. 120.8 Injection of a dilute solution of a vasoconstrictor into the posterior compartment

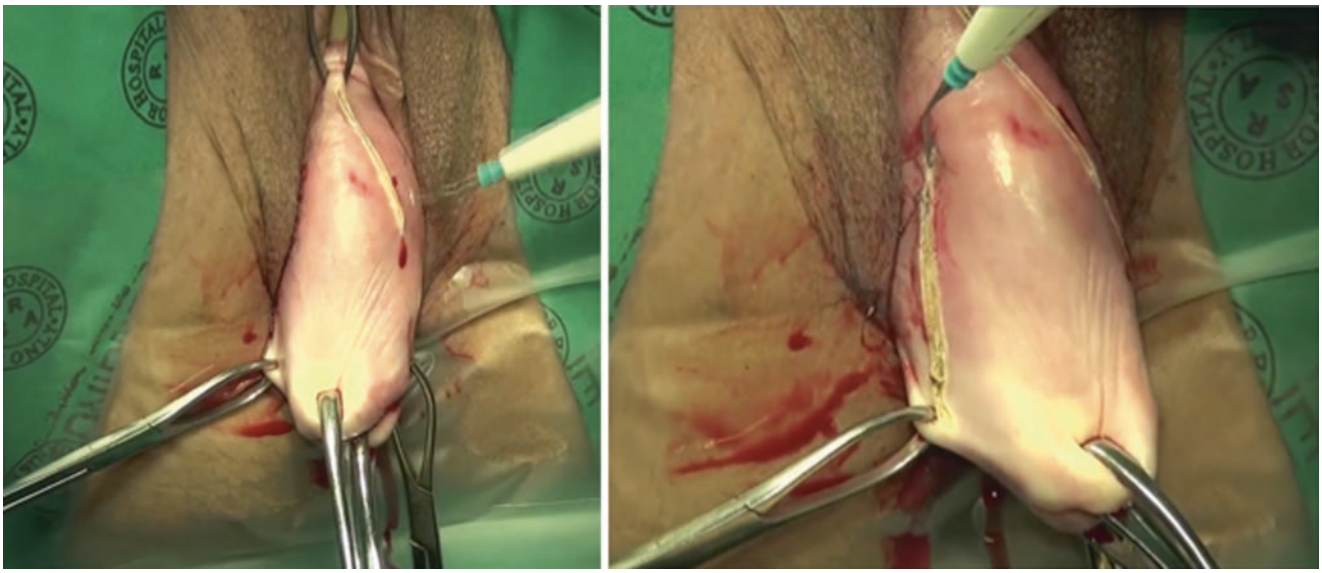

Fig. 120.9 (**a**, **b**) Commencement of the operation with an incision in the anterior compartment

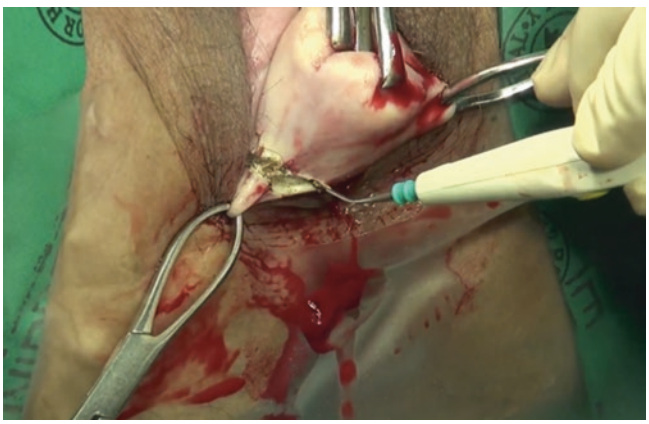

Fig. 120.10 Extension of the incision around posteriorly

skin flap and to apply traction towards yourself with the forefinger exerting countertraction on the outside of the vaginal skin (Fig. 120.12). A sharp Metzenbaum scissors is used to dissect this flap of skin off the bladder (Fig. 120.13). An assistant applies traction to the bladder with a Gillis forceps and this will reveal the most appropriate plane of dissection (Fig. 120.14). Once the skin flap dissection has reached the cervix, it is cut away horizontally between the 3 and 9 o'clock clamps (Fig. 120.15).

The next step includes an attempt at dissecting into the anterior pouch of peritoneal cavity between the bladder and cervix. The plane is most easily revealed by applying upward traction with a Gillis forceps to the bladder, while dissecting onto the cervix and looking for the peritoneal reflection of the

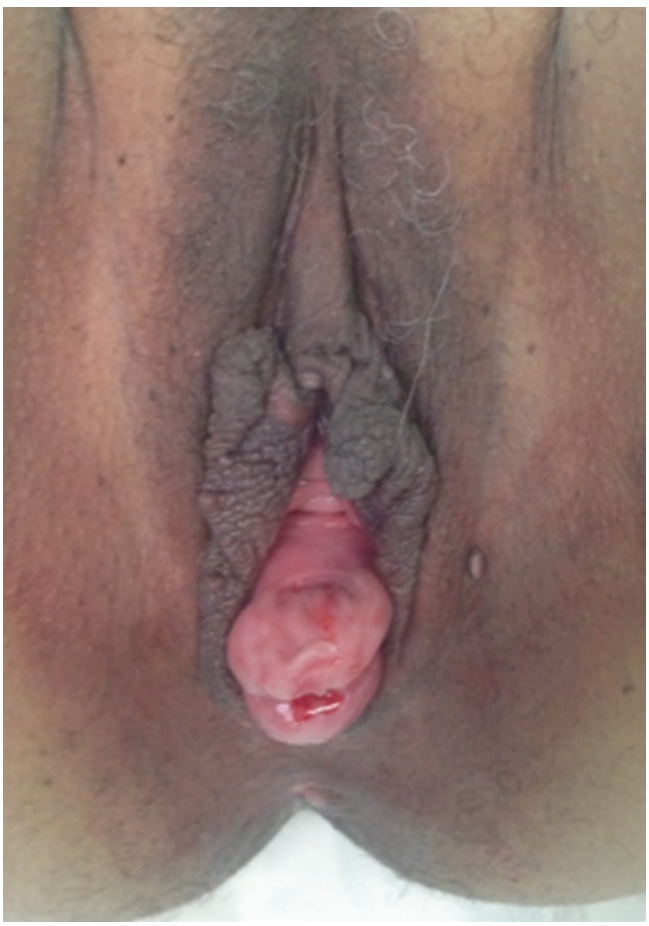

Fig. 120.11 In a case as depicted in this figure, a simple cervical circumcision may be suitable instead of the V-incision

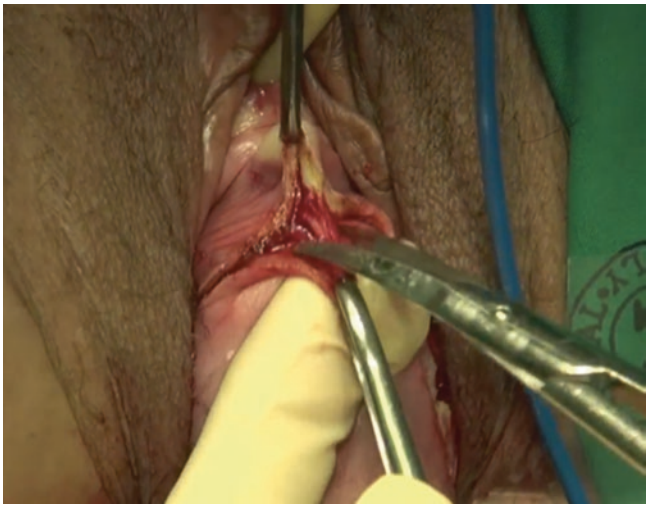

Fig. 120.12 Commencing the anterior dissection involves countertraction with the non-dominant hand

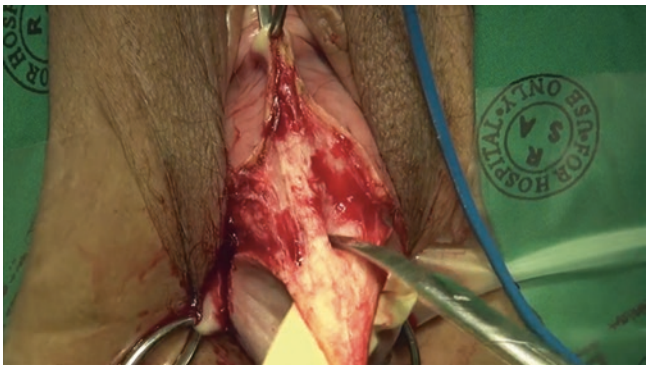

Fig. 120.13 Sharp dissection of the anterior triangle of skin created by the inverted V –incision

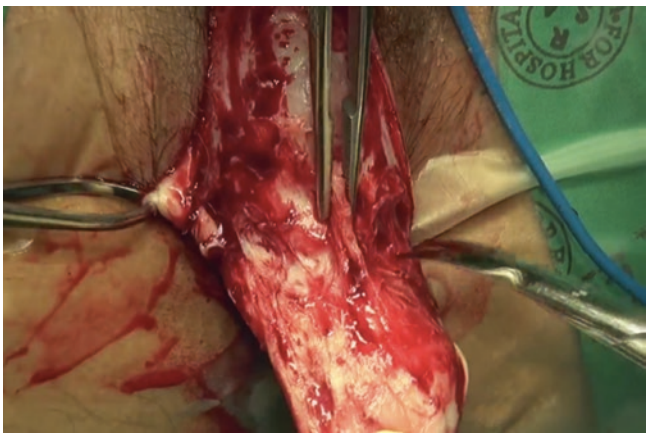

Fig. 120.14 The dissection of the triangular skin flap is extended down to the cervix

bladder onto the uterus. Sharp dissection for this step is preferable, but many experienced surgeons use a blunt dissection technique and push on the cervix with a Raytec swab draped

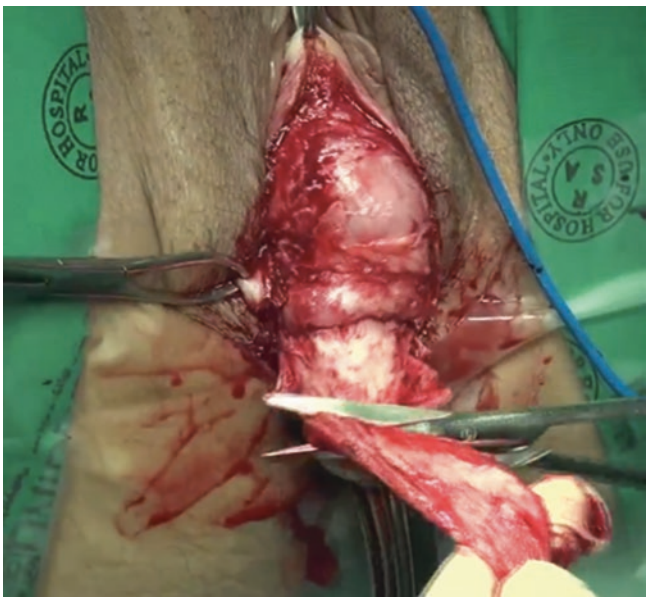

Fig. 120.15 The skin flap is excised at the level of the cervix

Fig. 120.16 Blunt dissection of the bladder from the cervix using a finger

over the index finger (Fig. 120.16). The disadvantage of this technique is that there is a greater risk of bladder injury.

The peritoneal reflection between the uterus and the bladder will be noted to be a clear shiny membrane and once this is clearly seen, a bold incision into this layer will take you into the vesico-uterine pouch. Once you have made your incision and are sure you are in the peritoneal cavity, place the end of

the retractor (Wertheims or Landon or equivalent) inside the peritoneum and ask your assistant to retract anteriorly.

Accessing the peritoneal cavity anterior to the uterus is often a challenging aspect of the vaginal hysterectomy and the dissection is often made even more difficult by a large concomitant cystocele. It helps if your assistant provides good retraction anteriorly over the bladder with the Wertheim (or equivalent) retractor. This pulls the bladder out of the operative field and provides good traction on the peritoneal tissues as you dissect upwards towards the fundus of the uterus. It is also made easier by pushing the front end of the retractor against the cervix and sliding it in a cephalad direction into the anterior pouch. The wider anterior tear-drop incision makes it easier to identify the bladder tissues in these circumstances. It is also important to ensure that the assistant is providing firm downward traction on the cervix by pulling on the vulsella.

Occasionally it is not possible to immediately access the peritoneal cavity in the anterior pouch. In these circumstances it is advisable to defer this and to move onto the next step, which includes accessing the posterior cul-de-sac.

Accessing the Recto-Uterine Pouch and Peritoneal Cavity

The posterior dissection is commenced by stretching the lower skin edge with two Allis clamps. Countertraction is provided by pulling upwards on the Vulsellum that is attached to the posterior cervix. This usually reveals the posterior peritoneal sac which is easily incised (Fig. 120.17). This incision is easily and safely enlarged by stretching laterally with the forefingers of both hands. A Simms speculum is usually placed into the posterior pouch once the peritoneal cavity has been opened.

If the anterior pouch has not been accessed as yet, by placing a finger into the posterior dissection and over the fundus, the anterior peritoneum is often easily distinguished from bladder tissue and incised on the surgeon's finger.

Difficulties Entering the Anterior and Posterior Cul-de-sac

In situations of extensive prolapse, it is occasionally impossible to gain access to the peritoneal cavity following the initial vaginal dissection. The bladder is also often tightly adherent to the cervix when the women has had a previous Cesarean Section. Under these circumstances, it is appropriate to ligate the uterosacral ligaments prior to gaining access to the cul-de-sac. Following this, a further attempt can be made. It remains important to ensure that enough of the bladder has been dissected from the cervix before any clamps are applied.

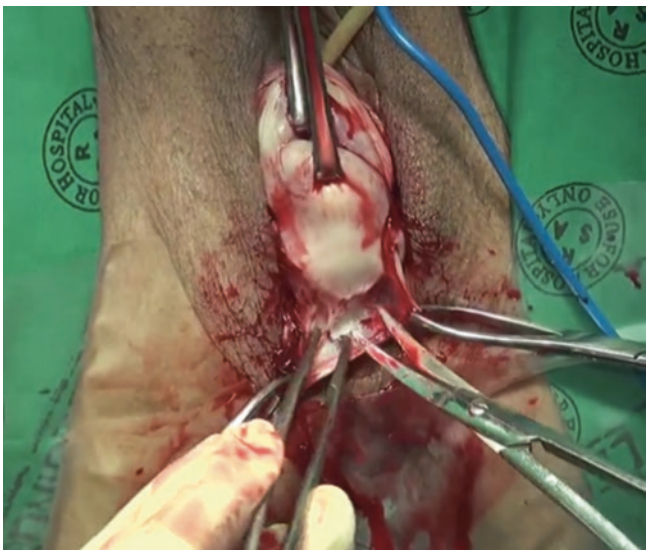

Fig. 120.17 Accessing the pouch of Douglas by applying traction to the vaginal skin to expose the peritoneum

Uterosacral Ligaments

With a Wertheim's retractor in the anterior dissection and Simms speculum in the posterior dissection, the uterosacral ligaments are clamped and tied. A Maingot or Heaney clamp is most suitable for this. A delayed absorbable Polydioxone 0 or 1 suture is used and both ends are kept long and tagged so that they can be attached onto the vaginal vault at the end of the procedure (Fig. 120.18).

Uterine Artery Pedicles

The next step includes the ligation of the uterine artery pedicle (Fig. 120.19). Using a Maingot or Heaney, place the clamp parallel to the uterine corpus. If you have entered the peritoneal cavity already, make sure you include the shiny surfaces of the peritoneum anteriorly and posteriorly in your clamp. This neatens the further dissection and pulls the uterine artery further into the pedicle. Ligate and tie the uterine pedicle with a Polyglycolic acid suture (Eg Vicryl 1). If the women has a particularly long cervix, a number of additional lateral pedicles may be required and this is performed in a similar manner to the uterine pedicle. If the uterus is very large, at this point it is possible to resect a wedge of uterine tissue in the midline to create space.

Bisection of Uterus

Another very useful step is to bisect the uterus after ligation of the uterine pedicles. This enables the surgeon to access the fundus of the uterus more easily and safely and is particularly

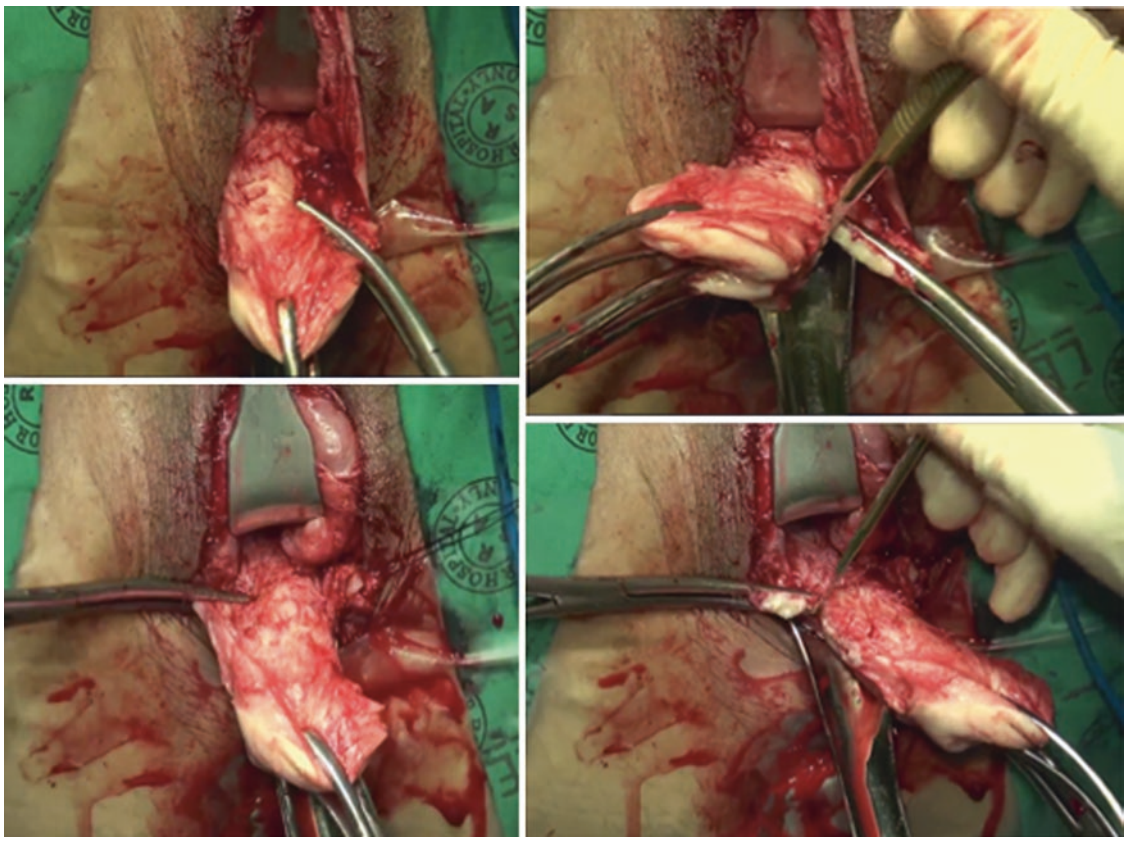

Fig. 120.18 (clockwise from the top left) The clamping and cutting of the right and left uterosacral ligaments

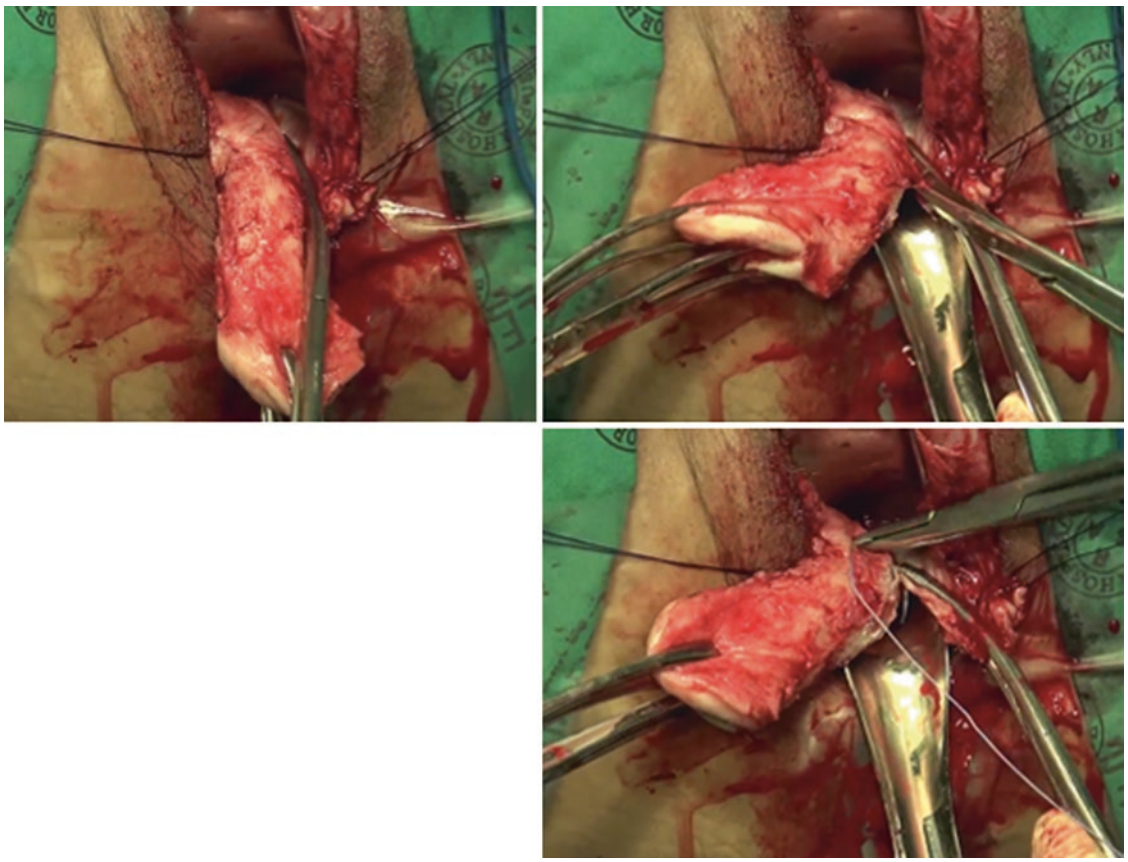

Fig. 120.19 Clamping, cutting and ligation of the left uterine artery pedicle

indicated when the uterus is large. To do this, move the two vulsella to the lateral aspects of the cervix and use a knife to cut the uterus in half from anterior to posterior. Continue up towards the fundus. It is essential to have retractors placed anteriorly and posteriorly. Once you are close to the fundus, place the forefinger of your non-dominant had in the back and over the top of the uterus and onto the fundus and pull down towards yourself. Cut the uterus onto your finger with a curved Mayo scissors and it will now be easy to complete the bisection.

Infundibulo-Pelvic Ligaments

The next step is to clamp and ligate the Infundibulo-pelvic ligaments and broad ligaments. Place two Maingots or Heaneys clamps on the remaining part of the broad ligament and infundibulo-pelvic ligament to create a pedicle and cut the uterus off on both sides. Use Polyglycoloic acid (Vicryl 1) for this step. It is useful to apply two ties on this pedicle, since slippage of this knot could result in haemorrhage which is difficult to access vaginally.

Salpingectomy

The Fallopian Tubes have recently been implicated in the aetiology of the development of ovarian cancers [7]. There is now excellent evidence to support a bilateral salpingectomy when performing a hysterectomy for benign conditions. This is easily done on completion of the hysterectomy by pulling the tube into the vagina using one or two Babcock clamps. A long curved artery forceps is then clamped over the tube and a Polyglycolic acid suture is used to ligate the pedicle.

Oopherectomy

Depending on the age of the patient and her ovarian cancer risk status, it may be necessary to perform a bilateral oophorectomy. A heavily curved Moynihan clamp is most suited to this step. Simply place the clamp over the ovary, cut and tie the pedicle.

Inspection of Pedicles and Ensuring Haemostasis

Once the uterus has been removed and before commencing with the vault suspension procedures, it is essential to take a minute or two to inspect all the pedicles and to ensure adequate haemostasis has been achieved. In order to obtain a better view, a wet pack should be placed into the vagina and peritoneal cavity. Using three lateral vaginal retractors, the pedicles are easily inspected.

Providing Adequate Vault Support

At this point, it is essential to re-emphasise that simply performing a hysterectomy for uterine prolapse is usually not adequate and that the vaginal vault always needs to be supported following the removal of the uterus. The most frequently employed vaginal vault suspension techniques include either a sacrospinous fixation (SSF) or a high uterosacral ligament suspension (HUSLS). Irrespective of whether a HUSLS or SSF has been done, a Modified Mccall culdoplasty should also always be performed as part of a vaginal hysterectomy for prolapse.

Modified Mccall Culdoplasty

The aim of a Mccall Culdoplasty is to place a purse-string suture that plicates the two uterosacral ligaments to each other and onto the posterior aspect of the vaginal vault (Fig. 120.20). This step also closes off the space of a potential enterocele. You will need a Polydioxone (PDS) 1 or 0 for this procedure. Littlewood clamps are placed on the remnants of the right and left uterosacral ligaments. Two long artery forceps are applied to the skin and peritoneum of the posterior vaginal vault, about 1 cm from the midline on either side. A Wertheim retractor in the posterior vagina, outside the incision, enables the surgeon to easily identify the posterior skin edge of the vault. By exerting traction on the two artery forceps that are attached to the vault, a suture is placed in the vagina, from exterior to interior at about a 4 o'clock position. Include some peritoneum in this bite as you come out on the peritoneal side of the incision.

Place the Wertheim retractor now into the incision and ask your assistant to retract posteriorly so that you can see the left uterosacral ligament clearly. Suturing is continued by taking a bite of the left uterosacral ligament. Now take a bite of the inside aspect of the posterior vaginal vault in the midline, including peritoneum and vaginal tissue in the suture (see Fig. 120.20). This closes off the cul de sac (hence the term culdoplasty) and prevents prolapse recurrence in the form of an enterocele. Continuing with the same suture, take another bite from the right uterosacral ligament and complete the Mccall's culdoplasty by coming out again through the vagina on that side, at about the 8 o'clock position.

Cut off the needle and place an artery on the end of this suture that has entered at 4 o'clock and exited the vault 8 o'clock. The McCall culdoplasty suture should be tied at the end of the operation after the vaginal vault has been closed.

Sacrospinous Fixation

This procedure, originally described by Amreich and Richter, was originally used to address post-hysterectomy vault pro-

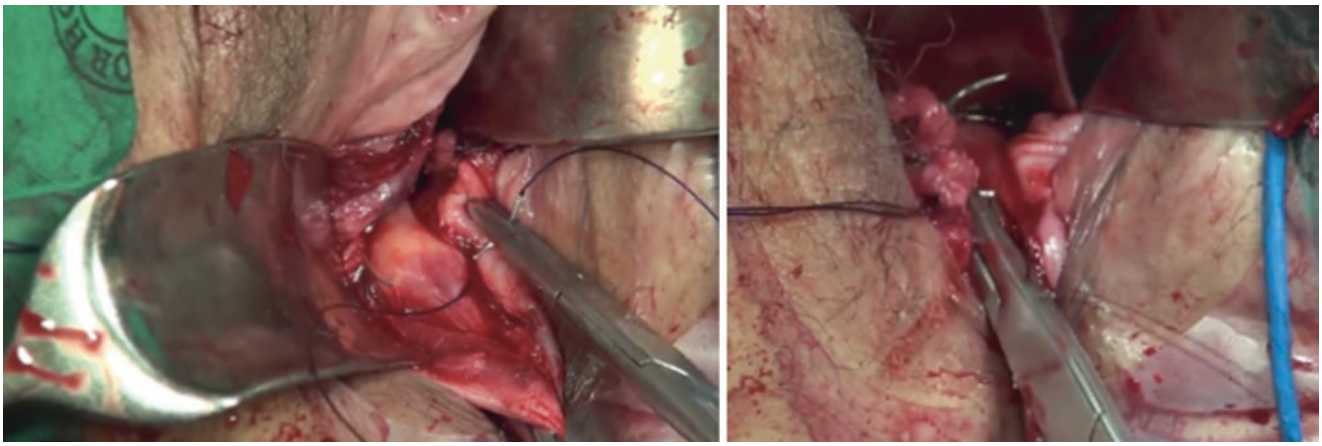

Fig. 120.20 Two steps of the McCall culdoplasty involving (**a**) including a part of the posterior peritoneal edge and (**b**) the right uterosacral ligament

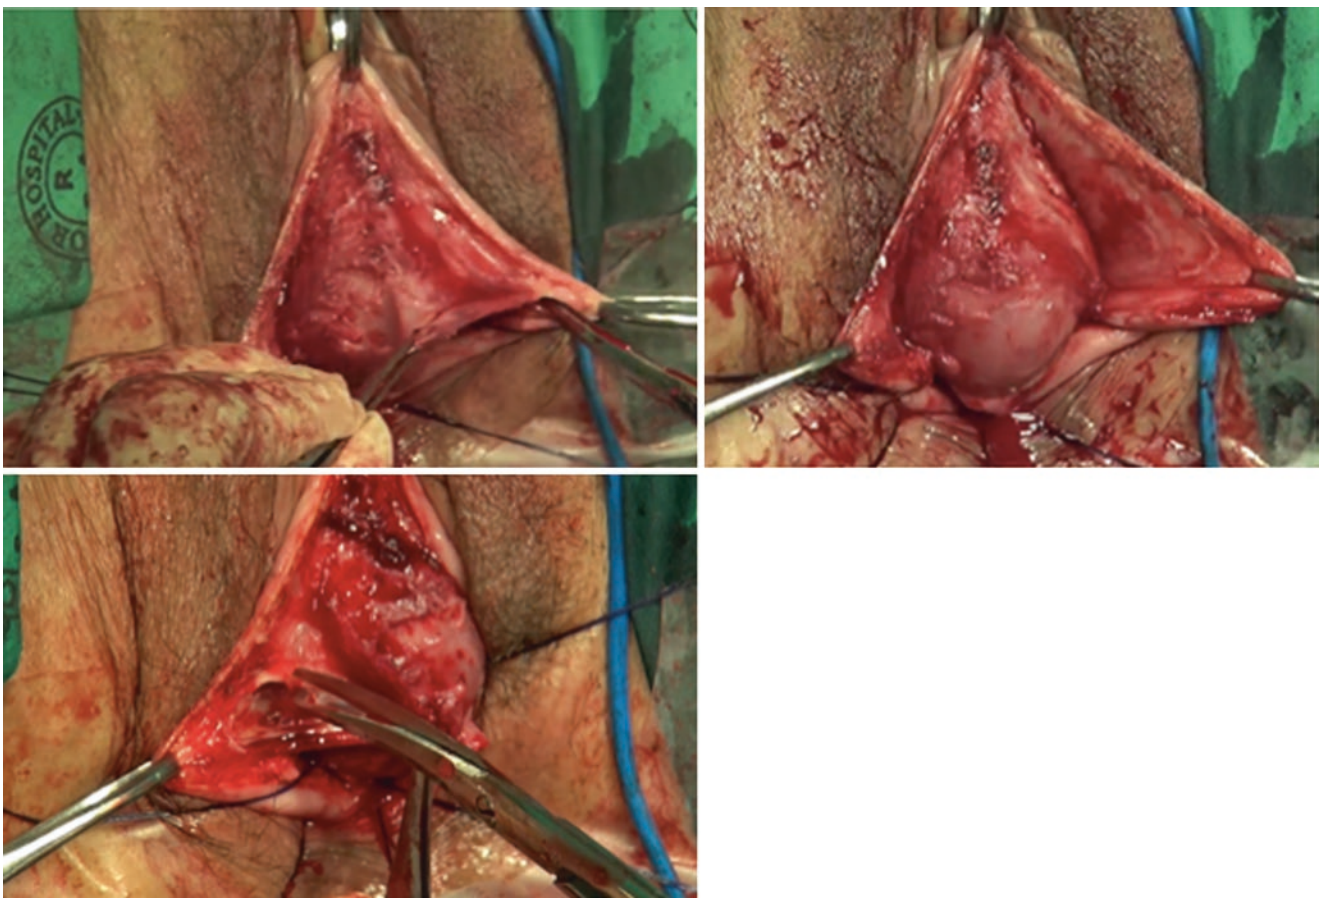

Fig. 120.21 (**a**–**c**) Dissection of the anterior compartment to access the sacrospinous ligament

lapse, but it has been shown to be a successful procedure for vaginal vault suspension following hysterectomy for uterine prolapse [8].

When performing a SSF for vault support at hysterectomy, it is possible to approach the ligament through an incision in the anterior or posterior compartment. My personal preference is to extend the vaginal vault incision anteriorly towards the urethra and bladder neck, in the midline, and then to continue the paravaginal dissection toward the Obturator fascia and Sacrospinous Ligament (SSL) (see Fig. 120.21).

Exposure of the ligament is commenced using sharp dissection, and once the Ischial Spine is palpated, the remainder of the dissection is completed with digital stripping of the tissues overlying the ligament. It is acceptable to perform a

unilateral fixation. This usually results in an asymmetrical vaginal axis, but this has not been shown to be associated with any functional disturbance. [9] It may be possible to restore a normal anatomical vaginal axis by performing a bilateral fixation, but this in turn has the potential risk for increased vaginal tension.

The advantage of performing the SSF through an anterior incision is that it may result in less de novo post-operative anterior prolapse. This has long been cited as a significant complication of a SSF when it is performed through a posterior approach [10]. It may, however, be easier to access the ligament posteriorly.

Attaching a suture to the SSL is one of vaginal reconstructive surgery's great challenges. The ligament is usually visualized using two or three long retractors. The suture is then secured using a Miya Hook, a Deschamps Ligature Carrier, or a long needle holder with sutures. The placement of the SSF suture has been made considerably easier by the introduction of a number of new devices that facilitate the suture attachment by digital palpation. These instruments include the Capio (Boston Scientific) (Fig. 120.22), Fixt (Bard) (Fig. 120.23), Digitex (Coloplast) (Fig. 120.24) and I-stitch (Akacia Surgical) (Fig. 120.25). The amount of dissection required to access the ligament using these minimally invasive devices is significantly less, making the operation quicker and with reduced morbidity (Figs. 120.26, 120.27, 120.28, 120.29, 120.30, 120.31, 120.32, 120.33, and 120.34 demonstrate the placement of the sutures using these

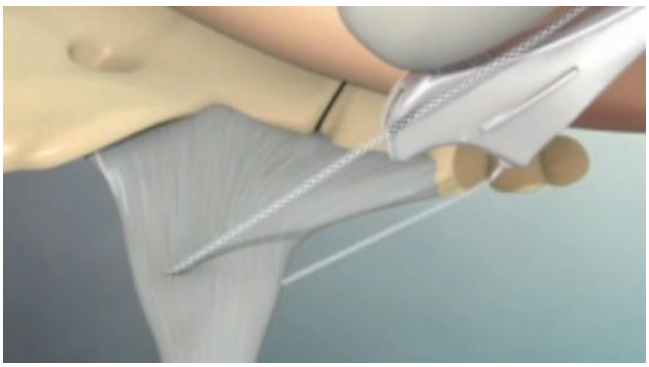

Fig. 120.34 The mechanism of the Fixt device

devices). It is essential to note that the sutures should be placed at least 2 cm from the Ischial spine to avoid entrapment of the Pudendal Nerve.

A recent randomized controlled trial (RCT) comparing the attachment of the SSF suture using the Capio to a traditional suture and needle-holder technique showed a 30 % reduction in operating times in the group where the Capio was used. [11].

A broad range of suture options is available when performing a SSF at vaginal hysterectomy for uterine prolapse. I prefer to use a delayed absorbable polydioxanone (PDS) suture. The advantage of using the PDS is that the suture can be brought out through the vaginal skin and tied outside the vault and this allows for a more secure vault fixation. Other options include a monofilament non-absorbabale suture (Prolene), or a non-absorbable braided suture (Ethibond). It is advisable to avoid using Ethibond since it has been shown to be associated with abscess formation [12]. The other advantage of the PDS suture is that it is possible to pull the suture through the vault in a more lateral position, i.e. further away from the skin edge, and this results in less vaginal tension when doing a bilateral fixation.

SSF is associated with excellent anatomic outcomes, as demonstrated in a review by Beer and Kuhn [10] of 2239 women, reporting success rates of up to 98 %. The greatest risk of sacrospinous fixation is long term buttock and perineal pain. This may be due to Pudendal or Inferior Rectal Nerve entrapment. If this occurs post-operatively, early recourse to suture removal is essential.

High Uterosacral Ligament Suspension (HUSLS)

The uterosacral ligaments connect the cervix and proximal portions of the vagina to the sacrum at about level S2 to S3. They provide the most important endopelvic support to the uterus and vagina. It therefore makes physiological sense to reattach the remaining portion of the vaginal vault to these ligaments when performing a hysterectomy for uterine prolapse.

For every surgeon embarking on a HUSLS, it is essential to appreciate the anatomical relationship between the uterosacral ligament and the ureter. As it descends in the pelvis, the ureter converges with the uterosacral ligament. In its distal portion it is only 1 cm from the ureter. More superiorly and closer to the sacrum it is about 4 cm from the ureter. When performing this procedure it is therefore safer to place the suture higher and closer to the sacrum.

From a technical perspective, the classic HUSLS procedure is commenced after the uterus has been removed. In order to visualise the appropriate site for suture placement, it is essential to use long narrow vaginal retractors and good lighting.

I prefer to use two Navritel-Briesky retractors, but narrow Deavor retractors also work. The original HUSLS technique was popularized by Dr. Bob Shull, and this involved the placement of six uterosacral sutures, three on each side. I prefer to start by placing a suture at the right corner of the posterior vaginal vault at about the 4 o'clock position. The next bite is high on the uterosacral ligament. It needs to be re-emphasized that the uterosacral ligament should be taken as high as possible to avoid ureteric involvement. The next step is to take a bite from the anterior aspect of the vaginal vault. This suture is kept in an artery forceps to be tied at the end of the procedure. Three individual sutures are placed in this manner, sequentially on each side of the vault so that six sutures have been placed to support the vault. These are then tied following vault closure. It is essential to confirm ureteric patency after performing the HUSLS. This is best done by performing a cystoscopy and inspecting the ureteric orifii for efflux. By injecting an intravenous dose of either Methylene-Blue or Indigo-Carmine, the ureteric efflux is easier to see. If a blue or green jet is not observed from either ureters, it is essential to remove the HUSLS sutures sequentially until ureteric patency is confirmed (Fig. 120.35).

There is some debate concerning the type of suture that should be used for the HUSLS. In a study comparing Prolene to PDS, Kasturi et al. [13] showed that there was no difference in anatomical outcomes between the two groups. There was, however, a high incidence of suture erosion (22 %) in those women in the Prolene group. I therefore prefer to use a monofilament delayed absorbable suture such as PDS.

Fig. 120.35 Cystoscopy with efflux of methylene blue confirming ureteric patency

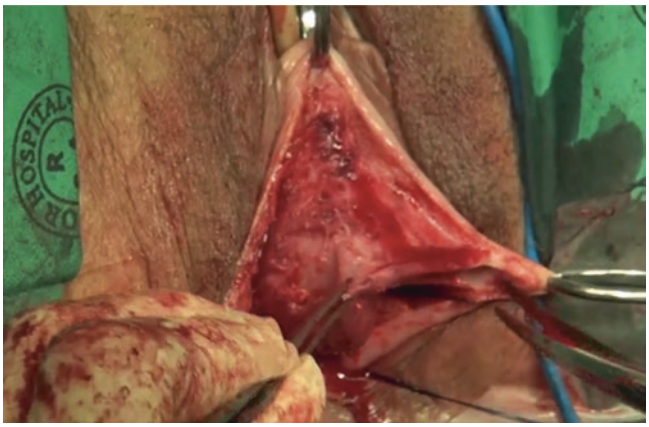

Fig. 120.36 Exposure of the bladder fascia for anterior repair

The HUSLS has been shown to be associated with excellent outcomes. In a review of the outcomes of HUSLS for uterine prolapse, Khunda et al. [14] reported anatomical success rates of between 87 % and 100 %, and in a systematic review of transvaginal uterosacral ligament suspension, Margulies et al. [15] reported a re-operation rate of 9.4 % and ureteric re-implantation rate of 0.6 %.

High Uterosacral Ligament Suspension Versus Sacrospinous Fixation

Both the SSF and HUSLS have been shown to be associated excellent functional and anatomical outcomes when done in women with uterine prolapse. Both procedures, however, have their own technical challenges and complications. These two procedures were looked at in a beautifully constructed RCT by Barber et al. [16] that was recently published in the JAMA. In their comparison of the HUSLS and SSF, they demonstrated no difference in anatomical or functional outcomes between the two groups. The success rates were 59 % and 60 % for the HUSLS and SSF respectively, but they did use very strict anatomical outcome measures. The re-operation rate was, however, very low in both groups, with 3 % of the HUSLS and 2.6 % of the SSF group requiring repeat surgical intervention for prolapse.

Barber et al. have shown the two procedures to be of equal efficacy, but the majority of the women in that trial had grade 2 uterine prolapse. In my opinion the SSF may be a better option in women with more extensive uterine prolapse. It makes anatomic sense that a more secure and higher suspension can be achieved with the SSF. In their systematic review, Margulies et al. [Marguiles] report a successful anatomic outcome in 92 % of women with pre-operative grade 2 prolapse compared to 67 % in those with pre-operative grade 3, which further suggests that the HUSLS should be reserved for smaller degrees of uterine prolapse.

It is also important to consider the complication profile of each of these procedures, which was also elegantly demonstrated by the Barber trial. [Barber] They reported a ureteric injury rate of 3.2 % in the HUSLS group compared to 0 % in the SSF group. Most of these were recognized intra-operatively and in only 0.5 % of the HUSLS cohort was there a need for post-operative intervention for a ureteric re-implantation. One of the potential concerns with the SSF is long term pain due to nerve damage. Barber et al. reported that 4.3 % of the SSF cohort had persistent pain, compared to only 0.5 % of the HUSLS cohort.

Anterior and Posterior Repair When Doing a Vaginal Hysterectomy

It is essential to address all prolapsing compartments when performing a vaginal hysterectomy in prolapse situations. This is usually easiest to do once the uterus has been removed. In order to proceed to the anterior repair, it is usually easiest to extend the original colpotomy incision, that was made for the vaginal hysterectomy, in the midline towards the urethral meatus. Para-vaginal dissection is then done (Figs. 120.36 and 120.37) followed by fascial plication (Fig. 120.38).

The incision and dissection can also be extended posteriorly if a rectocele is the predominant part of the prolapse. If one is using a Miya Hook or a suture and needle holder for the sacrospinous fixation, a posterior approach is also easier than an anterior approach. As stated earlier, approaching the ligament from an anterior dissection is only possible using the newer sacrospinous fixation devices such as the Capio.

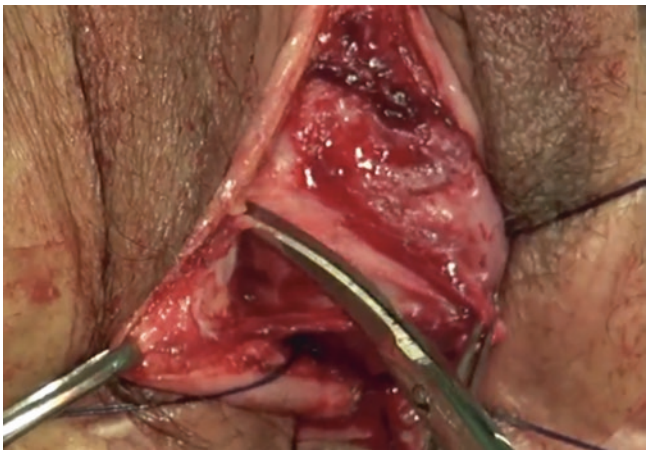

Fig. 120.37 Further dissection of vaginal skin from bladder fascia

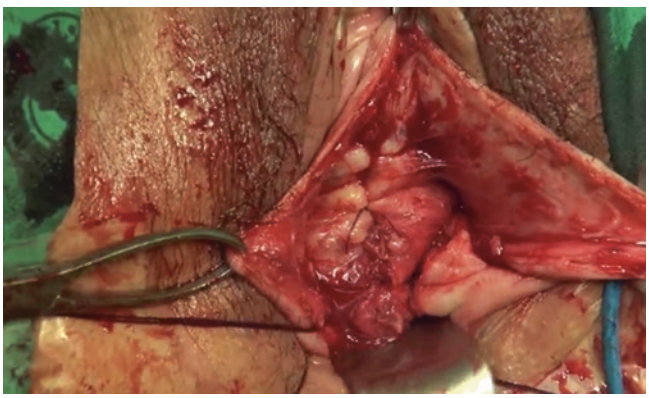

Fig. 120.38 Plication of vesical fascia to complete anterior repair

Attachment of Support Sutures to the Vaginal Vault

If a sacrospinous fixation was done, these sutures are exteriorised and brought separately through the vaginal vault at the apex. When a High Uterosacral Ligament Suspension is done, each suture is brought through the vaginal vault anteriorly and posteriorly. These are tied on completion of closure of the vault.

Closure of the Colpotomy

The vaginal incision is closed following the completion of the anterior and/or posterior repair. This usually involves a midline-type continuous non-locking suture. A transverse closure may be more suitable when an anterior repair has not been done or if a HUSLS has been performed.

Concomitant Stress Incontinence Surgery

Women with uterine prolapse often require a retropubic or transobturator mid-urethral sling for stress incontinence. This should be done on completion of the prolapse procedure and once the vault suspension sutures have been tied. A separate mid-urethral is made for this part of the operation.

Post-operative Care

A vaginal pack is placed on completion of the surgery. The catheter and vaginal pack are removed 24 h post-operatively.

Trachelectomy: Removal of Cervical Stump Following Supracervical Hysterectomy

121

Margaret G. Mueller and Kimberly Kenton

Introduction

Cervical stump extirpation (trachelectomy) is the removal of the cervix following supracervical hysterectomy. Subtotal or supracervical hysterectomy is an alternative to total hysterectomy (removal of uterine fundus and cervix) in women undergoing hysterectomy for many benign indications. There are several benefits to supracervical hysterectomy including reduced complications, shorter hospital stay, and faster resumption of activity; in addition, mesh complications are reduced when hysterectomy is done in conjunction with an abdominal sacrocolopexy Tan-Kim et al. [1], Bensinger et al. [2]. However, women considering supracervical hysterectomy should be counseled regarding risks of cervical retention, including need for cervical screening according to current guidelines, as well as the potential need for future surgery to remove the cervical stump. With increases in minimally invasive surgical techniques, many women will elect to undergo supracervical hysterectomy: therefore, it is likely that most gynecologists will encounter patients that require trachelectomy. In this chapter, we will review the indications for trachelectomy, advantages and disadvantages of different routes of access for trachelectomy, as well as complications associated with removing the cervix following subtotal hysterectomy.

Historical Perspective

The first successful abdominal supracervical hysterectomy was performed in 1853 for the treatment of uterine fibroids Thom et al. [3]. In the early half of the twentieth century, surgeons favored supracervical hysterectomy over total abdominal hysterectomy owing to the almost doubled complication rates of total compared to supracervical hysterectomy. However, by 1960 with advantages in surgical technique, anesthetic delivery and the discovery of antibiotics, most gynecologic surgeons abandoned supracervical hysterectomy as they were now able to safely perform total abdominal hysterectomy Jones et al. [4, 5]. It was not until the 1990s that surgeons began to reconsider supracervical hysterectomy for the surgical management of benign gynecologic conditions. Touted benefits included decreased risk of development of pelvic organ prolapse, sexual dysfunction and lower urinary tract symptoms Brown et al. [6], Kilkku et al. [7]. In addition, supracervical hysterectomy was thought to decrease intra and postoperative complications such as bladder and/or ureteral injury and cuff abscess/hematoma. However, recent randomized controlled studies do not support these benefits Learman et al. [8]; Greer et al. [9]. A US multicenter randomized trial of supracervical and total abdominal hysterectomy reported no difference in symptoms of pelvic pain/pressure, urinary incontinence, or voiding dysfunction 2-years after surgery Learman et al. [8]. In addition, they found no differences in complications, including blood loss/transfusion, lower urinary tract injury or fever, or sexual function Learman et al. [10]; Kuppermann et al. [11]. Long-term follow up using symptom assessments showed no difference in urinary incontinence, pelvic organ

prolapse or sexual function 9-years after surgery Greer et al. [9]. Similarly, a multicenter trial in UK showed no difference in urinary or pelvic floor symptoms 1-year after supracervical or total hysterectomy, but found quicker recovery and fewer short-term complications in the supracervical hysterectomy group Thakar et al. [12].

The first report of one of the more common long-term complications of supracervical hysterectomy (carcinoma of the cervical stump) came 50 years following the first successful supracervical hysterectomy [13]; Decker et al. [14]. A major proven disadvantage to supracervical hysterectomy is the development of cervical stump complications Gimbel et al. [15]; Boosz et al. [16]. In 1959, the Mayo Clinic reported their experience with cervical stump extirpation in 514 patients dating back to 1940 Welch et al. [17]. Most common complications requiring delayed removal of the cervix include pelvic organ prolapse, cyclical bleeding, and uterine and/or cervical abnormalities. One retrospective case series of 300 women who underwent supracervical hysterectomy for benign disease reported a 3 % re-operation for removal of cervix. Only one woman had re-operation for cervical bleeding; the majority underwent cervical stump removal for cervical or uterine abnormalities Boosz et al. [18].

Indications

While early case series suggest cervical carcinoma was the primary complication associated with supracervical hysterectomy [19], modern case series suggest the most common indications for this cervical stump removal are prolapse, bleeding, pelvic mass, abnormal cervical pathology, and pain [13]; Hilger et al. [20, 21]. In 1931, Mayo brothers reported a case series of nearly 100 women who presented with cervical cancer after supracervical hysterectomy; however, with modern cervical cancer screening, trachelectomy for cervical cancer is less common. In 2001, Okaro et al. reported that nearly one quarter (22.8 %) of women undergoing laparoscopic supracervical hysterectomy for pelvic pain inevitably required trachelectomy Okaro et al. [22]. Based on several large case series, the most common Indications for this procedure include prolapse, bleeding, pelvic mass, abnormal cervical pathology, and pain (Table 121.1) [13, 21]; Hilger et al. [20]. In addition with the increase in supracervical hysterectomies done at the time of open, laparoscopic, or robotic sacrocolpoepxies with permanent mesh, trachelectomy for foreign body complications or mesh extrusion from the cervical stump are more common. These procedures are often quite difficult secondary to the mesh suspending the cervical stump to the anterior longitudinal ligament of the sacrum.

Table 121.1 Indications for removal of cervical stump

Indication	Pratt and Jeffrey [13] N = 262	Pasley [21] N = 55	Hilger [20] N = 310 (patients had multiple indications)
Prolapse	101	47	161
Pelvic mass	47	0	78
Abnormal cervical cytology	57	6	36
Non-cervical cancer	6	0	19
Bleeding	42	1	28
Pelvic Pain	3	0	31
Other	6	1	23

Surgical Techniques

Route

When possible, the vaginal route is the preferred route of trachelectomy for benign gynecologic indications owing to its significantly lower rates of intra- and perioperative complications compared to the abdominal route (20 % vs 43 %) Hilger et al. [20]. The vaginal route also provides a minimally invasive option to the abdominal approach with its inherent benefits including quicker recovery and shorter hospital length of stay Hilger et al. [20]. Certainly, there are some clinical scenarios when an abdominal approach is favored, such as in the case of a large pelvic mass or a prior abdominal sacrocolpopexy with permanent mesh. As focus on minimally invasive surgery continues to grow, laparoscopic and/or robotic trachelectomy for benign disease are gaining popularity. Nezhat described laparscopic trachelectomy for pelvic pain following SCH in six women and noted no intra or postoperative complications Nezhat et al. [23].

Vaginal Trachelectomy

The technique that we use for trachelectomy is similar to Welch's initial description in 1959. Prior to induction of anesthesia, the patient is given preoperative antibiotic prophylaxis. The patient is then placed in dorsal lithotomy using supportive yellow-fin stirrups. A Foley catheter is inserted to drain the bladder throughout the procedure. The anterior and posterior lips of the cervix are grasped with two Jacob's tenacula. A circumferential colpotomy is performed with a Bovie electrosurgical device. Gentle upward traction is applied to the anterior vaginal epithelium to facilitate exposure of the vesico-uterine plane. With downward countertraction, the bladder is sharply dissected off of the cervix until the vesicouterine peritoneum is identified and incised. Once

intra-peritoneal entry is confirmed, a right angle Heaney retractor is placed in the anterior cul-de-sac. Next, we turn our attention to posterior entry. Again with gentle traction on the posterior vaginal epithelium and upward counter traction of the cervix, the posterior cul-de-sac is identified and entered sharply. At this point, gentle manual exploration is performed to ensure that there are no adhesions between the cervical stump and bowel and/or omentum.

Next, the uterosacral ligaments on each side are identified, grasped with a Heaney clamp and suture ligated. Serial pedicles are suture ligated, including the cardinal ligament complex. Once the cardinal ligaments are suture ligated, the cervical stump is freed; however, there might be adhesions that need to be carefully lysed at this time. Once the cervix is removed, the vaginal cuff is re-suspended with a uterosacral ligament suspension and closed hemostatically Shull et al. [24].

Cystoscopy is routinely performed to ensure lower urinary tract safety paying particular attention to the integrity of the urothelium and brisk bilateral efflux of urine.

Open Abdominal, Laparoscopic or Robotic Trachelecomy

In rare cases, an abdominal approach via laparotomy, laparoscopy, or robotic assisted laparoscopy is appropriate. These routes of access should be considered based on indication for trachelectomy, particularly in cases of pelvic mass or prior sacrocolpopexy with permanent mesh, which preclude vaginal approach. The cervix is often difficult to identify using an abdominal approach due to dense bowel and bladder adhesions over the cervix. In cases of a prior sacrocolpopexy with mesh, the graft material extending from the cervix and vagina to the sacrum can be visualized and used to guide dissection and identification of the cervix. Placement of a Lucite stent in the vagina is also useful to facilitate identification of the cervix. Once the cervix is palpated, the bladder is sharply dissected to allow placement of Heaney clamps across the cervico-vaginal junction. Prior to removing the cervix, the uterosacral ligaments are identified bilaterally. These ligaments will be used to suspend the vaginal cuff. Once the cervix is removed, the cuff is closed hemostatically and suspended to the uterosacral ligaments. Cystoscopy is routinely performed to ensure lower urinary tract safety paying particular attention to the integrity of the urothelium and brisk bilateral efflux of urine.

Complications

Data on complications of trachelectomy are derived from several small case series. The largest retrospective case series included 335 women undergoing trachelectomy following supracervical hysterectomy. Trachelectomies performed via an abdominal route were associated nearly double the rate of intra- and perioperative complications compared to those performed via a vaginal route including infection, perioperative bleeding, intraoperative injury and venous thromboembolism. Moreover, in 47 women who underwent vaginal trachelectomy without other concomitant surgery, only 3 women (7 %) suffered complications (2 women with postoperative infections and 1 woman with postoperative bleeding).Hilger et al. [20].

Conclusion

Indications for supracervical hysterectomy change over time based on patient and surgeon preferences and skill; however, some women will develop complications associated with retention of the cervical stump that require trachelectomy. While cervical malignancy is the most concerning indication for cervical stump removal, it is uncommon secondary to modern cervical screening techniques. Trachelectomy for benign indications is more common with a recent rise in trachelectomy for mesh related complications after sacrocolpopexy. When feasible, a vaginal route of access for trachelectomy is preferred secondary to low rate of complications when compared to the abdominal route. In cases of malignancy, pelvic mass, or prior sacrocolpopexy, an abdominal route may be indicated.

Vaginal Salpingo-Oophorectomy

122

Shirish S. Sheth

Introduction

The female pelvic organs have two portals of entry: One, natural and the other artificially created at surgery. None other than a gynaecologist will have the in-depth knowledge of the art and science of making optimum use of the natural orifice for *per vias naturales* i.e. vaginal or gynaecological route for any surgery on the pelvic organs.

The vaginal approach has always been the hallmark of the gynaecological surgeon. For hysterectomy, the vaginal route has proved its supremacy over all other alternatives. Only when this natural route is unsafe or not possible, should the gynaecologist choose an alternative i.e. an abdominal access, either by laparoscopy or laparotomy [1, 2].

The most common secondary procedure performed in conjunction with hysterectomy is prophylactic oophorectomy and/or salpingectomy. Although there is controversy even today about prophylactic oophorectomy, there has been debate on the subject from the end of the nineteenth century, since Tait, the foremost advocate of spaying in women-and Spencer Wells slugged out their acrimonious differences on the subject [3, 4]. Even those who removed benign ovarian cysts were labeled "gelders" with a resultant ruined reputation. Be that as it may, the American College of Obstetricians and Gynecologists has recommended that women over the age of 50 years undergoing hysterectomy should consider with their physicians, the risk and benefits of concomitant oophorectomy [5]. The probability of a 40 year old woman developing ovarian cancer by age 85 ranges from 1.2 % (95 % CI 0.8–1.4 %) if she has no risk factors, to 6.6 % (95 % CI 5.0–8.6 %) if she has five or more risk factors [6, 7].

Low-risk women undergoing hysterectomy for benign indications should not be subjected to prophylactic oophorectomy, especially if lesser than 55 years of age. The author does not hesitate to perform prophylactic salpingo-oophorectomy after the age of 50–54 years as several other factors besides risk, hypertension, obesity, diabetes, resorting to Hormonal replacement therapy (HRT) and contraindication to HRT are to be accounted for. A clear advantage of prophylactic oophorectomy is demonstrated in women with endometriosis who have a 47 % chance of further surgery if the ovaries are preserved at hysterectomy for endometriosis [8]. J Donald Woodruff (personal communication) has said that if the ovaries warrant removal, they should be removed whether the hysterectomy is by the vaginal or abdominal route and even after age of 40 years [9]. The decision to perform prophylactic oophorectomy should not be influenced by the route of hysterectomy and is not a contraindication to perform hysterectomy by the vaginal route [5]. There is no place for risky surgical acrobatics, and only if transvaginal oophorectomy or salpingo-oophorectomy can be performed safely and under vision, should it be done. There appears to be some reluctance to combine vaginal hysterectomy (VH) with oophorectomy because it is thought to be a risky and difficult procedure. The correct paradigm substantiated by clinical evidence is to first attempt ovarian removal transvaginally [10, 11].

Incidence

A bilateral oophorectomy was carried out in 92 % for abdominal hysterectomy, and only 9.4 % during VH respectively in women between 55 and 60 years age group [12]. Concomitant oophorectomy at hysterectomy presented by Gross et al. [13] was in 89 % in total abdominal hysterectomy (TAH), 86 % in laparoscopic hysterectomy and 27 % at vaginal hysterectomy. This is accentuated by the fact that usually 75 % of hysterectomies are not performed by the vaginal route.

The test of our progress lies in overcoming what obstacles our fellow men.

Interestingly, 39 of 40 cases [14] had ovarian removal managed successfully per vaginum using the transvaginal endoscopic technique at hysterectomy without laparoscopic assistance. Obviously, where there is a 'will' there is a way. In the author's earlier series of 740 VHs, there was 95 % success in associated salpingo-oophorectomy [15–18].

The American College of Obstetrics and Gynecology guidelines recommend the use of laparoscopic assistance only for difficult oophorectomy at vaginal hysterectomy [19]. Removal of the ovaries at vaginal hysterectomy is usually not difficult and should not be made difficult to 'fit in' with ACOG's Guideline.

Routine prophylactic oophorectomy for postmenopausal women at abdominal hysterectomy is a standard practice but, paradoxically, not if the hysterectomy is performed by the vaginal route. This is often done without the slightest hesitation by gynecologists, who have double standards for prophylactic ovarian removal when the approach is vaginal compared to hysterectomy performed by laparoscopic technique or by opening the abdomen. Gynecologists today are stretching to add three or four abdominal punctures to perform laparoscopic oophorectomy or salpingo-oophorectomy to assist vaginal hysterectomy but are not willing to learn an additional step to perform oophorectomy or salpingo-oophorectomy concomitantly at vaginal hysterectomy [20, 21].

The trend is towards fashionable laparoscopic surgery. Quite often, the gynecologist's inability to perform and/or indifference to learn, adds to it. Scientifically, laparoscopic is obviously more invasive than per via naturales. Let us remain scientific, have maximum interest in what is best for the patient, cost, invasion, availabilities etc. and above all develop the art of vaginal surgery. It is useful to ask the question before every hysterectomy: 'if I were to carry out the hysterectomy abdominally, would I have retained or removed her ovaries and the same reply must be implemented at vaginal surgery.'

Oophorectomy or Salpingo-Oophorectomy?

Recent histologic, molecular, and genetic studies indicate that many ovarian cancers may have originated in the fimbrial end of the tube. Therefore, tubal removal is an absolute must at hysterectomy i.e. not just bilateral oophorectomy but bilateral salpingo-oophorectomy.

Three strategies for risk reduction in women with BRCA mutations have been recently tried [22]. They are (1) bilateral salpingo-oophorectomy, (2) bilateral salpingectomy, and (3) bilateral salpingectomy with delayed oophorectomy to find benefits in years-of-life expectancy and quality-adjusted life-year expectancy, and the primary outcome was the incremental cost-effectiveness ratio. The model estimated the number of future breast and ovarian cancers and cardiovascular deaths attributed to premature menopause with each strategy.

- Bilateral salpingo-oophorectomy was associated with the lowest cost and highest life expectancy compared with the other two strategies. Bilateral salpingo-oophorectomy yielded the lowest number of future breast and ovarian cancers compared with the other two strategies. Thus, bilateral salpingo-oophorectomy offers the greatest risk reduction for breast and ovarian cancer among BRCA mutation carriers.
- Salpingectomy followed by delayed oophorectomy yielded the highest quality-adjusted life expectancy with incremental cost-effectiveness ratios, relative to salpingectomy alone.
- When considering quality-adjusted life expectancy, bilateral salpingectomy with delayed oophorectomy is a cost-effective strategy and may be an acceptable alternative for those unwilling to undergo bilateral oophorectomy.

Understanding and implementing the above guidelines, it is clear that one should prefer salpingo-oophorectomy to prophylactic oophorectomy at hysterectomy. However, if the ovaries are to be preserved, it is worth performing bilateral partial salpingectomy which must include the fimbrial ends of tubes.

Technique

Nichols [10] has described the steps of oophorectomy at hysterectomy. Cengiz et al. in residency training [23] used laparoscopic evaluation and followed this successfully in 64.7 % cases by performing vaginal hysterectomy using Heaney technique and salpingo-oophorectomy using Sheth's technique. Kovac and Cruikshank found oophorectomy at vaginal hysterectomy is possible in the great majority of cases and is superior to other approaches [24].

The technique for concomitant salpingo-oophorectomy at VH as given below has been practised by the author since 1977 for more than 2000 cases, with a 3 % failure rate at present, [15, 17, 21] (Fig. 122.1).

1. The vaginal hysterectomy is begun as usual. All uterine lateral connections, including the cornual structures are severed on one side and upto the cornual structures or upper pedicle on the contralateral side. After uterus is severed from all its pedicles on one side, it hinges or hangs on the support of the contralateral upper pedicle. The decision to perform salpingo-oophorectomy comes into action only after the cornual pedicle or uppermost pedicle, comprising of the round ligament, utero-ovarian ligament and fallopian tube, have been cut on one side [15, 20, 21] (Fig. 122.2).

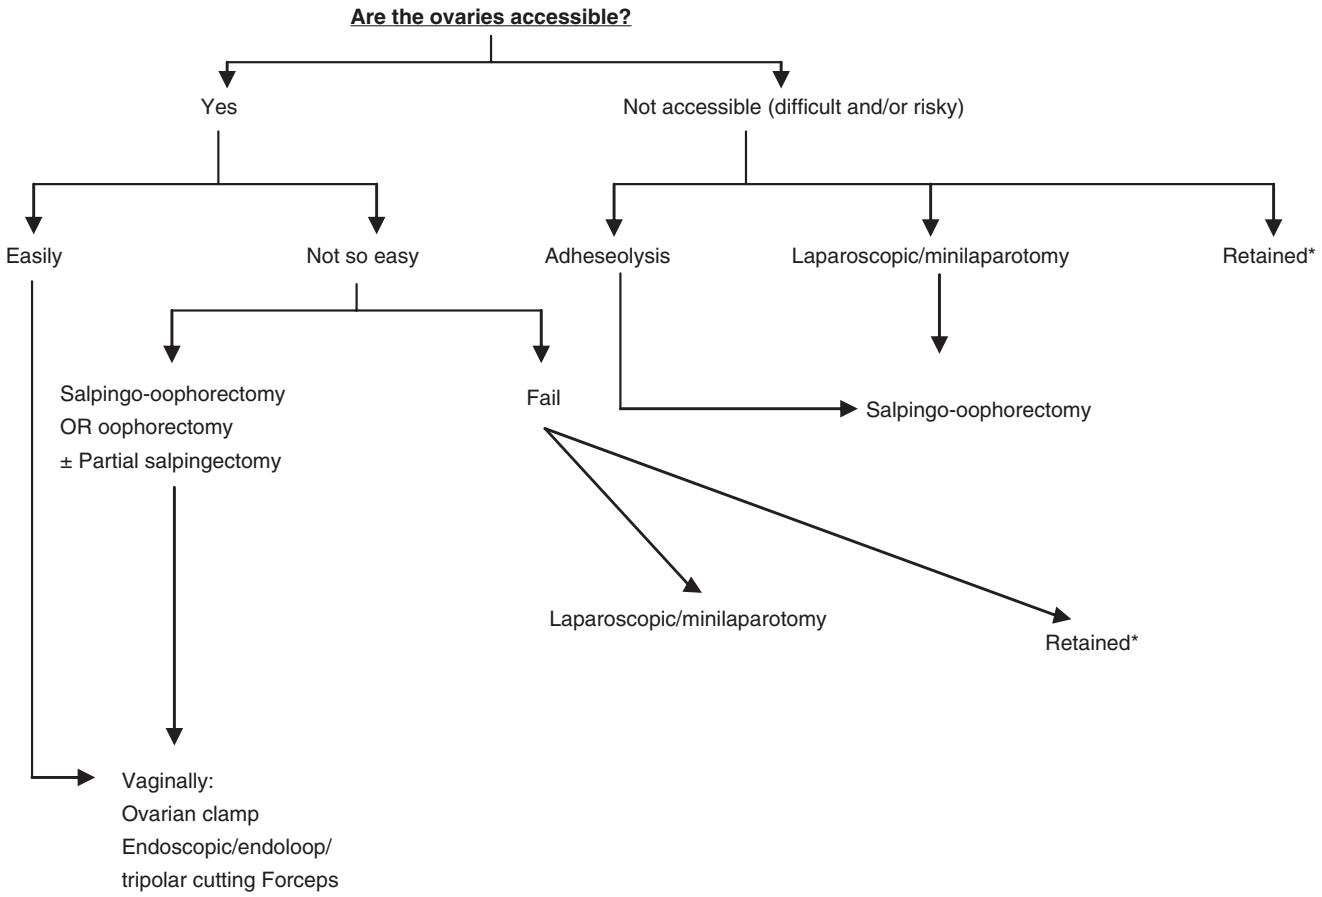

Fig. 122.1 Algorithm for prophylactic oophorectomy at VH, salpingo-oophorectomy at VH

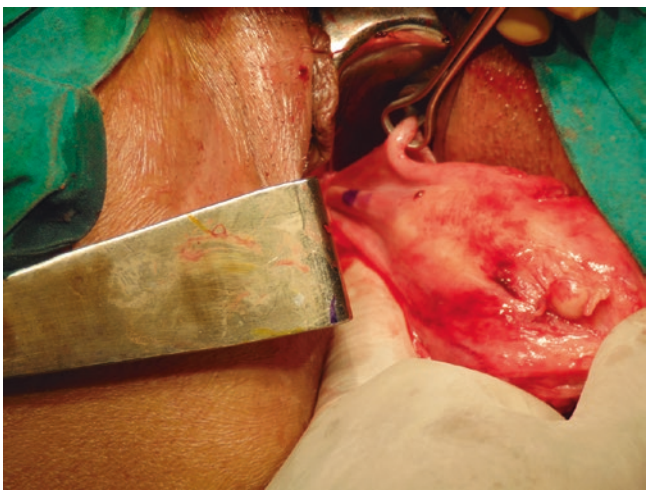

Fig. 122.2 Uterine anterior surface with all the lateral connections severed on left side and Babcock holding the right fallopian tube. Anatomically shows prominent round ligament with bit of anterior broad ligament, to be cut separately and distally from the uterus

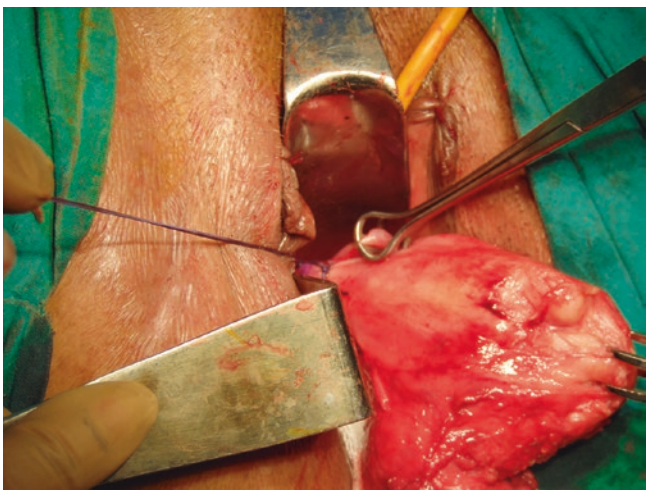

Fig. 122.3 Uterine anterior surface with all the lateral connections severed on left side and Babcock holding the right fallopian tube. Round ligament, seen distinctly is well secured with suture and will then be cut medially and separately away from the fallopian tube and mesosalpinx (tube is held with Babcock forceps)

2. The objective is to get an easy access to the infundibulopelvic ligament, for which it is mandatory that the round ligament is separately and distally clamped, cut, and ligated i.e. separated from other structures (Figs. 122.3 and 122.4). The round ligament of the intact upper pedicle is now severed, as laterally as possible – 4–5 cm away from the uterus after excising the inferiorly attached broad ligament. This makes the

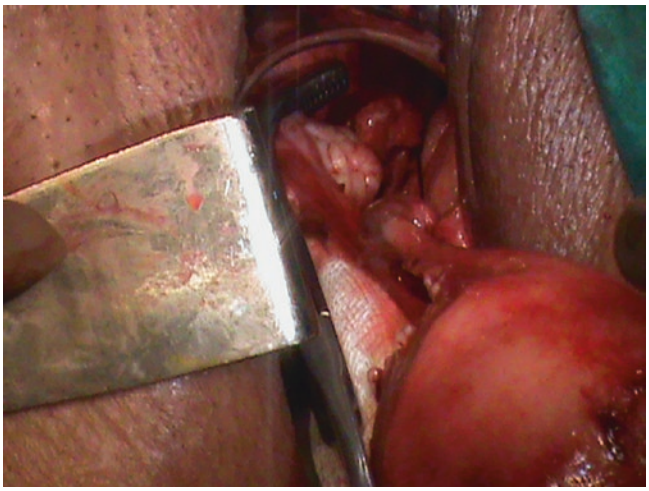

Fig. 122.4 Cutting round ligament paves the way to infundibulopelvic ligament for applying ovarian clamp. Well applied clamp is seen distally beyond the right ligament along with posterior uterine wall with right tube and part of ovary

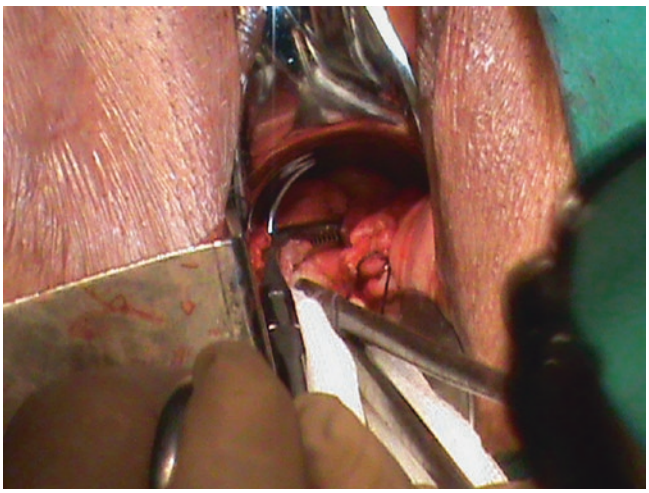

Fig. 122.5 Clamp applied to the right infundibulopelvic ligament with suture on pedicle to transfix and secure it

vascular pedicles as small as possible and leaves the tube and ovary attached only to the infundibulopelvic ligament [15, 16]. This is a vital step as it facilitates and paves the way to clamping of the infundibulopelvic ligament. Just as at an abdominal hysterectomy, the round ligament is cut separately and as laterally as possible to create space to facilitate clamping of the infundibulopelvic ligament well beyond the ovarian tissue (Fig. 122.4); for concomitant salpingo-oophorectomy at VH, the same principle is applied. Jones writes "that Sheth advocates clamping the round ligament and tube separately". The Author has repeatedly emphasized this for 35+ years [2, 15, 21]. The next step is to apply traction on the suture holding the round ligament laterally and on the tube and ovary medially with a Babcock forceps so as to have generous space between these two for application of the special ovarian clamp to the infundibulopelvic ligament and to proceed to complete salpingo-oophorectomy [15–17] (Figs. 122.4 and 122.5). The fibreoptic light of a laparoscope can illuminate the lateral vaginal wall, tube, the ovary and infundibulopelvic ligament, the bladder and bowel, and posterior loops of the small intestine, if popping out. A Sims speculum and bladder retractor, can have an attachment to fix a fiberoptic light (Figs. 122.6 and 122.7) [18, 25]. Trendelenburg position coupled with large roller gauze packing partially hanging out provides adequate exposure and safety, aided by excellent vaginal wall retraction, both laterally and anteroposteriorly, by experienced assistants. A Large sized Sim's speculum can be inserted anteriorly in reversed position to provide extra space and protect the bladder.

Fig. 122.6 Sim's vaginal speculum with attached fiberoptic light facility (With permission Sheth [25])

Fig. 122.7 Bladder retractor with attached fiberoptic light facility (With permission Sheth [25])

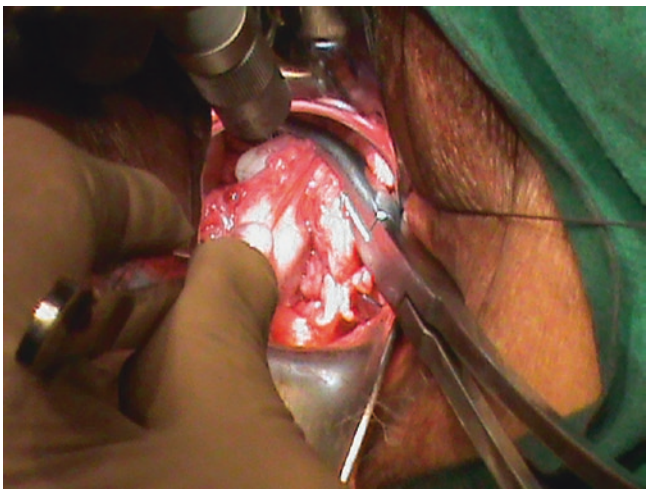

Fig. 122.8 After completion of salpingo-oophorectomy on right side, left round ligament is clamped to have it separated out from the left tube and ovary and create free space. Left tube and ovary are distinctly seen in the centre

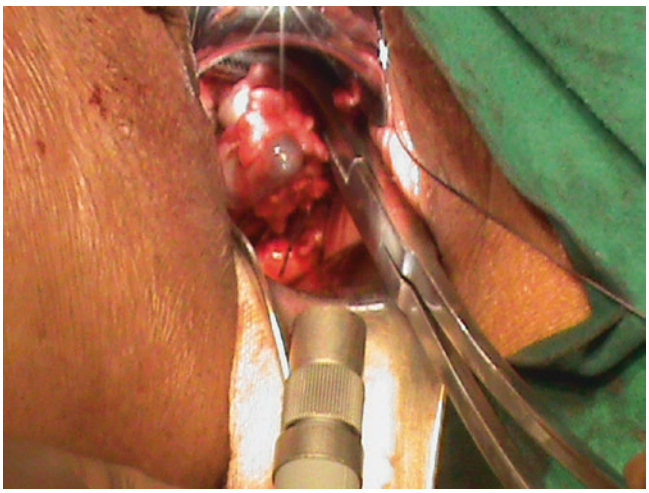

Fig. 122.10 After separating out left round ligament (suture is seen at approx. 3 O'clock position), ovarian clamp is easily applied to infundibulopelvic ligament with its tip well beyond the ligament to complete left salpingo-oophorectomy

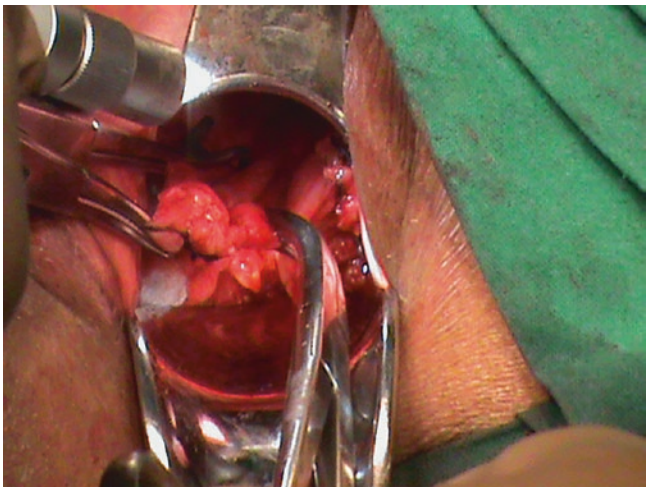

Fig. 122.9 After cutting left round ligament separately and distally (suture is seen at approx. 3 O'clock position), ovarian clamp is easily applied to infundibulopelvic ligament. Fibreoptic light facilitates and shows the tip of the clamp well beyond the ligament

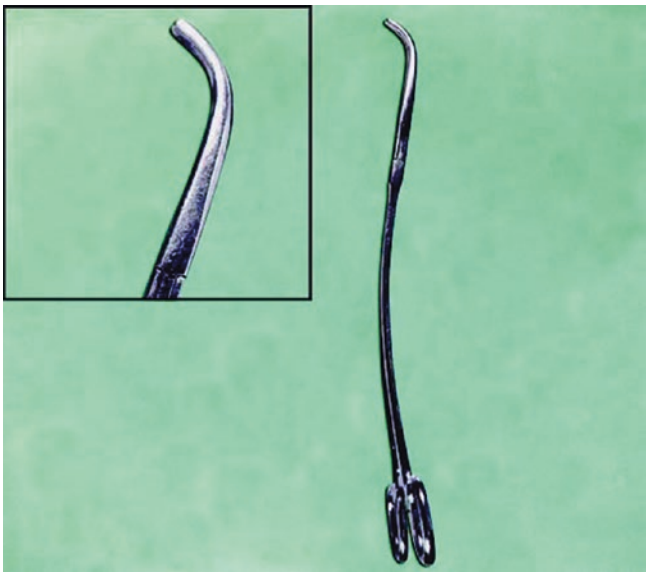

Fig. 122.11 Specially designed ovarian or adnexal clamp (Cooper Surgical, USA) (With permission Sheth [15])

Deaver's and Jayle's vaginal wall retractors are also useful, when required. Gentle handling and extra respect for the tissue is essential at this time to prevent tearing and bleeding.

3. Attention is now turned to the contralateral salpingo-oophorectomy of the remaining ovary and tube on the other side where all the uterine connections were severed earlier. The Round ligament is separated out from the earlier secured upper pedicle and the separated round ligament is cut laterally and distally, and pulled laterally; the tube and ovary are held with a Babcock forceps and are taken medially so as to get free space to permit application of the ovarian clamp on the infundibulopelvic ligament (Figs. 122.8, 122.9 and 122.10.). Separating out the round ligament after cutting it laterally paves the way to clamp the infundibulopelvic ligament and complete the contralateral salpingo-oophorectomy [15, 16, 21, 23, 26].

It is important to ensure that the pedicle is securely grasped by a specially designed clamp. The specially devised clamp(Fig. 122.11) [15, 16] a curved clamp of 2 cm, beginning 1 cm from the tip, facilitates and accommodates the infundibulopelvic ligament, which is well transfixed and doubly secured with a No.1 gauge polyglactin suture or 1/0 vicryl suture. Make sure that the clamp does not contain even a bit of

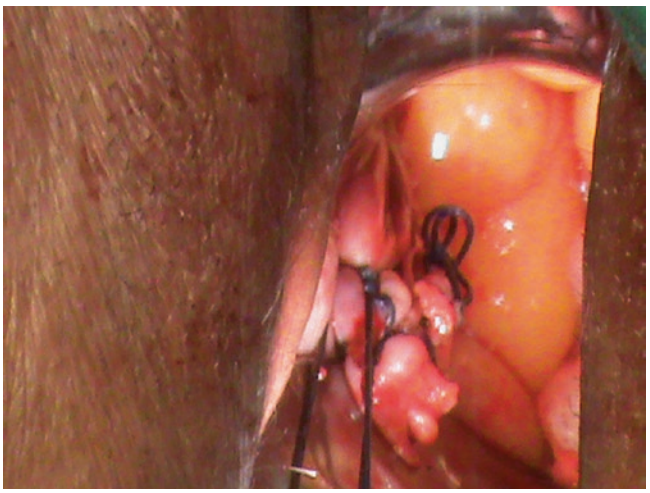

Fig. 122.12 Two sutures on round ligament and one medially on infundibulopelvic ligament (bunch of it) are seen. One on round ligament will be used to anchor vaginal vault (may be of no use). Haemostasis is well achieved

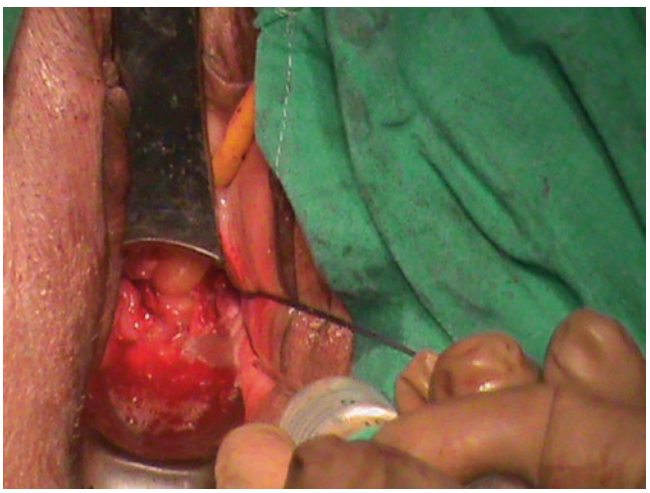

Fig. 122.13 Field is lavaged with saline via syringe

round ligament, as the rest of the tissue in the clamp is much thinner and makes application of the clamp improper. Single clamp application, at the first instance is most desirable.

After completion, it is essential to ensure that there is no raw area lateral to the sutures on the infundibulopelvic ligament that can bleed later [13, 15, 20] (Fig. 122.12). Thus, salpingo-oophorectomy is performed via two important steps (1) The round ligament being cut separately and laterally to create the space and access to the infundibulopelvic ligament and (2) applying an ovarian clamp carefully on the available infundibulopelvic ligament [2, 15, 16].

Closure of peritoneum is then performed in the routine fashion after lavage (Fig. 122.13), though the preferred option is to not close the peritoneum.

Special points to note are: (1) The round ligament cutting. (2) A specially designed clamp for the infundibulopelvic

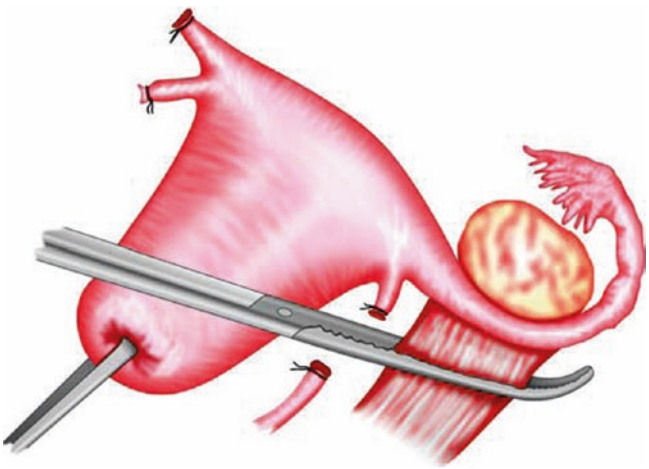

Fig. 122.14 Round ligament cut distally. A specially designed ovarian clamp is applied to the infundibulopelvic ligament (With permission Sheth [15])

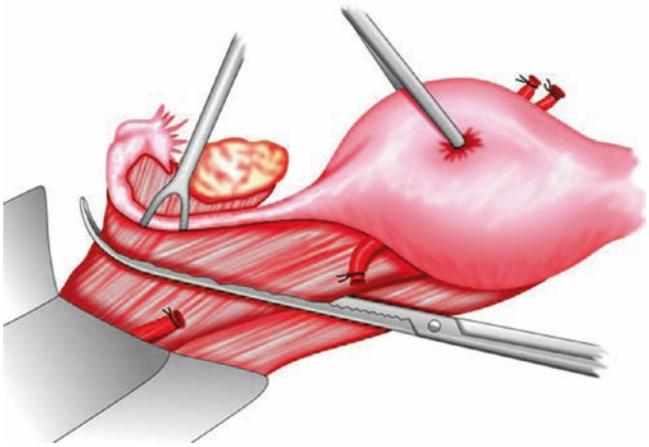

Fig. 122.15 A specially designed clamp is applied to infundibulopelvicligament for a salpingo-oophorectomy (With permission Sheth [20])

ligament, (3) Adequate exposure [15–18, 20, 26] (Figs. 122.14 and 122.15).

Preoperative

Pre-requisites: Normal tubes and ovaries.

Intraoperative: (1) easy access; (2) free mobility of the ovaries; (3) adequate exposure; (4) experienced assistants.

Factors like old age, nulliparity, obesity, reduced uterine descent, decreased space, and an enlarged uterus can lead to anxiety about performing VH and moreso concomitant salpingo-oophorecdtomy. In reality, they demand extra care, enhanced confidence and development of surgical skills.

In the age group of 60–70 years, the ovaries are likely to be placed at a greater distance than in the younger age group and at an even greater distance after the age of 70–75 years.

Fig. 122.16 Morbidly obese woman with BMI of 80, underwent a straightforward vaginal hysterectomy with bilateral salpingo-oophorectomy. She had a hospital stay of 48 h. A good look at the abdomen should ideally dissuade a surgeon to undertake the abdominal route for hysterectomy (With permission Sheth [27])

In other words, as age advances the distance between uterus and ovaries increases. Atrophy and shrinkage of tissues results in retraction of the infundibulopelvic ligament, a bit more atrophy than the utero-ovarian ligament, the uterine pull elongates the utero-ovarian ligament, distancing the ovaries and reducing access.

Nulliparous patients have decreased vaginal wall laxity and physiological uterine descent requires more traction. However, if it is possible to take out the uterus, there is no additional difficulty in taking out the ovaries. Nulliparity per se should not contraindicate or deter oophorectomy.

Obese patients are the surgeon's bugbear as it: (1) reduces access; (2) increases vascularity; (3) Tissue planes are less easy to access; (4) the ovaries may be enlarged; and (5) the patient may have decreased uterine descent. In obese woman with a narrow subpubic arch, the difficulty is accentuated and may demand LAVH.

Space is always at a premium and in reality, difficulties that obesity cause are much more at abdominal surgery when compared with similar difficulties during vaginal surgery [27]. In obese women especially, the labia increase the distance of the ovaries from the operator and the operative field, and therefore suturing the labia laterally and upward is helpful [27] (Fig. 122.16). Rarely, in the morbidly obese woman, a drooping mons needs suturing to the lower abdominal wall. The author has done this twice.

In obese and particularly the morbidly obese, when routine speculum examination does not yield satisfactory findings, speculum examination in "super flexion position" [28] will guide as well as persuade the operator to take the vaginal route.

Decreased ovarian accessibility can be because of short infundibulopelvic ligaments, unexpected periovarian adhesions or tubo-ovarian pathology, distally located ovaries, or very atrophic ovaries. The operator must analyse the reason or causative factor(s). Access is better when the ovary is still attached to the uterus through an intact upper pedicle rather than after severance of the upper pedicle. Occasionally, after extirpation of the uterus, keeping a Babcock's forceps or traction suture on the ovary helps to gain access.

If not, and the procedure appears risky, one needs to consider if removal of the ovaries is mandatory. If so, laparoscopic or mini laparotomy will help to complete the surgery. If not, they can they be left behind just as numerous colleagues do not attempt to remove them simply because hysterectomy is via the vaginal route. Any surgical procedure is likely to be associated with a small percentage of failures, but this will considerably decrease with passage of time and experience. [15, 20, 26].

When does oophorectomy fail?

- Inaccessibility
- Tubo-ovarian adhesions
- Risk of trauma and/or bleeding
- Poor assistance and/or fear and anxiety
- Inexperience
- Unfavourable findings

Adnexal Benign Pathology

For a benign ovarian mass, experience of concomitant salpingo-oophorectomy at VH as charted and shown in Fig. 122.17, permits an endeavour to deal with and tackle this pathology and to perform salpingectomy and/or oophorectomy at VH.

Examination under anesthesia (EUA) should suggest (a) free or minimally restricted mobility of the uterus; and (b) that the adnexal mass is freely mobile [21, 29]. Careful clinical examination, reliable ultrasound, CT or magnetic resonance imaging (MRI) scans and tumour markers can suggest the benign nature of the mass [30–33].

A mobile mass is not difficult to tackle and can be utilized as an opportunity to patiently persevere, cut the round ligament separately, and target the infundibulopelvic ligament as above to complete salpingo-oophorectomy; alternately, one can debulk the cyst and perform only cystectomy [17, 21, 34]. The size of an ovarian cyst is not by itself a limiting factor, as the cyst can usually be debulked by aspiration, exteriorized and excised if required. Exteriorisation of the ovary is easier vaginally with wider space than at laparotomy with a small incision, as there is added fear of a spill from the cyst into the open abdomen [10, 29, 34, 35] (Fig. 122.18).

In practice, as soon as a common ovarian endometrial cyst is suspected, vaginal hyseterctomy is ruled out even though, in reality, a significantly large number have only flimsy or no adhesions. In fact, salpingo-oophorectomy can

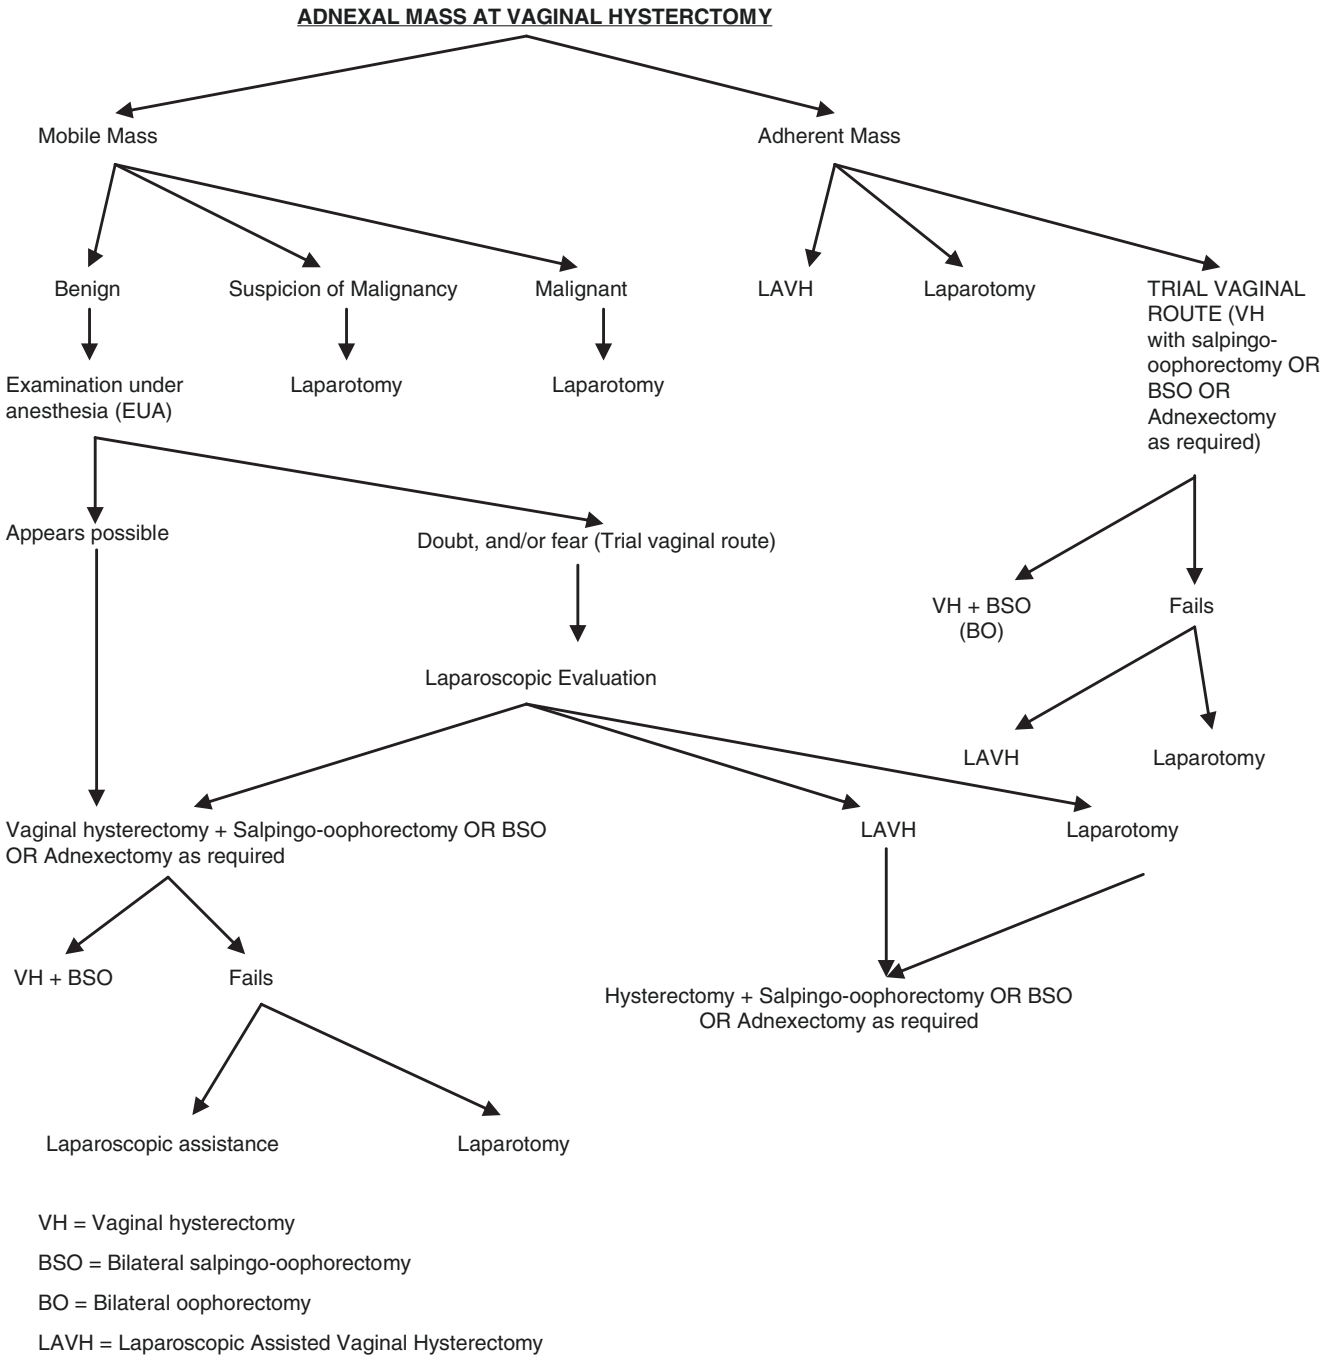

Fig. 122.17 Demonstrating clinical and surgical approach to deal with adnexal mass concomitantly at vaginal hysterectomy

be carried out in these cases as usual with excellent results. An ovarian cyst that is adherent will need something extra, and the vaginal surgeon may relish the challenge of accessing the posterior peritoneal cavity or posterior cul-de-sac through adheseolysis. Pre-operative counselling includes consent for a 'Trial' vaginal route and to have informed consent for frozen HP study, and a change to laparoscopic-assisted surgery or laparotomy if necessary. In case of doubt or anxiety, laparoscopic evaluation of the pelvic findings can be of great help [35, 36].

A surgeon with sufficient experience of vaginal hysterectomy and bilateral slapingo-oophorectomy can venture to consider VH with additional surgery for a benign, mobile adnexal pathology, , provided the prerequisites are complied with. This will greatly benefit the patient [34].

Undertaking this procedure regularly will enhance the gynaecologist's level of skill and enable him to deal even with conditions such as ovarian mass like fibroma, thecoma, broad ligament fibroid and other adnexal pathology concomitantly at vaginal hysterectomy without resorting to

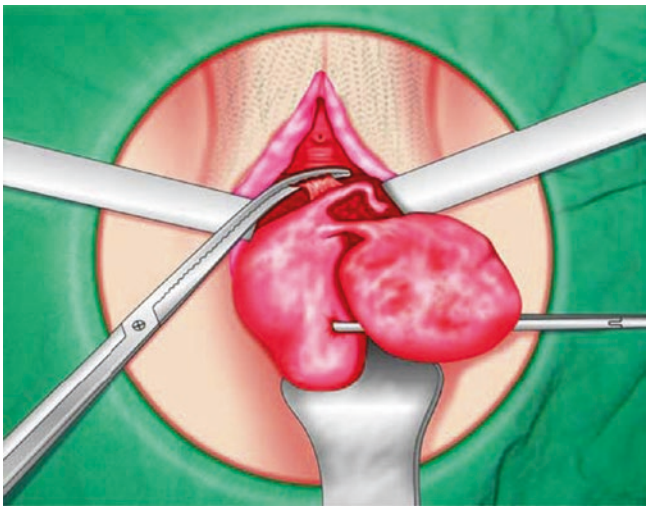

Fig. 122.18 With all connections on the normal right adnexal side severed, uterus with ovarian cyst with ovarian or adnexal clamp applied on infundibulopelvic ligament (With permission Sheth [29])

abdominal invasion. It will come to the rescue when an unexpected need arises during hysterectomy if the extirpated uterus shows endometrial malignancy or when the abdominal route is contraindicated due to previous incisional hernia repair with mesh following caesarean delivery(ies) in the past [1, 21].

During surgery, if the surgeon thinks that it will not be possible to remove the ovary or pathological mass vaginally, he or she should have no hesitation in resorting to laparoscopic assistance or perform a minilaparotomy for its removal, with the patient's safety as a prime consideration. Often, the abdominal surgery is remarkably easy to complete because all the pelvic pedicles have already been dealt with earlier during the vaginal surgery [21, 34]. He should later share the tubo-ovarian findings with the sonologist to verify whether they were correct or inaccurate.

Teng et al. [37] caution that before any vaginal approach via posterior culdotomy, laparoscopy is necessary.

This is a pessimistic precaution for the surgeon as he should develop, strong clinical sense and acumen. In select cases, frozen HP availability, take case as 'Trial vaginal route' and be prepared to change the route if the need arises.

Contraindications

- Woman wants to retain her ovaries. This is the strongest contraindication and must be respected.
- High and distally placed and/or immobile, atrophic distally placed ovaries
- Adhesions
- Tubal and ovarian pathology
- Risk of trauma and/or hemorrhage.
- The operator's lack of experience of vaginal hysterectomy.

Contraindicated situations for concomitant adnexectomy for pathological adnexa at VH are: an adherent mass; a suspicion of malignancy; frozen section facility not available; and insufficient informed consent.

If a benign adnexal mass is present and the gynecologist chooses to remove it concomitantly at VH, certain prerequisites should be satisfied. No doubt, case is to be taken as 'TRIAL VAGINAL ROUTE'

Prerequisites

- Preoperative investigations such as ultrasonography, Doppler studies, and blood CA-125.
- Accessibility and free mobility of the mass, which when held with a Babcock's and/or Ellis' forceps, brings the mass medially into the operative field.
- Visibly benign pathology
- Facilities for frozen histopathology, laparoscopic assistance, and/or laparotomy
- Surgeon with experience of vaginal surgery
- The woman and her family to be adequately counseled and informed consent taken for a "Trial vaginal route" [1, 34].

If removal is mandatory, barring the woman's wish to conserve, nothing contraindicates removal, unless surgery in itself is contraindicated.

If conventional surgery fails or is not be utilized, extirpation of the uterus totally or only on one side provides plenty of space to use an endoscope and reach the tubo-ovarian site on either side without difficulty.

Hoffman [38] suggests using an endoloop ligature of 0 plain catgut. Two endoloops were used on each pedicle. Surgeons experienced with Roeder's loop may use it freely to catch the mesovarium [14, 21]. This is followed by excision of the ovary and hemostasis. With due precautions, the mesovarium can be cut directly using bipolar cautery. Adequate exposure, isolation, and packing are essential. Hefni and Davies use an endoloop with the help of a Sheth's clamp, and two loops are usually applied before cutting. He finds this safe and easy to learn as an alternative to LAVH, in the absence of adhesions. A stapling device can occlude vessels in the mesovarium provided there is good exposure and it is done with care. High cost may not permit its liberal use. By using a stapler or seitsinger tripolar cutting forceps or endoloop, successful bilateral oophorectomy in 82 cases emphasized the endoscopic approach vaginally without using abdominal access [39].

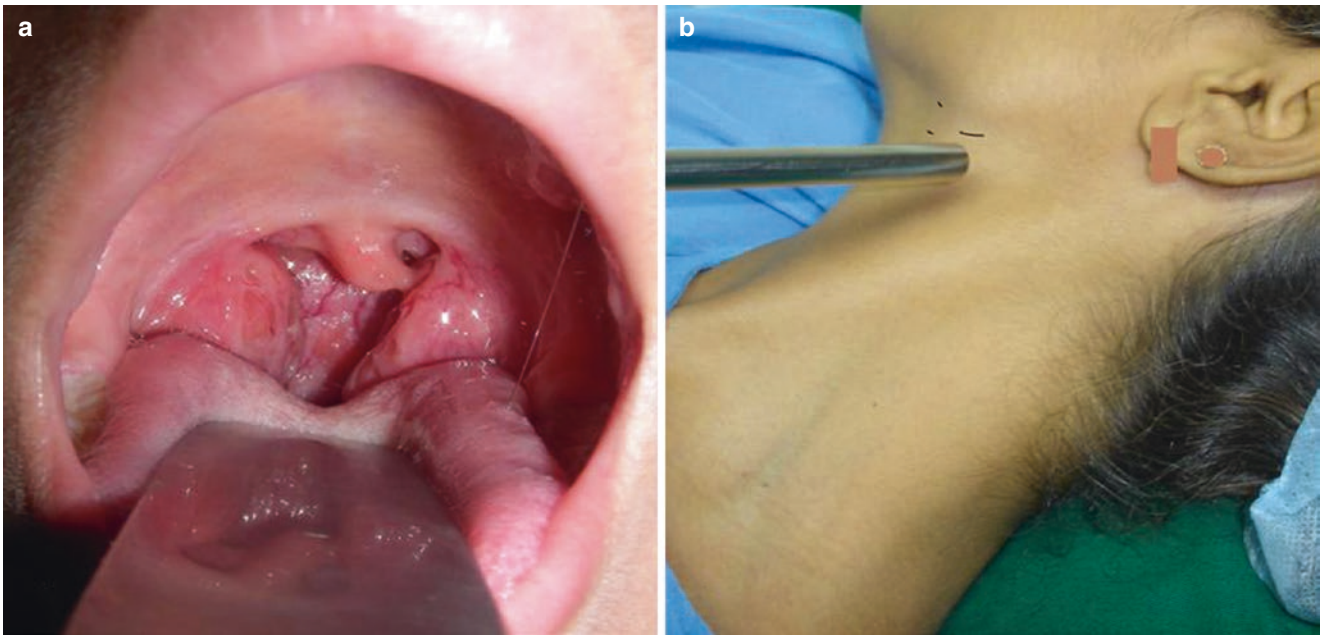

Fig. 122.19 (**a**) Tonsils are seen and can be easily removed from the natural orifice just as the uterus can be seen and removed vaginally. This are certainly less invasive than (**b**); (**b**) Tonsils removal via submandibular endoscopy and uterine removal via abdominally by laparoscope (With permission Sheth [2])

To perform an oophorectomy laparoscopically, at vaginal hysterectomy, when the same can be performed vaginally is only increasing surgical invasion [2] (Fig. 122.19). To avoid laparoscopy, all three laparoscopic methods [40], i.e. bipolar coagulation, pretied ligature placement, and automatic stapling devices, which are equally effective, with similar surgical operative times and uniformly good results for patients can be implemented vaginally.

With changing times, the era of prophylactic oophorectomy has changed to prophylactic salpingo-oophorectomy, with the need for extra vigilance and surgery.

Figure 122.1 shows the course of action to be taken for performing salpingo-oophorectomy at VH.

Hospital Stay

There is no difference in the duration of hospital stay, preoperative and postoperative management following with or without salpingo-oophoectomy at VH.

The operative time for additional salpingo-oophoectomy with VH increased generally by 5 to 15 min when compared with VH by itself. Laparotomy was required for reactionary hemorrhage in two and for bowel trauma in one out of first 1000 concomitant salpingo-oophorectomies at VH. In the next more than 500 such hysterectomies, not a single woman required post-operative laparotomy for reactionary hemorrhage. Laparotomy was required in eight cases of failed Trial vaginal route in 192 VH with surgery for concomitant adnexal pathology because of the adnexal pathology being either too adherent in four and ovarian malignancy in five on intraoperative frozen HP study [41]. Experience from those 192 cases has increased in following two decades. However, Trial VH OR Trial vaginal route is a totally different entity from routine prophylactic salpingo-oophorectomy at VH when at VH, tubes and ovaries are normal and non contraindicated.

Learning Comes From

1. A uterine prolapse particularly of a major degree will facilitate oophorectomy considerably by making the ovaries easily accessible. The slim, parous patient with a normal sized uterus and a third degree uterine prolapse is an ideal patient for learning concomitant salpingo-oophorectomy at VH. These ovaries are inviting and proximally placed for the surgeon to access the infundibulopelvic ligament.
2. At regular vaginal hysterectomy without concomitant salpingo-oophorectomy, the operator can put a Babcock's forcep on each ovary and tube to bring them medially into the central field and/or even cut only the round ligament laterally and access the infundibulopelvic ligament with an open clamp, without clamping the tissues. This is bound to instill confidence in performing salpingo-oophorectomy at vaginal hysterectomy. Experience always has to begin somewhere. Careful study of the

procedure through literature, video, and/or workshops can add to it [21].

Just as the gynecologist makes every attempt to remove the cervix completely at a technically difficult abdominal hysterectomy, I believe that the gynecologist should make every attempt to remove the ovaries vaginally, when indicated, at the time of vaginal hysterectomy. Sheth and Malpani [26] state that just as a supracervical abdominal hysterectomy is a subtotal operation and scientifically has limitation in gynecologic surgery, today, performing a simple vaginal hysterectomy for a postmenopausal woman without removing her ovaries, if and when required, is an incomplete operation.

I (**SSS**) [1] believe that every gynecologist can reach a stage when he or she should not be anxious about concomitant removal of ovaries at vaginal hysterectomy. The earlier this expertise is attained, the better.

Only Oophorectomy at Vaginal Hysterectomy When?

It is often less difficult or easier to remove the ovary only and leave the tube in situ [1, 20, 21, 42] (Fig. 122.20).

In cases where a salpingo-oophorectomy appears difficult – because of limited space or because of a long utero-ovarian ligament - access to the mesovarium could prove easier than access to the infundibulo-pelvic ligament, and a simple oophorectomy may be reluctantly performed. A compromise can be made by performing a simple oophorectomy by clamping, cutting, and ligating the mesovarium and not performing salpingo-oophorectomy. For oophorectomy alone, the ovary is gently pulled into the operative field and the mesovarium is clamped to include the space between the two leaves of the broad ligament. The fallopian tube is kept away. Access to the proximal mesovarium is easier than access to the infundibulopelvic ligament by the vaginal approach. The fallopian tube is then brought down to cover the raw area. However, the surgical method of choice is to perform as much of salpingectomy as possible and include its fimbrial end. The ovary is removed and clamped tissues are double sutured with No. One gauze polyglactin. The removal of either tube or as much of both tubes as possible depends on the ease of access [2, 21].

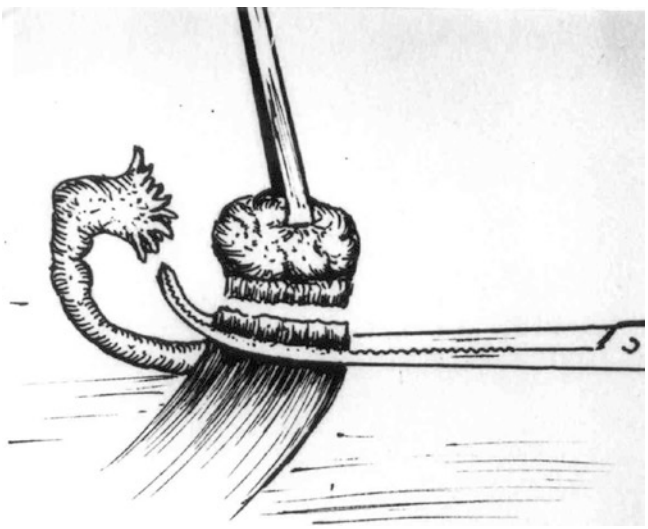

Fig. 122.20 Meso-ovarium is clamped so as to perform only oophorectomy (No salpingectomy) (With permission Sheth [20])

Oophorectomy Without Hysterectomy

In menstruating women with breast cancer, oophorectomy is a useful maneuver to manipulate the hormonal milieu. The risk is minimal and there are no long-term sequelae [43], apart from the standard response to oophorectomy in 40–50 % of patients [44]. Though Tamoxifen has changed the entire scenario, in some situations, the need for oophorectomy may arise and treating oncologists may advise it. The author has had the fortune of using the least invasive vaginal approach for oophorectomy without hysterectomy in more than 20 women with metastatic breast cancer, some high risk and some in the pre-laparoscopic days [45]. He has also used it to treat menorrhagia with normal pelvic findings in a woman with table risk to spare her from the otherwise recommended hysterectomy [46]. There is no doubt that the laparoscopic technique for oophorectomy is the preferred choice, but, in the absence of equipment and/or an endoscopist, this approach should be seriously considered in parous women, particularly if they are at high risk for the surgery. Removal of the ovaries with or without bilateral partial salpingectomy without hysterectomy by the vaginal route has the following advantages:

- Short hospital stay, < 24 h
- Easier convalescence
- Safer for frail or ill patients
- No risk of incisional hernia
- Avoidance of laparotomy and an abdominal scar
- Laparoscope not missed
- Economical.

Trial Vaginal Hysterectomy and Trial Vaginal Route

Trial vaginal hysterectomy was first described in 1993 [1]. Here, women with difficult or contraindicated hysterectomy via the vaginal route, are given the opportunity of undergoing

hysterectomy via the vaginal route but the options of laparoscopic assistance or laparotomy are kept open, if the attempt is unsuccessful. This is comparable to trial forceps delivery to prevent caesarean section in obstetrics. Large uteri, previous caesarean section and nulliparity are common indications to attempt a trial vaginal hysterectomy and adnexectomy. However, beyond the uterus, if an adnexal pathology complicates the vaginal route for hysterectomy, it becomes 'trial vaginal route' with or without 'trial vaginal hysterectomy' [13, 21, 34]. Such a choice provides a great learning opportunity for progressive gynaecological surgeons.

Gynecologists today are also stretching themselves to add three or four abdominal punctures to perform laparoscopic salpingo-oophorectomy at VH instead of learning an additional step to perform concomitant salpingo-oophorectomy or oophorectomy at VH and advance further.

If you give a man more than he can do
He will do it
If you only give him what he can do
He will do nothing
— R Kipling

The Mayo Technique for Vaginal Hysterectomy

123

John A. Occhino

I would like to begin this chapter with an excerpt from a manuscript titled *Vaginal Hysterectomy at the Mayo Clinic* published in 1961 by Dr. John S. Welch and Dr. Lawrence M. Randall [1].

> Great interest in vaginal hysterectomy has developed during the last 25 yr. With broadening of indications for this operation, numerous techniques have been developed, presented, and modified, each recommended for some real or assumed advantage over those preceding it; but most have not been retained in modern gynecologic practice. The Mayo vaginal hysterectomy is a good example of this evolutionary change. Proposed by Dr. Charles H. Mayo for distressing uterine prolapse and cystocele, this operation united the broad ligaments, after hysterectomy, to support the bladder and form a floor for the pelvic viscera. Many gynecologists recall the dismaying postoperative incidence of enterocele, which followed with especial frequency if care had not been directed toward complete ligamentous closure of the space between the joined broad ligaments and the rectum. This Mayo vaginal hysterectomy, in fact, has long been absent from the operative armamentarium of the gynecologic surgeons at the Mayo Clinic. The succeeding clamp-and-ligature technique, modified by the experience of several thousand repetitions, is a rather standardized procedure offering anatomic simplicity, wide application, and great safety.

Despite the continuous barrage of new technologies for hysterectomy, the vaginal hysterectomy remains the safest and most cost-effective approach and is supported by numerous organizations including the American College of Obstetrics and Gynecology [2].

The Mayo technique for vaginal hysterectomy has been refined over the years and incorporates several basic principles of surgery. Foremost is adequate exposure. Especially when operating in a small space. It is imperative that one is able to visualize the important structures and landmarks. The Mayo technique utilizes sharp dissection for avoidance of inadvertent damage to adjacent structures that can occur with blunt dissection. Mobilization and retraction of the bladder and rectum help to ensure their safety during vaginal hysterectomy. Hysterectomy is one of the most common surgeries leading to ureteral injury [3]. Identification of the ureter by palpation during hysterectomy is essential for avoidance of iatrogenic injury or obstruction. Re-support of the vaginal apex at the time of vaginal hysterectomy is essential in the avoidance of post-hysterectomy vaginal vault prolapse. Lastly, adequate assistance is vital to the successful completion of any surgery, especially vaginal hysterectomy.

Patient Positioning

Proper patient positions can help with visualization and avoidance of nerve injury. The dorsal lithotomy position is best and the author prefers legs in candy-cane stirrups as they afford the surgeon and assistants more space. The patient's hips should be flexed and mildly abducted and the knees flexed as well. The patient's buttocks should be on the edge of the table when the foot of the bed is removed.

Surgical Instrumentation

The surgical instruments used during the procedure include:

- Short weighted speculum
- 3 narrow Deaver retractors
- Right-angle Heaney retractor
- 2 non-perforating towel clamps
- 2 uterine tenacula (Henrontin Uterine Vulsellum forceps)
- Surgical scalpel (#10 blade)
- Mayo scissors (Mayo Harrington scissors, 8″ curved tip)
- 2 curved Heaney clamps
- Forceps with teeth (Walther tissue forceps)
- Russian forceps (8″)
- Kocher clamps
- Kelly (curved) clamps
- Suture scissor

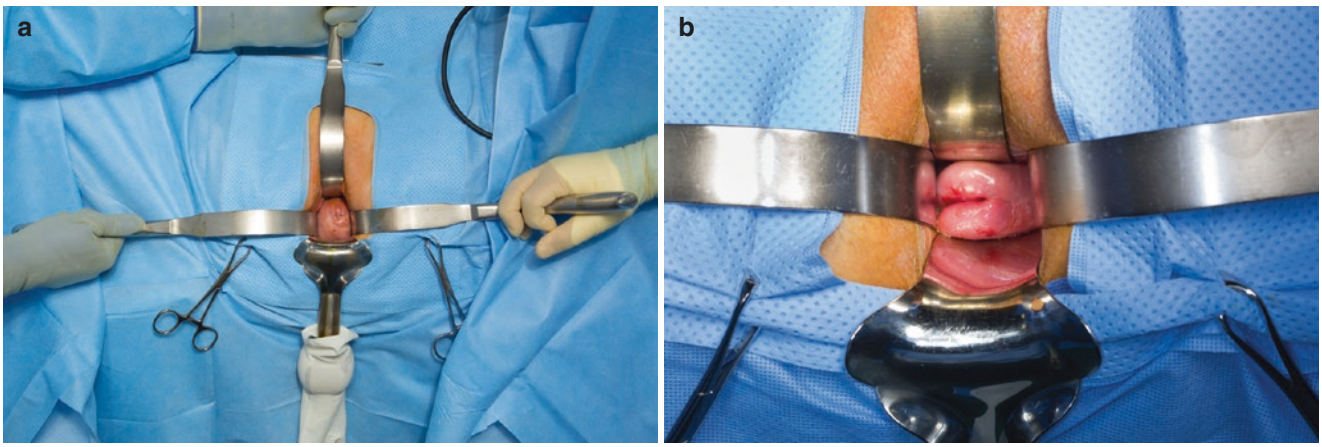

Fig. 123.1 (**a**) Setup for vaginal hysterectomy with Deaver retractors in place, (**b**) Close up view (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

Surgical Technique

Setup

After proper patient positioning and surgical cleansing, the procedure is begun. A short weighted speculum is placed in the vagina and two non-perforating towel clamps are attached to the drape, lateral to the speculum. These will later be used for managing tagged sutures. The authors prefer to empty the bladder with in-and-out catheterization prior to incision to decompress the bladder. Three narrow Deaver retractors are placed in the vagina at 12, 3, and 9 o'clock position to assist with retraction and visualization (Fig. 123.1). The surgeon is sitting on a stool with a magnetic pad on the lap and 2 assistants are used, one on each side. This is the routine setup for all vaginal hysterectomies at Mayo Clinic.

Vaginal Incision

The surgery begins with placement of two tenacula on the distal edges of the anterior and posterior lips of the cervix (Fig. 123.2). These are used for traction and manipulation of the specimen. Longitudinal incisions made along the cervix at 3 and 9 o'clock position. These are short (approximately 1–1.5 cm) and shallow (Fig. 123.3). These are done to identify the vaginal cuff angles during cuff closure, as their location tends to get distorted after re-suspension of the vaginal cuff. Firm traction on the tenacula is important as it allows the vaginal epithelium to separate fully as the incision is being made. A scalpel is used to make a circumferential incision around the cervix (Fig. 123.4). Posteriorly, this incision is brought to a "V" Fig. 123.5).

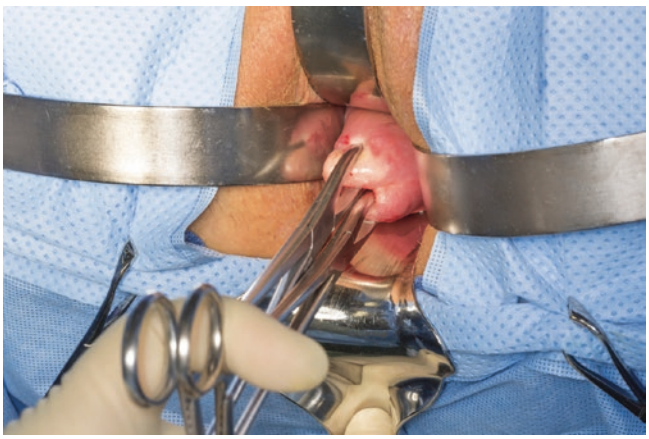

Fig. 123.2 Tenacula placed on the cervix for traction (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

Anterior Entry

An assistant continues to apply traction on the cervix while the surgeon grasps the cut edge of the vaginal epithelium with toothed-forceps (Fig. 123.6). Utilizing the Mayo scissor with the tips pointed toward the endocervical canal, sharp dissection is used to create a plane between the cervix inferiorly and the bladder superiorly (Fig. 123.7). Dissection continues until the peritoneum is visualized; only at this time will the surgeon insert a finger against the lower uterine segment and advance forward. Minimal resistance should be encountered when in the correct plane and the surgeon's finger should glide smoothly along the peritoneum of the anterior cul-de sac. The anterior Deaver retractor is now inserted to provide improved visualization and tooth forceps are used to grasp the peritoneum (Fig. 123.8). Note that there are 2 layers of peritoneum here and they merge to form the vesicouterine fold. They can be seen moving over each

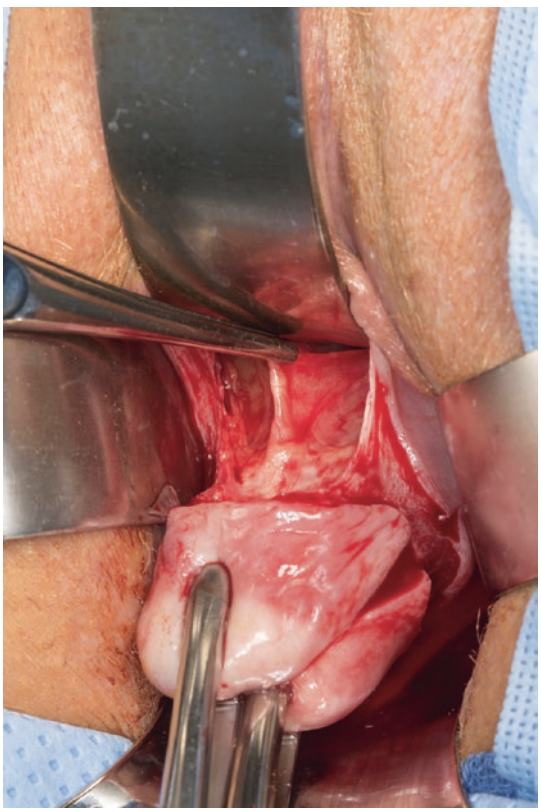

Fig. 123.8 Forceps grasping the peritoneum (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

other. The peritoneum is grasped with tooth forceps and scissors are used to incise the peritoneum superior to the where the peritoneum is grasped – this allows entry into the anterior cul-de-sac (Fig. 123.9). The incision is made superior to avoid undermining the peritoneum and failing to enter appropriately. Once the peritoneum is incised, the scissor is inserted into the peritoneal defect and spread (Fig. 123.10). This enlarges the peritoneal defect and allows the anterior Deaver to be inserted below the scissor and advanced into the peritoneal cavity. Appropriate location is checked using a right-angle Heaney retractor inserted into the peritoneal defect to visualize intra-abdominal organs (Fig. 123.11).

Posterior Entry

The assistant provides traction on the cervix in a superior direction to give access to the posterior vaginal fornix. Toothed-forceps are used to grasp the vaginal epithelium and give inferior traction (Fig. 123.12), while Mayo scissors are used to incise the fibromuscular tissue and peritoneum adjacent to the posterior uterus (Fig. 123.13). The tips of the scissors are pointing toward the body of the uterus and away from the rectum to avoid injury. Again, appropriate location is confirmed using a right-angle Heaney retractor.

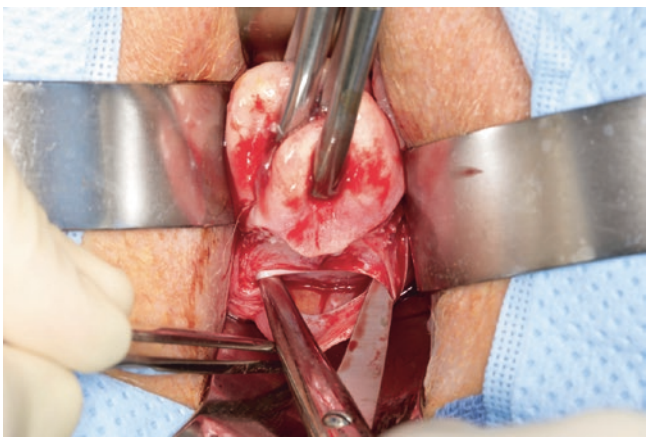

Fig. 123.13 Successful posterior cul-de-sac entry (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

Ligaments and Vascular Supply of the Uterus

Once entry into the anterior and posterior cul-de-sac is accomplished, one begins taking the ligamentous and vascular pedicles of the uterus. The surgeon ligates the uterosacral, cardinal and vascular pedicles on a single side of the uterus before addressing the opposite side. This aids in efficiency and flow of the procedure. The 9 o'clock Deaver is removed and the specimen is pulled towards the patient's right. The uterosacral ligament on the patient's left is skeletonized by sweeping the vaginal mucosal superiorly with a gauzed finger (Fig. 123.14). A Heaney clamp is placed on the ligament adjacent to the edge of the vaginal mucosa. When closed, the clamp should be perpendicular to the ligament itself (Fig. 123.15). The ligament is divided using Mayo scissors and with the incision taken just around/beyond the tip of the clamp (Fig. 123.16). Ligation of the pedicle is accomplished by placing a ligature through the middle of the pedicle (behind the Heaney clamp) after which a single tie is placed. One end of the suture is carried around the tip and the

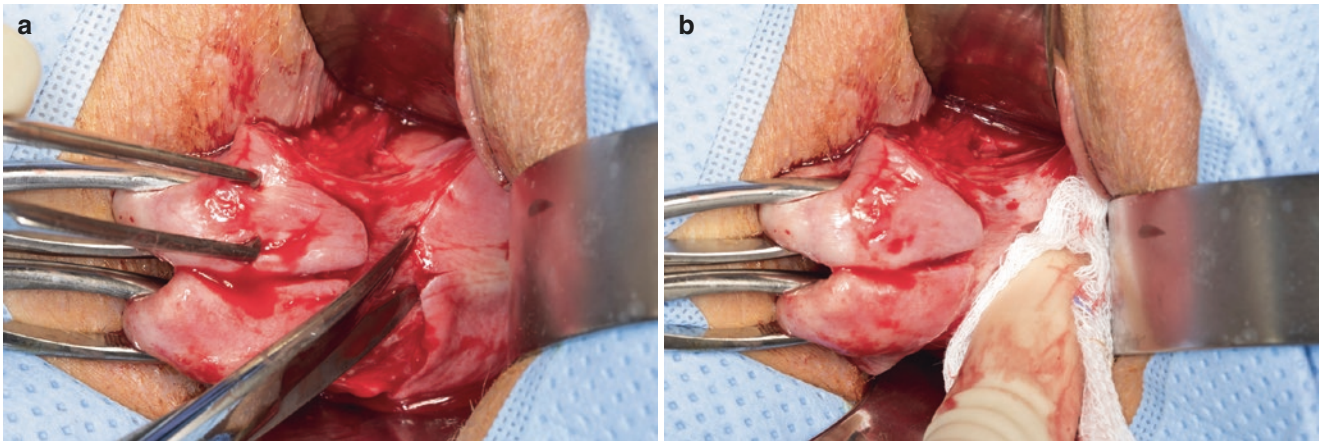

Fig. 123.14 (**a**) Sharp dissection of vaginal epithelium off of the uterosacral ligament; (**b**) Further exposure of the uterosacral ligament is performed with a gauzed finger (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

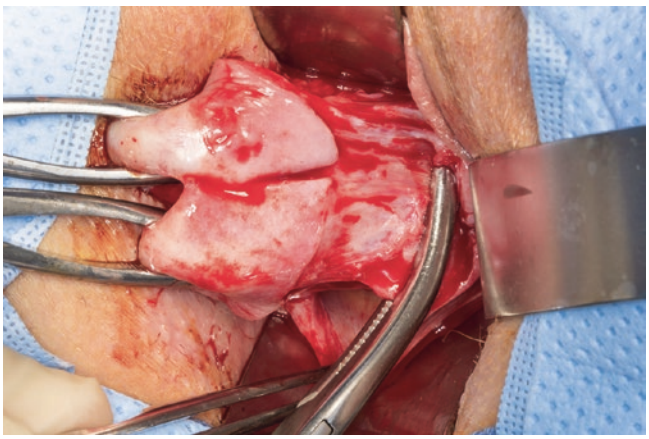

Fig. 123.15 Heaney clamp on the uterosacral ligament (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

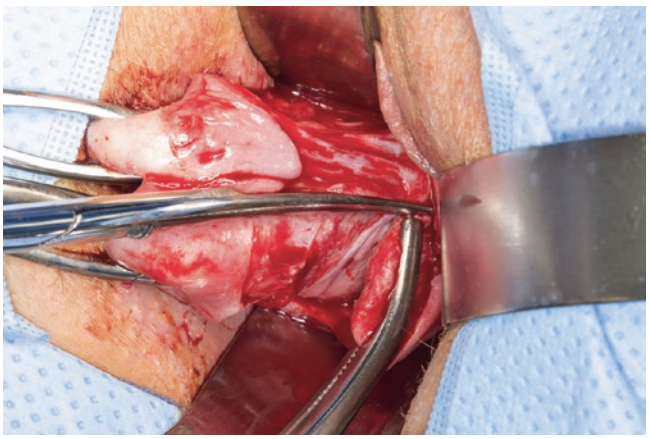

Fig. 123.16 Transection of the uterosacral ligament carried around the tip of the clamp (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

Heaney clamp is slowly opened with the first of the 3 additional ties (Fig. 123.17). The suture tail is tucked behind the side of the weighted speculum and tagged with a kocher clamp. This is done to allow identification of the uterosacral ligament later in the procedure for re-suspension of the vaginal cuff.

The surgeon's left index finger is inserted into the anterior cul-de-sac and the 3 o'clock Deaver is moved slight upward toward the 2 o'clock position. The surgeon slowly pulls their index finger along the retractor and this allows for the palpation of the left ureter against the retractor. A characteristic "snap" can be felt and heard. Identification of the ureter during hysterectomy is paramount in avoiding injury (Fig. 123.18a–c).

Once the ureter is identified, the Heaney clamp is placed on the lower portion of the cardinal ligament, with tips almost perpendicular to the cervix (Fig. 123.19). The ligament is incised, suture-ligated and tagged with a curved clamp. This suture tail is draped over the towel clamp on the drape for simple identification and separation from the uterosacral tag. The last clamp incorporates the peritoneum of the anterior and posterior cul-de-sac and typically transects the uterine artery (Fig. 123.20). This is transected a ligated in the same fashion and the suture tail is placed in the curved clamp along with the previous pedicle (Fig. 123.21).

An identical procedure is done on the right side of the uterus, taking the uterosacral, palpating the ureter (this time with the surgeon's right index finger), then taking the 2 cardinal pedicles. After this is completed, Fig. 123.22 shows the results. At this point, the uterus can be rotated and the fundus delivered through the posterior cul-de-sac into the vagina. The surgeon left hand is placed behind the uterus and the round and utero-ovarian ligaments on the right are clamped using a single Heaney clamp. The clamp is placed with the tips pointing inferiorly (Figs. 123.23 and 123.24). This is transected, however, ligation is delayed until the uterus is removed (Fig. 123.25). The same pedicle on the left is

clamped, however, the tips of the Heaney are pointed in a superior direction (Fig. 123.26). This is transected and the specimen delivered. Each pedicle is then ligated (Fig. 123.27) and tagged with a kocher which is placed over the patient's thigh on each side (Fig. 123.28). A pack is placed to elevate the bowel out of the pelvis (Fig. 123.29). Careful inspection of all pedicles is done and electrocautery is often used on the posterior vaginal cuff to obtain hemostasis (Fig. 123.30). In the appropriate patient, a salpingectomy or salpingo-oophorectomy can safely be accomplished at this point.

Salpingectomy

An Allis clamp is used to grasp the utero-ovarian pedicle; this contains the transected round ligament and fallopian

tube (Fig. 123.31). The fallopian tube is grasped with a Russian forceps and gentle traction is given toward the midline (Fig. 123.32). This exposes the mesosalpinx. An Allis clamp is used to grasp the fallopian tube and a Heaney clamp is placed across the mesosalpinx (Fig. 123.33). A free tie is passed around the tip of the Heaney (Fig. 123.34a) and tied as the assistant opens and closes the clamp (flash). Coordination with the assistant is imperative to avoid tearing the delicate mesosalpinx. The specimen is excised and removed (Fig. 123.34b, c) and one additional free tie is placed on the pedicle and the Heaney clamp is removed. Hemostasis is verified and the sutures are cut. The same is done on the opposite side.

Salpingo-Oophorectomy

An Allis clamp is used to grasp the utero-ovarian pedicle; this contains the round ligament and fallopian tube – see Fig. 123.31. A Russian forceps is used to grasp the fallopian tube and underlying ovary and gentle traction is given toward the

midline (Fig. 123.35). This exposes the infundibulo-pelvic ligament containing the ovarian vessels. An Allis clamp is used to grasp the tube and ovary and a Heaney clamp is placed across the infundibulo-pelvic ligament (Fig. 123.36). A free tie is passed around the tip of the Heaney (Fig. 123.37) and tied as the assistant opens and closes the clamp (flash). Coordination with the assistant is imperative to avoid tearing. The specimen is excised and removed and an additional suture ligation is performed followed by removal of the Heaney clamp. Hemostasis is verified and sutures are cut. The same is done on the opposite side.

Modified McCall Culdoplasty

Once all specimens have been secured, obliteration of the enterocele space and re-suspension of the vaginal cuff is begun. This incorporates techniques from Mayo, Torpin [4] and McCall [1] into a single procedure for closure of the enterocele sac and suspension of the vagina to the uterosacral ligaments.

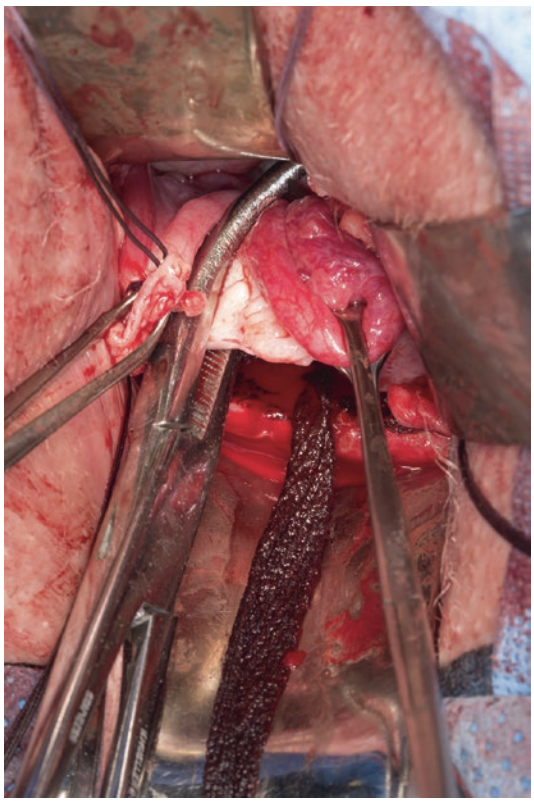

Fig. 123.36 A Heaney clamp being placed across the infundibulopelvic ligament containing the ovarian vessels (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

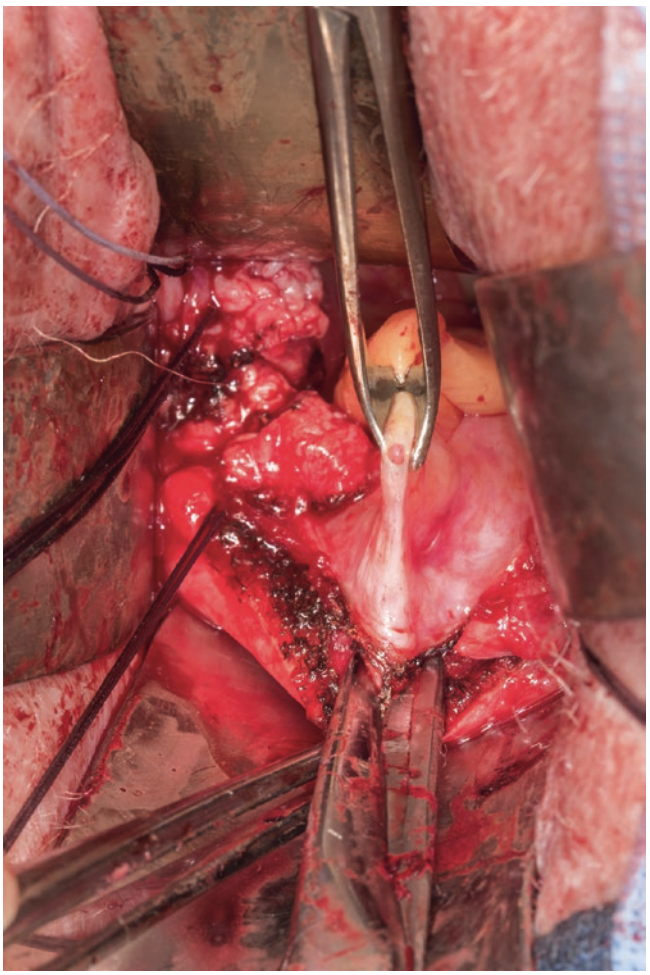

Fig. 123.38 Traction placed on the peritoneum using an Allis clamp and sharp dissection is begun (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

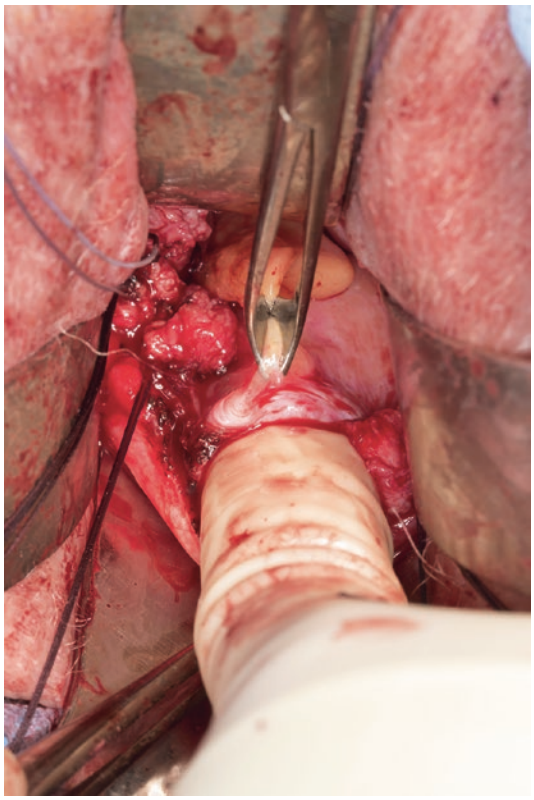

Fig. 123.39 Blunt dissection of the space after sharp dissection completed

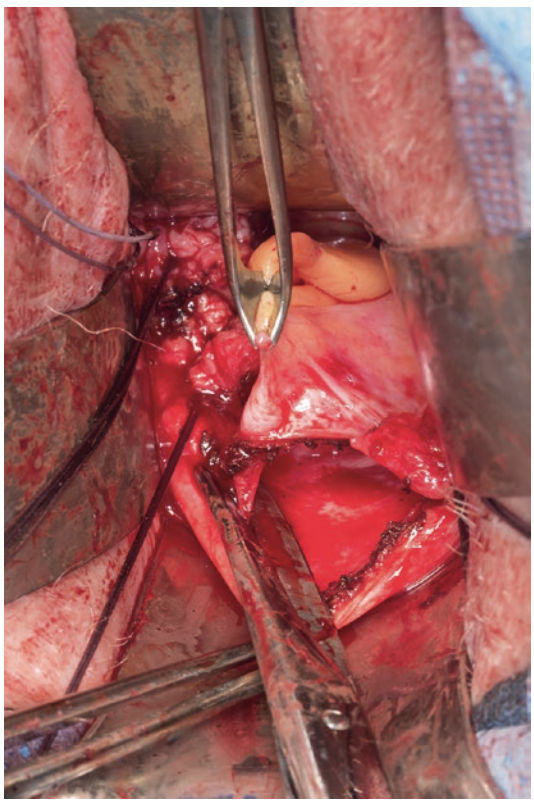

Fig. 123.40 Sharp dissection of the lateral peritoneal attachments (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

In many cases there is some redundancy along the posterior cul-de-sac, for which a wedge resection of a portion of the posterior fornix is taken. An Allis clamp is used to grasp the posterior peritoneum and sharp dissection is used to enter the avascular space and drop away the rectum from the posterior vaginal wall (Fig. 123.38). Once the space is entered, a single finger can be used to bluntly continue dissection (Fig. 123.39). Lateral attachments are further dissected sharply (Fig. 123.40) and a triangular wedge of the posterior vaginal wall is taken (Fig. 123.41a–d). Of note, if no redundancy is noted, then this step is not necessary.

Two external McCall sutures are placed using heavy absorbable suture. Grasping the cut edge of the posterior vaginal wall on the patient's left side, the first stitch is placed through the vaginal epithelium and peritoneum and exits intraperitoneally (Fig. 123.42). With traction placed on the uterosacral ligament by the assistant, the rectum is swept medially and the suture is placed through the uterosacral ligament and pararectal fascia (Fig. 123.43). Small bites continue across the anterior peritoneum of the rectum (Fig. 123.44) to the right uterosacral ligament/pararectal

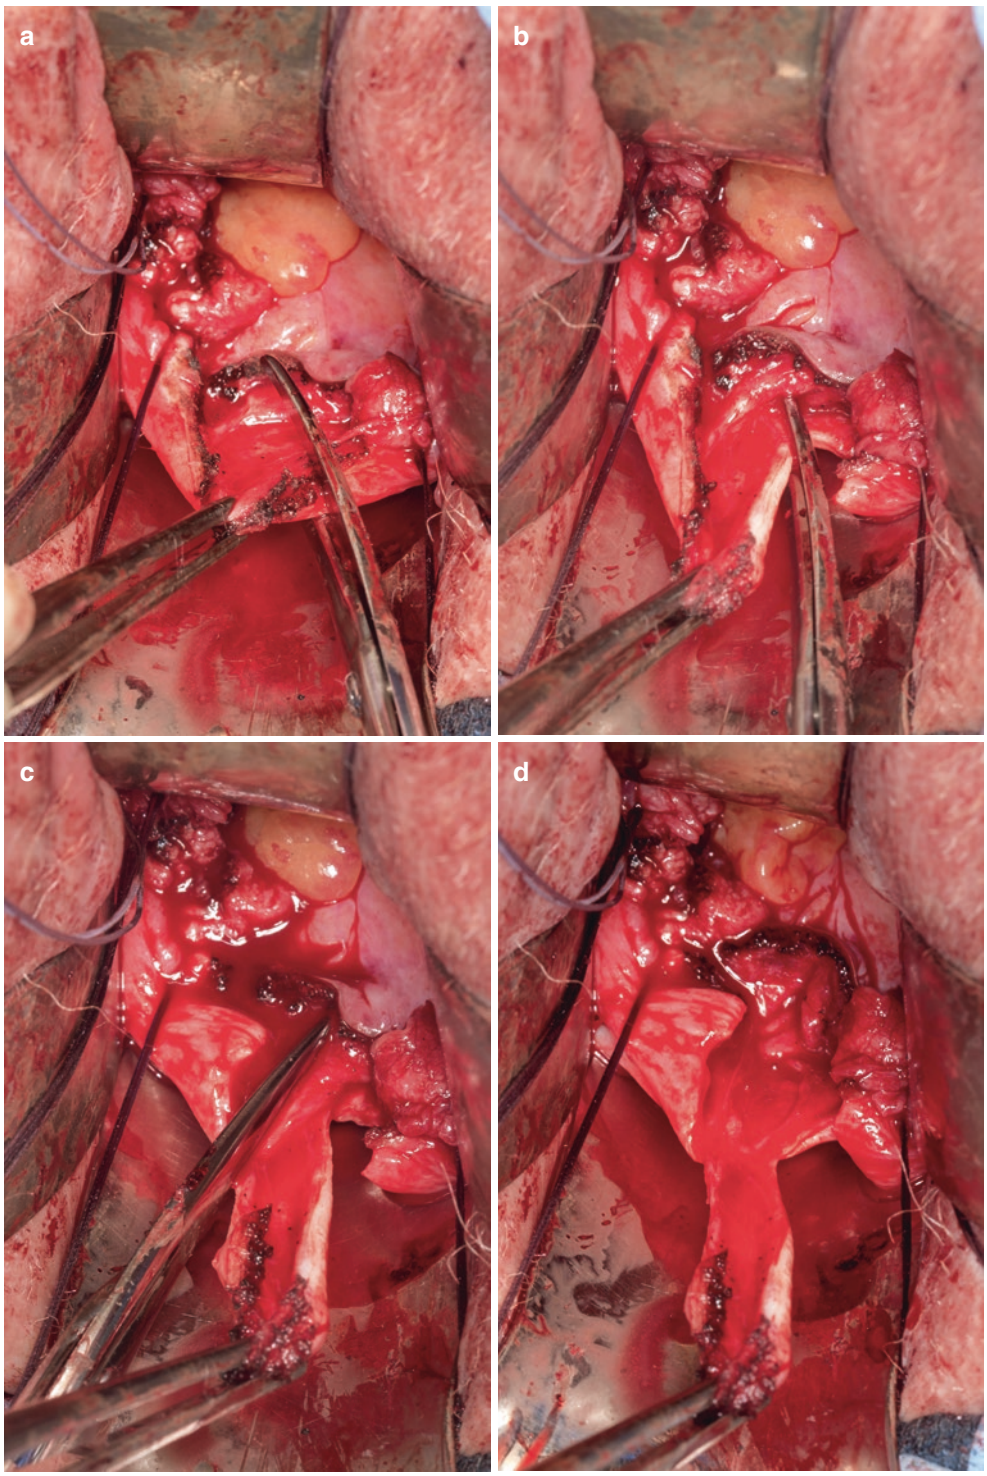

Fig. 123.41 (**a**) Beginning of removal of a wedge of the apical vagina; (**b**) After incision is made on one side; (**c**) After incision is made of the opposite side; (**d**) Completed wedge (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

fascia (Fig. 123.45). It is brought through the peritoneum and out through the vaginal epithelium on the right side (Fig. 123.46) and tagged with a Kocher clamp (Fig. 123.47). A second suture is placed in the same fashion beginning just superior to the first on the vaginal epithelium (Fig. 123.48). Entrapment of the first McCall should be avoided when placing the second (Fig. 123.49). This is tagged with a curved clamp (Fig. 123.50a, b) illustrates both modified-McCall sutures in place prior to peritoneal closure. Peritoneum closures is accomplished by placement of a third suture. This begins with a bite of the left uterosacral ligament cephalad to the highest McCall suture followed by incorporation of the pelvic sidewall peritoneum (Figs. 123.51 and 123.52). The anterior peritoneum of the bladder is incorporated and two knots are tied (Figs. 123.53 and 123.54). This closes the peritoneum from 5 o'clock to 12 o'clock. The same suture is brought inferior and the peritoneum of the rectum is incorporated in several small bites (Fig. 123.55) and finally it is

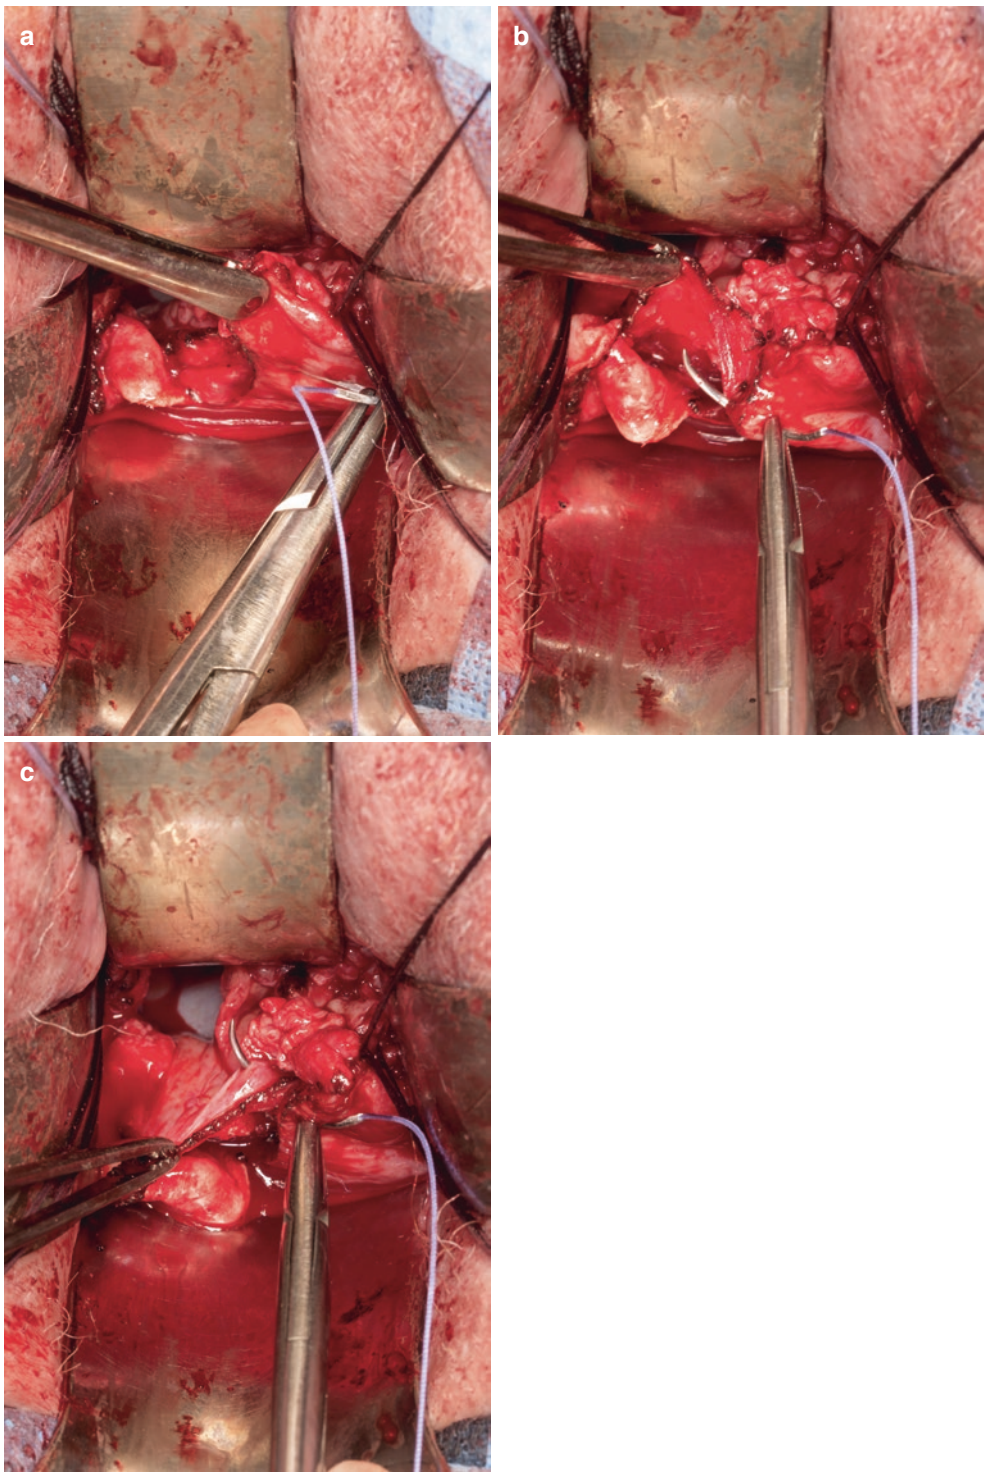

Fig. 123.42 (**a**) Starting point for placement of the first modified-McCall; (**b**) Placement through he vaginal epithelium; (**c**) Placement through the posterior peritoneum into the peritoneal cavity (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

brought through the uterosacral ligament on the right, again superior to the highest McCall. The pelvic sidewall peritoneum is incorporated (Fig. 123.56) followed by the anterior peritoneum of the bladder (Fig. 123.57). The pack is removed and traction is given on the suture to cinch it down, effectively closing the peritoneal; then the suture is tied. The suture end with the needle is brought through the vaginal epithelium (Fig. 123.58) on the patient's right side, while the free end is threaded through a bare needle and brought thought the vaginal epithelium on the left side (Fig. 123.59a, b). Each of the sutures placed can be visualized in Fig. 123.60a, b. The reperitonealizing suture is then tied once again, bringing the edges of the vaginal cuff together. The second McCall suture (curved tag) is tied followed by the

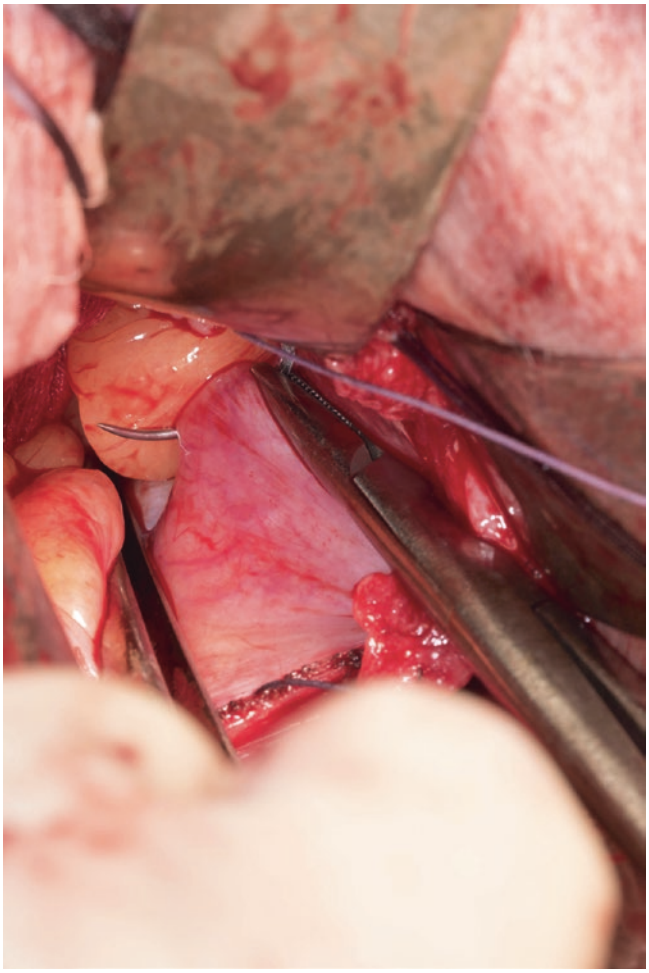

Fig. 123.43 Placement of the first modified-McCall suture through the left uterosacral ligament (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

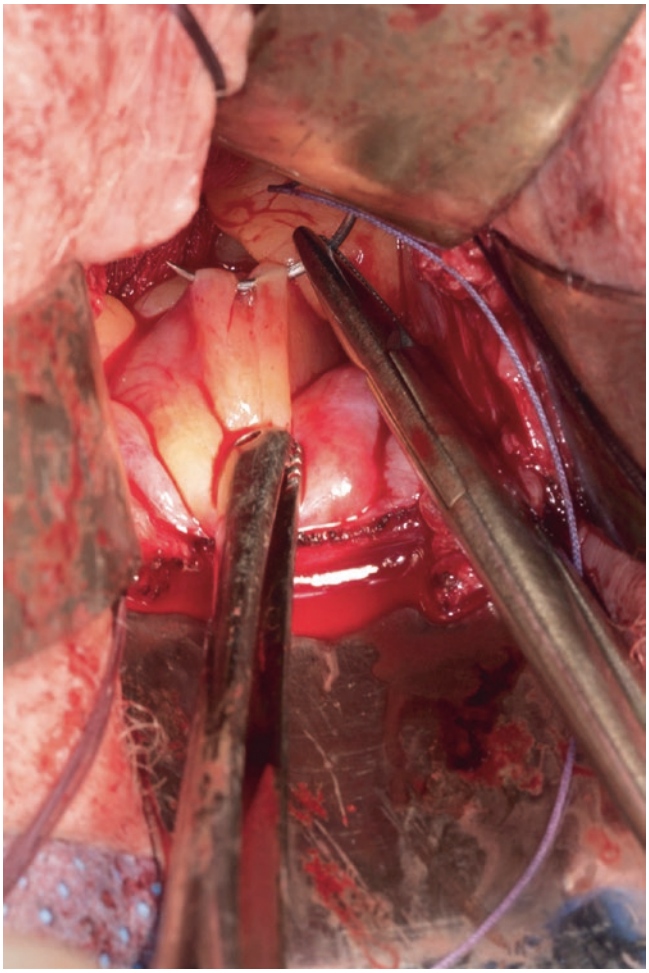

Fig. 123.44 Bites are taken across the peritoneum of the rectum to obliterate the enterocele space (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

first (Kocher tag). Cystoscopy is performed utilizing a 70-degree cystoscope for visualization of ureteral patency (Fig. 123.61).

Cuff Closure

Closure of the cuff begins on the patient's left side. The uterosacral tag is placed in the midline and the assistant on the right provides traction on the contralateral tagged sutures. After support of the vaginal apex, the vaginal cuff angles may be pulled inferiorly, however, identification of the angle is made easy by locating the area of the longitudinal incision made at the start of the case. A suture is passed through the inferior cuff angle, brought through the uterosacral ligament and out the vaginal epithelium, superior to the cuff angle and tied (Fig. 123.62). Additional interrupted sutures are placed to close the vaginal cuff until the midline is reached. The same is done on the right side, incorporating the uterosacral ligament into the corner of the cuff (Fig. 123.63a–c). The remainder of the cuff is closed in an interrupted fashion.

Vaginal-Assisted Laparoscopic Radical Hysterectomy and Pelvic Lymphadenectomy

124

Christhardt Köhler, Giovanni Favero, and Achim Schneider

Preliminary Remarks – History

At the turn of the twentieth century two competing operative schools had been developed in Vienna for operative treatment of cervical cancer patients: radical vaginal hysterectomy by Friedrich Schauta [1] and radical abdominal hysterectomy by Ernst Wertheim, Schauta's disciple [2]. Using the vaginal technique it was impossible to remove pelvic lymph nodes, whereas the abdominal approach at this time was associated with a high mortality rate (11.4 % vs. 25.2 %). However, Wertheim could reach better oncologic results, probably due to removal of metastatic lymph nodes (recurrence-free survival rates 42.4 % vs. 34.6 %). Consequently, with improvement of perioperative monitoring and antibiosis abdominal radical hysterectomy became standard of care in the surgical treatment of patients affected by early stage cervical cancer. Despite some attempts of modification Schauta's procedure was nearly completely forgotten.

After safe and oncologic adequate ability to perform laparoscopic pelvic lymphadenectomy as demonstrated by Dargent and Querleu in 1989 and 1991 [3, 4] the way was open for a renaissance of Schauta's procedure in combination with laparoscopic pelvic (±paraaortic) lymphadenectomy (please see chapter 6.14 – pelvic and paraaortic lymph node dissection). This technique was named by French colleagues as laparoscopic assisted radical vaginal hysterectomy (LARVH) [5–7]. A couple of Anglo-american and European gynecologic centres embarked on this innovative technique, which, however, never reached major popularity.

Almost at the same time total laparoscopic radical hysterectomy [8] was described by Nezhat et al. In 1997 the first and only randomized comparison between radical hysterectomy and radiotherapy in early stage cervical cancer was reported by Landoni et al. [9]. In this study oncologic equality of radical hysterectomy and primary (only) radiation for the treatment of patients with cervical cancer stages IB1-IIA with different profiles of toxicity was demonstrated. A comparison between chemoradiation (the new radiooncologic standard since the new millennium) and surgery has never been done in patients with cervical cancer. Careful and individual selection of patients to one of these treatments, i.e. unimodal modality, is essential in order to avoid increased toxicity which is associated with bimodal or trimodal therapy.

Only surgical staging, best done by laparoscopy, can provide exact staging of disease and helps to identify patients with early stage cervical cancer without lymph node metastases, who mostly profit from radical hysterectomy alone and do not need adjuvant chemoradiation [10] (Fig. 124.1).

Nowadays various techniques for radical hysterectomy are described: abdominal (ARH) with and without nerve-sparing (e.g. Total mesometrial resection – TMMR), Total laparoscopic (TLRH), Laparoscopic assisted vaginal (LARVH), and robotic (RRH) procedures. Besides technical details all available publications provide prospective, retrospective, or match-paired data (with historical cohorts) to characterize the clinical impact of each procedure. Except one phase II randomised study comprising only 15 patients no large prospective randomised study exists comparing different radical hysterectomy approaches [11, 12].

All comparisons between open and laparoscopic based radical operations for the treatment of women with early cervical cancer favour laparoscopy with respect to blood loss, hospital stay, recovery, cosmetic result, and show an identical oncologic outcome, if reported [13–48]. LARVH and TLRH have been successfully performed in more than 2000

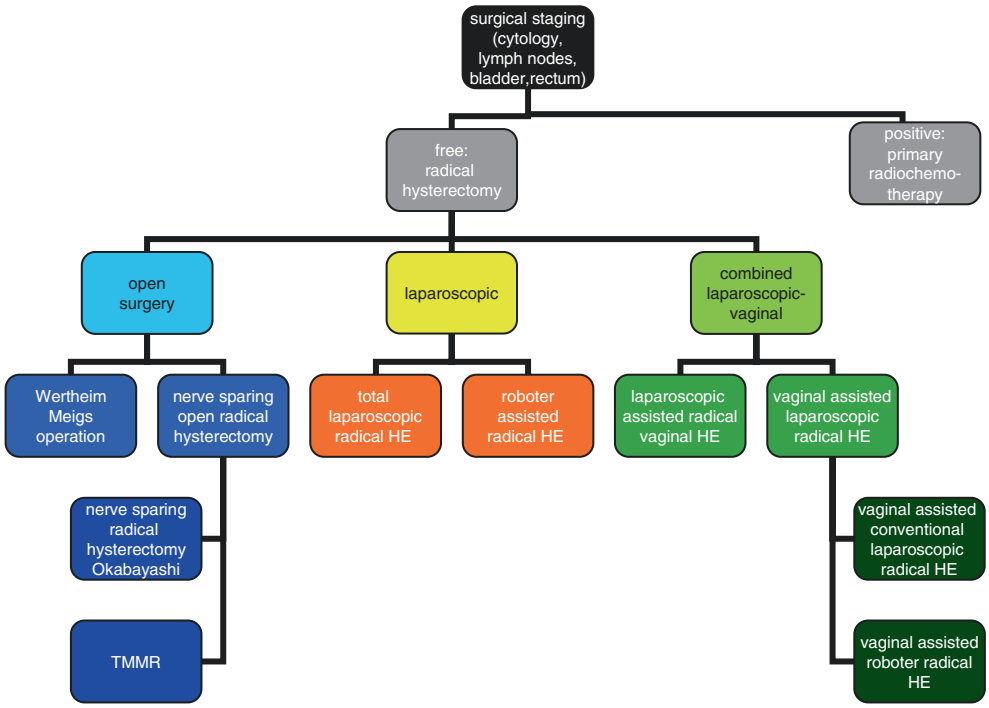

Fig. 124.1 Flowchart for staging and surgical options for patients with early stage cervical cancer. Comprehensive staging should encompass pevic (±paraaortic LNE), cytology fro cul-de-sac and biopsies from vesivocervical and rectovaginal septum

patients. TLRH is done using an uterine manipulator, which makes estimation of adequate vaginal resection difficult and can potentially lead to tumor spillage, especially when the vagina is opened and the tumor surface is exposed to circulating CO_2 [27, 30, 31, 35, 36]. First studies on RRH seem to overcome a few limitations of conventional laparoscopy such as two-dimensional visualization and limited degree of instrument motion which may lead to better acceptance of minimally invasive techniques in gynaecologic oncology [16, 22, 49–53]. However, with the roboter in place vaginal access is impossible and problems with vaginal cuff creation are similar to TLRH. Moreover, use of the robotic system is associated with high costs [54, 55].

Simultaneous with LeBlanc we modified LARVH into VALRH (vaginal assisted laparoscopic radical hysterectomy) which following laparoscopic staging ideally combines advantages of vaginal and laparoscopic approach after comprehensive staging [56]. In the current chapter we analyze the results of LARVH and describe the rationale for its modification into VALRH together with surgical and early oncologic data.

Laparoscopic Assisted Radical Vaginal Hysterectomy (LARVH)

Technique

For LARVH the patient is placed in deep Trendelenburg position (30°) with straight legs. After pneumoperitoneum is obtained five trocars are placed: a 10 mm trocar through the umbilicus, an additional 10 mm trocar in the left mediolavicular line two fingers above the umbilicus and three 5 mm trocars in the lower abdomen 2–3 cm below the umbilicus level bilaterally to the epigastric arteries and in the midline suprapubically. After careful inspection of the abdominopelvic cavity to rule out intraabdominal spread cytology is taken from the cul de sac. If present, adhesions are taken down.

The LARVH procedure can be subdivided into three steps: (1) laparoscopic lymphadenectomy and preparation of the vaginal part (2) radical vaginal hysterectomy and (3) relaparoscopy to control for haemostasis. Technique is described in detail by Roy and Plante [57].

During the first step paravesical as well as pararectal spaces are opened widely. After getting proof of tumor free lymph nodes from frozen section dissection, coagulation, and cutting of uterine arteries at their origin from the internal iliac artery is performed and the infundibulopelvic or ovarian proprium ligament are transected. The bladder peritoneum is now incised and the bladder separated from the uterine cervix down to the level of upper vagina in order to exclude involvement.

For the vaginal part the patient is placed in lithotomy position with hyperextended legs. A vaginal cuff is created by grasping the vaginal mucosa with six straight Kocher clamps 2 cm away from the lesion, depending on tumor size and location (Fig. 124.2). Diluted epinephrine solution is injected between clamps for haemostasis and aquadissection.

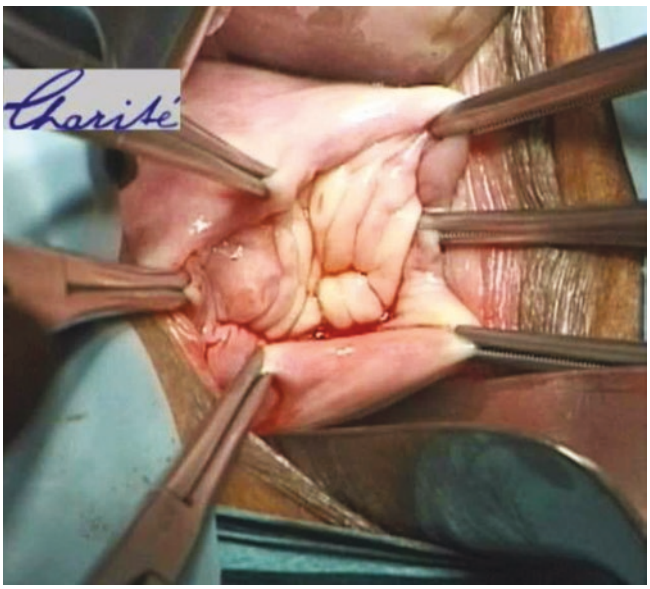

Fig. 124.2 Creation of tumor-adapted vaginal cuff

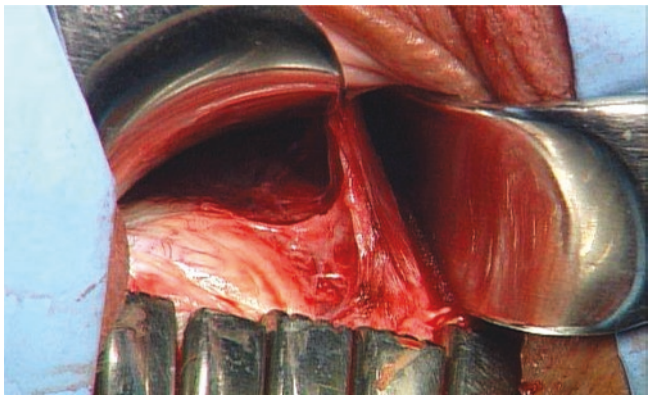

Fig. 124.3 The left bladder pillar limited by the paravesical space laterally and the vesico-cervical space medially

The vagina is now incised outside the clamps and the resulting vaginal cuff is closed with a running suture. Thus, the tumor is always covered. The vaginal cuff is put under tension using serrated clamps or Chrobak clamps. The vesico-cervical space is opened. The left paravesical space is accessed by placing a Kocher clamp at 1 o'clock and 3 o'clock at the transected vaginal mucosa and blunt dissection along the vaginal fascia using strongly curved scissors. Breisky specula are placed into the vesicovaginal and paravesical space. The tissue between both spaces, the bladder pillar, contains uterine vessels and ureter (Fig. 124.3).

Identification and dissection of the ureter is the key step of the operation. The bladder pillar is put under tension in order to facilitate dissection. The ureter is felt as a cord-like structure massaging the bladder pillar against the upper end of a pair of tweezers placed into the paravesical space (click-maneuver). Now, after the ureter has been

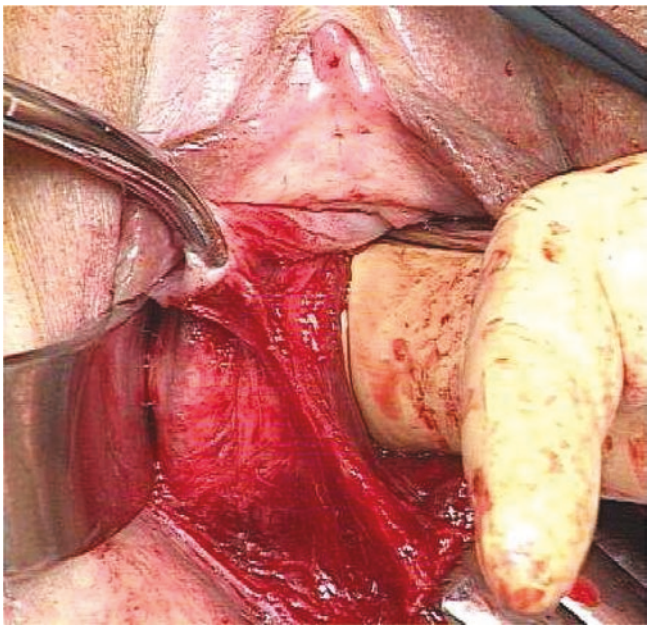

Fig. 124.4 Identification of the right ureter by click-maneuver

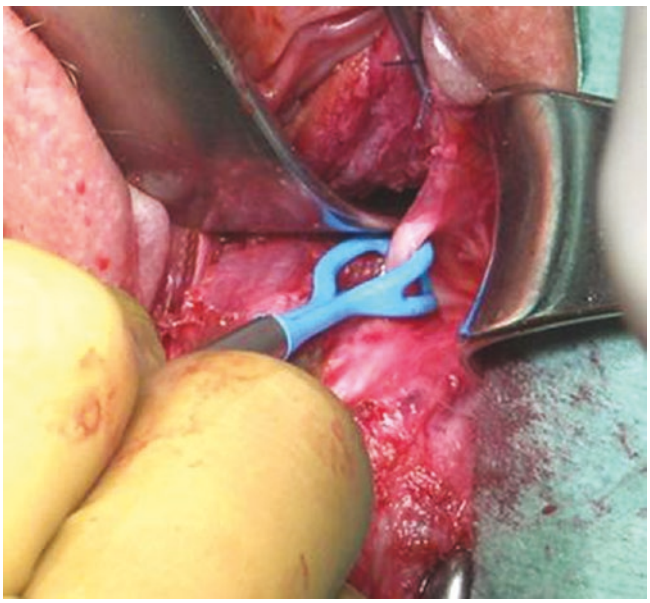

Fig. 124.5 Isolation of the left ureter

localized, the infraureteric bladder pillar is transsected (Fig. 124.4).

The ureter is now visualised by separating medial and lateral leaf of the bladder pillar and grasped with a silicone-covered Babcock clamp. The ureter can be secured with a silicone band and the ureteral tunnel is opened. The same procedure is carried out contralaterally (Fig. 124.5).

The cul-de-sac is opened, the peritoneum covering the rectovaginal ligament is incised, and the rectum is pushed down bluntly. Dissection and ligation of paracolpium and

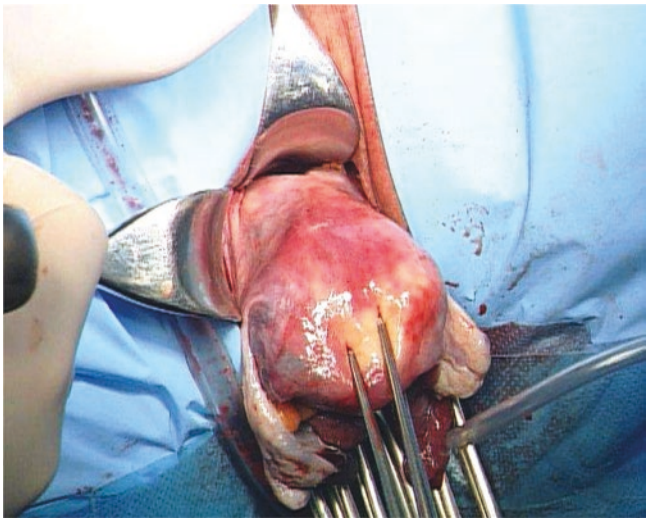

Fig. 124.6 Doederlein maneuver

distal rectovaginal ligaments are the next steps which are made easier by inverting the uterus (Döderlein-maneuver) in order to get more tension on the parametrium (Fig. 124.6).

The remaining parametrium is now transsected and ligated under permanent visualization of the course of the ureter. For a type III procedure the ureter is isolated completely from the bladder pillar, for a type II procedure only the medial part of the parametrium is transsected. Once the specimen is removed (Fig. 124.7a, b) the vagina is closed with interrupted sutures and a Foley catheter is placed again into the bladder. After this patient is repositioned for laparoscopy with extended legs in order to control haemostasis and place pelvic drain(s) (Table 124.1).

Table 124.1 Technique of LARVH step by step

Laparoscopy for:	Radical pelvic (and paraaortic) lymphadenectomy
	Opening of the para-rectal and para-vesical spaces
	Distal and proximal parametrectomy
	Section of the uterine arteries
	Section of the infundibulo-pelvic ligaments (when indicated)
Vaginal surgery for:	Vaginal cuff preparation
	Opening of the vesico-uterine space
	Opening of the para-vesical space
	Identification and dissection of the ureter
	Opening of the posterior cul de sac
	Section of the paracolpos and proximal parametrium
	Removal of the uterus
	Closure of the vagina
Laparoscopy for:	Verification of hemostasis

According to Renaud et al. [47]

Operative Results

Up to date operative data from more than 1000 operations are available (Table 124.2).

Conversion rate of planned LARVH varies between 0 and 16 %. Despite significant lower blood loss compared to abdominal radical hysterectomy transfusion rates are still considerably high (Table 124.3). Number of harvested lymph nodes is appropriate between 13 and 28. However, average operation time for LARVH is still long (Table 124.4). A number of possible intra- andapostoperative

complications can be encountered in LARVH (Tables 124.5 and 124.6) [53]. The rate of intra- and postoperative urologic complications is quite high [58]. Interestingly, there haven't been any new major series on LARVH published since 2010.

Table 124.5 Spectrum of possible perioperative complications in LARVH

Intraoperative Laparoscopic procedure	Trocar site injury (superficial epigastric vessels) Bowel injury Injury to the iliac vessels and obturator nerve Injury to the ureter
Intraoperative Vaginal procedure	Injury to the bladder and/or the ureter Hemorrhage from parametrial resection
Postoperative	Hemorrhage, Hematoma Pelvic abscess Lymphocysts Urinary fistulae (bladder or ureter) Bladder atony Vulvar edema

Oncologic Results

Available results clearly demonstrate oncologic equality to open radical hysterectomy especially in patients with tumors ≤4 cm (Table 124.7) [3].

Learning Curve

Intraoperative complication rate and operation time for LAVRH depend mainly on the skill and experience of the surgeon. Hertel et al. could demonstrate a significant reduction of complications after 100 operations [15], whereas Pahisa et al. and Sardi et al. see 20 operations as sufficient to familiarize with this technique

[14, 18] The learning curve for the vaginal part has never been analysed separately, but in our own experience approximately 50 procedures are necessary in order to master the (more difficult) transvaginal part of the operation. Pergialiotis et al. confirm in their review slow learning curve for LARVH [59].

Rationale for Modification

Even though LARVH is associated with an acceptable oncologic outcome the rate of intra – and postoperative problems, especially urologic complications, is higher compared to ARH and TLRH [15, 18, 25, 26, 33]. Moreover, the key part of this operation, which is the vaginal part, is difficult to teach [60]. Therefore reasons for modifying LARVH into VALRH are:

- the rate of urologic complications can be diminished
- comprehensive laparoscopic staging is mandatory to select appropriate patients for radical hysterectomy
- creation of vaginal cuff can be easier and oncologic adequate done by vaginal route
- there is no need for any uterine manipulator during all parts of surgery.
- sparing of the autonomic nerve supply for bladder, rectum and vagina easy and safe
- new technique should be easy to learn by fellows and residents.

Vaginal Assisted Laparoscopic Radical Hysterectomy (VALRH)

Technique

VALRH also consists of three parts: (1) laparoscopic staging including lymphadenectomy, to evaluate lymph node status, and dissection of vesicocervical and vesicovaginal septum to evaluate tumor relation to adjacent organs, (2) vaginal creation of a tumor-adapted cuff, and (3) laparoscopic radical parametrial resection.

For laparoscopic staging positioning of patient and trocar placement are identical to LARVH. Depending on tumor size pelvic (± paraaortic) lymphadenectomy is performed as previously described [4, 10]. During pelvic lymphadenectomy paravesical and pararectal spaces are opened. All lymph nodes removed are sent for frozen section. While waiting for frozen section result dissection of the bladder up to the level of the ventral vaginal wall is done. In case of lymph node metastasis radical hysterectomy is abandoned and patients are referred to primary chemoradiation. If frozen section reveals tumor free lymph nodes the patient is placed in lithotomy position with extended legs for the vaginal part.

The only aim of the vaginal part is to create a tumor-adapted cuff and to open vesicovaginal and rectovaginal spaces. In relation to tumor size an adequate length of vagina is grasped with six straight clamps (Fig. 124.8a, b). Diluted solution of epinephrine is injected under the vaginal mucosa for vasoconstriction followed by monopolar incision distally to the clamps. The vaginal cuff is now closed with a continuous suture (Fig. 124.9a, b) and, thus, tumor is always covered to prevent spillage of cancer cells. With six serrated clamps tension is brought on the closed vaginal cuff in order to open the vesicocervical and rectovaginal spaces as well as the cul-de-sac. The most inferior part of the rectovaginal ligament is now transected bilaterally and the uterus can be pushed intraabdominally after removal of the serrated clamps (Fig. 124.10a, b). The vaginal stump is continuously sutured for haemostasis. Additionally, interrupted sutures are placed, but not knotted, for later closure of the vagina (Fig. 124.11a, b). To preserve pneumoperitoneum a moistened surgical towel is placed into the vagina.

For the third part of VALRH the patient is placed again into Trendelenburg position with straight, slightly abducted legs. Now the parametrium is getting resected. As a result of the vaginal route both bladder pillars and the transsected vagina are easy to identify (Fig. 124.12a, b). The operation starts by coagulation and transection of the uterine vessels at

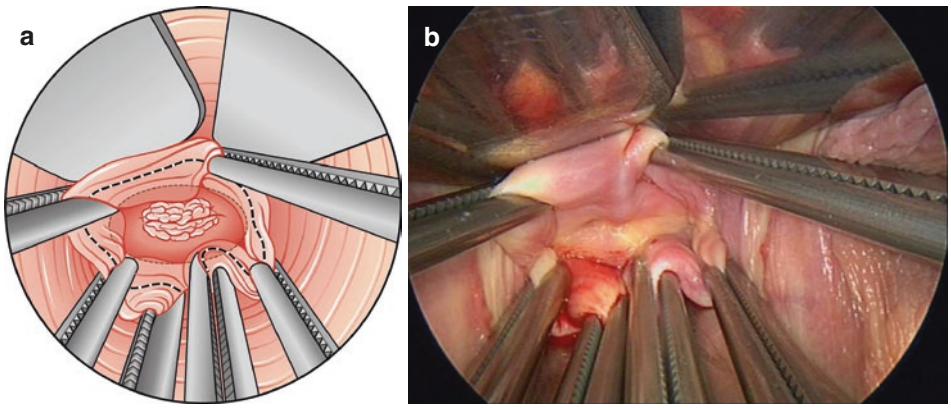

Fig. 124.8 (**a**, **b**) Creation of vaginal cuff

their origin from the internal iliac vessels (Fig. 124.13a, b). In case of salpingoophorectomy the infundibulopelvic ligaments are coagulated and cut. By pulling the vascular part of the cardinal ligament medially, the ureter is freed out of its tunnel up to it's entry into the bladder. Now the remaining part of the paracervix is identified, coagulated, and transected under permanent visualisation of the ureter (Fig. 124.14a, b). For nerve spearing plexus pelvicus as well as nervi splanchnici and hypogastrici are separated and preserved. The suture of the vaginal cuff is easy to identify and marks the endpoint of resection. The specimen is removed transvaginally and the vagina is now closed using the preplaced interrupted sutures (Fig. 124.15). Finally hemostasis is verified and a suprapubic catheter and drain(s) are placed. Radicality of parametrial resection in correlation to tumor size according to a type II (B) or type III (C) radical hysterectomy is chosen by the surgeon intraoperatively. No uterine manipulator is used at any time.

Operative Results

Up to now the retrospective series of VALRH by our team comprising 122 patients has been the largest published with respect to VALRH [61]. Indications for VALRH were histologically proved cervical cancer (n = 109) or endometroid endometrial cancer stage II (n = 12). One patient requested to undergo radical hysterectomy type B in case of extensive CIN III lesion not completely resected by conization (Table 124.8).

All 122 patients underwent VALRH without conversion to laparotomy. Type II (B) and type III (C) operations were performed in 82 and 40 patients, respectively. VALRH was combined with pelvic lymphadenectomy in 37 patients, and with pelvic and paraaortic lymphadenectomy in 85 patients. Mean operating time was 301 min. Operation time was nearly identical for type B and C procedures. Duration of surgery differed significantly in two patients, one with infiltrative sigmoid endometriosis, who had to undergo simultaneously bowel resection (operating time 665 min) and one patient with a BMI of 46 (605 min).

The median number of lymph nodes harvested was 36 (4–83) with 21 (4–43) pelvic and 15 (2–36) paraaortic lymph nodes. One patient (cervical cancer pT1a2 N0 L0 V0 R0) opted for sentinel lymph node dissection only and four sentinel lymph nodes were removed, which were tumor free on histology (Table 124.9).

There was not a single intraoperative complication, especially neither bladder nor ureter injury. Mean blood loss was 123 cc (10–400). One patient required blood trans-

Table 124.8 Patient's characteristics

Median time to urine residuals <50 cc (days)	7.9 (2–40)
Median hospital stay (range)	10.4 (4–31)

fusion due to stress-induced cardiomyopathy and two patients due to preoperative anemia on demand of the anaesthesiologists. Postoperative complication rate was 13.1 % (Table 124.10). No patient required postoperative referral to an urogynaecologist for postoperative bladder dysfunction and only one patient needed longer than 25 days to void her bladder adequately. Median time to urine residuals < 50 cc was 7.9 days. Four patients had to undergo re-laparoscopy; one due to lost drainage, two for suspected ileus (which could not be verified intraoperatively), and one for chylascos. Histologically parametrial and vaginal resection with sound margins was confirmed in all patients. The majority of patients with proven cervical cancer were found to have FIGO stage IB1 (75.5 %). In 6 patients (5.5 %) final pathology revealed parametrial involvement. Histological types were distributed as follows: squamous cell carcinoma 60.9 %, adenocarcinoma 36.4 %, and neuro-endocrine carcinoma 1.8 % (Table 124.11). Five out of 110 (4.5 %) patients with cervical cancer had positive micrometastases/metastases in the final histopathological examination undetected by frozen section.

Up to now we have performed more than 400 VALRH with only one intraoperative bladder injury. Operation time decreased to 235 min and blood loss to less than 50 cc. There is no need to ask for banked blood anymore.

Oncologic Results

Postoperative adjuvant therapy (radiation, chemotherapy, chemoradiation) was recommended for 30/122 patients (24.6 %), 8 with endometrial cancer and 22 with cervical cancer. Recommendation for adjuvant chemoradiation or chemotherapy was given for cervical cancer patients with proved high risk factors (N1, stage IIB) or the combination of two intermediate risk factors (tumor size > 4 cm, LVSI, adenocarcinoma, G3, deep stromal invasion). In 2 out of 122 patients neuro-endocrine tumor was found which was treated according to a multimodal protocol.

Only one patient (0.9 %) underwent vaginal brachytherapy based on surgical result (close vaginal margin of 5 mm). Individualized protocols were performed in two patients: one patient with cervical cancer stage Ib2 was treated by neoadjuvant chemotherapy, VALRH and postoperative chemoradiation, another patient received brachytherapy due to grading 3. In one patient with ovarian metastasis six cycles of platin-based chemotherapy were administered. Two patients denied recommended chemoradiation. After a median follow up of 19 months (4–40) the total recurrence rate in the entire cohort is 6.7 % (8/120), for cervical cancer patients 6.4 % (7/110), and for endometrial cancer 8.3 % (1/12), respectively. DFS and OS for all 110 cervical cancer patients are 93.5 % and 98.1 %, for the subgroup of patients (n = 90) with tumors ≤ pT1b1 N0 V0 L0/1 R0 96.7 % and 97.8 %, respectively.

Learning Curve

The learning curve was not separately analyzed in our initial study because VALRH had to be standardized for 25

Table 124.11 Histologic results after VALRH

operations and one side of lymphadenectomy and parametrial resection was performed by a resident or fellow. However, from 2007 to 2009 operating time decreased for VALRH type II and III from 317 to 268 min and from 345 to 303 min, respectively [61]. However, major advantages of the new technique compared to LARVH are easier standardisation reproducibility, less urologic complications and better preservation of the autonomic nerve-supply.

Comparison LARVH and VALRH

In a recently published match-pair analysis of our results from 109 patients with cervical cancer stage IA1 L1 to IIB who underwent VALRH compared to 200 patients after LARVH we could demonstrate a significant lower rate of blood transfusions, earlier resumption of bladder function and earlier discharge from hospital for the VALRH cohort. There was no intraoperative complication in the VALRH group compared to 7 % during LARVH. More importantly there was no difference in oncologic results [62].

Discussion

Today various techniques of radical hysterectomy are described: abdominal, laparoscopic assisted vaginal, total laparoscopic, robotic assisted, and vaginal assisted laparoscopic. LARVH was the first innovative technique in this field. Benefits of LARVH compared to abdominal radical hysterectomy include less blood loss, lower postoperative morbidity, shorter hospital stay, better cosmetic result, and earlier recovery after surgery. However, 20 years later it is time for a critical stock taking.

Three main criteria are used to evaluate and compare different techniques of radical hysterectomy: (1) possibility to triage patients and therefore avoid combined use of operation and chemoradiation, (2) complication rate and (3) oncologic outcome. Comprehensive operative staging including pelvic ± paraaortic lymphadenectomy is the key step to differentiate patients, who rather benefit from radical surgery from those, who are better treated by primary chemoradiation [9]. TLRH, RRH, LARVH, and VALRH offer the possibility to start with lymph node dissection (± sentinel node) and frozen section. We have abandoned radical hysterectomy in case of positive lymph nodes. However, frozen section

was not accurate in 4 out of 110 (3.6 %) patients with cervical cancer in our VALRH series. Bader et al. reported a false negative rate for frozen sections of up to 17 % [63].

Most published retro- or prospective studies on radical hysterectomy include cervical cancer patients with stages IA1 L1 – IIA (B) and only few patients with higher stages. This is in concordance with our study population of VALRH. Conversion rates are described in up to 5 %, 10 %, and 16 % for RRH, TLRH and LARVH, respectively. None of our planned VALRH-procedures had to be converted to open approach. ARH, LARVH, and our new technique of VALRH are done without any manipulator to create an adequate vaginal cuff, whereas all TLRH and RRH require a manipulator or sponge in the vagina. In our opinion creation of a vaginal cuff by transvaginal approach is easier and possible tumor distribution due to manipulator use is avoided [64]. With the described technique of VALRH, we are able to resect tumor always in sound vaginal margins in contrast to studies of ARH, TLRH and RRH where up to 20 % of positive vaginal margins are reported [16].

Blood loss in VALRH is low compared to ARH und LARVH and in the lower range of TLRH and RRH. In our series transfusion was given to only three patients, where the cause was not intraoperative blood loss. Operation time of 300 min in our VALRH series is in the range of LARVH but longer than the average time for ARH, TLRH, and RRH and therefore still a major argument against combined vaginal-laparoscopic techniques. However, one must consider that 85 out of 122 (69 %) of our patients in addition to VALRH also underwent paraaortic lymph node dissection with a duration of approximately 60 min. After more than 400 VALRH procedures mean operative time decreased to less than 4 h. The majority of radical hysterectomies in the literature are combined with pelvic lymph node dissection exclusively. Subsequently the mean number of harvested lymph nodes (n = 36) in our VALRH-cohort is in the upper range of all described studies and higher than in studies using open surgery.

Rate of operative complications is a major issue evaluating different types of radical hysterectomy. Intraoperative complications occur in 4 %–12.5 %, 0 %–11.8 %, 5.9 %–13.2 % and 0 %–14 % in ARH, TLRH, LARVH, and RRH, respectively. There was no one intraoperative complication in our study and in the extension of our experience to 400 patients only one patient with intraoperative bladder injury. Also postoperative complication rate after VALRH (13.1 %) is in the lower range of published data. Especially urologic intra – and postoperative complications are significantly lower compared to LARVH or TLRH [15] probably due modifying the vaginal part of the operation.

Oncologic data are difficult to compare because of different follow-up intervals and various oncologic cornerstones. Summarizing data from open, laparoscopic, laparoscopic-vaginal, and robotic series recurrence rates vary between of 0 and 13 %, and DFS between 82 and 100 % and OS between 89 and 100 %. Despite a relative short follow up of 19 months our DFS rate of 94 % and OS rate of 98 % for VALRH are promising. However, longer follow up is mandatory to confirm this observation.

In conclusion our new technique of VALRH is an oncologic valid alternative to ARH, LARVH, TLRH, and RRH in patients with cervical cancer FIGO stage < IB2 with low blood loss and few intraoperative complications. During the vaginal part of the operation it is always possible to create an adequate vaginal cuff and to avoid tumor spillage and disregard the use of any manipulators. LARVH should be replaced by VALRH due to less urologic complications, easier nerve-sparing and better teaching ability. The only argument for a gynecologic oncologist to continue with LARVH is to get familiar with its vaginal part to be able to perform radical vaginal trachelectomy or in special patients radical vaginal hysterectomy [65]. Further studies comparing the VALRH technique with other types of radical hysterectomies are necessary to underline the promising results of our monoinstitutional series.

Radical Vaginal Trachelectomy

125

Christhardt Köhler, Giovanni Favero,
and Achim Schneider

Preliminary Remarks

Cervical cancer is one of the most common cancers among women worldwide with approximately 530,000 incident cases and 275,000 deaths in 2008 [1]. More than other cancers, cervical cancer affects women younger than 45 years [1, 2]. However, in countries with high resources incidence of invasive cervical cancer is decreasing due to effective screening with a shift towards earlier stages of disease [3]. Additionally in western countries today first pregnancy is delayed until later age in the majority of women [4]. Thus, diagnosis of cervical cancer is more frequently detected in nulliparous women. Therefore, gynecologists are more increasingly faced with young patients affected by early stage cervical cancer who still seek motherhood. Sonoda et al. estimated that 48 % of women of reproductive age diagnosed with early stage cervical cancer would meet the criteria for treatment by RVT [5].

In 1952 Novak presented a radical trachelectomy operation for women of reproductive age with cervical carcinoma in situ, who insisted to be operated conservatively. His open surgical procedure comprised dissection of lymph nodes and radical extirpation of the cervix and upper part of the vagina, together with the corresponding paracervical and paravaginal tissues [6]. However, this operation did not become so known worldwide. With the feasibility to perform laparoscopic pelvic lymph node dissection safely, combination of laparoscopic lymphadenectomy with radical vaginal trachelectomy was developed and published by Daniel Dargent in the late eighties of the last century [7]. This procedure provided a fertility sparing alternative for women with early stage cervical cancer in contrast to radical hysterectomy, the standard procedure at this time. Due to significant higher recurrence rates in patients with invasive cancer larger than 2 cm in diameter, depth of infiltration of more than 10 mm, LVSI and close surgical margins careful selection of patients for RVT is mandatory [8].

The aim of radical trachelectomy is to remove residual tumor after biopsy and/or conization and or to reduce the risk of parametrial spread. After analyzing giant section of radical hysterectomy specimen in 180 patients with node negative early cervical cancer Winter et al. could find continuous tumor spread, discontinuous tumor spread, LVSI and parametric lymph node involvement in the medial and lateral parametrium in 0–2.2 % [9]. The real incidence of parametrial tumor involvement in cervical cancer <2 cm is low, but potentially life-threatening, if not recognized. Lanowska et al. found positive lymph nodes in parametria after RVT in 0.9 %, Brady et al. in 2.2 % and Schmeler et al. in 1 % [10–12], whereas others did not find any parametrial spread in low risk early cervical cancer [13–15]. Until results of ongoing randomized trials are pending, RVT should be considered as gold standard for fertility-sparing surgery in patients with early cervical cancer [16], because RVT can effectively reduce risk of parametrial tumor spread.

Multiple prospective and retrospective studies have reported that radical trachelectomy is feasible, safe and has equivalent disease free and overall survival rates when compared to radical hysterectomy (see Chap. 5). Different approaches for radical trachelectomy are described in Fig. 125.1.

Majority of data are available for RVT, less for abdominal radical trachelectomy [17–21] and total laparoscopic radical trachelectomy [22, 23] and only a few for robotic radical trachelectomy [24, 25].

Indications for RVT and Pelvic Lymphadenectomy

Patient selection is very important for a safe oncologic outcome. Internationally there are established indications for radical trachelectomy. These are:

- planned pregnancy
- cervical cancer stages IA1 L1 – IB1 <2 cm
- no haemo-vascular space involvement (Fig. 125.2)
- tumor free pelvic lymph nodes
- tumor-free endocervical margin 0.5 cm
- length of remaining cervix approximately 8–10 mm
- no high risk histology (neuroendocrine, carcinosarcoma, clear-cell, serous-papillary) [26]

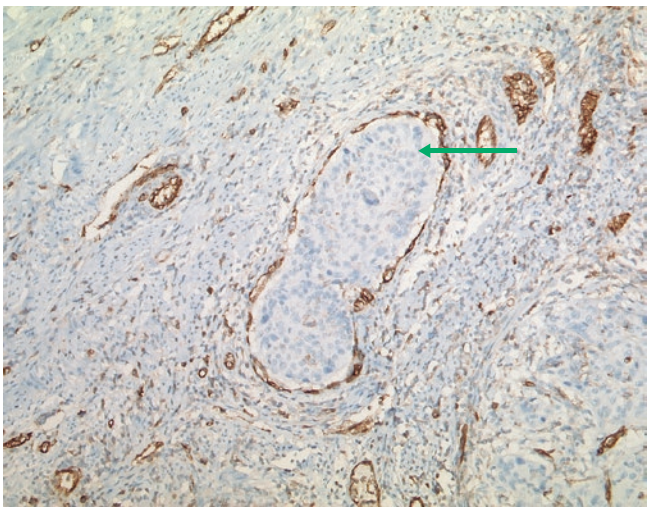

Fig. 125.2 Haemvascular space involvement (*green arrow*)

Technique of RVT

Technique of RVT is standardised and consists of three substeps: (1) laparoscopic pelvic lymphadenectomy and preparation for the vaginal part, (2) radical vaginal resection and (3) laparoscopic control of haemostasis.

1. After positioning of the patient in moderate lithotomy position, application of perioperative antibiotics, vaginal and skin desinfection and team time-out operation starts with subumbilical skin incision. Using Verres needle a sufficient pneumoperitoneum is created and a 10 mm trocar is placed in the lower umbilicus. Under visualisation three additional 5 mm trocars are inserted in the lower middle, right and left abdomen and a 10 mm trocar in the left upper abdomen. After exclusion of peritoneal spread and inspection of the whole abdominal cavity the patient is placed in deep Trendelenburg position. Cytology is taken from the cul-de-sac and the inner genital organs are inspected. By cutting the peritoneum lateral to the right infundibulopelvic ligament up to the pelvic rim the retroperitoneum is opened and the ureter is identified at its overcrossing with the common iliac vessels. Under preservation of the round ligament, the pararectal and paravesical fossae are opened widely after identification of the umbilical lateral ligament. Using a 10 mm sponge forceps the right ureter is always pushed medially. Following the identification of the oburator nerve complete pelvic lymphadenectomy is performed comprising

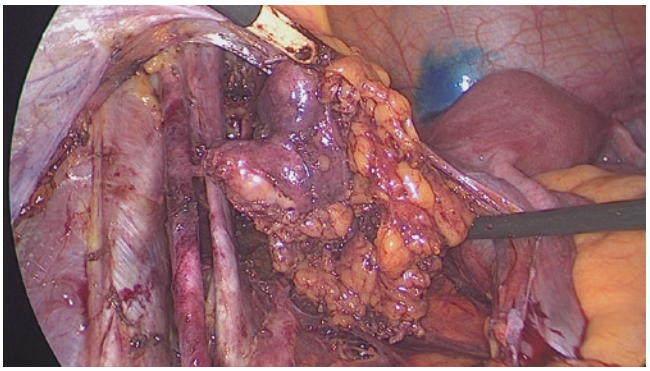

Fig. 125.3 Lymph node metastases in a patient with stage IA1 L1 cervical cancer and wish to preserve fertility

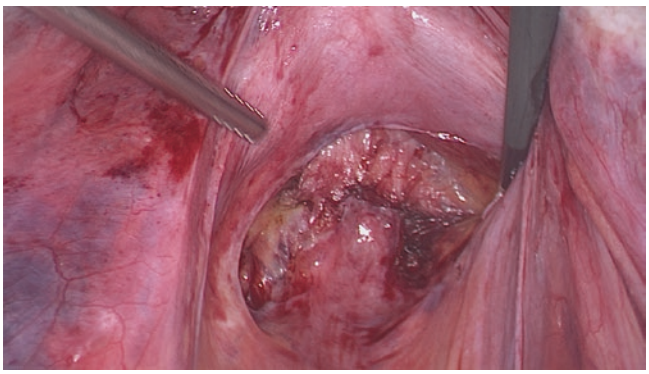

Fig. 125.5 Opened rectovaginal septum

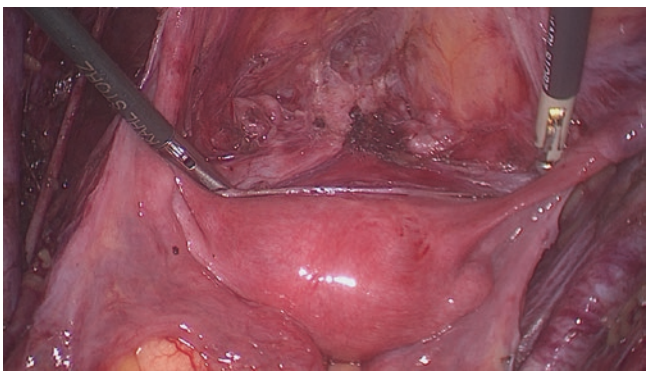

Fig. 125.4 Opened septum vesicouterinum and vesicovaginale

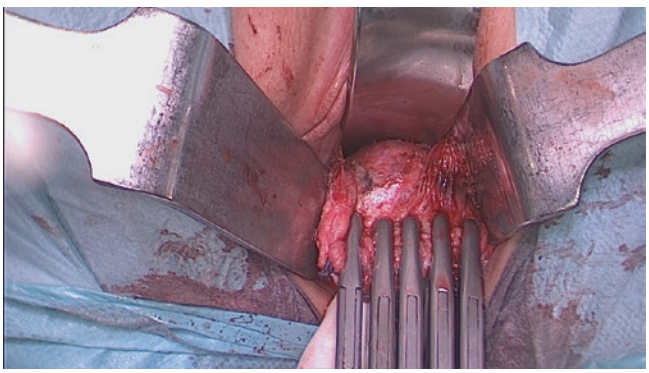

Fig. 125.6 Vaginal cuff under tension

common iliac, iliac external, obturator and iliac internal lymph nodes (please see chapter 106 – pelvic and paraaortic lymph node dissection and Fig. 125.3). Harvested lymph nodes are removed from the abdominal cavity using an endobag and send for frozen section. Identical procedure is done on the left side.

Waiting time for histologic result of lymph nodes can be used to prepare for the vaginal part of RVT. Under moderate filling of the bladder the vesicouterine peritoneal excavation is incised and bladder is brightly dissected away from the uterine cervix up to the upper vagina. During this procedure both uterine arteries are freed and become visible at their entry to the uterus. After voiding the bladder the uterus is elevated and the peritoneum of the cul-de-sac will be incised. Thus, the rectovaginal space is opened and rectum can be moderately pushed away from the posterior parametria. Finally the paravesical spaces on both sides are dissected to the level of levator ani muscle (Figs. 125.4 and 125.5). No uterine manipulator is used at any time of RVT.

2. For the transvaginal part of RVT the patient is placed in maximal lithotomy position. Only if pelvic lymph nodes are confirmed as histologic tumor free, the operation is continued. With six straight Kocher clamps an adequate vaginal cuff is grasped, that is large enough to cover the cervix with or without visible tumor. Between the clamps diluted adrenaline solution is injected for hemostasis and aquadissection. Following this vagina is incised between the clamps using monopolar diathermy. Afterwards a vaginal cuff is formed along the vaginal fascia over a distance of 7–8 mm circumferentially. Vaginal cuff is than closed using a continuous locking suture vicryl 0 that covers the cervix (with or without tumor) itself. The vaginal cuff is grasped with 5–6 serrated clamps. In order to avoid any tumor cell contamination instruments and gloves are changed at this point (Figs. 125.6 and 125.7).

The vaginal cuff is now brought under tension by pulling the serrated clamps. Under ventral tension it is easy to reach the former pouch of Douglas. With a large Breisky speculum rectum is pushed dorsally and therefore sacrouterine ligaments are tensed up. The rectum is pushed away from the sacrouterine ligaments using a small cotton swab. After removal of the posterior Breisky speculum the vagina is pulled down and vesicovaginal space is entered by sharp dissection. Bladder is now protected by middle-size speculum. Beginning on the left side transsected vagina skin is grasped

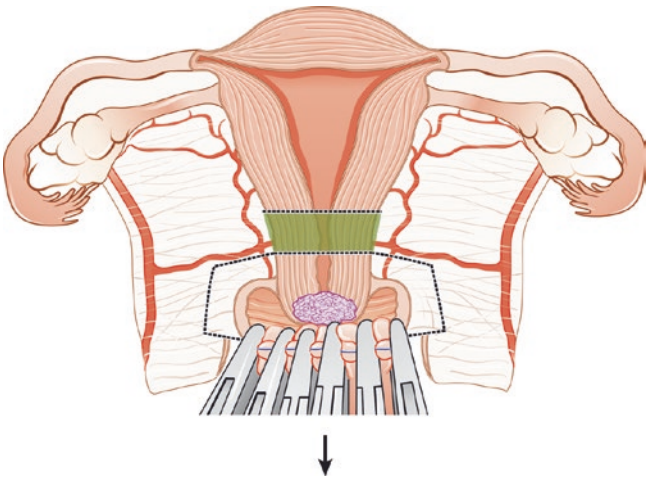

Fig. 125.7 Schema of resection during RVT and preserved cervical length

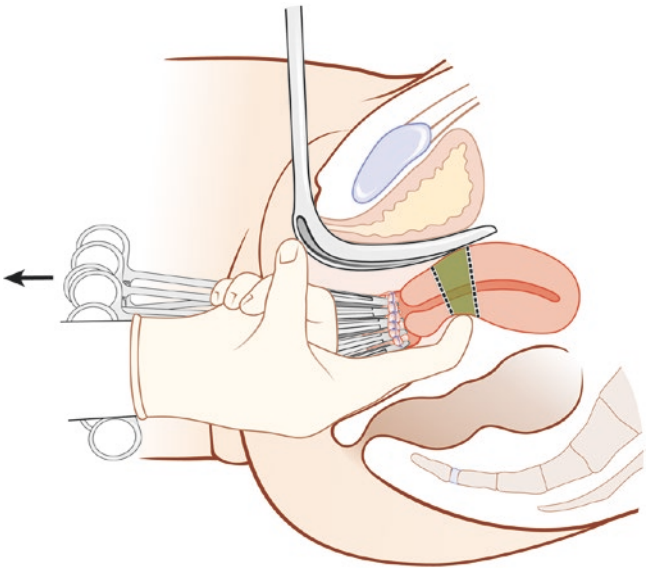

Fig. 125.9 Schema of vaginal examination for identification of the subsequent cervical resection line

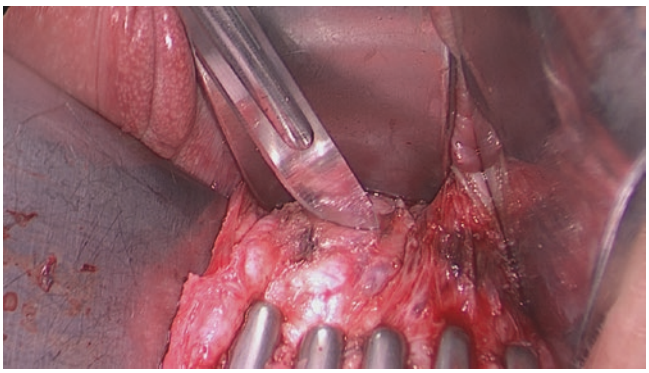

Fig. 125.8 Cervical incision is marked under direct palpation

at 01 and 03 o'clock with Mikulicz clamps. With strongly curved scissors blunt dissection is performed exactly along the vaginal fascia between the Mikulicz clamps in latero-ventral position. Thus, the paravesical space, that has already been prepared during laparoscopic part of RVT, is reached above the level of the levator muscle. A small Breisky speculum is inserted in this paravesical space and bladder pillar is now exposed between the anterior and lateral Breisky specula. Via click manoeuvre the knee of the left ureter can be identified. Familiar with the course of the ureter the surgeon can now perforate and transect the infra-ureteric bladder pillar. In order to know the necessary level of ureter dissection at this moment, the level of uterine cervix, where the resection has to be carried out, is now marked with a superficial scalpel incision (Fig. 125.8). To define this point surgeon introduces the index finger between posterior uterine wall and rectum and palpates exact in patients midline from uterine fundus in direction of the vaginal cuff (Fig. 125.9). Easily on can identify uterine isthmus and performs superficial incision 7–8 mm below the cervico-corporal junction to preserve cervical competence for further pregnancy.

In knowledge of this level surgeon has to decide, if ureter has to be mobilised more extensively. If necessary, bladder pillar can subdived into a medial and a lateral part using slightly curved Overhold dissector. It can be feasible to grasp ureter with a silicon covered Bebcock clamp and place a silicon loop around the distal ureter.

Following the identical operation contralaterally a large Breisky speculum is inserted in the posterior compartment (former cul-de-sac) in order to push the rectum dorsally and to put tension on the distal sacrouterine ligament. Using two slightly curved hysterectomy clamps the distal sacrouterine ligament is transsected and sutured. Using a 90° curved parametrial clamp the inferior part of the cardinal ligament is now be grasped und transected directly underneath the uterine artery. At this step it is important to have ureter's and uterine arterie's run under permanent visualisation. After same procedure on the other side, cervix is freed from paracervical structures up to the planned and marked resection line. The extent of paracervical resection is in accordance to type B radicality (Fig. 125.10).

Elevating the cervix the trachelectomy specimen is now transsected by cold knife in order to allow optimal histologic evaluation of the resection margins. Cervical curettage has always to be done. In patients with adenocarcinoma a small loop excision of the endocervical canal up to the level of the internal os is carried out using a 5 mm diameter loop. In order to prevent stenosis of the remaining cervix a temporary hard plastic catheter of 8 Ch is placed through the remaining cervix into the uterine cavum and fixed with a suture. Permanent cerclage according to the technique of McDonald is carried out circumferentially using non-resorbable prolene. Suture starts at 6 o'clock and after knotting the cerclage a

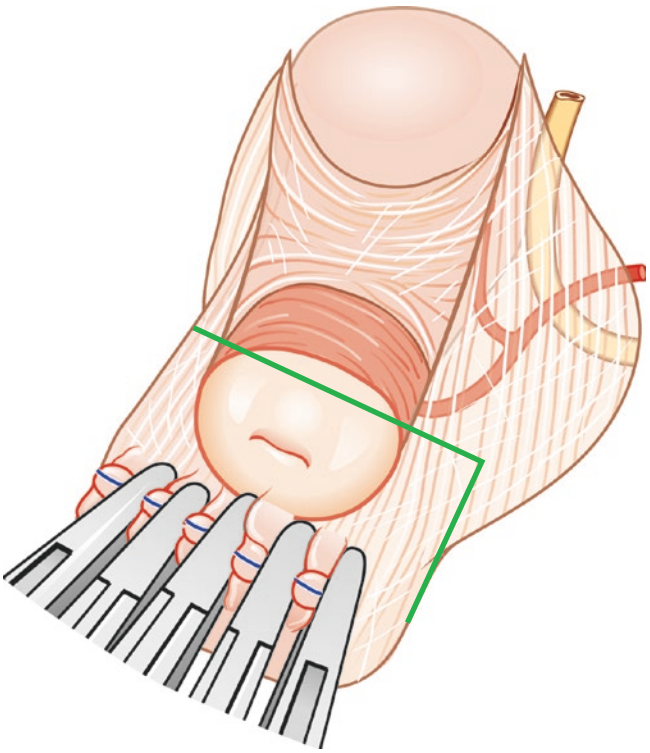

Fig. 125.10 Schema of parametrial resection during RVT according to type B radicality

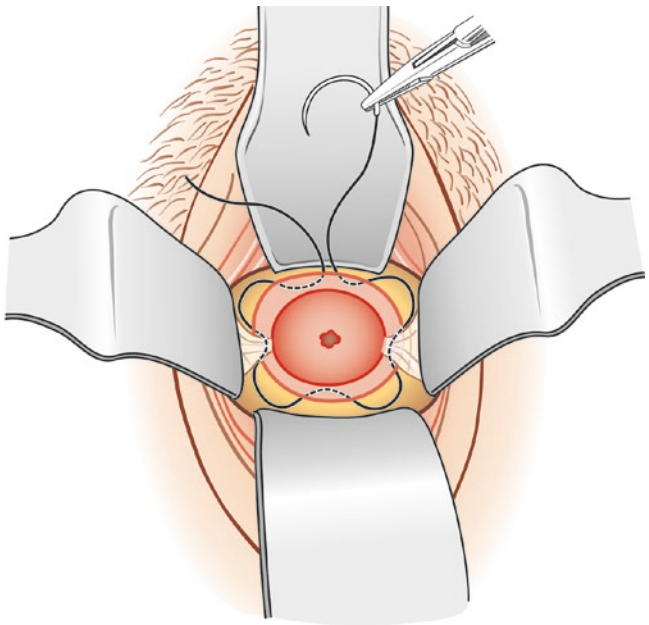

Fig. 125.11 Placement of permanent cerclage

last stich is done in direction to the uterine fundus to avoid perforation of the cerclage suture through the vaginal vault at a later date (Fig. 125.11).

Finally, the remaining vaginal skin is re-adapted to the remaining cervix with single sutures vicryl 0 at 1, 5, 7 and 11 o'clock. Colpotomy has to be closed to both sides and vagina is desinfected prior to re-insertion of a transurethral catheter (Fig. 125.12).

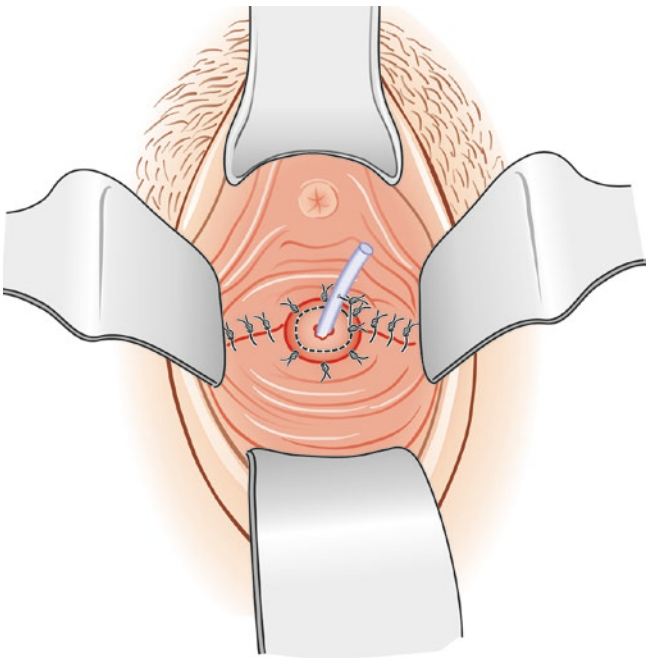

Fig. 125.12 Situs after vaginal part with indwelling catheter in situ

3. After re-positioning of the patient re-laparoscopy is performed via the trocars which are still in situ. Careful hemostasis and irrigation are performed. Intactness of the uterine arteries and regular function of both ureters are checked. Finally a 14 Ch Robinson drain is placed in the pelvis using a 5 mm trocar incision in the right or left lower abdomen (Fig. 125.13).

Up to 12 % of planned RVT have to be abandoned due to more extensive endocervical disease or positive lymph nodes [8, 27], which requires radical hysterectomy or chemoradiation. If pelvic lymph nodes or paracervical tissue are found to be tumor involved, RVT is aborted and paraaortic lymph node dissection has to be performed followed by primary chemoradiation. If permanent section confirms tumor-involved resection margins or endocervical tumor-free margin less than 5 mm or a tumor diameter of more than 20 mm (taking also into account the volume of tumor removed by prior conization), radical hysterectomy should be performed.

In comparison to abdominal radical trachelectomy, total laparoscopic radical trachelectomy and robotic radical trachelectom RVT is associated with clear advantages, but also disadvantages (Table 125.1). Analysing our cohort of 389 patients who underwent RVT major advantage in our opinion is the easy transvaginal definition of the extent of vaginal and cervical resection under direct palpation. A major

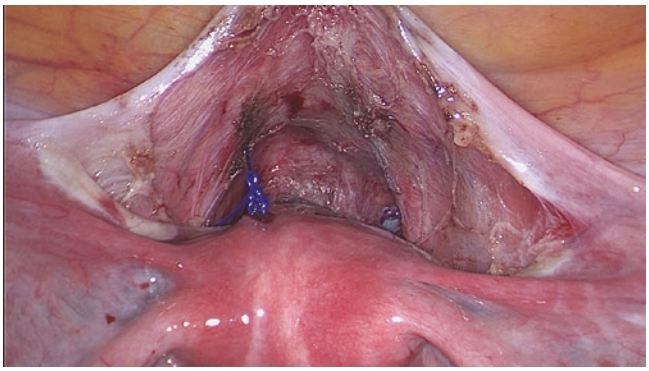

Fig. 125.13 Final laparoscopic situs showing the vesicouterine compartment with fixed knot of permanent cerclage at the level of uterine fundus

disadvantage is the difficulty to teach and learn the vaginal part of surgery. "Each of those approaches has advantages and disadvantages and requires different sets of skills. The surgical approach in and by itself does not matter that much, as long as the procedure is well done, that morbidity is low, that the oncologic and obstetrical outcome are good, and that patients are carefully selected" [28].

Intraoperative Complications and Postoperative Morbidity

Interestingly, more than 50 % of patients after RVT do not immediately attempt to get pregnant. Moreover, in small series by Carter et al., 20 % of women do not have sexual intercourse 12 months postoperatively due to miscellaneous reasons of fear [29].

Spectrum and incidence of perioperative morbidity of radical trachelectomy (3–6 %) is similar to radical hysterectomy in spectrum and incidence. Intraoperative complications such as injury to bladder, rectum, obturator nerve, pelvic autonomic nerves, and subcutaneous emphysema may occur. Postoperative complications such as infection, bleeding, leakage from urinary tract or rectum, urinary retention, urinary incontinence, lymphocele formation, ambulation problems, and ileus are observed [8, 27, 30]. Morbidity, specifically for this surgery may be secondary dysmenorrheal (up to 24 %), irregular bleedings (up to 17 %), problem with the permanent cerclage (up to 14 %), vaginal discharge (up to 14 %), cervical stenosis (up to 7 %) and deep dyspareunia

Table 125.1 Advantages and disadvantages of different trachelectomy techniques

Technique of radical trachelectomy	Advantages	Disadvantages
Radical vaginal trachelectomy	Best cosmesis – natural orificium surgery Probably less adheasions Highest pregnancy rate Minimal blood loss Best method to determine vaginal and cervical resection and place permanent cerclage Prevention of tumor spill and tumor cell contamination Preservation of uterine vessels and thus, optimal blood supply for potential pregnancy	History of conization – adverse vaginal anatomy Technical challenge due to narrow vagina Difficult to learn and to teach
Radical abdominal trachelectomy	Larger parametrial resection No special operative training necessary Easier placement of permanent cerclage	Large abdominal incision – thus suboptimal cosmesis Impairment of uterine blood supply Possible wound infection Possible adheasions – potential problem for further fertility Increased blood loss Longer hospital stay Lower pregnancy rate
Robotic radical trachelectomy	Good cosmesis Probably less adhaesions Minimal blood loss Better placement of permanent cerclage (?) Preservation of uterine arteries	High costs Need for extended robotic skills Difficulty to estimate vaginal and cervical resection Only few oncologic data Low pregnancy rate Possible intraabdominal spill of tumor cells
Total laparoscopic radical trachelectomy	Best cosmesis Probably less adhaesions Low blood loss Good pregnancy rate	Difficulty to estimate vaginal and cervical resection Advanced laparoscopic skills necessary Long learning curve Only few oncologic data available Risk of ureteric fistula formation Possible intraabdominal tumor spill

Table 125.2 Oncologic results after RVT

RVT	n	Median follow-up (months)	Recurrences	Death
Marchiole 2007 [8]	135	95 (31–234)	7 (5.7 %)	5 (4.2 %)
Plante 2005 [41]	72	60 (5–145)	3 (5 %)	2 (3 %)
Shepherd 2012 [42]	208	45 (1–120)	8 (3.8 %)	5 (2.4 %)
Covens 2013 [43]	180	30 (1–103)	9 (2.7 %)	2 (1.1 %)

Σ	1426			

(up to 5 %) [31, 32]. Cervical stenosis may be a relevant obstacle for planned pregnancy and requires individual solutions as described by Grund et al. [33].

Oncologic Results of RVT

Recurrence rate in tumors less than 2 cm is about 5 % and recurrence rate in tumors larger than 2 cm is about 20 % [34–38]. RVT combined with laparoscopic pelvic and parametric lymphadenectomy for the treatment of patients with early stage cervical cancer ≤2 cm results in a recurrence-free survival of 98 %. Mortality rate is about 2 % (Table 125.2). Histology, grade, and presence of LVSI are not associated with higher risk of recurrence. Majority of recurrences occur in the uterus, the parametrium or pelvic sidewall, whereas only few recurrences are reported in the pelvic, paraaortic, and/or supraclavicular lymph nodes or intraabdominally [39]. Therefore, the oncologic safety of radical hysterectomy and radical vaginal trachelectomy for patients with tumors of identical size appears to be comparable [40] (Table 125.2).

Obstetric Results

Ten percent of women for whom radical trachelectomy was planned could not have their fertility preserved due to histologic proven lymph node metastases or positive/close cervical resection margins [28, 53]. There is no clear consensus on interval waiting time between RVT and attempting pregnancy [54]. Complete healing of the vaginal wound may last up to 3 months. As the procedure usually is limited to small tumors, prognosis is excellent and there is need to wait longer to get pregnant. Between 10 and 15 % of patients after vaginal radical trachelectomy are diagnosed with impaired fertility. However, this rate is comparable to the general population and infertility might be existing before the operation or resulting from the operation [36, 55]. Fertility evaluation in trachelectomy patients revealed that 25 % have had a history of infertility before trachelectomy [56]. Patients who are subfertile or who had fertility problems prior to RVT should be managed by a gynecologist specialized in reproductive medicine. There is no contraindication against use of assisted reproductive methods.

In large monocentric studies 65–70 % of patients, who wish to get pregnant after RVT, were able to conceive (Table 125.3). The rate of first trimester miscarriage is similar compared to normal population but the risk of second trimester abortion is increased (9.5 % vs. 4 %). Preterm delivery is a major risk following radical trachelectomy (Table 125.3). The main cause of second trimester loss and premature delivery is PROM associated with ascending infection [57, 58]. The cervical length and shape has to be monitored in prenatal care. Vaginal infection must be excluded by regular assessment of vaginal pH and flora. Patients should abstain from physical strain and stress between 14th and 28th gestational weeks of gestation. Pregnancy after RVT has to be considered and managed as high-risk pregnancy. Therefore, there are specific recommendations of conduct

Table 125.3 Obstetrical outcome after RVT

Author	Pregnancies (n)	First trimester	Second trimester	Third trimester	<32 weeks	32–36.6 weeks	>37 weeks
Speiser 2011 [60]	60	5 (8 %)	3 (5 %)	50 (83 %)	3	15	32
Shepherd 2012 [54]	125	27 (22 %)	18 (14 %)	73 (58 %)	14	26	33
Plante 2011 [61]	106	21 (20 %)	3 (3 %)	77 (73 %)	4	15	58
Covens 2008 [62]	86	14 (16 %)	7 (8 %)	65 (76 %)	11	11	43
Mathevet 2003 [59]	56	9 (16 %)	8 (14 %)	34 (61 %)	2	3	29
Kim 2012 [63]	16	1 (5 %)	0	15 (78 %)	0	6	9

during pregnancy following RVT [59]. Delivery after RVT has always done by cesarean section due to the permanent cerclage (Table 125.3).

Follow-up after RVT

There are no consensus and no generally accepted guidelines on the follow-up protocol in patients after radical trachelectomy. We advocate that patients should be followed-up at 3 months interval for the first 2 years since the majority of recurrences occur in the first 24 months, then at 6 months for 3 years. Thereafter the patient goes back into normal screening (Fig. 125.14). In contrast to the follow-up protocol for patients having been treated for cervical cancer by radical hysterectomy or chemoradiation patients with a history of RVT need regular control of the remaining cervix which should be done by cytology, colposcopy and HPV testing [39, 64].

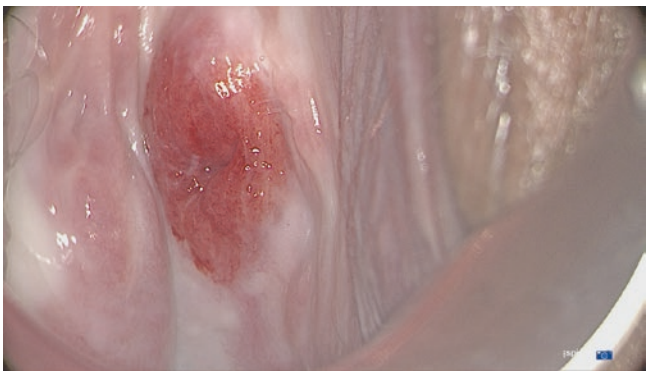

Fig. 125.14 Colpophotogram after RVT

Pending Questions

Due to the low rate of parametrial involvement (≈1 %) in cervical cancer with favorable pathologic characteristics and tumor-size <2 cm less radical surgical procedure may be discussed with women fulfilling these criteria [10, 65–68]. Moreover, 2/3 of radical trachelectomy specimens contain no residual disease. This issue is still under debate since controversial findings have been published on incidences of parametrial spread [9, 40, 69].

Radicality of RVT can be reduced either by less comprehensive lymphadenectomy (complete pelvic lymphadenectomy versus sentinel lymphadenectomy), and/or by less radical cervical resection (from radical trachelectomy versus simple trachelectomy versus conization) or both [70]. In a recently published study by Lindsay et al. 43 women underwent repeated conization and pelvic lymphadenectomy which lead to 5 % recurrences [71]. Therefore, prospective studies should be undertaken to determine the safety of simple conization or simple trachelectomy (like CONES study – ClinicalTrials.gov: NCT01048853) for the treatment of young women with early cervical cancer who wish to preserve their fertility.

RVT does not provide guarantee for later pregnancy. This is underlined by the fact, that 30–35 % of patients get not pregnant following TVZ for unknown reasons. This needs further investigation.

Another controversial topic is whether to perform of hysterectomy following completion motherhood. There is no international consensus to perform hysterectomy in general in this situation, nor any suggestion for extend of hysterectomy, if done.

Follow-up after RVT is not standardized and there is a couple of pending questions with respect to limited or extensive use of imaging modalities, tumor markers, cytology and/or HPV-testing. Moreover, best obstetric management of pregnancies after RVT (high-risk pregnancies) has not been defined. According to scanty data our recommendations and personal opinions are summaries by Lanowska et al. [72].

Finally, few patients with cervical cancer >2 cm may insist to preserve their uterus since they prioritize preservation of fertility above oncologic safety. In these patients neoadjuvant chemotherapy followed by RVT can be offered

after primary confirmation of tumor-free pelvic lymph nodes. However, this is still an experimental approach with very limited oncologic data on long-term follow up [72, 73].

Future of RVT

"Vaginal radical trachelectomy with pelvic lymphadenectomy is currently the standard fertility preserving procedure" [74]. This statement is still valid because RVT in combination with pelvic laparoscopic lymphadenectomy is a standardised gynaecologic-oncologic procedure with low complication rate, excellent oncologic safety according to large data with long-term follow-up and a good chance to get pregnant. However, criteria for less radicality of lymphadenectomy and parametrectomy in the concept of fertility-preserving surgery have to be defined in randomised trials. Patients with indication for RVT should be referred to experts who know the indication, perform the surgery frequently and monitor their results accurately with self-criticisms for the benefit of the patients and their families.

Difficult Vaginal Hysterectomy

126

Shikha Seth and Narendra Malhotra

Traditional vaginal hysterectomy represents operation that is suited for removal of prolapsed organ with pelvic floor repair and non-prolapsed organ in favourable situations. In prolapse cases it is mandatory to preoperatively check all the pelvic defects and repair them, while in non-descent cases one needs to identify the difficulty levels. Since inception, out of enthusiasm many reproducible techniques have been described to permit safety and bypass the limitations of vaginal hysterectomy by Pean (1886), Schroeder (1880) [1] Richelot, (1894) [2], Doyen [3] and others. In 1909 Schauta [4] first described radical vaginal hysterectomy, and Mitra combined it with extraperitoneal lymphadenectomy to achieve cure in cervical malignancy, which is now a days done laparoscopically [5, 6]. This chapter deals with the difficulty aspects of the vaginal hysterectomy and simple techniques of tackling them without increasing the complication rate and morbidity.

As with any surgery plan patient selection is the important aspect and the gynaecologist must know how to assess the suitability of a case for the vaginal surgery. There are few absolute contra-indications to vaginal approach such as:

1. Advanced pelvic malignancy,
2. Severe endometriosis,
3. Fixed uterus,
4. Adnexal mass – Tubo-ovarian mass
5. History of
   (i) Fistula repair as recto-vaginal or vesico-vaginal (RVF, VVF)
   (ii) Perineal tear repair
   (iii) Suspension operations as sling, or ventrosuspension.
   (iv) Vaginal procedures as Brachytherapy, Fothergill's operation etc. (relative)

Difficult Situations

Problems are anticipated if there is (1) enlarged uterus i.e., greater than 10–12 weeks size (2), restricted mobility (3), previous pelvic surgery (4), caesarean delivery (5), chronic pelvic inflammatory disease (PID) (6), nulliparity (7), android pelvis (8), parametritis or (9) short cervix with shallow fornices. But with skill, patience and experience difficult vaginal hysterectomy can be made comfortable. Although challenging, but the safety can be largely secured if we judge all the difficulty aspects by history, detailed pelvic bimanual examination, a good sonography and imaging reports [7]. Today with the advent of laparoscopy and robotics the rate of vaginal hysterectomy is reducing in difficult situations. Only 21.8 % are performed vaginally in United States with no substantial increase in rate in the last 13 years [8]. The reason is, it is difficult to teach and learn because of limited exposure.

Benefits should be considered before deciding the mode of hysterectomy. Vaginal approach is better compared to abdominal, laparoscopy and robotics as it is minimally invasive, has fast recovery, no post-operative discomfort, requires shorter hospital stay of 48–72 h, few surgical instruments and has less complications due to early mobilization. It is cost effective for developing countries and more suitable in some high risk women with medical disorders like obesity and diabetes etc. [9, 10].

Main problems with vaginal approach to hysterectomy are [11]:

1. Exposure
2. Entry to cul de sac; anterior and posterior
3. Securing Vascular pedicles
4. Delivering out the enlarged or less mobile uterus.
5. Adnexectomy if required
6. Avoiding visceral injury in previous surgery cases.

A difficult situation requires pertinent modifications in the conventional vaginal technique individualized based on patient's anatomy or the underlying disease process. Following are the major precautions and steps to successfully tackle the vaginal route challenges.

Assessment the Difficulties

History

First part of any clinical case assessment is the thorough history taking. Ask for any abdominal, pelvic, or vaginal surgeries in past and check for the findings/notes if available as it may distort the pelvic anatomy, have chances of fibrous adhesions considerably and few are the contra-indications as mentioned earlier. Past history of repeated Lower Reproductive Tract Infections (RTI), Pelvic inflammatory disease (PID), Pelvic or genital tuberculosis, trauma, septic abortions and treatment taken should also be noted. Check for medical disorders as Diabetes mellitus, Hypertension, pulmonary tuberculosis, respiratory tract infections, constipation, urinary tract infections etc. as they may affect the surgery or post operative healing.

Pre-operative Work Up

Pre-operative work up should be done step by step noting the three important points:

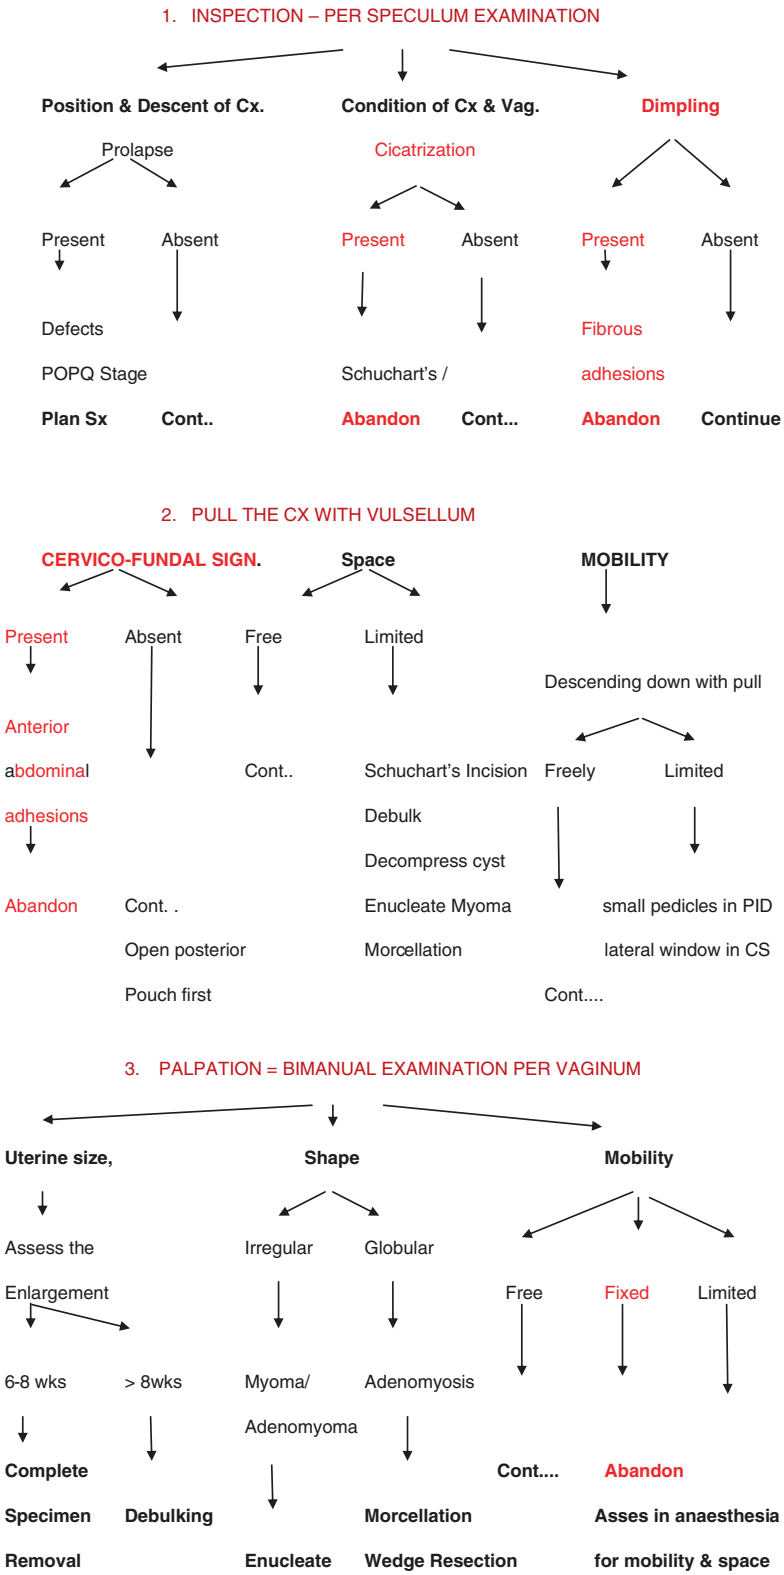
1. Uterus (size, shape, contour, consistency, pathology)
2. Mobility (free, limited, restricted, frozen pelvis)
3. Available space (vaginal capacity, distencibility, adnexal mass, pubic arch)

Inspection: Any examination starts with 'Inspection', which in gynaecology is done via Sim's speculum. Cervix normally seen hanging in the vagina up to the level of the ischeal spine or may be low in cases of uterine descent. All the compartments anterior, posterior & apical be checked for the degree of descent and quantified by the standard Pelvic Organ Prolapse Quantification (POPQ) system. Anterior vaginal wall have three distinguishable grooves on it, 1st just below the urethra (Submeatal sulcus), 2nd at the junction of urethra with bladder neck (Transverse sulcus), and 3rd lower most (Bladder sulcus) defines the bladder extent and descends down in cases of cystocele. These cases should also be evaluated for the stress urinary incontinence (SUI) and if present Bonney's test be done for the prediction of success of mid urethral sling surgery, which can be easily combined with the vaginal hysterectomy.

Any dimpling seen on the lateral or posterior fornix (Dimple sign) is highly suggestive of thick dense adhesions either due to endometriosis or previous surgeries. Thin dry vaginal mucosa in cases of chronic long standing uterine prolapse needs local estrogen therapy and reposition of prolapsed part.

Next step is to check for the mobility which is done by grasping both lips of cervix with vulsellum and try to pull it by gentle traction in downward direction. Normally cervix can be pulled down by 1 cm (one station), but in pathological situations (as fixity, huge size, adnexal mass) it may not be possible. If while pulling, patient feels pain or suprapubic abdominal depression appears (**Cervico-fundal sign**); one should get alert for possibility of adhesions with anterior abdominal wall. Cervix should be manoeuvred in opposite direction to assess mobility and visualize the fornices completely. i.e., to visualize the posterior fornix pull the cervix up towards patient's abdomen.

Palpation



Speculum examination is always followed by thorough bimanual pelvic examination with empty bladder to assess the size, shape, contour, consistency, position and mobility. Restricted mobility is a sign of difficulty and ideally tackled by an expert hand. Fixed, completely non motile uterus with tubo-ovarian mass is a contraindication for vaginal route and these steps should never be taken casually while pre-operative assessment. Restricted mobility cases needs requantification after regional anaesthesia (spinal/epidural) immediately prior to surgery. Re-evaluation of case just prior to surgery, under anaesthesia (EUA) confirms the previous findings, gives additional idea of mobility and adnexal pathologies as patient does not resist examination.

Some recommends Laparoscopic visualization and adhesiolysis if required in difficult cases followed by vaginal delivery of uterus. All the difficulty aspects judged properly during pre-operative workup, dissection skills and knowledge of pelvic anatomy are all that is needed to successfully manage a case vaginally in complicated scenerios.

Tackling Principles

1. **Uterus**: size can be reduced by different morcellation techniques after ligating the uterine vessels. Irregular shape and bossilations due to myomas specially lateral wall reduce the available work space and proper application of clamps. Localization, type and size of myomas should be clearified by clinical examination and imaging. They should be enucleated first if required to create space and mobility.

Chart 126.1 Preoperative workup

2. **Mobility**: It should be checked in all directions and compartments. Limited or restricted mobility is due to dense, fibrotic adhesion bands developing in cases of Endometriosis, pelvic tuberculosis, previous surgeries etc. Mobility is achieved as we start dividing supporting ligaments. Assistant pulls the cervix to opposite side while the surgeon palpates the uterosacral ligament by his left index finger in posterior fornix and places the posterior

prong of clamp grasping it and then close it by sliding over the cervix anteriorly (Fig. 126.1). This is followed by transverse cervical ligament that too in two bites (Small & Multiple clamping) in a large adherent uterus to make it descend.

There is no fixed rule in difficult cases which pouch to be opened first, whichever is easily assessable should be opened first and then surgeon's finger guides the way for the other. The key is to start from the comparatively free side to get the necessary plane and advance. Example: In previous caesarean cases, there is high chance of adhesions anteriorly at utero-vesicle area that too in centre where the incision was made. Mobilisation by sharp dissection is recommended compared to blunt finger dissection, as finger may poke the bladder taking the path of least resistance in cases of adhesion bands (Fig. 126.2). In such cases to avoid bladder injury we start the dissection laterally near the broad ligament folds to identify the utero-vesicle plane. (**Sheth's Lateral Window**). In endometriosis chances are more for posterior adhesions –rectal probe or the assistant can put a finger in rectum and manipulate to get free area to start with without injuring the bowel. If no plane is found, last resort is leaving a thin layer of uterine serosa in situ to avoid visceral injury.

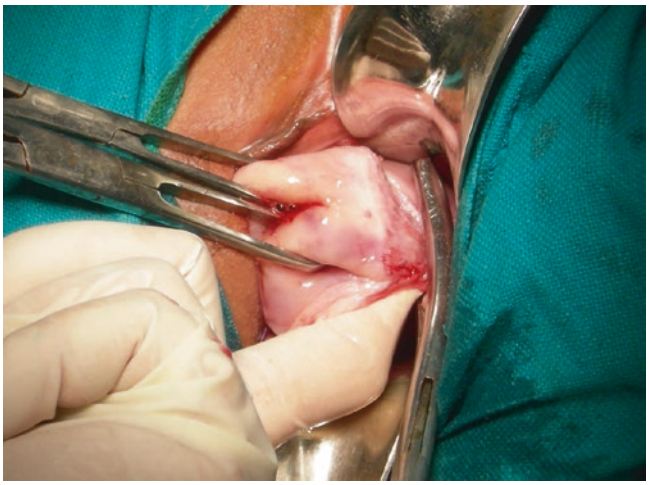


Fig. 126.1 Uterosacral Mackenrodt's ligament clamping

3. **Space**: Vaginal walls should be retracted by proper retractors. Correct size and angled retractors helps the surgeon a lot in easing the procedure. We prefer Posterior single bladed weighted Sims, anteriorly bladder retractor and long bladed Deaver's retractor once the pouch is opened and lateral obtuse angled retractors. Self retaining Magrina-Bookwalter vaginal retractor can also be used (Fig. 126.3). Cicatrizing vagina, narrow introital space can be enlarged to some extent by posterior vaginal 'Schuchardt's incision'. Fibroids coming in way should be enucleated for easy manoeuvrability. Ovarian cysts can be punctured but they should be tackled in the end after hysterectomy to get ample space and avoid pulling the infundibulo-pelvic ligaments.

Vaginal approach is facilitated by knowing the exact dimensions, mobility, space, compartment wise defects and experience of the surgeon. Clinically a mobile uterus just

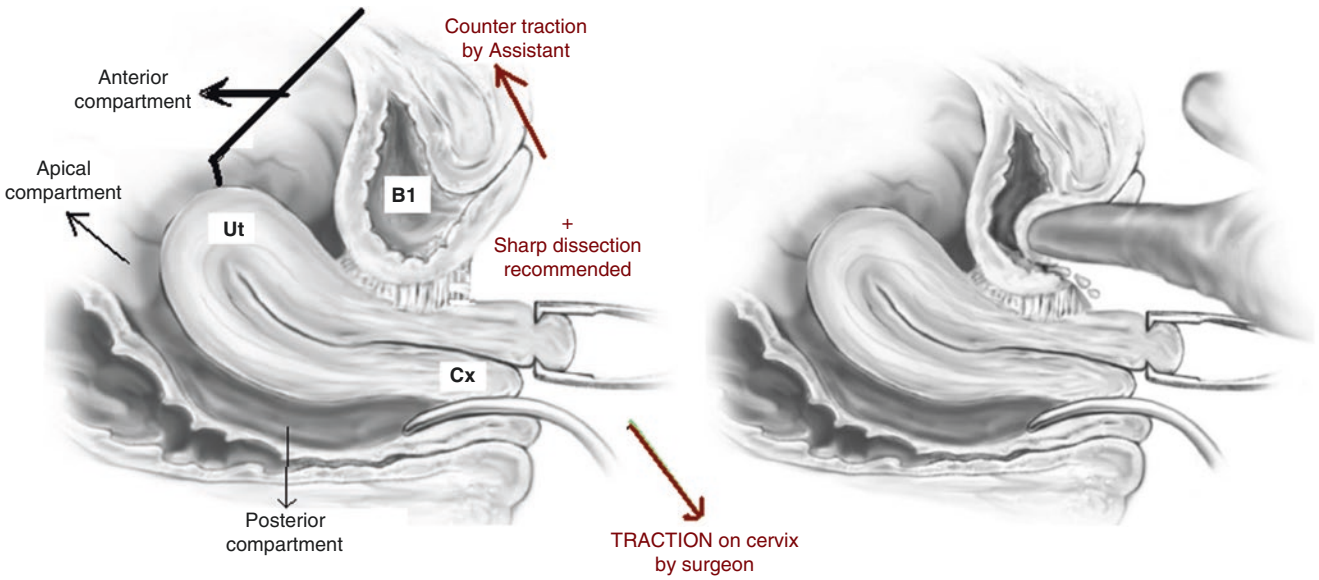

Fig. 126.2 Pelvic compartments and traction & counter traction directions (*Left*), avoid blunt finger dissection to avoid cystostomy (*right*). *Ut* Uterus, *B1* Bladder, *Cx* Cervix

Fig. 126.3 Retractors used for vaginal hysterectomy. (**a**) Sim's weighted single blade. (**b**) Bladder retractor, (**c**) Lateral obtuse angle retractors, (**d**) Self-retaining retractor Magrina-Bookwalter

palpable abdominally or less than 12 week's gestational age size is the best case for vaginal hysterectomy. One can make use of the sonography and other imaging modalities like MRI if available to be clear of the anatomical distortions.

Tentative or Trial Vaginal Hysterectomy

When vaginal approach is planned in difficult and borderline conditions, there is always the chance of conversion (more for beginners) which should be relayed to patient beforehand during the pre-operative discussions, saying that clinical findings will be re-evaluated under anaesthesia in operation theatre, and the final decision of best route of hysterectomy will be taken at that time only. Explained consent should be there.

Stepwise Surgical Considerations in Difficult Cases

1. **Positioning:** Modified lithotomy positioning and the procedure is best accomplished under regional anaesthesia. We use manoeuvrable fully padded stirrups as they avoid nerve compressions and allows surgeon and assistants to

Fig. 126.4 Fully padded stirrups with hand held control

position it themselves if required during surgery to gain optimal exposure, avoid hyperflexion or extreme external rotation and abduction (Fig. 126.4). Regional anaesthesia is best choice for

2. Conventional procedure describes emptying the bladder before surgery with catheter to avoid injury, but we prefer to keep post void urine to be left in bladder in difficult cases as it better delineates the boundaries of the bladder and inadvertent injury results in gush of urine for intra-operative identification. Urethral sounding or filling the bladder retrograde with methylene blue should be done to evaluate the suspected injury site per-operatively.
3. **Anaesthesia:** Regional or general, proper lightening source (fibre optic cable) with suction irrigation and appropriate traction and debulking instruments on traully must be checked.
4. **EUA:** Always reassess the pelvic findings under anaesthesia (EUA) before start so that surgical plan be finalized. We don't prefer self retaining fixed vaginal retractors in difficult enlarged uteri cases as they occupy the space and specific manipulations may be required time to time which is not possible with them. They are really good for freely mobile average size uterus. Avoid using long bladed specula posteriorly as they increase the distance to the cervix. Bladder extent ideally be noted by the bladder sulcus, palpating the bladder reflection on the cervix and should be confirmed by the bladder sound pushed through urethral meatus**.**
5. **Hydrodissection:** Submucousal fluid infiltration is recommended using 100 ml saline (0.9 %) or antibiotic solution with local anaesthetic (0.5–1 % lignocain) and 1: 200,000 adrenaline or 20 unit vasopressin. The goal is to create an area of circumferential blanching around the cervix of approx 4 cm wide and along the length of utero-sacral ligaments, avoiding intra-vascular injection [12]. Saline takes the path of least resistance and separates the planes, lyse filmsy adhesions, pushes the bladder up, antibiotic takes care of post operative infections, anaesthetic relaxes the pelvic floor and adrenalin reduces the bleeding.
6. In nullipara, vaginal cicatrisation or cases with limited introital opening (less than 2.5 cm) a 2–3 cm longitudinal incision can be made either in midline or laterally in distal portion of posterior vaginal wall (Gynaecological episiotomy or Schuchartd's incision) to allow better exposure.
7. **Sharp dissection** is preferred while dissecting between the two viscera as it maintains surgical planes and avoids inuring the soft tissue. Blunt dissection using finger or the gauze on instrument at utero-vesicle junction have the higher chances of cystotomy in previously operated cases (Fig. 126.2). Always keep the tip of scissors towards the cervix.
8. **'Traction and counter-traction mechanism'** be used judiciously. Cervix is kept on continuous traction downward by left hand by surgeon himself and assistant pulls the bladder up which clearly shows the bladder pillars at both sides. These pillars are cut near the cervical side with Mayo's scissors and bladder is pushed up gently in cephalad direction. Dense white adhesive bands can be found in previous caesarean cases which should be tackled from lateral broad ligament to medial side (Sheth's Lateral Window). If no plane can be identifiable a thin serosal layer of uterus can be left towards the bladder.
9. **Cul de sac entry:** Pelosi has described that a posterior small midline cervical colpotomy done first with the stout scissors at the level of cervico –vaginal junction is safe, avoids rectal injury, facilitates entry without unnecessary tissue stripping, blood loss and operating time. While taking the posterior incision, the cervix is pulled up & cephalad by the assistant and the surgeon picks up the loose vaginal mucosa at posterior cervico-vaginal junction in centre with Allie's forceps and pulls down to give a bold nick just above the allies keeping the tip directing towards uterus to open the posterior pouch in one go if possible and then this nick is extended bilaterally. Sims speculum is now placed in the opened cul de sac (Fig. 126.5).

There is no hard and fast rule about which cul de sac be opened first. Surgeon should decide this on his own, based on findings of individual case. The dictum is to start with the easier section to facilitate entry on the difficult sac later. In inaccessible or thick pelvic peritoneum anteriorly, open the pouch of douglas first and insinuate the finger around the fundus of the uterus to make the anterior peritoneum bulge

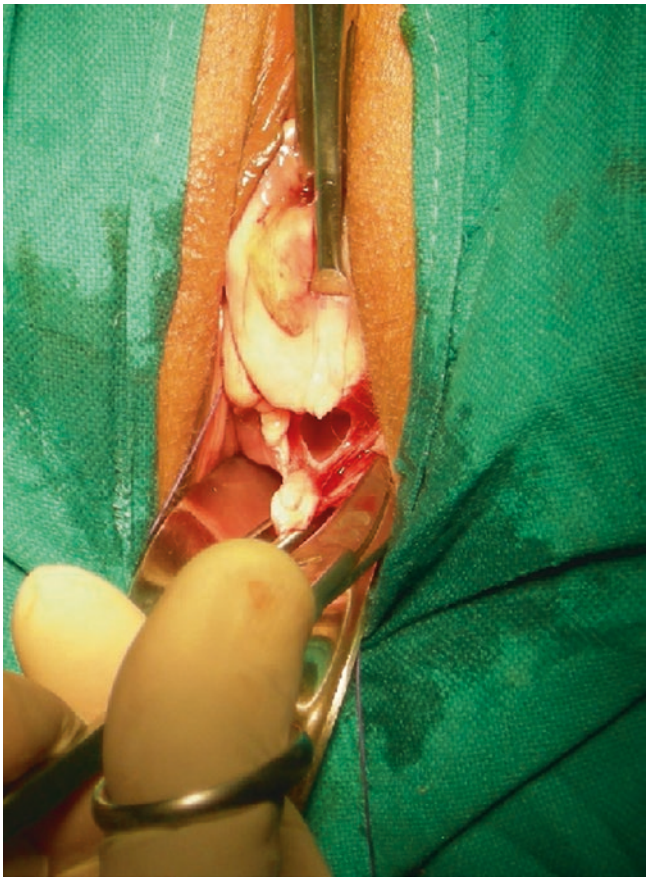

Fig. 126.5 Posterior colpotomy via single bold nick

Fig. 126.6 Access to anterior pouch adhesions from posteriorly

against surgeon's fingers, where it is incised under vision (Fig. 126.6).

During dissection, the scissors tip is always pointed towards the uterine side as it is better to cut into the uterus than to go superficially and end up opening the urinary bladder anteriorly or rectum posteriorly. Keep high index of suspicion during whole surgery. Once any of the cul de sac is opened, re-evaluate the exact uterine size, shape, mobility, associated prolapse, adhesions and adnexal mass if any before proceeding further.

Entry to the peritoneal pouch should never be struggled much, transverse cervical and uterine pedicles can be ligated securely extra-peritonealy also and this paves the way to the pelvic cavity. Once these support ligament complex is separated bilaterally, uterus becomes more free and descends down on manipulate.

Rarely if plane is not found and cystotomy does occur inadvertently, one should not panic, and it should be utilized to determine the appropriate plane through which anterior cul de sac be entered. Cystotomy area is marked by suture for later identification. Bladder extent is better identified through the cystotomy and dissection is done. Hysterectomy should be completed first and the bladder repair is made at the end following the guidelines of repair of the fistula in two layers using 3-0 delayed absorbable suture. In cases of suspected injury, bladder can be filled retrograde with diluted methylene blue solution to check the integrity. Cystoscopy helps in testing the water- tightness, ureteral distance and their patency. After vaginal cystotomy repair, the urinary bladder should be continuously drained for at least 10 days post-operatively through foley's catheter for proper healing

10. **Vaginal Pillars:** Laterally, we prefer cardinal ligament to be divided enmass with vaginal wall thus creating bilateral 'pillars' having strong ligament support to prevent vault prolapse in future. Otherwise if circumferential incision is given on vaginal mucosa then keep the uterosacral- cervical ligament ligatures long to be tied to the vaginal angle in the end. If difficult, take the utero-sacral separately and only cardinal ligament is tied with the vaginal angle**.** Enmass clampless (Fig. 126.7) *or sutureless* division using electro-coagulation of para-cervical attachments has substantial benefits when exposure is limited and there is no space available for applying the clamp [12].
11. **Securing vascular pedicles:** Uterine artery enters the uterus at the level of isthmus identified by the anterior peritoneal reflection. Ascending and descending branches run a tortuous course along the lateral border or uterus. Cervix is pulled to the opposite side and downward to view the stretched out the broad ligament. One should feel the uterine artery pulsations with left index finger and the clamp should be applied at broad ligament as close to the uterus as possible with the tip overlapping the anterior isthmus. Don't transfix the vascular pedicle as one may prick the artery or vein and invite bleeding (Fig. 126.8). Vascular pedicle should be well skeletonised well, before ligation to avoid reactionary haemorrhage later from slippage or retraction of vessels from ligature.

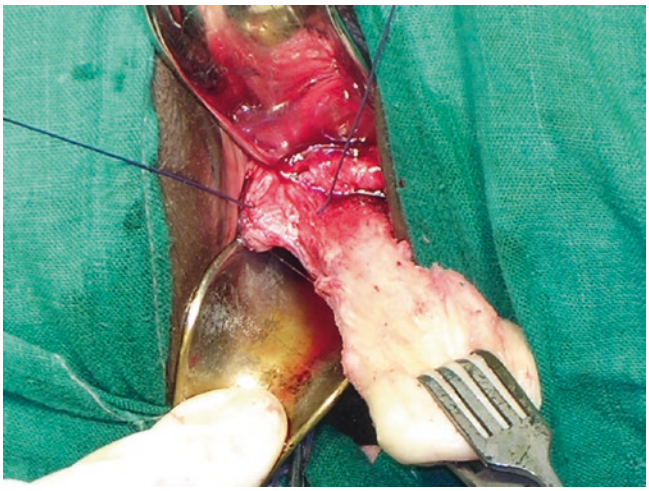

Fig. 126.7 Clampless approach of ligation of pedicles in limited space cases

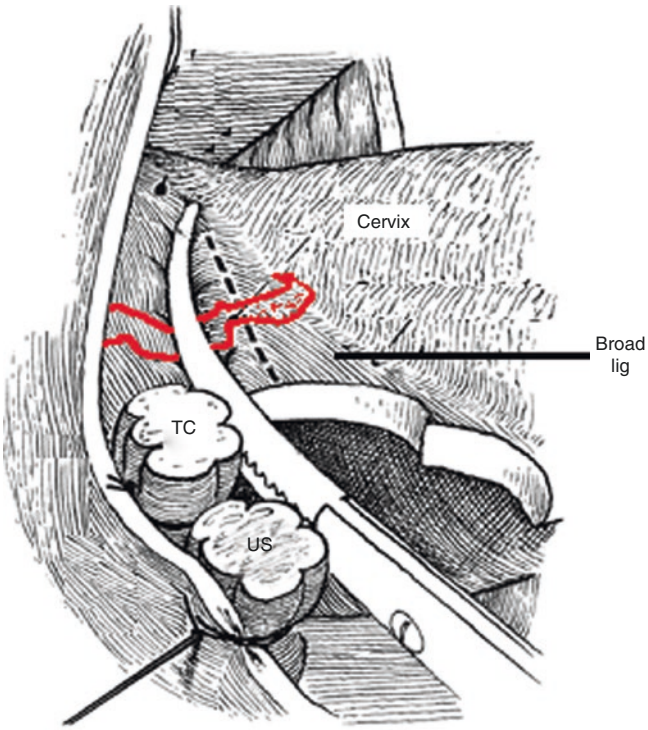

Fig. 126.8 Uterine artery ligation in broad ligament

It is often difficult to place the suture around the clamp and tying it with fingers deep in the vagina with limited space. Endoloops, bipolar coagulation or use of electrosurgical vessel sealing devices helps the surgeon a lot in situations of restricted space. They reduce surgical time, post operative pain, fever and discomfort by reducing necrotic tissue [13].

Ureteric injury although rare but possible by the tip of clamp at the level of cardinal and infundibular ligament clamping. Tips to avoid that are: (1) Apply the clamp as near to uterus as possible. (2) Don't try to take blind sutures in case of pedicle slippage (3) Once the utero-vesicle peritoneum is opened surgeon should palpate the ureters with index finger at 2 and 10 'O'clock against the curved retractor placed outside peritoneum on lateral vaginal wall and then make them out of surgical field by retractors.

12. **Delivering the uterus:** It is impossible to predict whether a grossly enlarged uterus can be removed vaginally or not until the actual attempt is made. With experience even 26 weeks size uterus or up to 1–1.5 kg weight can be removed vaginally using basic principles of debulking or morcellation with experience. Debulking should always be started only after ligating the uterine vessels bilaterally. Commonest procedure is bisection or hemisection, starting at the level of lower uterine segment towards the cervix in midline to divide the uterus and gain access to the cornual structures [14]. Many other debulking procedures are described below.

Forceful traction on the cervix or struggle to deliver out the fundus must be avoided during debulking as this can result in the avulsion of vascular infundibulo-pelvic pedicle. Anatomic orientation should be maintained while morcellating and avoid going far laterally as it may tear or avulse the pedicle. Patiently surgeon should continue morcellation as long as descent of the uterus is maintained or until utero-ovarian pedicle is visible.

13. **Enterocele:** Medial reinforcement of potential space to avoid herniation should be provided by 'vaginal Mc Call culdoplasty' using non-absorbable sutures which are left untied until vaginal mucosa is repaired. Traction on the dependent part of posterior pelvic peritoneum is applied with allies and two to three rows of transverse sutures are taken in it starting from one Mckenrodt's ligament pedicle and ending into another (Fig. 126.9).
14. **Re-peritonization:** Peritoneal closure is debatable but should preferably be done as it exteriorises the pedicles to avoid intra-peritoneal collection later and early identification of the secondary haemorrhage. Any other compartmental defect is repaired if there.
15. **Vault suspension:** Further reinforcement can be done to enforce durability of vault support and making it more anatomical is high utero-sacral attachment of vaginal apex. To locate the uterosacral, palpate the pelvic structures posterior to ischeal spine at 4 and 8 'O'clock and grasp the strong tissue originating from sacrum, keeping the vaginal apex pulled on opposite side. Non-absorbable suture is passed through the medial end of uterosacral and then through the pubocervical and recto –vaginal tissue. Bilateral uterosacrals are plicated in the midline and these sutures move the vaginal apex towards the

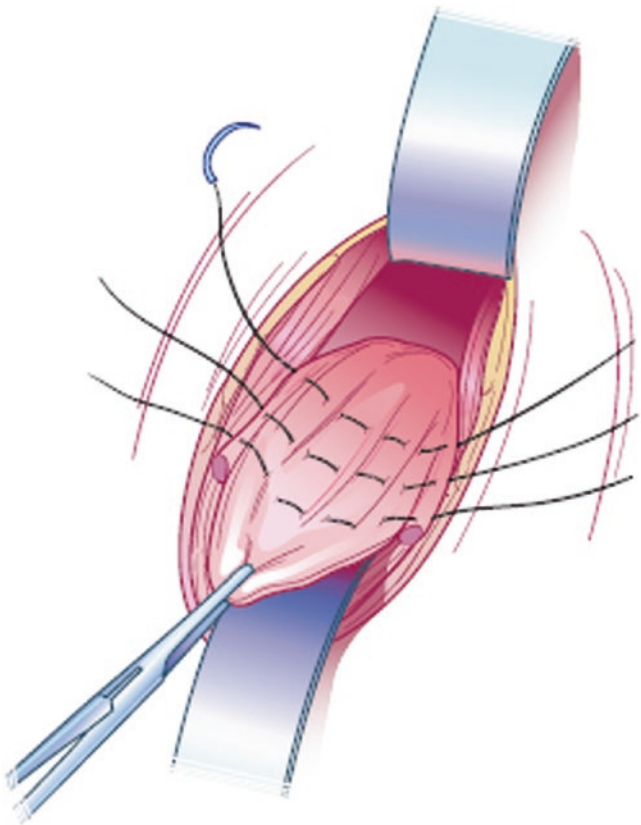

Fig. 126.9 McCall's culdoplasty for enterocele repair

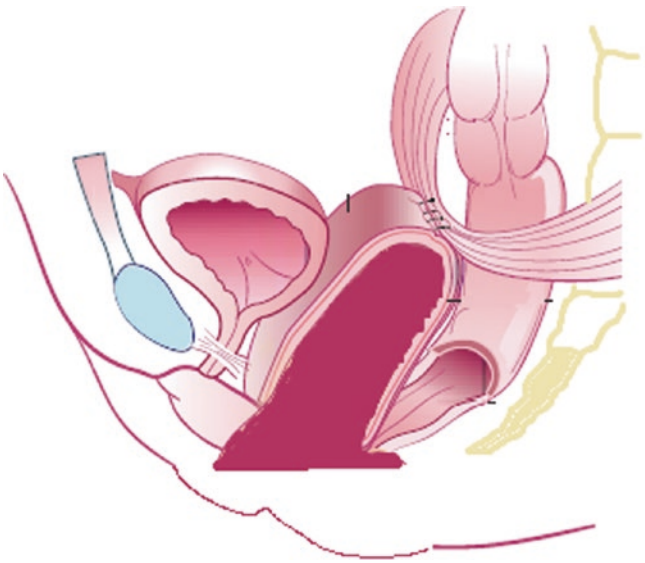

Fig. 126.10 Vault advancement to Utero-sacrals and placation

sacrum and establish continuity of pubocervical and rectovaginal tissues (Fig. 126.10).

16. **Vault closure:** Edges are closed by three interrupted sutures, two at the vaginal angles and one central to allow space for drainage of any collection. Others suggest keeping the vault open.

Conversion in Tentative Vaginal

One should be diligent enough to identify the time to abort vaginal approach and convert it to abdominal in borderline cases. Such conversion is recommended when

- Descent can not be achieved despite morcellation,
- Profuse bleeding.

Conversion is required frequently in cases where

- Pre-op workup and judgment is inadequate or wrongly done,
- Slippage of vascular pedicle with retraction of bleeder in pelvic side wall,
- Lack of experience and Overconfidence.

This has to be differentiated from conversions made in tentative or trial vaginal hysterectomies where possibility was anticipated [15].

Debulking procedures have the major role in removing the enlarged, irregular shaped, adherent uterus.

1. Bisection (Fig. 126.11),
2. Morcellation,
3. Myomectomy,
4. Wedge resection (Fig. 126.12),
5. Coring (Fig. 126.13),
6. Lash procedure (Fig. 126.14),
7. Cervical amputation

Pre-requisites: Debulking should be attempted only after uterine vessels are secured to avoid haemorrhage. Until the anterior cul de sac is opened extra care should be exercised to keep the bladder away. Blood should be kept handy in challenging cases. Literature reports vaginal hysterectomies in 780–1000 cm^3 volumic uterus without laparoscopic assistance [16].

Volumetric landmarks for debulking related to uterine size are;

1. 100–200 cm^3:- easy or average,
2. 201–300 cm^3 = 12–14 weeks size:– expert can do,
3. 301–400 cm^3:- always needs debulking,
4. 401–500 cm^3:- be scheduled as tentative or trial vaginal hysterectomy.

Bisection/Hemisection/Bivalving: means dividing the uterus and cervix longitudinally in two equal halves (Fig. 126.11). It is the first and the commonest debulking procedure tried by gynaecologists to gain access to upper pedicles in chronic pelvic inflammation, enlarged uterus and fibroid for enucleation. In moderate size cases partial bisection often serves the purpose but for larger ones uterus is completely divided into two halves by gradually moving up and up from

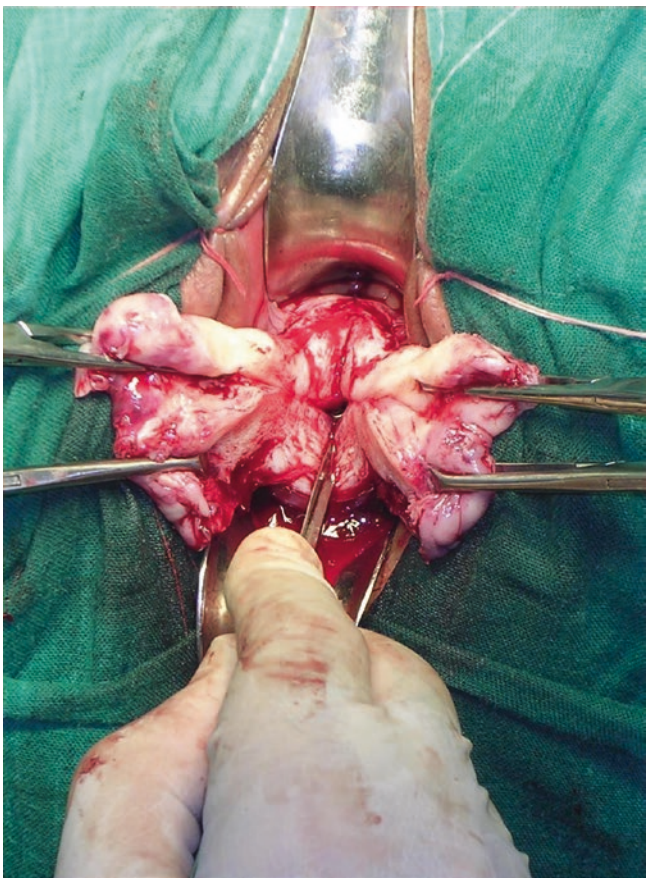

Fig. 126.11 Uterine Bisection

the isthmic region under vision grasping cut edges at higher ends with moderate traction. After hemisection one half is internalized which increases the exposure of cornual structures and mobility of contra-lateral half through introitus [17].

Morcellation: Concept pioneered by Dupuytren, but Amussat first used it in vaginal hysterectomy small elliptical or wedge shaped tissues are cut under vision from the required area to reduce the bulk in transversely enlarged or globular adenomyotic uteri. **Pryor's Technique** of '*systematic anterior wedge morcillation'* on both sides of midline after anterior wall bisection avoids complications. Always take care of reaching the serosa while debulking as it may increase chances of visceral injury.

Myomectomy: Fibroid is the commonest cause of enlarged uterus followed by adenomyosis, and chronic inflammation [18]. Both size and location of fibroid plays important role in decision making. Urography or if feasible MRI should be prescribed in cases with uterus more than 24 weeks size, rapid growth, marked vascularity, adnexal pathology, cervical or lateral wall fibroid, suspected adenomyosis or history of episodic retention of urine [19]. Ureteric catheterization has not much role in vaginal approach as in abdominal one.

- ***Very large fibroid*** of more than 8 cm , fundal or cornual fibroids, those causing transverse enlargement of corpus, large broad ligament fibroids are usually inaccessible and pose real challenge in delivering out because, cornual and infundibular vascular pedicle may tear or bleed. In such cases one should select the most accessible fibroid first, incise at the maximal bulging on uterine wall anteriorly or posteriorly and try to enucleate as a whole or piecemeal using myoma screw or any other stabilizing instrument.
- Large fundal ***fibroid*** inaccessible from below can be approached either from compressed posterior surface or through cavity after bivalving.
- ***Posterior wall myoma*** are accessed from incision on posterior wall. If placed high, first bisect partially to gain better access followed by enucleation.
- In cases of ***multiple fibroids*** central proximal fibroids are removed first followed by the lateral wall fibroids from proximal to distal.
- ***Medical debulking*** can be tried by using GnRH analogues as leuprolide acetate 3.75 mg/month for two doses intramuscularly or low dose Mifepristone 20–25 mg or Ulipristil acetate 5 mg daily orally in medically unfit or severely anaemic women. Maximal effect is seen at 12 weeks.

Wedge Resection: good for irregular uterine enlargement. Wedge shaped tissues are excised from the most accessible part with apex being carried from the highest level surgeon can reach with the scalpel. Continued gentle traction on cervix and simultaneous supra-pubic pressure helps in the procedure (Fig. 126.12).

Coring = Core Enucleation: Doyen described that removing cylindrical column of tissue from the centre of dense myometrium leaving just the thin layer, works well in delivering the fundus. Incise at the lines of tension produced y downward traction results in descent further & further. Coring aims to convert a globular enlarged uterus into an elongated sausage like structure (Fig. 126.13). Coring tube can also be pressed into the centre of tissue and advanced to the depth of 3–4 cm by firm rotation [20].

Lash Procedure/Spiral Incisions: Lash advocated the method of multiple zig zag or z shaped"spiral intra -myometrial incisions" up to two third the depth of myometrium (Fig. 126.14) for reducing size without entering the uterine cavity for pyometra or endometrial cancer cases [21].

Cervical Amputation: in cases of grossly hypertrophied cervix or where the uterocervical angle is obtuse as a consequence of solid big myoma trapped above brim, access can not be achieved through hemisection and requires amputation followed by other morcellation techniques.

Adenexectomy: Recommended to be done after completion of hysterectomy as for infundibulo-pelvic ligaments long curved clamps are required which needs space for manipulation. Traditional/Classical approach is through "Lateral pedicle technique" which has a high risk of vessel retraction, incomplete removal (Fig. 126.15). Difficult to do with uterus in situ when fundus is pulled to the opposite side and surgeon passes

his finger around infundibulo-pelvic ligament to pass a clamp around it laterally and high chances of ureteric entrapment.

Recently "Round ligament medial approach" is preferred to remove the adnexal structures, in which tube and ovary are placed on traction using Babcock while round ligament is secured and divided first. Broad ligament is then incised laterally, preferably by electrocautery to skeletonise the infundibular vessels and long curved clamp is placed across it medially to secure ovarian vessels (Fig. 126.16). Polyglactin endoloop ligatures can be used instead of routine sutures

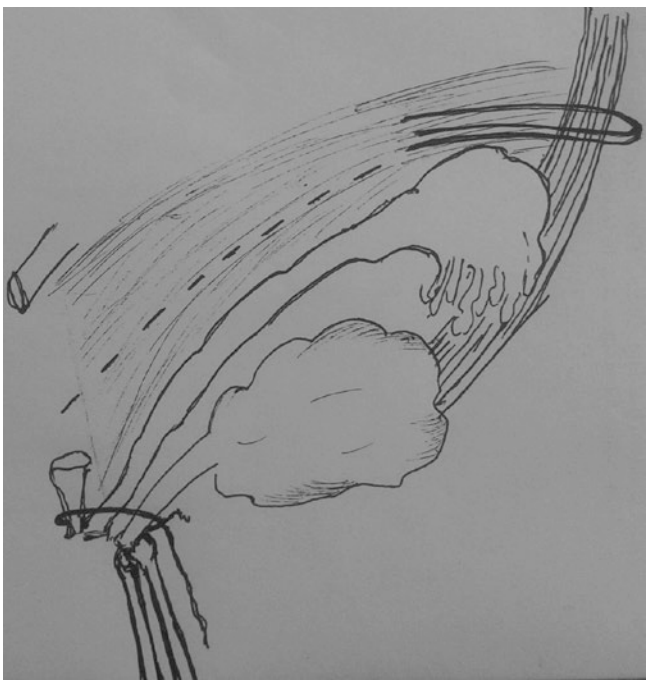

Fig. 126.16 New medial round ligament approach to salpingo-opherectomy

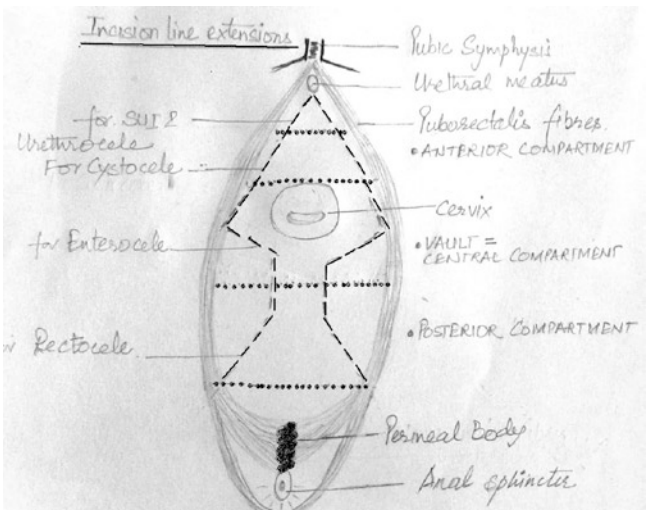

Fig. 126.17 Racquet shaped incision in cases of Utero-vaginal prolapse

around the infundibular ligament to facilitate tying deep within the vagina [22, 23].

Ward Mayo's operation is another type of vaginal hysterectomy which includes thorough reconstitution of endopelvic fascia and pelvic floor musculature in cases of utero-vaginal prolapse. Most of the steps are similar to non-descent hysterectomy except a few as follows.

1. Pre-operative assessment of defects of all the compartments needs to be analyzed properly by Pelvic Organ prolapse Quantification (POPQ) system along with evaluation of stress urinary incontinence (SUI), perineal body and anal sphincter to decide the surgical plan of colporrhaphy, colpo-perineorrhaphy and enterocele repair vaginally.
2. Instead of circumferential incision all around the cervix, it is preferred to give a "racquet shaped incision" (Fig. 126.17).
3. There is increased chances of bladder and ureteric injuries specially in procedentia cases which should be dealt with as described above by assessing the location and extent of both.
4. After hysterectomy by hooking the index finger in pouch of douglas any potential hernia sac should be defined and dissected from the rectum below. This Enterocele sac should be excised as far as its upper limit after pushing the bowel loops and edges are transfixed at highest point with utero-sacral ligaments and left untied for the end.
5. Cystocele and rectocele occurs due to facial defects and weakness which needs buttressing and excision of redundant vaginal mucosa (Fig. 126.18) while in recurrent and severe cases one can use the mesh strips along with buttressing for the better support and prevention of recurrence.
6. For stress urinary incontinence, bladder neck and urethra should be dissected from vaginal wall laterally up to the anterior fibres of puborectalis is seen. Continuous fascial buttress is created in front of bladder neck using series of Lambert sutures. In severe cases this can be reinforced with second layer of sutures inserted in puborectalis termed as 'Pacey technique'. We prefer to do the Transobturator tape (TOT) in same sitting if patient had demonstrable Incotinence on cough impulse and urethral hypermobility on sonography.

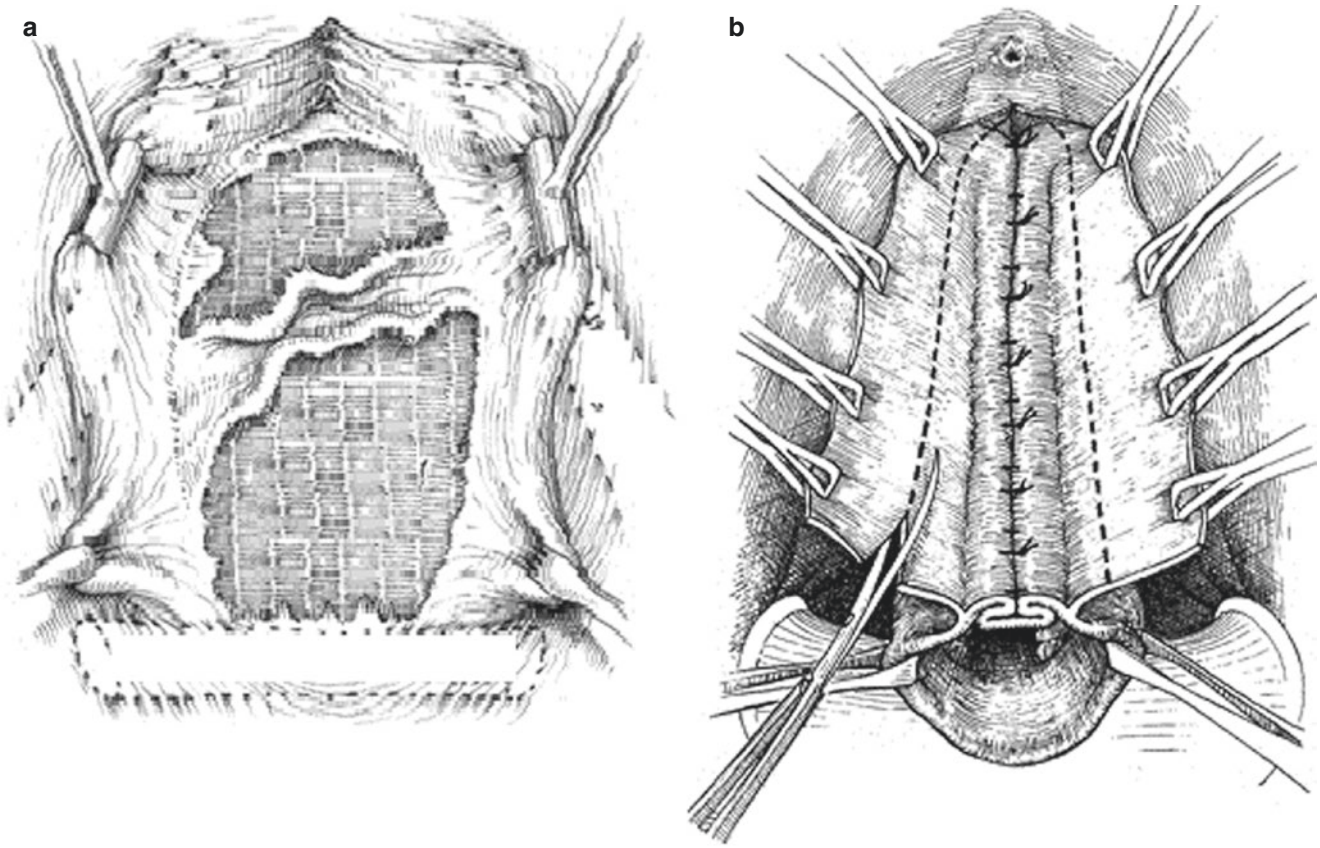

Fig. 126.18 Fascial tears in posterior wall – Rectocele (**a**) and buttressing of fascia done in Cystocele (**b**)

Complications: complication rates are least in vaginal route (7.8 %) compared to the abdominal (9.1 %) or laparoscopy (8.8 %) [24, 25].

Haemorrhage: requirement of blood transfusion is less 8.3 % in vaginal route compared to 15.4 % in the abdominal [26].

- Primary Haemorrhage occurs due to retracted uterine or infundibular vessels. In such cases try to relocate the vessel but there is high chances of ureteric injury on blind clamping or ligature. If difficult, convert to abdominal route.
- Reactionary haemorrhage occurs due to slippage of ligature later leading to intra-abdominal bleed, pain, and shock which can be confirmed by sign, symptoms, sonography and paracentesis. If bleeding is continuous or profuse and causing haemodynamic instability, reopen the case in emergency, identify bleeder & secure it or go for internal iliac artery ligation or embolization if facility available.
- Pelvic haematoma – explore vaginally for bleeding, create tunnel for drainage, give antibiotics and haemostatics to manage.
- Secondary haemorrhage due to sepsis occurs after 1–2 weeks, which requires cleaning of the vault, antibiotics and at times drainage under anaesthesia.

Viceral Injuries: Bladder, Bowel & Ureteric injury (0.2/1000) incidence is less in vaginal hysterectomy compared to other routes. Bowel is prone in chronic PID, pelvic tuberculosis, endometriosis, malignancy, crohn's disease, ulcerative colitis & in previous surgery cases [27].

Nerve injuries due to poor positioning in prolonged surgeries – femoral, sciatic & paroneal [28].

Vault prolapse if proper suspensory precautions as vault fixation with cardinal ligaments, placation of uterosacrals, enterocele repair etc. are not used during surgery. Right sacrospinous colpopexy can be done along with hysterectomy to avoid it [29].

Infection leading to febrile morbidity. Pre-op cleaning, intra-op antibiotic infiltration and post-op prophylactic antibiotics can decrease the incidence.

Vault Evisceration first reported by McGregor in 1907 of bowel, omentum and tubes through ruptured vault [30]. Reposition the content if non-necrotic under anaesthesia and re-suture the vault.

Late squeal: Granulation tissue causes blood stained discharge. If large, requires excision followed by chemical cauterization by silver nitrate. Dysparunea, sexual dysfunction, depression due to shortened and constricted vagina, residual ovary syndrome, and postmenopausal symptoms occurs after 1–2 years [31].

Lately Jacob analysed mode of hysterectomy in US and found 64 % are done abdominally 22 % vaginally and 14 % by laparoscopy with increasing trend in laparoscopic approach from 1997 to 2005 [32, 33]. In economically poor developing countries, where facilities for regular check up are not available to the masses, it may then be prudent to opt for hysterectomy rather than conservative approach requiring regular monitoring. Vaginal route is best for them as it saves time, money, energy and does not require advanced technology and instrumentation. Technology advancement should be used as adjuvant in selected cases to help completing vaginal hysterectomy safely and securely [34].

Conclusion

Cochrane database suggests that vaginal hysterectomy should be the procedure of choice when technically feasible as it has significantly better outcome on all parameters. Routine use of laparoscopy or robotics should be avoided as it is unnecessary expense of time, money, resource and morbidity.

Hysterectomy in Women Without Previous Vaginal Delivery

127

Kurush P. Paghdiwalla

If you are going to have your tonsils removed, would you prefer they be taken out through your throat or through an incision on the side of your neck? J. Chassar Moir, MD

There are numerous reports of vaginal hysterectomy performed as early as AD by the Greek physician Soranus, but there is some doubt that the entire uterus was removed. In 1813, the German surgeon Langenbeck performed the first planned and successful removal of the uterus through the vaginal route. Langenbeck must be credited with helping to establish an important surgical procedure, as he had to devise his own plan for the first vaginal removal of the uterus. On September 15, 1815, Joseph Glover of South Carolina performed a vaginal hysterectomy in a nulliparous woman and removed a solid tumour mass weighing five pounds and measuring 11 in. from the fundus in a direct line to the point of section and was 15–18 in. circumference at its greatest diameter. This was the first report of a vaginal hysterectomy in a nulliparous woman. It was Langenbeck in Europe and Glover in the United States who deserve the honour of performing the first planned and successful vaginal hysterectomies [1].

A Nulliparous patient is one, who has never given birth to a viable child, by any route, vaginal birth or caesarean delivery. For the sake of vaginal access, these women could be further categorized, as, those who have been sexually active and those who have never had sex.

Even women, who are parous as a result of a caesarean delivery, and by strict definition, not nulliparous, fall into the category of nulliparous, as far as their vaginal dimensions and access are concerned. Hence it would be best to address this issue as "Vagina Hysterectomy in Women without previous Vagina Delivery"

This chapter will address, issues and minutiae's of vaginal hysterectomy, for benign pathology, (barring Pelvic Organ Prolapse) amongst such women.

Hysterectomy for benign uterine pathology is one of the most practiced surgical interventions in women. The advantages of the vaginal approach in terms of morbidity, operative length of time, post-operative pain, duration of hospital stay, and costs have been very well documented and defined [2–4].

The most common factors limiting the use of vaginal hysterectomy have been a lack of uterine prolapse, nulliparity, history of pelvic surgery, enlarged uterine size, obesity and the need for prophylactic oophorectomy. These criteria have greatly limited the use of the vaginal route and have supported a high frequency of abdominal and laparoscopically assisted or laparoscopic hysterectomies in women without a uterine prolapse. None of them is an absolute contraindication to vaginal hysterectomy [5]. The large variations in practice indicate that the route of surgery is more dependent on the surgeon's skill, and training and mind set, rather than on scientifically defined guidelines, particularly, if considered in the best interest of patients.

This chapter is not a treatise, on the superiority of the vaginal route over all other routes, if practically and technically feasible. There are enough references in the literature to support the claim.

Cochrane database systemic evidence based review, [6] and evidence based studies distinctly conclude that vaginal hysterectomy has the best outcomes and that, when vaginal hysterectomy is not possible, laparoscopic hysterectomy has advantages over abdominal hysterectomy. Reich, who

pioneered the first laparoscopic hysterectomy, recommended vaginal hysterectomy when it can be safely carried out in preference to laparoscopic hysterectomy [7]. Donnez et al. [8] presented a series of 3190 laparoscopic hysterectomies for benign disease from 1990 to 2006, wherein complications of TLH/LAVH were compared with those of AH and VH. The authors concluded that in experienced hands, TLH is safe, cost-effective, and without any increase in major complication rates. However, when VH can be performed safely, laparoscopic method does not come into picture. In other words, TLH can replace AH. Remarkably, TLH has reduced the incidence of AH to a paltry 3.8 % but only in hands of Donnez.

USA: 264,758 hysterectomies in 2007–2010: [4]

- Abdominal 40 %
- Vaginal 20 %
- Laparoscopic 30 %
- Robotic 10 %

The VALUE national hysterectomy study [9] surveyed 37,298 cases, which is estimated to reflect about 45 % of hysterectomies performed during the period studied. The median age was 45 years, and the most common indication for surgery was dysfunctional uterine bleeding (46 %). Most hysterectomies were carried out by consultants (55 %). The proportions of women having abdominal, vaginal or laparoscopically-assisted hysterectomy were 67 %, 30 % and 3 %, respectively. Forty-three percent of women had no ovaries conserved after surgery. The median length of stay was 5 days. The overall operative complication rate was 3.5 %, and highest for the laparoscopic techniques. The overall post-operative complication rate was 9 %. One percent of these was regarded as severe, with the highest rate for severe in the laparoscopic group (2 %). There were no operative deaths; 14 deaths were reported within the 6-week post-operative period: a crude mortality rate soon after surgery of 0.38 per thousand (95 % CI 0.25–0.64).

> It is interesting to note that those who persist in perfecting themselves in the technique of vaginal hysterectomy gradually disregard more and more of the contraindications so intensely laid down by those with little to no familiarity with the operation. N. Sproat Heaney, MD.

Nulliparity

Absence of prior vaginal delivery, has historically been viewed, if not as an absolute contraindication to the vaginal route, but as a very formidable, unfavourable clinical challenge.

It does have its difficulties, making the procedure less comfortable for the operator, particularly when the space or access is diminished. But this in itself should not encourage the gynaecologists to opt for the laparoscopic or abdominal route, unless there is a clear cut contraindication for the vaginal route.

Although nulliparous patients have narrower or less patulous vaginal dimensions and lesser descent than multiparous may have; in the absence of pelvic pathology when examined under anaesthesia every nullipara with normal pelvic findings will show physiological descent to permit start of a vaginal hysterectomy and each further step facilitates the next one.

Examination under Anaesthesia, invariably allows an experienced vaginal surgeon to complete the procedure successfully.

EUA is ideally performed after placing the patient in Extended Lithotomy position, by careful speculum examination using a vulsellum or tenaculum on the cervix, which gives an accurate estimate of the possible descent. An inaccessible cervix, in this position, should immediately arouse suspicion of some pathology. Another important finding to look for is the accessibility of the posterior pouch. A freely mobile lax posterior sulcus assures the operator of no pathology in the POD, whereas a high dimpled depression in the posterior isthmus, should definitely alert the surgeon to the possibility of an obliterated pouch. Such examination also provides valuable information, about uterine size, adnexal normalcy and uterus-free pelvic space. This coupled with preoperative sonography findings like adnexal normalcy and uterine volume are very reassuring.

Vaginal Accessibility

The initial assessment in determining the route of hysterectomy is vaginal accessibility for transvaginal removal of the uterus. In a study to determine why physicians make decisions regarding abdominal hysterectomy, it was reported that those predisposed to the abdominal route were less likely to take note of uterine mobility or vaginal accessibility in their preoperative examinations, as these factors do not appear to be issues in their decision making [10].

Nulliparity is also not an absolute indication for abdominal hysterectomy. Although access to the vagina may be restricted in some nulliparous women, lack of vaginal accessibility cannot be assumed in all cases. In fact, there is no evidence in the literature to support the widely held belief that nulliparity makes vaginal hysterectomy difficult [11]. In fact, in 1815 Glover [1] performed a vaginal hysterectomy on a nulliparous woman of a considerable size uterus.

Virginity may represent a relative contraindication to the vaginal route. In addition, orthopaedic conditions may restrict the lithotomy position as well as a vagina that is narrower than the two finger-breaths, especially at the vaginal

apex. If the vagina is inaccessible, is the vaginal route deemed not feasible? Even though inaccessibility of the vaginal passageway may be frequently offered as justification to avoid the vaginal approach, one study documented that of 617 women, only 1 % of patients had a vaginal passageway that excluded the performance of the vaginal route [12]. Therefore, abdominal-type or laparoscopic-type hysterectomies are only indicated when vaginal inaccessibility is accurately confirmed.

Sheth et al. have reported the largest series of successful vaginal hysterectomies in 120 young nulliparous women with intact hymen, who were with severe mental handicap or learning disability, that too without any perineal enlarging incisions [13].

Chauveaud et al. in a large series from August 1991 to June 2000 compared the different techniques of hysterectomy for a nonprolapsed benign uterus in 148 women without vaginal deliveries. Forty-four patients had previous caesarean sections (29.7 %), and 104 (70.3 %) were nulliparous. Twenty-four patients had had abdominal myomectomies (16.2 %). The vaginal route (group 1) was used for 77 patients (52 %), 56 (37.8 %) had laparotomies (group 2), and 15 (10.2 %) had laparoscopically assisted Vaginal hysterectomies (group 3). The uterine weight was 275 (+/− SD 140) g in group 1, 830 (+/− SD 1620) in group 2 and 331 (+/− SD 160) in group 3. Mean operation time was 87 (+/− SD 76) min in group 1, 96 (+/− SD 41) in group 2 and 112 (+/− SD 56) in group 3. There was one serious complication with the vaginal route (sigmoid injury). The hospital stay was 4 (+/− SD 3.1) days in group 1, 7.1 (+/− SD 3.8) in group 2 and 4.3 (+/− SD 1.5) in group 3 [14].

Agostini et al., have reported a prospective series, comparing vaginal hysterectomies in nulliparous and multiparous women. Three hundred and forty-five consecutive patients without genital prolapse requiring hysterectomy for benign conditions and without previous pelvic surgery or caesareans were treated prospectively by vaginal hysterectomy. Fifty-two patients were nulliparous and 293 were primiparous or multiparous. The mean operative time was significantly longer in nulliparous patients [95 (55.2) vs 79.9 (34.9) min, $P < 0.01$]. The overall complication rate was significantly higher [7/52 (13.46 %) vs 13/293 (4.44 %), $P = 0.02$, RR = 3.03 (1.27–7.23)] as was the haemorrhage rate in nulliparous compared with the primiparous and multiparous women [4/52 (7.69 %) vs 5/293 (1.7 %), $P = 0.03$, RR = 4.51 (1.25–16.23)]. Vaginal hysterectomy was successfully performed in 96.2 % (50/52) of the nulliparous and 99.7 % (292/293) of the parous patients [$P = 0.06$, RR = 1.04 (0.98–1.09)] [15].

Thus concluding that the success rate of vaginal hysterectomy in nulliparous women is high. However, the risk of complications seems higher than in the parous women, particularly in early learning phase.

Although we are enthusiastic about vaginal hysterectomy in the nulliparous patient, this can be a difficult operation. Needs a level of training, from the easy hysterectomies to the difficult ones. In Figueiredo's series, three hundred consecutive women with nonprolapsed uteri requiring hysterectomy for benign uterine conditions, without suspected adnexal disease, were treated prospectively by vaginal hysterectomy. Twenty-one women (7 %) were nulliparous, and 219 (73 %) had history of pelvic surgery (150 had previous caesareans). Operating time, estimated blood loss, surgical techniques (Heaney, Pelosi, uterine morcellation) operative complications, conversion to laparoscopy or laparotomy, and length of hospital stay were recorded for each case. Vaginal hysterectomy was successful in 297 women (99 %). Morcellation (hemisection, Intramyometrial coring, myomectomy, and wedge resection) was done in 170 cases (56.7 %). The mean operating time was 51 min (range 20–130 min), mean estimated blood loss was 180 mL (range 50–1050 mL), and mean length of hospitalization was 22 h (range 16–72 h). Four operative complications occurred (three cystotomies, one rectal laceration) and were repaired transvaginally. One woman needed a blood transfusion. Eleven urinary tract infections occurred. Two conversions to laparotomy and one conversion to laparoscopy were necessary. This shows that vaginal hysterectomy is an effective and safe procedure for benign nonprolapsed uteri irrespective of nulliparity, previous pelvic surgery, or uterine enlargement. This should make us question the need for laparoscopic or laparotomy route, for a large majority of cases [11].

When uterine enlargement is the only impediment to removal of a relatively mobile uterus, the critical uterine size that predicts morcellation ranges from 10 to 12 weeks gestational equivalent, depending on operators experience and pelvic factors in form of ease of descent, laxity and patulousness, all-round uterus free space, myoma location and adnexal normalcy. However, if the uterus is relatively immobile, morcellation is needed even with a smaller uterine size. The advantage of morcellation in both settings is improved access to the broad ligament attachments and proximal adnexal pedicles. The morcellation technique most commonly used in this study was simple hemi-section. Few uteri needed additional or alternate maneuvers, progressive wedge morcellation of thick uterine walls, techniques that demand more experience but which are readily learned. Supported by these findings, we believe that if hemisection alone were taught and practiced widely and then applied to the majority of contraindicated vaginal hysterectomies, when conventional intact uterine removal was not possible, most surgeons would be able to complete vaginal hysterectomies more safely and effectively.

Careful assessment of the pelvic findings, particularly under anaesthesia, and the operator's ability to deal with it

are essential. Experienced assistance, favourable pelvic tissues and importantly, surgeon's inclination to use the vaginal route are important to accomplish identical results as in the multiparous [16].

Patient Review

Patient evaluation should begin with a good and thorough history of any current problems and should include a detailed gynaecologic medical and surgical histories should be obtained along with a family history of gynaecologic, gastrointestinal tract, or breast malignancies. A sexual history, noting any reports of dyspareunia, should be obtained before surgery. Need for adnexal removal should be ascertained. A thorough physical examination should include general abdominal and pelvic examinations. During the pelvic examination, particular attention should be paid to the size and mobility of the uterus and its physiological descent, associated pelvic relaxation, adnexal masses, uterosacral tenderness, and any areas of pelvic pain during the examination. Patients quite often may not permit a thorough examination, in the clinic setting, so a final review under anaesthesia, is to be considered as a very necessary step. Imaging and laboratory testing should be obtained for anaesthetic fitness.

Practical Steps

- EUA
- Laparoscopic Evaluation, if in doubt, or start procedure vaginally and complete laparoscopically if required
- Smaller instruments
- Schuchardt's Incision or any other perineal enlarging incision (Figs. 127.1 and 127.2).
- Morcellation/Bisection/(Figs. 127.3, 127.4, and 127.5)

However, as one learns and advances some of the steps may be needed lesser and lesser.

Intra-operative

Uterocervical Broad Ligament Space

In cases with suspected anterior uterine adhesions, a surgical window or Sheth's space [17]. Uterocervical broad ligament space can provide required access to the uterovesical peritoneum during vaginal hysterectomy [18].

Clamps and Sutures

Clampless technique allows the operative field to be roomier, facilitating the surgery, and crushing, necrosis, pain, infection and chance of clamp slippage are avoided. However, common practice is to clamp, cut, and ligate.

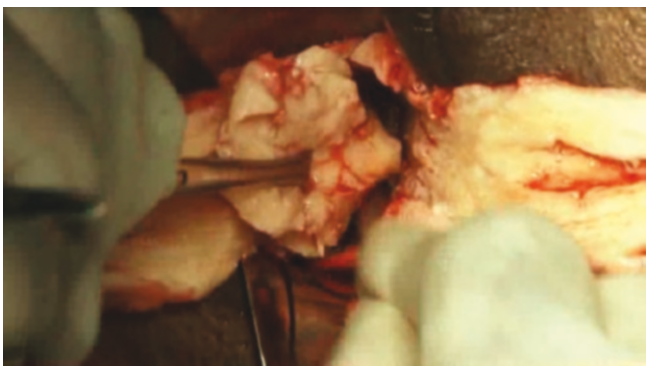

Fig. 127.3 Uterine morcellation

Fig. 127.4 Starting uterine bisection

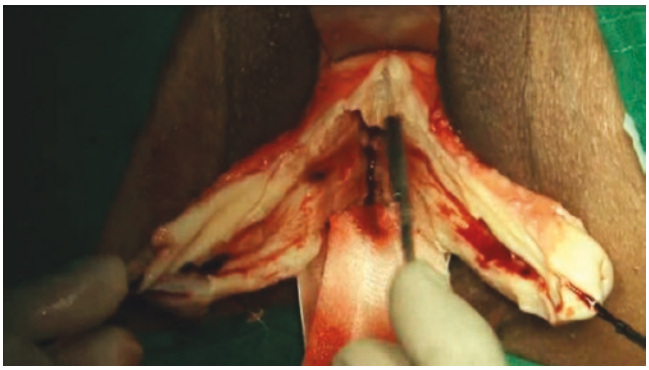

Fig. 127.5 Uterine bisection, increasing access

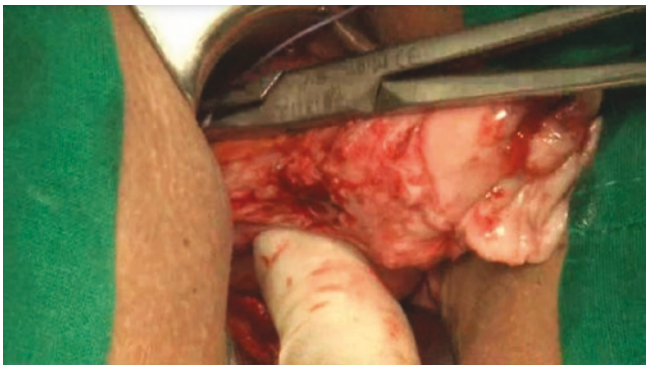

Fig. 127.6 Clamp, cut & ligation technique

Debulking

Debulking is gratifying and easier in a myomatous rather than an adenomyomatous uterus. Debulking either by myomectomy and/or by morcellation is to be carried out only after and never before the uterine vessels are properly secured, so that bleeding, if at all, is negligible [19].

Place of Laparoscopy

Laparoscopic assistance in form of surgery is indicated in patients to undo the contraindication or obstacle [20] and permit vaginal hysterectomy. However, laparoscopic assistance, only to evaluate is indicated in patients in whom there is reason to fear trauma or possible failure to complete vaginal hysterectomy or one that is contraindicated or during formative period to gain the confidence.

Technique

Vaginal hysterectomy involves two important major steps:

- Getting an access to the anterior and posterior peritoneum i.e.: Access to both pouches
- Severance of all lateral connections of the uterus.

It is necessary to have expertise and great familiarity with the anatomy of the tissues to reach both the pouches and for safely securing all lateral connections respectively.

Narrow bladed and/or long reaching vaginal retractors, in some cases, Jayle's self-retaining lateral vaginal wall retractor, different sizes of Sim's and Auward's heavy speculum are useful. Sutures inserted directly are preferred; the clampless technique saves space occupied by the clamps and provides better grip on tissues though latter is practiced by most (Fig. 127.6). After emptying the bladder, careful bimanual examination under anaesthesia confirms the presence or absence of contraindications to the surgery. If required, rectovaginal abdominal examination can be done. The drape is

Fig. 127.7 Circumferential incision on the anterior vaginal wall

anchored to the perineal skin just above the anus. The cervix is preferably seized by two traction sutures with thick silk instead of a vulsellum. Infiltration of the sub epithelial tissues around cervix with 10–15 ml of 0.005 % phenylephrine in saline after receiving clearance from the anaesthesiologist or 100–150 ml of sterile saline to act as an internal tourniquet to reduce bleeding facilitates the planes for dissection and reduces post-operative infection from phenylephrine.

Access to the Anterior Pouch: Vesico-Uterine Peritoneum

The intra-operative identification of correct planes and space depends on the surgeon's knowledge of surgical anatomy and especially the surgical landmarks as seen in the operative fields. The surgeon takes separate anterior and posterior incisions or has a circumferential incision around the cervix below the line of the bladder (Fig. 127.7). Making the incision anteriorly, first and getting access to the peritoneum is more reassuring with less bleeding, than getting access from the posterior edge. For the correct plane of dissection between the bladder and utero-cervical surface, note the point of attachment of the vaginal mucosa to the cervix and the bladder bulge above it (Fig. 127.8). The bladder margin on the anterior

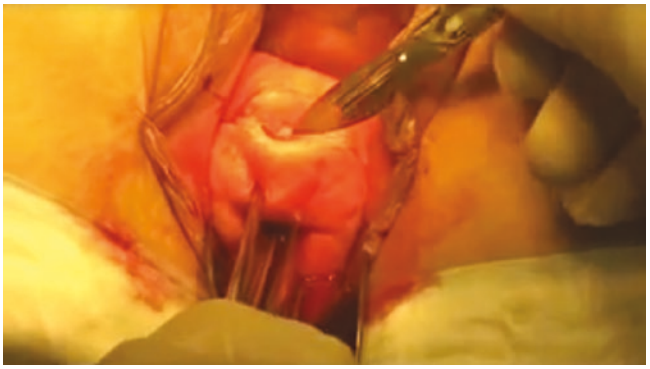

Fig. 127.8 Correct plane for bladder separation, between vagina and cervico-vaginal fascia

Fig. 127.10 Creating proper plane of cleavage between bladder and cervix

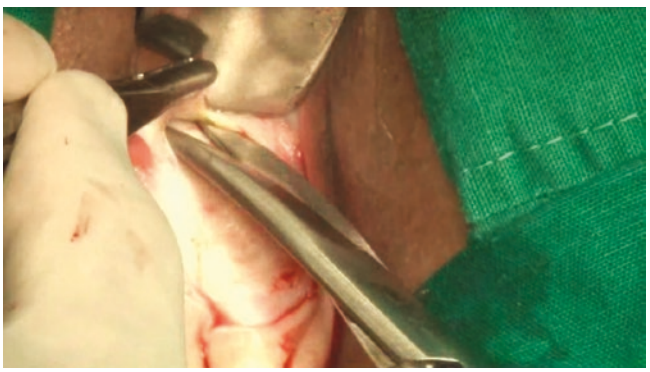

Fig. 127.9 Correct depth of dissection, by retraction of vaginal mucosa

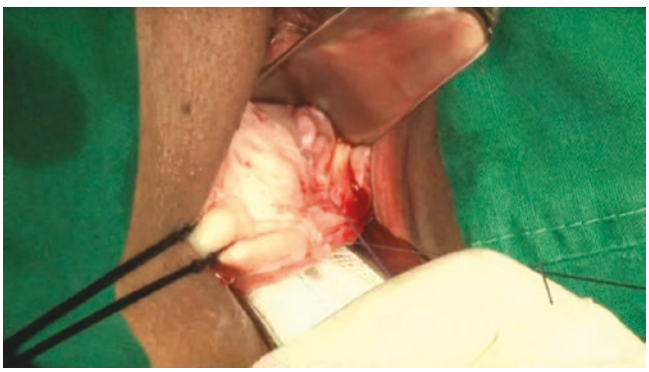

Fig. 127.11 Visualization and severance of lateral uterine attachments

cervical surface typically forms a crease in the overlying vaginal epithelium, which can be accentuated by in-and-out displacement of the cervix with the vulsellum. The incision is above the border between the smooth cervical mucosa and the vaginal rugae and at the same time below the bulge of the bladder. Retracting mucosa guides the depth of the incision (Fig. 127.9). Strong traction on the cervix and counter pressure on the upper vaginal mucosal margin with Allis forceps will display cervico- vesical ligaments stretching from the bladder to the cervical surface to be divided with scissors. A central approach should be the routine but in those with a history of caesarean the approach should always be from lateral space. Familiarity with these strands acts as a useful guide. A pair of scissors with point directed downward against the uterus now cuts the strands of fibres close to the cervix, which paves the way for the next stroke of the scissors to obtain a proper plane of cleavage between the bladder and the cervix. A bladder retractor or the tip of the index finger (Fig. 127.10), flexed at the first metacarpal joint, pressing hard on the cervix, and pushed upwards, and the uterine body is well felt and seen covered by thin peritoneum – the bladder is separated. A similar motion is carried out using a sponge holder at the time of an abdominal hysterectomy. Avoid oozing by pushing upwards with a gauze-covered index finger. A retractor must be placed

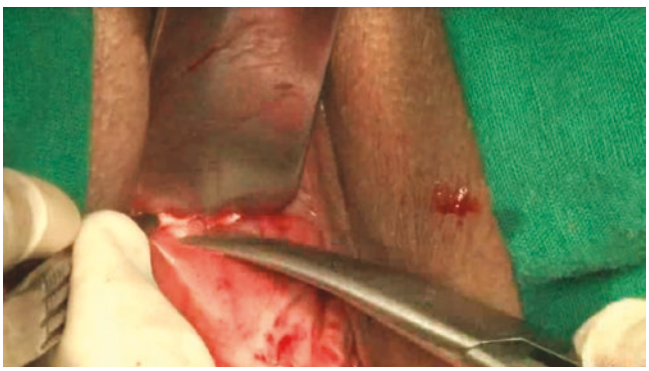

Fig. 127.12 Opening the anterior pouch or utero-vesical peritoneal fold

into the anterior cul-de-sac to retract the bladder superiorly, and to place the lateral uterine attachment on tension to protect the ureters and to facilitate severance of lateral pedicles (Fig. 127.11). A gentle feel with the finger clearly confirms that only a thin pearly white translucent layer of peritoneum is lying on the V shaped with wider arms, shiny serosal surface of the uterus, which is easily picked up with a toothed forceps (Fig. 127.12). The peritoneum may be opened now or later.

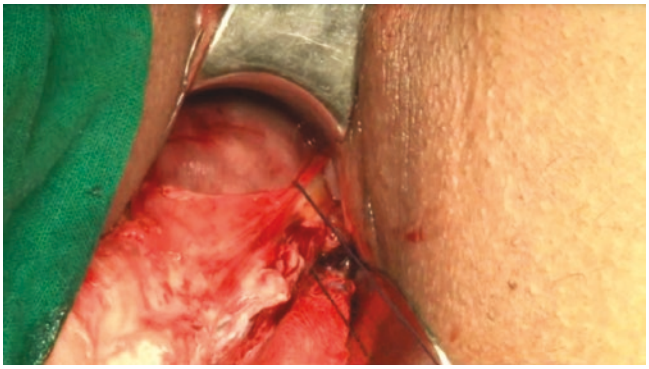

Fig. 127.13 Severance of the upper uterine pedicle

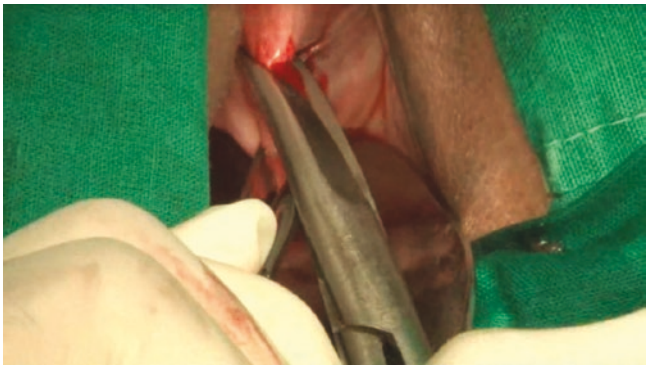

Fig. 127.14 Posterior crease for accessing Posterior Pouch of POD

Occasionally, peritoneal fluid escapes freely and the surgeon is tempted to check once again that all is right.

When not being able to reach the peritoneal site earlier, careful severance of the cardinal, uterosacral, vesicouterine ligaments and uterine vessels bilaterally, will lead to the anterior peritoneal reflection, provided angles of the bladder and the bladder are retracted laterally and superiorly away from the uterus by a bladder retractor between the utero-cervical surface and bladder. When at this stage, if an anterior access is difficult the index and middle fingers of the left hand can be inserted through the posterior cul-de-sac and brought to the front or uterovesical reflection so as to permit an incision of the thin peritoneum as it rests on the fingers under direct vision followed by severance of upper pedicles (Fig. 127.13).

During early parts of the learning curve or in case of the occasional difficulty, bladder sound or metal catheter or instilling a few milliliters of methylene blue in the bladder can act as a guide to get the plane of dissection.

Special Situations

Previous Abdominal Pelvic Surgery

No less an advocate of vaginal hysterectomy than Heaney [21] believed that a history of previous pelvic surgery precluded removal of the uterus through the vagina. This has proved to be totally unacceptable. Coulam and Pratt [22] mention that the chief concern in such cases is the risk of injury to the bladder and difficulty in gaining entry through the scarred anterior cul-de-sac.

Based on observations in women with caesarean section in the past that if the bladder is adherent, it is always in the central 3/5 and not the lateral 1/5 and MRI studies at the isthmic level through different planes show a distinct vacant space medial to the line joining the maximally bulging uterus above and the cervix below, with its continuity medially between the uterocervical surface and the bladder, until they come extremely close to each other in the midline and continue laterally between the two leaves of the broad ligament. This non-adherent portion of bladder can be easily approached for separation through Sheth's utero-cervical broad ligament space or a surgical window [18]. Separation is from lateral to medial, occasionally depressed adherent scarred surface guides. Familiarity with this and normal serosal surface are helpful.

Access to the Posterior Pouch: Recto-Vaginal Peritoneum

This access was once the primary method of peritoneal evaluation in infertile women and tubal sterilization, and to date remains a convenient and effective route for retrieval of myomas and ovarian cysts during laparoscopic surgery. The cervix is drawn anteriorly and upwards using traction sutures or a vulsellum, whereas the posterior vaginal wall is retracted with a Sims' speculum. Next, the uterosacral ligaments are noted and the junction of the cervix with the epithelium of the posterior vaginal fornix is identified by pushing the cervix slightly inwards and looking for the characteristic transverse rugosity or crease (Fig. 127.14).

A depression is seen between the two utero-sacral ligaments, which indicate the situation of the floor of the pouch of Douglas. In most, it lies about 3–4 cms from the external os and the pouch of Douglas lies approximately 1–2 cms posterior to or below the first rugosity.

For access to the POD, the posterior vaginal mucosa is incised in one of the two ways:

1. The experienced surgeon may give a bold transverse cut of 3–4 cms just above Allis forceps firmly grasping a chunk of vaginal mucosa including underlying the peritoneum, 1–2 cms posterior to or below the first rugosity or crease on the vaginal mucosa. This straightaway gives gratifying entry into the peritoneal cavity (Fig. 127.15) OR

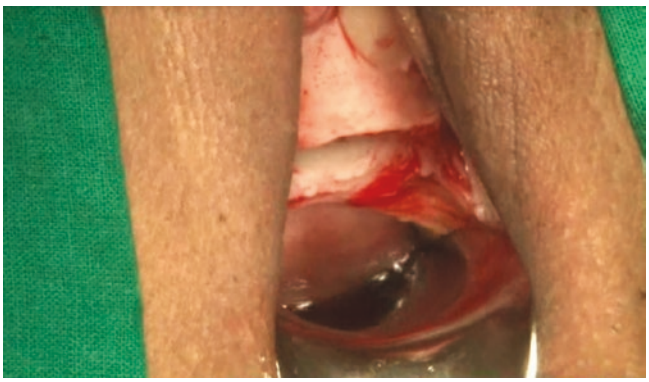

Fig. 127.15 One snip access to the POD

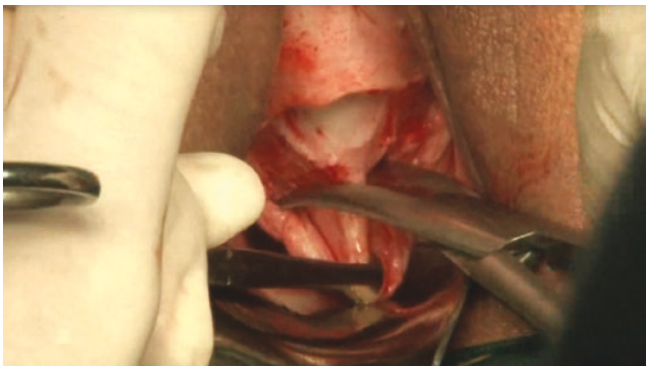

Fig. 127.16 Dissection of the vagina and identifying posterior peritoneum

2. Gently incise 3–4 cms of vaginal mucosa at the same site and the posterior vaginal fornix is exposed. The vaginal skin is then separated with a swab on a sponge holding forceps or the forefinger, to open the cellular tissue between the vagina and rectum and to separate the vagina from the rectum (Fig. 127.16). With a swab firmly pressing and pushing away the tissue from the posterior cervical surface and backwards, this provides the space that distinctly displays bulging thin peritoneum or bulging perirectal tissue containing the peritoneum. Fingers can palpate or experience confirms that the thin bulging translucent tissue is indeed peritoneum. The thin cellular tissue and subjacent peritoneum is picked up in dissecting forceps and opened carefully with scissors, to avoid injury to the rectum. Peritoneal entry is usually heralded by the efflux of a small amount of straw-coloured peritoneal fluid and the characteristic, shiny, white appearance of the peritoneum that lines the cul-de-sac and posterior serosal surface of the uterus. The posterior cul-de-sac is explored with the index finger to exclude adhesions or other pathology and for considering the need to convert the surgery to abdominal approach or to take laparoscopic assistance. Bleeding from the posterior vaginal cuff must be controlled and weighted retractor of appropriate width and length be placed in the cul-de-sac.

Usually a smooth opening of the pouch heralds smooth sailing for the hysterectomy; in fact, obtaining entry to both the pouches is like a trump card for the surgeon. Anyone wanting to learn vaginal hysterectomy will need to be familiar with the anatomy for access to the pouches. Anyone who masters this access will master vaginal hysterectomy.

Special Situations

Presence of a dimple in the posterior vaginal wall adjacent to the pouch of Douglas denotes adhesions due to ovarian endometriosis. Such cases need a second thought even for the experienced vaginal surgeon. Vaginal mucosa overlapping the anterior or posterior cervical lip should not discourage the surgeon, as it needs small dissection close to the respective lip to find the space to reach the peritoneum. Rectal examination is a useful guide in such cases.

Obliterated Pouch of Douglas

Sub-cervical Extra-peritoneal Tunneling

Patients with endometriosis, previous genital tuberculosis, pelvic inflammatory disease, or previous surgery are often found to have an obliterated cul-de-sac. Such cases are ideal for LAVH or abdominal hysterectomy. The safest and most effective approach is to tunnel beneath the posterior cervical surface towards the uterine serosa using digital palpation, until the affected area has been passed. It is vital to remain hugging with pressure to the posterior cervico-uterine surface to avoid rectal trauma and mobilize the obliterated area, facilitate dissection until the free peritoneal space is encountered. Rectal examination is a good guide in these cases. Occasionally, even the uterine arteries must be ligated extraperitoneally, as long as they are close to the uterocervical border. A drop of peritoneal fluid or chocolate like material should delight the operator as access to the peritoneal cavity is obtained. Insertion of a finger or artery forceps through the same opening will then provide further access. Colpotomy performed through the vagina may actually have a lesser potential for morbidity than colpotomy through an abdominal or laparoscopic approach.

Transcervical Access

The cervix is then pulled anteriorly with firm traction. With stout scissors, the surgeon initiates a full-thickness division

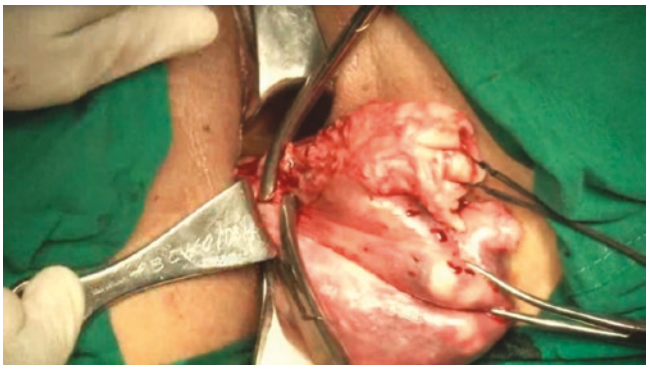

Fig. 127.17 Cornual clamping in case of ovarian conservation

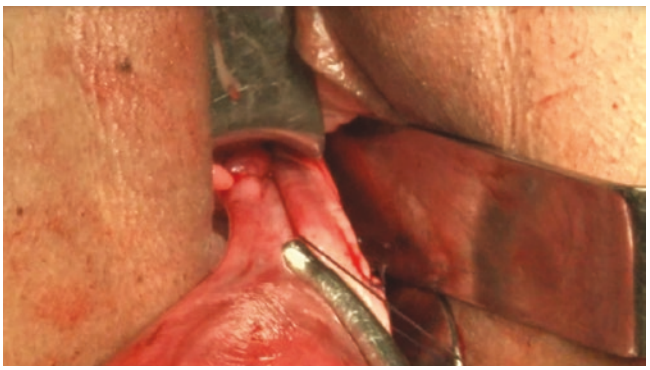

Fig. 127.18 Separate ligation of round ligament to access infundibulo-pelvic ligament

of the posterior cervical wall in the midline – with one blade inserted in the cervical canal, cut from canal to external wall, keeping the rectum away until the peritoneum of the cul-de-sac is entered.

Severance of Uterine Supports and Lateral Connections:

The following three to five pedicles are to be secured on both sides.

If the ovaries are to be preserved, the tubo-ovarian and round ligament as one pedicle (Fig. 127.17).

If not, the tubo-ovarian and round ligament as two separate pedicles (Figs. 127.18 and 127.19). The uterine vessels the cardinal and uterosacral ligament complex pedicle or as two pedicles, approximated later as one. The operator's left index finger enters the peritoneal cavity behind the cardinal and uterosacral ligaments and puts them on stretch. The surgeon has the choice of applying a clamp to the utero-sacral ligament, dividing it and securing the pedicle with a No.1 Vicryl or No. 2 catgut suture, OR placing a direct suture to pierce the upper limit of the pedicle with a needle, to tie and cut it medially.

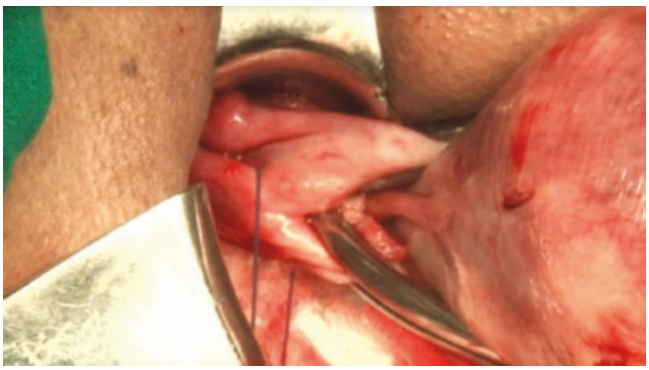

Fig. 127.19 Clamping infundibulo-pelvic ligament through broad ligament window

A suture on a heavy round body needle loaded with vicryl or chromic catgut is passed from front with the left finger in the peritoneal cavity behind the pedicle and with its medial surface of finger in close contact with the lateral border of the uterus. The gloved finger easily senses the progress of the needle and gets reflexly withdrawn as the needle moves forward, and presents its tip for needle holder and thus surrounds the ligament with a suture, away from the cervix and close to vaginal mucosa. Alternatively, the same pedicles are clamped, cut and transfix sutures placed. The pedicles are uterosacral – Mackenrodt's complex, uterine artery, round ligament and infundibulo-pelvic ligament OR round ligament along with tube and utero-ovarian ligament. The uterine vessels, which may include ligamentous tissue, are secured in a similar fashion. Then after, if the open mouth of the cut end of the uterine artery can be seen or uterine vessel with surrounding ligamentous tissue is sutured and secured again i.e. doubly secured but without use of clamp. , it should be picked up with pressure forceps and ligated separately. After the uterine vessels are ligated on each side and threads cut short, the remaining portions of the broad ligament, including the anterior and posterior peritoneum of the broad ligaments on each side are secured and the level of round ligaments is reached. If the operator's fingers at this stage can easily reach the fundal surface, it is apt to deliver the uterus. If not, after rechecking on the uterine size and uterine volume further lateral severance or debulking is required, till the fundus is well felt or else the alternative is to bisect the uterus from cervix upwards and deliver each half to complete hysterectomy. The uterus is delivered from anterior or posterior pouch, though it is simpler, from the spacious posterior pouch. Bulldog vulsellum or large towel clip or Leahey's thyroid clamps may be used for traction on the fundus for uterine delivery (Fig. 127.20). Using undue traction to deliver the uterus puts strain and the risk of tearing the upper pedicle. Ligatures on utero-sacral and cardinal ligament pedicle and upper pedicle on each side are held for suspending the vaginal vault. The surgeon should always doubly ligate all the pedicles. A careful

Fig. 127.20 Uterine fundal delivery for severance of upper pedicles

watch for adherent intestine close to the fundus is necessary. A Roller gauze or recently introduced pneumo pack will keep the field clear [23]. Releasing adnexal adhesions vaginally is easy but must be done cautiously and gently. Before the start of surgical closure, the tubes and ovaries must always be inspected and the extirpated uterus opened in the theatre in order to exclude endometrial carcinoma. Suspicious findings require recourse to frozen section histopathology. Though rare, there is no way to avoid an unfortunate finding of malignancy and this must be kept in mind to spare another surgery for salpingo-oophorectomy in future. If this be found, both appendages must be removed. The basic principles of meticulous haemostasis, copious irrigation, gauze or mop count and elimination of dead space and devitalized tissue in wound closure should be observed. Since the last few years, we prefer to keep the peritoneum open [24] and reconstitute it only if hysterectomy is followed by bladder neck suspension or sacrospinous fixation, to keep encroachment away. If peritoneum is closed purse string closure through transfixing upper and lower pedicles with required bites on utero vesical and Pouch of Douglas peritoneum, should easily place all the pedicles extraperitoneal and provide watertight closure. If peritoneum is kept open, the vaginal cuff must be closed. Surgeon has an option to close the peritoneum and if he does, he has the option to keep vault open, though preferably this is to be closed. After the uterus is removed, restoration of normal anatomy and support must be a major concern. The vaginal vault is closed using the secured pedicles, as anchoring supports. The ideal method is Lower pedicle comprising of uterosacral and cardinal ligament complex of two sides are approximated to each other and then after anchored to anterior vaginal wall margin near its angles, keeping long ligature uncut.

If salpingo-oophorectomy is performed, ligature, on both sides, holding infundibulo-pelvic ligament is approximated and tied to that holding round ligament. Ligature holding round ligament is next approximated and tied to that of opposite side and anchored to posterior vaginal wall margin near its angle on both sides and left uncut. If only oophorectomy is done, ligature is cut short. In the absence of prophylactic oophorectomy, ligature holding upper pedicle comprising of importantly round ligament, tube and utero-ovarian ligament is anchored to posterior vaginal wall margin near its angle on both sides and left uncut. Not crisscrossing ligatures and pedicles from one side to the other will avoid bringing the ovaries towards the midline. Additionally, it is worth approximating the distal part of two utero-sacra's, include intervening posterior peritoneum and obliterate the dead space. Support for the vaginal vault and upper posterior vaginal wall especially must be such as to secure permanent normal position for the vaginal walls. As peritoneum is not routinely closed, prefer to close vaginal mucosa with continuous suture using two zero vicryl. Having anchored upper and lower pedicles to vaginal margins, ligatures on each side anchoring anterior and posterior vaginal walls are tied to each other and this visibly pulls up vaginal vault. We must approximate the uterosacral and cardinal ligament bundles of the two sides to each other and use these sutures to anchor the anterior vaginal margin near angles. Similarly, in an oophorectomised case, approximate the round ligament pedicles to each other and use this to anchor posterior vaginal wall margin near its angles. When ovaries are preserved, each upper pedicle is anchored, similarly to the posterior vaginal wall separately on the same side. Not crisscrossing ligatures and pedicles from one side to the other will avoid bringing the ovaries towards the midline. It is worth to additionally approximate the distal part of uterosacrals, include intervening posterior peritoneum and obliterate the dead space. Support for the vaginal vault and upper posterior vaginal wall especially must be such as to secure permanent normal position for the vaginal walls. Rarely, in a nullipara, limited exposure requires a median episiotomy or a small Schuchardt's incision, which is sutured. There is no need for a vaginal pack unless the field is oozy. Instruments and assistance play a very important role. An indwelling catheter for 24 h helps the patient, nursing and resident staff, but this is optional.

Special Clinical Situation

Large size demands debulking [19].Surgically, enucleation of myoma, morcellation of adenomyotic walls, bisecting cervix or from cervix to fundus, coring, Lash's technique and/or medical debulking using GnRH agonist's earlier [25].

Endoscopic But Vaginally

Magos [26] used an endoscope through the space created by extirpation of the uterus at VH.

Hefni [27] used stapler or bipolar forceps or endoloop for successful bilateral oophorectomy with vaginal endoscopic approach. Surgeons experienced with Roeder's loop may use it freely to catch the meso-ovarium and excise the ovary.

Above is preferred to laparoscopic oophorectomy by one of bipolar coagulation, pre-tied ligature placement, and automatic stapling devices [28] Sheth [29] reported 95 % success while performing prophylactic oophorectomy at vaginal hysterectomy in 740 cases.

Certain prerequisites which should be satisfied in order to safely perform oophorectomy at VH.

1. Experience of vaginal hysterectomy.
2. Normal tubes and ovaries,
3. Easy accessibility and free mobility of the ovaries.
4. It is mandatory to cut the round ligament separately and as laterally as possible, similar to the procedure while performing a salpingo-oophorectomy at abdominal hysterectomy.
5. Better exposure with a steep trendelenburg position, and by using a long roller gauze pack or pneumo pack.

   Post-menopausal women with third degree uterine prolapse form ideal candidates for learning and mastering this technique and avoiding misuse of LAVH or laparotomy.

Subtotal Hysterectomy (Doderlein's Hysterectomy)

Leaving the cervix behind makes laparoscopic or abdominal hysterectomy safer and easier unlike VH, wherein, preservation of the cervix makes the hysterectomy less easy besides advantages of retained cervix are nebulous and disadvantages are disturbing [30, 31]. It is not easy for the inexperienced at vaginal hysterectomy to perform this. Leaving behind the cervix offers no advantage and invites the complications of a retained cervix. Can and should only be used in case of obliteration of the pouch of Douglas, with no contraindication to leave the cervix in-situ. However, if woman is keen, it still avoids an abdominal invasion, and or laparoscopy.

Benign Adnexal Pathology

Can be dealt vaginally concomitantly at VH even in nulliparа. No doubt prerequisites are to be met with before attempting. For example, for a benign, mobile dermoid (Teratoma) cyst, one can without difficulty perform salpingo-oophorectomy at VH. In fact, hysterectomy provides adequate space for the required surgery. Therefore, let mere nulliparity not contraindicate adnexectomy at VH, provided gynecologist is well experienced with BSO at VH[32].

Conclusion

Nulliparity, does not impede successful vaginal hysterectomy, if carried out by an experienced vaginal surgeon. As the surgical skills improve, nulliparity along with other relative risk factors, such as previous caesarean deliveries, obesity, non-prolapsed uteri, and bulky uteri can be successfully tackled through the vaginal route, with or without oophorectomy, without increasing the risk of bladder or bowel injury, or the need of blood transfusions as compared to laparoscopic or abdominal hysterectomies.

Probably the most important aspect, is Examination under Anaesthesia (EUA) and a readiness to convert to a laparoscopic or abdominal route if necessary.

Surgical steps, in addition to routine steps, would be perineal enhancing incisions, uterine bisection, or morcellation.

Difficult is what I do today, the impossible tomorrow!!

Vaginal Hysterectomy in the Obese Patient

128

Karl Tamussino

All types of hysterectomy are more challenging in the obese patient. This applies to the technical aspects of access and getting the operation done, to the comorbidities encountered in these patients, and to the increased risk of postoperative complications.

Since obesity is a major risk factor for abdominal surgical site infections, avoiding abdominal incisions per se will reduce complications in overweight women requiring hysterectomy. Accordingly, the vaginal approach has long been considered the procedure of choice for benign hysterectomy in obese women [1] and this has been borne out in recent analyses.

Shah et al. [2] analyzed complications according to BMI in 55,409 hysterectomies for benign conditions in the National Surgical Quality Improvement Project in the United States. For abdominal hysterectomy, women with BMIs of ≥40 had an odds ratio of about five for wound dehiscence or wound infection and an OR of 1.9 for sepsis. The magnitude of the association between wound infection and BMI was smaller after vaginal hysterectomy and the authors concluded that in obese women vaginal or laparoscopic hysterectomy should be performed whenever feasible. Osler et al. [3] revewed 20,353 hysterectomies in Denmark and found an association between BMI and increased bleeding and postoperative infection for abdominal hysterectomy but not vaginal hysterectomy. Similarly, a recent Committee Opinion on gynecologic surgery in obese women from the American College of Obstetricians and Gynecologists reconfirmed that in obese patients, as in others, vaginal hysterectomy is associated with better outcomes and fewer complications than laparoscopic or abdominal hysterectomy [4].

K. Tamussino, MD, FACS
Department of Obstetrics & Gynecology, Medical University of Graz, Auenbruggerplatz 14, A-8036 Graz, Austria
e-mail: karl.tamussino@medunigraz.at

Obesity is a risk factor for endometrial cancer and these patients will require hysterectomy. While vaginal hysterectomy does not provide access to the rest of the abdomen or to lymph nodes, it is certainly an option for selected women with this disease [5].

The technique and the tips described below derive from the descriptions of vaginal hysterectomy by Reiffenstuhl [6, 7] and Lee [8]. Bipolar vessel sealing has advantages for vaginal hysterectomy [9] and appears particularly useful for more difficult vaginal hysterectomy, as is frequently the case in the obese patient [10].

Practical Aspects

- When performing a curettage (or hysteroscopy) in a woman who may subsequently require hysterectomy, the surgical note on the examination under anesthesia should indicate whether a vaginal approach would be feasible.
- During the preoperative consent explain that the plan is to remove the uterus vaginally but that lapaoscopic assistance or laparotomy may become necessary.
- Good surgical assistants are particularly valuable for vaginal hysterectomy in the obese patient.
- It may be helpful to have one or both of the assistants to stand outside the patient's legs, to provide more room for the surgeon.
- Vessel sealing appears particularly useful in the obese patient in whom exposure at vaginal hysterectomy may be limited [10].
- Instruments. Posteriorly a weighted speculum. The assistants will be asked to guide three Breisky specula. A variety of Breisky specula in different lengths and widths is helpful. Remember that large instruments take up space.
- During vessel sealing there should be no tension on the tissue being sealed: relax traction during vessel sealing.

Step-By-Step Vaginal Hysterectomy in the Obese Patient/Tips and Tricks

- Adequate anesthesia and positioning.
- Antibiotic prophylaxis (preferably single dose of a first generation cephalosporin).
- Empty the patient's bladder – but not completely. Leaving a bit of urine in the bladder may alert one to a bladder injury, should one occur.
- Examination under anesthesia. Confirm that vaginal hysterectomy appears feasible.
- Place tenacula on the uterine cervix. Use as few tenacula as possible -- they take up valuable space.
- Paracervical infiltration with a local anesthetic (preemptive analgesia) [11, 12].
- Circumcision of the cervix with a scalpel or cautery.
- Development of the vesicocervical space. If the vesicouterine peritoneum can be opened, do so. Confirm entry into the abdomen (not the bladder) by visualizing bowel or omentum; consider bladder injury if opening the "peritoneum" yields fluid. Put a slender Breisky retractor in the anterior cul de sac and leave it there for the rest of the operation.
- Posteriorly, open the pouch of Douglas. Tag the posterior vaginal wall with a suture.
- Division of the uterosacral ligaments. We try to do this with the conventional clamp-and-suture technique to attach the vaginal vault to the uterosacral ligaments and provide support. If space is very limited and uterine descent modest this step can be done with a vessel sealing instrument.
- Division of the parametrial tissue and uterine arteries. Vessel sealing instruments are useful here. We go back and forth between the right and left sides of the uterus, as space permits. The uterine arteries are usually identifiable.
  - If the vesicouterine peritoneum has previously been opened, proceed as far up the lateral margins of the uterus as possible.
  - If the vesicouterine peritoneum has not been opened, attempt to do so after having "crossed" the uterine artery. Again, confirm the correct space by visualizing bowel or omentum.
  - Once the vesicouterine peritoneum is open and demonstrated with a Breisky retractor continue division of the parametrial tissue with vessel sealing as far as feasible.
- When as much as possible of the parametrial tissue on both sides bas been divided it is time to develop the uterus through the posterior cul de sac.
- Once the uterine has been rotated through the posterior cul de sac it needs to be detached from the round ligaments and the adnexa (tubes and ovarian ligaments). Because the specimen is usually under traction at this point, particularly in the obese patient, and because having a tag on these pedicles can be useful later, we recommend placing a single curved clamp across the left round ligament, tube and ovarian ligament and cutting the pedicle. Then we do the same on the patient's right side. Thus, the uterus is detached and removed.
- If after complete division of the parametrial tissue the uterus cannot be delivered through the cul de sac it needs to be bivalved and possibly morcellated. This usually works, and progress towards completing the hysterectomy can be made. If despite the best efforts of the surgical team progress towards mobilizing the uterus cannot be made, consider converting the operation to an open procedure.
- Once the uterus has been removed, consider salpingectomy or salpingo-oophorectomy as appropriate (we recommend salpingectomy with vessel sealing for all benign hysterectomies). The adnexa are more easily mobilized and visualized if their attachments to the uterus have been clamped and tied and the sutures tagged with a small clamp.
- If the tubes and ovaries cannot be visualized safely, leave them alone.
- Check the pedicles and the vaginal margins for bleeding. If there is oozing consider leaving atransvaginal 18- or 20-F Foley catheter in the abdomen.
- Closure of the peritoneum and vaginal cuff. If there is a large potential enterocele we perform routine high closure of the peritoneum with two semicircular pursestring sutures. If there is little descensus of the vagina and little room we close the vaginal, usually with two full-thickness mattress sutures in an anterior-posterior fashion.
- We do not routinely pack the vaginal or place a catheter in the bladder.

Postoperative Care

We try to avoid bladder catheters and vagnal packs in patients with vaginal hysterectomy without concomitant procdures for prolapse or incontinence. DVT prophylaxis with compression stockings, early mobilization and low-molecular-weight heparin is appropriate. Oral pain medication usually suffices and lets patients be mobilized quickly. Most patients leave the hospital 1–2 days after the operation [13]. Extended LMWH prophylaxis may be appropriate for patients at high risk of DVT.

We encourage a quick return to normal activity, excluding intercourse, and a follow-up examination at 4–6 weeks. Issues to be addressed at discharge from the hospital include a review of the procedure and what was removed, pain medications, postoperative restrictions, what happens with the

space previously occupied by the uterus (can be compared to taking something from the bottom of a salad bowl – something else moves into the space), reviewing that menstrual bleeding will no longer occur, and that there is no reason to expect marked deterioration in bladder, bowel or sexual function after hysterectomy. The patient is instructed to come back to our unit promptly if signs such as pain, fever or bleeding develop, although these problems are uncommon.

Vaginal Cuff Dehiscence Following Hysterectomy

129

Michael L. Sprague, Katrin S. Arnolds,
Stephen E. Zimberg, and Tommaso Falcone

Introduction

Vaginal cuff dehiscence after total hysterectomy is a rare, but serious postoperative adverse event. The incidence of vaginal cuff dehiscence in general is reported to be very low, with an overall incidence approximating 0.30–0.39% [1–3]. Although multiple risk factors have been proposed, the incidence of vaginal cuff dehiscence is reported to be higher following conventional and robot-assisted laparoscopic hysterectomies compared to abdominal and vaginal procedures. The mean time to occurrence ranges from 6.1 weeks to 1.6 years following total hysterectomy [4] and ranges in severity from mild separation (Fig. 129.1) to evisceration (Fig. 129.2) of abdominal contents. Most commonly, the intestine is the eviscerating organ, however, the fallopian tube, omentum, and appendix have also been reported [5]. Vaginal cuff dehiscence is potentially life threatening if associated with intestinal ischemia or intra-abdominal infection and must be managed appropriately to limit adverse long-term sequella [6].

Clinical Manifestations

Patients with vaginal cuff dehiscence typically complain of specific, acute onset symptoms, including abdominopelvic pain (58–100 %), vaginal bleeding or watery discharge (33–90 %), and vaginal pressure (30 %). In a significant number of cases, evisceration is present (70 %) [4]. Events commonly preceding vaginal cuff dehiscence include valsalva (16–30 %) and coitus (8–48 %). However, no significant event is definable in 70 % of patients who present with vaginal cuff dehiscence [4]. Therefore, it is clinically prudent to promptly evaluate all patients with symptoms possibly consistent with vaginal cuff dehiscence.

Risk Factors

Patient characteristics that are associated with poor wound healing, surgical technique, perioperative complications, factors leading to increased intra-abdominal pressure, and trauma are generally cited as primary risk factors for vaginal cuff dehiscence. Although the proposed factors are reasonable, it is difficult to draw firm conclusions about the significance of each of these proposed risk factors due to the relatively low incidence of vaginal cuff dehiscence, the inconsistency of reporting risk factors, and selection bias, as many studies are case reports. Many recent reports, however, cite the surgical technique as being a risk factor for vaginal cuff dehiscence (Table 129.1) [1, 3].

Table 129.1 Proposed risk factors for vaginal cuff dehiscence [7]

Increased age	Previous radiation	Postoperative hematoma
Obesity	Malignancy	Postoperative infection
Menopausal status	Surgical approach	Valsalva
Vaginal atrophy	Poor surgical technique	Coitus before healing
Previous vaginal surgery	Poor wound healing	

Table 129.2 Incidence of cuff dehiscence based on surgical approach

Abdominal	0.21–0.25 %	[1, 3]
Vaginal	0.13–0.15 %	[1, 3]
Laparoscopic	0.64–0.80 %	[1, 3]
Robotic	0.40–4.10 %	[8–10]

Mode of Hysterectomy

Two large, multicenter, retrospective studies demonstrate trends in vaginal cuff dehiscence based on the mode of hysterectomy. Ceccaroni et al. reported surgical outcomes from 8635 patients who underwent total hysterectomy at four large centers in Italy over 14 years. A total of 34 vaginal cuff dehiscences were observed, corresponding to an overall incidence of 0.39 %. Of these 34 patients, 8 (0.25 %) had undergone abdominal hysterectomy, four underwent transvaginal hysterectomy (0.15 %), and 22 underwent total laparoscopic hysterectomy (0.80 %) [3]. Subsequently, Uccella et al. reported the outcomes of 12,398 patients undergoing surgery at six centers in Italy over 14 years. They observed a total of 38 vaginal cuff dehiscences corresponding to an overall incidence of 0.30 percent. Similarly, they observed a trend in which the greatest incidence of vaginal cuff dehiscence occurred in the total laparoscopic hysterectomy group (0.64 %), compared to the vaginal hysterectomy (0.13 %), and abdominal hysterectomy (0.21 %) groups [1]. Robot-assisted hysterectomy has likewise been associated with increased risk of vaginal cuff dehiscence. Different groups have published retrospective analyses of their center-specific experience, with estimated incidences of vaginal cuff dehiscence to ranging from 0.4 to 4.1 % (Table 129.2) [8–10].

Approach for Colpotomy and Cuff Closure

The role of energy use in promoting vaginal cuff dehiscence is unclear. Researchers have proposed that the use of energy devices to perform colpotomy during laparoscopic hysterectomy is the primary reason for the observed increased incidence of vaginal cuff dehiscence [11].

Subset analysis of the total laparoscopic hysterectomy group from Uccella's study demonstrated a different trend. The patients from the total laparoscopic hysterectomy group were subcategorized based on the approach for cuff closure. Although colpotomy was made with monopolar energy in each of the patients from the total laparoscopic hysterectomy group, cuff closure was performed by either laparoscopic or transvaginal approaches. The incidence of vaginal cuff dehiscence for patients who underwent laparoscopic colpotomy repair was greater than the patients who underwent transvaginal repair (0.86 % vs. 0.24 %, respectively; $p = 0.028$). The incidence of vaginal cuff dehiscence following total laparoscopic hysterectomy with transvaginal colpotomy repair was compared to the transvaginal hysterectomy group and the difference in relative incidences was not statistically significant [3].

A retrospective analysis of data entered into a prospective database compared patients who underwent either total laparoscopic hysterectomy or laparoscopic-assisted vaginal hysterectomy. Colpotomy was made using an ultrasonic scalpel in the total laparoscopic hysterectomy group and a monopolar pencil in the LAVH group. Cuff closure was performed laparoscopically in the total laparoscopic hysterectomy group and transvaginally in the LAVH group. Again, the incidence of cuff dehiscence was greater in the patients who underwent laparoscopic cuff closure (4 %) compared to those who underwent transvaginal cuff closure (0 %) [12].

These data suggest that the laparoscopic approach for cuff closure may be a greater risk factor for vaginal cuff dehiscence than a laparoscopic approach for colpotomy.

Prevention of Vaginal Cuff Dehiscence

Perioperative Considerations

Vaginal cuff dehiscence may result from activities such as coitus and strenuous physical exertion and most patients should be advised to avoid both for approximately 6–8 weeks

following surgery. Additionally, optimization of medical conditions associated with vaginal cuff dehiscence is important during the perioperative period. Specifically, management of conditions that are associated with increased intra-abdominal pressure, poor wound healing, and infection should be identified and addressed.

Increased intra-abdominal pressure exerts force on the vaginal tissues that displace them towards the introitus, which can lead to traumatic separation of the vaginal cuff during the postoperative period. Postoperative constipation resulting from intraoperative bowel manipulation, intra-abdominal inflammation, and postoperative narcotic use is common and may be treated with liberal use of stool softeners and osmotic laxatives. Pre-existing conditions resulting in repetitive cough, such as chronic obstructive pulmonary disease, asthma, and gastroesophageal reflux disease, should be addressed preoperatively by consultant physicians to minimize their impact on the patient's postoperative course.

Certain medical conditions that result in poor wound healing may likewise increase a patient's risk for vaginal cuff dehiscence. Patient-specific factors such as obesity and smoking are easily identified and potentially modifiable prior to non-emergent surgery. Medical conditions such as diabetes and thyroid disorders affect the rate of wound healing and must be tightly controlled medically during the perioperative period. Medications that affect wound healing such as corticosteroids should be tapered when feasible. Vaginal atrophy is another proposed risk for delayed vaginal wound healing and perioperative estrogen therapy has been employed to address this potential risk factor.

Post-hysterectomy pelvic infection is a commonly cited risk factor for vaginal cuff dehiscence. Bacterial vaginosis, specifically, has been linked to postoperative vaginal cuff cellulitis and subsequent abscess formation. Bacterial vaginosis is associated with increased concentrations of potentially pathogenic microorganisms within the vagina that may compromise vaginal cuff health through ascending infection of the healing tissues. A study in which patients with preoperative bacterial vaginosis were randomized to receive perioperative metronidazole or no treatment demonstrated a significantly greater risk for vaginal cuff infection for those patients who did not have their bacterial vaginosis treated [13]. Other risk factors for postoperative vaginal cuff infection include postoperative hematoma or untreated pelvic inflammatory disease and should be promptly addressed. It is required that all patients receive preoperative antibiotics prior to skin incision to minimize surgery-related superficial and organ space infections. Continuation of antibiotics during the postoperative period is not generally recommended. It may be reasonable to extend activity restrictions and vaginal rest if patient deemed to be high risk for vaginal cuff dehiscence.

Surgical Technique

Colpotomy and cuff closure are two steps of total hysterectomy in which a surgeon's technique impacts a patient's risk for vaginal cuff dehiscence. The goal for colpotomy is efficient tissue division while preserving tissue integrity and vascular supply of the vaginal tissues. Whereas colpotomy is most oftentimes performed sharply in abdominal and vaginal procedures, laparoscopic colpotomy is usually performed using energy devices.

Monopolar electrodes and ultrasonic devices are typically employed for laparoscopic colpotomy. In the context of monopolar electrosurgery, factors such as current waveform, electrode manipulation, and dwell time impacts the overall tissue effect. The electrosurgical unit should be set to a low-voltage, uninterrupted waveform such as pure cut. The tissue should be divided by linear vaporization, which is a non-touch technique in which energy arcs from the electrode tip to the target tissue (Fig. 129.3). Linear vaporization leads to a sharp increase in intracellular temperature and rapid division of tissue, with minimal thermal spread. Tissue dwell time should be minimized to avoid unintended thermal injury and compromise to the adjacent vaginal cuff tissue.

Ultrasonic scalpels transduce radiofrequency energy into mechanical energy to achieve tissue effect. Typically, these devices have a 'min' and 'max' setting, which refers not to the speed of the active blade, but to the excursion distance of the active blade. The 'max' setting favors rapid tissue division over hemostasis, which is preferred for laparoscopic colpotomy. The surgeon can also increase the rate of tissue division by applying traction and counter-traction to the tissue, as well as by squeezing the device hand piece more firmly (Fig. 129.4).

Colpotomy during total hysterectomy disrupts the pericervical ring, a coalescence of fascial and ligamentous

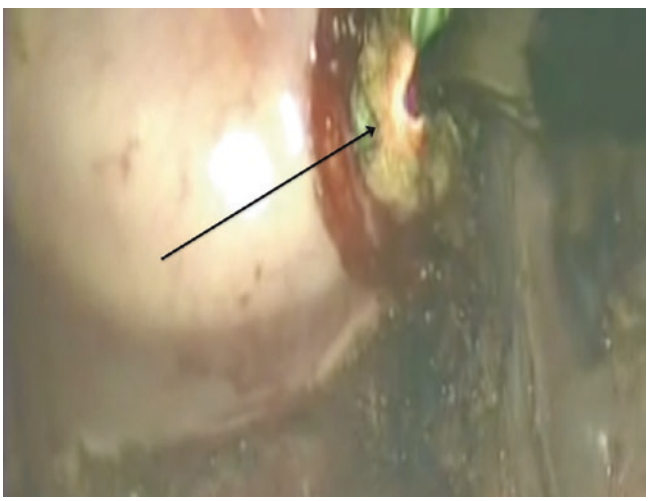

Fig. 129.3 Colpotomy using monopolar vaporization. Note the arcing of energy from the electrode tip to the tissue (*arrow*)

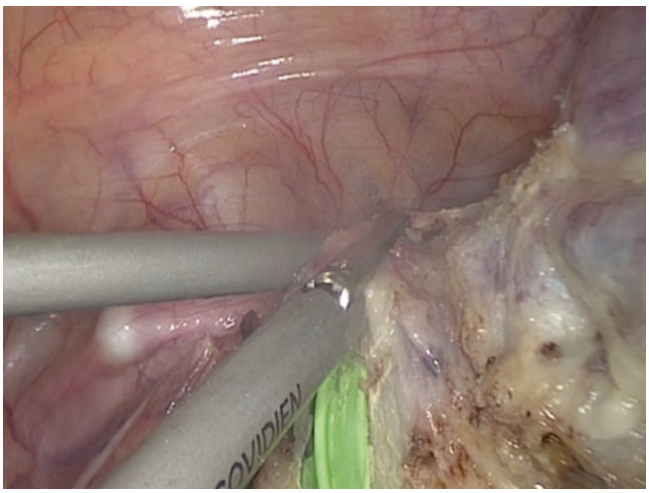

Fig. 129.4 Colpotomy using ultrasonic scalpel

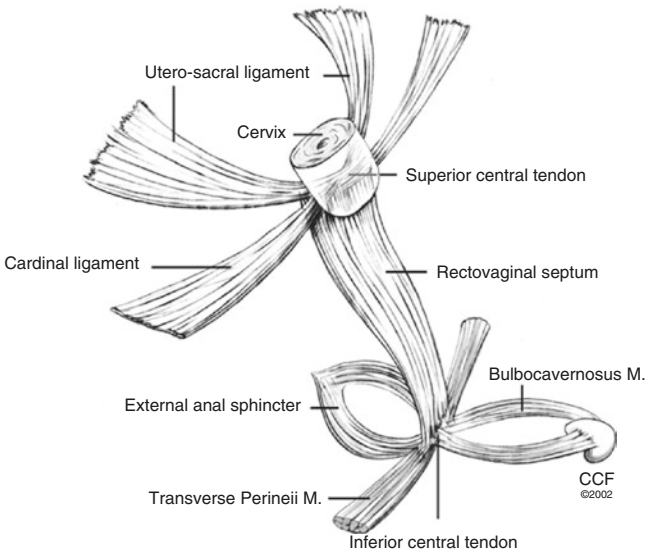

Fig. 129.5 Anatomy of the pericervical ring (pubocervical fascia is not pictured)

tissues that provide support and integrity for the vaginal apex. Anatomically, the pericervical ring lies at the level of the ischial spines and is comprised of the pubocervical fascia, rectovaginal septum, and cardinal-uterosacral ligament complexes (Fig. 129.5). Disruption of the pericervical ring compromises apical support, leaving the vaginal walls vulnerable to intrabdominal forces that drive them toward the vaginal hiatus.

Durable cuff closure hinges upon proper reconstruction of the pericervical ring and restoration of the vaginal apex to the level of the ischial spines. Following colpotomy, the surgeon should palpate the ischial spines to determine the target final position of the vaginal apex. Using delayed absorbable suture, the angles of the vagina are approximated by incorporating purchases of the uterosacral ligament, the rectovaginal septum, the cardinal ligament and the pubocervical fascia. Vaginal cuff closure is then completed in figure-of-eight or running fashion by taking full-thickness tissue purchases that incorporate and approximate the vaginal epithelium and fascial planes (Fig. 129.6a–c). These principles for vaginal cuff closure are applicable to all approaches for total hysterectomy.

Care must be taken to take adequate purchases of tissue, approximately 1 cm from the cuff edge, with each suture. Likewise, the surgeon must not place sutures too great of distance apart. Typically, tissue purchases 1 cm from the cuff margin separated by one-half centimeter is adequate. Obtaining adequate tissue purchases is particularly problematic during laparoscopic or robotic cuff closure as magnification of the surgical field distorts a surgeon's perception of distance. At the completion of cuff closure, the surgeon palpates the suture line transvaginally to evaluate for areas of inadequate approximation within the vaginal cuff and, if necessary, additional sutures are placed to reinforce the weak areas. At present, randomized studies that indicate the optimum suture material and closure technique for prevention of dehiscence are not available.

Management of Cuff Dehiscence

Vaginal cuff dehiscence ranges in severity from separation of the vaginal epithelium to evisceration. Abdominal examination is performed to assess for peritonitis. Careful digital and speculum vaginal examinations are performed to confirm the presence and extent of the vaginal cuff dehiscence, as well as evisceration. The location, size, and depth of any defect should be specifically documented. Additionally, assessment of the cuff for tissue viability and possible infection is likewise important. Basic laboratory evaluation includes a complete blood count and metabolic profile. Computed tomography scan with contrast is indicated for patients who demonstrate symptoms or signs of systemic infection, abscess, peritonitis, bowel compromise, or hematoma. As there is currently no consensus for a single management algorithm for vaginal cuff dehiscence, optimal management depends on the clinical features of each individual patient [14].

Small separations of the vaginal cuff measuring without evidence of infection, hematoma, or evisceration can be observed for spontaneous closure over the course of 6–8 weeks. For larger vaginal cuff separations (Fig. 129.7), transvaginal repair using 0 gauge, monofilament, delayed-absorbable suture in interrupted fashion following cuff debridement is advised [14] (Fig. 129.8). A laparoscopic or abdominal approach is indicated when transvaginal suturing is not feasible, or if cuff hematoma or infection is suspected. Patients are typically observed in the hospital overnight and discharged home on postoperative day one if clinically stable.

Vaginal cuff evisceration is a surgical emergency and must be managed properly and efficiently to avoid long-

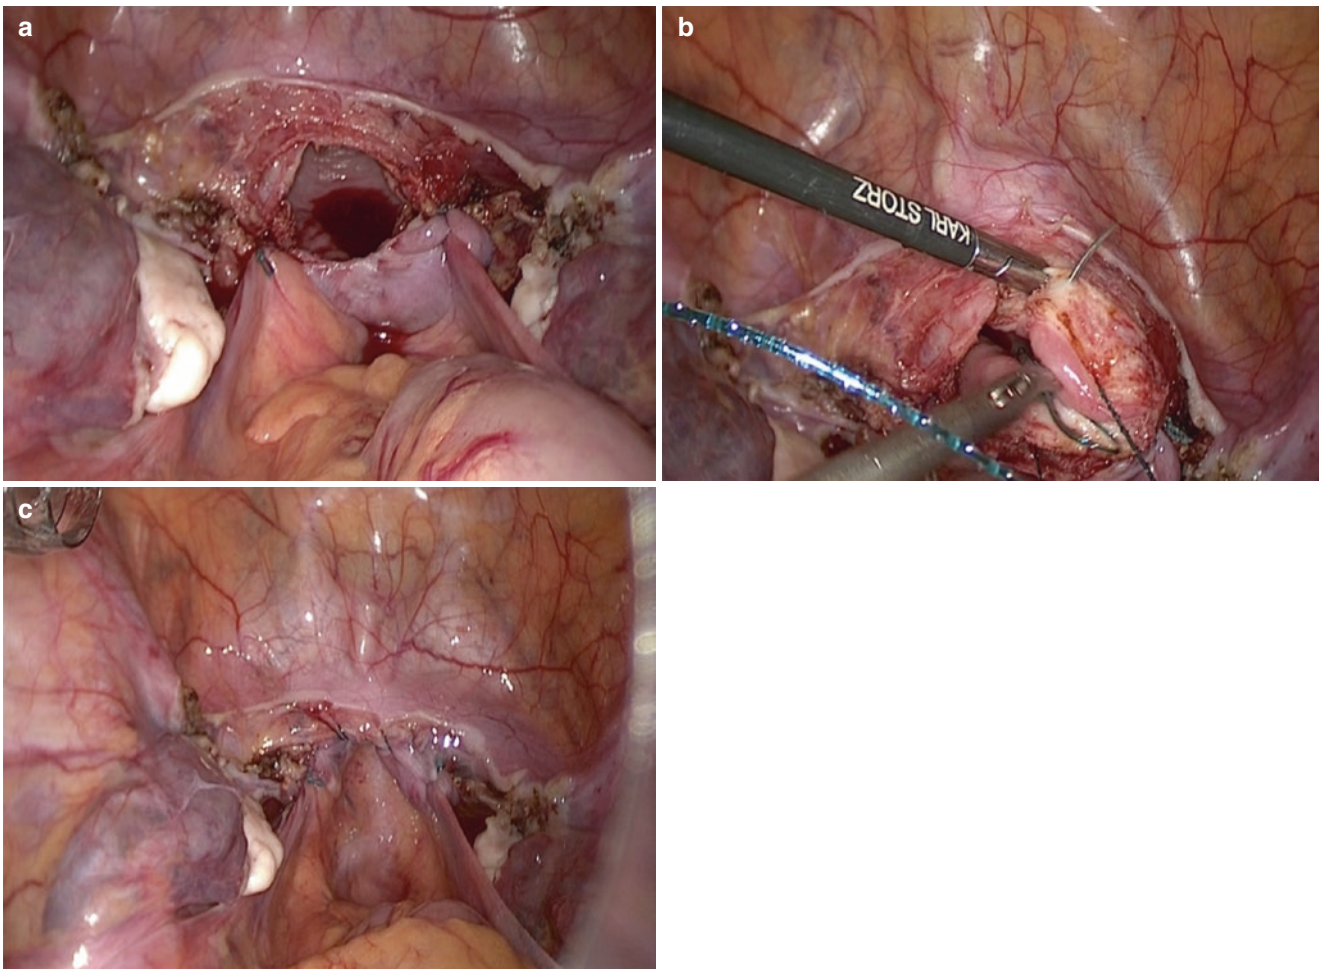

Fig. 129.6 (**a**) Durable cuff closure: completion of vaginal angle sutures. (**b**) Durable cuff closure: suturing of vaginal cuff. (**c**) Durable cuff closure: completion of vaginal cuff closure

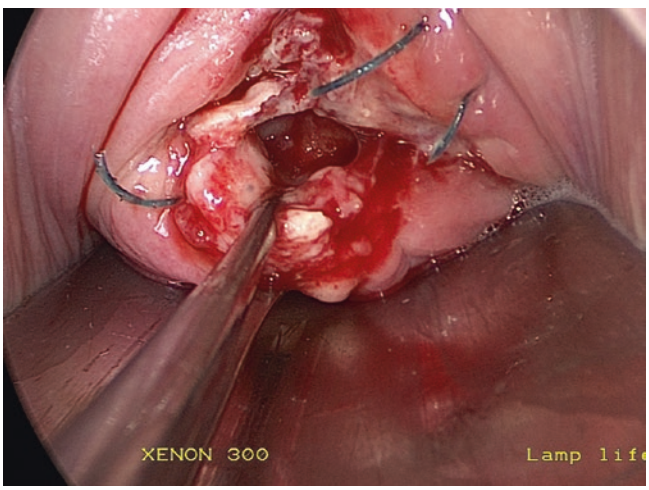

Fig. 129.7 Vaginal cuff separation requiring operative repair

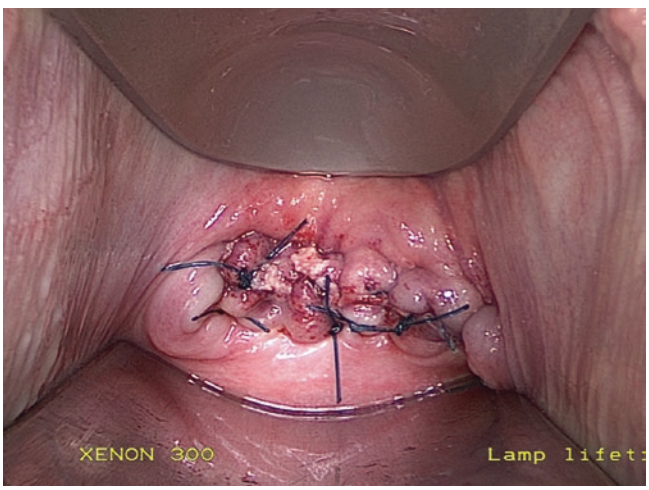

Fig. 129.8 Completed repair of vaginal cuff separation

term sequellae. If evisceration is detected at the time of initial examination, bowel present beyond the vaginal orifice should be immediately wrapped in gauze saturated with warm sterile saline. Broad-spectrum antibiotics should be initiated while diagnostic studies are obtained and the patient is prepared for surgery. For patients without signs or

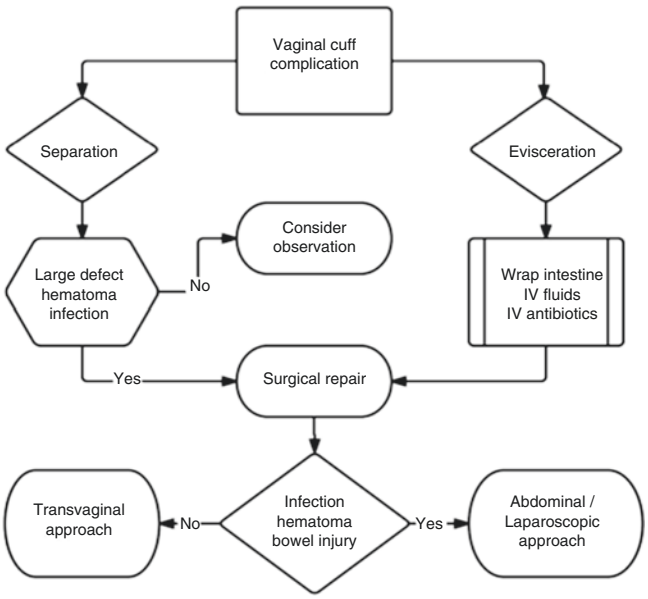

Fig. 129.9 Algorithm for management of vaginal cuff dehiscence

symptoms of infection, hematoma, or bowel compromise, the eviscerated bowel is visually inspected for viability and injury while the patient is under anesthesia. If the bowel appears intact, pink, and well perfused, a transvaginal repair is feasible. The intestine is copiously irrigated with warm saline. The patient is placed in Trendelenburg position and the eviscerated bowel carefully reduced through the vaginal cuff. The vaginal cuff is sharply debrided until all necrotic tissue is excised and viable tissue observed at the cuff margin. The vaginal cuff is then reapproximated with 0 gauge, monofilament, delayed-absorbable suture in interrupted fashion. The surgeon must ensure that adequate purchases of the tissue are taken and that knots are secure, but do not strangulate the tissue. Care must be taken not to injure the bladder, ureter, or intestines during cuff debridement and repair. If concern for injury exists, cystoscopy or laparoscopy is indicated. Again, a laparoscopic or abdominal approach is indicated if transvaginal suturing is not feasible. Likewise, a laparoscopic or abdominal approach should be employed if the patient demonstrates signs of infection, hematoma, or bowel compromise. Of note, bowel surgery was required in 14.7 % of evisceration cases in a large multicenter retrospective study [3]. Pelvic drain may be placed if clinically indicated. Co-management with a consultant surgeon may be considered if bowel compromise is suspected (Fig. 129.9).

Inpatient management is indicated following repair of vaginal cuff evisceration. The patient is observed for excessive vaginal bleeding and signs of systemic infection. White blood cell count is monitored with the aim of detecting early abdominopelvic infection or mesenteric ischemia. Clear liquid diet is initiated immediately following surgery and advanced as tolerated. Anti-emetics are provided as needed, but persistent nausea and vomiting should not be ignored and further evaluation and imaging considered. Nasogastric tubes are generally not indicated, with the exception of severe bloating or emesis refractory to medications. The patient may be discharged home following return of bowel function if stable clinically. Patients are typically evaluated in the outpatient setting 2, 6 and 10 weeks following surgery. Conditions that may lead to increased intraabominal pressure such as asthma, chronic cough, and constipation are tightly managed. Vaginal estrogen cream may be considered to aid healing for women with vaginal atrophy. Patients are instructed to maintain pelvic rest for 12 weeks, or until adequate healing of the vaginal cuff has been observed.

Conclusion

Vaginal cuff dehiscence is a significant, albeit infrequent, complication following total hysterectomy. Although many risk factors have been proposed in the literature to account for this complication, a laparoscopic approach for cuff closure may be the most relevant due to the increasing frequency of conventional and robot-assisted laparoscopic hysterectomy procedures performed today. The optimal management strategy must be individualized for the patient and their unique clinical picture. Minimizing long-term complications depends on early diagnosis and prompt management, with consultation of consultant surgeons when appropriate.

Postoperative Care

130

Karl-Günter Noé

The postoperative care is related to the technique performed by the surgeon. The traditional technique with a subtotal closure of the vaginal cuff is different to the nowadays performed procedure closing the cuff completely.

The postoperative care considers the risks of surgical strategy. The possible complications after the operation are:

- Urinary infection
- Heavy bleeding
- Hematoma
- Stump-Infection
- Damage to surrounding organs (bladder, ureters or bowel)
- Tubal prolapse
- Wound dehiscence
- Vault-prolapse
- Blood clots in the legs or lungs

Surgical risks are higher in women who are obese or who have diabetes or high blood pressure.

Urinary infections after gynecological surgery occur frequently. We can find a range from 10 to 25 % in Literature [1]. Usually they are clinical relevant in the first days after surgery. To minimize the risk, catheterization and other manipulation should be performed as less as possible. If a catheterization is required it is useful to introduce an additional sterilization procedure. Before placing the catheter the orifice of the urethra should be disinfected three times and the catheter should be introduced by using a sterile pair of tweezers. We could reduce our own rate [2] with this simple procedure by 50 %. An unproblematic infection can often be cured with a single shot of Fosfomycin. Multi-morbid patients and in case of a larger surgical field, (combined surgery) the treatment has to be designed after a microbiological examination.

K.-G. Noé
Department of OB/GYN, University of Witten/Herdecke, Hospital Dormagen, Dormagen, Germany
e-mail: Karl-guenter.noe@kkh-ne.de

If the uterine artery starts bleeding after surgery, high blood loss can occur. Even if this complication is rare (0.1–1.4 %), it is an important thread for the live of the patient. Therefore a clinical observation for the first 24 h is to recommend [3]. Drainage is not required.The contact of blood with the peritoneum often causes pain and in case of a late bleeding the patient will attract attention on herself. If the bleeding will occur early after the surgery the pain can be masked by the analgesic treatment. A bleeding of an artery causes a high volume loss in a short time so that it will lead to a shock syndrome. A vaginal or laparoscopic revision of the bleeding should only be done by very experienced vaginal or laparoscopic surgeons. To deal with a large quantity of blood can be extremely challenging. In a life-threatening situation a laparotomy may be the safest way. The slow bleedings by small vessels or late bleedings most of the time cause hematoma. If the surgeon is used to close the peritoneum, most of the time you will find them retroperitoneal.

Hematoma at the vaginal stump can cause problems as an optimal habitat for bacteria and resulting infection with the risk of peritonitis. As they can be clinical silent it is important to know the complication. A hematoma can easily be diagnosed with a vaginal ultrasound during the examination before release. In hematomas larger 2 cm a revision must be considered. Large hematomas regularly cause pressure sensations in the pelvis and need a long resorption time. Therefore a surgical treatment by vaginal or laparoscopic route is required.

An antibiotic prophylaxis is given at the beginning of the surgery as a single shot (cephalosporin). Infection after vaginal Hysterectomy has to be estimated in 4–10 % [4]. Pain and fever (>38 C) should be treated early. In case of an abscess formation a surgical drainage is essential. Most of the time an abscess can be opened by vaginal route. If there is no pus after the opening of the vaginal suture, a laparoscopy should be considered. As an adhesion of the bowel has to be estimated always, a forced vaginal approach has a high risk and should be avoided.

Damage to surrounding organs (bladder, ureters or bowel) is rare but can be serious for the patient. (Ureter 0–0.1 % / bladder 0.5–2 % {all Hysterectomies}). In case of doubt an imaging method is required. Therefore in most clinics a postoperative ultrasound of the kidneys is a standard. By the ligature of parametric tissue an obstruction of the ureter is possible and can be visualized by ultrasound. (According to some case-reports a reflective anuria is possible). By usage of bipolar ligation instruments a thermic damage can occur. Clinical signs most of the time will come to surface after demission of the patient.

If a ligature is the reason for the obstruction, most of the time an early surgical intervention can save the ureter (Don't hesitate – in case of doubt).

To summarize, it should be emphasized that a minimum postoperative observation of 24 h is to be ensured. In case of signs of infection an early antibiotic therapy is to be started. Uncomplicated urinary infection can be treated by single dose Fosfomycin. Other and stump-infections should be treated after micro-biological examination. Ultrasound of the kidney can point on an obstructive complication of the ureter and is useful 1 day after surgery. Low dose heparin has to be given pre and postoperatively. For an early recovery of the vaginal flora a combination of estrogen and lactobacillus is useful. During the examination before release, wound dehiscence and tubal prolapse should be excluded. The vaginal stump, the bladder and adnexa should be examined by vaginal ultrasound. If the cuff is not close completely the patients are to inform that it is normal to have bloody vaginal discharge for several days to weeks after a hysterectomy.

A full recovery may take 3–4 weeks. As the uterine ligaments in the apex are cut during the procedure, lifting more than 20 pounds (9.1 kg) or having vaginal intercourse until 6 weeks after surgery is not required. Sports and intensive exercises of the pelvic floor should be avoided in this period. During the consultation before discharge the problematic of anxiety around sexual dysfunction should be addressed [5]. It is important to clarify possible expectations according to the procedure. The latter can be influenced by reports of friends and lay press. If not all questions around sexuality and influence on the pelvic health are answered before the surgery, it is problematic to clear doubts retrospectively.

Part XII

Conservative Management

What Is the Place of Myoma Surgery with the Advent of Selective Progesterone Receptor Modulators (SPRMs)?

131

Jacques Donnez, Olivier Donnez, and Marie-Madeleine Dolmans

Introduction

Uterine fibroids are the most common benign uterine tumors in women of reproductive age, occurring in 20–25 % of women [1, 2]. Depending on localization, the symptoms include pelvic pain, pressure, dysmenorrhea, anemia caused by heavy bleeding, reduced quality of life, and infertility [3].

Current management strategies involve mainly surgical interventions, but the choice of treatment is guided by the patient's age and desire to preserve fertility and avoid "radical" surgery such as hysterectomy [3, 4]. In the early 1980s, hysterectomy was routinely proposed to women with submucous fibroids who did not wish to conceive. Since then, other surgical and nonsurgical approaches, including myomectomy by laparotomy or laparoscopy or hysteroscopy, uterine artery embolization, and other interventions performed under radiologic or ultrasound guidance [3–5], have been proposed.

Medical therapies with progestin, progestin-releasing intrauterine devices, and gonadotropin-releasing hormone (GnRH) agonist are also available [6–8], the use of oral progestin may cause breakthrough bleeding and promote myoma growth [6]. GnRH agonist can be used [7–8], but such treatment is approved only for short-term therapy because of safety concerns linked to artificially induced menopause (severe side effects like loss of libido, vaginal dryness, hot flushes, loss of bone mineral density) [7–8].

Progesterone plays an important role in promotion of myoma growth [9, 10]. Modulating the progesterone pathway [11, 12] represents one of the possibilities of medical therapy, opening the way to use of selective progesterone receptor modulators (SPRMs) [10, 13–19].

The chapter presents new algorithms of myoma management in 2015, taking into account recent developments in long-term intermittent therapy with SPRMs [15, 16].

Hysteroscopic Myomectomy

Over the last 30 years, advances in instruments and techniques have promoted hysteroscopic myomectomy to the rank of a standard minimally invasive surgical procedure for submucous myomas (for review, see [20]).

There is some evidence suggesting that fibroids may impede fertility [3, 21]. Although the absence of randomized studies does not allow any firm conclusions to be drawn, many authors report an improvement in spontaneous fertility after hysteroscopic myomectomy, especially when the uterine cavity is distorted by the presence of submucous myomas.

More recently, the FIGO classification [22] was published describing eight types of fibroids, including a hybrid class (association of two types of myomas) (Fig. 131.1). As different types of fibroids are often present at the same time (according to the site), this classification offers a more representative 'map' of fibroid distribution.

Use of GnRH agonist before surgery is still a matter of debate, but "preoperative use of GnRH agonist appears to be relevant and beneficial in patients with submucous fibroids."Benefits include resolution of preoperative anemia, decrease in fibroid

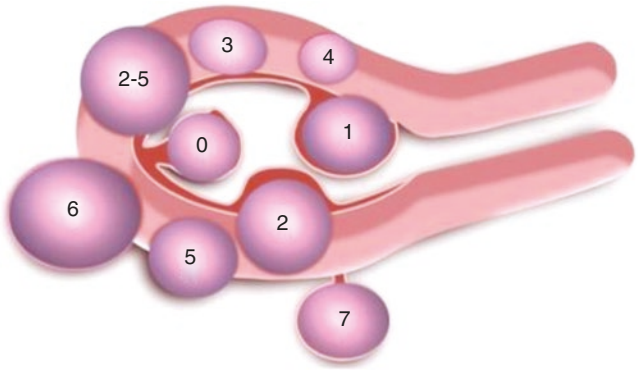

Fig. 131.1 FIGO classification according to Munro et al. (2011) (Adapted from Munro et al. [22], Copyright 2011, with permission from Elsevier). Fibroid types range from 0 to 7: *0* Pedunculated, intracavitary; *1* Submucosal, <50 % intramural; *2* Submucosal, ≥50 % intramural; *3* Contact with endometrium, 100 % intramural; *4* Intramural; *5* Subserosal, ≥50 % intramural; *6* Subserosal, <50 % intramural; *7* Subserosal, pedunculated

size, reduction of endometrial thickness and vascularization with subsequently improved visibility and reduced fluid absorption, and the possibility of surgical scheduling [7].

Conversely, this preoperative treatment is associated with some side effects, like hot flushes and post-injection endometrial bleeding due to the flare-up effect.

Myomectomy by Laparoscopy/Laparotomy

Despite the fact that studies investigating intramural myomas have suggested a negative effect on fertility outcome, the evidence remains far from conclusive. On the other hand, studies found adverse pregnancy outcomes associated not only with submucous and intramural fibroids distorting the uterine cavity, but also those not distorting the uterine cavity [23].

In case of symptomatic myomas, myomectomy is clearly indicated. Laparoscopic myomectomy is a minimally invasive alternative to conventional laparotomy. Reports of uterine rupture after laparoscopic myomectomy emphasize the importance of adequate closure of the myometrial defect. Contraindications to laparoscopic myomectomy usually include: (1) the presence of an intramural myoma > 10–12 cm in size, (2) multiple myomas (≥4) in different sites of the uterus requiring numerous incisions, and (3) anemia (this contraindication is also valid for laparotomy). In some cases, uterine artery ligation may be beneficial to reduce bleeding during sugery.

Recurrence of leiomyomas has been reported to be greater after laparoscopic myomectomy than after laparotomy. However, in a randomized study, 81 patients assigned to either abdominal or laparoscopic myomectomy were observed postoperatively for 40 months to compare recurrence rate. Nine recurrences (23 %) were observed in the abdominal myomectomy group, compared with 11 recurrences (27 %) in the laparoscopic myomectomy group.

Postoperative morbidity is less severe and recovery faster with laparococoscopic procedures. Studies comparing reproductive outcomes after laparoscopic or abdominal myomectomy (by minilaparotomy) show no significant difference ([3], for review see [20]), but laparoscopic myomectomy is perceived by many gynecologic surgeons to be more difficult.

Depending on the skill of the surgeon and his/her ability to suture the myometrial defect without delay, either laparoscopy of minilaparotomy may be chosen.

Hysterectomy: Which Approach?

Hysterectomy has long been considered standard surgical treatment for symptomatic intramural and submucous fibroids, particularly for women not wishing to conceive or those of premenopausal age (40–50 years). In the United States, hysterectomyis associated with a substantial impact on healthcare systems that amounts to approximately $2.2 billion/year. Fibroids are the main indication for hysterectomy and, in this last decade, laparoscopic hysterectomy (LH) has become the ideal surgical route to replace laparotomy. In some departments, the rate of LH exceeds 90 %. Vaginal hysterectomy (VH) still remains indicated in some conditions, depending on the skill and habits of the surgeon.

Some studies have reported an increased risk of complications after LH, but in a very large series, similar rates of major complications were found after LH, VH, and abdominal hysterectomy (less than 1 % [0.44 %] of major complications) [24, 25]. In a recent report, it was demonstrated that laparoscopic hysterectomy has become more common and is associated with decreased complication rates, despite the higher preoperative risk for patients. Of course, a uterine volume of ≥13–14 weeks represents a relative contraindication. In such cases, preoperative treatment with GnRH agonist may be effective to reduce the size of myomas and facilitate surgery.

In a very recent publication, O. Donnez et al. [26] demonstrated that THL (total laparoscopic hysterectomy) is a feasible procedure, allowing same-day discharge and generating low levels of pain. Of course, lower the weight of the uterus is, easier the procedure is.

Conclusions on the Surgical Approach in Cases of Uterine Myomas

From a recent review, it can be concluded that:

1. Laparoscopic myomectomy is indicated in cases of:
   (a) Myomas <10–12 cm in size.
   (b) No more than three to four intramural myomas.
   (c) Intramural myomas >3–5 cm in size with cavity distortion in cases of infertility.

2. Hysteroscopic myomectomy in indicated in cases of:
   (a) Submucous myomas ≤5 cm in size.
   (b) Partially submucous intramural myomas >5–6 cm in size (two steps).
3. Laparoscopic hysterectomy (if no desire to conceive) is indicated if the volume of the uterus is <13–14 weeks.

In all other circumstances, laparotomy (or minilaparotomy) shoud be considered.

Because SPRMs are now available and have proved effective, it is time to focus on a very important question: what is the remaining role of surgery with the advent of these drugs? If surgery remains indicated, do these drugs enable less invasive surgery? Indeed, the real question is whether SPRMs (UPA) allow less invasive surgery or complete avoidance of surgery.

With the Advent of SPRMs, What Is the Place of Myoma Surgery in Current Practice?

Since SPRMs are now available and have proved effective, it is time to focus on a very important question: what is the remaining role of surgery with the advent of these drugs?

Mode of Action of SPRM

SPRMs and the Progesterone Receptor

The effects of progesterone on target tissues are mediated by the progesterone receptor (PR), which belongs to the nuclear receptor family. PRs are known to be upregulated in uterine fibroids compared with adjacent myometrium at the mRNA and protein levels [16]. Very recently, PR-B mRNA and PR-A and PR-B proteins were found to be more concentrated [17] and more abundant in fibroids than in adjacent myometrium.

SPRMs are synthetic compounds that compete at the PR binding site, displaying either agonist or antagonist activity on PRs [27–29]. When bound, this also results in dimerization and binding to the progesterone response element sequence, but induces an intermediate conformation, allowing the receptors to interact with co-activators and/or co-repressors [18, 19].

Whether a SPRM acts more as an antagonist or agonist depends on its structure and how it alters the PR conformation, leading to exposure or inactivation of particular binding domains, which affect the association of co-repressors and/or coactivators with the PR [19]. This is impacted by the presence of co-regulators in a particular cell type and by the ratio of co-activators and co-repressors. The activity of an SPRM varies with tissue type and physiological context (e.g. pregnancy) and may be different from one cell type to another [27].

SPRMs and Their Mechanism of Action on Uterine Fibroids: Uterine Fibroid Size Reduction

In vitro studies have demonstrated that progesterone stimulates fibroid cell proliferation, while SPRMs such as asoprisnil, telapristone acetate and UPA inhibit cell proliferation and induce apoptosis selectively in fibroid cells by down-regulating anti-apoptotic factors and anti-fibrotic activity and reducing or blocking growth factor expression [30, 31, 32].

In a recent publication, Courtoy et al. [33] reported findings of cellular and tissue analysis of UPA-treated myomas and compared them with untreated myomas, evaluating proliferation, apoptosis, extracellular matrix components, and matrix metalloproteinase-2 expression. The authors demonstrated multifactorial and successive events involving maintenance of a low proliferation rate, transitory stimulation of cell death that is not caspase-3 dependent, and a dramatic reduction in the ECM, essentially after long-term treatment, which may be partially explained by increased MMP-2 expression. This suggests direct regulation of MMP-2 expression by UPA in myomas. It also identified MMP-2 as an important player in ECM resorption in myomas to reduce their volume (Fig. 131.2).

SPRMs and Control of Uterine Bleeding and Ovulation

It should be stressed that the interest of SPRM treatment for uterine fibroids is also its impressive capacity to reduce uterine bleeding and control ovulation and the menstrual cycle. A high rate of bleeding control is reported with all SPRMs, with frequent occurrence of amenorrhea. This amenorrhea has been suggested to be due to a direct effect on the endometrium, and also partly related to anovulation [34, 35]. Indeed, the administration of UPA blocked the LH surge, but does not inhibit FSH secretion.

However, the exact mechanism of action by which daily SPRM administration inhibits ovulation and leads to amenorrhea is not yet entirely clear [36]. Single-dose SPRM treatment in the follicular phase or around the LH peak can delay ovulation and follicular maturation, as demonstrated with UPA and mifepristone [37, 38]. Chronic low-dose SPRM treatment (5 or 10 mg UPA) results in anovulation and amenorrhea in most women, without reducing endogenous estrogen secretion [13–16].

Therapeutic Potential of SPRMs

A main advantage of UPA therapy is that estradiol remained at mid follicular phase level avoiding menopause symptomas (hot flushes, bone loss), as frequently observed in women

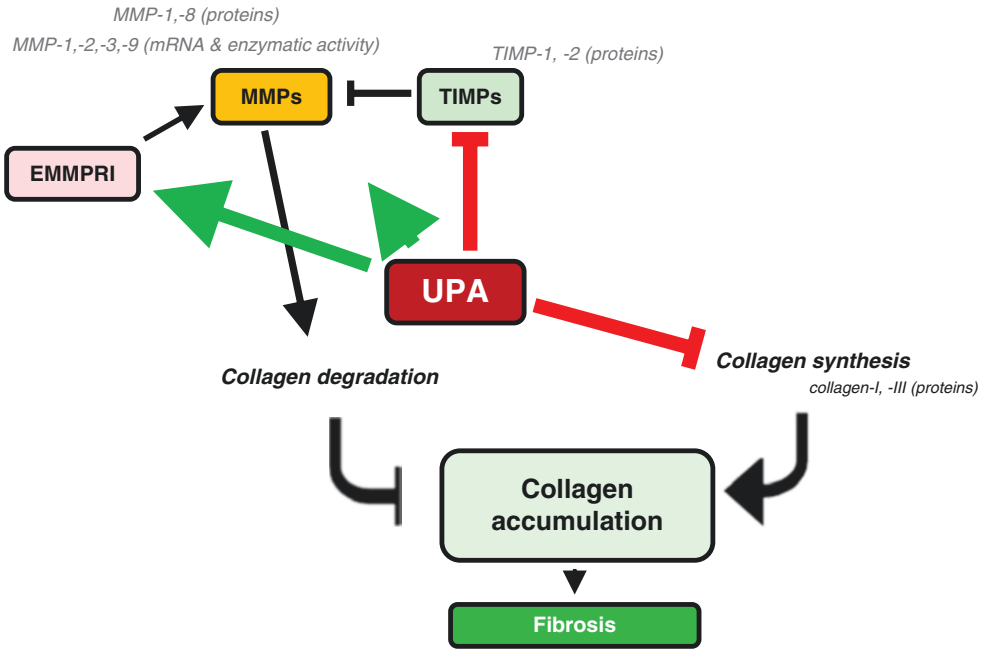

Fig. 131.2 In vivo mechanisms explaining the action of UPA on myomas

treated bye GnRHa. The main side effect is the induction of PAEC (selective progesterone receptor modulator associated endometrial changes) [39]. The different PEARL studies [13–16] clearly demonstrated that the changes are benign and reversible.

Use of UPA for Preoperative Management of Uterine Fibroids: Results from PEARL I and PEARL II Clinical Trials

PEARL I [13] was a randomized, double-blind, placebo-controlled trial evaluating 3-month treatment with UPA tablets (5 or 10 mg daily) in women with symptomatic fibroids, excessive uterine bleeding and anemia. By 13 weeks, uterine bleeding was under control in more than 90 % of women receiving 5 mg UPA, or 10 mg UPA (Fig. 131.3a). More patients achieved correction of anemia (hemoglobin >12 g/dL) by the end of the 3-month treatment period. This effect is of high clinical relevance, given that it has been well documented that preoperative anemia , even to a mild degree, is associated with an increased risk of morbidity and mortality in patients undergoing surgery [40].

In a similar setting, PEARL II [14] compared 5 and 10 mg UPA tablets with the existing standard medical treatment with GnRHa (3.75 mg leuprolide acetate depot injection once monthly).

The key findings of this study demonstrated that uterine bleeding was controlled in 90 % of patients receiving 5 mg UPA, 98 % of those receiving 10 mg UPA, and 89 % of those receiving leuprolide acetate. Median times to controlled bleeding were 5–7 days for patients receiving UPA (5 and 10 mg respectively), and 21 days for those receiving leuprolide acetate. In both UPA groups, plasma estradiol levels were maintained in the mid-follicular range, while patients in the leuprolide group on average showed a significant reduction to postmenopausal levels.

Follow-up in a subgroup of women who did not undergo surgery after the 3-month study period showed that UPA had a sustained effect (up to 6 months) after the end of treatment (Fig. 131.3b). By contrast, GnRHa-treated women experienced rapid regrowth of fibroids, reaching almost pre-therapy dimensions by 6 months post-treatment. Key efficacy results from the PEARL I and II trials are summarized in Fig. 131.3.

Long-Term Medical Management of Uterine Fibroids: Results of PEARL III and PEARL IV Clinical Trials

Thanks to the sustained effect observed in PEARL I and II, additional intermittent courses of 12-week UPA treatment with off-treatment intervals are a potential option for the long-term medical management of fibroids.

The **PEARL III** study [15] was designed to evaluate the efficacy and safety of long-term intermittent open-label 3-month courses of 10 mg/day UPA for the treatment of symptomatic uterine myomas, each course followed by randomized, double-blind treatment with norethisterone acetate (NETA) or a placebo in order to explore any effect on the reversibility of PAECs or timing and magnitude of the next off-treatment menstruation.

After the first UPA course, amenorrhea occurred in 79 % of women. Amenorrhea rates were respectively 89 %, 88 %,

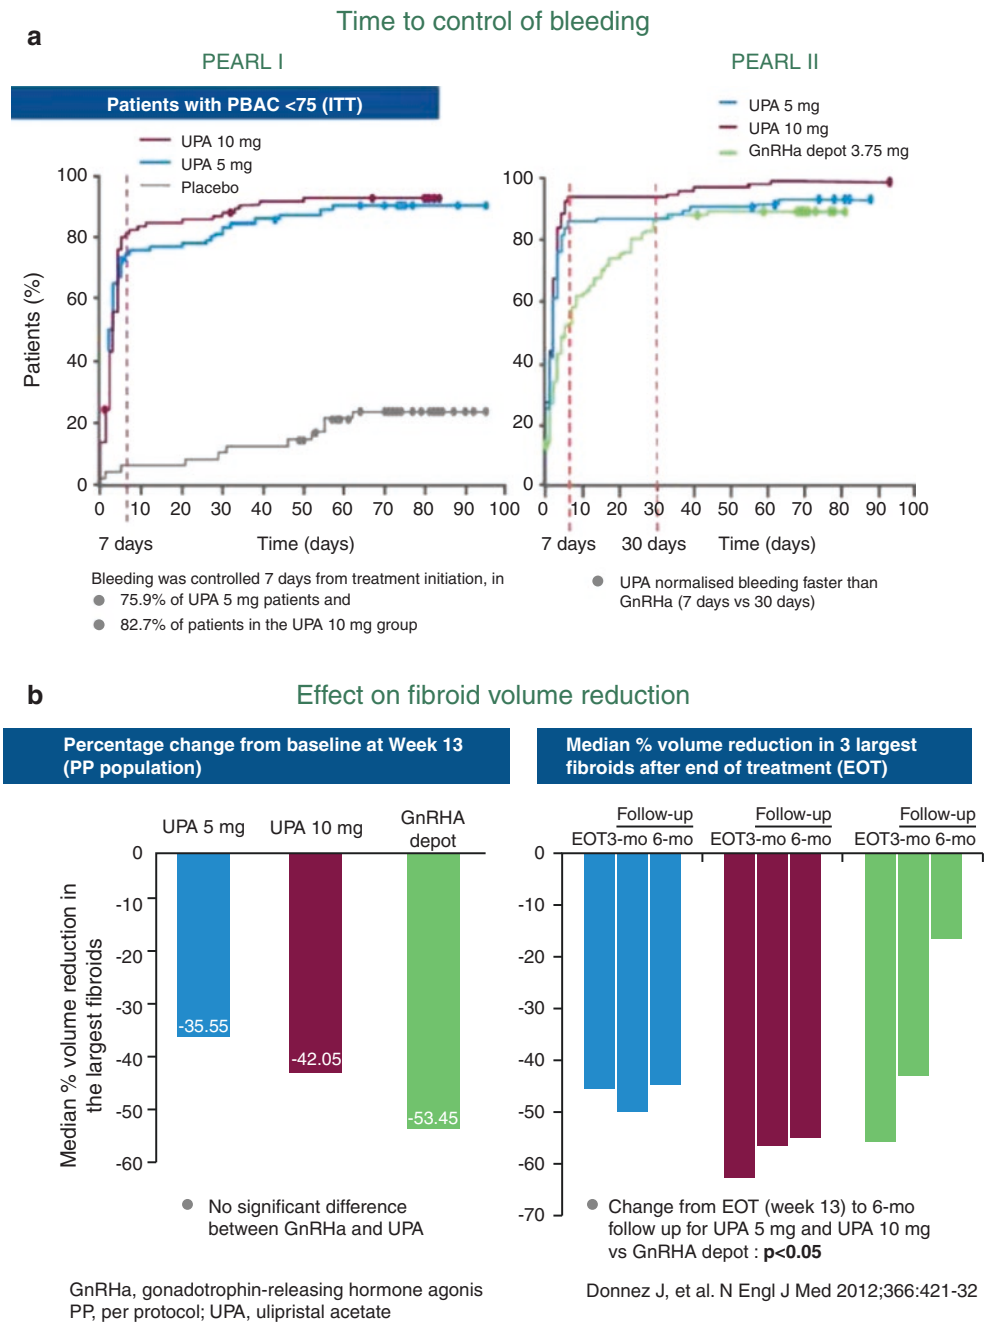

Fig. 131.3 Effects of UPA on bleeding control (**a**) and on fibroid volume reduction (**b**) (From Donnez et al. [13], Copyright © 2012 Massachusetts Medical Society, reprinted with permission from Massachusetts Medical Society; and Donnez et al. [14], Copyright © 2012 Massachusetts Medical Society, reprinted with permission from Massachusetts Medical Society)

and 90 % in women who received 2, 3 and 4 treatment courses. Median time to amenorrhea was 3.5 days from the start of treatment.

Median fibroid volume reduction from the baseline was 49.9 %, 63.2 %, 67.0 %, and 72.1 % after 1,2, 3, and 4 treatment courses respectively (Fig. 131.4).

All endometrial biopsies showed benign histology without hyperplasia [39]. NETA did not affect fibroid volume or endometrial histology, including PAECs. A 10-day course of progestin, administered immediately after each UPA treatment course, was associated with a significantly reduced and earlier occurrence of menstrual bleeding during off-treatment periods. However, these findings are probably insufficient to suggest that progestins should be routinely used in conjunction with UPA treatment, unless there is a need to control the timing or amount of menstrual bleeding, for example, before a planned invasive procedure.

In conclusion, the results of PEARL III and its extension study indicate that administration of more than one course of UPA maximizes the potential benefits of treatment in terms of bleeding control and fibroid volume reduction, while the association of NETA is of limited clinical benefit.

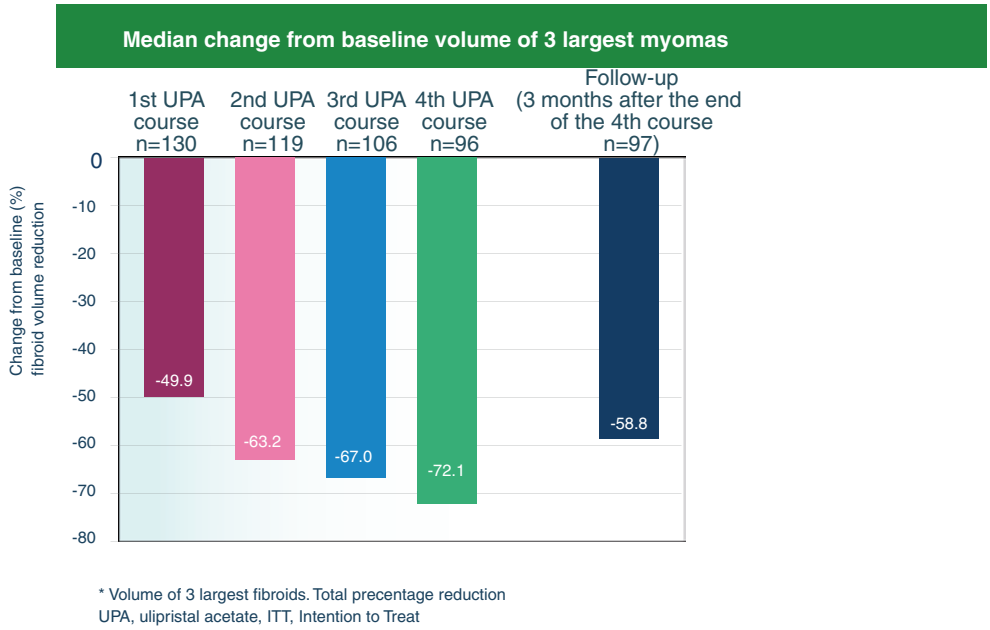

Fig. 131.4 Fibroid volume reduction in the PEARL III trial (Reprinted with permission) (Reprinted from Donnez et al. [15], Copyright 2014, with permission from Elsevier)

The last clinical trial, PEARL IV [16], investigated the efficacy and safety of repeated 12-week courses of 5 or 10 mg UPA daily for intermittent treatment of symptomatic uterine fibroids. In the 5 and 10 mg treatment groups, respectively 62 % and 73 % of patients achieved amenorrhea. The proportion of patients achieving controlled bleeding was indeed >80 % in both cases. After the second treatment course, the median reduction in fibroid volume from the baseline was 54 % and 58 % in patients receiving 5 and 10 mg UPA respectively. Pain and quality of life improved in both groups.

Based on these results, the dose of 5 mg should be recommended.

Will Intermittent Use of UPA Change our Approach to the Management of Uterine Fibroid?

Because SPRMs are now available and have proved effective, it is time to focus on a very important question: what is the remaining role of surgery with the advent of these drugs?

If surgery remains indicated, do these drugs enable less invasive surgery? Indeed, the real question is whether SPRMs (UPA) allow less invasive surgery or complete avoidance of surgery.

So the question remains open: will intermittent use of UPA change the approach to the management of uterine fibroids? To answer this question, it is important to consider the factors influencing the choice of therapy, such as the severity of symptoms (pain, bleeding), infertility related to myomas, tumor characteristics (volume, localization), age, wish to preserve the uterus, and wish to preserve fertility. Based on these factors, two new treatment algorithms can be proposed:

Women < 40 Years of Age Presenting with Symptomatic Myomas Distorting the Uterine Cavity and Infertility (Fig. 131.5)

If type 0 myomas (FIGO classification) are present, cutting the pedicle by hysteroscopy is indicated and no preoperative treatment is required [20]. For type 1 myomas (<3 cm), two options exist: either hysteroscopic myomectomy or UPA treatment in one or two courses of 3 months, followed by hysteroscopic myomectomy in case of inadequate response. In the majority of cases, hysteroscopic myomectomy for type 1 myomas is relatively easy to perform.

If (as is often the case) myomas are of type 1 but larger than 3 cm, or of type 2, UPA may be given in one or two courses of 3 months. Type 1 and 2 myomas often respond to this preoperative therapy and regress in size. This reduction allows a hysteroscopic approach that can be planned after the first menstrual bleed induced by NETA (10 mg/10 days), administered immediately after UPA treatment [20]. It should be pointed out that in some cases (if myomas regress so much that they no longer distort the uterine cavity), surgery may not be required. If the myomas are multiple (two to six) or of different classes (class 2–5), as is frequently observed, UPA can be given in two courses of 3 months.

After these two courses of 3 months, there are four possible outcomes:

1. Myoma regression is very significant (>50 % decrease in volume). The uterine cavity is no longer distorted, and the patient can try to conceive naturally or undergo assisted reproductive techniques, if indicated. Recently, a first series of pregnancies after UPA was reported [41] (Figs. 131.6 and 131.7).

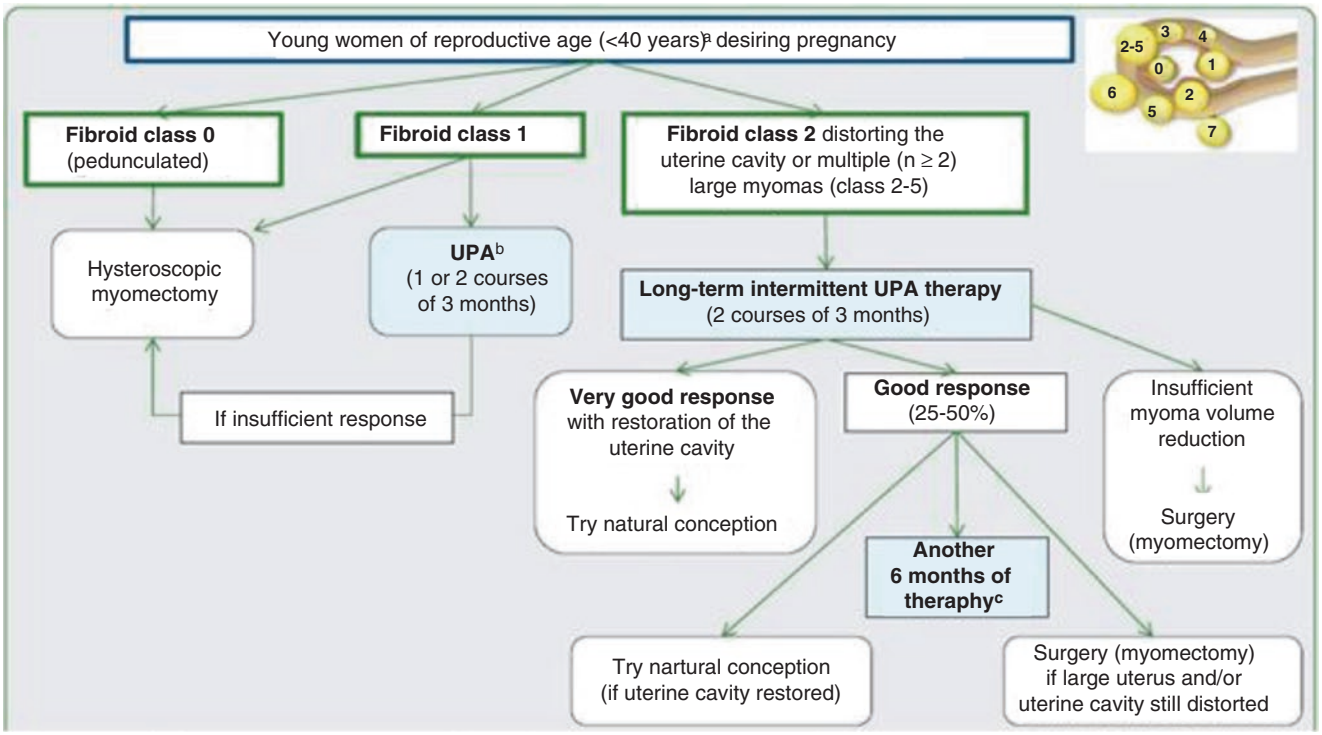

Fig. 131.5 Women <40 years presenting with symptomatic myomas distorting the uterine cavity and infertility. [a]After 40 years of age, any discussion about medical or surgical therapy should take into account the ovarian reserve and possible delay due to medical therapy. [b]Depending on the size (Reprinted from Donnez et al. [20], Copyright 2014, with permission from Elsevier)

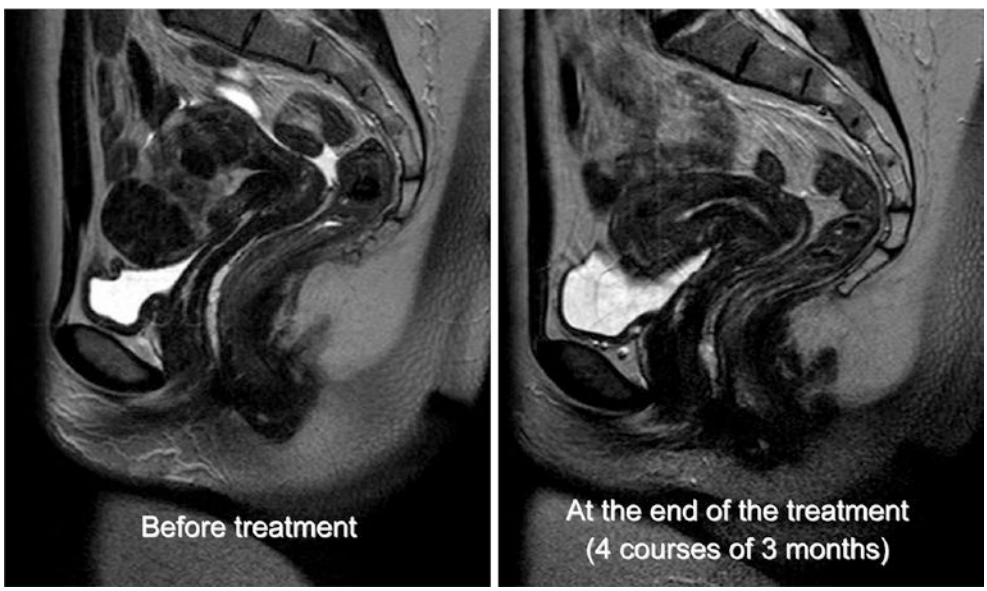

Fig. 131.6 After four courses of 3 months, myoma disappeared

2. Myoma regression is significant (>25 % but <50 %), but the baseline volume is so great that the indication for surgery remains. In this case, UPA may allow surgery to be performed by a laparoscopic approach once the hemoglobin level is normalized, avoiding laparotomy.
3. Myoma regression is moderate (>25 % but <50 %), but the uterine cavity remains distorted. In this instance, two options should be discussed with the patient: either [1] prolong medical therapy for another two courses of 3 months or [2] proceed with surgery.
4. Myoma regression is insufficient. Surgical indications should then be followed according to the size and site of myomas and treatment needs.

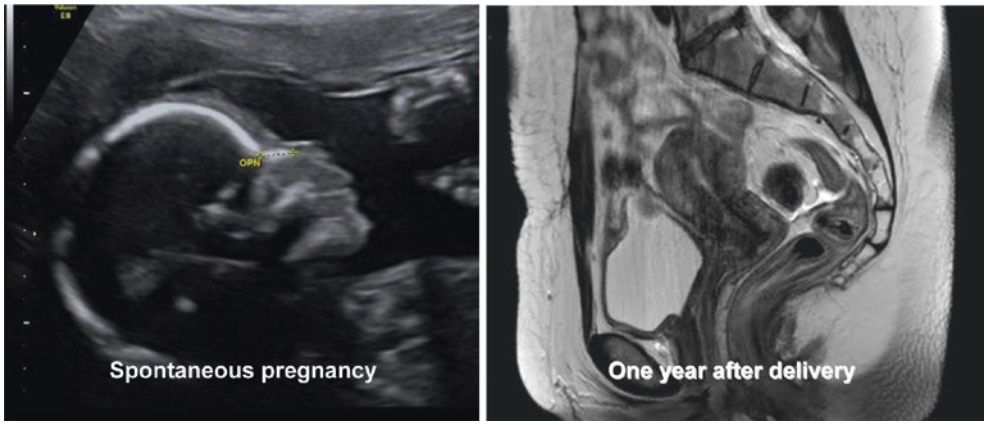

Fig. 131.7 The patient was pregnant and delivered. There was no regrowth during pregnancy. One year after delivery, the uterus was normal as well as the uterine cavity

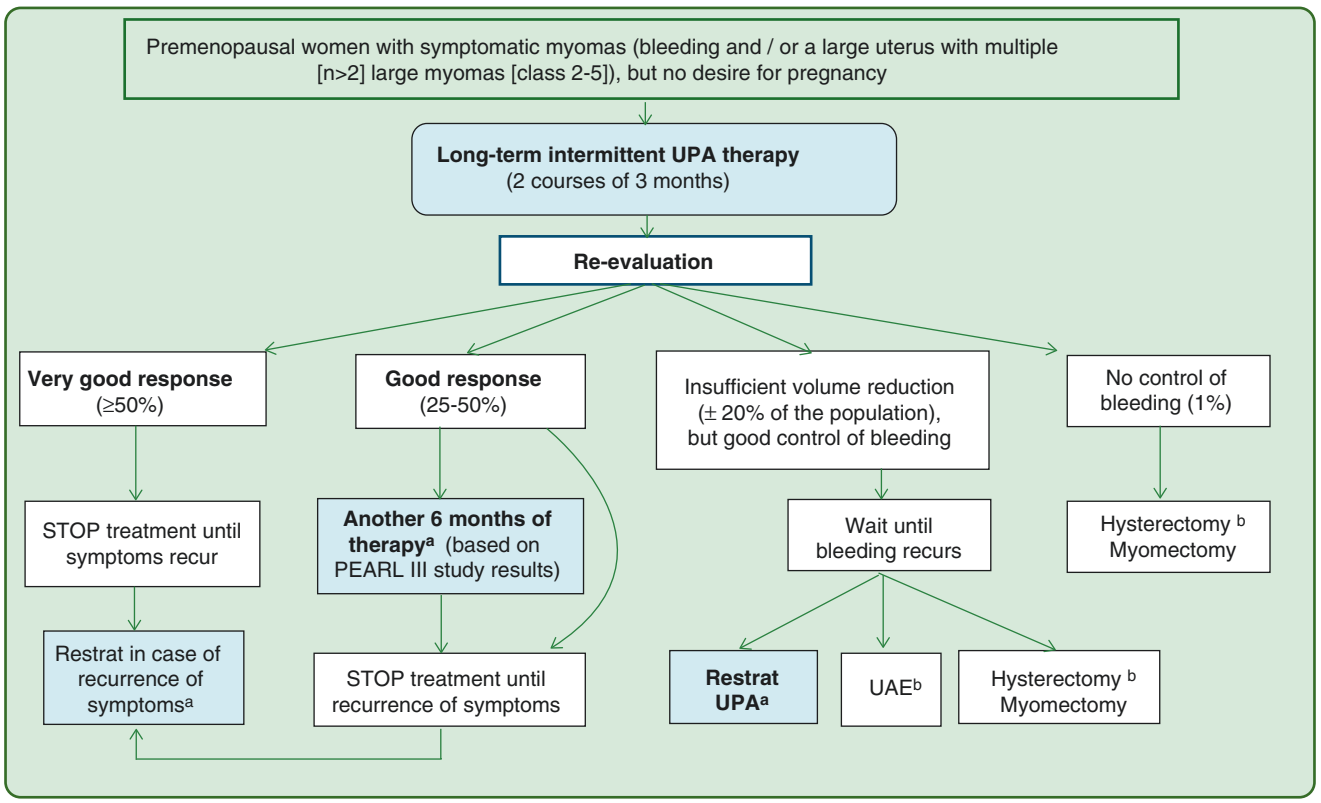

Fig. 131.8 Premenopausal women presenting with symptomatic myomas but no desire for pregnancy who wish to keep their uterus. [a]Currently approved. [b]Depending on wish to preserve fertility (Reprinted from Donnez et al. [20], Copyright 2014, with permission from Elsevier)

Premenopausal Women Presenting with Symptomatic Myomas but no Desire for Pregnancy, Who Wish to Keep Their Uterus (Fig. 131.8)

If type 0 or type 1 myomas are present, the algorithm in Fig. 131.1 can be applied. In case of type 2 fibroids distorting the uterine cavity or multiple (R2) large myomas (class 2–5), long-term intermittent therapy may be proposed in the knowledge that the PEARL-III study clearly demonstrated that repeated courses of UPA maximize the effect. If after two courses of 3 months myoma regression (>50 %) is such that the patient is free of symptoms, she can be observed until symptoms recur. Further courses of UPA may then be proposed. No data are so far available to determine the interval before recurrence, but a sustained effect was observed after treatment completion [14–16].

This proposed treatment could well prove beneficial in some instances. Indeed, if a young woman of 20 years were to present with multiple myomas and severe bleeding, she

could undergo UPA treatment not only to restore hemoglobin levels, but also to avoid surgery. It is well known that myomas frequently recur after myomectomy (25 % after 3 years), especially in young patients with a genetic predisposition, such as the African population. By treating these women medically, repeated surgery responsible for pelvic adhesions and subsequent infertility, as well as the risk of uterine rupture during pregnancy, may be avoided.

We are not suggesting that UPA will eradicate all indications for myomectomy, but it does mean that surgery can be avoided in case of a very good response, or at least be postponed until the patient wishes to become pregnant. In case of insufficient fibroid volume reduction or persistent bleeding, surgery (myomectomy) is indicated.

In premenopausal women with symptomatic myomas, long-term intermittent therapy may be proposed. In case of a moderate response (>25 but <50 % reduction), another two UPA courses can be given based on the results of the PEARL-III study , which showed that efficacy can be maximized this way. However, stopping UPA treatment until recurrence of symptoms may be considered another option.

In case of insufficient response in terms of fibroid reduction but good control of bleeding, it may be feasible to wait until bleeding recurs. In this instance, restarting UPA treatment or performing hysterectomy or uterine artery embolization may be three different options. In case of persistent heavy bleeding (1 % of the intent-to-treat population), surgery is of course indicated.

In conclusion, among the latest possible therapeutic options [32], UPA has proved to be most effective for the medical management of fibroids and will undoubtedly serve to modify the surgical approach.

Acknowledgments The authors thank Mira Hryniuk, BA, for reviewing the English language of the manuscript and Deborah Godefroidt for the secretariat help.

Part XIII

Future Perspectives

Future Perspectives in Hysterectomy

132

Artin Ternamian and Liselotte Mettler

Introduction

Hysterectomy has been practiced for different reasons over centuries and despite contemporary medical and surgical advancements, there remains marked regional and international differences in hysterectomy rates, methods and costs.

Although universally accepted evidence based indications, practice guidelines and less disabling contemporary remedies, there appears to be no consensus on what constitutes an acceptable operative rate, as significant global, national, regional and practitioner differences continue to render this most important health index elusive.

Considering that hysterectomy remains the second most frequently performed major gynecological operation after Caesarean Section, it is important that we invest time and effort to better understand why such differences remain, so as to better advise our patients, improve quality of care, manage health funds and fulfill our societal and academic obligations.

Globally, women stand a 20–40 % life time risk of having a hysterectomy for benign, non-life threatening medical conditions; where prevalence variances, reflect local clinical practice patterns rather than pathological differences between regions.

While academic institutions and health organizations grapple with integrating emerging technologies and contemporary surgical remedies, in an ever expanding and changing teaching curriculum; it remains critical to remember that a considerable number of conditions that used to require extirpative surgery, have now alternate non-surgical, cost effective and less disabling remedies.

As Gynecology heads towards an uncertain future, when societal expectations are shifting, national practice guidelines are changing and payer scrutiny is ubiquitous, our discipline should be leery of investing precious, ever shrinking health and education resources, on training surgical technocrats who deliver *outdated remedies* using *innovative technologies*, to well informed clients, under the watchful eyes of learned health executives.

It is clear that new technology cost scrutiny and its impact on health outcomes may undermine unchecked expansion and adoption of emerging surgical technologies and innovations, as risk-based pressures and quality indicators heighten emphasis on competency standards.

Historical Perspective

The earliest recorded emergency hysterectomy is purported to have been performed by Themision of Athens in 50 BC.

Often, patients developed fistulas, infections and subsequently succumbed as these procedures inadvertently excised part of the patient's bladder.

By 1880, abdominal hysterectomy became common practice; however, mortality remained high, close to 70 %. Eventually, advances in blood transfusion, anesthesia, antibiotics and operative methods led to hysterectomy becoming a widespread and much safer operation.

Mortality rates following hysterectomy improved steadily and by 1910 the rates had dropped to 2.5 % for vaginal hysterectomy, while rates for abdominal hysterectomy lagged behind, until early in the twentieth century, when subtotal abdominal hysterectomy was practiced, and post operative mortality rates toppled to 3.5 %. Eventually this trend got replaced in the 1950s, by total abdominal hysterectomy and the mortality rates of both vaginal and abdominal hysterectomy settled to about 0.1 % [1].

Global Perspectives

Several decades of improved patient safety, enhanced surgical methods and innovative operative techniques resulted in a significant global increase in the number of surgical operations performed; by mid 2000, hysterectomy became the most common major gynecologic surgery performed. According to the United States National Center for Health Statistics-CDC, 617,000 hysterectomies were performed in 2004, with 73 % having an oopherectomy as well [2].

This corresponds to an annual 20 % hysterectomy rate by 40 years of age, 33 % by 65 year of age and a staggering 43 % by 85 years of age for United States women [3–5].

Interestingly, lifetime risk of having a hysterectomy differs considerably between countries and regions alike. In Europe, there are about 100,000 hysterectomies performed every year in the United Kingdom [6], 60,000 in France [7], 10,000 in Finland [8] and about 5000 in Denmark [9]. The annual hysterectomy rate ranges from a high of 3.7 per 1000 Italian women [10], to a low of 1.8 per 1000 Norwegian women [11]; comparatively the rate is much different in the United States, with a rate of 5.38 per 1000 women per year [12].

According to the Centers for Disease Control and Prevention (CDC), United States women appear to have the highest hysterectomy rates in the entire industrialized world and rates remain higher on the West compared with the East Coast [13].

Measuring and interpreting global hysterectomy rates as straight comparisons of national rates is often difficult if not misleading; as significant differences in definition and interpretation exists. When publishing hysterectomy rates, considerable variances in the choice of numerators exist; authors may include or exclude outpatient operations, may refer to all procedures or include operations for benign disease only, and denominator may include women of all ages or those of a specific age group, among others.

Given that a majority of hysterectomies are performed electively, for non-malignant reasons, some have suggested that 10–90 % of hysterectomies performed in the United States may not be medically necessary [14].

At this point, it is difficult to explain which of these operative rates is 'correct' and why an observed fourfold difference in incidence exists; however, it is clear that most of these non cancerous surgeries are performed for treatment of uterine fibroids, abnormal uterine bleeding (AUB), pelvic organ prolapse (POP) or endometriosis (chronic pelvic pain).

Although we do not understand the exact etiology why these condition occur, it is clear that an ever increasing menu of conservative non-surgical treatment options are developed that have proven to be less disabling and more cost effective.

As risk based pressures mount and yearly total hospital costs for operative procedures near five billion US dollars, administrators, quality improvement specialists and health policy experts will increasingly question use of operative remedies to treat benign conditions, when non-surgical treatments exist [15, 16].

Although alternative remedies, careful application of "appropriateness criteria" and a host of other societal factors helped decrease the overall hysterectomy rate, their overutilization is purported to remain between 16 and 70 % [17].

Our practice patterns do not appear to be concordant with current American College of Obstetricians and Gynecologists (ACOG) clinical practice guidelines, where non-surgical and uterine-sparing alternatives to hysterectomy are espoused (Table 132.1). [18].

It is no wonder that more recent USA hysterectomy statistics reflect this downward trend, to about 400,000 inpatient procedures performed annually, where one in three North American women are expected to have a hysterectomy by the time they turn 60 years old [12, 19, 20].

Notwithstanding this marked drop in hysterectomy rates, appropriateness of all methods of hysterectomy remains an important national quality improvement concern that deserves serious consideration, before further time and resources are invested in adopting prohibitively costly newer operative remedies.

Table 132.1 American College of Obstetricians and Gynecologists (ACOG) clinical practice guidelines

Summary of Recommendations & conclusions based on limited or inconsistent scientific evidence (Level B)
Levonorgestrel IUD effective in AUB & should be considered for all age groups
Medical treatment options for AUB-O (oligo-ovulation or anovulation) include progestin therapy & combined hormonal contraceptives
Women who completed childbearing, were medical therapy failed, or have contraindications to medical therapy are candidates for total hysterectomy
As AUB-O is endocrinologic abnormality, underlying disorder should be treated medically instead of surgically. Surgical therapy rarely indicated for AUB-O, unless medical therapy fails, is contraindicated, is not tolerated or patient has concomitant intracavitary lesions
Following recommendations & conclusions based primarily on consensus and expert opinion (Level C)
Medical management failure requires more investigation, including imaging or hysteroscopy
Choice of treatment of AUB-O guided by goals of therapy, which may be to stop acute bleeding, avoid future irregular-heavy bleeding, simultaneously provide contraception & prevent complications, such as anemia, unnecessary surgical intervention & diminished quality of life
Endometrial ablation not recommended as first line AUB-O therapy
Physicians must provide thorough informed consent & adequate counseling to women with AUB-O who desire endometrial ablation

Practice Bulletin No. 136. Non-surgical and uterine-sparing alternatives to hysterectomy

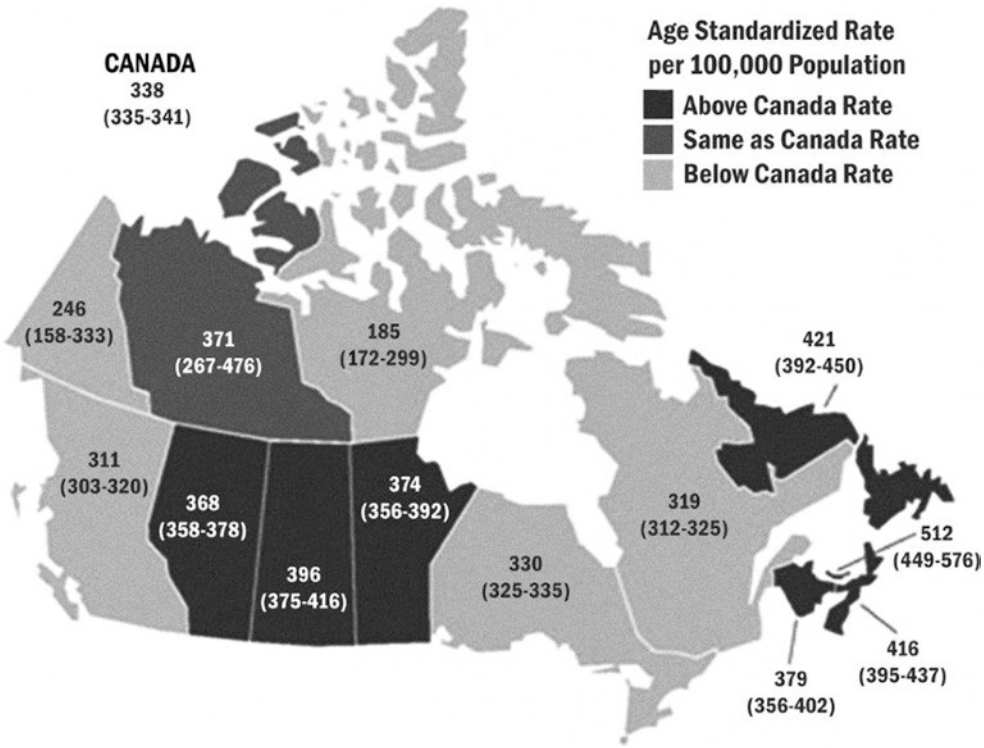

Fig. 132.1 Age-Standardized Hysterectomy Rates by Province & Territory, Canada, 2008–2009. Hysterectomy Rate: 338/100,000 women aged 20 years or older, down from 484/100,000 women in 1997 (By permission of the Canadian Institute for Health Information, Health Care in Canada 2010)

In a recent publication, Corona et al., observed that the commonest indication for hysterectomy in the USA remains AUB and an effective treatment for this condition is use of the Levo Norgestril medicated intrauterine device (Mirena ®); however, its use is greatly underutilized.

Given that as much as 18 % of surgical pathology results fail to demonstrate need for a hysterectomy, they remain convinced that if ACOG practice guidlines are carefully followed, further decrease in hysterectomy rates is real and attainable [21].

The situation in Canada is similar to its southern neighbor, although Canadian hysterectomy rates for benign and malignant gynecological conditions have gradually slumped since early 1980s; it remains the second-most frequently performed operation on women, second to Caesarean Section [22].

According to the Canadian Institute for Health Information, the most recent 2012-2013 figure is 47,127 operations; about 338 hysterectomies for every 100,000 women age 20 years or older, down from 484 per 100,000 women in 1997 (see Fig. 132.1).

Although evidence-based national clinical practice guidelines are published and hysterectomy indications are clearly articulated in Canada, considerable differences abound among provincial hysterectomy rates [23, 24].

These age-standardized hysterectomy rates differed threefold inter-provincially, ranging from a low of 185 per 100,000 in Nunavut to a high of 512 per 100,000 women age 20 or older in Prince Edward Island.

The west coast province of British Columbia has the lowest rate among all regions; 311 per 100,000. These rate variations may indicate differences within and between jurisdictions in care provider culture, patient expectations, practice patterns and approaches to this operative remedy [22, 25].

Besides considerable inter-provincial variation, age-standardized hysterectomy rates are more frequent for women living in rural areas; 464 per 100,000, compared to those living in urban areas; 318 per 100,000 women. These rate differences may be due to urban area dwellers having better access to alternate non-operative treatment options, compared to rural dwellers. Most urban dwellers elected to have a hysterectomy due to uterine myomas whereas rural dwellers for menstrual disorders [22].

Irrespective, when clinical practice fails to follow evidence-based guidelines and clinical consensus, questions about inappropriate practice patterns and quality assurance-may be suggested.

Current guidelines do not provide a benchmark for hysterectomy rates to be measured against; though, rate variation itself may suggest overuse in some jurisdictions and underuse in others [26]. Contemporary clinical guidelines provide clear recommendations on how to best treat benign gynecological conditions, where hysterectomy is touted as being one of several less disabling options.

Despite significant decline in the overall hysterectomy rate in Canada between 2000–2001 and 2006–2007 (22 %), clearly there remains considerable variation across the country and there is plenty of work to be done, to further improve treatment of benign gynecological conditions.

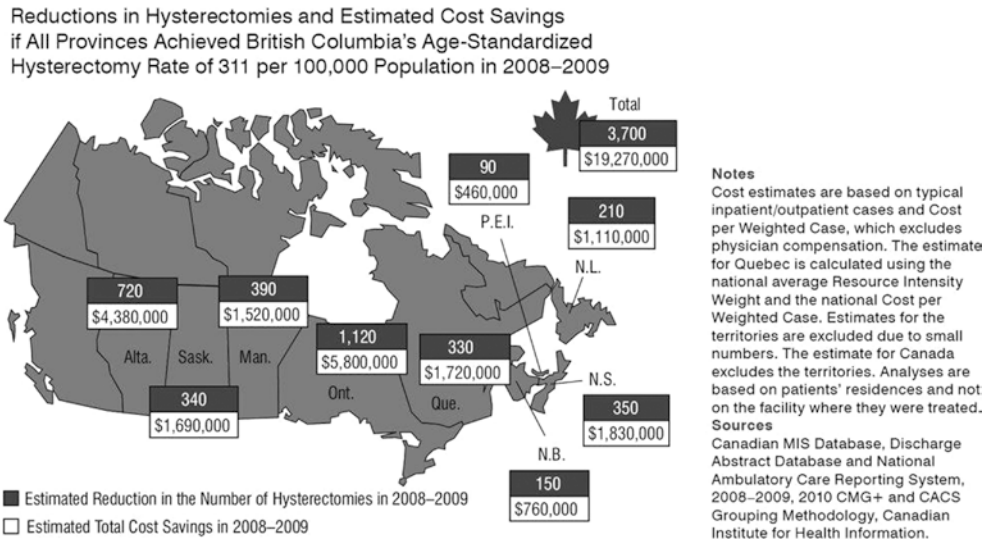

Fig. 132.2 Reductions in Hysterectomies and Estimated Cost Savings if All Provinces Achieved British Columbia's Age-Standardized Hysterectomy Rate of 311/100,000 population in 2008–2009. Hysterectomy Rate reduction results on health care cost (By permission of the Canadian Institute for Health Information, Health Care in Canada 2010)

In general, evaluating how much rate reduction will impact quality of care and health care costs is challenging. If all Canadian provinces had similar hysterectomy rates as the west coast province of British Columbia (*311 per 100,000 women*), there would be around 3700 hysterectomies performed nationally, an 11 % reduction; resulting in >19 million $CD in hysterectomy hospitalization savings, of an estimated total hospitalizations cost, 2008–2009, of 192 million $CD (see Fig. 132.2) [22].

Globally, there is a growing perception that some hysterectomies are performed unnecessarily and in many cases, too many are carried out overall, without offering women available non-surgical or at the very least less invasive surgical options to remedy non-malignant gynecological conditions [15].

In 2002, The Ontario Women's Health Council suggested a road map to reduce hysterectomy rates in the province that include; offering non-surgical medical alternatives prior to entertaining surgery; empowering and educating women about available treatment options and access to contemporary medical and non-extirpatory surgical remedies; implementing regular quality assurance checks, such as internal and external chart audits, with feedback on appropriateness of practice; and ongoing continuing professional education for practicing gynecologists, about new surgical and non-surgical alternatives to hysterectomy [27].

In Germany, like elsewhere in the world, about 80 % of hysterectomies are performed to treat non-malignant gynecological conditions [28–30].

National hysterectomy rates have shown regional differences as well; where the prevalence is higher in West compared to East Germany. As elsewhere, there is an inverse association between levels of education, employment and prevalence of hysterectomy [31, 32].

Although population-based hysterectomy rates in the 16 Federal German States between 1970-2004, are not available, their hysterectomy rate appears to have remained relatively stable to 2006, when a total of about 149,456 operations were performed, among a population of 42 million women. Those between ages 40 and 49 accounted for 50 % of hysterectomies, while those between ages 50 and 59 accounted for 20 % [33].

More recently, in 2007, the number of hysterectomies performed decreased slightly to 138,164 operations [34]. It is suggested that introduction of emerging non-operative advancements and wider adoption of endoscopic remedies, may have influenced this recent downward trend [35].

A recent nationwide German analysis indicated that the peak hysterectomy rate remains between 44-47 years of age [36]. Admittedly, prevalence-corrected, age-standardized hysterectomy rates provide more accurate statistics on use of this form of therapy.

Although hysterectomy rates in Britain have slowly fallen over the last few years (42/100,000 population) and is now lower than North America and some European countries, they suffer from similar widely varying rates between regions and individual gynecologists.

It is difficult to explain these disparities as several factors determine the lower hysterectomy rate including health care resource differences; compensation plans; surgeons' attitudes; health care organization variances and differences in patients' expectations.

The 2006 UK Chief Medical Officers Report suggests that one in five women will have a hysterectomy by age 60 and about 20 % will have had their ovaries removed as well. The main recommendation of this report is to develop clear clinical guidelines for hysterectomy based on evidence based criteria and empower women to make informed choices [37].

In England, 38,000 hysterectomies were performed 2004-2005 and a great majority of them were performed for non-cancerous benign conditions [38].

The commonest reason for surgery was AUB, which accounted for 46 % of all hysterectomies; pelvic organ prolapse accounted for 20 %, while uterine myomas for an additional 18–21 % [6].

As in other jurisdictions, UK hysterectomy rates are inversely related to social class and education with sizeable geographic regional variations in operative rates, where lower socio-economic regions demonstrated a higher hysterectomy rates compared to more affluent areas [39].

The Royal College of Obstetricians and Gynaecologists give the following recommendation on hysterectomy for AUB; hysterectomy of all forms, remain an effective and established remedy for menorrhagia, however; its use should be tempered by societal norms, costs and potentially serious morbidity and mortality [40]. Admittedly, conventional dilatation and curettage may not be therapeutic, whereas outpatient endometrial ablative remedies are.

The 2006 Cochrane review on hysterectomy conceded that vaginal hysterectomy should take precedence over abdominal hysterectomy whenever possible, as it is clearly less disabling and associated with less morbidity; at the time, no outstanding benefit was observed with laparoscopic hysterectomy over vaginal hysterectomy, although laparoscopic approach appeared to have a longer operative time [41].

The present health care cost implications as it relates to hysterectomy cannot be overstated. On average, surgical cost for this surgery is about £2362, whereas Levo Norgestril medicated intrauterine device (Mirena ®), including insertion and removal fees is about £227; resulting in an annualized cost of £70 to the National Health Services, which is significantly less than the cost of hysterectomy.

Given that about three-quarters of hysterectomies are performed for non-cancerous AUB, it is clear that a good percentage of these can be managed successfully by less invasive, non-surgical remedies, averting close to 34 % of non-cancerous hysterectomies; incurring a significant amount of health care savings [42].

An exact cost comparison between hysterectomy and use of some of the more recent medical remedies, such as selective progesterone receptor modulators (SPRMs), is not readily available; however, they are not inexpensive at the moment. Their ability to reversibly block progesterone receptors in target tissues such as endometrium and act quickly as a potent, orally active anti-progestational agent, promises to be an important additional medical treatment option available.

Besides, irrespective of surgical method, hysterectomy is not without its own risks, the literature suggests that one in 30 women will have intra-operative complications, while one in ten patients can succumb to post-operative complications of all sorts [6].

Additionally, the VALUE study demonstrated that of the 46 % of patients having a hysterectomy for AUB; only 4 % of women had a less invasive endometrial ablation-resection attempt.

A majority of women with AUB with non-malignant gynaecological pathology, can be successfully treated with a variety of less invasive endometrial ablative remedies and use of non-extirpative techniques, forestalling up to 75 % of hysterectomies [6].

Irrespective, uterus removal with whatever means or method will remain a desirable option for some women, as about half of women who try the Levo Norgestril medicated intrauterine device (Mirena ®), go on to have a hysterectomy [43].

Given that vaginal hysterectomy is less disabling than abdominal hysterectomy, one would expect that it is the commonest method used by gynecologists, however the VALUE study demonstrated that, like in many developed countries, more than two third of hysterectomies are still being performed abdominally [1, 6].

The newer minimally invasive surgical methods in all its forms, including robotically assisted and single port hysterectomy, show promise but no evidence of a clear advantage over vaginal hysterectomy; additionally, they appear to require longer operative time [44].

Generally, a small minority of patients find long-term medical treatments compatible with their expectations and more than half who start oral medication, progress on to having a hysterectomy [45].

In Northwestern European countries, hysterectomy remains the commonest gynecological operation; their rate has been relatively stable though a resent slow decreas is observed.

The Netherlands appears to have a low hysterectomy rate compared to other developed industrialized countries, *(1995–2005, average yearly crude hysterectomy rate, for benign conditions only; 17.2 per 10,000 women of all ages),* where a significant, 50.8 % are performed vaginally; they remain convinced that given their regional differences, further decrease in hysterectomy rate is possible and further increase in vaginal hysterectomy proportion is feasible [46].

Not only is hysterectomy rates in the Netherlands low when compared with other Western countries, those operations performed specifically for AUB, dropped by about a quarter percent between 1995 and 2005. It is suggested that this substantial decrease is mainly because of introduction of less invasive contemporary treatment alternatives, such as endometrial ablation-resection, interventional Magnetic Resonance guided Focused Ultrasound myoma ablation, uterine arteries embolization and Levo Norgestril medicated intrauterine device (Mirena ®), among others [44, 47–49].

The same is true in Denmark and other Scandinavian-Nordic countries, where hysterectomy rates for benign conditions remained steady for several decades and now appears

to have further declined slightly for similar reasons [50–52]. Admittedly, their operative rates are much lower (lifetime hysterectomy prevalence is only 10.4 %), than reported rates from North America [53], and Germany [36].

As European society embraces increasing numbers of immigrants from different parts of the world and become less homogenous, women of different ethnicity will influence their future operative rates; women of African ancestry, will have a higher incidence of uterine fibroids, with associated increased prevalence of AUB, requiring treatment [54, 55].

As in other jurisdictions, women's socio-economic status appears to determine operative rates; women with a lower socio-economic status are more likely to have a hysterectomy [56, 57].

Several papers indicate that despite the fact that socio-economic and ethnic demographics account for variances in hysterectomy rates within and among nations, operative rates and surgical method is also influenced by gynecologist's training, age, academic setting and compensation structure [58–60].

When analyzing hysterectomy rates for a specific benign condition like pelvic organ prolapse, several papers from Denmark, Sweden, UK and USA, demonstrated a marked increase is the vaginal hysterectomy rates [50, 53, 61–63].

It is suggested that this increase of hysterectomy for POP could be attributed to changes in patent's attitude or a higher prevalence of POP risk factors, such as obesity and delivery of larger size babies [64].

While reliable hysterectomy rates for benign disease and related statistics is published in industrialized countries such as Australia, Canada, North Europe and the United states, consistent data from Southern and Eastern European countries, are difficult to compile or compare, given their different reproductive and socio-cultural environments.

A paper by Materia et al., studied the connection between inpatient hysterectomy rates for benign disease and socio-economic status in the city of Rome, they determined that the operative rate for all methods was 30.2 per 10,000 women aged 35 years or more.

They demonstrated that affluent women may receive minimally invasive remedies, compared with those from a lower socio-economic status; that are more prone to undergo unnecessary hysterectomies irrespective of their reproductive age [10].

As elsewhere, the overall hysterectomy rates in Northern Italy has steadily declined over the last decade, where younger patients <55 years had their surgery for treatment of fibroids and older ones for POP; with a considerably increased incidence of vaginal hysterectomy route and a marked decrease in abdominal hysterectomy rates [65].

These changes are ascribed to a widespread use of hysteroscopic ablative methods where the number of these procedures increases significantly during the same time [66, 67]. Interestingly, the impact of Levo Norgestril medicated intrauterine device (Mirena ®) is less clear, as intra uterine contraceptive device use in Italy, has been notoriously very unpopular.

Hysterectomy rates elsewhere in the non-industrialized or underdeveloped world is more challenging to estimate and nuanced to interpret, let alone to compare. Although isolated centers of health-care excellence exist; large populated regions of Asia or Africa, have precarious health care systems, where local practice statistics are inaccessible and rates difficult to measure [68].

In a paper by Chao et al., a panel of experts reviewed claims submitted to the Taiwan National Health Insurance Bureau; discovered that about 75 % of women had hysterectomy for apparent acceptable reasons, 5 % for uncertain reasons and 20 % for inappropriate reasons. These latter operations were mostly performed in younger women for chronic pelvic pain (42.9 %), AUB (37 %), and endometriosis (27 %).

Their study reveals a significantly high hysterectomy rate in Taiwan and urges better patient selection, as these operative interventions, irrespective of method, results in increase patient morbidity, mortality and health-care costs [69].

In an effort to improve quality of care and control escalating health-care expenditure, the Taiwan National Health Insurance Bureau, introduced a simplified case payment system, based on diagnosis-related groups (DRG); compensating health centers at a fixed rate for certain surgical procedures and related inpatient care, determined according to hospital accreditation level.

So as to steer gynecologists towards less invasive methods, laparoscopically assisted and conventional non-laparoscopic total hysterectomy, are defined in the payment plan by the Bureau of NHI as separate procedure items; where reimbursement for the former method is approximately 1.5 times that of non-laparoscopic total hysterectomy [70].

As in other jurisdictions worldwide, the frequency of laparoscopically assisted hysterectomy is steadily increasing, at the expense of conventional abdominal methods; 31.4 % in the United States [63, 71], >29 % in Finland [72], 12 % in Germany [30], and 10 % in the Netherlands [73]. The rate of laparoscopically assisted hysterectomy in Taiwan evolved from 5.2 % in 1996 to 40.4 % in 2005 [74].

The recent Cochrane collaborative meta-analysis suggests the recommended order of hysterectomy method preferences to be the vaginal route, followed by the laparoscopically assisted method and finally the abdominal hysterectomy way [75].

There are no reliable audits published recently in India, as there are no available national statistics for hysterectomy and the number of operations performed every year appear to be vastly under-reported. A publication from the northern region of Haryana suggests incidence of hysterectomy to be about 7 % amongst married women older than 15 years of age [76].

A paper by Desai et al., from the western state of Gujarat, estimated that more than 7 % of rural and about 5 % of urban women already had a hysterectomy, at an average age of 37 years [77].

The recent British Broadcasting Corporation world service depiction by Jill McGivering of unscrupulous hysterectomies performed in India may appear comparatively excessive, however one has to appreciate the vastly different societal and economic challenges women and practitioners endure in impoverished remote areas, where contemporary health remedies are lacking and oversight difficult http://www.bbc.co.uk/go/em/fr/-/news/magazine-21297606. *[accessed 26 March 2015].*

As an exact contemporary global hysterectomy rate remains elusive, it could be argued that regions with lower hysterectomy rates, such as Nordic countries, may be denying women an operation that could significantly enhance quality of life, while areas with higher hysterectomy rates, such as India, are subjecting women to unnecessary procedure, with known risks and complications.

Simple locally crafted guidelines can have noteworthy effects towards assuring that patients are offered surgery only when absolutely necessary and operations are not denied when it can significantly improve quality of life.

Understandably, patient participation in decision-making prior to surgery remains fundamental, as research determined that when women are engaged in these important health related decisions, their post-operative satisfaction with hysterectomy is higher; as such life altering procedures impact the very core of womanhood.

Gynecologists practicing in underdeveloped regions must be seriously attentive and vigilant about their current hysterectomy rates, while those in industrialized regions cannot remain content with their wildly varying hysterectomy rates, as substantial and difficult work remains to be had in both extremes.

Hysterectomy is usually performed to improve a patient's quality of life; however sometimes they are performed for life saving purposes; as with all surgical operations, intraoperative and postoperative complications are inevitable and they do occur with all methods of hysterectomies; generally reported to vary from 0.5 to 43 % [78].

Hysterectomy mortality rate is roughly 0.38 (0.25–0.64) per 1000 women, where serious intraoperative complications include soft tissue injuries, such as ureter, bowel, bladder, excessive bleeding and reoperation; incidences vary, 3.6 % during abdominal and 3.1 % during vaginal hysterectomy, where an additional 1 % will have serious complications during the post operative period, irrespective of method [60].

These relatively reduced peri-operative morbidity and mortality rates and purported cost-effectiveness renders hysterectomy, an attractive, definitive and *contemporary* treatment option for several gynaecological conditions [79].

A recent publication from Sweden by Lundholm et al., confirms that hysterectomy in younger pre-menopausal women aged 50 years or less, substantially increases risk of cardio-vascular events later in life; oopherectomy further adds to this risk for stroke and coronary heart disease, which may have significant and important societal health consequences.

In addition, contemporary hysterectomy trends for managing benign conditions show both a worrying inclination towards broadening indications for surgery, as well as a move towards offering younger aged (reproductive and peri-menopausal) patients a more definitive operative remedy for their gynaecological conditions [61].

Research has determined that following hysterectomy, patients grapple with considerable psycho-sexual, emotional issues [80], pelvic floor laxity and increased vaginal prolapse; it is suggested that ovarian endocrine function declines progressively following removal of the internal genitalia. The mean age of onset of the climacteric in women who had a hysterectomy is 3.7 years earlier than average, even with ovarian preservation [81].

A paper by Pandey et al., from Manipal University, Kasturba Medical College teaching hospital, in Southern India, determined that most of their hysterectomies (98.9 %) were justified, based on the postoperative patho-histologic reports; however, they conceded that out of a total of 527 hysterectomies performed in 2012, only 76 cases could have been avoided. More than three quarters had abdominal hysterectomy, 17.8 % had vaginal hysterectomy and only 6.6 % had laparoscopic hysterectomy [82].

More than 15 years ago, Broder et al., published a paper describing frequency of inappropriate non-emergency and non-oncologic hysterectomies in the USA [15]. Sadly, there is some truth to the statement by Magon, that hysterectomy, is a surgery which continues to be used and misused, underused, and abused at different times in the practice of gynecology [83].

Amin et al., from Mercy Teaching Hospital, Peshawar Medical Collage, Pakistan, retrospectively reviewed as a quality assurance initiative their 2010–2012 hysterectomies, they determined that 91.1 % of all operations were justified. The clinical diagnoses were related to presenting complaints and histo-pathologic findings were confirmed ($p = 0.000$); the majority of their operations were performed abdominally as few of their patients presented with POP [84].

Their commonest presenting complaint was AUB (52 %) and POP (30 %) of patients; whereas the commonest indication for surgery was uterine fibroids followed by POP. These are similar to observation by Qamar-un-Nisa et al., at Muhammad Medical College Hospital, Mirpurkhas [85], and by Iftekhar et al., at the Karachi Hospital, where AUB related to uterine myomas was the commonest complaint (30 %) and most common histo-pathological diagnosis [86].

However, Ahsan et al., from Liaquat National Hospital, Karachi, found adenomyosis to be their most common histopathological diagnosis, followed by uterine myomas [87].

Admittedly, economic and ethno-social demographics temper some of the differences in hysterectomy rates between and within regions, it appears that operative route choices and rates are mostly prejudiced by surgeons' inclinations and financial considerations of a given healthcare environment [58, 59]. It appears that younger surgeons are less likely to opt for a hysterectomy compared with older gynecologists, and those practicing in academic settings tend to prefer a surgical solution significantly less often than those in community settings; reflecting differences in training and ability [60].

The Robotic Paradigm

Addition of robot-assisted surgery to the minimally invasive palette certainly provides significant advantages, to our ability to perform, technically challenging procedures with less patient disability; however, it has the potential of confounding the complex *hysterectomy rate* conundrum further. A pressing issue with this emerging technology is not whether robotics has any role in gynecological endoscopy, but rather to clearly articulate and define the role it plays in an academic and clinical institutional environment.

Although adoption of the robotic assisted platform appears to contributed to a significant decrease in the overall *abdominal* hysterectomy rates, institutions must be cautious not to disproportionately endorse robotic methods, at the expense of other forms of hysterectomy, as they run the risk of allowing volume and quality of vaginal or conventional laparoscopic surgery to dwindle; where delivery of health become hostage to its own advertising practices, to the advantage of industry and detriment of patient care.

Notwithstanding the reality that robot-assisted surgery is *just* an evolutionary offshoot of contemporary minimally invasive surgery, considerable unabashed efforts and capital has been dedicate by industry to steer the complex and usually non-medical conversation towards institutional marketing, faculty-resident training and recruitment [88].

The commercially available robotic platform in use to date is the da Vinci (Intuitive Surgical, Inc., Sunnyvale, California); it is equipped with twin optic capability to offer surgeons at the work console only, 3-dimensional vision. This enabling aspect compensates for loss of tactile haptic feedback when using a robotic arm. Generally, access ports have a comparatively larger diameter (8 mm robotic arm ancillary ports and 12 cm primary ports), and are required to be inserted higher in the abdomen, resulting in more cosmetically conspicuous port sites.

Magrina et al., in a case series confirmed that expert robotic endoscopists can perform radical hysterectomy with results similar to laparotomy, a significantly shorter operative time than conventional laparoscopy, with equivalent lymph node harvest, appreciably less blood loss and shorter length of post-operative hospital stay [89].

Moreover, several recently published, peer-reviewed, randomized controlled trials have demonstrated that in the hands of expert endoscopists, no significant clinical improvement or cost-effective advantage is evident, when using a robotic platform to perform a hysterectomy or other benign gynecologic operations, over traditional laparoscopy [90–92].

Ever since the Food and Drug Administration approved its use in gynecology in 2008, several serious questions, regarding its applications for benign conditions remain; it is unclear if a robotic platform is best reserved for accomplished endoscopic surgeons or is an enabling technology, to help transition conventional open surgeons to advanced "expert" laparoscopists.

While it is true that a robotic platform is an important addition to gynecologic surgery, the exact role it plays in an institutional environment must be seriously pondered; as it remains hard to determine whether it can simultaneously sustain or enhance safe application of vaginal and laparoscopic surgery in an integrated minimally invasive program.

Institutions offering robotically assisted endoscopic surgery must institute a clearly articulated and independent oversight mechanism, to remain insulated from ancillary manufacturer's pressures to preferentially support robotic over other conventional forms of endoscopic or vaginal surgeries.

A worrying recent publication from Arizona, suggested that the proportion of hysterectomies performed vaginally, significantly decreased when institutions adopted robotic technology and more importantly, they observed that the proportion of hysterectomies with resident involvement decreased compared to when other routes were practiced [93].

Although robotic technology was designed to minimize complications of conventional surgery, inadvertent mishaps have been reported and investigated by the FDA; where the very first product liability was for the defendant [94]. Soon after, several spectacular attention-grabbing web sites announcements began appearing on the net, attempting to lure disgruntled patients (BadRobotSurgery.com), *"da Vinci Robot Allegedly Marketed to Less-Skilled Doctors" LawyerandsandSettlements.com. 23 April 2013. Retrieved 24 November 2016.*

Despite their considerable purchase and maintenance costs (about 2 million USA dollars, with limited-use ancillary instruments; $2000 each and related support costs), there are close to 2500 units operational globally, according to industry statistics.

The technology has been adopted quickly over the past few years by endoscopists of all shades, in Europe and the United States. The number of overall robot-assisted operations performed globally tripled since 2007 and number of Intuitive

Surgical, da Vinci units installed in U.S. institutions increased by 75 % 2007–2009, while the number installed elsewhere in the world doubled, according to the manufacturer.

Even though early publications are encouraging, further comparative trials should be undertaken prior to wider acceptance [1]. When cost differences among robotic and other methods of hysterectomy are compared, it appears that the overall, vaginal hysterectomy is less costly than robotically assisted hysterectomy. Abdominal hysterectomy and robotically assisted hysterectomy appeared to have similar costs [95].

One must consider that new additional costs incurred will be compensated for by reductions in postoperative hospital costs, length of stay and productivity gains, as patients recover quicker and return to work sooner.

Estimates of the net per-procedure cost of robotic surgery varies with utilization; when all published robot-assisted procedure's cost studies are examined since 2005, it appears that on average, across a range of 20 types of operations, the additional variable cost of using a robotic-platform is about $1600 (6 % of procedure cost); if the platform's amortized cost is also added, then the total cost per operation increased to about $3200 (13 % of procedure cost). Additionally, it is generally accepted that their use will require longer operating time than conventional or laparoscopic alternatives [96].

As several robotic operations (hysterectomy, myomectomy) were previously being carry out laparoscopically; introduction of this new technology influences institutional expenses, principally by escalating cost per procedure. Whereas operations that were frequently carry out as conventional open laparotomy, introduction of robots possibly will affect both operative cost and frequency of operations performed.

Moreover, there are no published large-scale randomized trials of robot-assisted operations, and the few observational publications do not demonstrate that long-term outcomes of robot-operations are better than conventional operations in different disciplines [97].

Where as in conventional surgery, skill sets of individual surgeons determine outcomes, the same is not true in a more integrated and interdependent robotic environment, where proficiency of the entire team is important for seamless efficient performance.

Furthermore, skills acquisition and maintenance of competence simulation programs will be required to shorten the learning curve, especially in centers where a limited number of procedures are performed.

Several contemporary publications have supported the importance and usefulness of simulation and skill laboratories when evolving technologies are introduced, such as robotic surgery, where a considerable learning curve is observed [98].

Ultimately, specific minimally invasive surgical methods, conventional or robotic, must be adapted to accommodate patient preferences, operator skills and technological availability [99, 100].

It is accepted that surgeons must perform 150 to 250 robotically assisted procedures to become adept in their use; the absolute yearly minimum procedure number, to remain proficient is not known or determined.

Given these realities, one wonders if it is justifiable to invest educational capital and scarce health funds to support training and credentialing residents and faculty, in a yet unproven and costlier method, when we have hardly completed transition from conventional to endoscopic operations.

Other Considerations Prior to Surgery for Benign Disease

National Institute for Health and Clinical Excellence (NICE guideline) advocates hysterectomy should be entertained only when other treatment remedies have proved unsuccessful, are contraindicated, is refused by patient, or when client specifically wishes a hysterectomy [101].

Several established national organizations including The American College of Obstetricians and Gynecologists (ACOG) supports use of alternate treatments instead of hysterectomy, including hormonal management, hysteroscopic remedies and use of Levo Norgestril medicated intrauterine device (Mirena ®) as first line management for a variety of benign gynecological conditions [18, 102–104].

Although use of these alternative treatments, including uterine artery embolization and MR Guided Ultrasound, helped temper hysterectomy rates, assessing appropriateness of hysterectomy continues to be a target for quality improvement [15, 17].

Clearly, alternatives to hysterectomy appear to be grossly underutilized among patients having hysterectomy for AUB, myomas, pelvic pain or endometriosis; these practice patterns are inconsistent with guidelines from ACOG that clearly recommends use of alternate medical rather than surgical therapy for primary management where indicated.

Effectively, observance of management guidelines and documentation of nonsurgical treatment attempts prior to hysterectomy may become essential, not only for improving outcomes, but also for reimbursement and maintenance of privileges.

During the past several years, there has been a significant decrease in the number of hysterectomies performed annually in the United States.

The annual *inpatient* hysterectomy rates demonstrated an impressive 36.4 % decrease in number of hysterectomies performed in 2010 (433,621) as compared to 2002 (681,234); however, this does not account migration numbers to *outpatient* endoscopic hysterectomies performed; consequently, numbers may appear better than they actually are. As a result, appropriateness of the overall hysterectomy rates in the United States is still generating considerable debate [20].

Innovative systems-based quality improvement initiatives to reduce unnecessary hysterectomies have been quite effective; Hullfish et al., demonstrated that when a pre-operative hysterectomy checklist is instituted for benign indications, rates fell significantly with a 50 % reduction of unsupportive pathology [16].

Application of the highly effective Levo Norgestril medicated intrauterine device (Mirena ®), for treatment of pelvic pain and AUB, represents an invaluable cost-saving method that is considered by only 12 % of patients, where only one third of these women actually trialed treatment.

While some believe that up to 42 % of those treated may eventually require a hysterectomy, 58 % will not. Consequently, underutilization of the Levo Norgestril medicated intrauterine device (Mirena ®), in the United States represents another important quality improvement and cost savings opportunity to be pursued.

Uterine Artery Embolization

Uterine artery embolization and myomectomy are safe and successful alternatives to hysterectomy in women with symptomatic fibroids (ACOG guideline) [104, 105].

Ever since its description more than 15 years ago, this uterine sparing minimally invasive remedy has generated considerable controversy in the treatment of symptomatic myomas [106].

Increasing patient interest in uterine preservation coupled with significant innovative advances in interventional radiology, motivated gynecologists to consider this alternative instead of conventional operative treatment options [107].

Uterine artery embolization is now a safe and well-accepted therapeutic alternative for women with symptomatic uterine myomas; however its use in those desirous of preserving reproductive competence remains controversial. Patients who are not interested in fertility preservation or cannot tolerate operative myomectomy; uterine artery embolization is recommended.

In patients wishing to preserve fertility and reduce miscarriage potential, it remains prudent to recommend laparoscopic myomectomy if technically feasible.

Uterine artery embolization and myomectomy are analogous as far as symptomatic effectiveness, technical success rate and frequency of early or late complications are concerned.

Although the former appears to be less-invasive compared with laparoscopic myomectomy (shorter hospital stay, recovery period, lower acute phase markers), a cautious approach in recommended in patients desirous of future pregnancy, until further evidence is available [108].

As it relates to hysterectomy, some preliminary publications indicate that uterine artery embolization can reduce size, decrease menstrual flow and relieve pressure symptoms related to uterine myomas. A small RCT comparing uterine artery embolization with abdominal hysterectomy, demonstrated that women who have embolization experience shorter hospitalization and earlier return to normal activities compared with those who had abdominal hysterectomy [109].

Magnetic Resonance Guided Focused Ultrasound Surgery

This new minimally invasive method was introduced in 2004, as a less disabling treatment for uterine fibroids.

It uses highly focused sound waves to generate thermal ablation by heating the mapped tissue to a critical 55 °C, to result in thermo-coagulation, cell death and tissue necrosis.

Magnetic Resonance Imaging (MRI) guidance offers precise target identification and provides real-time thermal mapping, that measure thermal does delivery to targeted tissue and spares thermal build up in non-targeted organs.

In effect, this United States Food and Drug Administration (FDA) approved treatment for uterine fibroids requires no arterial puncture, no endoscopic incisions, is less disabling, shrinks fibroids and producing symptom relief.

When compared with Uterine Artery Embolization or operative hysterectomy, Kong et al., suggested that Magnetic Resonance guided Focused Ultrasound Surgery, is the most cost effective remedy, when compared with the former options; in effect it is a short outpatient procedure, with few adverse events or minor complications associated with its use [110].

Cost Consideration

Health care technological innovations are often credited for an important driver of health cost growth; as newly adopted technologies are often more expensive to purchase and maintain, compared to previously practised treatment options.

It has been described that introduction of innovative technologies invariably leads to a significant increase in the types and volume of patients treated with the new technology; additionally, some less rigorous trialed remedies may result in substantial additional medico-legal costs (electric morcellator, non-absorbable mesh) from their use.

As risk-based pressures escalate, institutions will increasingly analyse costs of incorporating new technology, the effect it has on quality of care and patient outcomes; besides, shifting market dynamics can undermine adoption of innovative surgical remedies and intensify emphasis on competency standards [111].

Ever since the German gynecologist Kurt Semm carried out the first laparoscopic appendectomy in 1983, surgeons

around the world quickly adopted laparoscopic methods and today, it represents the preferred standard for several surgical procedures in all disciplines [112, 113].

Although endoscopic operations are not new and are practised everywhere to different degrees, institutional managers continue to pursue the concept of establishing integrated minimally invasive surgery centers.

In an increasingly competitive health market, administrators are lured to the minimally invasive surgery center model given its marketing potential; branding facilities as a specialized minimally invasive surgi-center can improve market appeal and draw women in search of less invasive alternatives and faster recovery.

Unlike disease-based integrated multidisciplinary care centers, where patient approach is anchored by a defined disease condition, the main impetus of these endoscopic centers remain innovative technology-driven care; hence their independent clinical implementation can sometimes be difficult to justify in comparison. Moreover, pending radical health care risk-based payment reforms, may compel institutions to re-embrace disease-centered programs, at the expense of technology-centered costly initiatives.

Though emerging innovative surgical technologies will prevail, the climate in which they are scrutinized and utilized will change, given an evolving global healthcare funding landscape, with more rigorous utilization scrutiny and credentialing oversight.

Furthermore, parameters used to appraise new clinical technologies will expand to accommodate risk-based payment pressures that highlight long term disease management; where emerging technological investments may recruits an ancillary role, at a time when population health management demands more attention and commitment to healthcare cost containment along with quality concerns, overriding other considerations [96].

As healthcare improvement efforts take effect and cost cutting measures are weighed, it is expected that institutions will adopt a more seasoned, cost-savvy, and unadventurous position concerning adoption of new, expensive and sometimes unproven technologies.

It is apparent that surgeons and patients frequently hasten to adopt new treatment methods before merits and risks are fully explored, which raises the question of credentialing and competency. Often, when a new technology is introduced, no standard credentialing guidelines are available, which raises concerns about surgeon competence and maintenance of proficiency; all of which have to do with training, education and quality of care.

Given our present day technology, it is unlikely that robot-assisted operations will entirely overtake conventional gynecological operations any time soon; if theoretically such a changeover were to happen in general surgery alone, it is estimated that it could amount to an additional $1.5 billion health care cost annually. When the robot's amortization costs are also included, the grand total could amount to be more than $2.5 billion. If increased utilization by different disciplines is factored in addition, the total additional health cost burden would be prohibitive.

As it stands, local hospitals determine to establish a robotic facility, with little discussion with payers, where individual health centers vie to draw patients and surgeons with no regional coordination or oversight; competing institutions, are unable and unwilling to pass the technology lure, seeking to enhance their surgical volume and keep up with market demands, so as not to lose patients, even when favorable direct reimbursement is lacking.

Future Considerations

After enduring 150 years as the main procedure of our discipline, it appears that the era of hysterectomy, as a first line of treatment has ended and we are finally moving towards applying more innovative, less disabling methods and technologies to treat non-cancerous conditions that affect a significant segment of our population.

Our clients have also evolved, and are generally better informed, more demanding, wish to understand their treatment options and available alternatives. They are open to evaluate relative benefits and shortcomings of alternative therapies to extirpative surgery; they wish to make shared informed decisions about their reproductive health [114].

Ultimately, the future of health care is tempered by quality of service rendered, patient safety and health costs to society.

Regional hysterectomy rate variations is not new, what appears to be emerging as an important quality determinant is the relative cost of procedures; where surgical outcomes and cost in low-volume versus high-volume surgeons may temper outcomes and hospital privileging.

Departments may soon be compelled to include practitioner's case volume data in their operating room privileging processes, to improve patient outcomes, reduce costs and strive for highest quality of care [115].

Undoubtedly, hysterectomy in most of its forms is here to stay; however, its global prevalence is bound to change. Surgical rates will not be as high as in previous decades and it is anticipated that hysterectomy will be a much safer operation [116, 117].

As always, when dealing with global rates and statistics, one must remain vigilant as interpreting and comparing national and regional hysterectomy rates can often be difficult if not confusing; as considerable differences in definition and interpretation abounds, such as choice of numerators [118].

Effectively there may be no 'true' hysterectomy rates as numerous non-medical and clinical factors, such as local

customs, patient attitudes, socio-economic status, patient affluence, age and practitioner biases need to be considered.

Interestingly, significant technological improvements in endoscopic surgery coincided with a time of markedly decreasing hysterectomy need, when several effective non-extirpatory remedies for AUB, myomas and endometriosis, among others have been introduced [119].

This timely development is much encouraging, however, when non extirpative treatments become unsuccessful; hysterectomy then remains the only viable and definitive alternative again.

Although hysterectomy rates in certain jurisdiction may have already reached an absolute *ideal rate*, a new study from Michigan reveals that alternate non-operative remedies are markedly underused and treatment guidelines are often not followed.

Post-operative pathology results revealed that 1 in 5 (18 %) of operations done for benign indications were "unnecessary", and that nearly 2 in 5 (37.8 %) of women aged younger than 40 years had unsupportive pathology; they concluded that it appears that surgical rates are nowhere close to an ideal hysterectomy rate in North America [21].

Given that a great majority of hysterectomies with benign disease, are performed to enhance quality of life rather than to save lives, essential outcome measures must comprise cost-effectiveness and effect on quality of life.

Decreasing the number of operations performed in patients who may not necessarily need surgery in the first place, may potentially have a more significant impact in diminishing adverse outcomes and cost, than optimisation of postoperative care. As reimbursement policies shift, suitability for surgery will undoubtedly become an even greater imperative for patients and payers.

Given current client expectations, fiscal constraints and medico-legal concerns, clinicians and administrators must acknowledge that minimally invasive complex solutions and evolving medical technologies entail new innovation-specific vulnerabilities that may result in inadvertent patient harm with considerable additional costs [120].

Future discussions will consider how to administer the least invasive technique, to provide maximal clinical outcome, with minimal disruption of patient's life; driven by client satisfaction and payment reform that incorporates quality care and 'disability time', under total cost of care.

Equipment advances and consumer pressures will make innovative technologies affordable and highly specialized surgical techniques will be performed only by techno-surgeons, who do sufficient volumes to maintain expertise.

Operating rooms will be enabled to support integrated peri-operative imaging with dye and marker capabilities, in addition to teleconferencing, tele-mentoring, virtual reality projection and digital archiving connectivity, among others.

In a three part recent publication about the future of gynecology, Lagrew and Jenkins describes the coming onslaught and suggests that leadership and compassion is required to navigate these uncertain and treacherous currents [121].

As surgeons embark on to this *post minimally invasive era*, we need to empower future residents to the absolute best of our teaching capabilities, create a climate of knowledge exchange-transfer and invest in emerging medical and surgical educational technologies, so as to improve outcomes, restrain cost, and enhance patient experiences [122].

The advent of minimally invasive surgery has been a defining moment for all and it is time to amend *procedure based surgical teaching curriculums* and implement contemporary, *competency based teaching* initiatives; as we embrace patients advocacy and students stewardship [123].

It appears that the slow global transition toward minimally invasive and less disabling endoscopic hysterectomy, in all its methods and forms, has finally taken root to the benefit of our patients. It is now essential that we remain diligent, as a lot more hard work is required, to achieve our respective regional and elusive absolute ideal hysterectomy rates.

Given the context of unprecedented global financial constraint and dwindling health care expenditure; calls for improving efficiency-quality while reducing costs-savings appear indispensible and inevitable. However, framing health care discussion in terms of efficiency and costs risks alienating clinical practitioners as it tends to discourage willing participation in the challenge of altering the way health care is delivered.
