Resolution of Inflammation and Tissue Repair

53

Pentraxins in the Orchestration of Defense and Tissue Repair during the Acute Phase Response

53.1 The General Scenario

Microbial invasion and tissue injury trigger a complex response at the organism level commonly referred to as acute phase response [1,2]. Cytokines are key triggers of a complex set of changes centered on the liver, with IL-1 and IL-6 playing a key role in their orchestration. In general, the liver protein factory is reoriented from albumin synthesis to production of proteins relevant to defense and tissue repair (Table 53.1).

The general significance of this complex set of changes can be viewed in the perspective of defense and orchestration of tissue repair (Table 53.2). During an acute phase response, levels of components of the humoral arm of innate immunity increase (Table 53.2). These include the classic short pentraxins C-reactive protein (CRP) and serum amyloid P component (SAP), the long pentraxin PTX3, mannose-binding lectin (MBL), and C1q. These molecules act as fluid phase pattern recognition molecules (PRMs) with antibody-like properties [3]. They recognize microbial moieties, have opsonic activity, and activate and regulate the complement cascade. Moreover, as discussed later, they interact with matrix components [4]. Another set of acute phase reactants include components of the complement cascade (Table 53.2). Activation and regulation of the complement cascade parallels PRM production and can be viewed in the same general perspective of augmentation of antimicrobial resistance and regulation of inflammation.

It is important to note that CRP was originally identified by Tillet and Francis as an antibody-like molecule recognizing the C-type polysaccharides of pneumococcus in the blood of infected patients [3]. Thus, CRP, a component of the humoral arm of innate immunity, can be considered the first pattern recognition molecule to be identified [3].

Another set of acute phase proteins is related to the extracellular matrix (ECM) and tissue repair. These include fibronectin and fibrinogen which, by generating fibrin, provide a provisional matrix (Table 53.2). The production of protease

inhibitors is likely a mechanism to limit tissue damage and contribute to the orchestration of repair.

It is important to emphasize that the distinction between antimicrobial PRM and matrix components is a useful oversimplification. Indeed, PRMs interact with matrix components, and matrix components have opsonic activity for microbes and may contribute to defense, as discussed later [4,5].

Having presented a general scenario of acute phase proteins in the perspective of antimicrobial resistance and tissue repair, we will now focus on pentraxins and, in particular, on the long pentraxin PTX3 used as a paradigm for humoral innate immunity.

Table 53.2 General significance of acute phase proteins.

√	Amplification of humoral innate immunity (complement, pentraxins – CRP, PTX3, etc.)
√	Metabolic innate resistance (Fe)
√	Coagulation (fibrinogen)
√	Tissue repair (e.g., fibronectin, fibrinogen)
√	Inhibition of tissue damage (α1 antitrypsin)

53.2 Genes and Proteins

The human *CRP* gene has been mapped in the chromosome 1q23.2 locus and comprises two exons: the first coding for the leader peptide (1–18) and the initial two amino acids of the mature protein (19–20); the second for the remaining 21–224 sequence [6,7]. The expressed protein is made of five identical non-glycosylated subunits, whose tertiary structure is stabilized by an intrachain disulfide bond (Cys36—Cys97), highly conserved among pentraxins [8]. The human *SAP* gene has been identified as close paralog of *CRP* on chromosome 1, where the two genes share the same exon/intron architecture, and code for 51% identical protein sequences. SAP is a plasma glycoprotein that comprises 5 or 10 subunits, which again noncovalently associate into pentameric rings. As opposed to CRP, human SAP carries a single *N*-glycosylation site at Asn32 that is occupied by complex-type oligosaccharide [9]. X-ray crystallography allowed generating 3D atomic models of both short pentraxins in association with small ligands. Based on these, CRP and SAP protomers adopt a flattened jelly-roll topology, analogous to lectins, and expose composite binding sites on opposite sides of the pentamers [9–11]. Moreover, modeling of the SAP/FcγRIIa complex has provided a general structural frame for the interaction of pentraxins with FcRs [12], and highlighted similarities to antibody recognition by these receptors, thus bridging molecular functions of the innate and adaptive immune systems [13].

CRP and SAP are soluble PRMs in the serum. As such, they recognize pathogen-associated molecular patterns (PAMPs) as well as membrane phospholipids and nuclear components (collectively known as danger-associated molecular patterns, DAMPs) that appear on, and are released by, host cells at the sites of injury [14]. Indeed, CRP and SAP can opsonize microbial pathogens and apoptotic cells, and promote their complement-mediated clearance [15]. Their synthesis mainly occurs in the liver and is primarily induced by IL-6, typically as a reaction to microbial challenge or tissue damage. CRP expression has been reported in other tissues than liver; however, extrahepatic sites marginally contribute to the plasma levels of this protein [16]. CRP is a major acute phase protein in humans, with levels ranging from 5 mg/l at baseline up to 1000-fold higher in the acute response [17]. Therefore, since its first report in the 1930s, CRP has found extensive clinical applications as a sensitive yet nonspecific systemic marker of infection, inflammation, and tissue damage [18]. SAP is an acute phase protein in the mouse, whereas its levels in the human serum are constitutively found in the 30–50 mg/l range [19].

The human and murine *Ptx3* genes both localize on chromosome 3 and comprise three exons, which code for the leader peptide, N-terminal domain, and C-terminal domain of the protein, respectively. Proximal promoters of both genes share several regulatory elements, including Pu1, AP-1, NF-κB, SP1, and NF-IL-6. The NF-κB site is required for the transcriptional response of *Ptx3* to TNF-α and IL-1β, while AP-1 mediates its basal transcription [20–22]. In addition to inflammatory cytokines, Toll-like receptor (TLR) agonists, such as microbial moieties (e.g., lipopolysaccharide (LPS), OmpA, lipoarabinomannans) and intact microorganisms, can rapidly induce PTX3 expression in several cell types, including myeloid dendritic cells (DC) and macrophages (Figure 53.1).

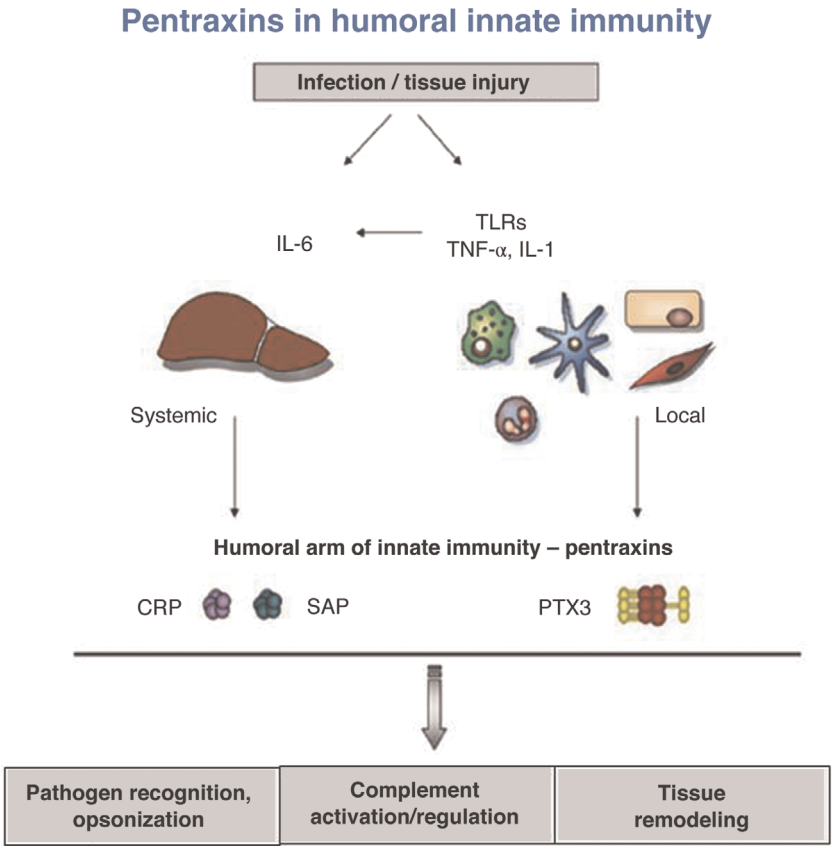

Figure 53.1 Complementary functions of CRP and SAP versus PTX3. The liver is the main source of CRP and SAP and these acute phase proteins are present in huge amounts in the circulation. PTX3 is made mainly in tissues and serves a local defense function.

PTX3 is a homomultimeric glycoprotein made of eight protomer subunits, each containing 381 amino acids, including a 17aa signal peptide [20]. Like other long pentraxins, the PTX3 protein comprises a unique N-terminal region (residues 18–178 in the preprotein) and a C-terminal domain (residues 179–381 in the preprotein) homologous to the short pentraxins (with up to 57% similarity) [23]. The N-terminal region is unrelated to any known protein structure; however, secondary structure predictions suggest that this domain contains coiled-coil elements, which likely drive the quaternary assembly of the protein [24]. Three-dimensional models of the C-terminal pentraxin domain have been generated instead, based on the crystal structures of CRP and SAP, which show this region to adopt a jelly-roll topology, typical of the family [25–27]. Interestingly, the calcium-binding pocket of CRP and SAP is missing in the pentraxin domain of PTX3, which might explain some differences in the binding properties across these pentraxins (i.e., calcium is not required for the interaction of PTX3 with C1q). A single *N*-glycosylation site has been identified in the C-terminal domain of PTX3 at Asn220, which is fully occupied by core-fucosylated and sialylated

complex-type oligosaccharides. This glycosidic moiety modulates the interaction of PTX3 with other soluble PRMs, including C1q [27], factor H [28], and ficolin-1 [29], and is required for recognition of influenza virus [30] and engagement of P-selectin [31]. Biophysical investigations indicate that the PTX3 octamer has an elongated conformation with a large and a small domain interconnected by a stalk region [24]. The rather unique quaternary structure and protein glycosylation status dictate ligands recognition by PTX3 and, ultimately, the biological functions of this prototypic long pentraxin [24,32].

53.3 Microbial Recognition

The first ligand described for CRP was the C-polysaccharide of *Streptococcus pneumoniae* to which CRP binds through phosphorylcholine (PC), a major constituent of C-type capsule polysaccharides. Moreover, CRP binds various microorganisms, including fungi, yeasts, bacteria (e.g., *S. pneumoniae*, *Hemophilus influenzae*, *Salmonella thyphimurium*), and parasites (*Plasmodium*, *Leishmania*) through PC and carbohydrate structures, promoting complement activation, opsonization, phagocytosis, and resistance to infections [33]. Like CRP, SAP binds various bacteria, such as *Streptococcus pyogenes* and *Neisseria meningitidis*, and to influenza virus, playing a protective role [33,34]. SAP binds to LPS, but controversial consequences have been described in SAP-deficient mice challenged in endotoxemia models [35]. SAP also interacts with and neutralizes Shiga toxin 2, the main mediator of severe hemorrhagic colitis and hemolytic uremic syndrome that occurs following ingestion of enterohemorrhagic *Escherichia coli* O157:H7 [36].

PTX3 was originally described as a humoral pattern recognition molecule exerting a protective role in resistance against selected fungal (*Aspergillus fumigatus*) and bacterial (*Pseudomonas aeruginosa*) pathogens [37]. Its nonredundant protective role in innate resistance to infections was extended to *Paracoccidoides brasiliensis* and *Klebsiella pneumoniae* [30,38]. PTX3 was shown to act as an opsonin for bacteria and fungi, facilitating recognition and phagocytosis by myeloid cells in a complement- and FcγR-dependent manner, and by neutralizing virus infectivity [14].

In addition, PTX3 emerged as an essential component of the innate resistance against uropathogenic *E. coli*, playing a nonredundant role in both animal models and humans in urinary tract infections [39]. In particular, PTX3, which is produced locally by the uroepithelium and by infiltrating myelomonocytic cells in a TLR4/MyD88-dependent manner, bound *E. coli* and facilitated the clearance of microbes by phagocytosis, and tuned detrimental local inflammatory responses and tissue damage [39]. PTX3 was also shown to reduce the bacterial load in an infant rat model of meningococcal meningitis by interacting with acapsular *N. meningitidis*, through outer membrane vesicles and selected meningococcal antigens, and acting as an amplifier of humoral responses to this bacterium [40].

Like for SAP, the interaction between PTX3 and certain influenza A viruses occurs through sialic acids expressed on the glycosidic moiety of PTX3 and the viral hemagglutinin (HA) glycoprotein, and results in virus neutralization and

antiviral activity. The specificity of this interaction determines the susceptibility of H1N1, H3N2, and H7N9 strains to the antiviral activities of PTX3 and SAP [30,38]. It has recently been shown that amino acid residues in the vicinity of the receptor-binding pocket of HA are critical determinants of sensitivity to PTX3, and that in a mouse model of infection, PTX3-resistant mutants were responsible of increased virus replication, pulmonary inflammation, and lung injury [41]. In contrast with the protective role in influenza virus infection, PTX3 was shown to interact with arthritogenic alphaviruses (chikungunya virus and Ross River virus) through the N-terminal domain, and to facilitate viral entry and replication during the acute phase of infection, leading to enhanced viral infectivity and prolonged disease [42].

PTX3 genetic variants have been recently described and associated with susceptibility to different infections, in particular pulmonary tuberculosis [43], *P. aeruginosa* infections in cystic fibrosis Caucasian patients [44], *A. fumigatus* infections in patients undergoing hematopoietic stem cell transplantation [45], fungal infections in solid organ-transplanted patients [46], and urinary tract infections [39], thus suggesting the relevance of functional evolutionary conservation of PTX3 in innate immunity. The protective haplotypes are associated with higher protein expression and circulating levels [45,47], although they are still poorly understood molecular mechanisms.

53.4 Complement and FcγR

Pentraxins recognize a number of complement components, and shape activation of this primordial system in a variety of physiopathological settings, including infection, inflammation, and cancer [48].

Both CRP and SAP, in an aggregated or ligand-bound form, interact with C1q, the recognition unit of the classical complement pathway (CCP), and lead to the activation of CCP on pathogens [49]. In addition, CRP can synergize with ficolins in amplifying the effector functions of the lectin pathway (LCP) on bacteria, such as *Salmonella enterica* [50]. The crosstalk between these two protein families might also contribute to the removal of cellular debris, thus subsidizing tissue homeostasis [49]. For instance, when bound to self-antigens (e.g., apoptotic cells, damaged tissue), CRP retains the ability to enhance CCP activation; however, this effect is restricted to the initial stages of the proteolytic cascade, with little deposition of the late components C5–C9 [51]. However, whether these short pentraxins exert protective or pathogenetic roles in Complement-mediated inflammation is still controversial [18,52,53]. Nonetheless, surface-bound CRP engages in a complex with factor H, the major soluble inhibitor of the alternative pathway (ACP), and inhibits ACP deposition [54,55]. In addition, both CRP and SAP bind C4b-binding protein (C4BP), the main soluble inhibitor of CCP and LCP [56,57]. These processes might restrain complement activation and prevent tissue injury, especially where the regulatory functions of factor H and C4BP are impaired, like in the case of factor H mutations and autoantibodies associated with atypical hemolytic uremic syndrome (aHUS) and age-related macular degeneration (AMD) [58].

C1q was the first PTX3 ligand identified [59,60]. This interaction has opposite functional outcomes, depending on settings; when immobilized on a surface, PTX3 induces CCP deposition, whereas it inhibits this cascade in solution, possibly due to competitive blocking of activating sites on C1q [59]. PTX3 also recognizes ficolin-1, ficolin-2, and MBL [29,61,62]. In particular, the association with ficolin-2 or MBL results in a functional cooperation that promotes recruitment of either molecules onto microbial pathogens (i.e., *A. fumigatus*, *Candida albicans*) and LCP amplification [61–63]. Furthermore, similar to the short pentraxins, PTX3 binds factor H and C4BP [28,64]. The interaction with factor H downmodulates ACP by promoting factor H recruitment onto PTX3-coated surfaces and preventing exaggerated complement activation [28]. It has been reported that aHUS-associated mutations within the PTX3-binding region of factor H and factor H autoantibodies inhibit the interaction of factor H with PTX3 [65]. In addition, PTX3 recruits C4BP onto apoptotic cells or ECM, increasing the rate of C4b inactivation and reducing deposition of the lytic C5b-9 terminal complex [64]. Most interestingly, we have recently described that PTX3 can act as an extrinsic oncosuppressor gene by regulating complement-dependent, macrophage-sustained, and tumor-promoting inflammation [66].

Other than complement, both PTX3 and short pentraxins share with antibodies the interaction with FcR. In this regard, SAP and IgGs bind FcγR with similar affinity, compete for common sites on FcγR, and inhibit immune complex-mediated phagocytosis [12]. Thus, pentraxins and antibodies have similar ancestral functions, and activate both complement and FcγR pathways [67].

53.5 Tissue Repair

SAP is a normal tissue protein as well as a plasma protein. SAP binds fibronectin, and is an abundant nonfibrillar component of all amyloid deposits of systemic amyloidosis because it avidly binds to and stabilizes all types of amyloid fibrils. It was recently shown that the administration of a small-molecule drug (CPHPC), which effectively depletes circulating SAP, and reduced SAP from systemic amyloid deposits, followed by a monoclonal anti-SAP antibody, which activates complement- and macrophage-dependent destruction of the SAP-containing amyloid deposits in tissues, safely cleared amyloid deposits and had therapeutic effects both in mice and humans [68,69].

SAP was shown to be involved in wound healing and regulation of fibrosis. In particular, SAP-deficient mice are more susceptible to bleomicin-induced lung fibrosis [70], and SAP was shown to prevent the differentiation of monocytes into fibroblast-like cells (fibrocytes) *in vitro* in part by interacting with Fc*γ*RI and delay normal murine dermal wound healing, through this mechanism [71]. Furthermore, animal studies and human phase 1 and phase 2 clinical trials showed that treatment with SAP decreases fibrosis in chronic fibrosing conditions, such as interstitial pulmonary fibrosis and myelofibrosis [72]. It has recently been shown that SAP plays antifibrotic effects independently from the interaction with Fc*γ*RI [73]. Indeed, in the absence of FcγR, SAP reduced but did not completely inhibit fibrocyte differentiation.

PTX3 plays a nonredundant role in tissue repair and remodeling, but through a different mode of action [5]. In different models of tissue damage (skin wound healing, chemically induced sterile liver and lung injury, arterial thrombosis) PTX3 deficiency was associated with increased clot formation, fibrin deposition, and persistence, followed by increased collagen deposition. In these conditions of damage, macrophages and mesenchymal cells produced PTX3 in response to TLR activation and amplification by IL-1, which localized in the pericellular matrix of macrophages and mesenchymal remodeling cells. PTX3-deficient remodeling cells showed defective pericellular fibrinolysis *in vitro* and defective directional collective migration in the provisional fibrin-rich inflammatory matrix *in vivo*.

The phenotype of PTX3-deficient mice in skin and liver damage was attributed to the interaction of PTX3 with fibrin and plasminogen at acidic pH, occurring *in vivo* in conditions of tissue damage-associated hypoperfusion and hypoxia, and to facilitated plasminogen-dependent fibrinolysis. Upon injury, fibrin acts as a provisional matrix protein, and its timely remodeling plays a major role for subsequent normal repair, as demonstrated by the phenotype of mice with genetic deficiency of components of the fibrinolytic pathway [74]. These data indicate that PTX3-dependent promotion of fibrin-rich inflammatory matrix remodeling ensures a normal tissue repair, providing a novel link between innate immunity, hemostasis, and tissue repair [75].

53.6 Concluding Remarks

Pentraxins are a phylogenetically conserved superfamily of proteins exerting common essential functions in defense from pathogens and in tissue repair. CRP is a widely used biomarker of inflammation in humans; however, lack of a strict evolutionary conservation between mouse and humans has precluded the use of straightforward genetic approaches to explore its functions *in vivo*. On the contrary, gene-targeted mice have allowed defining the functional role of PTX3 in innate immunity and inflammation as a functional ancestor of antibodies. Interaction with microbes and ECM components is a common characteristic for pentraxins, in particular SAP and PTX3 and collectins. In addition, several ECM components (e.g., fibronectin, mindin, osteopontin, and vitronectin) interact with microbes. Among humoral PRM, ficolines and collectins contain ancestral collagen and fibrinogen domains [14]. Altogether, these data suggest the evolutionary link between microbial and ECM recognition in the humoral arm of innate immunity.

Anti-Inflammatory Cytokines, Soluble Receptors, and Natural Antagonists

Willem Joost Wiersinga and Tom van der Poll

University of Amsterdam, Department of Internal Medicine, Division of Infectious Diseases and Center for Experimental Molecular Medicine (CEMM), Academic Medical Center, Meibergdreef 9, 1105 AZ Amsterdam, The Netherlands

54.1 Introduction

For any successful host response to danger, a careful equilibrium between the inflammatory and anti-inflammatory response is vital to success. In this respect, it should be noted that, as has been suggested by Matzinger, our immune system is more concerned with entities that do damage than with those that are foreign [1]. Thus, a delicate balance is needed in the immune response, wherein pro- and anti-inflammatory processes in response to stress (e.g., trauma, burns, infection, germinating pollen grains, and so on) must be balanced to maintain homeostasis and prevent host damage. Lack of regulation will lead to inflammation and autoimmunity [2]. This chapter reviews recent insights in the anti-inflammatory response offered by the impressive amount of research that has been conducted in this field over the last two decades. The focus is on anti-inflammatory cytokines, soluble receptors, and natural antagonists and their regulation.

54.2 Anti-Inflammatory Cytokines and Soluble Receptors

54.2.1 Regulation of the Activity of IL-1 Family Cytokines

The interleukin (IL)-1 family of cytokines consists of 11 members, including 7 cytokines with agonist activity (IL-1α and β, IL-18, IL-33, IL-36α, IL-36β, and IL-36γ), 3 receptor antagonists (IL-1 receptor antagonist [IL-1Ra], IL-36Ra, and IL-38), and an anti-inflammatory cytokine (IL-37) (Table 54.1) [3,4]. Members of the IL-1 receptor (IL-1R) family include six receptor chains forming four signaling receptor complexes: two decoy receptors (IL-1R2 and IL-18 binding protein [IL-18BP]) and two negative regulators (Toll/IL-1R 8 [TIR8] or single-immunoglobulin IL-1R related [SIGIRR], and IL-1R accessory protein b [IL-1RAcPb]). Some of the family members are produced in proforms that need to be cleaved for

Table 54.1 Interleukin-1 family of cytokines.

Cytokine	Receptor	Coreceptor
IL-1α (IL-1F1)	IL-1R1, IL-1R2	IL-1RAcp
IL-1β (IL-1F2)	IL-1R1, IL-1R2	IL-1RAcp
IL-1Ra (IL-1F3)	IL-1R1	
IL-18 (IL-1F4)	IL-18Rα	
IL-33 (IL-1F11)	ST2 (IL-33R)	IL-1RAcp
IL-36α (IL-1F6)	IL-36R	IL-1RAcp
IL-36β (IL-1F7)	IL-36R	IL-1RAcp
IL-36γ (IL-1F8)	IL-36R	IL-1RAcp
IL-36Ra (IL-1F5)	IL-36R	
IL-37 (IL-1F7)	IL-18Rα	
IL-38 (IL-1F10)	IL-36R	

Italicized family members indicate negative regulators. IL-1R1, type I IL-1 receptor; IL-1R2, type 2 IL-1 receptor; IL-1RAcP, IL-1 receptor accessory protein.

generation of active cytokines. Caspase-1 is important for the cleavage of pro-IL-1β and pro-IL-18 upon inflammasome activation. N-terminal processing is also required for the IL-36 cytokines to generate both agonist and antagonist activities. IL-1α or IL-1β binds first to the type I IL-1R, the ligand-binding chain, followed by recruitment of the coreceptor IL-1RAcP and signaling via the adapter protein MyD88 (myeloid differentiation primary response-88). Multiple mechanisms regulating the activity of IL-1 family members have been revealed, involving decoy receptors, receptor antagonists, and negative regulators. The presence of so many levels of inhibition reflects the physiological need to control the potential damaging proinflammatory effects of the IL-1 system.

IL-36α, IL-36β, and IL-36γ bind to IL-36R and use IL-1RAcP as a coreceptor [3,4]. IL-36 cytokines copy many IL-1 activities and likely contribute to amplification of innate immunity and inflammation in certain tissues, including lung and skin. IL-36Ra shares more than 50% homology with IL-1Ra and acts as a receptor antagonist.

The anti-inflammatory cytokine IL-37 does not have a murine homolog, making functional *in vivo* studies somewhat difficult. Transgenic mice overexpressing human IL-37 display attenuated inflammation during endotoxic shock, colitis, and ischemic heart and liver injury. In accordance, silencing of IL-37 in human monocytes resulted in enhanced lipopolysaccharide and IL-1β induced proinflammatory cytokine release. IL-37 is located in the nucleus where it inhibits gene transcription. Recombinant IL-37 binds with the IL-18Rα chain after which it can deliver an inhibitory signal through TIR8.

IL-38 shares 41% homology with IL-1Ra and 43% homology with IL-36Ra [3,4]. IL-38 likely serves an anti-inflammatory role considering that it binds to the extracellular domain of recombinant IL-36R. IL-38 acts as a partial receptor

antagonist of IL-36R, as illustrated by the finding that IL-38 can attenuate IL-36γ-induced IL-8 release by human peripheral blood mononuclear cells. Genetic association studies have implicated IL-38 in human inflammatory diseases, including the metabolic syndrome, psoriatic arthritis, and ankylosing spondylitis.

The IL-1R family entails two decoy receptors, IL-1R2 and IL-18BP [3,4]. IL-1R2 exists as a transmembrane receptor with a short cytoplasmic tail lacking signaling capacity and a soluble form released after proteolytic processing or alternative splicing, thereby acting as a molecular trap for IL-1. Soluble IL-1R2 exerts additional inhibitory activity by binding pro-IL-1β and blocking its processing by caspase-1. Similarly, cytoplasmatic IL-1R2 interacts with pro-IL-1α precluding its cleavage and activation by different enzymes such as calpain and elastase. Although IL-1R2 can also bind IL-1Ra, it does so at least 100 times less efficiently than IL-1. In addition, IL-1R2 can form a complex with IL-1 and IL-1RAcP, exerting a dominant-negative effect. Soluble IL-1RAcP, generated by alternative splicing, enhances the affinity of soluble IL-1R2 for IL-1, thereby exerting an IL-1 inhibitory effect. IL-1RAcPb is a different form of IL-1RAcP limited to the central nervous system. IL-1RAcPb deficiency results in neuronal damage, suggesting that it may dampen IL-1-induced neurotoxicity. IL-18BP is structurally and functionally similar to IL-1R2. IL-18BP binds mature IL-18 but not pro-IL-18. The human *il18bp* gene encodes four different isoforms (IL-18BPa–IL-18BPd), produced by alternative splicing. Physiologically, IL-18BP is present in blood at a 20-fold molar excess to IL-18, suggesting it is a circulatory safe keeper of systemic IL-18 activity. While IL-18 is an important cofactor for interferon (IFN)-γ production, IFN-γ induces IL-18BP expression, indicating that IL-18BP is part of a negative feedback loop limiting IFN-γ-elicited inflammation.

The IL-1 family contains two receptor antagonists, IL-1Ra and IL-36Ra [3,4]. IL-1Ra binds IL-1R1 with a higher affinity than IL-1, but does not induce cell signaling because it fails to engage IL-1RAcP. Four isoforms of IL-1Ra have been identified, of which one is secreted (soluble IL-1Ra) and three remain intracellularly (intracellular IL-1Ra1-3). Intracellular IL-1Ra isoforms can be released by dying cells or secreted by an unknown mechanism. The anti-inflammatory potency of IL-1Ra is illustrated by children born with IL-1Ra deficiency that suffer from severe inflammation involving the skin, blood vessels, and bone. In accordance, IL-1Ra-deficient mice display arteritis, arthritis, and psoriatic-like skin disease. IL-36Ra acts as a specific receptor antagonist for IL-36R, thereby inhibiting the IL-36-elicited pathway comprising IL-23, IL-17, and IL-22. Recombinant human IL-1Ra (Anakinra) is an approved drug for the treatment of rheumatoid arthritis and autoinflammatory diseases such as cryopyrin-associated periodic syndromes.

TIR8, which is expressed in several tissues, mostly in the kidney, digestive tract, liver, lung, and lymphoid organs, attenuates signaling in response to stimulation of IL-1R family members (IL-1R, IL-18R, and ST2) or Toll-like receptors (TLR1–TLR4, TLR7, and TLR9). The anti-inflammatory effects of TIR8 have been demonstrated in TIR8-deficient mice during experimental infections, kidney ischemia and transplantation, colitis, and autoimmune disorders. Intracellular negative regulators of IL-1R signaling include IRAK-M (IL-1R-associated kinase-M) and MyD88short.

54.2.2 IL-2

IL-2 controls inflammation via various mechanisms. First, IL-2 is essential for maintenance of regulatory T cells in the periphery, and elimination of IL-2 results in autoimmunity [5]. Second, IL-2 regulates inflammation by inhibiting T helper 17 differentiation through inhibition of IL-6-dependent signaling [6]. Third, IL-2 impairs the development of follicular helper T cells, a subset of T cells that regulate humoral immune responses; as an illustration of the functional consequences thereof, IL-2 reduced influenza virus-specific immunoglobulin G1 titers in mice infected with influenza virus [7]. The anti-inflammatory properties of IL-2 may have therapeutic implications, as indicated by two recent studies showing that the administration of low-dose IL-2 can reduce inflammation and improve disease in patients with chronic graft-versus-host disease [8] or hepatitis C virus-related vasculitis [9].

54.2.3 IL-6

IL-6 exerts wide-ranging effects on immune and nonimmune cells and often has hormone-like features that affect homeostatic processes [10]. IL-6 can have pro- and anti-inflammatory properties. Mice with a targeted deletion of the *il6* gene display impaired innate and adaptive immunity to viral, parasitic, and bacterial infection. On the contrary, enhanced IL-6 activity contributes to the maintenance of chronic inflammation such as in arthritis, autoimmune encephalomyelitis, lupus, and plasmacytomas. The IL-6R complex is composed of a ligand-binding portion IL-6R (CD126) and gp130, the signal-transducing β-receptor subunit (CD130). Gp130 also functions as the signaling receptor for several other mediators, including IL-11, IL-27, oncostatin-M, ciliary neurotrophic factor, cardiotrophin-1, leukemia inhibitory factor, and cardiotrophin-like cytokine. IL-6R expression is confined mainly to hepatocytes, leukocytes, and megakaryocytes. A variety of stimuli can induce the shedding of IL-6 from the cell surface, giving rise to soluble IL-6R, which can promote IL-6 signaling.

While IL-6 has been implicated in modulation of many components of the innate immune system, its inhibitory properties include inhibition of the expression of the chemokines CXCL1, CXCL8, and CX3CL1; inhibition of neutrophil accumulation upon TLR stimulation; reduction of influenza virus-induced inflammation; inhibition of nuclear factor (NF)-κB activation in dendritic cells; and induction of IL-1Ra and soluble TNFR type I release. In addition, IL-6 can inhibit the microbicidal activities of macrophages and the production of proinflammatory cytokines. Together, there is ample evidence that besides its clear proinflammatory effects (most notably during the acute innate immune response during infection), IL-6 also directs anti-inflammatory activities necessary for resolution of inflammation.

54.2.4 IL-10

IL-10 belongs to a family of cytokines that further includes IL-19, IL-20, IL-22, IL-24, and IL-26 [11].These cytokines are grouped in a family based on their

similarities with respect to the structure and location of their encoding genes, their primary and secondary protein structures, and the receptor complexes used. Nonetheless, in spite of their resemblances, IL-10 family members possess different biological functions. While IL-10 is a prototypic anti-inflammatory cytokine, IL-19, IL-20, IL-22, IL-24, and IL-26 primarily act on epithelial cells, protecting these from invasion by extracellular pathogens. Some authors also reckon the more distantly related IL28A, IL-28B, and IL-29 to the IL-10 family of cytokines; this latter group of cytokines elicits antiviral responses in especially epithelial cells. IL-10 is produced by almost every type of immune cell. The main cellular sources of IL-10 *in vivo* are monocytes, macrophages, and T cells. The IL-10 receptor is composed of IL-10R1 and IL-10R2. While IL-10R1 is specific for the IL-10 receptor complex, IL-10R2 is also part of the receptor complexes of other ligands (i.e., IL-22, IL-26, IL-28α, IL-28β, and IL-29). IL-10 influences immune responses at multiple levels resulting in efficient inhibition of inflammation. IL-10 confines the immune response during infection, thereby reducing inflammation-mediated injury to the host. IL-10 constrains the production of proinflammatory cytokines and chemokines by dendritic cells, macrophages, and monocytes; impairs antigen presentation by reducing major histocompatibility complex expression; and inhibits phagocytosis. IL-10 can also modulate T-cell functions, for example, IL-10 inhibits the proliferation of proinflammatory T helper 17 cells *in vivo* and also acts on so-called T helper 1 plus T helper 17 cells. The anti-inflammatory properties of IL-10 are particularly clear in the gut. Mice with targeted disruption of the *il10* gene develop colitis after colonization by particular microorganisms [12], and humans with mutations in the genes encoding IL-10 or IL-10 receptor components suffer from the early-onset severe inflammatory bowel disease [13], indicating an essential role for IL-10 in intestinal homeostasis. Treatment with recombinant IL-10 has been evaluated in patients with various inflammatory conditions. While early studies showed promising results in patients with psoriasis and Crohn's disease, larger studies have been unable to confirm these findings. Conceivably, targeted administration rather than systemic injections could be of value in limiting inflammation in patients. Notably, enhanced production of IL-10 has been implicated in the pathogenesis of a variety of diseases, including autoimmune diseases, such as systemic lupus erythematosus, malignancies like melanoma, and infectious diseases such as leishmaniasis.

54.2.5 IL-27 and IL-35

The IL-12 cytokine family consists of four heterodimers, that is, IL-12, IL-23, IL-27, and IL-35 (Figure 54.1) [14]. While IL-12 and IL-23 are considered proinflammatory cytokines, IL-27 and IL-35 have anti-inflammatory properties. IL-27 and IL-35 share the β-chain Epstein–Barr virus-induced gene 3 (EBI3); IL-35 shares its α-chain p35 with IL-12, while IL-27 (together with IL-23) has a unique α-chain (p28 or IL-30). IL-27 and IL-35 are secreted in small quantities by myeloid cells (mainly macrophages and dendritic cells) and regulatory T cells, respectively.

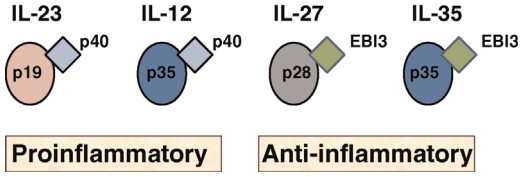

Figure 54.1 Interleukin-12 family of cytokines. The heterodimeric IL-12 family cytokines consist of an α chain (p19, p28, or p35) and a β chain (p40 or EBI3). The p40 chain can pair with p35 or p19 to form IL-12 or IL-23, respectively, while EBI3 can pair with p28 or p35 to form IL-27 or IL-35, respectively. While IL-23 and IL-23 are proinflammatory cytokines, IL-27 and IL-35 exert a variety of anti-inflammatory effects.

The anti-inflammatory function of IL-27 was clearly shown in IL-27R-deficient mice with leishmaniasis, which die from excessive immune responses [14]. Mechanistically, IL-27 converts activated, inflammatory $CD4^+$ T cells into IL-10-producing T cells. IL-27 also precludes the expansion of T helper 2 and T helper 17 cells in various inflammatory conditions. Notably, IL-27 also inhibits IL-2 production, which might hinder the growth of regulatory T cells, thereby contributing to the initiation of colitis in mice. The IL-27 subunit p28 can function as a gp130 antagonist, thereby inhibiting signaling mediated by IL-6 and IL-11. The anti-inflammatory properties of IL-30 are illustrated by its capacity to reduce hepatotoxicity mediated by IL-12, interferon-γ, and concanavalin A.

Knowledge of IL-35 is still limited [15]. IL-35 can mediate the transformation of $CD4^+$ effector T cells into so-called inducible IL-35-producing regulatory T cells ($iT_{reg}35$ cells), a subset of regulatory T cells that express IL-35 but lack expression of Foxp3, TGF-β, and IL-10. $iT_{reg}35$ cells can stop and revert the development of autoimmunity in various mouse models, including autoimmune encephalitis and inflammatory bowel disease. Moreover, ectopic IL-35 expression in pancreatic beta cells averts diabetes, and IL-35 protects against collagen-induced arthritis. IL-35 also controls T-cell-driven immune responses in allergic disease. The signaling pathway of IL-35 is not clear yet.

54.2.6 Transforming Growth Factor-β

Transforming growth factor (TGF)-β belongs to a family with more than 40 members, among which the TGF-β subfamily have six isoforms, of which three are expressed in mammals [16]. TGF-β1 is involved in embryogenesis and has the most important role in the immune system, controlling inflammatory responses, T-cell differentiation, B-cell isotype switching, and tolerance. Many different cell types can produce TGF-β, but it is always produced as an inactive complex that needs to be activated to become functional. As such, activation of latent TGF-β is an essential step in the regulation of TGF-β function. TGF-β triggers cellular signaling via the TGF-β receptor complex, a tetrameric structure composed of two TGF-βRI and two TGF-βRII.

Dependent on the inflammatory context and the presence of cell surface coreceptors, TGF-β can inhibit adaptive immune responses (through induction of regulatory T cells and by suppressing T helper 1 and $CD8^+$ T cells) or enhance

adaptive responses (e.g., through induction of T helper 17 cells). TGF-β1-deficient mice suffer from fatal inflammatory disease mediated by $CD4^+$ and $CD8^+$ T cells, possibly as consequence of autoreactivity. Unlike IL-10, TGF-β is constitutively expressed in many tissues, suggesting a role for this mediator in immune homeostasis. Alterations in TGF-β signaling may contribute to several pathologies, such as cardiovascular diseases, fibrosis, and cancer.

54.2.7 Soluble Cytokine Receptors

Most transmembrane receptors for cytokines also exist in a soluble form, which can be generated by either shedding (as a consequence of proteolytic cleavage) and/or alternative mRNA splicing [17]. Several of these soluble cytokine receptors have already been discussed. Most soluble cytokine receptors function as competitive inhibitors by virtue of their ability to prevent binding of a cytokine to its membrane-bound signaling receptors. Prominent "inhibitory" examples are the type I (p55) and type II (p75) soluble TNFRs. The extent to which a soluble cytokine receptor can inhibit biological activity of its ligand depends on multiple factors, including the concentrations of cytokine and soluble receptor, the ligand affinities of membrane-bound versus soluble receptors, the density of membrane-bound receptors on target cells, and the portion of membrane-bound receptors that need to be occupied to trigger a biological response. Of note, some soluble cytokine receptors have agonistic effects, including soluble IL-6Rs, which can interact with gp130, thereby inducing IL-6-mediated signal transduction and allowing cells that lack IL-6Rα but do express gp130 to respond to IL-6. For some soluble cytokine receptors, including soluble TNFRs, a carrier function has been suggested, which may result in enhanced ligand activity.

54.3 Negative Regulation of Toll-Like Receptor-Mediated Immune Responses

The innate immune system can sense danger via a limited number of pattern-recognition receptors (PRRs). PRRs recognize so-called pathogen-associated molecular patterns (PAMPs), which are conserved motifs expressed by micro-organisms [18,19], or danger-associated molecular patterns (DAMPs), which are endogenous molecules released by cells injured directly by, for instance, bacteria or indirectly as a consequence of, for example, ischemia or necrosis [20]. Prominent examples of PAMPs include lipopolysaccharide, peptidoglycan, lipopeptides (a component of many pathogens), lipoteichoic acid (a cell wall component of Gram-positive bacteria), flagellin (a mobility factor of bacteria), and bacterial DNA. Examples of DAMPs include extracellular matrix components (e.g., fibronectin, hyaluronan, and heparan sulfate), stress-response molecules (e.g., heat shock proteins, high mobility group box-1, histones, and nucleic acids [RNA, DNA]), and immunomodulatory proteins (e.g., calprotectin, β-defensins, surfactant proteins, and uric acid). The main classes of PRRs identified so far include TLRs, C-type lectin receptors (CLRs), RIG-I-like receptors (RLRs), and

NOD-like receptors (NLRs) [19]. NLRs are further subcategorized based on differences in the N-terminal domains: NODs are NLRs that recognize common fragments of bacterial peptidoglycan, while the largest NLR group, comprising 14 members, has an N-terminal pyrin domain (PYD) and is therefore called NLRP. In recent years, a growing number of new extracellular and intracellular PRRs have been characterized, including a rising number of cytoplasmic nucleic acid sensors [21].

Extensive crosstalk exists between PRRs in mounting an effective immune response toward eminent danger. Not surprisingly, this reaction has to be tightly regulated. Direct or indirect degradation or destabilization of signal transduction factors are the principal mechanisms that regulate TLR signaling [22,23] (Table 54.2). Transmembrane receptors that act as negative regulators of TLR-mediated inflammation include SIGIRR (TIR8) and IL-1R-like 1 (ST2) and radioprotective 105 (RP105). Cells that lack either one of these receptors respond more avidly to TLR stimulation. In addition, the adapter proteins involved in efficient signaling by TLRs (MyD88, TIRAP [TIR-containing adapter protein]/Mal, TRIF [TIR domain containing adapter inducing IFN-β], and TRAM [TRIF-related adapter molecule]) are target for negative control by several mechanisms. For example, TAG (TRAM adapter with Golgi dynamics domain) is a TRAM variant that competes with TRAM for TRIF binding, thereby inhibiting the TRIF-dependent pathway [24]. TAG also mediates internalization of TLR4 to the endosomes for subsequent degradation. Together with TMED7 (transmembrane emp24 protein transport domain containing 7) TAG disrupts the TRAM–TRIF complex, resulting in inhibition

Table 54.2 Negative regulators of the TLR signaling pathway [23].

Regulator	Affected TLR	Mechanism
sTLR2	TLR2	TLR2 antagonist
sTLR4	TLR4	Blocks interaction of TLR4 and MD2
MyD88s	TLR4	MyD88 antagonist
IRAK-M	TLR4, TLR9	Inhibits phosphorylation IRAK-1
SOCS1	TLR4, TLR9	Suppresses IRAK
NOD2	TLR2	Suppresses NF-κB
PI3K	TLR2, TLR4, TLR9	Inhibits p38, JNK, and NF-κB function
TOLLIP	TLR2, TLR4	Autophosphorylates IRAK1
A20	TLR2, TLR3, TLR4, TLR9	Deubiquitylates TRAF6
SIGIRR	TLR4, TLR9	Interacts with TRAF6 and IRAK
TRAILR	TLR2, TLR3, TLR4	Stabilizes IκBα

IRAK, interleukin-1 receptor-associated kinase; NF-κB, nuclear factor-κB; NOD2, nucleotide-binding oligomerization domain protein 2; PI3K, phosphatidylinositol 3-kinase; SIGIRR, single immunoglobulin interleukin-1-related receptor; SOCS1, suppressor of cytokine signaling 1; sTLR, soluble decoy TLR; TOLLIP, Toll-interacting protein; TRAILR, tumor-necrosis factor-related apoptosis-inducing ligand receptor. (Adapted from Ref. [23].)

of TLR4 signaling from the endosome [25]. SARM (sterile α- and armadillo-motif-containing protein) is another TIR domain containing protein that binds and inhibits TRIF [26]. Moreover, inflammatory signaling can be shut down by ubiquitination, a process during which proteins are "tagged" with ubiquitin for proteasome-mediated degradation. SHP (small heterodimer partner) inhibits TLR signaling by suppressing the ubiquitination of an essential downstream signaling molecule (TRAF6 [TNFR-associated factor 6]) [27]. Consequently, SHP-deficient cells release increased levels of proinflammatory cytokines upon lipolysaccharide stimulation. USP4 (ubiquitin-specific peptidase 4) also negatively regulates TRAF6, by a mechanism that involves removal of polyubiquitin chains. A20 is an essential intracellular negative regulator of TLR signaling, regulating NF-κB activation via multiple mechanisms. A20-deficient mice display spontaneous inflammation in various organs, which is caused by enhanced MyD88-dependent signaling as indicated by the fact that mice with combined A20 and MyD88 deficiencies do not show aberrant inflammation [28]. Other intracellular negative TLR regulators include MyD88 short, TOLLIP (toll-interacting protein), suppressor-of-cytokine signaling (SOCS), IRAK-M, TNF-related apoptosis-inducing ligand receptor (TRAILR), and phosphatidylinositol 3-kinase (PI3K) [23]. In addition, recent work has indicated a fundamental role for microRNAs (miRNAs) in regulating PRR-induced immune responses [29]. Some key soluble negative regulators of the TLR signaling pathway are discussed in the following sections.

54.3.1 Soluble Decoy Toll-Like Receptors

Soluble decoy TLRs are one of the mechanisms by which the biological activities of TLRs are under control. These soluble TLRs compete with TLR agonists and can directly diminish TLR signaling activation and therefore prevent further exacerbation of inflammatory responses [23]. Soluble forms of TLR2 have been described that attenuate the inflammatory response by direct binding to PAMPs; for instance, the extracellular TLR2 domain can directly bind peptidoglycan derived from *Staphylococcus aureus* [30]. Similarly, soluble TLR4 can inhibit TNFα release following lipopolysaccharide stimulation [31]. The mechanism involved in the inhibitory capacity of soluble TLR4 remains to be elucidated; it has been hypothesized that soluble TLR4 blocks the interaction between TLR4 and its coreceptors MD2 and CD14, leading to the termination of signaling [32,33].

54.3.2 Soluble ST2

Soluble ST2 is a decoy receptor that inhibits membrane-bound ST2 signaling. The transmembrane form of ST2L, which is expressed on macrophages, mast cells, and Th2 cells, serves an important negative regulatory function for TLR signaling [23,34,35]. This is illustrated by the fact that mice lacking ST2L are unable to develop endotoxin tolerance [23,34,35]. Of note, IL-33 mediates its biological effects via ST2L, which activates NF-κB and MAP kinases, and drives production of Th2-associated cytokines. Soluble ST2 can bind to IL-33, thereby inhibiting signaling by ST2L [36]; as such sST2 functions as a decoy receptor for

IL-33. Blood concentrations of sST2 are increased in inflammatory and heart disease, and are considered a valuable prognostic marker in both conditions [37]. For instance, in patients with sepsis, sustained elevation of serum soluble ST2 levels correlates with disease severity and mortality [38]. Functional studies showed that administration or overexpression of soluble ST2 attenuates inflammation in mouse models of ischemia/reperfusion injury and allergic lung inflammation [39,40].

54.3.3 Soluble TREM-2

Upon recognition of still unspecified ligands, TREM (triggering receptor expressed by myeloid cells)-1 and TREM-2 recruit and phosphorylate the adapter molecule DAP12 (DNAX adapter protein 12) after which the cellular response is initiated [41,42]. TREM-1 is expressed on neutrophils and subsets of monocytes [43], and has been demonstrated to act as an amplifier of the proinflammatory response *in vitro*, enhancing the TLR response to specific TLR ligands [44]. TREM-2 is primarily expressed on macrophages, dendritic cells, microglia, and osteoclasts [45–48]. In contrast to TREM-1, TREM-2 is thought to act as a negative regulator of inflammatory responses in macrophages and dendritic cells [45,47]. In addition, TREM-2 is involved in phagocytosis [49,50] and killing of bacteria by macrophages [51]. Blocking TREM-2 by a recombinant protein in a mouse model of polymicrobial sepsis showed that TREM-2 was not only required for bacterial clearance but also led to an improved survival [52]. Soluble TREM2 was found to be elevated in cerebrospinal fluid (CSF) of patients with multiple sclerosis and other inflammatory neurological conditions in comparison to patients without inflammatory neurologic disorders [53]. It has been suggested that these elevated levels of soluble TREM2 in patients may inhibit the anti-inflammatory function of the membrane-bound receptor [53].

54.4 Additional Anti-Inflammatory Mechanisms

Neuronal and hormonal mechanisms can also attenuate abundant proinflammatory reactions [54,55]. The so-called neuroinflammatory reflex can inhibit inflammation upon sensory input transmitted through the afferent vagus nerve to the brainstem; this results in stimulation of the efferent vagus nerve and subsequent activation of the splenic nerve in the celiac plexus, norepinephrine release in the spleen, and acetylcholine secretion by a subset of CD4+ T cells. The neurotransmitter acetylcholine diminishes proinflammatory cytokine release by macrophages. The *in vivo* relevance of the neuroinflammatory reflex is illustrated by animal studies, demonstrating that vagotomy renders animals more vulnerable to endotoxin shock, while stimulation of the efferent vagus nerve reduces systemic inflammation in experimental sepsis. Catecholamines can inhibit the production of proinflammatory cytokines primarily via an effect on β-adrenergic receptors. Inflammation can also be inhibited by other hormones (glucocorticoids, vasoactive intestinal peptide, α-melanocyte stimulating hormone) and lipid mediators (e.g., prostaglandin E2).

54.5 Concluding Remarks

Greater understanding of the balance between pro- and anti-inflammatory pathways will increase our understanding of infectious and inflammatory diseases and will pave the way for novel approaches of selective therapeutic manipulation of immune signaling pathways. The delivery of anti-inflammatory cytokines, soluble receptors, or their natural antagonists holds great potential. In this respect, the success story of recombinant IL-1Ra is a prime example. The commercialized version of this anti-inflammatory cytokines is now widely used to treat patients with rheumatoid arthritis, adult-onset Still's disease, and Behcet's disease. As research continues in this field, an improved understanding of these anti-inflammatory cytokine networks will bring renewed approaches to the treatment of a wide range of inflammatory diseases [2].

55.1 Introduction

The concept of immunosuppression mediated by T cells is a remarkable example in the history of science. Originally described in the early 1970s by Gershon and Kondo [1], so-called "T suppressor cells" turned into an area of intense research until the mid-1980s when molecular genetics failed to confirm proposed suppressor factors and receptors, and it became very unpopular to use the "S"-word [2]. One of the major difficulties in those early days of immunology was also the exact definition of T suppressor cells as a distinct cellular subset, and with the discovery of T helper (T_H) 1/2 cells, "suppression" was more and more thought to reflect the activities of counterregulatory cytokines [3]. The use of CD4 and CD25 as defining surface markers and the renaming of T suppressor cells into "regulatory T cells" (T_{REGS}) by one of the pioneers in the field, Shimon Sakaguchi [4], was a key step toward the rediscovery and rehabilitation of these fundamental negative regulators of the immune system. It was also the revival of one of the most significant immunological concepts since Paul Ehrlich coined the term "horror autotoxicus" over 100 years ago and postulated that counterregulatory mechanisms against autoimmunity must exist [5]. Since then, several milestone publications have corroborated the concept of T_{REGS} and introduced a paradigm shift away from central tolerance, highlighting the previously underestimated importance of peripheral tolerance mechanisms: (i) the observation that the absence of a transcription factor, Foxp3, leads to fatal autoimmunity [6–8]; (ii) the finding that Foxp3 expression is highly restricted to

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

the T_{REG} compartment [9–12]; (iii) the proof that Foxp3 expression confers suppressive capacity [9,11,12]; and (iv) the direct demonstration in Foxp3-driven diphtheria toxin receptor (DTR) transgenic mice that $Foxp3^+$ T_{REGS} are indeed indispensable for protection from fatal autoimmunity [13–15]. Of note, although other subsets, such as IL-10-producing T_R1 and TGF-β-producing T_H3 cells (reviewed in Ref. [16]), have also been described to possess regulatory capacity, they will not be considered in this chapter as they are less well characterized on a molecular level. Instead, we will focus only on Foxp3-expressing $CD4^+CD25^+$ T_{REGS} as they are currently the best-defined T_{REG} population.

$Foxp3^+$ T_{REGS} can suppress immune responses on several levels, acting, for example, on effector T cells, NK cells, dendritic cells, and other proinflammatory effectors of the innate and adaptive immune system. This may be one of the reasons why there is no unique mechanism of suppression, and many different modes of action have been demonstrated experimentally. Some examples of T_{REG} suppressive functions include competition with effector T cells for IL-2, CTLA-4-dependent suppression of dendritic cell activation, secretion of anti-inflammatory cytokines (TGF-β, IL-10, IL-35), granzyme B-mediated killing, and galectin-1- and cAMP-dependent inhibition (reviewed in Ref. [17]). Although this is still an area of ongoing research, the use of these different mechanisms may depend not only on the target cell, the target organ, and/or the particular disease context but also on specific T_{REG} subpopulations. In fact, more and more subsets of $Foxp3^+$ T_{REGS} have been characterized in recent years which are discussed in Section 55.2. Most T_{REGS} positively selected in the thymus are skewed toward recognizing self (more precisely thymic self-ligands) and are referred to as "natural" or thymic-derived T_{REGS} (tT_{REGS}). T_{REGS} that recognize foreign antigens are induced in the periphery and are therefore termed "induced" or peripherally derived T_{REGS} (pT_{REGS}). These pT_{REGS} play important roles in the maintenance of immune homeostasis at mucosal surfaces and are most prominent in barrier tissues, such as the intestine, where particular mechanisms (e.g., the conversion of vitamin A to retinoic acid) promote the conversion of naïve T cells toward a Foxp3-driven T_{REG} phenotype. We will explicitly concentrate on the molecular events occurring during thymic and peripheral T_{REG} development and their differentiation into highly suppressive tissue-resident effector T_{REGS}, as these molecular checkpoints might have clinical relevance for the translation of basic science into immunotherapy. Apart from a better understanding of the mechanisms that govern the differentiation and function of T_{REGS}, some central questions still remain: Why did we evolve to have T_{REGS} and, most importantly, how can we exploit them therapeutically in the future to treat human diseases? Key gain-of-function events occurred during the evolution of Foxp3 in higher vertebrates, suggesting that T_{REG} development allowed placentation to occur and prevented rejection of the semiallogeneic offspring in mammals [18,19]. The importance of T_{REGS} for the recognition of self-antigens and prevention of autoimmunity is discussed in detail in Section 55.3. We will consider the clinical perspectives of interfering with T_{REG} numbers and function in autoimmunity and cancer. Some of the most interesting approaches include the transfer of T_{REGS}, for example, to prevent graft rejection in graft-versus-host disease (GvHD) or the precise ablation of T_{REGS} to trigger antitumor immunity. Many pathogens causing chronic

infections, on the other hand, may have evolved to trick the immune system by inducing immunosuppressive T_{REGS}, hence permitting immune evasion. Depletion of T_{REGS} could therefore be an interesting therapeutic option to boost cellular immunity against certain microbes, as discussed in Section 55.4. We will focus our overview mainly on recent work where $Foxp3^{DTR}$ transgenic models have been used, as other approaches targeting T_{REGS} less accurately have sometimes led to controversial results. While we are well aware of the differences between mice and men, we still believe that with regard to Foxp3 essential mechanisms and functions are sufficiently well preserved to guide ideas for novel clinical approaches harnessing T_{REGS}.

55.2 T_{REG} Subpopulations

55.2.1 Thymus-Derived versus Peripherally Derived T_{REGS}

T-cell precursors develop in the bone marrow and migrate as uncommitted progenitors to the thymus. Immature thymocytes then undergo differentiation passing through a series of stages from double-negative cells (DN1, DN2, DN3, and DN4) to double-positive (DP) cells and finally single-positive (SP) CD4 and CD8 T cells. SP CD4 or CD8 T cells that were not eliminated by negative and positive selection exit the thymus and populate the spleen, the lymph nodes, and also other organs as naïve T cells. Alternatively, SP CD4 T cells can give rise to "natural" T_{REGS}, more recently redefined as thymus-derived T_{REGS} (tT_{REGS}) [20,21]. While the processes of negative and positive selection are controlled by c-Kit, the SCF receptor, IL-7, Notch signaling, and the TCR itself [22], the developmental pathways that govern tT_{REG} development have only recently begun to be understood. In this sense, it has been proposed that tT_{REG} commitment occurs via a two-step process [23]. The first signaling events are dependent on the TCR and the costimulatory molecule CD28, and lead to the expression of the α and β chains of the IL-2 receptor (CD25 and CD122) as well as to epigenetic changes at the Foxp3 locus [24]. In the second step, expression of Foxp3 is induced in $CD25^{+}Foxp3^{-}$ precursors via an IL-2/STAT5-dependent, but TCR-independent, pathway [23,25]. Signaling via the IL-15R, which shares the β chain and the common γ chain (CD132) with the IL-2R, can also promote Foxp3 expression in $CD25^{+}Foxp3^{-}$ thymocyte precursors, suggesting that IL-15 contributes to tT_{REG} development or, at least, can act as a compensatory mechanism in the absence of IL-2 signaling [26–28].

Since the TCR repertoires of T_{REGS} and conventional CD4 T cells only show a small overlap and T_{REGS} are more resistant to TCR-induced clonal deletion, the current paradigm proposes that tT_{REGS} develop from thymocytes that carry TCRs with "intermediate" affinity between that driving positive and negative selection [29]. Recent evidence, however, suggests that besides the affinity of the interaction between the TCR and the self-peptide/MHC-class-II complex, other factors, including the amount of cognate antigen presented by thymic antigen-presenting cells (APCs) and the number of APCs presenting a specific antigenic complex, determine the tT_{REG} lineage [29]. Of note, tT_{REG} differentiation is, in

part, dependent on Aire-driven expression of self-antigens by medullary thymic epithelial cells (mTECs), suggesting that TCR activation plays a major role in commitment toward this subset [30].

Under defined experimental conditions, $CD4^+Foxp3^+$ T_{REGS} can also be generated in the periphery by antigen-driven conversion of naïve T cells. These *de novo*-induced T_{REGS} (formerly known as induced or adaptive T_{REGS} and now renamed as peripherally derived (p)T_{REGS}) usually recognize environmental antigens such as food- or commensal flora-derived antigens [31,32] and are thus believed to contribute to adaptive tolerance. *In vivo*-generated pT_{REGS} share many characteristics of tT_{REGS}, including the expression of T_{REG} canonical genes, stable Foxp3 expression, and similar epigenetic changes at the Foxp3 locus [33]. As for tT_{REGS}, signaling emanating from the TCR is crucial for pT_{REG} development, although it is believed that generation of pT_{REGS} occurs preferentially following weak and short TCR stimulation, mild costimulation, and in an anti-inflammatory environment [34]. Indeed, while costimulation via CD28 favors commitment toward tT_{REGS} [35,36], it impairs pT_{REG} development [37,38]. Yet once differentiated, T_{REGS} seem to require CD28 expression for proliferation and the maintenance of tolerance [39]. Similar to what is seen for tT_{REGS}, differentiation into pT_{REGS} also requires IL-2. IL-2 upregulates prosurvival signals that prevent apoptosis and maintain cellular fitness, and at the same time it directly acts on the Foxp3 locus via STAT5 [40]. TGF-β, in turn, promotes pT_{REG} formation by engaging the transcription factor Smad3, which acts in cooperation with NFAT to directly promote Foxp3 transcription. TGF-β alone, however, is not sufficient for the stable expression of Foxp3, which is a prerequisite for T_{REGS}' suppressive function and stability, especially when they encounter an inflammatory environment. In addition, the particular genetic signature of T_{REGS} is only partially dependent on Foxp3; other genes such as Eos, IRF4, SATB1, and GATA-3 cooperate with Foxp3 to induce the complete transcriptional program [41,42].

Induction of pT_{REGS} is also influenced by environmental cues [43]. In the gut, metabolites present in the intestinal microenvironment such as retinoic acid, a derivative from vitamin A, favor the TGF-β-dependent generation of pT_{REGS} by attenuating costimulatory signals and promoting histone acetylation at the Foxp3 promoter [44]. Similarly, short-chain fatty acids (SCFA), which are the product of fiber digestion by the gut microbiota, have also been shown to promote pT_{REG} conversion from naïve T cells [45]. Furthermore, defined commensals such as *Bacteroides fragilis* and *Clostridia* have been associated with pT_{REG} induction [46]. Thus, emerging data reveal that pT_{REG} development and function can be shaped by environmental signals, such as nutrients, bacterial products, and host-derived metabolites with the potential to be exploited as immunomodulators [47].

55.2.2 Molecular Mechanisms Underlying T_{REG} Differentiation

From a clinical point of view, understanding which events determine tT_{REG} lineage commitment in the thymus and how these cells retain a stable phenotype under inflammatory conditions will be critical to design strategies aiming to expand stable T_{REGS} for immunosuppression purposes, as in the case of autoimmunity. Furthermore, approaches tending to attenuate or increase T_{REG}

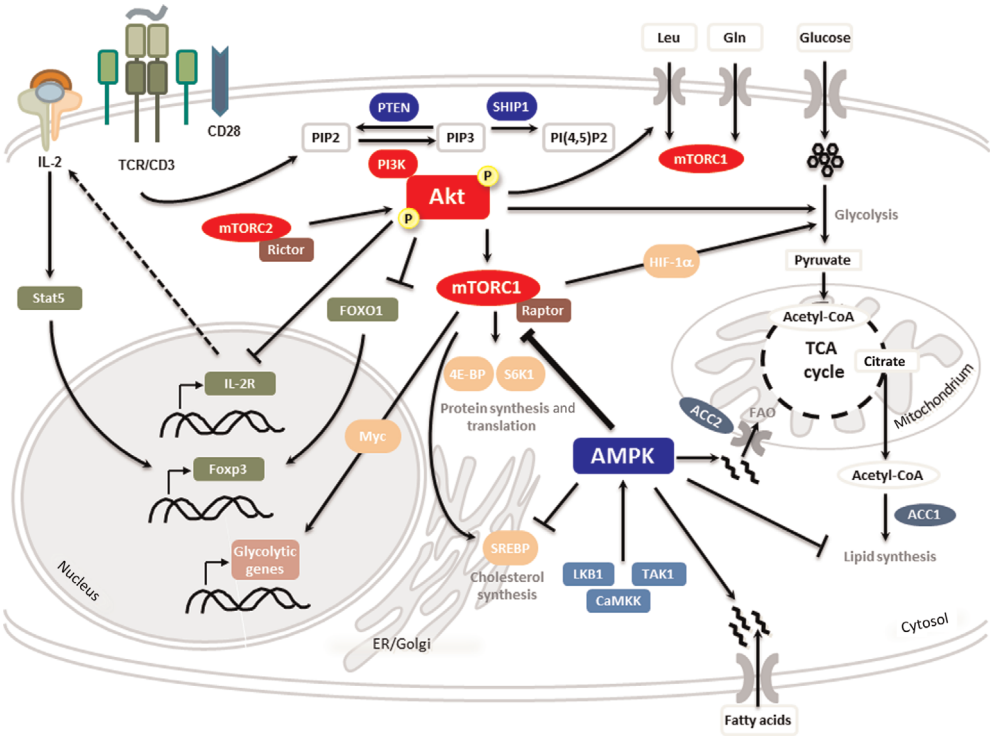

Figure 55.1 Role of activated mTORC1 in several key aspects of T-cell biology.

suppressive activity will profit from a better knowledge of how to discriminate pT_{REGS} from tT_{REGS} in terms of stability, specificity, localization, and function. In this sense, a comprehensive view of the molecular mechanisms required during T_{REG} development will help in designing new strategies and will also be beneficial when considering additional novel applications for drugs previously designed for other medical purposes.

Ligation of the TCR, CD28, or the IL-2R leads to the activation of class IA phosphoinositide 3-kinases (PI3K) and the consequent accumulation of the second messenger phosphatidylinositol-(3,4,5)-triphosphate (PIP3), which serves as a docking platform for proteins containing pleckstrin-homology domains, such as the phosphoinositide-dependent kinase 1 (PDK1) and the serine/threonine kinase protein kinase B (PKB/Akt). Phosphorylation of Thr308 in Akt by PDK1 initiates the mechanistic target of rapamycin complex 1 (mTORC1) cascade via the phosphorylation and consequent inactivation of tuberous sclerosis complex (TSC) (reviewed in Ref. [48]). Activated mTORC1 is then required for several key aspects of T-cell biology, including the integration of cellular and environmental cues for cell proliferation and differentiation [49] (Figure 55.1). How and whether these pathways are differentially regulated during tT_{REG} versus pT_{REG} differentiation is still not known; however, recent evidence suggests that the intensity and/or type of intracellular signals emanating from these receptors in thymocytes and $CD4^+$ naïve T cells might be crucial in determining T_{REG} fate.

Class IA PI3K are heterodimeric kinases composed of a 100 kDa catalytic subunit (p110α, p110β, or p110δ) and a regulatory subunit (p85α, p85β, and p55γ). Studies on the role of class IA PI3K have been hampered by the fact that, except for PI3Kδ, these kinases are ubiquitously expressed, and therefore germline deletion of the p110α or p110β subunit leads to embryonic lethality, while mice with a deletion of either p85α alone [50] or p85α and its alternative splicing variants p55α and p50α die soon after birth [51–53]. RAG-complementation analyses, however, suggest that these mice have impaired B-cell development and function, but normal T-cell compartments [54], similar to mice lacking the p85β subunit [55]. Unfortunately, direct proof for a role of these subunits in T_{REG} differentiation is still missing, as many of the studies mentioned above did not measure Foxp3 directly. More recent data, however, indicate that mice with deletions of both p85α and p85β in T cells only (known as r1ΔT/r2n mice) have reduced T_{REG} numbers in the periphery but not in the thymus and develope spontaneous autoimmunity as they age [56,57]. Similar studies have focused on PI3Kδ, which is mostly restricted to hematopoietic cells, and therefore p110δ knockout mice have a normal life span. While p110δ-deficient mice have no defects in thymocyte development, $p110\delta^{D910A\text{-}D910A}$ mice, which retain the expression of a catalytically inactive subunit, have more T_{REGS} in the thymus but less in peripheral lymphoid organs [58–60]. The differences in these two systems can therefore be attributed to the compensatory expression of other isoforms, as has previously been observed upon deletion of other individual subunits [53,61]. In addition, $p110\delta^{D910A\text{-}D910A}$ mice develop mild inflammatory disease in the intestine, probably due to an inability of T_{REGS} to secrete IL-10 and to suppress autoimmune reactions [60]. Thus, although these data propose that PI3Kδ activity restrains tT_{REG} differentiation, a direct proof for the intrinsic requirement of this kinase and the other class IA PI3Ks for T_{REG} lineage commitment is still missing.

Indirect evidence for a role of PI3K in T_{REG} differentiation and function comes from studies using mice with a genetic deletion of the phosphatases opposing PI3K activity. Phosphatase and tensin homolog (PTEN) catalyzes the conversion of PIP3 to PI(4,5)P2, whereas Src homology 2 domain-containing inositol-5-phosphatase (SHIP1) converts PIP3 into P(3,4)P2. $PTEN^{+/-}$ mice develop autoimmunity due to excessive T_H1 responses and B-cell proliferation, initially associated with resistance to FAS activation-induced cell death [62]. Besides, targeted ablation of PTEN in T cells (using either CD4-Cre or Lck-Cre) leads to fatal thymic lymphoma development, partly attributed to defective thymic negative selection [63,64]. Yet, after thymectomy, these mice are affected by a multiorgan autoimmune disorder, suggesting that PTEN is required to maintain self-tolerance. An interesting question is whether this phenotype is due to the overactivation of the PI3K pathway in conventional T cells or due to an intrinsic defect in the T_{REG} compartment. Interestingly, disruption of PTEN using OX40-cre, which is expressed in tT_{REGS} and also T_H cells upon activation, prevents autoimmunity despite exacerbated T-cell responses, possibly due to the presence of T_{REGS} with normal suppressive function [65]. Recently, mice carrying a specific deletion of PTEN in $Foxp3^+$ cells were generated [66,67]. Although initially having a normal thymic T_{REG} compartment, Foxp3ΔPTEN mice develop a

progressive lymphoproliferative disease due to the loss of $CD25^{+}Foxp3^{+}$ cells over time. Thus, PTEN seems to be required for the stability of Foxp3 because its disruption leads to altered T_{REG} homeostasis and function. Interestingly, a slightly different phenotype is observed in mice with unrestrained PI3K signaling as a consequence of absent SHIP1 expression. Using several mouse models, Collazo *et al.* demonstrated that germline or systemically induced disruption of SHIP1 expression leads to an increase in the proportion, but not the total number of T_{REGS} in the thymus [68]. Furthermore, SHIP-deficient mice show increased numbers of peripheral T_{REGS} that retain normal suppressive function [68,69]. As a consequence, SHIP1 knockout mice do not develop autoimmunity, but instead suffer from a myeloproliferative disorder and are protected from GvHD. In addition, SHIP1 is required for the differentiation of effector T_H cells [69]. Since SHIP1 was believed to terminate PI3K signaling similar to PTEN, it was surprising that deletion of the two phosphatases has differential effects. Evidence now suggests, however, that SHIP may not just act as a repressor of the PI3K pathway, but instead may redirect the signal, recruiting PH-domain containing proteins that bind PI(3,4)P2 [70].

PI3K is believed to restrict T_{REG} development via the Forkhead box family (Foxo) of transcription factors. Phosphorylation of Foxo proteins by fully activated Akt (via mTORC2) prevents translocation to the nucleus and binding to the Foxp3 locus [71,72]. Mice lacking Foxo1 and Foxo3a have reduced numbers of T_{REGS} in the thymus, suggesting a role during tT_{REG} development [72–74]. Similarly, mice with a constitutively active form of Akt develop signs of autoimmune disease [75]. Hyperactivation of Akt blocks canonical genes related to Foxp3 induction and T_{REG} lineage specification such as *Il2ra* and *Ctla-4* [76,77]. Furthermore, nuclear localization of Foxo1 is also pivotal to T_{REG} function [78]. Engagement of the IL-2R in T_{REGS}, but not on effector T cells, maintains PTEN upregulated and prevents activation of PI3K downstream targets such as Akt [69,79,80]. Thus, limited Akt activity is required for efficient T_{REG} induction and stability.

The PI3K/Akt axis has also a central role in the regulation of cell growth and metabolism. While naïve T cells use mostly catabolic processes to obtain energy, the proliferation burst occurring upon antigen encounter shifts T-cell metabolism toward increasing cell biomass. Indeed, quiescent naïve T cells rely on the oxidative phosphorylation (OXPHOS) of glucose, amino acids, and lipids in the mitochondria to generate ATP for their survival, whereas activated T cells obtain energy by the less efficient process of aerobic glycolysis (Warburg effect) that allows the synthesis of biomolecules such as proteins and lipids (reviewed in Refs [81–84]). Notably, T_{REGS} preferentially use fatty acid oxidation and external fatty acid uptake as a process to obtain energy [85,86], but the importance of these pathways for T_{REG} lineage decision is still not known. PI3K can coordinate metabolic changes at different levels. For example, Akt drives glucose metabolism and aerobic glycolysis both at the transcriptional and posttranscriptional levels, by increasing the translocation of glucose and amino acid transporters to the plasma membrane and by augmenting the enzymatic activity of glycolytic enzymes. Furthermore, activation of mTOR, an evolutionarily conserved serine/threonine kinase, is critical for the control of T-cell metabolism and lineage

commitment [49,87]. MTOR exists as two distinct complexes, mTORC1 and mTORC2, both of them being activated within minutes of TCR restimulation. MTORC1 is associated with the scaffolding protein Raptor, and acts via p70 ribosomal protein S6 kinase 1 (S6K1) and the eukaryotic translation initiation factor 4E-binding protein (4E-BP) to initiate ribosome formation and increase protein translation. Furthermore, mTORC1 activation sustains the glycolytic response via hypoxia-inducible factor 1 (HIF1-α) and MYC and augments the activity of sterol regulatory element-binding protein (SREBP) transcription factors that are responsible for *de novo* synthesis of cholesterol and fatty acids [88,89]. Although it is widely accepted that Akt is directly required for mTORC1 activation, Navarro and Cantrell have recently proposed that mTORC1 activation depends mostly on amino acid metabolism [90]. TCR activation controls the activation of the leucine transporter Slc7a5 and the glutamine transporter ACST2, thus regulating the availability of these amino acids inside the cells [91,92]. MTORC1 therefore acts by integrating signals from the environment such as nutrient availability with T-cell activation. The second complex, mTORC2, associates with Rictor and is required for full Akt activation in T cells via the phosphorylation of Ser473 in response to cytokines and costimulation. Deletion of mTOR at the DP stage of T-cell development (using CD4-cre), which abrogates the activity of both mTORC1 and mTORC2 complexes, did not disturb naïve or tT_{REG} differentiation [93]. However, engagement of the TCR in naïve cells from CD4ΔmTOR mice promotes spontaneous *in vitro* T_{REG} differentiation. Since repression of Foxp3 expression by Akt is partly counteracted by rapamycin treatment, it has been proposed that mTORC1 activation could prevent T_{REG} differentiation [76,94]. However, rapamycin can also affect mTORC2 under certain circumstances [95] and mice that lack mTORC1 signaling alone (CD4ΔRheb) did not have more T_{REGS} or spontaneous T_{REG} induction [93]. Furthermore, mice lacking Raptor in $Foxp3^+$ cells develop a fatal inflammatory disorder due to the loss of T_{REG} function accompanied by an increase in mTORC2 phosphorylation [96]. Thus, mTORC1 seems to be mainly involved in T_{REG} function by counteracting mTORC2 activity. Likewise, PTEN-deficient T_{REGS} upregulate the activity of mTORC2 and loss of this activity restores their function [67]. Further studies will be therefore required to reconcile these findings with the fact that optimal mTOR activation requires both the activation of the TCR and CD28 costimulation, as occurs during tT_{REG} commitment.

Activation of the TCR also leads to an increase in mitochondrial mass, membrane potential, and mitochondrial DNA (mtDNA) [97]. Part of these effects is mediated by AMP-activated protein kinase (AMPK), a highly conserved serine–threonine protein kinase, implicated in the regulation of mitochondrial function [98]. AMPK is a heterotrimeric complex composed of α-catalytic subunits and regulatory β and γ subunits. Upstream kinases such as the serine–threonine kinase liver kinase B1 (LKB1) phosphorylate Thr172 in the α-subunit in a constitutive manner, whereas upon TCR ligation, AMPK is activated via the Ca^{2+}-calmodulin-dependent protein kinase kinase 2 (CaMKK) [98]. In addition, AMPK activity is regulated by the levels of AMP and ATP found in the cells. Binding of AMP or ADP (signifying low energy) to the γ subunit of the enzyme causes a change in the conformation that allows for phosphorylation of Thr172

linking the activity of AMPK to the energy status of the cells. Activation of AMPK induces catabolic processes in the cells, and at the same time by preventing mTORC1 activation, it inhibits anabolic metabolism, including lipid synthesis (via SREBPs), polysaccharides, ribosomal RNA, and protein synthesis, as well as the induction of HIF-1α. AMPK also directly inhibits ACC1 and ACC2 to prevent lipid synthesis and promote fatty acid oxidation (FAO). We have previously demonstrated that inhibition of ACC1 particularly affects T_H17 development, although it promotes T_{REG} differentiation [85]. Similarly, Michalek *et al.* suggest that T_{REGS} are characterized by the activation of AMPK and the preferential use of FAO as a mechanism to obtain energy [86]. However, whether AMPK activation is a prerequisite for T_{REG} differentiation remains to be defined. Interestingly, AMPK also directly phosphorylates Foxo3 [99] and can modify the transcriptional activity of several genes by altering chromatin structure [100]. Mice deficient in AMPKα1, the main isoform expressed in lymphocytes, displayed normal thymocyte development and peripheral T-cell homeostasis, although primary immune responses are altered [101,102]. Likewise, LKB1-deficient T cells exhibit defects in T-cell activation, glycolytic and lipid metabolism, as well as excessive inflammatory cytokine production. However, ablation of LKB1 in T cells (using Lck-cre) led to severe defects in thymic cellularity and a reduction in peripheral T cells [103], suggesting that LKB1 exerts AMPK-independent functions essential for T-cell development. Although mTORC1 activity was elevated in LKB1- and AMPKα1-deficient T cells, and elevated cytokine production by these T cells could be reversed by rapamycin treatment, no data are yet available on the effect of AMPK or LKB1 deletion on T_{REGS}.

Besides LKB1 and CaMKK, transforming growth factor (TGF)-β-activating kinase 1 (TAK1) also leads to AMPK phosphorylation. TAK1 belongs to the MAP3Ks family and, in addition to the TCR, is involved in IL-2, IL-15, and TGF-β signaling [104]. T-cell-specific TAK1-deficient mice have markedly reduced SP populations in the thymus in both the CD4 and CD8 compartments, with fewer mature T cells in lymphoid organs [104,105]. Despite this, spleens of TAK1-deficient mice are enlarged compared with those of wild-type mice, with a 50% reduction in the number of T_{REGS} due to the lack of tT_{REG} development. TAK1 is required for the TCR-induced expression of members of the TNF superfamily (TNFSF) such as glucocorticoid-induced tumor necrosis factor receptor (GITR), tumor necrosis factor receptor superfamily member 4 (OX40), and member 1B (TNFR2) on tT_{REG} progenitors which participate in fine-tuning TCR signaling [106]. Yet, it remains to be determined which particular signals activate TAK1 and whether its effects are mediated, at least partially, via AMPK.

Despite the vast knowledge accumulated in the last decade of T_{REG} research, many questions are still open regarding the molecular pathways that can control their differentiation, function, and stability. The PI3K/Akt/mTOR pathway is generally considered to be detrimental for T_{REG} development, while PTEN activation and the AMPK axis seem to promote T_{REGS} and prevent excessive inflammation. Recent studies, however, suggest a higher level of complexity. For example, it is difficult to reconcile the idea that PI3K signaling inhibits T_{REG} development with the fact that tT_{REG} differentiation requires more potent TCR signaling than do naïve T cells undergoing positive selection. In addition, many of

the above-mentioned pathways are common to conventional T cells and T_{REGS}. Deletion of particular signaling molecules using conditional knockout mice crossed to Lck- or CD4-cre lines has narrowed the search, although in these mice deletion occurs in all mature thymocytes at the DP stage of development and thus new studies will be required to determine cell intrinsic versus cell extrinsic defects. Similarly, the use of Foxp3-cre lines does not allow any conclusions about these pathways in tT_{REG} differentiation because these events may be upstream of Foxp3 expression itself. Furthermore, more information is needed regarding tT_{REG} precursors as well as better markers to discriminate tT_{REGS} from pT_{REGS}. Helios and neuropilin have been proposed as such markers only recently, but they can be upregulated upon inflammation and their expression levels may therefore change in situations of autoimmune activation. Thymic T_{REGS} are believed to develop from $CD25^+Foxp3^-$ precursors. However, the existence of thymic IL-15-dependent $CD25^-Foxp3^+$ cells with the ability to differentiate into $CD25^+Foxp3^+$ tT_{REGS} in response to IL-2 has recently been described [107]. Moreover, the presence of recirculating T_{REGS} that arrive at the thymus from the periphery should be taken into account when analyzing the contribution of particular pathways to tT_{REG} differentiation [108]. Another important aspect is the role of enzymatic isoforms. For example, PI3K isoform-specific inhibitors have been designed as possible candidate drugs not only against autoimmunity, but also for cancer therapy, and many of them are already being tested in phase II and III clinical trials. The action of such inhibitors in T-cell and, particularly, T_{REG} function should be taken into consideration. Further studies clarifying these questions will help to safely target defined pathways for immune modulation.

55.2.3 Effector T_{REGS} (eT_{REGS})

Stable expression of Foxp3 is the key feature of T_{REGS} and distinguishes them from all other T-cell populations. Yet, the $Foxp3^+$ T_{REGS} that can be identified in the different tissues of the body do not represent a homogeneous group of cells. In addition to their different thymic or peripherally derived origins that have already been discussed, T_{REGS} can be further divided into several phenotypic subsets. The definite phenotype of a given T_{REG} subset is not only closely related to its activation status and suppressive function, but is also determined by its location and is thus a consequence of the environmental conditions that are present in the different lymphoid and nonlymphoid tissues.

In lymphoid organs such as the spleen or the peripheral lymph nodes, most T_{REGS} display naïve T-cell markers, including the homing receptors CD62L and chemokine CC receptor (CCR)7, which allow them to recirculate through peripheral lymphoid tissues [40]. However, a substantial fraction of T_{REGS} in lymphoid tissues shows a surface marker phenotype similar to that of "activated" or effector conventional T cells. Those effector (e)T_{REGS}, while maintaining high expression of Foxp3 and CD25, have downregulated CD62L. In addition, they display high expression of CD44, inducible T-cell costimulator (ICOS), GITR, killer lectin-like receptor subfamily G member 1-positive (KLRG1), and varying expression of markers such as CD69 and CD103 [40,109]. Although the molecular events that lead to the induction of the activated eT_{REG} phenotype are only poorly

defined, recent findings suggest that continuous TCR stimulation is an essential prerequisite to maintain the activated phenotype of T_{REGS} *in vivo* [110]. Transcriptional profiling of T_{REG} populations from different origins and anatomical sites demonstrated that *in vivo*-converted splenic $Foxp3^+CD103^+KLRG1^+$ T_{REGS} display substantial similarity to intestinal lamina propria (LP)-resident T_{REGS}, supporting the notion that the majority of T_{REGS} that reside in nonlymphoid tissues display an activated phenotype that is very similar to the population of eT_{REGS} that is found in lymphoid organs [111].

Besides displaying an activated surface marker phenotype, $Foxp3^+$ eT_{REGS} can co-opt the expression of key transcription factors that are associated with the differentiation and function of conventional effector $CD4^+$ T_H cell lineages. This adaptation leads to further phenotypic and functional heterogeneity that enables T_{REGS} to modulate different types of immune responses at both lymphoid and nonlymphoid tissue sites. $Foxp3^+$ T_{REGS} can selectively upregulate T-bet, considered to be the "master-regulator" of T_H1 differentiation. T-bet promotes the expression of the T_H1-associated chemokine receptor CXCR3 on T_{REGS}, leading to the accumulation of T-bet^+ T_{REGS} at the site of T_H1-mediated inflammation. Consequently, T-bet-deficient T_{REGS} display diminished expression of CXCR3 and fail to rescue Foxp3-deficient mice from T_H1-cell-mediated inflammatory disease [112]. Interestingly, it was demonstrated that IFN-γ produced by effector T cells can induce T-bet expression in T_{REGS} in a STAT1-dependent manner. Yet, IL-12-mediated activation of STAT4, another critical component of T_H1 differentiation, was not functional in T_{REGS}. Thus, by adapting only a part of the molecular T_H1 differentiation program, T-bet^+ T_{REGS} can be generated that effectively modulate T_H1-cell responses, without acquiring proinflammatory effector functions themselves [113]. In addition to T-bet, it was shown that T_{REGS} can also express the T_H2-associated transcription factor GATA-3 [114,115]. Intriguingly, GATA-3-deficient T_{REGS} displayed defects in their ability to suppress inflammatory responses, failed to accumulate at inflamed tissue sites, and even upregulated the expression of inflammatory cytokines. It appears that GATA-3 functions in a large multiprotein complex with Foxp3 to control a set of Foxp3 target genes as well as the expression of high levels of Foxp3 itself [116]. Consequently, GATA-3-deficient T_{REGS} display decreased levels of Foxp3 expression, which may account for the loss of suppressive function in these cells [114,115].

A special subset of eT_{REGS} has been identified in the germinal centers of mice and humans. Similar to their follicular helper $T_{(FH)}$ cell counterpart, these $Foxp3^+$ follicular regulatory $T_{(FR)}$ cells express Bcl-6, CXCR5, and PD-1 [114,117]. It was shown that expression of CXCR5 depends on Bcl-6, and cells lacking Bcl-6 expression did not give rise to T_{FR} cells despite the presence of germinal centers. Lack of T_{FR} cells resulted in enhanced germinal center reactions, including increasing numbers of germinal center B cells, enhanced affinity maturation of antibodies, and differentiation of plasma cells. Together, this indicates that T_{FR} cells play a defined and essential role in the regulation of germinal center reactions.

The expression of STAT3 also seems to have a critical function for the *in vivo* regulatory capacity of T_{REG} cells because Foxp3-specific deletion of STAT3 resulted in a dysregulated, exaggerated T_H17 response and severe intestinal

inflammation [118]. STAT3-deficient T_{REGS} displayed a normal suppressive capacity *in vitro*, but lacked CCR6 expression, resulting in an impaired recruitment of T_{REGS} to the intestine. Neutralization of IL-17 but not IFN-γ prevented colitis induction, indicating that STAT3 expression in T_{REGS} is indeed essential to specifically regulate the T_H17 lineage. Interestingly, it was shown that STAT3–Foxp3 complexes can recruit the enzyme histone acetyl transferase-1, which epigenetically modifies the *il10* promoter, making a space for docking STAT3–Foxp3 complexes to this locus [119]. Thus, STAT3 expression in $Foxp3^+$ T_{REGS} enhanced transcriptional activity of the *il10* locus, which lacks Foxp3-responsive elements and is therefore not directly regulated by Foxp3. In fact, IL-10 is an important immunosuppressive cytokine that is produced by a wide variety of innate and adaptive cells including T_{REGS}. Although not required to suppress systemic autoimmunity, IL-10 plays a critical role in limiting inflammation at epithelial and mucosal barrier sites [120]. Of note, $Foxp3^+IL\text{-}10^+$ cells display a cell surface phenotype characteristic of eT_{REG} cells and are highly enriched in the intestine [121]. Interestingly, T_H17 cells express the IL-10 receptor, and the expansion of this lineage is efficiently controlled by IL-10 [122]. It is thus possible that the colitis phenotype observed in mice with a T_{REG}-specific deletion of STAT3 can be attributed, at least in part, to suboptimal IL-10 production by T_{REGS} [123].

Blimp-1 and IRF4 are two other important factors required for the development and function of eT_{REGS}. IRF4 is a transcription factor with pleiotropic functions in the immune system, and is critically involved in the differentiation of $CD4^+$ T cells into the T_H2, T_H17, and T_{FH} lineages [124]. With respect to its function in T_{REGS}, it was shown that mice carrying a T_{REG}-specific IRF4 deletion develop a T_H2-mediated autoimmune phenotype with enhanced levels of T_H2 cytokines and IL-4-dependent IgG1 and IgE concentrations in the serum [125]. This was not due to reduced amounts of T_{REGS} or a general inability to suppress, as IRF4-deficient T_{REGS} were suppressive *in vitro*. However, IRF4-deficient T_{REGS} lacked ICOS expression and were unable to produce IL-10. Interestingly, a recent report indicated that IRF4-deficient T_{REG} cells also failed to upregulate T-bet, suggesting a broader role of IRF4 for the development of eT_{REG} cells [126]. In the same study, it was also shown that IRF4 interacts with Blimp-1 in the induction of ICOS and IL-10 expression, suggesting that IRF4 and Blimp-1 jointly govern the differentiation and function of eT_{REGS}. These data are in accordance with the notion that eT_{REGS} sorted from splenic $Foxp3^+$ cells on the basis of Blimp-1 expression showed a distinct transcriptional profile consistent with functional differentiation and active suppression [127]. This included the enhanced transcription of IL-10, CTLA-4, granzyme B, the coinhibitory molecule Tigit, and the ectonucleotidase CD39. Expression of T-bet, GATA-3, and RORγt, as well as KLRG1 and genes encoding peripheral tissue homing chemokine receptors and adhesion molecules, was also upregulated in $Blimp\text{-}1^+$ T_{REGS}, further supporting the idea that eT_{REG} cells constitute an activated, highly suppressive population of T_{REG} cells.

Importantly, T_{REG} populations that mirror the characteristics of murine eT_{REGS} have also been identified in humans. Based on the expression of chemokine receptors such as CCR6, CXCR3, and CCR4, several different T_{REG} populations have been found in peripheral blood and showed enhanced expression of

CTLA-4, ICOS, and IL10, as well as factors associated with effector T_H cell lineages, including T-bet, GATA-3, or RORγt [128].

55.2.4 Nonlymphoid Tissue-Resident T_{REG} Cells

In addition to their presence in secondary lymphoid organs, distinct T_{REG} populations have been described in various nonlymphoid tissues of humans and mice, including the skin, lung, liver, intestinal mucosa, adipose tissue, muscle, and placenta (reviewed in Ref. [129]). As mentioned earlier, nonlymphoid tissue-resident T_{REGS} display an activated phenotype and express factors that are characteristic of eT_{REGS}. Yet, the analysis of T_{REGS} in nonlymphoid tissues revealed additional features, such as the expression of certain transcription factors, homing molecules, and surface receptors, that indicate a substantial degree of adaptation to the tissue environment. It has been suggested that most lymphoid tissue-resident eT_{REGS} develop from tT_{REGS}. However, as will be discussed in this section, there is now good evidence that the majority of eT_{REGS} found at mucosal sites such as the intestine are derived from pT_{REGS}. Since the best described examples for nonlymphoid tissue-resident T_{REGS} to date are adipose tissue T_{REGS} and intestinal T_{REGS}, we will concentrate our description on those two populations.

55.2.4.1 Adipose Tissue T_{REGS}

The expansion of visceral adipose tissue (VAT) in obesity is associated with a proinflammatory milieu and enhanced amounts of proinflammatory immune cells, including $CD8^+$ T cells and M1-polarized macrophages. It is believed that this low-grade inflammation in obese VAT contributes to the development of insulin resistance, type-2 diabetes, and fatty-liver disease [130]. More recently, it has been reported that a unique subset of T_{REGS} exists in the VAT of mice. Interestingly, such VAT T_{REGS} were enriched in VAT of lean male mice, but their numbers were strikingly reduced in models of obesity [131]. VAT T_{REGS} were shown to express a range of eT_{REG} markers, including KLRG1, GATA-3, Blimp-1, GITR, CD69 (but not CD103), and high amounts of IL-10 [127,131]. In addition, VAT T_{REGS} expressed also a distinct chemokine receptor pattern that may account for the accumulation in lean VAT: CCR1, CCR3, CCR5, CCR9, and CXCR6, but not CCR6 or CXCR3 [131]. VAT T_{REGS} also displayed a TCR repertoire distinct from lymphoid organ T_{REGS} as well as the local conventional T cells, and the presence of repeated VAT T_{REG} cell TCR clones suggest that VAT T_{REGS} expand due to the recognition of local antigens. T_{REGS} found in VAT also express high levels of the IL-33 receptor ST2 [127]. IL-33 is a cytokine that promotes the development and function of multiple cell types, and is also considered to be an "alarmin" that is produced in response to inflammation and tissue damage [132]. It was shown that IL-33 is essential for the development of VAT T_{REGS} by maintaining their proliferative capacity and by increasing the expression of GATA-3 and Foxp3 [127]. Intriguingly, IRF4 together with BATF was found to cooperate at the *Il1rl1* locus (encoding for ST2) to induce the expression of the IL-33 receptor. Thus, in the absence of either IRF4 or BATF, ST2 expression was not detectable on T_{REGS} and, as a consequence, the

development of VAT T_{REGS} was abolished. Of note, IRF4 was also essential for the expression of another VAT T_{REG}-associated factor: peroxisome proliferator-activated receptor (PPAR)γ. PPARγ, the "master regulator" of adipocyte differentiation, is not only expressed by VAT T_{REGS} but also turned out to be crucial for VAT T_{REG} accumulation, phenotype, and function [133]. In mice carrying a T_{REG}-specific deletion of PPARγ, T_{REG} numbers were decreased in VAT. Furthermore, PPARγ-deficient T_{REG} cells failed to induce the VAT T_{REG}-defining gene expression profile. Interestingly, treatment of $Foxp3^+PPAR\gamma^+$ T cells with PPARγ agonists induced the expression of several factors associated with fatty acid metabolism, including upregulation of the fatty acid transporter CD36 as well as several key enzymes involved in fatty acid metabolism such as Lipe, Scd, Dgat1, and Cpt1a. These findings suggest that the co-option of local metabolic programs may be crucial for the adaptation of tissue T_{REGS}, and further underlines the general importance of the fatty acid metabolism in T cells (reviewed in Ref. [81]). From a therapeutic point of view it is important to mention that *in vivo* treatment with pioglitazone, an antidiabetic drug and agonist of PPARγ, resulted in a strong increase of VAT T_{REGS} in mice fed with either a standard or a high-fat diet. In the latter case, this positively correlated with an improvement of insulin resistance [133]. Thus, targeting the exact molecular and metabolic requirements of VAT T_{REGS} may offer novel ways to interfere with obesity-related pathologies.

55.2.4.2 Intestinal T_{REGS}

The gastrointestinal tract harbors the largest reservoir of tissue-resident T_{REGS} in the body. The gut and its associated lymphoid organs are also a major site for the development of peripheral-induced T_{REGS}, which are of functional importance for maintaining tolerance to food- and microbiota-derived antigens. Many factors contribute to the preferential induction and accumulation of T_{REGS} to the intestine, including food-derived vitamins and their derivatives, as well as the presence of certain commensal bacteria or commensal-produced metabolites such as SCFA, which are derived from the fermentation of dietary fibers (reviewed in Ref. [43]). Not surprisingly, the T_{REGS} found in this environment show several particular adaptations, for example, the expression of the SCFA receptor GPR43, which was shown to be essential for normal T_{REG} homeostasis in the colon [45]. A fraction of colonic T_{REGS} also expresses the IL-33 receptor ST2 together with GATA-3 [134]. Similar to what was observed in VAT T_{REG} cells, IL-33-mediated signaling enhanced Foxp3 expression by activation and recruitment of GATA-3 to the Foxp3 promoter. In addition, it was also shown that IL-33 provides a signal for the accumulation and proliferation of colonic T_{REGS} in response to epithelial damage. Nevertheless, the vast majority of T_{REGS} found in the intestine are negative for GATA-3, but instead express the T_H17 "master" transcription factor RORγt [135–138]. These $ROR\gamma t^+$ T_{REGS} express many eT_{REG}-associated factors, including IRF4, Blimp-1, ICOS, CTLA-4, CCR4, CCR6, CCR9, and IL-10 [135,137,138]. Importantly, the development of $ROR\gamma t^+$ T_{REGS} requires the presence of microbiota, as shown by the fact that germfree mice are completely devoid of this subset [136,137,139]. Indeed, several different bacterial species can induce the induction of $ROR\gamma t^+$ T_{REGS}. Also, feeding mice with a diet

rich in the SCFA butyrate increased the frequency of these cells [136,137]. Intriguingly, it seems that the expression of GATA-3 and RORγt by gut T_{REGS} is mutually exclusive. Since the majority of RORγt$^+$ T_{REGS} in the colon does not express Helios, and therefore is likely to be induced peripherally, it is tempting to speculate that the induction of GATA-3 in tT_{REGS} represents the default pathway, which is counterregulated in the gut by bacterial colonization and induction of RORγt$^+$ T_{REGS}. In line with these considerations, IL-23, a proinflammatory cytokine secreted by intestinal dendritic cells in response to activation by bacteria-derived pathogen-associated molecular patterns, restrained the expansion of GATA-3$^+$ T_{REGS} [134]. In contrast, IL-23 seems to be involved in the selective expansion of RORγt$^+$ T_{REGS} because mice deficient for the IL-23 p19 chain developed significantly fewer RORγt$^+$ T_{REGS} [136]. So far, the exact role of RORγt in T_{REG} function is not clear. In Ref. [136], it was demonstrated that mice with a T_{REG}-specific deletion of RORγt exhibited higher susceptibility toward T_H2-mediated oxazolone-induced colitis, but, on the other hand, were more resistant to infection by the helminth *Heligmosomoides polygyrus*, indicating that loss of RORγt leads to a dysregulation of type 2 responses. Yet, another study demonstrated that chemical blockade of RORγt results in dysregulation of T_H17/T_H1 responses, with mice showing enhanced susceptibility to disease in the T_H17/T_H1-mediated TNBS colitis model [137]. It is therefore possible that the exact role of RORγt$^+$ T_{REGS} is highly context dependent. In any case, RORγt$^+$ T_{REGS} display a very stable phenotype *in vivo* and were also shown to be highly suppressive in a transfer colitis model, suggesting that these cells indeed represent a potent eT_{REG} lineage, being highly specialized to regulate immune responses at intestinal sites [138].

55.3 Control of Immunity to Self-Tissues by Foxp3$^+$ T_{REGS}

55.3.1 Autoimmunity

Antigen receptors are generated through the random and imprecise assembly of V(D)J gene segments during lymphocyte development [140]. In addition, rearranged immunoglobulin genes are further modified by somatic hypermutation and class-switch recombination during antigen-driven B-cell selection in germinal centers [141]. The enormous diversity of antigen receptors that is produced ensures optimal protection from infections through adaptive immunity, but bears the risk of generating self-reactivity. Indeed, the majority of developing human B cells are self-reactive [142]. Moreover, immature T cells are positively selected to recognize self-peptides loaded onto MHC-class-II molecules [143]. Several checkpoints known as central tolerance usually eliminate highly self-reactive lymphocytes before they complete their development and are released into the circulation. This can, for example, be achieved by editing the antigen receptor specificity or by inducing cell death [143,144]. However, autoreactive T and B cells readily escape central tolerance and access the periphery [145,146]. In addition, somatic hypermutation can generate new autoreactive B cells in germinal centers [146,147]. Thus, self-reactive lymphocytes must be controlled

by additional mechanisms of peripheral tolerance to prevent autoimmune diseases [145,148].

The nonredundant function of Foxp3$^+$ T_{REGS} to prevent autoimmunity is best exemplified by rare *Foxp3* mutations that disrupt T_{REG} activity. In humans, those mutations lead to the IPEX (immunodysregulation, polyendocrinopathy, enteropathy, X-linked) syndrome characterized by multiorgan autoimmunity in newborn boys [6,149,150]. Similarly, male *scurfy* mice harboring a *Foxp3* frame-shift mutation develop a fatal autoimmune disease closely resembling the human IPEX syndrome [7,151,152]. *Scurfy* mice played a historic role in identifying Foxp3, but have also been valuable for studying IPEX pathogenesis, experimental therapies and T_{REG} biology [153–155]. *Scurfy* T_{REGS} exhibit a complete loss of their immunosuppressive function, which can be measured by functional assays *in vitro* [156–159]. The *scurfy* phenotype could be linked to activated autoreactive CD4$^+$ T cells which are sufficient to transfer multiorgan inflammation to RAG-deficient mice in the absence of B cells [156,160,161]. Consistently, interfering with T_H1 CD4$^+$ T-cell effector functions reduces inflammation and prolongs the survival of *scurfy* mice [162]. Moreover, dampening the activation of effector CD4$^+$ T cells through blockade of the CD4 co-receptor ameliorates autoimmunity [161,163]. Although less is known about the cross talk of T_{REGS} with humoral immunity, it has recently been shown that autoantibodies contribute to *scurfy* disease pathology, and the transfer of *scurfy* CD4$^+$ T cells into B-cell competent *nude* mice is sufficient to trigger autoantibody production [164–167]. *Scurfy* mice and/or IPEX patients have been shown to develop antinuclear antibodies (ANA) (including anti-dsDNA, anti-histone, anti-Sm, and anti-RNP-A subtypes), rheumatoid factor, antimitochondrial-, anti-glucose-6-phosphate isomerase-, anti-bullous pemphigoid 180 (BP180)-, anti-keratin-14-, anti-tryptophan hydroxylase 1 (TPH-1)-, anti-autoimmune enteropathy-related 75 kDa antigen (AIE-75)- and anti-villin antibodies [161,164,165,167,168]. This diverse self-reactive response can be explained by increased autoreactive T-cell help in the absence of T_{REGS}. In addition, recent evidence suggests that T_{REGS} directly regulate humoral immunity. One study reported the expansion of autoreactive naïve B cells in IPEX patients, suggesting defective peripheral tolerance [169]. Furthermore, the CTLA-4-dependent regulation of germinal center reactions by a specialized population of T_{FR} was recently reported by several groups [114,117,170–172]. T_{REGS} also seem to inhibit the differentiation of long-lived plasma cells [173]. Thus, T_{REGS} regulate B-cell immunity on several levels. Frequent human autoimmune diseases, such as type I diabetes, rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and multiple sclerosis (MS), are caused by an incompletely understood interplay of genetic and environmental factors. However, a partial T_{REG} dysfunction has been discussed to contribute to some of them [174,175]. Notably, expanded autoreactive naïve B cells and the presence of serum autoantibodies are hallmarks of RA and SLE in humans [146,176], similar to IPEX patients and *scurfy* mice. Interestingly, B-cell-deficient *scurfy* mice eventually succumb to death despite a greatly extended life span and reduced inflammation [164], underlining the important pathogenic role of CD4$^+$ T cells. Indeed, *scurfy* mice are protected from disease on the athymic *nude* background [177]. Seminal experiments showed that

autoimmunity is also induced in normal mice after neonatal thymectomy, which simulates transient T_{REG} depletion, as well as in athymic *nude* mice after the transfer of $CD4^+$ T cells depleted of $CD25^+$ T_{REGS} [178].

The identification of Foxp3 as a T_{REG}-specific marker and the development of Foxp3 reporter mice greatly extended our knowledge of this important cell population. $Foxp3^{DTR}$ mice, including bacterial artificial chromosome (BAC)-transgenic DEREG mice developed in our laboratory, proved that the selective depletion of Foxp3$^+$ T_{REGS} in neonates is sufficient to induce the *scurfy* phenotype [13,14]. However, a high degree of T_{REG} depletion or functional inactivation (>90%) is necessary to initiate the *scurfy*-like disease in adult $Foxp3^{DTR}$ BAC transgenic mice [15,179]. This is in good agreement with the finding that a modest wild-type T-cell chimerism of 3–6% is sufficient to rescue *scurfy* mice [180]. These findings could relate to the characteristics of T_{REGS} to sense their niche size and to rapidly compensate for a reduction in T_{REG} numbers and/or suppressive capacity through activation, proliferation, and reduced apoptosis [15,181,182]. This is a particular advantage of the DEREG mouse strain in studying T_{REG} biology [15,183], as adult $Foxp3^{DTR}$ knock-in mice allowing nearly complete T_{REG} depletion develop lethal autoimmunity, notably even after transient DT treatment on a Balb/c background [13,184]. The different mouse models thus allow valuable insights into how T_{REGS} prevent autoimmunity *in vivo*. In addition to the mentioned role of T_{REG} depletion efficiencies, genetic susceptibilities can lower the threshold at which autoimmune diseases occur [15,185]. Additionally, differences may also exist in the depleted T_{REG} repertoire or in environmental factors.

55.3.2 Cancer

Why is there such a high degree of self-reactivity in the lymphocyte repertoire despite the associated risk of developing autoimmunity? On the one hand, autoreactivity may be seen as an erroneous by-product of the adaptive immune system and the price for its highly diverse and protective repertoire. On the other hand, there is a high degree of flexibility in T-cell receptor specificities, and many human antibodies can bind various structurally unrelated antigens including self-antigens [146,186]. Autoreactivity may thus also reflect significant advantages such as the ability to broaden the lymphocyte repertoire or to increase antibody avidity through heteroligation [186,187]. Another intriguing role of autoreactive lymphocytes is the possibility to attack self-tissues that have transformed into tumors. Tumor development is usually prevented by several cell-intrinsic checkpoints. However, it is well accepted that the immune system makes an important contribution to the cancer cell-extrinsic control of tumor development and progression, also known as cancer immunosurveillance [188,189]. Consequently, the circumvention of cancer immunosurveillance has been suggested to be one hallmark of tumor development [189,190], and there is increasing evidence that T_{REGS} are involved in this process. T_{REGS} expand in the peripheral blood of tumor patients and have been shown to accumulate in murine and human tumor tissues [191,192]. Special care needs to be taken in the analysis of clinical data because Foxp3 can also be upregulated in human activated effector T cells, confounding some of the studies that may have to be reanalyzed focusing

exclusively on CD45RA$^-$CD25^{high}Foxp3^{high} T_{REGS} (reviewed in Ref. [193]). Importantly, however, the presence of tumor-infiltrating T_{REGS} often negatively correlates with patient survival [192,194,195] and the adoptive transfer of T_{REGS} inhibits tumor-specific immunity in animal models [196,197]. Thus, certain tumors may harness T_{REGS} to shield themselves from immunosurveillance through various mechanisms [148,192,198,199]. T_{REGS} likely also interfere with clinical attempts to induce tumor regression by vaccination [192,200]. Consequently, an effort has been made to deplete T_{REGS} through anti-CD25 antibodies or CD25-targeted diphtheria toxin (Denileukin diftitox). Yet, clinical responses were limited in animal models and patients with established tumors [201–205]. As effector T cells and many other immune cells express CD25, the true potential of targeting T_{REGS} in cancer remained unclear for many years. Using DEREG mice, we could for the first time demonstrate that the selective depletion of Foxp3$^+$ T_{REGS} has potent therapeutic effects on established B16 melanoma, MCA-induced fibrosarcoma, and B16F10 lung metastases, accompanied by CD8$^+$ T-cell activation and infiltration of tumors [206,207]. Transient T_{REG} elimination also enhanced the efficacy of vaccination against tumor antigens [206,208]. The detrimental role of T_{REGS} in cancer has been confirmed with two independent Foxp3^{DTR} strains and was extended to oncogene-driven cancer models [209–211]. Thus, the therapeutic potential of targeting T_{REGS} in cancer has previously been largely underestimated. Foxp3 is widely accepted as the most selective T_{REG} marker known to date, although some discussion arose concerning Foxp3 expression in other cell types. We, along with others, have found no evidence for Foxp3 expression outside the T-cell lineage, especially in naïve and B16 melanoma-associated macrophages, and in non-hematopoietic cells including epithelial cells [157,212–216]. Therefore, T_{REGS} seem to be a promising target for cancer therapy. Notably, anti-CTLA-4 checkpoint inhibition acts, in part, by depleting T_{REGS} in tumors but also directly on effector T cells [217]. In mice, T_{REG} depletion does not synergize with anti-CTLA-4 or anti-PD-1 therapy, but with tumor irradiation and vaccination highlighting potential new treatment strategies [206,209]. In summary, T_{REGS} clearly contribute to the escape of cancer cells from immunosurveillance and may be an interesting target for future immunotherapy.

55.4 T_{REGS} in the Context of Infections

While regulation of the immune response is necessary to protect the host from autoimmunity and tissue-destructive immunity directed toward commensal bacteria and innocuous antigens, T_{REG}-inducing mechanisms are also used by a large number of pathogens to promote immune evasion and their own survival within the host [218]. The role of T_{REGS} in infection is, however, a double-edged sword: While enhanced T_{REG} activity or T_{REG} numbers almost always correlate with higher pathogenic burden, immunopathology in the infected tissue is generally reduced. This observation led to the hypothesis that, from the host perspective, in certain chronic infections it may even be favorable to live with the pathogen (and high T_{REG} numbers) rather than inducing sterilizing immunity and

tissue damage. This view, however, has been challenged by studies showing that anti-inflammatory T_{REGS} can in certain cases also facilitate effective proinflammatory T_H17-mediated immunity [219,220] as well as the formation of long-term memory [221], suggesting additional levels of complexity on the biology of T_{REGS} during infection.

55.4.1 Viral Infections

The role of T_{REGS} during viral infections is probably the most ambiguous. Coevolution of mammals and viruses has led to an intertwined network with many different outcomes of T_{REG} induction in response to viral infection. Numbers of T_{REGS} and viral load often correlate, which suggests that T_{REGS} may be induced during chronic infection to allow viral immune evasion. One of the most prominent examples is human immunodeficiency virus [222]. Generally, unsuccessfully treated HIV patients present higher T_{REG} frequencies [223], while successfully treated patients show normalized T_{REG} numbers [224]. HIV patient-derived T_{REGS} can dampen both effector and bystander $CD8^+$ T-cell responses *in vitro* [225,226]. Conversely, T_{REGS} can also restrain the activation of effector T cells needed for efficient HIV replication [227], thereby inhibiting early viral spread. Yet, during later stages of the disease, T_{REGS} can block $CD8^+$ T-cell activation – this being one of the main causes of AIDS development [228]. A different controversial example is hepatitis C virus infection, another relevant human chronic disease, where spontaneous recovery correlates with a loss of T_{REG} activity [229], but excess pathology and liver inflammation [230,231].

From an evolutionary point of view, it seems likely that T_{REGS} play beneficial roles during acute infection when the immune pathology induced by the virus is most detrimental to the host. T_{REGS}, through dampening the immune response, might in fact be the major cause for the establishment of infections while, at the same time, protecting the host from immunopathology. This dual role of T_{REGS} has been addressed experimentally in various mouse models. T_{REG} depletion during lymphocytic choriomeningitis virus (LCMV) infection led to a reversal of $CD8^+$ T-cell exhaustion, but caused morbidity and increased weight loss in infected mice. Interestingly, the viral load was not affected [232]. Enhanced immunopathology as a consequence of T_{REG} depletion seems to be a common phenomenon during various viral infections: T_{REG} depletion during mouse MHV coronavirus infection can be fatal [233] possibly because T_{REGS} reduce infection-induced demyelination [234]. In a mouse model of RSV infection, T_{REGS} also dampen the immune response and limit the pathology, but similar to the findings in the LCMV model [232], depletion does not alter viral load [235,236]. Depletion of T_{REGS} during the initial immune response toward HSV-1 in a mouse model of stromal keratitis also causes massively enhanced ocular inflammatory lesions [237,238]. Here, T_{REGS} mainly seem to be protective during the early development of ocular lesions, but not during their progression at later stages [239]. While the aggravated pathology in response to T_{REG} depletion during HSV-1 infection clearly correlates with a stronger immune response, the opposite was observed in a mouse model of HSV-2. Here, surprisingly, T_{REG}

depletion results in an altered cytokine milieu and fewer effector cells at the site of infection resulting in a blockade of protective immunity [240].

T_{REG} depletion during Friend retrovirus (FV) infection has been shown to be exclusively advantageous for the host. T_{REGS} expand in response to both acute and chronic FV infection. Depletion of T_{REGS} using DEREG mice [14] led to reversal of T-cell exhaustion and strong FV-specific CD8 T-cell responses together with diminished viral load, without causing measurable immunopathology [241,242]. Transient depletion of T_{REGS} together with blocking of inhibitory ligands (PD-1 ligand and Tim-3) on $CD8^+$ T cells efficiently lowered the viral load in chronically infected mice beyond the level of any individual treatment strategy [243]. This suggests that inhibitory receptor expression on the effector T cells and suppression by T_{REGS} are, at least in part, nonredundant mechanisms. This is an encouraging finding in relation to the strategy of transient T_{REG} depletion as part of a combinatorial treatment strategy for viral chronic infections.

Importantly, T_{REG} depletion could also strongly enhance short-lived effector T-cell responses to modified vaccinia virus Ankara (MVA; used as live viral vector for vaccinations) and hence presumably also to natural infections with similar characteristics, such as vaccinia virus itself. In a mouse model of MVA infection, it could be demonstrated that T_{REG} depletion during the development of the immune response is absolutely crucial for this effect, which can mediate direct protective immunity. The CD8 memory T-cell pool was, however, unaffected, showing a time-dependent mode of action of the T_{REGS} and arguing for a use of T_{REG} depletion primarily for therapeutic (as opposed to prophylactic) vaccination regimen [244].

Together, the specificity, efficacy, timing, and duration of T_{REG}-depleting therapies seem to be the key factors for the successful treatment of chronic viral infections, while cases of virus-induced immunopathology may even require T_{REG}-expanding approaches to prevent overshooting immune responses from causing tissue damage.

55.4.2 Bacterial Infections

In contrast to the controversial role of T_{REGS} during viral infections, T_{REG} activity during bacterial infection has primarily been proven to be disadvantageous for the host. One possible explanation for the differing roles of T_{REGS} in viral and bacterial infections might be the evolutionarily different levels of host invasion by the two pathogenic classes: While viruses adapt more easily than bacteria, and the human genome, in part, even consists of viral components, nonmucosal tissues within the body are regarded as sterile with respect to bacterial colonization. As a consequence, immune-mediated clearance of bacteria seems a better defined goal, and the main action of T_{REGS} in this task is the termination of a protective immune response. As mentioned in Section 55.2, T_{REGS} can be efficiently induced in the intestine by members of the commensal microbiota and their metabolic products. In line with this, beneficial roles for T_{REGS} have been reported in models of inflammatory bowel disease, where pathology is triggered by immune recognition of commensal bacteria that breach the mucosal

barrier. This section, however, presents the role of T_{REGS} during infections driven by pathogenic bacteria and disregards commensal species that can become pathogenic upon barrier breach, immune suppression, or other extrinsic factors.

One example of pathogenic bacteria that are very efficient at inducing T_{REGS} is *Mycobacteria* spp. In humans, T_{REG} numbers were reportedly elevated in patients infected with *Mycobacterium leprae* [245] and *Mycobacterium tuberculosis* [246,247] and immunity to the latter inversely correlated with T_{REG} numbers. Increases in T_{REG} numbers and function after infection have also been modeled in mice, which showed an induced delay in priming and migration of effector T cells [248]. *Mycobacterium bovis* BCG infection in mice also caused an expansion of pulmonary T_{REGS} [249], and BCG vaccination of mice led to an initial increase in T_{REGS} [250], underlining the importance of studying the role of T_{REGS} in vaccination regimens [218,251]. Surprisingly, in the DEREG model only complete T_{REG} ablation coinciding with autoimmune side effects significantly improved mycobacterial clearance. This illustrates again that during chronic bacterial infection, the risk of autoimmunity seems to be the price we pay for sterilizing immunity [15,252].

On the other hand, in acute bacterial infections such as those caused by *Listeria monocytogenes*, the combination of vaccination and subsequent T_{REG} depletion (day 1 and 2 after vaccination) strongly enhanced protective $CD8^+$ T-cell immunity without obvious side effects [253]. Again, the timing of the T_{REG} depletion might be the critical difference because a decrease in specific $CD8^+$ T-cell memory was observed if T_{REG} depletion was carried out before infection with *L. monocytogenes* (day −1 and day 0) [221]. In this setting, T_{REGS} suppress low affinity responder T cells upon primary infection, and in turn promote the high affinity response, which is associated with the development of functional immune memory.

55.4.3 Fungal Infections

Besides few pathogenic species, fungi comprise many commensal organisms that can cause opportunistic infections in immune-compromised patients. Human T_{REGS} have been shown to expand antigen specifically in response to mucosal fungi (*Aspergillus* spp. and *Candida* spp.), potentially reflecting an important mechanism to suppress allergic asthma [254]. In contrast to their role during most other infections described above, T_{REGS} were exclusively beneficial in a model of *Cryptococcus neoformans* infection. Here, T_{REGS} were shown to suppress pathologic T_H2 responses while promoting T_H1-mediated pathogen clearance [255]. The role of T_{REGS} during *Candida* infection seems to be more complex. Depletion of T_{REGS} leads to improved resistance [256]. However, similar to what is seen in *Listeria* and *Leishmania* infections, T_{REGS} have also been shown to allow the establishment of immune memory, as T_{REG} depletion impaired protection from reinfection [257]. Interestingly, T_{REGS} also promote T_H17 responses against *Candida albicans* during acute infection (as also shown for *Citrobacter rodentium* infection [220]), while they prevent the establishment of T-cell-mediated transfer colitis (a model of inflammatory bowel disease) during later stages of infection [219]. The dynamics of T_{REGS} during the course of

infection are thus an important parameter to take into account when planning the manipulation of T_{REGS} during infection [258].

55.4.4 Parasitic Infections

One of the most important diseases worldwide is malaria, caused by *Plasmodium* spp. As already described above for viral infections, the debate as to whether T_{REGS} are beneficial or detrimental during parasitic infections is ongoing. Parasite load correlates with T_{REG} numbers in humans [259], although it is discussed that a certain threshold of parasitic load is needed to cause the observed increase in T_{REGS} (reviewed in Ref. [260]). Malaria patients were shown to be in a transiently immune suppressed state in response to many unrelated triggers, a so-called "bystander" effect of T_{REG} function [261,262]. Of note, although T_{REG} numbers correlate with infection, the appearance of effector T cells follows, leading to a stable T_{REG}/T effector ratio [260]. T_H1-prone C57Bl/6 and T_H2-prone Balb/c mice differ in their response to T_{REG} depletion during *Plasmodium* infection [263]. In C57Bl/6 mice, anti-CD25-mediated T_{REG} depletion greatly reduced parasitic burden and prevented features of cerebral malaria [264]. While Balb/c mice are generally resistant to the T_H1-driven cerebral malaria, the consequence of the same depletion strategy in these mice was likewise a reduction of the parasitic burden, but accompanied by enhanced features of the disease [265,266]. Interestingly, the T_H2-driving cytokine IL-33 could mediate protection from experimental cerebral malaria in C57Bl/6 mice and depletion of T_{REGS} using C57Bl/6-DEREG mice led to abrogation of this protection [267]. Mouse strain-dependent differences were also found in models of leishmaniosis: blocking IL-10 signaling (one of the major T_{REG}-driven suppressive mechanisms described in this model) in C57Bl/6 mice was shown beneficial due to the enhancement of a clearing T_H1 response [268]. Depletion of T_{REGS} in Balb/c mice could enhance pathogenesis by promoting the predominant T_H2-type immunity [269]. The absence of CD103 in Balb/c mice has, however, been shown to block susceptibility to *Leishmania major* infection, presumably due to inhibition of the T_{REGS} access to infected sites [270]. While enhanced pathogenicity in response to T_{REG} depletion does not seem predominant in *Leishmania* models, loss of long-term immunity to reinfection after initial clearance was observed [268]. It is tempting to speculate that mechanisms similar to those discussed earlier in this chapter for CD8 memory in response to *Listeria monocytogenes* are involved [221].

Schistosoma, such as the trematode helminths that cause Bilharzia, establish long-term chronic infections associated with immune suppression [271]. Studies showed that depletion of T_{REGS} in mice infected with *Schistosoma mansoni* leads to aggravated liver pathology and enhanced destruction of the worm eggs [272]. Infection with filarial nematodes also induces T_{REGS}, and defective T_{REG} activity was shown to correlate with the development of immunopathological symptoms, such as lymphedema and elephantiasis [273]. Using a mouse model of filarial nematode infection, it was established that T_{REG} induction takes place in two distinct waves, of which at least the first wave was necessary for the establishment of the parasite [274]. The third group of helminths is composed of intestinal

nematodes, which also trigger expansion of T_{REGS} at the site of infection, as shown in mouse models (reviewed in Ref. [271]). Systemic numeric expansion in humans could not be detected, but the general immunosuppressed state in infected individuals suggests a qualitative increase in T_{REG} activity [271]. Whether depletion of T_{REGS} during intestinal nematode infection can contribute to expelling of worms is not fully established. T_{REG} depletion in a *Heligmosomoides polygyrus* mouse infection model led to no differences in worm burden, but elevated T_H2 responses [275]. In line with these findings, *H. polygyrus*-induced T_{REGS} were shown to have a suppressive effect on the development of allergic airway inflammation [276]. While parasite burden was not affected by T_{REG} depletion in infections with *Trichinella spiralis* [277], T_{REG} manipulation led to enhanced immunopathology and lowered the overall worm burden in a model of *Trichuris muris* infection [278]. Depletion of T_{REGS} in a *Strongyloides ratti* model also led to enhanced worm expulsion in Balb/c mice (but not in C57Bl/6 mice) [279]. Taken together, T_{REGS} are important players in the host–parasite interaction, and breaking tolerance against the parasite generally leads to a decrease in parasitic burden.

55.5 Clinical Perspectives

With the tremendous amount of knowledge gained in the field of T_{REG} biology over the last decades, we could only review a few of the outstanding studies addressing T_{REG} manipulation in experimental settings. Future clinical perspectives might involve the inhibition of T_{REGS} during vaccination, chronic infection, or tumor therapy. Another example calling for more careful investigation is the role of T_{REGS} in coinfections such as with helminths and malaria or tuberculosis [280], as well as the impact of infection-induced T_{REGS} on vaccination or allergy [281]. More specific drugs will be needed to target these important cells directly *in vivo* – interference with the molecular pathways discussed in Section 55.2 could therefore lead to novel therapeutic avenues and will require intense research activities. The recently documented therapeutic effects of so-called checkpoint inhibition (e.g., anti-CTLA-4/ipilimumab, anti-PD-1/pembrolizumab/nivolumab/MK-3475, anti-PD-L1/MPDL3280A) and chimeric antigen receptor (CAR) strategies have led to a revolution of cancer immunotherapy [192,282–284]. Yet, tools to more selectively target $Foxp3^+$ T_{REGS} in humans are still of great interest with regard to their therapeutic potential and side effects in comparison to available therapies. One promising approach is targeting human effector T_{REGS} by anti-CCR4 antibodies or immunotoxins [285,286]. Various combinatorial approaches of checkpoint/T_{REG} inhibitors, conventional therapies, and/or vaccination strategies will also be an important future question [283,287]. Conversely, the opposite scenario of T_{REG} transfer, expansion, and stimulation could be envisioned when tolerance is defective, for example, during autoimmune diseases or when immunopathology is caused by excessive immune responses to foreign antigens. The first phase I and II clinical trials in GvHD treatment and prophylaxis, type 1 diabetes, MS, Crohn's disease, steroid-resistant asthma, and uveitis are to be initiated or are already ongoing and

some of the results are truly encouraging (reviewed in Ref. [288]). While cellular transfer of T_{REGS} will always be limited by the specific requirements of individualized medicine, including expensive and laborious GMP production steps, new approaches such as the manipulation of metabolic pathways to increase T_{REG} numbers and reduce effector cell responses might be of future importance [47,81].

To conclude, it is evident that T_{REG} manipulation is a double-edged sword: evolution has led to a fine-tuned balance of immunity, immunopathology, and immune tolerance, and these aspects need careful attention when designing putative treatment strategies. More research and careful evaluation of studies using T_{REG} depletion or stimulation as a means of immune engineering are thus necessary for every individual approach.

Acknowledgments

We would like to thank to Drs. Lucy Walker, Shimon Sakaguchi, Benoit Salomon, and Penelope Kay-Fedorov for fruitful discussion and critical comments. We apologize to all colleagues whose work we may have not been able to cite due to space constraints. LB is supported by the Ellen-Schmidt Program from the Medical School Hannover. This work was supported by the SFB900 to TS and the HiLF Program to LB.

Leukocyte Reprogramming

Jean-Marc Cavaillon

Institut Pasteur, Unit Cytokines & Inflammation, 28 rue Dr. Roux, 75015 Paris, France

56.1 Introduction

Inflammation is an extremely fast response of the host to any type of sterile or infectious insult. However, the proinflammatory response needs to be rapidly counteracted, even in the maintained presence of activating signals. Indeed, an overzealous inflammatory response, as illustrated by the cytokine storm seen during sepsis, can quickly become deleterious. Many mediators are produced soon after initiation of the inflammatory response to dampen it: anti-inflammatory cytokines, resolving lipid mediators, neuromediators, acute-phase proteins, glucocorticoids, and cross-talk with regulatory T cells (Treg) (Figure 56.1). Some inhibitors can specifically neutralize proinflammatory cytokines (e.g., soluble TNF receptor, IL-1 receptor antagonist (IL-1Ra), IL-36Ra, soluble IL-1 receptor, and IL-18 binding protein). Furthermore, a complex mechanism of cell reprogramming is initiated. This aims to limit the perpetuation of the inflammatory process, while maintaining the capacity of the host to fight the infection, and favoring the resolution of inflammation. First identified as endotoxin tolerance, the process is now recognized to not be specific to endotoxin [1] but to occur following any activation by ligands of pattern recognition receptors (PRRs) such as Toll-like receptors (TLRs) or NOD-like receptors (NLR). Triggering factors can be pathogen-associated molecular patterns (PAMPs) released by microbes or damage-associated molecular patterns (DAMPs) released by injured or necrotic cells. This process is not a global switch off of all bioactivity but rather an adaptation. The term "reprogramming," first coined by David Morrison, perfectly describes the situation [2].

56.2 Endotoxin Tolerance

In 1946, Paul Beeson (1908–2006) injected rabbits with typhoid vaccine (1.25×10^8 heat-killed *Salmonella typhosa*) on a daily basis [3]. On the seventh

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

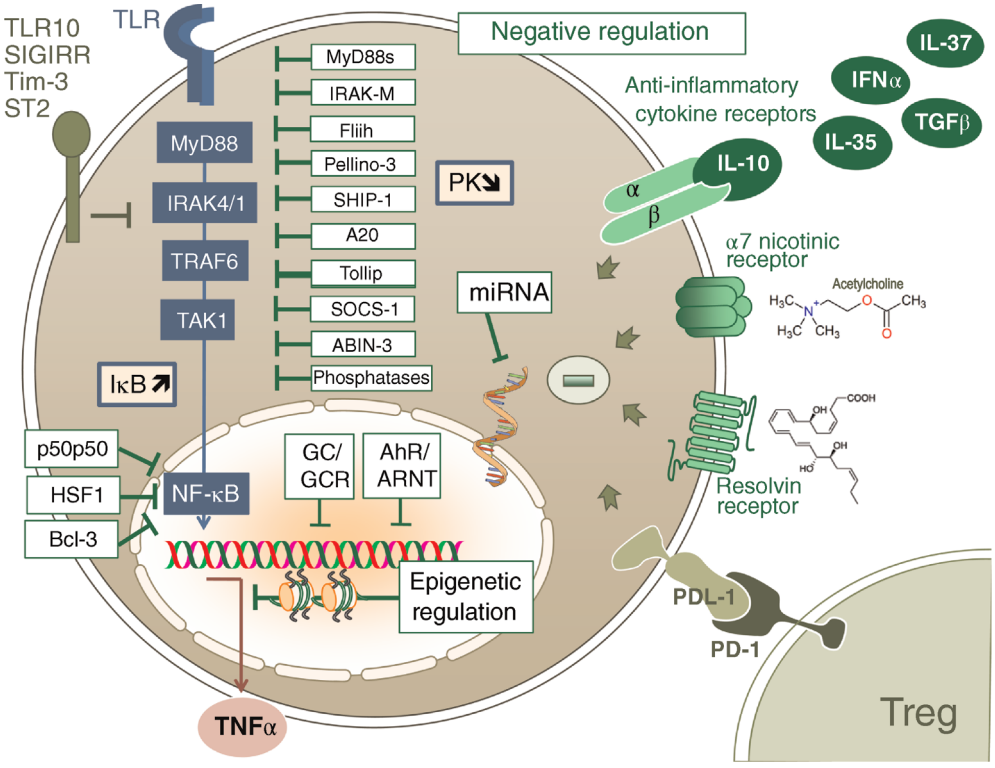

Figure 56.1 Exogenous signals, intracellular negative signaling molecules and intracellular mechanisms aimed to dampen the intracellular inflammatory cascade initiated by TLR ligands, ending to reprogrammed leukocyte.

day, he observed that the rabbits developed a markedly attenuated febrile response as compared to the first day during which they displayed a typical biphasic fever over 8 h following the injection. The next year, Beeson reported that tolerance to bacterial pyrogens was not bacterial strain-specific and could be abolished by blocking the reticuloendothelial system [4,5]. A similar observation on pyrogenicity was obtained using endotoxin instead of whole bacteria and could be conveyed by passive transfer of tolerant plasma [6]. In 1948, Morgan showed that human volunteers receiving repeated iv injection of somatic antigens from *S. typhosa*, *S. schottmuelleri*, and *Shigella dysenteriae* became tolerant as judged by their reduced febrile response [7]. He postulated that the tolerance was reciprocal for all three bacteria.

Pretreatment was soon associated with protection against a second lethal challenge. In 1955, Rowley reported that *Escherichia coli* cell walls (when given either ip or iv 48 h earlier) could protect mice against a lethal infection induced by 2×10^6 *E. coli* ip [8]. The following year, Landy and Pillemer showed that protection of mice could be achieved with the *S. typhosa* endotoxin given 1–3 days before different lethal bacterial infections (e.g., *E. coli*, *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, and *S. typhosa*) [9]. The authors similarly showed that injection of a nonlethal dose of (lipopolysaccharide) (LPS) could protect

against a subsequent lethal dose. In rabbits, endotoxin tolerance was associated with protection against the lethal effect of LPS [10].

Numerous studies have been undertaken to decipher the phenomenon of endotoxin tolerance. Although the process can be fully mimicked *in vitro* with many cell types, macrophages were shown to be the main cells *in vivo* orchestrating endotoxin tolerance. In elegant transfer experiments performed in the LPS-nonresponding strain C3 H/HeJ rendered sensitive to LPS by the injection of normal C3 H/HeN macrophages, Freudenberg and Galanos [11] showed that prior transfer of tolerized macrophage from C3 H/HeN protected the mice against a lethal LPS injection. If one excludes the regulation of endogenous pyrogen, interferon was the first cytokine for which circulating levels were shown to be markedly depressed in LPS-pretreated mice challenged with a virus or LPS itself [12]. In rabbits, endotoxin tolerance was associated with a failure to detect circulating tumor necrosis factor (TNF) after the second challenge [13]. Of note, the diminished release of circulating cytokines is not a global defect: in mice, circulating levels of TNF, IL-6, and interferon-γ (IFNγ) were profoundly abolished by endotoxin pretreatment before an LPS challenge; however, reduction of IL-12, CXCL1, and CCL2 was less pronounced while levels of IL-1β and IL-18 were almost unchanged [14]. The abolished production of circulating TNF in tolerant mice was not observed if the mice were adrenalectomized [15], suggesting a role for glucocorticoids in this *in vivo* phenomenon.

The *in vitro* capacity of LPS to directly affect the capacity of macrophages to produce TNF was first established with cell lines [16,17], rabbit peritoneal macrophages [13], and human monocytes [18]. These observations indicate that even if circulating mediators present in plasma can contribute to the state of tolerance, the process can be intrinsic to the macrophage lineage. However, the phenomenon has been described with most cell types, including mast cells, endothelial cells, dendritic cells, epithelial cells, and fibroblasts.

56.3 Cross-tolerance

The cross-tolerance between endotoxins from different bacterial origins was rapidly recognized [9]. As early as 1957, Zweifach *et al.* [19] used the word cross-tolerance to characterize the finding that rats in whom endotoxin tolerance was induced by repeated doses of LPS became highly resistant to the lethal effects of both drum trauma and hemorrhagic shock. The following year, another cross-tolerance was reported between virus and endotoxin in terms of induction of endogenous pyrogen [20]. The concept of cross-tolerance was then forgotten; indeed, a review published in 1973 considered tolerance to be specific to endotoxin [21]. Rather surprisingly, Sheldon Greisman, the co-author of this review, had published the results of a very important experiment a few years earlier that he did not even dare to mention in the abstract of the paper! Rabbits treated with turpentine administered via different routes were rendered tolerant to the pyrogenic effects of LPS, with a 70% reduction of fever [22]. With the contemporary understanding that sterile inflammation induced by turpentine is associated with the generation of DAMPs, these findings displayed an undeniable

innovation, demonstrating indirectly for the first time the cross-tolerance between DAMPs and PAMPs. Whether the reverse would be possible, that is, an endotoxin injection protecting against a sterile inflammation was addressed in the late 1990s and renamed LPS preconditioning. Such pretreatment with LPS showed protection in various models of ischemia/reperfusion of the heart, brain, neurons, kidney, liver, or lungs, and after myocardial infarction and stroke.

Different stimuli can induce endotoxin tolerance, including alcohol, complete Freund adjuvant, sodium arsenite, phorbol-12-myristate-13-acetate (PMA), heat stress, and exercise. In addition, Gram-positive bacteria (*Corynebacterium parvum*, *Streptococcus pyogenes*, *S. aureus*), bacterial toxin (Shiga toxin-2, Cholera toxin), fungi (*Candida albicans*), mycobacterial lipoarabinomannan, and parasites (*Toxoplasma gondii*, filarial nematode) can also induce endotoxin tolerance. The reverse is also true: LPS can induce tolerance to heat-killed bacteria and zymosan, a fungal glucan [23]. Most importantly, the two main proinflammatory cytokines, IL-1 and TNF, can also induce endotoxin tolerance [24–26] in a synergistic manner [27].

56.4 From Endotoxin Tolerance to PRRs Ligands Tolerance

Most lipopolysaccharides activate cells via the TLR4/MD2 complex, with a contribution from CD14 and, eventually, LPS binding protein (LBP). TLR4 is the only TLR that can initiate two signaling pathways: the MyD88-dependent pathway shared with all TLRs except TLR3, and the TRIF-dependent pathway that is shared with TLR3. Of note, the MyD88 pathway is also shared with the IL-1 and IL-18 receptors. Accordingly, it is not surprising that cross-tolerance exists between most TLR ligands, IL-1 and IL-18.

The cross-tolerance between endotoxin and TLR2 ligands was established with the synthetic lipopeptide Pam3Cys–Ala–Gly even before this activator was recognized to be a TLR2 agonist [28]. Specific TLR2 agonists, such as the mycoplasmal "macrophage-activating lipopeptide-2" (MALP-2) [29], the lipoteichoic acid (LTA) of Gram-positive bacteria [30], *Yersinia* V-antigen [31], *Propionibacterium acnes* [32], fimbriae [33], or *Porphyromonas gingivalis* LPS, a rare endotoxin known to be a TLR2 ligand [34], were also demonstrated to cross-tolerize with LPS.

The cross-tolerance between poly I:C (polyinosinic:polycytidylic acid), a TLR3 ligand, and other TLR ligands led to controversial results. On the one hand, some authors reported that poly I:C pretreatment failed to induce tolerance to LPS [35,36], but could instead prime the response to TLR2 and TLR9 ligands [37]. Surprisingly, pretreatment with a TLR3 agonist tolerized cells when the Lipid A moiety of LPS was employed as the challenge [38]. Other reports showed that poly I:C could tolerize LPS responsiveness both *in vivo* and *in vitro* [39]. LPS and TLR2 agonists induce tolerance to flagellin, a TLR5 ligand, but the reverse seems only true with TLR2 ligands [37,40]. Stimulation via TLR7 tolerizes cells to TLR2 and TLR4 ligands [35,41]. Similarly a cross-tolerance exists between LPS and the oligodesoxynucleotide CpG, which is a TLR9 ligand [42,43]. CpG pretreatment protected against sepsis [44], and against

CpG + galactosamine-induced shock [45]. Of note, when human volunteers were injected with LPS, their peripheral blood cells tested a few hours after were tolerized to TLR2, TLR3, TLR4, TLR5, and TLR7 ligands [46].

Nucleotide-binding oligomerization domain-containing protein 1 (NOD1) and NOD2 are cytoplasmic PRRs. Muramyl tripeptide (MTP) and muramyl dipeptide (MDP), subunits of peptidoglycan, a constituent of both Gram-negative and Gram-positive bacteria, are NOD1 and NOD2 ligands. MTP pretreatment was protective against bacterial sepsis and LPS-induced shock [47,48], while MDP could induce self-tolerance and cross-tolerance to TLR2 and TLR4 ligands [49]. In contrast, LPS did not tolerize MDP either *in vivo* or *in vitro* [50,51]. Finally, LPS can also desensitize unrelated signaling pathways, as shown by its action prior to CD40 stimulation by CD40 ligand [52].

The demonstration of cross-tolerance between bacterial or synthetic ligands of TLRs is mimicked with DAMPs such as mitochondria [53], high mobility group box 1 (HMGB-1) protein [54], heat shock protein (HSP) [55], myeloid-related protein 8 (MRP8) (S100A8) and MRP14 (S100A9) [56], or fragments of hyaluronan [57].

56.5 Does Endotoxin Tolerance Affect Anti-Infectious Immunity?

As mentioned earlier, endotoxin tolerance was identified in the mid-1950s to protect against subsequent bacterial infection in mice [8,9], rats, and guinea pigs [58]. It was subsequently reported that endotoxin tolerance could induce protection against viral (influenza virus) [59] and fungal infection (*C. albicans*) [60]. More recent studies confirmed that mice pretreated with LPS had enhanced protection against bacterial [61], fungal [62], and viral [63] infections. However, other studies showed that the anti-infectious defenses could be altered [64,65]. These differences could reflect different protocols, timings, dosages, or routes of injection. Enhanced immunity following LPS pretreatment can be due to an increased killing capacity of macrophages [66], increased macrophage resistance to bacterial-induced apoptosis [63], improved bacterial clearance [67], increased formation of neutrophil extracellular traps (NETs) [68], redirection of neutrophils toward the site of infection [69], enhanced capacity of neutrophils to produce hydrogen peroxide [69], and limitation of the cytokine storm [70] that prevents the occurrence of multiple organ injury [71].

56.6 Clinical Relevance

The hyporesponsiveness of human leukocytes to LPS was first reported in 1949 in patients with malaria who displayed a lower febrile response to typhoid vaccine compared to healthy controls [72]. A similar reduced pyrogenic response was also observed in patients convalescing from typhoid fever [73]. The association of malaria with a reduced endotoxin-induced fever was directly demonstrated in

prisoner volunteers inoculated with *Plasmodium cynomolgi* or *P. vivax* before injection with endotoxin [74]. Still assessed in terms of fever, patients with infectious pyelonephritis were shown to be tolerant after a typhoid vaccine injection [75]. The tolerized status of circulating monocytes from sepsis patients was demonstrated *ex vivo* in terms of reduced production of TNF, IL-1α, IL-1β, and IL-6 in response to LPS [76]. Similar tolerant-like status was demonstrated with circulating leukocytes of patients with bacterial, parasitic, or viral infections, after severe surgery, particularly after cardio-pulmonary bypass, pancreatitis, burns, trauma, severe heart failure, acute coronary syndrome, chronic liver failure, liver cirrhosis, cystic fibrosis, and in patients resuscitated after cardiac arrest [77].

The altered immune status of these patients has been qualified in different ways: deactivation, adaptation, desensitization, anergy, refractoriness, immunodepression, immunosuppression, or immunoparalysis. The concept of leukocyte reprogramming most probably appears as the best expression to qualify these various situations after infectious or sterile insults [78]. Of importance, the systemic inflammatory response syndrome (SIRS) and the compensatory anti-inflammatory response syndrome (CARS) are occurring both concomitantly [79] and very soon after the insult [77,80]. The *ex vivo* hyporesponsiveness of the leukocyte to LPS is proportional to the severity of the insult [81] and the clinical severity of the patient [82]. In this study, the authors found an "endotoxin tolerance signature" generated by 99 genes uniquely differentially expressed in endotoxin-tolerant human peripheral blood mononuclear cells in patients with sepsis; this was associated with the severity of the disease in terms of the occurrence of organ dysfunction [82].

56.7 From Tolerance to Reprogramming

Zhang and Morrison [2] employed the word "reprogramming" when they found that release of nitric oxide (NO) and tumor necrosis factor was independently regulated in LPS-tolerized macrophages. Numerous authors have subsequently claimed that not all macrophage functions are extinguished in LPS-tolerant cells. For example, NO production [83], hydrogen peroxide release [82], lipocalin-2 expression [84], MRP8 & MRP14 expression [85], and phagocytosis [86,87] can be enhanced. The concept that endotoxin tolerance was not a global immunosuppression was convincingly demonstrated when Medzhitov's group studied chromatin modification [88]. They demonstrated that on repeated exposure to LPS, one class of gene ("tolerizeable" including inflammatory cytokines) was transiently silenced to prevent the pathology associated with excessive inflammation. The second class of genes (nontolerizeable) includes antimicrobial effectors, which remained inducible to protect the host from infection. That this process is not a global defect is illustrated in sepsis patients whose monocytes display enhanced phagocytosis, antimicrobial activity and capacity to produce matrix metalloproteinase 9 & 14, and vascular endothelial growth factor (VEGF) despite an altered response to LPS in terms of inflammatory cytokine production [89]. This process is not observed in all tissues; indeed, alveolar macrophages

and Kupffer cells of mice undergoing trauma-hemorrhage plus sepsis displayed an enhanced capacity to produce TNF in response to LPS [90]. This finding contrasted with that seen using blood or spleen macrophages. Neither murine alveolar macrophages [91] nor human alveolar macrophages [92,93] could be tolerized.

56.8 Reversal

Granulocyte-macrophage colony-stimulating factor (GM-CSF) and IFNγ are well-known macrophage-activating factors. They are also the two main cytokines able to counteract the induction of tolerance. To exert their counter-regulatory activity, they can be added either during the first contact with LPS, or added subsequently to LPS preculture or before the second LPS challenge. Addition of IFNγ (but not IFNα or IFNβ) to Mono-Mac-6 cells during the LPS preculture period led to an inhibition of desensitization [94]. Using THP-1 cells, Shi *et al.* mitigated endotoxin-induced tolerance with interferon-α2 [95]. The capacity of IFNγ to prevent endotoxin tolerance was confirmed with human monocyte-derived macrophages [96] and *in vivo* in mice [97]. Not only could GM-CSF and IFNγ prevent the induction of tolerance, but also their pretreatment of human mononuclear cells could prime the responsiveness of the cells [98]. Both cytokines could also reverse the protective effects of endotoxin tolerance in a lethal LPS challenge [99]. These cytokines prevent endotoxin tolerance induced by low, but not high, doses of LPS by inhibiting IRAK degradation and also by promoting its association with MyD88 after a second LPS stimulation. This in turn leads to NF-κB activation and TNF production [100]. The properties of GM-CSF and IFNγ to reverse endotoxin tolerance were further demonstrated in sepsis and trauma patients by their capacity to reverse the acquired status of tolerization [101,102].

56.9 Mechanisms

56.9.1 Anti-Inflammatory Cytokines

As expected, pretreatment of human monocytes by anti-inflammatory cytokines such as IL-10 and TGFβ can mimic endotoxin tolerance [23]. Of note, *in vitro* pretreatment of monocytes by IL-10 requires cells to be adherent to the plastic wells [103]. If this adherence is prevented, either in cultures of whole blood samples or on Teflon, the IL-10 pretreatment can prime the subsequent LPS response. The involvement of IL-10 and TGFβ was fully established by Randow *et al.* [104] when they prevented the induction of LPS tolerance using anti-IL-10 and anti-TGFβ antibodies. In human sepsis, IL-10 was found to be a major functional deactivator of human monocytes [105]. However, IL-10-deficient mice can be rendered fully tolerant to LPS [106] illustrating that one anti-inflammatory cytokine alone cannot explain the whole reprogramming mechanism. Among anti-inflammatory cytokines, IL-1 receptor antagonist (IL-1Ra) behaves differently in its capacity to prevent the induction of LPS-induced tolerance [107]. This observation has to

be associated with the capacity of IL-1α or IL-1β to mimic LPS-induced tolerance [23], and their possible involvement within an autocrine loop after LPS activation.

56.9.2 Glucocorticoids

As previously mentioned, the observation of endotoxin tolerance requires the presence of intact adrenals; glucocorticoid administration restored the capacity of adrenalectomized mice to be rendered tolerant to LPS [15]. This early observation was confirmed by the use of the glucocorticoid receptor antagonist RU486 that prevented LPS tolerance [108]. Similarly, RU486 counteracted the LPS-induced protection against hypoxia-ischemia induced brain damage [109]. LPS activates the hypothalamic–pituitary–adrenal axis, ending in the production of adrenocorticotropic hormone (ACTH) and corticosterone [110]. Endotoxin tolerance also alters the responsiveness of the hypothalamic–pituitary–adrenal axis itself [111]. While glucocorticoids can modulate nearly 2800 genes [112], half of them are induced, including the glucocorticoid-induced leucine zipper (GILZ). Using GILZ KO mice, it was demonstrated that this molecule contributes to endotoxin tolerance [113]. Whether other glucocorticoid-induced molecules play a similar role is not known. Of note, annexin-1, which is known to dampen monocyte activation, was also shown to act through GILZ [114].

56.9.3 Regulatory Signaling Downstream TLRs

TLR dimerization following their interaction with their ligands results in the binding of their Toll-interleukin receptor (TIR) domain to TIR domain-containing signaling adapter proteins, that is, the myeloid differentiation primary-response protein 88 (MyD88) and, eventually, the MyD88–adapter-like (MAL) protein. Their engagement stimulates downstream signaling pathways that involve interactions between IL-1R-associated kinases (IRAKs), the adapter molecules TNF receptor-associated factors (TRAFs), and TGFβ-activated kinase (TAK). An activated IκB-kinase high-molecular-weight complex favors IκB phosphorylation, which is then followed by its ubiquitination and dissociation from nuclear factor-κB (NF-κB). NF-κB then translocates into the nucleus and binds to promoters of numerous genes, favoring their transcription.

Numerous intracellular signaling molecules are upregulated in tolerized cells and act at different levels on the positive signaling cascade to counteract the different players (Figure 56.1). For example, MyD88short (MyD88s), a splice variant of MyD88, termed MyD88 short, competes with MyD88. Once bound it prevents the binding of IRAK4 and the phosphorylation of IRAK1 [115], IRAK-M prevents the formation of IRAK/TRAF6 complex [116,117]. Suppressor of cytokine signaling (SOCS)-1 is a negative regulator molecule of the JAK-STAT signal cascade [118]. SHIP-1 (SH1-containing inositol-5′ phosphatase), which is produced in response to TGFβ, exerts its inhibitory effects primarily through the hydrolysis of phosphatidylinositol 3-kinase [117,119]. A20 accomplished its termination of the TLR response by directly removing ubiquitin moieties from the signaling molecule TRAF6 [117,120]. ABIN-3 (A20 binding

inhibitor of NF-κB activation) inhibits NF-κB activation, downstream of TRAF6 [121]. Pellino-3b deactivates IRAK-1, TBK1, MyD88, and TRIF-dependent signaling cascades [122]. Toll-interacting protein (Tollip), an adapter protein that associates with the cytoplasmic TIR domain of IL-1R, TLR2, and TLR4, potently suppresses the activity of IRAK after TLR activation [123]. Flightless I homolog (Fliih) directly interferes with the formation of the TLR4-MyD88 signaling complex, and acts as a negative regulator [124]. Of note, numerous phosphatases also contribute to leukocyte reprogramming [125] while different kinases are deactivated [126–128].

Some players prevent the binding of the active p50p65 NF-κB heterodimer such as Bcl-3, which is induced by IL-10 [129], p50p50 homodimer [130], and HSF1 [131]. Furthermore, IκB is more rapidly regenerated in endotoxin-tolerant cells [132], reflecting a failure of IκB kinase induction on second exposure to LPS [133]. Negative signals can also be delivered by cell surface receptors such as SIGIRR (single immunoglobulin IL-1R-related molecule) [134], TIM3 (T-cell immunoglobulin domain and mucin domain 3) [135], ST2 [136], and TLR10 [137]. Of interest, some of these negative regulators are upregulated in cells from sepsis or SIRS patients [89,138–143].

56.9.4 Epigenetics

During leukocyte reprogramming, chromatin remodeling, histone acetylation, and methylation occur at the promoter sites of many genes. For example, during LPS tolerance, phosphorylation at serine 10 and methylation at lysine 9 of histone H3 prevent the binding of NF-κB p65 onto the IL-1β promoter [144]. Depending on the nature of the modification, some genes will be tolerized and non responsive to a second stimulus whereas others will not be tolerized [88]. Accordingly, cells display a reduced capacity to produce proinflammatory genes while maintaining their capacity to produce anti-inflammatory, anti-microbial, and healing players. The group of Charles McCall further deciphered the epigenetic mechanism in tolerized cells (see Chapter 38). For example, they showed that H3K9 histone methyltransferase G9a and heterochromatin-binding protein-1 (HP1) cooperatively interact to silence TNF and IL-1β expression [145,146]. Of note, the H3K9 histone methyltransferase G9a is recruited by the stress-response transcription factor, ATF7 [147].

The relevance of the *in vitro* epigenetic analysis has been illustrated in a murine model of sepsis by the observation of a long-term altered histone methylation on the *il12* promoter [148]. In human sepsis, McCall's group found that the NAD^+-dependent sensor, sirtuin 1 (SIRT1), which is known to deactivate RelA/p65 through lysine 310 deacetylation during endotoxin tolerance, was increased in both promoters of TNF and IL-1 of patient leukocytes as compared to healthy controls [149]. Similarly, the expression of H3K4me3, H3K27me3 and H3K9Ac was either increased or decreased in leukocytes from septic patients as compared to healthy controls, depending on the nature of the genes [150].

56.9.5 miRNA

MicroRNAs (miRNA or miR) are regulators of gene expression acting at the posttranscriptional level via an mRNA interference mechanism. miR-146a is

critical for endotoxin tolerance [151]. miR-146a expression gradually increases by 8 h post-LPS exposure in a dose-dependent manner. Transfection of miRNA-146a mimics LPS priming in an LPS tolerance assay while its blockade abrogates LPS-induced tolerance. miR-146a promoted binding of the transcription repressor RelB to the TNF promoters [152]. Furthermore, overexpression of miRNA146 resulted in a marked reduction of IRAK-1, a key signaling molecule downstream of TLR, and attenuated IκBα phosphorylation [153]. miR-146a also represses TRAF6, another adapter kinase downstream of TLR [154]. miR-146a is not only induced by LPS but also by peptidoglycan, Pam3CSK4, flagellin, and IL-1β [154], suggesting an universal role for this miRNA independent of the agonist. Of note, morphine abrogated LPS tolerance and downregulated miRNA146a expression resulting in a persistent inflammation during sepsis [155]. Other miRNAs (miR-125b, miR221, and miR-579) are significantly increased in tolerant cells [156]. Their concurrent inhibition allows TNF mRNA and protein expression in LPS-tolerant cells. These three miRNAs are significantly induced in the macrophages of septic mice. The protein kinase Akt1 is required for the development of endotoxin tolerance. Akt1 positively regulates miRNA Let-7e, which represses TLR4, and negatively regulates miR155 that represses SOCS1, a negative regulator of cytokine signaling. Overexpression of let-7e and suppression of miRNA-155 in $Akt^{-/-}$ macrophages restored their capacity to undergo endotoxin tolerance [157]. Other miRNAs involved in the regulation of cytokines such as IL-10 which contribute to cell reprogramming can be indirectly involved in endotoxin tolerance. For example, miR-98 negatively regulated IL-10 and endotoxin tolerance [158].

56.10 Macrophage Plasticity

Charles Mills discovered that macrophages could be subdivided into two subsets: M1 and M2. M1 cells are involved in the fight against pathogens whereas M2 cells contribute to the healing phase of inflammation. M1 are characterized by the processing of arginine by inducible nitric oxide synthase (iNOS) to generate NO, while M2 are characterized by processing of arginine by arginase leading to the production of ornithine [159]. Others authors established that LPS or IFNγ was favoring M1, while M2 was induced by IL-4, IL-13, or IL-10 [160]. M1 and M2 produce different subsets of chemokines, and express different cell surface receptors [160]. This is an oversimplification since the gene transcription profile in response to IFNγ or IL-4 is greatly influenced by the compartment from which the macrophages are derived [161]. Endotoxin tolerance was associated with an M2 polarization [162,163]. Of note, for cells recovering from endotoxin tolerance, a unique hybrid status was reported [164]. Some gene expressions had returned to their initial status, some were expressed as in tolerized cells, while others were upregulated. Although the duration of this new profile was not addressed, this observation fits with the new concept of trained innate immunity, which associates a type of immunological memory for innate cells such as macrophages and NK cells [165]. In macrophages, changes in expression of PRRs and cytokines following molecular modification (epigenetic changes, different miRNA

expression . . .) contribute toward priming the cells during their encounter with a new pathogenic stimulus.

Roles of Specialized Proresolving Lipid Mediators in Inflammation Resolution and Tissue Repair

Matthew Spite and Charles N. Serhan

Brigham and Women's Hospital and Harvard Medical School, Department of Anesthesia, Perioperative and Pain Medicine, Center for Experimental Therapeutics and Reperfusion Injury, Building for Transformative Medicine, 60 Fenwood Rd., Boston, MA 02115, USA

57.1 Resolution of Acute Inflammation: Identification of Specialized Proresolving Mediators

Acute inflammatory responses are necessary for survival because they protect against exogenous pathogens that disrupt host homeostasis. In contrast, inappropriate activation of the immune system by inert stimuli or endogenous neoepitopes can lead to persistent chronic inflammation and can promote tissue fibrosis and dysfunction (Figure 57.1a) [1]. Indeed, chronic unresolved inflammation is classically associated with many chronic diseases, including asthma and neurological degenerative disorders, metabolic diseases, arthritis, and periodontitis [2-5].

The acute inflammatory response is divided into an initiation phase and a resolution phase [6]. The initiation phase is accompanied by the cardinal signs of inflammation known to ancient civilizations as heat, swelling, and pain [1] with eventual loss of function that are controlled for the most part by local chemical autacoids. These include proteins (cytokines, chemokines) as well as lipid-derived mediators (e.g., eicosanoids) that form chemical gradients to regulate leukocyte trafficking into the injured tissue. Polymorphonuclear neutrophil (PMN) infiltration and monocyte/macrophage accumulation ensues as a characteristic sequence of events during the initiation of the acute inflammatory response (Figure 57.1a). Once in tissues, these phagocytes contain invading microbes and clear apoptotic cells. Without an appropriate termination and clearance of phagocytes from the injured tissue, their continued presence is associated with collateral tissue damage, as is observed in chronic inflammation [5]. Hence, controlling the infiltration of leukocytes, as well as promoting their clearance from tissues, could attenuate nonresolving chronic tissue inflammation and is a characteristic feature of active resolution of acute inflammation.

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

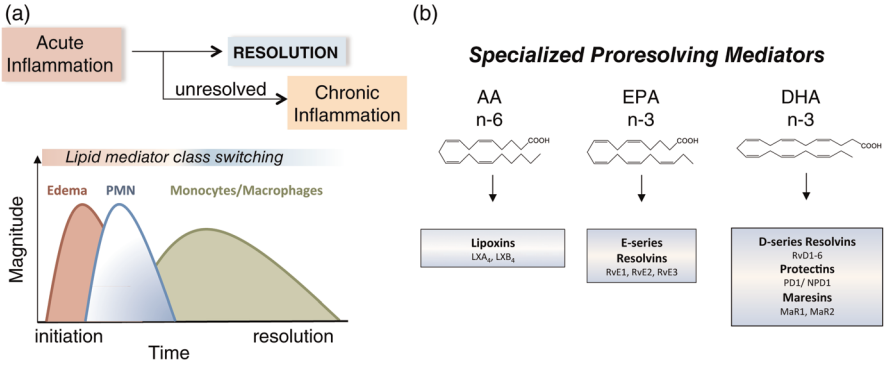

Figure 57.1 Role of specialized proresolving lipid mediators in resolution of acute inflammation. (a) Diagram of the acute inflammatory response, highlighting the initiation and resolution phases and that distinct lipid mediators are associated with each phase. (b) Polyunsaturated fatty acids serve as precursors to the biosynthesis of specialized proresolving mediators. AA, arachidonic acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

The resolution of inflammation and return to homeostasis was previously thought to occur via dissipation of initiating chemotactic signals during the acute inflammatory response [1]. Indeed, several intrinsic negative feedback systems blunt production of inflammatory mediators, such as transcriptional repressors, including activating transcription factor 3 (Atf3) [7]. However, substantial evidence now shows that resolution of contained inflammatory exudates is regulated by temporal biosynthesis of novel chemical mediators during the resolution phase [6]. These proresolving mediators not only counter-regulate inflammatory gene transcription, but also directly limit excessive PMN migration (e.g., downregulate adhesion receptors) and *stimulate* distinct cellular processes, such as macrophage uptake of apoptotic PMN, microbes, and cellular debris, that are required for tissue homeostasis to be reestablished [8-11]. These findings raised the possibility that failed resolution of an inflammatory challenge could potentially lead to recurring bouts of persistent tissue inflammation and diseases associated with chronic inflammation, as well as that proresolving mediators could be a new class of targeted therapeutics [6,12]. Using a systems approach with LC-MS/MS-based analysis of self-limited inflammatory exudates (ones that resolve to homeostasis on their own) new families of specialized proresolving mediators (SPM) were identified. These SPM comprise four families, the lipoxins, resolvins, protectins, and maresins, that have unique structures and are biosynthesized in exudates within the resolution phase of acute inflammation [8,9,11,13]. The identification of these new locally produced mediators demonstrated that the resolution phase of acute inflammation is a biosynthetically active process [10]. Importantly, SPM are conserved from invertebrates to nonhuman primates to humans and several recent studies have documented the presence of SPM in human tissues (e.g., spleen, plasma, serum, urine, and breast milk) at levels commensurate with their biological actions [14-21].

57.2 Lipid Mediator Class Switching During Inflammation and Its Resolution

Lipid mediators play integral roles in both the initiation and resolution of the inflammatory response and lipid mediator class switching governs the duration of acute inflammation (Figure 57.1a) [11]. The eicosanoids, such as prostaglandins (PGs) and leukotrienes, are formed from arachidonic acid (AA; omega-6) and regulate blood flow, endothelial permeability, and PMN chemotaxis [22]. Transendothelial migration and chemotaxis of PMN toward injured tissue and/or pathogens are governed in part by leukotriene B_4 (LTB_4), which is itself a major product generated by PMN and regulates their activation in an autocrine manner [22,23]. After PMN enter tissues, there is a temporal switch in lipid mediators from the initiation phase to resolution in which AA is diverted away from LTB_4 biosynthesis and toward lipoxin biosynthesis [11,24]. Lipoxin A_4 (LXA_4) serves as an endogenous "stop" signal that attenuates PMN infiltration in part by downregulating the surface expression of adhesion receptors. The biosynthesis of lipoxins and related SPM can occur in a single cell or via transcellular biosynthesis (e.g., leukocyte:leukocyte or leukocyte:epithelial interactions) and their biosynthesis also increases when macrophages are actively clearing apoptotic PMN [25]. These SPM also act in an autocrine manner to facilitate phagocytosis. This mechanism of biosynthesis, coupled with potent regulation of inflammatory gene transcription, is similar to that of other "find me" and "eat me" signals (e.g., adenosine, ATP, and CX_3CL1) generated by phagocytes that play a key role in the immunologically silent process of apoptotic cell clearance [26,27]. Systematic identification of these endogenous SPM indicates that they are novel structures and that the precursors for resolvins, protectins, and maresins are omega-3 essential fatty acids EPA and DHA, while the lipoxins are generated from the ω-6 polyunsaturated fatty acid (PUFA), AA (Figure 57.1b). An update on the biosynthesis and biological actions of lipoxins and resolvins is given below and readers are referred to more extensive reviews covering protectins and maresins [28].

57.3 Lipoxins

The lipoxins were the first lipid mediators recognized to have both anti-inflammatory and proresolving actions [29] and are comprised of two distinct regioisomers denoted lipoxin A_4 (LXA_4) and LXB_4. They are biosynthesized from AA via lipoxygenase (LOX) enzymes, whereby 15-LOX generates 15-hydroperoxyeicosatetraenoic acid (15-HpETE), which is further transformed via 5-LOX to LXA_4 and LXB_4 during cell:cell interactions (i.e., transcellular biosynthesis). An alternate lipoxin biosynthetic route involves platelet:leukocyte interactions, in which the intermediate in leukotriene biosynthesis, leukotriene A_4 (LTA_4), is produced within leukocytes and converted to lipoxins by platelet 12-LOX [30]. This biosynthetic mechanism allows for direct shunting of the same intermediate from leukotrienes to lipoxins, thus regulating the duration of leukocyte recruitment. Lipoxins (and their aspirin-triggered epimers; see below)

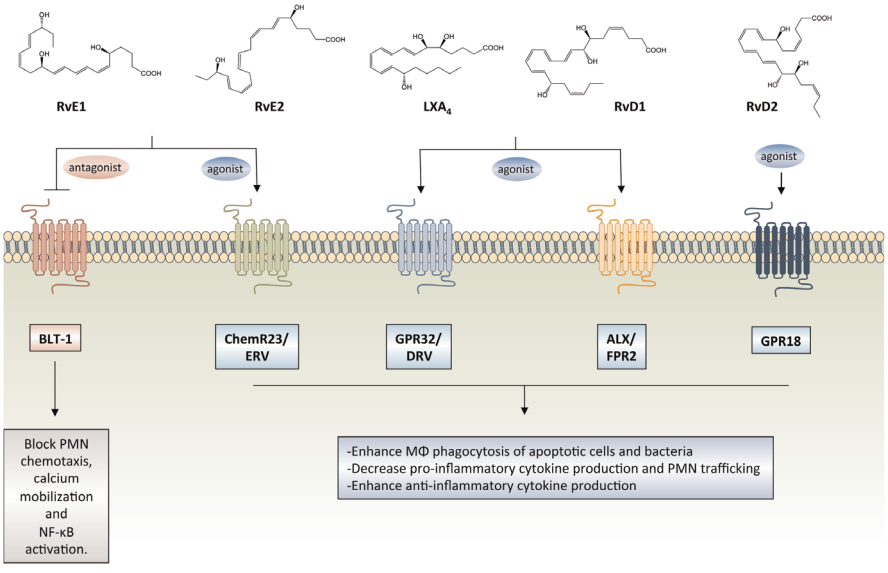

Figure 57.2 Specific receptors and key biological actions of SPM.

are formed in humans, with their levels inversely correlating with peripheral artery disease, local aggressive periodontitis, cystic fibrosis, heart failure, and Alzheimer's disease [31-35].

The biological actions of LXA_4 are mediated in part by a specific G-protein-coupled receptor (GPCR) termed ALX (also denoted formyl peptide receptor 2; FPR2) [30,36]. Specific high-affinity binding (low nanomolar range) of LXA_4 to ALX is stereoselective and ALX signaling mediates the protective actions of LXA_4 in myeloid cells, which include inhibition of NF-κB activation, blockade of leukotriene biosynthesis, attenuation of superoxide production, and regulation of leukocyte chemotaxis (Figure 57.2). Overexpression or genetic deletion of both human and murine homologs of ALX/FPR2 [37] has provided unequivocal evidence that ALX is a bona fide target for LXA_4 [38,39]. Interestingly, ALX also serves as the endogenous receptor for other SPM, including resolvin D1 (RvD1; see below) as well as the proresolving glucocorticoid-inducible protein, annexin A1 [40]. This agonist diversity positions ALX as a central mediator of the resolution of inflammation. In addition to ALX, which is a receptor for LXA_4 and RvD1 in mice and humans, these SPM also bind an additional receptor in humans, termed GPR32 [41].

The anti-inflammatory role of lipoxins has been demonstrated in both animal and human systems, in which administration of LXA_4 or LXB_4 reduces PMN transmigration, PMN-mediated vascular permeability, adhesion receptor expression, and proinflammatory cytokine generation in response to inflammatory stimuli [42-46]. Lipoxin biosynthesis initiated by platelet:leukocyte interactions during ischemia-reperfusion is associated with protection from vascular inflammation in an ALX-dependent manner [47]. In addition to this anti-inflammatory role, lipoxins also stimulate resolution. That is, lipoxins stimulate macrophage-mediated clearance of apoptotic PMN in a noninflammatory manner [48,49].

Interestingly, lipoxins also promote macrophage efflux to peripheral lymph nodes. Thus, lipoxins are dual acting mediators that not only reduce further leukocyte infiltration but also promote their removal from inflamed sites [49,50]. In addition to innate immune cells, lipoxins also have direct actions on adaptive immune cells (e.g., B cells, T cells, and natural killer cells), vascular endothelial and smooth muscle cells, fibroblasts, and epithelial cells. For an extensive chronicle of these cell-specific targets, the reader is referred to a recent review on lipoxins by Romano *et al.* [51].

The identification of the lipoxins as inflammation-resolving mediators raised the possibility that they could be used as a novel genus of agonist-based therapeutics for diseases in which inflammation plays a causal role. Indeed, lipoxins stimulate resolution of inflammation associated with cystic fibrosis, periodontitis, asthma, and sepsis [51]. More recently, it was demonstrated that both LXA_4 and LXB_4 resolve allergic and LPS-driven lung inflammation and that topical administration of LXA_4 promotes corneal wound healing [52-54]. The endogenous role of PMN-derived LXA_4 in mediating resolution of corneal injury was recently established [55]. Lipoxins stimulate the resolution of adipose tissue inflammation in obesity, which translates into improved systemic metabolism [56,57]. In addition to regulating inflammation in metabolic disease, a recent study assigned new biological roles to lipoxins by demonstrating that they promote reverse cholesterol transport in the context of hypercholesterolemia [58]. Lastly, a multicenter, double blinded, placebo-controlled randomized clinical trial recently reported that a stable lipoxin analog denoted 15 *R*/*S*-methyl LXA_4 (which resists metabolic inactivation) blunts the progression of infantile eczema, providing direct evidence that proresolution therapeutics could be a novel approach to treating maladaptive inflammation in humans [59].

57.4 E-series Resolvins

Like the ω-6 PUFA AA, ω-3 PUFA, including eicosapentaenoic acid (EPA), is also used as substrates for cyclooxygenase (COX) and LOX enzymes to generate novel families of SPM. The ω-3 PUFA have long been regarded to have anti-inflammatory actions and have been shown to reduce inflammatory cytokine production in humans [60], although the mechanisms underlying these actions remained unclear. Using murine models of self-resolving acute inflammation, initial studies identified that EPA is converted a novel trihydroxy-containing mediator, which was denoted resolvin E1 (RvE1) [61]. In these studies, mice were administered both EPA and aspirin, because the combination of ω-3 PUFA and aspirin was shown to be protective in cardiovascular disease patients enrolled in the GISSI Prevenzione trial [62]. In addition, it had previously been shown that aspirin acetylation of COX-2 increases the formation of epimeric lipoxins by converting AA to 15*R*-HETE [63]. Like the lipoxin biosynthetic pathway, monohydroxy fatty acids derived from EPA, including 18-hydroxyeicosapentaenoic acid (18-HEPE), were also present in exudates of mice given EPA and it was postulated that this product could potentially be a biosynthetic intermediate derived from acetylated COX-2. Further studies demonstrated that this is indeed the case, whereby

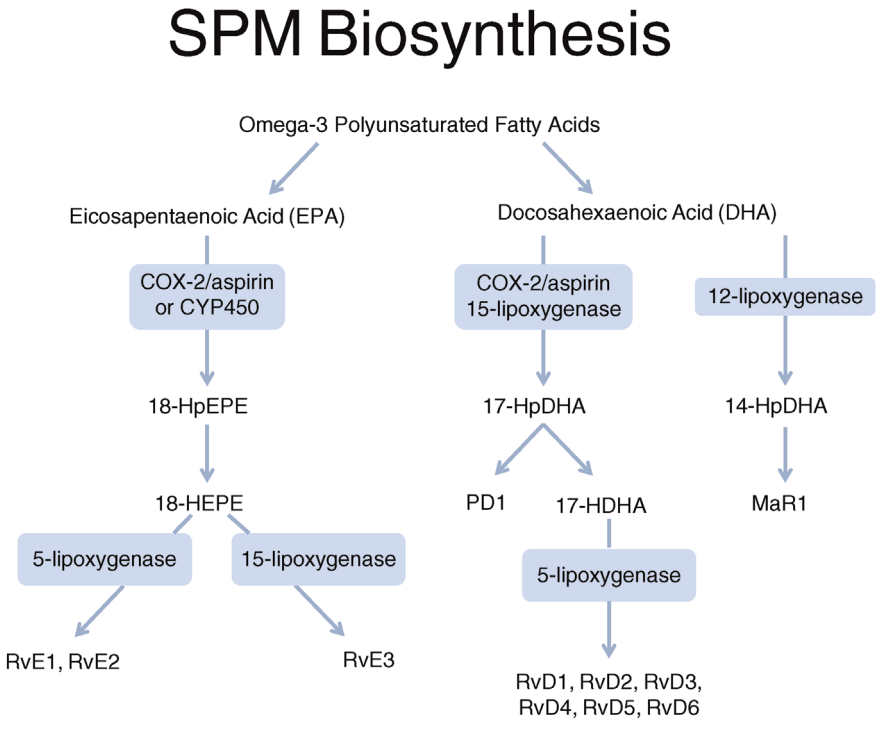

Figure 57.3 Biosynthesis of specialized proresolving mediators generated from omega-3 polyunsaturated fatty acids. Omega-3 polyunsaturated fatty acids serve as substrate precursors for specialized proresolving mediator (SPM) biosynthesis, in which EPA is converted to the E-series resolvins (RvE1, RvE2, RvE3), and DHA is converted to D-series resolvins (RvD1-6), protectins (PD1), and maresins (MaR1).

acetylated COX-2 generates 18-hydroperoxy(Hp)EPE, which is converted by 5-LOX to RvE1. The RvE1 biosynthetic pathway was recapitulated in isolated human cells, which elucidated that 5-LOX and LTB_4 hydrolase act sequentially to form RvE1 from 18-HpEPE [18]. The complete structural elucidation and stereochemical assignment of endogenous RvE1 was subsequently completed by matching the chromatographic and physical properties with synthetic stereoisomers [64]. Importantly, several studies have documented RvE1 formation in humans [18,64-66]. A summary of the E-series resolvin biosynthetic pathway is shown in Figure 57.3.

In animal models of acute inflammation, RvE1 reduces PMN infiltration in response to an inflammatory challenge, which is partially related to its ability to block LTB_4-dependent actions on PMN [64]. Indeed, RvE1 signals as a partial agonist/antagonist of the LTB_4 receptor, BLT1, and attenuates LTB_4-induced proinflammatory signaling in PMN [67] (Figure 57.2). Thus, both the biosynthesis and biological actions of RvE1 compete with proinflammatory LTB_4. In addition to regulating the proinflammatory functions of PMN, RvE1 also stimulates macrophage phagocytosis. Unbiased receptor screening approaches revealed that in addition to BLT1, RvE1 binds and activates ChemR23 (also

denoted ERV) as an agonist. RvE1 inhibits TNF-α-stimulated NF-κB activation in cells transfected with ChemR23, consistent with *in vivo* actions of RvE1 in blocking TNF-α-stimulated leukocyte trafficking and the endogenous role of ChemR23 in counterregulating inflammation was recently demonstrated [68]. Mechanistically, RvE1 stimulates the phosphatidylinositol-3 kinase (PI3K)/Akt pathway, leading to activation of the translational regulator, ribosomal protein S6 [69]. This pathway is involved in RvE1 stimulation of macrophage phagocytosis. Pretreatment of ChemR23-expressing cells with pertussis toxin blocks the effects of RvE1; suggesting downstream signaling through $G\alpha_{i/o}$. ChemR23 is highly expressed on dendritic cells and monocytes, although its expression is low on PMN [64,67]. RvE1 regulates leukocyte trafficking and proinflammatory signaling to promote resolution of peritonitis, colitis, periodontitis (a chronic infectious inflammation), and retinopathy [49,70-72]. Industrial scale-up synthesis has been achieved and RvE1 is currently in clinical development for the treatment of inflammatory pathologies of the eye under the International Nonproprietary name, *Navamepent* [73,74]. More recently, RvE1 was found to blunt the progression of atherosclerotic plaques in a rabbit model of periodontitis and atherosclerosis [75].

The stereochemistry and downstream metabolism are important determinants of the biological actions of RvE1. Aspirin acetylation of COX-2 produces more 18*S*-HEPE (and therefore more 18*S*-RvE1) than 18*R*-HEPE [18]. The 18*S* isomer binds to RvE1 receptors with a higher affinity, but is also inactivated more rapidly. Like eicosanoids, RvE1 can be enzymatically converted into further downstream metabolites. Indeed, RvE1 is a substrate for 15-hydroxyprostaglandin dehydrogenase (15-PGDH; an eicosanoid oxidoreductase; EOR [76]), which converts RvE1 to 18-oxo-RvE1 [77]. This metabolite is essentially inactive compared with RvE1 and is a major metabolic route for RvE1 inactivation in the lung [77]. Other RvE1 metabolites include the ω-oxidation product, 20-hydroxy-RvE1, and 20-carboxy-RvE1 and 10,11-dihydro-RvE1, the latter two of which are essentially inactive [78]. Therefore the structure-function relationship of resolvins is critical to their targeted actions on multiple cell types and the stereochemistry of each resolvin is a unique determinant of their endogenous effects. Importantly, these studies also suggest that a failure of resolution could potentially be related to both impaired biosynthesis of resolvins, as well as accelerated metabolic inactivation. Along these lines, a stable analog that resists metabolic inactivation, denoted 19-(*p*-fluorophenoxy)-RvE1 methyl ester, shows similar biological activity as RvE1 *in vivo* [77], suggesting that this and related stable analogs may be important new candidates for resolution pharmacology approaches.

Two additional members of the E-series resolvin family have been characterized, namely RvE2 and RvE3 (Figure 57.3). The 5*S*-hydroperoxide formed prior to epoxidation can undergo reduction to 5*S*,18(*R/S*)-dihydroxy-eicosapentaenoic acid, denoted RvE2 [79]. Like RvE1, RvE2 blunts PMN infiltration in murine models of acute inflammation, stimulates macrophage phagocytosis, and promotes the generation of anti-inflammatory cytokines (Figure 57.2) [80]. The newest member of the E-series resolvin family is RvE3, which unlike RvE1 and RvE2, does not require 5-LOX for its biosynthesis, but rather only depends on

12/15-LOX to form the 17, 18 dihydroxyEPE product [81]. Like RvE1, both 18*R* and 18*S* isomers of RvE3 are biologically active and reduce PMN chemotaxis [81,82].

57.5 D-series Resolvins

Like EPA, DHA is also enzymatically biotransformed into structurally diverse families of mediators that comprise D-series resolvins, protectins, and maresins (Figure 57.3) [28]. Similar to the biosynthetic route elucidated for RvE1, aspirin acetylation of COX-2 leads to the formation of 17*R*-hydroperoxy(Hp)DHA when DHA is available as a substrate. In the absence of aspirin, 15-LOX converts DHA primarily to 17*S*-HpDHA [83]. Subsequently, both epimers of 17-HpDHA are converted to a 7,8 epoxide intermediate by 5-LOX and then hydrolyzed enzymatically into 7*S*,8*R*,17*R*-trihydroxy-4*Z*,9*E*,11*E*,13*Z*,15*E*,19*Z*-DHA and 7*S*,8*R*,17*S*-trihydroxy-4*Z*,9*E*,11*E*,13*Z*,15*E*,19*Z*-DHA [9,83]. These two mediators were given the names aspirin-triggered-resolvin D1 (AT-RvD1) and RvD1, respectively. Both RvD1 and AT-RvD1 attenuate trans-endothelial migration of human neutrophils and reduce excessive PMN accumulation during acute inflammation [83]. As noted above, RvD1 elicits its biological actions by binding to specific GPCRs. Two human receptors have shown to transmit RvD1 signals, the LXA_4 receptor (ALX/FPR2), and the previous orphan receptor GPR32 (Figure 57.2) [41]. This overlap in biological function may exist to ensure adequate resolution of inflammation in the presence of different nutritional fatty acid sources (i.e., AA vs. DHA). Importantly, RvD1 does not activate ChemR23, a receptor for RvE1, illustrating selectivity among SPM receptors. That these two resolvins have some overlapping but also other unique actions (*vida infra*), emphasizes the potential that each individual resolvin possesses in mediating resolution-phase processes.

In PMN, RvD1 reduces actin polymerization, actions that are abolished by pertussis toxin, and not cholera toxin, suggesting downstream signaling through $G\alpha_{i/o}$. Additionally, RvD1 stimulates macrophage phagocytosis of both apoptotic neutrophils and opsonized-zymosan. This enhancement of phagocytosis in macrophages is increased when ALX/FPR2 or GPR32 are overexpressed, while short-hairpin (sh) RNA knockdown of each receptor decreases rates of phagocytosis by RvD1, implicating direct receptor signaling in this biological actions of RvD1 [41]. Interestingly, a positive feed-forward loop was recently identified wherein RvD1 stimulates LXA_4 production in macrophages by promoting the redistribution of 5-LOX [24]. Specifically, RvD1 blunts the activation of p38 and MK2 kinases, thereby preventing the phosphorylation and subsequent nuclear localization of 5-LOX [24]. This mechanism promotes a sustained shift in the production of SPM (e.g., LXA_4) instead of proinflammatory LTB_4 in macrophages. Along these lines, RvE1 also stimulates endogenous LXA_4 production in the lung [84]. Interestingly, 5-lipoxygenase activating protein, which is classically associated with leukotriene production, has also been implicated in both lipoxin and resolvin biosynthesis [85]. In addition to regulating proinflammatory lipid mediators, RvD1 also downregulates the transcriptional co-activator, CARM1,

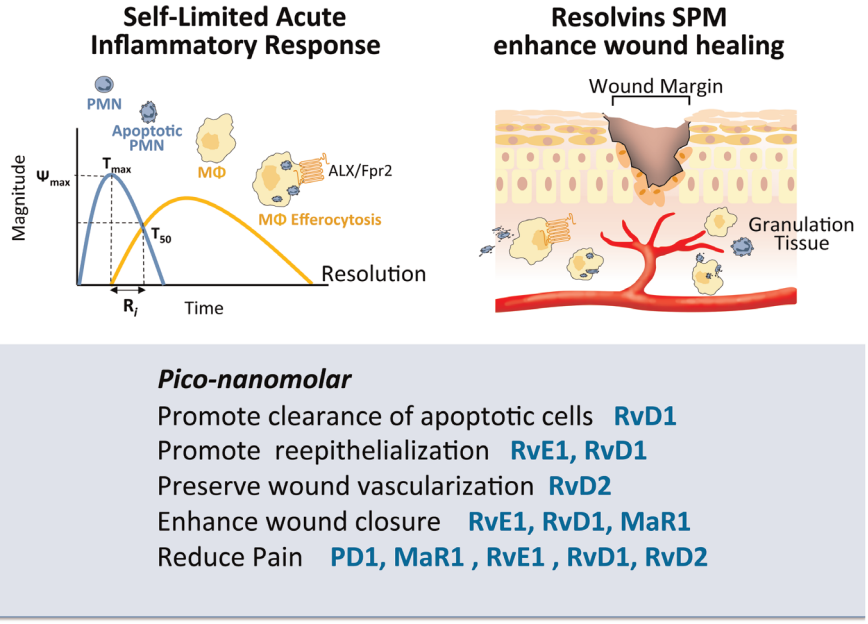

Figure 57.4 Resolution of inflammation and wound healing. The key cellular events during an acute inflammatory response are depicted, in which infiltrating polymorphonuclear neutrophils (PMN) undergo apoptosis and are cleared by macrophages during resolution. Resolution indices are shown, in which T_{max} represents the time at which maximum PMN infiltration occurs, T_{50} represents the time point at which PMN have declined to half of their maximum levels, and R_i represents the resolution interval, the time interval between T_{max} and T_{50}. SPM receptors, including ALX/Fpr2, mediate the biological actions of SPM, which include stimulation of macrophage clearance of apoptotic cells during resolution. Similar events take place during tissue injury and wound healing, whereby SPM resolve inflammation while promoting wound reepithelialization and reducing pain.

which in turn reduces the expression of mediators that regulate PMN activation and chemotaxis (e.g., GM-CSF and CXCL2) [86].

Protective actions of RvD1 have been demonstrated in several animal models of inflammatory diseases [87]. In adipose tissue from obese rodents and humans, RvD1 and its receptors are present and exogenous administration of RvD1 improves insulin sensitivity in obese mice by resolving adipose tissue inflammation, effects that are associated with improved cutaneous wound healing (see Figure 57.4) [15,88-90]. The resolution of adipose tissue inflammation and promotion of wound healing are in part related to actions on monocytes and macrophages, as RvD1 reduces monocyte transmigration in adipose tissue and restores defective efferocytosis [91]. Along these lines, apoptotic cells are a stimulus for RvD1 production in macrophages, which is in part related to the delivery of SPM precursors from microparticles shed by apoptotic cells [25]. Using this system as a form of biomimicry, humanized nanoparticles loaded with RvD1 reduce inflammation in the temporomandibular joint and accelerate keratinocyte wound closure *in vitro* [92]. In the context of cardiovascular disease, RvD1 reduces neointimal hyperplasia during vascular injury and accelerates

resolution of inflammation and tissue repair during myocardial ischemia [93,94]. A similar protection against ischemia-reperfusion injury by RvD1 was observed in the liver [95].

Additional members of the D-series resolvin family have been subsequently identified and their structures have been systematically deduced [96]. The complete structure of RvD2 was recently determined as 7*S*,16*R*,17*S*-trihydroxy-4*Z*,8*E*,10*Z*,12*E*,14*E*,19*Z*-DHA [97]. Both RvD1 and RvD2 are generated from a common precursor, namely 7,8-epoxy-17-HpDHA and, analogous to LXA_4 and LXB_4, are regioisomers of each other. RvD2 was originally identified in resolving inflammatory exudates and its structure was elucidated using total organic synthesis and matching with endogenous RvD2 to confirm its structure and stereochemistry by LC-MS/MS and GC/MS (i.e., functional group derivatization). In murine models of acute peritoneal inflammation, RvD2 reduces PMN infiltration at low picogram levels and its actions are stereospecific, as a Δ10-*trans*-RvD2 isomer is essentially inactive. Using intravital microscopy, it was determined that RvD2 reduces leukocyte adhesion to postcapillary venules, as well as transmigration. While like other resolvins RvD2 reduces the expression of PMN adhesion receptors, RvD2 also has direct endothelial actions, promoting the production of anti-adhesive mediators such as nitric oxide and prostacyclin [97,98].

In the context of polymicrobial sepsis, RvD2 reduces the amount of live bacteria in both the peritoneum, as well as the blood, which translates into markedly increased survival rates [97]. Interestingly, this increased survival and reduced infection occurs concomitantly with a reduction in peritoneal PMN recruitment. At the cellular level, RvD2 stimulation of neutrophils promotes their phagocytosis of live *E.coli*, providing evidence that SPM can combat infection. Several subsequent studies have determined that other resolvins (i.e., RvD5; 7*S*,17*S*-dihydroxydocosa-4*Z*,8*E*,10*Z*,13*Z*,15*E*,19*Z*-hexaenoic acid) stimulate bacterial clearance by phagocytes and thus reduce the amount of antibiotics needed to control infection [99,100]. In addition to infection, RvD2 (nanogram doses) also reduces PMN-mediated tissue damage in cutaneous burn wounds [101,102]. Recently, a specific GPCR was found to mediate the biological actions of RvD2 during acute inflammation. Using an unbiased GPCR screen, RvD2 was found to activate GPR18 in both PMN and macrophages, and specific binding was demonstrated using radiolabeled RvD2 and both heteroligand and homoligand competition in cells overexpressing GPR18 (Figure 57.2) [103]. Knockdown of GPR18 abolishes the stimulatory effects of RvD2 on macrophage phagocytosis and mice deficient in *Gpr18* fail to respond to exogenous RvD2 [103]. Importantly, RvD1 does not compete for RvD2 binding to GPR18, indicating that this RvD2 receptor is unique and specific. Given that GPR18 is abundantly expressed in the bone marrow, lymph nodes, spleen, and several individual leukocyte subsets, it is likely that RvD2 has additional biological roles that remain to be revealed.

The complete stereochemistry of an additional D-series resolvin member, RvD3, was recently elucidated as 4*S*, 11*R*, 17*S*-trihydroxydocosa-5*Z*, 7*E*, 9*E*, 13*Z*, 15*E*, 19*Z*-hexaenoic acid [104]. Like RvD1 and RvD2, an aspirin-triggered epimer (17*R*) of RvD3 is also formed in the presence of acetylated COX-2. Both epimers of RvD3 were identified in human plasma, spleen, and breast milk [14,16]. Unlike other D-series resolvins, RvD3 appears much later during

the resolution phase of acute inflammation, indicating distinct controlled biosynthesis that may be related to different leukocyte subsets during resolution [104]. Given that RvD3 binds GPR32, which is a proresolving receptor that is shared with RvD1 and LXA_4, RvD3 biosynthesis may serve to preserve SPM receptor ligands during all phases of resolution. Both epimers of RvD3 are biologically active in murine models of acute inflammation, reducing PMN trafficking to inflammatory loci, proinflammatory cytokine production and enhancing macrophage efferocytosis [104].

57.6 Novel Statin-Induced 13-Series Resolvins

Analogous to aspirin-mediated acetylation of COX-2 that drives the biosynthesis of AT-resolvins, it was recently found that *S*-nitrosylation of COX-2 by statins (e.g., atorvastatin) leads to the production of a novel series of resolvins generated from omega-3 fatty acid, docosapentaenoic acid (DPA) [105]. These newly identified resolvins were denoted 13-series resolvins (RvTs) because they carry an alcohol group at carbon 13 in the DPA backbone. The RvTs are generated during PMN:endothelial cell interactions via transcellular biosynthesis, as occurs during acute inflammation, and involves the initial formation of a 13-HpDPA intermediate in endothelial cells in a COX-2-dependent manner. This intermediate is converted to RvTs by 5-LOX in PMN [105]. The biosynthesis of RvTs is increased by atorvastatin and inhibited by nitric oxide synthase inhibitors, suggesting that nitrosylated COX-2 plays a role in their biosynthesis. Along these lines, nitrosylation of recombinant COX-2 by *S*-nitrosoglutathione increases the formation of 13-HDPA. The biological actions of these novel RvTs (i.e., RvT1, RvT2, RvT3, and RvT4) include promoting the resolution of acute inflammation and phagocyte-mediated containment of bacterial infection, leading to increased survival in *E. coli* peritonitis. The elucidation of these novel mediators may help to explain in part the anti-inflammatory actions of statins and may overcome therapeutic limitations to prolonged statin use.

57.7 Role of Novel Sulfido Lipid Mediator Conjugates in Tissue Regeneration

During tissue injury, a temporal program of events (i.e., inflammation, proliferation, and remodeling) ensures a restoration of homeostasis and function. While the inflammation phase is required to combat infection, prolonged activation of immune cells can cause tissue damage and impede its repair. As such, timely resolution of inflammation could be considered integral to this "wound healing" program. In addition to the aforementioned SPM that play a role in resolving inflammation and combating infection, recent studies have identified that novel families of sulfido-conjugated lipid mediators are generated during the transition from inflammation to tissue repair [106,107]. Specifically, glutathione conjugates of SPM are formed from DHA precursor during resolution, as well as by human

phagocytes, and they actively promote tissue regeneration. As such, they were given the names "conjugates in tissue regeneration" (CTR) and consist of maresin conjugates (MCTR), resolvin conjugates (RCTR) and protectin conjugates (PCTR) [106,107]. They are novel structures and their biosynthesis involves enzymatic conjugation of glutathione to the epoxides formed during the production of each respective family. Further downstream products of γ-glutamyl transferase, including cysteinylglycinyl and cysteinyl conjugates, are also formed and have biological activity. These novel conjugates were identified in regenerating plenaria during head resection, as well as in human and murine cells and tissues (e.g., spleen, breast milk, and inflammatory exudates) [106,107]. Overall, the identification of these novel CTRs provides evidence that the resolution of inflammation is directly linked to tissue regeneration in an active manner.

57.8 Summary

The resolution of inflammation is an active process characterized by the generation of SPM that potently resolve inflammation, promote clearance of infection, and stimulate tissue regeneration. These mediators are evolutionarily conserved and their identification has helped to open up a new era of "resolution pharmacology" based on using agonists of resolution, rather than inhibitors of the initiation events in inflammation [28]. In contrast to traditional pharmacologic agents that suppress inflammation, SPM enhance host defense and tissue repair. Given that inflammation is emerging as a central causative factor in numerous chronic diseases, the implications of SPM as proresolving therapeutics has considerable promise for the future of medicine, as well as potential for diagnosis and predicting clinical outcomes [108,109].

58.1 Introduction

58.1.1 Historical Introduction

The fatal consequences of adrenal gland damage were first described in 1855 by Addison, in a series of autopsy cases [1]. Of note, Addison's findings were based on anatomical observations, preceding experimental studies. Experimental confirmation was provided by Brown-Séquard who demonstrated that bilateral adrenalectomy in laboratory animals invariably proved fatal [2]. Subsequent observations demonstrated that the adrenal cortex, producing specific hormones named corticosteroids, was in fact essential for survival. Two distinct families of corticosteroids were isolated, regulating on the one hand the metabolism of electrolytes and fluids (thereby earning the name mineralocorticoids) and on the other the metabolism of carbohydrates (named glucocorticoids). While mineralocorticoids, through their capacity to retain sodium and water, were found to be responsible of prolonging life in adrenalectomized animals, glucocorticoids were found to possess powerful anti-inflammatory properties. The synthesis of artificial corticosteroids, the first of which being cortisone, enabled physicians to use corticosteroids therapeutically [3]. Cortisone was administered for the first time to patients suffering from rheumatoid arthritis by Hench [4]. The 1950 Nobel Prize in physiology and medicine was awarded for findings pertaining to the structure and biological effects of adrenal hormones. It soon became apparent that glucocorticoid administration was associated with significant side effects. In order to reduce these side effects, numerous synthetic glucocorticoids, as well as novel ways of administrating these drugs, were developed making glucocorticoids one of the most frequently prescribed classes of drugs, available for a range of inflammatory or immune pathologies.

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

58.1.2 Corticosteroid Biosynthesis

The adrenal glands lie at the superior pole of the kidneys and are divided into two distinct parts: the adrenal medulla and the adrenal cortex. The adrenal cortex synthesizes a group of hormones called corticosteroids. Natural steroids derive from cholesterol and possess four carbon rings. Cholesterol is either produced *in situ*, or else transported to the adrenal gland by cholesterol-transporting low-density lipoproteins (LDL). Circulating LDL recognize specific receptors on the adrenal cells, leading to the internalization of the LDL–LDL receptor complex in intracellular vesicles that fuse with lysosomes, leading to the degradation of LDL and the release of cholesterol. Steroid precursors are then shuttled between the mitochondria and the endoplasmic reticulum, where corticosteroid synthesis occurs. Each step of biosynthesis is controlled by a specific enzyme (Figure 58.1). Corticosteroids are preferentially produced in distinct regions of the adrenal cortex. Indeed, the adrenal cortex is anatomically and functionally composed of three different layers. These layers are, from the outermost layer beneath the

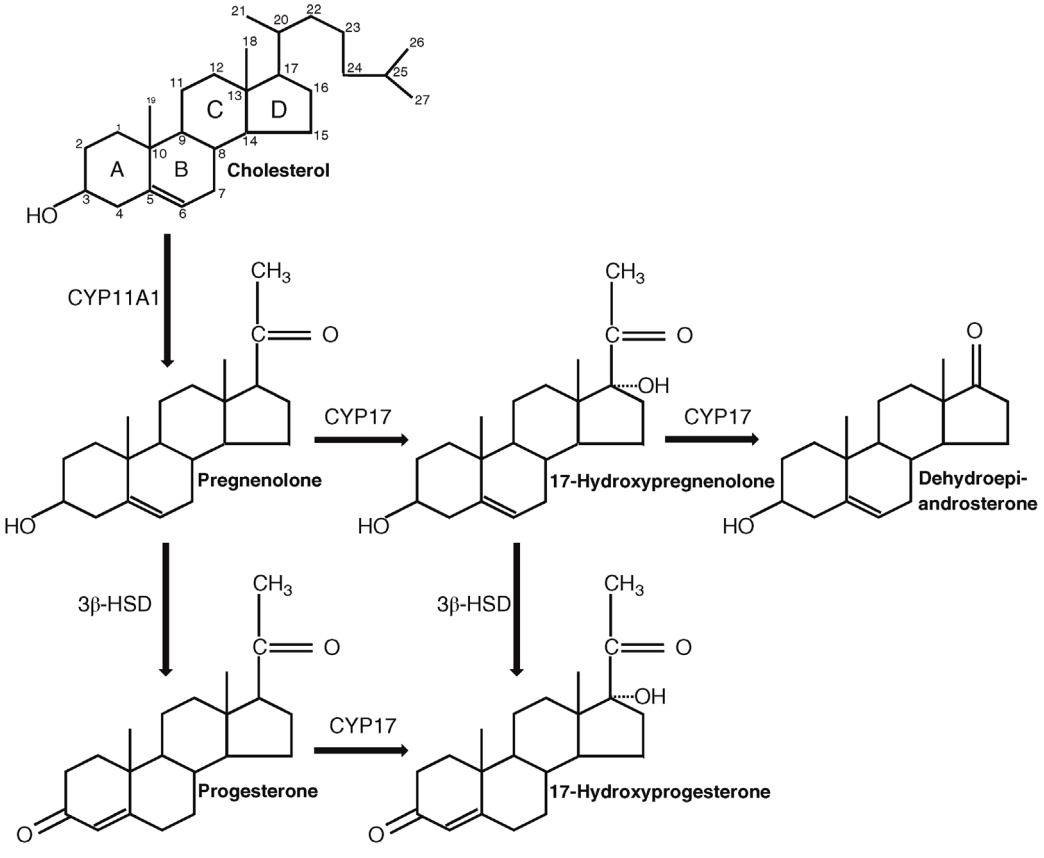

Figure 58.1 Pathways for corticosteroids biosynthesis. CYP11A1: cholesterol desmolase; 3β-HSD: 3β hydroxysteroid dehydrogenase; CYP17: steroid 17α-hydroxylase; CYP21: steroid 21-hydroxylase; CYP11B2: aldosterone synthase; CYP11B1: steroid 11β-hydroxylase.

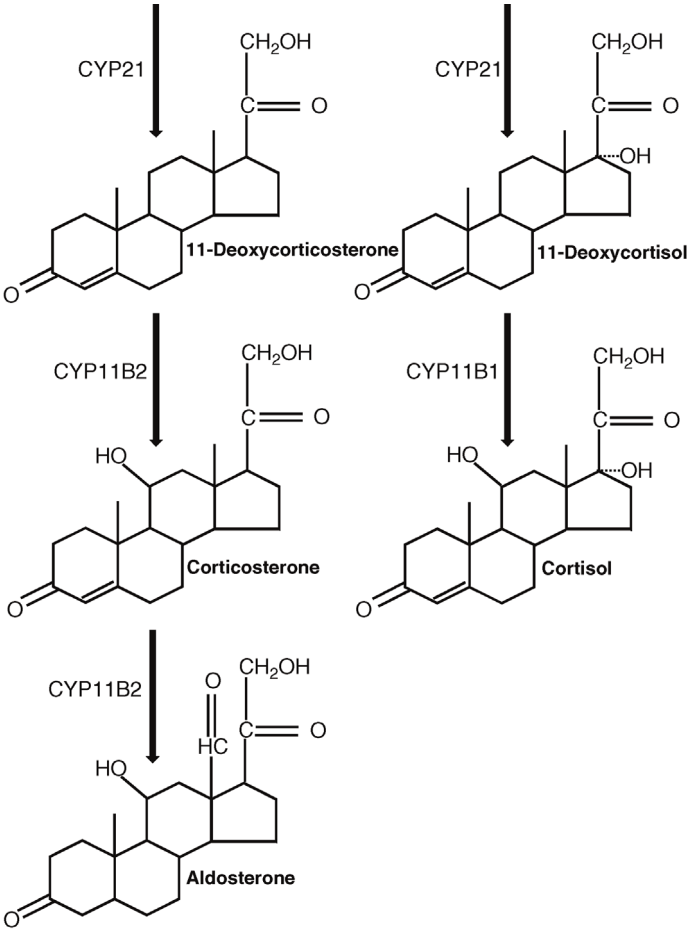

Figure 58.1 (*Continued*)

capsule, the zona glomerulosa, which secretes the mineralocorticoid aldosterone, the zona fasciculata, which mainly secretes the glucocorticoids cortisol and corticosterone, while the innermost layer, the zona reticularis secrets the adrenal androgen dehydroepiandrosterone (DHEA).

58.1.3 Hypothalamic–Pituitary–Adrenal Axis

Glucocorticoid production is regulated by the hypothalamic–pituitary–adrenal (HPA) axis. Indeed, steroids do not accumulate in the adrenal gland, their secretion and release is almost entirely controlled by the adrenocorticotropic hormone (ACTH), produced in the anterior pituitary gland. ACTH is synthesized as part of a large precursor protein, proopiomelanocortin (POMC). Other biologically relevant peptides, including the melanocyte-stimulating hormone, lipotrophin, and endorphins derive from the same precursor. ACTH is a 39 amino

acids polypeptide. The receptors for ACTH belong to the melanocortin receptor family, which are G-protein-coupled receptors. When ACTH binds its receptor, the adenylyl cyclase is activated, which induces a rapid rise in intracellular cAMP concentration, followed by the activation of the protein kinase A and the conversion of cholesterol to pregnenolone. In turn, ACTH production is controlled by the corticotropin-releasing hormone (CRH), a 41 amino acid peptide produced by the parvocellular region of the periventricular nucleus of the hypothalamus. CRH is secreted in response to proinflammatory stimuli (such as bacterial LPS as well as physical or psychological insults). Secreted CRH enters the hypophyseal portal system then reaches the pituitary gland where it binds to the CRH receptor, another G protein receptor that interacts with the adenylyl cyclase, leading to the biosynthesis and release of ACTH. Overall, the HPA axis is tightly regulated by several factors including (1) The circadian rhythm in basal steroidogenesis; plasma cortisol concentrations reach a peak in the morning and a trough in the evening/at night. (2) Negative feedback mechanisms control the level of circulating glucocorticoids. Circulating glucocorticoids bind to specific glucocorticoid receptors (GR) in the hypothalamus and pituitary gland, inhibiting the production and release of CRH and ACTH. (3) Inflammation; cytokines including interleukin 1 (IL-1), IL-6, and TNF affect the brain, which responds by regulating the immune system through the HPA axis and the production of glucocorticoids [5].

58.2 Pharmacokinetics

Most steroids exhibit both a glucocorticoid and a mineralocorticoid activity. The relative glucocorticoid and mineralocorticoid activity of steroids is presented in Table 58.1. In order to manipulate the relative mineralocorticoid or glucocorticoid action of glucocorticoids, thereby limiting their side effects, a number of synthetic drugs have been produced. The pharmacokinetics of glucocorticoids depends on their physicochemical properties. Glucocorticoids are usually administered as prodrugs. Glucocorticoids have a very good bioavailability [6]. Corticosteroids circulate bound to proteins. For instance 80%–90% of plasma cortisol binds to cortisol binding globulin (CBG, also known as transcortin), a protein produced by the liver, and to a lesser extent to albumin [7]. CBG may also bind synthetic glucocorticoids as well as steroids albeit with reduced affinity [8,9]. In basal conditions (in the absence of stress), approximately 5% of circulating cortisol is unbound. The free hormone hypothesis postulates that only the free fraction of cortisol is biologically active [10]. Free cortisol is converted in peripheral tissues into the inactive compound cortisone by the 11 β-hydroxysteroid dehydrogenase [11]. Since glucocorticoids derive from cholesterol, they are easily soluble in lipids and may easily diffuse through the cell membrane into the cytoplasm, where glucocorticoids bind their specific receptor. Glucocorticoids modulate gene transcription through modifications of the production of mRNA. Most metabolic effects are therefore delayed, requiring 60 minutes for proteins to be synthesized and several days for their full effect to be developed. Cortisol half-life is between 60 and 90 min. Corticosteroids are mainly metabolized by the liver,

Table 58.1 Relative potencies of natural and synthetic steroids.

Compound	Glucocorticoid activity	Mineralocorticoid activity
Natural steroids		
Cortisol	1	1
Corticosterone	0.3	15
Aldosterone	0.3	3000
Deoxycorticosterone	0.2	100
Synthetic steroids		
Cortisone	0.8	0.8
Fludrocortisone	10	125
Prednisone	4	0.8
Prednisolone	4	0.8
Methylprednisolone	5	0.5

Dexamethasone	25	0

Glucocorticoid and mineralocorticoid activity of natural and synthetic steroids, relative to cortisol.

where they are transformed into inactive glucuronic acid. These metabolites are then excreted into the bile or by the kidneys. Topically administered glucocorticoids may exhibit systemic effects such as growth retardation in asthmatic children, or diabetes following intra-articular injections of glucocorticoids.

58.3 Mechanisms of Action (Figure 58.2)

58.3.1 Genomic Effect of Glucocorticoids

Glucocorticoids exhibit potent anti-inflammatory actions, both through increased synthesis of anti-inflammatory and repressed synthesis of pro-inflammatory proteins. Glucocorticoids mediate their activity through their interaction with a specific intracellular receptor, the GR. The GR belongs to the nuclear receptor family of transcription factors. The gene for the human glucocorticoid receptor is located on chromosome 5q31-31 [12]. Glucocorticoid-regulated transcription factors are 94 kD proteins, exhibiting specific regions; a ligand binding region composed of 12 α-helices, dedicated to the recognition and binding of glucocorticoids, a region specializing in the interaction of the hormone–receptor complex with specific DNA sequences, composed of two zinc fingers and a region dedicated to the binding of other transcriptional factors. Posttranscriptional modifications of the GR, such as phosphorylation, modulate the activity of the GR [13]. Nonbound glucocorticoid receptors reside in the cytoplasm and are stabilized by small proteins, including heat-shock proteins 70 (Hsp70) and Hsp90 as well as immunophilin. On binding with glucocorticoids, the GR is activated, leading to

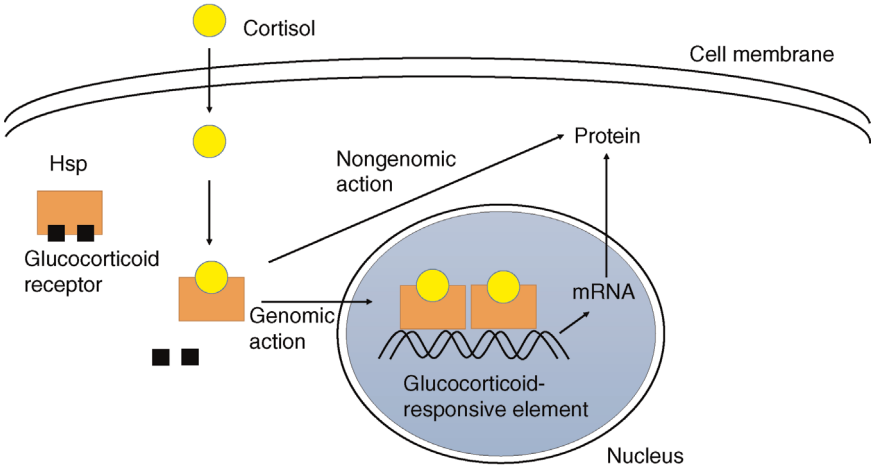

Figure 58.2 Schematic mechanism of action of glucocorticoids.

dissociation with chaperone proteins and nuclear translocation. In the nucleus, homodimers of the hormone–GR complex interact with specific DNA sequences within the regulatory region of target genes. DNA sequences recognized by the hormone–GR complex are named glucocorticoid-responsive elements, characterized by a consensus sequence of 15 base pairs GGTACAnnnTGTTCT, where n is any nucleotide. The expression of target genes for the hormone–GR complex is regulated through chromatin remodeling through the facilitation or inhibition of the assembly of key elements of the transcriptional machinery [14,15]. Chromatin consists of nucleosomes; DNA associated with core histone proteins. Resting state genes are characterized by DNA tightly wound around histone proteins, which hamper the capacity of the RNA polymerase to bind to the DNA and to produce mRNA. Core histones possessing Leu-rich N-terminal tails may be acetylated, leading to a modification of the nucleosome structure and an opening up of the chromatin, ultimately leading to gene expression. Indeed proinflammatory transcription factors such as NF-κB activate histone acetyltransferases (HAT) leading to acetylation of core histones, loosening of the chromatin and activation of the target gene. By opposition, histone deacetylases (HDACs) induce a tightening of the structure of the chromatin, repressing the expression of target genes. Activated glucocorticoid receptors inhibit HATs while activating HDACs, repressing the expression of proinflammatory genes.

For instance, glucocorticoids induce the synthesis of annexin 1, an anti-inflammatory protein inhibiting the expression of the phospholipase A2 and the subsequent production of proinflammatory elements derived from arachidonic acid, including prostaglandins and leukotrienes [16]. Glucocorticoids also repress the expression of proinflammatory genes. The expression of the IRF3 transcription factor, which is implicated in interferon production and viral protection, is downregulated by glucocorticoids [17,18].

Second, the GR–glucocorticoid complex inhibits the expression of proinflammatory proteins by directly interfering with other transcription factors, such as NF-κB [19]. NF-κB is particularly implicated in the transcription of proinflammatory cytokines genes [16,20]. In a resting state, inactive NF-κB is bound to IκBα. On cellular activation, NF-κB and IκBα dissociate and NF-κB translocates into the cellular nucleus. Glucocorticoids interfere with NF-κB by increasing the expression of the inhibitory protein IκBα that sequesters and therefore inhibits NF-κB in lymphocytes [21]. Glucocorticoids also induce the expression of glucocorticoid-induced leucine zipper (GILZ) that in turn inhibits NF-κB [22] as well as the anti-inflammatory protein MAP kinase (MAPK-1) phosphatase 1, which inhibits the nuclear translocation of GATA-3 implicated in Th2-type cytokine expression [23,24].

58.3.2 Nongenomic Effect of Glucocorticoids

The genomic action of glucocorticoids occurs over several minutes, with clinically relevant effects observed after several hours, following nuclear translocation of activated GR and gene regulation. This latency is related to the time needed for mRNA to be produced and modified, proteins to be synthesized, transported and reach a significant concentration threshold in order to exert a meaningful cellular effect [25]. Following glucocorticoid administration, rapid effects have been observed, which occur in a time frame too short for classic, genomic mechanisms to be implicated. These actions are described as nongenomic and they occur *in vitro* in the presence of inhibitors of DNA transcription and of protein synthesis. Nongenomic actions may also be triggered by macromolecule-bound glucocorticoids, unable to penetrate the cellular membrane. Nongenomic actions of glucocorticoids are either specific (i.e., mediated by the interaction of the hormone with a steroid receptor) or nonspecific (i.e., no receptor is involved, the effect is probably mediated by interactions with the cellular membrane and subsequent modification of ion transport) [26]. For instance, glucocorticoids, through the activated GR, may inhibit NF-κB by direct protein–protein interactions, such as with p65, one of the subunits of NF-κB as well as with other proinflammatory transcription factors such as activator protein 1 (AP-1) [27–29]. Glucocorticoids rapidly activate the endothelial nitric oxide synthetase (eNOS) through the protein kinase Akt pathway [30]. Glucocorticoids also induce posttranscriptional changes of mRNA coding for inflammatory proteins [31]. Early glucocorticoid action on neurons has been described [32] as well as rapid behavioral changes in response to corticosterone, the main glucocorticoid in amphibians and in rodents [33]. It has also been suggested that glucocorticoids might induce cellular signals through their interaction with membrane-bound receptors. Indeed, a glucocorticoid receptor-like protein has been detected in the membrane of human lymphoma cells [34]. Overall, these nongenomic actions although not completely elucidated, appear to be linked to the administration of higher doses of systemic glucocorticoids.

58.4 Pharmacological Effects

58.4.1 Immunomudulation

Cortisol reduces capillary permeability and fluid loss into the interstitium. Cortisol, through reduced production of leukotrienes and prostaglandins, reduces the migration of leucocytes into inflamed areas and inhibits phagocytosis of damaged cells. Glucocorticoids suppress the expression of endothelial adhesion molecules implicated in cell trafficking, including endothelial-leukocyte adhesion molecule 1 (ELAM-1), intracellular adhesion molecule 1 (ICAM-1), and vascular adhesion molecule 1 (VCAM-1) thereby interfering with the capacity of inflammatory cells to adhere and migrate through the endothelium [35–37]. Glucocorticoids inhibit the production of chemokines implicated in leucocyte chemoattraction [38–40]. Glucocorticoids also suppress the production of acute-phase reactants. Glucocorticoids exert powerful anti-inflammatory and immunomodulatory actions affecting cells from both the innate and adaptive arms of the immune system. Broadly speaking, glucocorticoids repress the maturation, differentiation, and proliferation of leucocytes of all subtypes.

58.4.1.1 Innate Immunity

Glucocorticoids reduce the number of monocytes/macrophages and of dendritic cells. The number of circulating neutrophil granulocytes increases through increased release by the bone marrow associated with increased demargination, while the number of eosinophil and basophil granulocytes is reduced. Glucocorticoids reduce the membrane expression of MHC class II receptors and Fc receptors and their production of proinflammatory cytokines [41–44]. Crosstalk between the Toll-like receptor 2 (TLR2) and the glucocorticoid receptor pathways accounts for the surprising observation that TLR2 KO mice exhibit impaired corticosterone production as well as alterations of adrenal tissues [45]. Corticosteroids stabilize the lysosomal membranes thereby causing the amount of proteolytic enzymes released by lysosomes to be greatly reduced. For instance, reduced IgE-dependent release of histamine and leukotriene is observed in steroid-treated allergy. The release of arachidonic acid and its metabolites (e.g., prostaglandins and leukotrienes) is also inhibited through inhibition of cyclooxygenase-2 and of phospholipase A2 and the expression of annexin 1. Cortisol attenuates fever by reducing the production of IL-1, TNF, IL-8, and MCP-1 by monocytes and macrophages. By contrast dendritic cells treated by glucocorticoids produce increased levels of the anti-inflammatory cytokines IL-10 and TGF-beta [46]. Glucocorticoids also promote the expression of another anti-inflammatory protein, MAPK phosphatase 1 [29]. Activating signaling induces a kinase cascade that phosphorylates and activates the transcription factor c-Jun a subunit of AP-1, implicated in the transcription of proinflammatory signals [47]. MAPK phosphatase 1 inhibits c-Jun-mediated transcription. Additionally, the GR binds directly and inhibits through protein–protein interaction the activity of AP-1.

58.4.1.2 Adaptive Immunity

Activation, proliferation, and the production of immunoglobulins by B cell lymphocytes are depressed in the presence of glucocorticoids [48,49].

Corticosteroids deplete thymic stroma cells and T cells by apoptosis [50,51]. Circulating T cell numbers are also reduced. Additionally, glucocorticoids induce a shift from a T helper 1 (Th1) to a T helper 2 (Th2) phenotype, both directly through the inhibition of the transcription factor T-bet and indirectly by effecting antigen presenting cells [52–55]. Additionally, glucocorticoids also inhibit the expression of Il-23, which promotes the differentiation of Th17 cells and the production thereof [56,57]. Interestingly, it has been proposed that glucocorticoids may expand the number of Foxp3(+)CD4(+)CD25(+) regulatory T cells that are functionally suppressive, these findings are however discrepant between different teams [58–61]. Glucocorticoids suppress the production by lymphocytes of the proinflammatory cytokines IL-2, IL-4, IL-5, IL-13, and INF [24,62].

58.4.2 Other Effects

Glucocorticoids are usually administered for their anti-inflammatory and immunomodulatory effects. Their administration, especially at higher doses and over a longer period of time is associated with multiple side effects. Some of these adverse effects include atherosclerosis and arterial hypertension, through sodium retention and the enhancement of vasopressor responses to angiotensin II and catecholamines [63]. Inhaled glucocorticoids have been reported to impede growth in children through systemic absorption [64,65]. In children, longitudinal growth depends on the proliferation and differentiation of chondrocytes, which is mediated in part by insulin-like growth factor I. Glucocorticoids inhibit insulin-like growth factor I and promote chondrocyte apoptosis through the Akt pathway [65,66]. Reduced bone density and osteoporosis occur in adults treated by glucocorticoids, through decreased activity of osteoblasts while increasing the activity of osteoblasts [67,68]. Wound healing is altered during glucocorticoid treatment through the inhibition of the synthesis of collagen and matrix metalloproteinase, implicated in wound repair [69]. Glucocorticoids promote liver gluconeogenesis, degradation of muscle proteins to free amino acids leading to muscle atrophy and lipolysis leading to hyperglycemia [70]. These modifications of the metabolism of carbohydrates, fatty acids, and proteins lead to the development of diabetes mellitus, increase of body weight, redistribution of body fat, and myopathy. Other unwanted effects include eye cataract, electrolyte imbalance, increased risk of infection, and mood changes, including euphoria or depression [71,72].

58.5 Therapeutic Use of Glucocorticoids

58.5.1 General Principles

With the exception of opotherapy for adrenal insufficiency, the therapeutically use of glucocorticoids is largely empirical. Both the risk and benefits of glucocorticoid administration must be balanced for all patients. Since side effects are both dose and time dependent, immunosuppressive treatments may be associated with corticosteroids in order to spare steroid usage. When treating potential life

threatening conditions, high doses of glucocorticoids must be administered until the condition is controlled. The smallest effective dose of glucocorticoids will thereafter be sought. Tapering should be progressive in order to avoid a flare of the disease or adrenal insufficiency. Glucocorticoids are usually administered in the morning, in order to preserve the HPA axis and to limit sleep disorders. Outlined below are important uses of glucocorticoids in a series of conditions. The reviewed indications for corticosteroid therapy are not inclusive. Additionally, we indicate through a grading system the level of evidence supporting the use of glucocorticoids in specific conditions.

58.5.2 Allergy and Asthma

In anaphylaxis and asthma, symptoms are mediated by IgE binding to antigens. In the case of anaphylaxis, symptoms are systemic, while in asthma the lung is preferentially affected. Anaphylaxis, which is life-threatening, must be immediately treated by epinephrine. Since the onset of action of glucocorticoids is delayed; they are used as a second-line treatment during anaphylaxis (very low quality of evidence) [73]. Corticosteroids should be administered intravenously for severe allergic conditions. Topical applications are appropriate for milder conditions. Asthma is a chronic inflammatory disorder of the airway characterized by bronchial hyperresponsiveness and the occurrence of transient symptoms of bronchial obstruction. Inhaled glucocorticoids are recommended as maintenance treatment for adults with symptoms more than twice a month (moderate quality of evidence) [74]. Exacerbation that are severe or do not respond to 48 h of treatment should receive oral glucocorticoids (high quality of evidence) [74]. Usual doses for adults are 1mg/kg/day of prednisone over a period of 5–7 days.

58.5.3 Rheumatic Disorders

Glucocorticoids are a cornerstone of the treatment of most severe inflammatory rheumatic diseases such as systemic lupus erythematosus (SLE) and most vasculitic disorders. Severe SLE flares affecting approximately a third of all patients at one time of their disease, typically mandate the use of high doses of glucocorticoids and/or initiation or intensification of immunosuppressive treatment [75]. In rheumatoid arthritis, because of the serious side effects associated with chronic use, glucocorticoids are administered temporarily if the disease remains active despite usual antirheumatic drugs or if the disease flares [76].

58.5.4 Renal Diseases

Glucocorticoids are recommended as the first-line treatment for nephrotic syndrome secondary to minimal change disease both for children (moderate quality of evidence) and for adults (low quality of evidence) [77]. Diminished proteinuria is usually observed within a month and most patients achieve remission within 3 months. Additionally, renal diseases secondary to SLE are treated by pulse IV followed by oral glucocorticoids (low quality of evidence) [78].

58.5.5 Preventing Graft Rejection

High doses of glucocorticoids in conjunction with other immunosuppressive agents are given at the time of transplant surgery. Most patients are thereafter kept on low-dose glucocorticoid maintenance regimen. Of note, the outcome of glucocorticoid-free immunosuppressive regimens following islet transplantation in type I diabetes mellitus seems to be improved [79].

58.5.6 Infectious Diseases

Preliminary data indicate that the daily administration of prednisone hastens recovery and hospital discharge in adults with community-acquired pneumonia [80,81]. Glucocorticoids (prednisone 40 mg twice a day for 5 days followed by progressive tapering over 3 weeks) for documented *Pneumocystis jirovecii* pneumonia in the acquired immunodeficiency syndrome causing hypoxemia (room air $PaO_2 < 70$ mmHg) reduces both the occurrence of respiratory failure (moderate quality of evidence) and mortality (high quality of evidence) [82,83]. Dexamethasone (0.15 mg/kg to a maximum dose of 10 mg, four times daily for 4 days) administered before or immediately after antibiotics in bacterial meningitis was found to reduce the incidence of hearing loss and long-term sequelae in both children and adults (high quality of evidence) [84]. Additionally, glucocorticoid administration also reduces the risk of death in HIV negative subjects affected by tuberculous meningitis (moderate quality of evidence) [85]. Steroid infusion (hydrocortisone; 200 mg/day) is currently the only adjunctive treatment available in septic shock. International guidelines suggest its use in case of persistent shock despite fluid resuscitation and vasopressor therapy (low quality of evidence) [86].

58.5.7 Adrenal Insufficiency

Adrenal insufficiency results from direct insults to the adrenal gland (primary adrenal insufficiency) or from insults affecting the anterior pituitary or the hypothalamus (secondary adrenal insufficiency). Acute adrenal insufficiency is a life threatening condition associating nausea, vomiting, and abdominal pain with dehydration hyponatremia, hyperkalemia, weakness, and hypotension. Management is based on intravenous vascular expansion, supplementation by hydrocortisone, 200 mg/day (moderate quality of evidence), and treatment of the precipitating factor [87].

58.5.8 Miscellaneous

Topical glucocorticoids are used in a variety of inflammatory dermatoses such as eczema. The risk of systemic absorption increases when the drug is applied on inflamed skin. Systemic glucocorticoids may be administered for severe episodes or for exacerbations of chronic disorders. Life threatening autoimmune dermatological conditions such as pemphigus are treated by systemic corticosteroids [88].

Mild forms of Crohn's disease confined to the ileum and/or right colon are effectively treated by controlled-ileal-release budesonide, a synthetic glucocorticoid that is inactivated by first pass hepatic metabolism and thus theoretically exhibits decreased levels of systemic toxicity (high quality of evidence). Moderate-to-severe Crohn's disease benefits from a treatment by corticosteroids until resolution of symptoms and weight gain (high quality of evidence) [89].

During severe liver disease, prednisolone should be used instead of prednisone, which requires hepatic conversion to be active. The first line of treatment for severe forms of autoimmune hepatitis is glucocorticoids (high quality of evidence) [90]. Patients with severe alcoholic hepatitis – defined as a Maddrey score of > 32 – should receive prednisolone (40 mg/day for 28 days, typically followed by discontinuation or a 2-week taper) (high quality of evidence) [91].

Glucocorticoids, which possess anti-lymphocytic effect, are used at high doses as a component in the chemotherapy of both lymphocytic leukemia and lymphoma. Corticosteroids are also commonly used in neurological conditions where inflammation is thought to be responsible of clinical symptoms such as brain metastases (low quality of evidence) [92] and spinal cord compression (moderate quality of evidence) [93]. In pulmonary sarcoidosis, glucocorticoids improve patients symptoms and spirometry over 3–24 months and may be of benefit in moderate-to-severe forms of the disease (low quality of evidence) [94].

Glucocorticoids are potent anti-inflammatory and immunosuppressive agents that are administered in a variety of conditions. However, except for adrenal insufficiency, glucocorticoids are nonspecific, symptomatic agents. Given the amount of serious undesirable side effects linked to these agents, both the risks and benefits must be carefully assessed before initiating glucocorticoid treatment.

59.1 Introduction

Numerous studies have shown that neurons, immune cells, and other cells with immune function communicate with one another. Neuroimmune communications occur throughout the entire body, involve many cell types, mediators, and pathways, and serve to maintain health in the face of environmental challenges. Neuroimmune communication in the central nervous system (CNS), in the periphery, and between the immune system and the brain serves to protect the host from damage and promotes repair. By contrast, dysregulated neuroimmune communication potentially contributes to numerous pathophysiological conditions, which are characterized by excessive and unresolved inflammation. In this chapter, we present an integrative view of neuroimmune communications during inflammation, which we term the neuroimmune communicatome. We also discuss new and emerging therapeutic approaches in disease treatment based on this neuroimmune communicatome.

59.2 What is Inflammation?

Classical inflammation is a critical component of the body's innate immune response to tissue injury caused by infectious or sterile stimuli. Inflammation involves a series of highly regulated, complex, and overlapping protective processes that require communication between different cell types. It is characterized by recruitment of immune cells to the site(s) of tissue injury/infection following specific interactions between pattern recognition receptors (PRRs) expressed by host immune cells, which recognize damage-associated molecular patterns (DAMPs), released by injured, metabolically deranged, or dead cells,

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

and/or pathogen-associated molecular patterns (PAMPs) – which are highly conserved structures associated with pathogenic organisms [1,2]. Ligation of most PRRs with PAMPs and DAMPs results in activation of intracellular signaling and production of cytokines, chemokines, and other bioactive molecules. These molecules activate immune cells and the endothelium initiating a series of complex processes to recruit activated immune cells to the sites of infection or injury. Initially, this process is protective because it delivers critical host defense cells and molecules to affected sites. If the resultant inflammation is not proportional to the threat and subsequently resolved in a timely manner, it can lead to chronic inflammation and continual tissue damage. Inflammation resolution is an active, complex, and precisely orchestrated process [3]. Inflammation is mediated through both proinflammatory mediators (e.g., cytokines and chemokines) and inflammatory cells, as well as production of numerous biochemical factors, including anti-inflammatory factors (e.g., chemokines/chemokine receptors) [4] and proresolving mediators. These proresolving factors include lipids (e.g., lipoxins, maresins, and resolvins), proteins/peptides (e.g., annexin A1) [5], neurotransmitters such as acetylcholine (ACh) [6], and neuropeptides and axon guidance molecules, including substance P (SP) and netrin [7]. Chronic, nonresolving inflammation is a hallmark feature of numerous diseases (e.g., arthritis, inflammatory bowel disease, asthma, cardiovascular disease, diabetes, and cancer) [8].

Until recently, understanding of the neural involvement in inflammation was limited, but it has become clear that communication between immune cells and neurons plays an important role in the regulation of inflammation and restoring homeostasis [6,9–11].

59.3 Neuroimmune Dialogue in Inflammation and the Concept of the Neuroimmune Communicatome

The nervous system regulates a myriad of physiological functions and integrates cardiovascular, gastrointestinal, respiratory, and other vital functions to maintain homeostasis. Numerous scientific observations have challenged the concept that immune function is devoid of nervous system regulation and demonstrated that neural signaling regulates immune activation and inflammation. In addition, immune cell activation with the release of proinflammatory mediators affects neuronal activity and brain function. Neuronal and neurohumoral mechanisms, including catecholaminergic pathways, the hypothalamic–pituitary–adrenal (HPA) axis, and the vagus nerve-based inflammatory reflex regulate inflammation and are currently being explored in clinical studies for the treatment of inflammatory diseases with promising results. Ongoing research on neuroimmune interactions is expanding the range of neuronal circuits that regulate immune function and this novel insight holds promise for the development of innovative therapies for inflammatory disease. Herein, we highlight pathways and mechanisms of neuroimmune communications in inflammation and the concept of the neuroimmune communicatome (Figure 59.1).

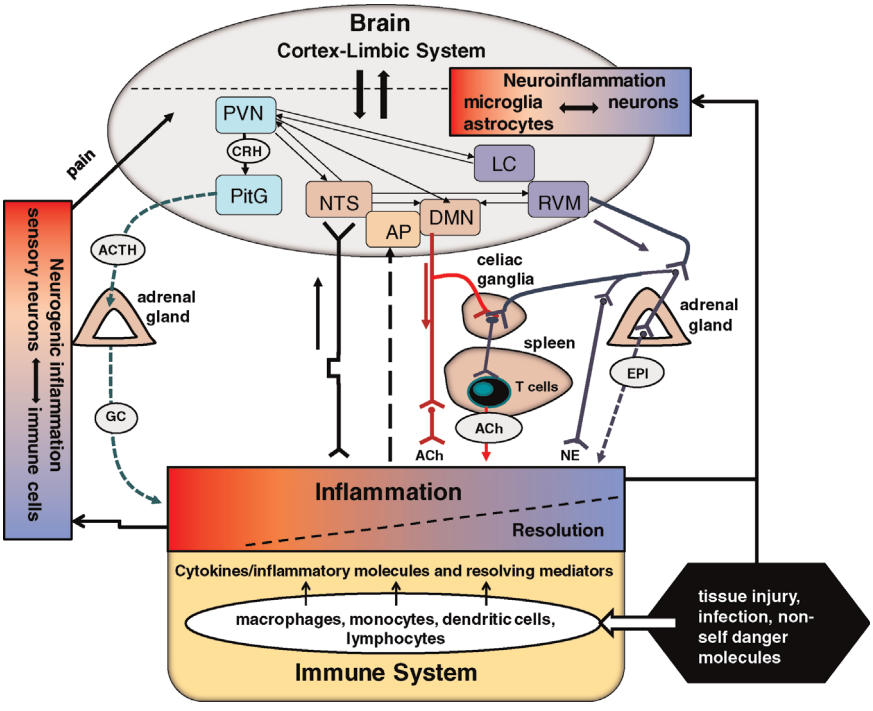

Figure 59.1 The neuroimmune communicatome.
Infection, tissue injury, and nonself danger molecules trigger complex inflammatory responses mediated by the activation of host macrophages and other immune cells of the host, which release cytokines and other inflammatory mediators. Inflammation is protective when it is localized and resolved in a timely manner, but also can be disease promoting and lethal when it is excessive, systemic, unresolved, and/or chronic. Multiple forms of bidirectional neuron – immune cell and immune system – CNS/brain communication occur during inflammation; these interactions govern its progression and resolution. We refer to these multifactorial interactions and communication in inflammation as the neuroimmune communicatome. Extensively studied specific loci of the neuroimmune communicatome are neuroinflammation in the CNS/brain and neurogenic inflammation, achieved within a sensory neuron axon–axon reflex manner in the periphery. The peripheral release of cytokines and other inflammatory products also trigger active communication between the immune system and the brain. Peripheral inflammatory signaling reaches the brain via afferent (sensory) vagus nerve fibers, circumventricular brain areas such as area postrema (AP), and other immune – to – brain pathways. Inflammatory molecules released in the periphery can promote or cause neuroinflammation and alter brain function ranging from temporary sickness behavior to chronic and severe neuropsychiatric manifestations. Peripheral inflammatory responses also trigger brain-derived immunomodulatory output. Afferent vagus nerve fibers terminate in the nucleus tractus solitarius (NTS) of the brainstem, which is interconnected with the dorsal motor nucleus of the vagus (DMN), where efferent (motor) vagus nerve fibers originate. These interactions mediate the brainstem integration of the vagus nerve-based inflammatory reflex, which suppresses peripheral proinflammatory cytokine release and controls inflammation. Interactions between the vagus nerve and the splenic nerve in the celiac ganglia mediate the release of acetylcholine (ACh) by T lymphocytes in the spleen. ACh exerts its anti-inflammatory effects by interacting with α7nAChRs expressed on macrophages and other immune cells. NTS and DMN are connected in a reciprocal manner with the hypothalamic paraventricular nucleus (PVN), a key component of the hypothalamic–pituitary–adrenal (HPA) axis, the rostroventrolateral medulla (RVM), and the locus coeruleus (LC), major brain components of the sympathetic

59.3.1 Major Components of the Neuroimmune Communicatome

A typical scenario of inflammation is triggered via activation of Toll-like receptors (TLRs), NOD-like receptors (NLRs), or other PRRs in macrophages and other innate immune cells. Subsequent activation of NF-κB and other transcription factors stimulates production of cytokines (e.g., TNF, IL-1β, IL-6, and IL-10), immune cell recruitment, eradication of invading pathogens and subsequent tissue repair. In parallel, an active cellular program to resolve the inflammatory response is initiated (Figure 59.1). The resolution of inflammation is a necessary step for restoration of homeostasis. Specialized proresolving mediators (SPMs) such as resolvins and protectins, limit leukocyte infiltration, cytokine production, and promote macrophage uptake of cellular debris and microbes. Failure of resolution results in a prolonged inflammatory response, a key factor in the pathogenesis of many inflammatory and autoimmune disorders, including sepsis, rheumatoid arthritis, inflammatory bowel disease, obesity, and diabetes. Aberrant inflammatory responses significantly add to the spectrum of pathological features of these disorders, which also involves metabolic, cardiovascular, and other homeostatic derangements [6,12–14]. Preventing and counteracting excessive and sustained inflammation are critical for homeostasis and present possibilities for therapeutic interventions.

Multiple mechanisms control the inflammatory response. In addition to the regulatory mechanisms that are inherent in the immune system, such as the release of anti-inflammatory cytokines and soluble cytokine receptors, neural signaling plays an important role in balancing defense and repair mechanisms in inflammation. Several scenarios of neuroimmune communication have been described. One example is neurogenic inflammation, which involves release of neuropeptides from sensory neurons that promotes fluid leakage, leukocyte activation, and pain (Figure 59.1) [15], as described in detail in Section 59.4.1.2. Neurogenic inflammation can be purposeful and protective, but excessive and sustained manifestations can contribute to autoimmune diseases and allergic symptoms [15]. Another example is the intricate interplay between neurons and resident cells with immune function in the CNS. Under normal conditions, microglia and astrocytes interact with neurons and modulate neurogenesis, synaptic functionality, and neurotransmission [16–19] and safeguard the integrity of the blood–brain barrier [17] (Figure 59.1). Importantly, microglia and astrocytes, major brain cell types with immune functions [17,18], actively participate and interact with neurons also in the so-called "neuroinflammation."

catecholaminergic outflow. The RVLM and LC also participate in the brain processing of pain (not shown). PVN neurons release corticotropin-releasing hormone (CRH), which in turn activates the release of adrenocorticotropin hormone (ACTH) by the pituitary gland (PitG). ACTH stimulates the secretion of anti-inflammatory glucocorticoids (GC) from the adrenal cortex. The release of norepinephrine (NE) and epinephrine (EPI) from catecholaminergic axon terminals and the adrenal medulla, respectively mediates proinflammatory and antiinflammatory effects via interactions with α- and β-adrenoreceptors expressed on immune cells. The role of forebrain regions and the limbic system in the brain integration of the neuroimmune communicatome and the involvement of the cholinergic and other neurostransmitter systems are areas of active research. See text for details.

Presence of PAMPs and DAMPs in the CNS can activate local TLRs and other PRRs and trigger production of proinflammatory cytokines, chemokines, and reactive oxygen species. Neuroinflammation is a necessary defensive event aimed at neuronal protection and preservation of brain function in response to threats. However, persistent neuroinflammation contributes to tissue injury and neurodegeneration and has been implicated in the pathology of neurodegenerative disorders, including Alzheimer's disease, Parkinson's disease, and multiple sclerosis [18,20]. In addition, there is active communication between the immune system and the brain in response to inflammation outside the CNS [21–25]. This is easily appreciated by considering how brain function is altered during inflammation manifested by typical "sickness behavior," including fever, fatigue, and anorexia [21,23]. In addition to these well-known symptoms, inflammation in the periphery also triggers immunomodulatory CNS output, including activation of the HPA axis, catecholaminergic signaling, the cholinergic anti-inflammatory pathway, and other neuronal mechanisms that regulate immune cell behavior [26] (Figure 59.1). Several sensory mechanisms play a role in "informing the brain about peripheral inflammation." For example, afferent vagus nerve fibers that terminate in the brainstem nucleus tractus solitarius (NTS) respond to increased levels of IL-1β and other proinflammatory cytokines in the periphery [25] (Figure 59.1). The signals are then communicated to other brain areas [25]. Blood-borne cytokines signal the brain through area postrema (AP) and other circumventricular organs [21,26]. Secondary mediation through the release of prostaglandins or activation of perivascular macrophages has also been documented [26]. In addition, infiltration of neutrophils, T cells, and other immune cells into the brain during inflammatory conditions has been described [22].

The HPA axis is an important neurohumoral immunomodulatory pathway. Major brain structures in the HPA axis are the hypothalamic paraventricular nucleus (PVN) and the pituitary gland [26–29] (Figure 59.1). The PVN contains neurons, specialized in synthesizing corticotrophin-releasing hormone (CRH) [27,29]. PVN neurons project to the pituitary gland and release CRH in its portal system, which leads to subsequent production of adrenocorticotropin hormone (ACTH) from the anterior pituitary [27,29]. The resultant ACTH action in the adrenal cortex generates the release of glucocorticoids. Glucocorticoids suppress proinflammatory cytokine production and promote production of anti-inflammatory mediators, suppress adhesion molecule expression, and inhibit neutrophil and monocyte infiltration in inflammation [29] (Figure 59.1). Based on these insights, synthetic glucocorticoids have long been used clinically to treat inflammatory disease and these mechanisms have been extensively reviewed elsewhere. [27,29].

Catecholamines, including the predominant postganglionic neurotransmitter in the sympathetic division of the autonomic nervous system, norepinephrine (NE), and epinephrine (Epi) from the innervated adrenal medulla, regulate leukocyte function by interacting with cognate receptors on immune cells [26,30] (Figure 59.1). Depending on context, the involved receptor and cell type, catecholamines can exert both pro inflammatory and anti-inflammatory effects [26,30]. For instance, NE acts on α_2-adrenoceptors on monocytes and macrophages to promote the production of TNF, and other cytokines [31]. NE

can also stimulate neutrophil accumulation and aggravate inflammation [30]. Conversely, NE and Epi inhibit proinflammatory cytokine production and stimulate anti-inflammatory cytokine production through activation of β2-adrenoceptors [30]. Brain structures, including the locus coeruleus (LC) and the rostroventrolateral medulla (RVM), regulate sympathetic neuronal activity through interactions with spinal cord preganglionic neurons (Figure 59.1) [24,30]. The specific interactions between these neural networks, afferent neural signals, inflammatory cytokines, and leukocytes remain to be characterized and understood in detail. The effects of local and systemic catecholamine release in inflammation are quite complex, have been extensively reviewed elsewhere, and are an area of ongoing research [30].

Cholinergic signals also play a key role in the control of inflammation. In this context, the vagus nerve-based inflammatory reflex has been well studied [11]. In this reflex circuit, cytokines and other inflammatory molecules activate afferent vagus neurons, which transmit signals to the nucleus tractus solitarius (NTS). Neuronal projections from the NTS to the dorsal motor nucleus (DMN) of the vagus make functional connections with efferent vagus nerve fibers, which provide a multistep anti-inflammatory signal that suppresses proinflammatory cytokine release (Figure 59.1) (see Section 59.3.2. for details) [11,26,32–36].

The brain integration of the inflammatory reflex in the brainstem medulla oblongata occurs through reciprocal neural projections between the NTS and the DMN, which also interact with the AP in a functional unit, termed the dorsal vagal complex (Figure 59.1) [26]. Neural projections among the constituents of the dorsal vagal complex, the main brain components of the HPA axis, and regions involved in the regulation of the catecholaminergic immunomodulatory outflow, including locus coeruleus and rostroventrolateral medulla, provide a neuroanatomical substrate for further brain integration of the inflammatory reflex with other brain-derived immunomodulatory pathways (Figure 59.1) [26]. In addition, the cortex and other brain components of the limbic system, including the hippocampus and amygdala, regulate peripheral immune responses [37]. These forebrain areas interact with the dorsal vagal complex and regions involved in the sympathetic and neuroendocrine regulation of immune function directly or through multisynaptic pathways [38].

59.3.2 Reflex Principles: The Inflammatory Reflex and Beyond

Nerves are uniquely capable transmitters of information. In contrast to endocrine factors, neurons can instantaneously deliver precisely targeted signals. Reflex circuits consist of sensory (afferent) neurons sending signals from the periphery to the CNS and motor (efferent) neurons that project from the CNS to peripheral target tissues. Sensory and motor neurons provide for information exchange between the CNS and practically the entire organism. The complex arrangement of the brain with sophisticated layers of multiple types of highly organized neuronal systems constantly process the numerous external and internal inputs and integrate set points and sensory signals to fine-tune motor responses. In this way, autonomic homeostatic reflexes provide rapid and precise control of a wide variety of physiological functions. In particular, reflexes based on autonomic

neuronal circuits help protect from a wide range of harmful events by regulating key physiological processes, including body temperature, heart rate, blood pressure, and metabolism. This system of balanced integration of input signals and set points provides for sophisticated optimization. It is easy to appreciate that dysfunction of the homeostatic reflexes can contribute to organ damage and even death.

Given the insights that the nervous system has evolved to provide control of key physiological functions for health and survival, it is reasonable that antimicrobial defense and wound healing – functions where the immune system plays a central role – are monitored and regulated by the brain and autonomic reflexes [39]. In this system, information on alterations in the immune function and inflammation are sent to the brain (Figure 59.1). Peripheral nerves are equipped with receptors for cytokines as well as PAMPs and DAMPs. Activation of these sensory mechanisms trigger brain-derived immunoregulatory mechanisms that may result in systemic release of anti-inflammatory factors, including corticosteroids, activation of specific motor neurons, and release of immune-regulatory neurotransmitters (Figure 59.1). The inflammatory reflex, in which the vagus nerve plays a key role, is a well-described circuit that regulates cytokine release. In this reflex, sensory signals are elicited by proinflammatory factors in tissues innervated by the sensory vagus nerve, and give rise to brain-derived motor activity in the vagus nerve (Figure 59.1). The efferent vagus nerve travels to the celiac ganglia where the splenic nerve arises. Electrical activity in the splenic nerve eventually triggers neuronal NE release that activates a particular subset of ACh-producing T cells in spleen. These choline acetyltransferase (ChAT)-expressing T cells release ACh and relay the neural signal to α7nAChRs on immune cells in the spleen, which ultimately reduces their release of proinflammatory cytokines. Intracellular mechanisms triggered by this interaction involve suppression of NF-κB nuclear translocation to mediate cholinergic suppression of TNF and other proinflammatory cytokine production [6]. The efferent arm of the inflammatory reflex, the cholinergic anti-inflammatory pathway, can be activated by electrical vagus nerve stimulation (VNS) and conversely, disrupted by surgical transection of the vagus nerve – vagotomy or splenic nerve transection [10,40]. The role of vagus nerve–splenic nerve functional integration regulating ACh release in the spleen is reflected by the increased splenic ACh levels in animals following VNS [35,41]. An immunomodulatory role of efferent cholinergic fibers innervating the liver, heart, gastrointestinal tract, and other visceral organs has also been demonstrated. Cholinergic anti-inflammatory output from these fibers is inversely correlated with proinflammatory cytokine levels and disease severity in animal models of hemorrhagic shock, ileus, pancreatitis, and inflammatory bowel disease [6,10,42,43]. Moreover, VNS decreases TNF and other proinflammatory cytokine levels and alleviates disease severity in various inflammatory conditions [39]. The study of the cholinergic regulation of inflammation activity, including the role of the α7nAChR on macrophages, has spawned investigation of the anti-inflammatory efficacy of selective α7nAChR agonists [44,45]. Inhibition of inflammation by GTS-21, choline, and other selective α7nAChR agonists has been observed in preclinical models of endotoxemia, sepsis, rheumatoid arthritis, type 2 diabetes, and other inflammatory and autoimmune disorders [10,46–48].

Hence, the detailed understanding of the inflammatory reflex has opened a number of novel avenues in the search for potential efficacious treatments of excessive inflammation.

Interestingly, in *Caenorhabditis elegans*, which is one of the least complex animals with a nervous system, the innate immune response to bacterial invasion of non-neural cells is regulated by neural signals [49]. In higher animals, neural control of inflammation has been reported in peripheral nerves other than the vagus nerve. For example, TRPV1 and Nav1.8-expressing neurons interact with dermal dendritic cells to regulate skin inflammation in a model of psoriasis [50]; however, the neurophysiology and molecular biology of these pathways are not completely understood. Neuronal activity also regulates the movement and homing of leukocytes with important effects on disease progression in experimental models. For example, alteration of the functional neural signals to hepatic invariant natural killer T (iNKT) cells can significantly decrease this post-stroke pneumonia-induced mortality in mice [51]. In another study, elimination of specific proprioceptive signals entering the lumbar spinal cord prevented CNS entry of pathogenic T cells in a murine model of multiple sclerosis [52]. Furthermore, electrical stimulation of the sciatic nerve can regulate production of catecholamines via vagus-nerve activation, and significantly reduces the mortality in sepsis [53]. Recent insights into these mechanisms have fundamentally changed our understanding of immune system regulation, which now includes neural reflex circuits. These discoveries are paving the way for the application of revolutionary ideas for support of tissue healing and treatment of chronic inflammatory diseases using electrical nerve stimulation [39,54–56]. Further research in the emerging field of bioelectronic medicine is likely to significantly expand our understanding of immune-regulatory neural reflexes in the years to come.

59.4 Points of Interaction in the Neuroimmune Communicatome

Inflammation affects neuronal activity and brain function, and neuronal circuitry has a major involvement in the regulation of inflammation. Specific features of this reciprocal communication and impact, and the loci of the neuroimmune communicatome in inflammatory conditions are described next.

59.4.1 How the Nervous System Is Affected in Peripheral Inflammation

The impact of peripheral inflammation on the nervous system is multifaceted. An example of this impact is neurogenic inflammation. Of note, neurogenic inflammation also implicates an active neural output modulating immune function. In classical inflammation, peripheral inflammatory products can be sensed by afferent vagus nerve fibers and the signal is transmitted to the brain. Moreover, brain neuronal function is altered during peripheral inflammation and these alterations can be protective. However, they can be exacerbated to the

level of life-threatening neurological complications in the context of inflammatory diseases.

59.4.1.1 Neurogenic Inflammation

The term "neurogenic inflammation" was introduced by Jansco and colleagues to describe the plasma leakage and edema following the application of capsaicin to the skin and/or mucus membranes of experimental animals [57]. The effect was abolished by surgically transecting the peripheral nerves or by desensitizing via repeat applications, thus, the authors concluded that sensory nerve stimulation contributes to inflammation in the periphery via the local release of biologically potent mediators that promote vascular permeability [57]. Today, the term "neurogenic inflammation" describes a complex and orchestrated response in the periphery mediated through a series of interactions between ligands and receptors on sensory neurons and immune cells. Sensory neurons serving as nociceptors signal afferent communication about noxious, and/or damaging stimuli leading to the perception of pain (Figure 59.1). Upon activation, these neurons release, in an antidromic fashion (i.e., in the opposite direction to normal conduction), neuropeptides and other mediators (e.g., SP, calcitonin gene-related peptide [CGRP], neuropeptide Y, and glutamate. These mediators trigger local release of histamine and other bioactive substances (primarily by mast cells), including 5-HT, adenosine, elastase, matrix metalloproteinases, chemotatactic factors for eosinophils and neutrophils, prostaglandins, thromboxanes, NO, and TNF and other cytokines and neuropeptides. Collectively, these substances increase vasodilation, vascular permeability, plasma extravasation, and recruitment of immune cells to the site [58–60]. Triggers for neurogenic inflammation include classical, infectious microbes (e.g., bacteria, viruses, and fungi), autoimmune processes, DAMPs, and other factors that increase neuronal activity (e.g., noxious stimuli). Similar to the classical inflammatory response of the innate immune system, neurogenic inflammation includes anti-inflammatory and resolving "regulatory components," including anti-inflammatory cytokines, neuroprotectins, SPMs, neurotransmitters, and neurotrophic factors [60]. However, prolonged stimulation and positive feedback release of proinflammatory factors from the tissue and immune cells can cause a sustained increase in vascular permeability, a disproportionately strong recruitment of immune cells, further tissue damage, and ultimately result in a state of persistent pain [59]. Hence, neurogenic inflammation can be beneficial, but also dangerous and destructive.

59.4.1.2 Neural Sensing of Inflammation

A sensory link between inflamed tissue and the nervous system was illustrated when Aulus Cornelius Celsus included "pain" among the four hallmarks of inflammation some two millennia ago. However, the molecular interactions between the nervous and immune systems long remained unexplored and are yet incompletely understood. Clearly, infection, injury, and inflammation can provoke wide-ranging and purposeful modifications of CNS-controlled behavior and physiological set points within the scope of sickness behavior, including

elevated body temperature, hyperalgesia, reduced food intake, and increased sleep [61]. Experimental evidence indicates that the nervous system and the immune system are hardwired in monitoring damage, microbial invasion and inflammation.

Signals for inflammation reaches the brain through a number of specific mechanisms, for example, via neural pathways, circumventricular organs, and receptors in CNS [25,26,62]. Interestingly, the systemic levels of TNF significantly influence the perception of pain in experimental models of inflammatory disease [63]. Furthermore, signals in peripheral sensory nerves are directly activated by inflammation-related events in the body. Body surfaces contain a dense network of sensory nerves equipped with similar molecular sensors as leukocytes, including Fc receptors [15,64,65]. The sensory vagus nerve and the carotid body express receptors for cytokines, TLRs, and other inflammation-associated molecules. Ligation of these receptors can elicit electrical activity in the vagus nerve [50,66,67] and may constitute a mechanism to inform the brain about peripheral inflammatory events. In peripheral tissues, immune cells commonly reside in close proximity of nerve fibers. Leukocytes are found near the vagus nerve in viscera, which provides an anatomical basis for a rapid neural response to factors released by these immune cells. In addition, invading bacteria can directly activate sensory nerves and elicit axonal signals [68]. Abdominal surgery provokes vagus nerve signals that regulate intestinal leukocyte recruitment [69]. Endotoxin and proinflammatory cytokines elicit sensory signals that result in a motor nerve response [32,67]. For instance, IL-1β injection in the portal vein increases splenic nerve activity [66]. Together, these and other sensory mechanisms enable a supply to the CNS of afferent information on dynamic changes in tissue integrity, microbial invasion and inflammation. Although important aspects of the neural sensing of immune-related signals have been delineated, understanding of the complete stepwise process is incomplete.

59.4.1.3 Brain Function in Peripheral Inflammation

Brain function can be altered in conditions characterized by peripheral inflammation. These brain alterations range from sickness behavior to severe neurological complications. Sickness behavior encompasses fever, changes in sleep, reduced physical activity and social interaction, appetite suppression, and other events [21,70]. A major contributor to and a mediator of sickness behavior is proinflammatory signaling within the brain, which is triggered or activated by cytokines and other inflammatory products released in the periphery (Figure 59.1) [21,36,71]. Peripheral inflammatory signals reach the brain via afferent nerve signaling, circumventricular organs, and other mechanisms described in Section 59.3. Local proinflammatory signaling in the brain is associated with microglial and astrocyte activation [36]. In classical scenarios of neuroinflammation following brain injury, infection and neurodegeneration, microglia, and astrocytes produce proinflammatory and anti-inflammatory cytokines, chemotactic factors, and neuropeptides and cytotoxic factors. These mediators of neuroinflammation interact with neurons to promote neuronal repair and restore neuronal function. However, chronic, unresolved neuroinflammation can lead to neuronal dysfunction. At least

some aspects of this pathophysiology are observed when the trigger is a peripheral inflammatory insult. Sickness behavior can be considered an important temporary protective mechanism. However, multiple transformations of sickness behavior can result in neuropsychiatric manifestations, described in septic patients and sepsis survivors, as well as patients with liver failure and cirrhosis, obesity and diabetes, systemic lupus erythematosus, and other inflammatory and autoimmune diseases [36,72,73]. The symptoms of such neurological complications range from relatively mild cognitive deterioration to delirium and coma within characteristic encephalopathies with debilitating and life-threatening consequences [36,74]. The clinical importance of these neuropsychiatric manifestations dictates the urgent need for early diagnoses and adequate treatment options. Despite increasing research efforts, the underlying pathogenesis of these neurological complications remains poorly understood. Proinflammatory signaling in the brain, derangements in cerebral blood flow and microcirculation, and alterations in brain metabolic activity have been described.

Dysfunctions of brain neurotransmitter systems have also been reported. For instance, brain cholinergic hypofunction has been observed in delirium and in sepsis encephalopathy [36,75]. This is an important finding for several reasons. The brain cholinergic system has a critical role in cognition, sleep, movement control, and peripheral/visceral function [76–78]. Brain cholinergic muscarinic acetylcholine receptor (mAChR)-mediated signaling has been implicated in the regulation of peripheral inflammation [6,41,79], and brain cholinergic mechanisms also regulate local brain inflammatory responses [80–83]. Therefore, brain cholinergic insufficiency may potentially be causally linked to brain neurological complications and may thus be targeted therapeutically. Centrally acting drugs such as acetylcholinesterase (AChE) inhibitors are clinically approved for treating cognitive impairment in Alzheimer's disease. Centrally acting AChE inhibitors also have powerful anti-inflammatory properties [36], and it is therefore conceivable that these modalities may provide therapeutic benefits in the context of neurological complications of inflammatory disease. Alterations in catecholaminergic, dopaminergic, GABA-ergic glutamatergic, and orexinergic systems have also been described in the context of sepsis [36]. Hepatic encephalopathy, manifested by a spectrum of symptoms such as cognitive and sleep deterioration, impairments in motor activity and coordination, lethargy, confusion, and sometimes delirium and coma, occurs during acute and chronic liver failure in cirrhosis [84,85]. Metabolic and immune derangements, including elevated ammonia levels, astrocyte enlargement and dysfunction, microglia activation, increased proinflammatory signaling, and oxidative stress, have been implicated in the pathogenesis of this neurological condition [84,85]. Increased AChE activity and alterations in brain cholinergic neurotransmission have been described in hepatic encephalopathy in the context of acute liver failure [86]. Interestingly, these brain alterations may occur in parallel with autonomic nervous system alterations and decreased vagus nerve activity as determined by heart rate variability analysis [14,87,88]. These observations suggest new therapeutic options for neuropsychiatric complications in diseases with inflammatory and metabolic etiology [36].

59.4.2 How Immune Functions and Inflammation Are Regulated by the Nervous System

The nervous system regulates and integrates a spectrum of physiological defense mechanisms. The bidirectional communication between the nervous system and the immune system facilitates the neural regulation of immune functions and various forms and aspects of inflammation.

59.4.2.1 Neural Regulation of Immune Cell Trafficking and Infiltration

Inflammation involves an orchestrated collaboration between immune/effector, vascular, and neural components to achieve immune cell infiltration to the site of inflammation or injury.

In neurogenic inflammation, sensory neurons residing in the periphery release neuropeptides and other bioactive agents upon stimulation [89]. Through ligand–receptor interactions, these neuronally derived substances communicate with a variety of cells (endothelium, immune cells, neurons found in the periphery) to enhance vasodilation, vascular permeability, plasma extravasation, and leukocyte infiltration [89]. For example, neuron-derived vasoactive intestinal peptide (VIP), a neuropeptide produced and released in the gut, enters circulation to promote vasodilation and subsequent immune infiltration in surrounding tissues [90]. Similarly, substance P (SP), produced by unmyelinated nerve fibers, induces vasodilation in the periphery, as well as plasma extravasation, leukocyte activation, and leukocyte migration and thus regulates immune cell trafficking [91,92]. Mast cells, which express specialized adhesion molecules for nerve fibers, are found within close proximity to the nerve fibers in the periphery and are thus proposed to be the dominant immune cell involved in neurogenic inflammation [93]. Furthermore, mast cells have receptors for numerous neuropeptides and neural factors implicated in promoting neurogenic inflammation [60]. Mast cells, as well as nerve fibers, produce and release several mediators that activate the vasculature and attract additional immune cells (e.g., macrophages, T cells, and dendritic cells) to the site [60]. These responses during neurogenic inflammation primarily serve to protect the host and maintain health; however, when these responses are continuous or amplified, they can lead to disease.

Neural regulation of immune cell trafficking can occur through controlling the production and/or the release of neuron-derived substances, including VIP, SP, CGRP, neuropeptide Y, adrenomedullin, neurokinins A and B, glutamate, and cytokines/chemokines (e.g., eotaxin) that promote: (1) vasodilation and/or vascular permeability, (2) immune cell chemotaxis, and/or (3) activation of immune/effector cells and/or endothelial cells, as well as immune cell-endothelial cell interactions required for immune cell trafficking during inflammation [15].

Neural regulation of immune cell trafficking can be achieved by actively suppressing the production of mediators that increase vasodilation and vascular permeability or activate immune/effector cells and endothelial cells that promote leukocyte or immune cell infiltration in the periphery. For example, neurons can produce mediators (e.g., ACh) that suppress endothelial activation, immune cell activation, and leukocyte trafficking. Consistent with the known functions of the cholinergic anti-inflammatory pathway, as the efferent or motor arm of the

inflammatory reflex and the neural circuit that responds to and regulates innate immune responses, including inflammation [34], endothelial cell activation, and subsequent leukocyte trafficking, have been reported to be regulated by ACh and nAChR agonists [94]. Suppression of endothelial cell activation by neural mediators could in this way help resolve inflammation. Thus, neural regulation of immune cell trafficking can involve production of neural factors that promote the resolution of inflammation and tissue repair processes.

59.4.2.2 Neurotransmitters in Neuronal Circuits Controlling Inflammation

Immune cells express receptors for neurotransmitters and respond to neuronal outflow. In the nervous system, neurotransmitter release commonly occurs in synapses, that is, anatomically defined structures between neurons or a neuron and a non-neuronal target cell. In addition, neurotransmitters released outside synapses (e.g., volume transmission) propagate by diffusion, and form tissue gradients with effects on multiple cells and regions. Immune cells may be targets of both types of signal transmission and a variety of neurotransmitters exert significant effects on immune cell function. Recent progress has provided important insights as outlined below.

NE and other catecholamines mediate interactions of sympathetic neurons with immune cells. These interactions can occur in a synapse-like fashion. Alternatively, NE diffuses through the parenchyma of the innervated tissue before interacting with these receptors [24,30]. This communication regulates immune responses and inflammation (Figure 59.1). Catecholamines interact with different types of G-protein-coupled adrenergic receptors (ARs) expressed on immune cells [30]. For example, NE activates β2 adrenergic receptors (β2ARs) on T cells, B cells, macrophages, dendritic cells, mast cells, and neutrophils [95]. This activation triggers subsequent activation of a traditional or canonical pathway via G-protein-dependent cAMP-protein kinase A (PKA)-mediated signaling, which results in suppression of immune responses and inflammation. These findings suggest that β2AR signaling pathways in immune cells could be targeted to reduce chronic inflammation, promote resolution of inflammation, and improve tissue homeostasis. However, a shift toward noncanonical signaling via β2AR-induced ERK1/2 activation has also been described in some inflammatory conditions [95]. This signaling pathway is G-protein-independent and occurs in a cell-type-dependent manner that augments and sustains cell-mediated immune and inflammatory responses [95]. In addition, ligation of NE with αARs on immune cells is associated with proinflammatory signaling [26,30]. Dopamine activates a multitude of dopamine receptors expressed on T cells with specific effects on cell migration and cytokine release [96,97]. Therefore, catecholamines, and specifically NE, exert multiple cell- and receptor-dependent effects on immunity and inflammation.

ACh, released from cholinergic neurons, T cells, or B cells inhibits macrophage release of proinflammatory cytokines by activating α7nAChRs through a mechanism that involves NF-κB and JAK2/STAT3 [35,40,98,99]. Glutamate has been reported to regulate the activation of modified T cells, possibly by controlling cAMP-mediated signaling and the MAPK pathway [100]. Serotonin can promote T cell activation and modulate function at different phases of the immune response [101].

Much remains to be learned about the role of neurotransmitters in the regulation of immune cell function and inflammation. Improved understanding may provide valuable tools in therapeutic regulation of immune responses.

59.4.2.3 Neural Regulation of Inflammation Resolution

As described above, signaling through the vagus nerve controls inflammation through suppression of proinflammatory cytokine responses and prevents excessive, damaging inflammatory reactions [12,40]. This modulation can be explored in treating acute and chronic inflammatory conditions [12,102]. Another critically important aspect of a "protective" inflammatory process is the resolution of inflammation [103,104], as described in Section 59.2. Resolution is actively mediated through numerous proresolving mediators, including SPMs such as resolvins, lipoxins, protectins, and maresins [104]. Inflammation resolution occurs through limiting leukocyte infiltration and increasing the phagocytosis of dead/dying cells by neutrophils and macrophages – a process termed efferocytosis [103,104]. Serhan and colleagues have recently reported that vagus nerve signaling is an important neural regulator of inflammation resolution, thus bridging the anti-inflammatory effects of the vagus nerve with the active immune processes mediating resolution [7]. By utilizing unilateral right side cervical vagotomy in mice, they discovered a pivotal role for the vagus nerve in controlling the axon guidance molecule netrin-1, a suppressor of local inflammation and endogenous proresolving mediator [7]. Leukocyte subsets – including granulocytes, monocytes, macrophages, T lymphocytes, and B lymphocytes – found in the lungs following zymosan-induced peritonitis produced netrin-1 in zymosan-induced peritonitis [7]. Vagotomy significantly reduced *Nnt1* gene and netrin-1 protein expression in the lungs and peritoneum, as well as netrin-1 localization in lung neurofilaments [7]. Lower netrin-1 levels found in vagotomized mice correlated with lower ACh and increased localized inflammation. In addition, leukocyte infiltration was increased in netrin-$1^{+/-}$ mice and inflammation resolution was significantly delayed when compared to wild-type netrin-$1^{+/+}$ mice [7]. Vagotomy also reduced the levels of resolvin D1 (RvD1) and other proresolving mediators [7], while RvD1 administration counteracted the effects of vagotomy and decreased proinflammatory cytokine levels [7]. Likewise, administration of RvD1 shortened the time to resolution of inflammation in netrin-$1^{+/+}$ mice, which was abolished in netrin-$1^{+/-}$ mice [7]. A bidirectional functional relationship between netrin-1 and specialized proresolving mediators was further established by the finding that netrin-1 enhanced the biosynthesis of proresolving lipid mediators, including protectin D1 (PD1) and RvD5 in mice [7]. Netrin-1 also decreased leukocyte migration and stimulated the uptake of apoptotic leukocytes by human macrophages, and efferocytosis was synergistically enhanced when netrin-1 and RvD1 were coincubated with macrophages [7]. Collectively, these findings reveal that vagus nerve signaling regulates inflammation resolution via modulation of netrin-1 and proresolving mediators. These findings strongly implicate a potential role of neural circuitry and specifically the vagus nerve in the resolution of inflammation. Further experimental studies of the effects of vagus nerve stimulation and manipulation of signals in other neural reflex

circuits, on proresolution pathways will provide additional insight into these intriguing possibilities.

59.4.2.4 Immune Cells and Cells with Immune Function in the Periphery Implement the Neuronal Repertoire

As discussed above, immune cells and other cells associated with immune/inflammatory responses in the periphery (e.g., endothelial cells) express receptors for neurotransmitters and these receptors mediate neural regulation of immune responses, including inflammation. Many of these same cells synthesize and release substances classically identified as neurotransmitters, which have been implicated in the regulation of immune processes through paracrine and autocrine mechanisms. These substances and neurotransmitter receptors are important components of the communication between the nervous system and the immune system. Below, we will focus on the functional role of non-neuronal ACh and catecholamines, including dopamine and NE.

ACh, synthesized from acetyl CoA and choline by choline acetyltransferase (ChAT), is a major modulator of immune cell responses. Although commonly designated as a neurotransmitter, ACh is synthesized and released by many cells in the periphery, including T cells, as well as other immune cells (e.g., monocytes, macrophages, B cells, dendritic cells, and endothelial cells) [105]. Lymphocyte-derived ACh participates in local innate immunity [99] through its interactions with both mAChRs and nAChRs, which are widely expressed on immune cells and nonimmune cells in the periphery [105,106]. ACh-producing T cells in the periphery suppress cytokine production following vagus nerve stimulation [35]. Fujii and coworkers have recently reported that ACh found in the blood was primarily produced by $CD4^+$ T cells [106]. The factors controlling the release of ACh are not completely understood [106]. ACh is rapidly degraded by ubiquitously expressed AChE and thus, ACh must act on its receptors in proximity of its release. ACh neuronal receptors are relatively well characterized. The nAChRs form ion channels comprised of five homologous subunit structures surrounding a pore [107]. The mAChRs are G protein-coupled receptors, with five main subtypes (M1-M5) [107]. In contrast to the neuronal ACh receptors, non-neuronal mAChRs and nAChRs (including those on immune cells) are not fully characterized. ACh, produced by T cells is known to exert immunomodulatory effects through binding to α7nAChRs present on macrophages and suppresses TNF production/release (Figure 59.1) [35]. Interestingly, a recent study has reported that interaction of ACh with α7nAChRs expressed on mitochondria results in stabilization of mitochondrial membrane permeability after ROS exposure, prevention on inflammasome activation and reduction IL-1β, IL-18, and HMGB1 release [108]. Endothelial cells also express α7nAChRs and cholinergic agonists have been shown to regulate endothelial cell activation and subsequent leukocyte trafficking via nAChRs *in vivo* [94]. Therefore, the α7nAChR is a possible molecular target for anti-inflammatory treatments. Interestingly, a recent study showed that peritoneal B cell-derived ACh can suppress neutrophil trafficking; this action is not the result of reduced cytokine/chemokine expression, but is regulated via mAChR-dependent modulation of adhesion molecule expression on endothelial cells [99]. As described above, there

is a potential role for ACh in regulating the development of inflammation as well as in the active resolution of inflammation [7]. However, much remains to be learned about detailed mechanisms and the functional implications of ACh released from immune and other non-neuronal cells in the regulation of inflammation.

Catecholamines, including dopamine, Epi, and NE, are produced and released within the CNS, and by peripheral neurons, where they function as neurotransmitters. Epi, produced mainly in the adrenal medulla, functions as a hormone (Figure 59.1) [109]. Sympathetic postganglionic fibers produce and release NE in the periphery (Figure 59.1) where it can bind immediately to neighboring immune cells or diffuse through the parenchyma of innervated tissue before interacting with immune cells [24,30]. Like ACh, NE can be found in numerous immune cells, including peritoneal macrophages, mast cells, and numerous lymphocyte subsets [110]. β2-adrenergic receptors (β2ARs), a common ARs on immune cells [110], are found on lymphocytes, monocytes, macrophages, dendritic cells, mast cells, NK cells, and neutrophils [95]. Binding of NE to β2ARs on immune cells can lead to cAMP production and functional changes that inhibit immune responses, including inflammation (Figure 59.1). For example, NE activation of β2AR on T lymphocytes reduces the production of proinflammatory cytokines, including IFNγ, IL-4, and IL-5 [111]. Similarly, NE-mediated signaling impairs NK cell cytotoxic potential [112] and adhesion to the endothelium [113]. In most cases, activation of β2ARs on LPS-stimulated monocytes typically produces anti-inflammatory responses, characterized by decreased cytokine (TNF, IL-12, and IL-18) and chemokine (CCL3/MIP-1α) production, as well as suppression of ICAM-1 adhesion molecule expression, which together limit leukocyte accumulation [110]. These findings suggest that modulation of AR signaling in immune cells may serve as a therapeutic target to reduce chronic inflammation, promote resolution of inflammation. It should be noted, however, that under certain conditions, βAR signaling can be proinflammatory [26,30] and significant differences have been reported in rodent vs. human immune cell responses following NE treatment [110].

Finally, to the best of our knowledge, other than its ability to suppress proinflammatory mediator production, the role of NE in resolution of inflammation has not yet been explored. Thus, further studies are warranted to better characterize the role of AR-mediated signaling in immune cells during inflammation.

Dopamine acts in the periphery as a paracrine or autocrine factor by binding to and activating either dopaminergic receptors or α- and β-AR. Several immune cells, including T and B lymphocytes, macrophages, bone marrow-derived mast cells, and granulocytes synthesize dopamine [110], and measurable amounts of dopamine are found in the circulation. Dopamine signals through five different dopamine receptors (D1-D5), which are categorized as either D1-like or D2-like dopamine receptors based on their activation or inhibition of adenylate cyclase, respectively [114]. Various immune cells (e.g., T and B lymphocytes, monocytes, neutrophils, and NK cells) express dopamine receptors [114,115]. Similar to NE, dopamine regulates immune cell activation and cytokine production, as well as cell proliferation [114,116]. For example, dopamine promotes T lymphocyte

proliferation and cytokine production following LPS stimulation [117]. A very recent study highlights the modulation of the NLRP3 inflammasome activation by dopamine [118], which leads to the release of mature/active IL-1β and IL-18 [119]. Excessive NLRP3 activation and subsequent overproduction of proinflammatory IL-1β and IL-18 are implicated in several chronic inflammatory conditions (e.g. diabetes, metabolic syndrome, and atherosclerosis) [119]. Thus, targeting the dopamine/dopamine receptor pathway may have therapeutic potential for treating inflammatory conditions.

59.4.2.5 The Brain as an Active Player in the Regulation of Peripheral Inflammation: Focusing on Cholinergic Mechanisms

The brain is not merely a passive recipient or a "victim" of peripheral inflammatory insults, but rather an active participant in the regulation of peripheral immune functions and inflammation. The role of the vagus nerve as a conduit of bidirectional immune system – brain communication has triggered interest in elucidating brain mechanisms regulating the efferent arm of the inflammatory reflex. We focus below on research that highlights a pivotal role for brain cholinergic mechanisms and mAChRs in this regulation. The brain cholinergic system, with somata localized in the basal forebrain and mesopontine tegmentum provides innervations to the cortex, hippocampus, amygdala, hypothalamic nuclei, thalamus, and other brain regions [76,120]. Postsynaptically located mAChRs, which predominantly belong to the M1 subtype, play a major role in processing ACh neurotransmission in the cholinergic synapses in these and other brain regions [76,120]. Brain areas innervated by the cholinergic system interact directly or via multisynaptic pathways with the dorsal vagal complex, the brainstem integrative center of vagus nerve activity, and the inflammatory reflex. These neuroanatomical substrates provide a means of brain cholinergic regulation of anti-inflammatory output via the efferent vagus nerve. The role of brain mAChR signaling in controlling peripheral inflammatory responses has been indicated by the observation that intracerebroventricular (icv) administration of an M1 mAChR agonist significantly suppresses serum TNF levels in endotoxemic rats [121]. In addition, icv injection of a mAChR ligand activates efferent vagus nerve activity, determined by heart rate variability analysis based on ECG recording [121]. M1 mAChR agonist delivery via icv infusion also reduces colonic cytokine production and disease severity in two models of colitis [41,122]. An intact vagus nerve and a splenic nerve are required to mediate these effects [41,122]. Another recently published study evaluates the anti-inflammatory potency of peripheral administration of xanomeline – a centrally acting M1 mAChR agonist studied for the treatment of Alzheimer's disease and schizophrenia [123]. Brain mAChRs and an intact vagus nerve-splenic nerve axis are required for xanomeline-mediated suppression of TNF in a mouse model of endotoxemia [123]. An anti-inflammatory role of brain mAChRs has also been shown in experimental hemorrhagic shock [124,125] and other preclinical settings of inflammatory disorders [36]. Intriguingly, anticholinergic drugs (and specifically centrally acting anticholinergics), which are frequently prescribed to the elderly, have been found to exacerbate inflammatory responses to endotoxemia in a murine model of neurodegenerative tauopathy [126,127].

In addition to using M1 mAChR agonists and other centrally acting mAChR ligands, brain cholinergic activation can be achieved by using AChE inhibitors, which inhibit ACh breakdown in the synaptic cleft and potentiate brain cholinergic signaling. Some of these agents are in clinical use for the treatment of Alzheimer's disease. The anti-inflammatory properties of these drugs have been demonstrated in murine endotoxemia, inflammatory bowel disease, and other inflammatory conditions [36]. For instance, peripheral administration of the centrally acting AChE inhibitor, galantamine, significantly reduces serum TNF and improves survival in mice with endotoxemia [79]. Brain mAChRs and vagus nerve α7nAChR-mediated signaling are required for the anti-inflammatory effects of galantamine in endotoxemia [79]. Galantamine also stimulates the efferent vagus nerve in rodents [128]. Treatment with galantamine alleviates inflammation and disease severity in a model of inflammatory bowel disease through brain mAChRs and activation of vagus nerve – splenic nerve neuronal axis [41]. Together these findings indicate that brain mAChR-mediated cholinergic activation by galantamine is functionally linked to activation of the efferent arm of the inflammatory reflex. Anti-inflammatory and disease alleviating properties of galantamine and other centrally acting AChE inhibitors have also been demonstrated in adjuvant-induced arthritis [129], spontaneous hypertension [130], obesity and the metabolic syndrome [131], type 2 diabetes [132], type 1 diabetes [133], and other preclinical models of diseases [36]. Of note, peripheral inflammation has been reported in patients with Alzheimer's disease, which is characterized by neurodegeneration affecting basal forebrain cholinergic neurons. Treatment of Alzheimer's patients with AChE inhibitors, which may provide a temporary boost in brain cholinergic signaling, results in suppression of peripheral inflammatory responses [134–136]. Together, these findings suggest an interesting connection between brain cholinergic signaling and peripheral inflammation.

59.5 Translational Exploration Based on the Neuroimmune Communicatome

The available therapy for treating excessive inflammation remains limited. Steroidal and nonsteroidal anti-inflammatory drugs, small molecule compounds, and specific anti-cytokine drugs in clinical use are not selective to particular tissues and often produce serious undesirable side effects. For example, systemic anti-TNF therapy, which has revolutionized the treatment of several chronic inflammatory diseases, may increase the risk of serious opportunistic infections [137,138]. The need for new, selective, and adaptable treatment options in inflammation is, therefore, pressing [8].

Providing insight into neuroimmune communication has gone hand in hand with evaluating new therapeutics for treating inflammatory and autoimmune conditions. This avenue of clinically oriented research has already identified several pharmacological agents that can be used in the context of human disease. In addition, harnessing neuroimmunomodulation by utilizing electrical stimulation and other types of device-generated output has identified new therapeutic strategies

for disease treatment in the growing field of bioelectronic medicine. Below we focus on the emerging clinical development of some of these new approaches.

59.5.1 Pharmacological Anti-Inflammatory Approaches Based on the Inflammatory Reflex

Active preclinical research on the inflammatory reflex in the context of septic shock, sepsis, hemorrhagic shock, arthritis, inflammatory bowel disease, obesity, type 2 diabetes, and other disorders [6,12,102] has identified new pharmacological approaches that can be further studied in clinical settings. Some of these approaches, utilizing clinically approved α7nAChR agonists and centrally acting AChE inhibitors are being tested in human inflammatory conditions. For instance, the α7nAChR agonist, GTS-21, at doses previously reported to be safe in humans [139] has been recently tested in human endotoxemia [140]. Although no significant anti-inflammatory effects were found, a correlation between higher plasma GTS-21 levels and lower plasma levels of TNF, IL-6, and IL-1 receptor agonist were observed [140], raising the question of whether higher GTS-21 doses would be effective. Treatment with another α7nAChR agonist, choline, has been reported to significantly lower TNF and other inflammatory molecules, reduce oxidative stress, and alleviate disease scores in patients with asthma [141], further supporting the potential benefit of targeting α7nAChR.

The pandemic proportions of obesity and obesity-driven disorders coupled with the health risks they present identify a large unmet medical need [6]. The preclinical efficacy of α7nAChR agonists and galantamine in alleviating inflammation and insulin resistance in preclinical settings has led to recent exploration of these drugs in clinical scenarios of obesity-driven disorders. The effects of the selective α7nAChR agonist, TC-6987, are being evaluated in type 2 diabetes (https://clinicaltrials.gov/ct2/show/NCT01293669?term=Targacept&rank=11). A recent trial is evaluating the effects of clinically approved (for the treatment of Alzheimer's disease) galantamine doses in individuals with metabolic syndrome (https://clinicaltrials.gov/ct2/show/NCT02283242?term=cholinergic+obesity&rank=2).

59.5.2 Bioelectronic Medicine

The inflammatory response must be fine-tuned to purge invading pathogens and promote resolution without causing excessive tissue damage and development of inflammatory diseases. The onset and resolution of inflammation are complex processes involving phenotypic changes in immune cells, switching effects of inflammation-related molecules, secretion of proresolving mediators, and more. Current pharmacological treatment carries a significant risk for serious adverse effects, partly because the treatment is commonly not sufficiently specific in terms of anatomical location and targeted mechanism. The complexity of involved mechanisms makes development of useful treatments difficult, and conceptual innovations in inflammatory and autoimmune disease therapy are urgently needed [8].

The emerging understanding of the neuroimmune communicatome described in this chapter suggests that interventions in neural signaling can be used for

therapeutic regulation of inflammation. By interfacing with the physiological autonomic reflexes that are already in place, more specific treatment in terms of anatomical and molecular targets coupled with immediate evaluation of effect of interventions might be possible, although an intense multidisciplinary experimental effort will be required to bring this concept from vision to reality. This effort brings neuroscience, immunology, molecular biology, engineering, and clinical medicine together in developing new technology to discover, define, and therapeutically modulate neural circuits and molecular mechanisms of the neuroimmune communicatome, and has spawned the field of bioelectronic medicine [36,142,143].

Importantly, bioelectronic medicine relies on detailed insights into the neurophysiological and molecular mechanisms that constitute the homeostatic neural reflexes that regulate immune activity. The experimental observations thus far have identified potential targets for nerve stimulation therapy in the peripheral nervous system and in the CNS. We anticipate that basic science studies of the neuroimmune communicatome will continue to identify a multitude of interesting potential therapeutic targets. These advances should provide insights for optimization of clinical trial design and a more detailed prediction of effects and potential side effects. Current experimental findings defining the inflammatory reflex have enabled the design of clinical trials for treatment of inflammatory disease. Studies of the effect of implanted vagus nerve stimulators on symptoms in rheumatoid arthritis (https://clinicaltrials.gov/ct2/show/NCT01552941) and Crohn's disease (https://clinicaltrials.gov/ct2/show/NCT02311660) have been performed. Results from these trials, demonstrating the efficacy of these treatments were recently published [144,145].

The prospect of using electrical stimulation of specific nerves to regulate inflammation and treat disease is attractive. The emerging concept of using nerve recording and stimulation for therapy tentatively provides a novel approach in personalized medicine: It may be possible to integrate sensory information on inflammation and other clinical data, and to use it to continuously guide disease diagnosis and treatment. It is tempting to speculate that perhaps even a fully implantable closed-loop device might be developed to provide uninterrupted access for clinicians and patients to data on disease development to optimize diagnosis and treatment, as well as monitor responses to treatment. However, much remains to be learned about the anatomy and physiology of the neuroimmune communicatome before the feasibility of such prospects can be determined.

59.6 Conclusions

Herein we have described important aspects of the current understanding of neuroimmune communication in inflammatory conditions by introducing the unifying concept of the neuroimmune communicatome. Inflammation has many facets and multiple forms. It represents a native defense mechanism when localized and resolved in a timely fashion. However, inflammation can be disease promoting and lethal when unbalanced and unresolved. Immune cells and neurons interact and communicate with each other during inflammation and

inflammation resolution in order to maintain and restore biological homeostasis. Specific forms of active neuroimmune communication occur during neurogenic inflammation in the periphery and neuroinflammation in the CNS and in the brain respectively (Figure 59.1). Peripheral inflammatory conditions also trigger active communication between the immune system and the brain, mediated by vagus nerve neurons and other mechanisms (Figure 59.1), which provide a reflex control of peripheral inflammation. Other brain-integrated and coordinated reflex pathways have also been described. Introducing the concept of the neuroimmune communicatome is aimed at providing an integrative view of the involvement of the nerves in inflammation. It is evident that various forms of neuroimmune communication do not occur in isolation. For instance, sensory neurons, which, in an axon–axon reflex fashion mediate and regulate inflammation, also serve as nociceptors that transmit pain sensation to the brain and potentially alter brain function. Moreover, in addition to triggering brain-derived anti-inflammatory output, peripheral forms of inflammation can exacerbate neuroinflammation and even generate brain proinflammatory signaling that contributes to aberrant brain function, even to a life-threatening extent. Neuroimmune communication takes place through multiple mechanisms. Neurotransmitters such as ACh and NE along with cytokines and other immune cell-derived inflammatory molecules are important mediators. Expression of neurotransmitter receptors on immune cells and cytokine receptors on neurons facilitate this communication. Release by immune cells of ACh and other substances classically perceived as neurotransmitters is also implicated. Preclinical findings in neuroimmune communication have provided a rationale for clinical studies using pharmacological modalities and electrical nerve stimulation to treat inflammatory disease and spawned the field of bioelectronic medicine. Clearly, the basic science underlying the neuroimmune communicatome is in its infancy and new pathways and mechanistic insights will be elucidated in time. Implementing optogenetics, Cre-lox, and CRISPR/Cas9 genetic modifications and other state-of-the-art methodologies should facilitate preclinical research in this area. The knowledge generated holds the potential of implementing new strategies in disease treatment.

Acknowledgments

This work was supported by a grant from the National Institute of General Medical Sciences, NIH: RO1GM089807 (to VAP), and by grants from Knut och Alice Wallenbergs Stiftelse and Svenska Läkaresällskapet (to PSO). The authors thank Tom Coleman (PhD), Jared Huston (MD), Ulf Andersson (MD), and Kevin Tracey (MD) for critically reading the manuscript.

Abbreviations

ACh	acetylcholine
AChE	acetylcholinesterase
ACTH	adrenocorticotropic hormone

AP	area postrema
AR	adrenergic receptor
AVN	afferent vagus nerve
CAP	cholinergic anti-inflammatory pathway
ChAT	choline acetyltransferase
CGRP	calcitonin gene-related peptide
CNS	central nervous system
CRH	cortotropin-releasing hormone
DAMP	danger/damage-associated molecular patterns
DMN	dorsal motor nucleus of the vagus
ECG	electrocardiogram
Epi	epinephrine
HPA	hypothalamic–pituitary–adrenal
icv	intracerebroventricular
iNKT	invariant natural killer T cells
LC	locus coeruleus
LPS	lipopolysaccharide
mAChR	muscarinic acetylcholine receptor
nAChR	nicotinic acetylcholine receptor
NF-κB	nuclear factor kappa B
NK	natural killer
NLRP3	NACHT, LRR, and PYD domains-containing protein 3
NOD	nucleotide-binding oligomerization domain
NE	norepinephrine
NTS	nucleus tractus solitarius
PAMP	pathogen-associated molecular pattern
PD1	protectin D1
PitG	pituitary gland
PRR	pattern recognition receptor
PVN	periventricular nucleus
RvD1	resolvin D1
RVM	rostroventrolateral medulla
SNS	sympathetic nervous system
SP	substance P
SPM	specialized proresolving mediator
TLR	Toll-like receptor
VIP	vasoactive intestinal peptide
VNS	vagus nerve stimulation

The Inflammatory Response in Tissue Repair

Nikolaos G. Frangogiannis

The Wilf Family Cardiovascular Research Institute, Department of Medicine, Albert Einstein College of Medicine, 1300 Morris Park Avenue Forchheimer G46B, Bronx, NY 10461, USA

60.1 Introduction

In multicellular organisms, millions of years of evolutionary pressures led to the emergence of sophisticated systems for recognition of injury and repair of damaged tissues. The effectiveness of the reparative response following injury is dependent on the severity and type of injury, the organ affected, and species-specific characteristics. The ability for regeneration of certain tissues by some species, but not others cannot always be explained by species-specific differences in the level of complexity of the injured structure. Amphibians, but not reptiles, birds, or mammals can regenerate limbs [1]. Fish can regenerate myocardium following injury [2,3]; in contrast, adult mammalian hearts do not regenerate and heal through formation of a collagen-based scar [4,5]. Despite a wide range of functional outcomes, reparative responses following injury share common characteristics. Healing of injured tissues is dependent on timely activation and suppression of an inflammatory cascade that serves to eliminate the noxious stimulus, and clear the injured area from dead cells and matrix debris, while setting the stage for activation of reparative cells. Perturbations of the inflammatory reaction following injury may result in defective repair, prolonged injury, fibrosis, and development of organ dysfunction. This chapter discusses the cellular effectors and molecular signals involved in regulation of the inflammatory and reparative reaction following tissue injury.

60.2 Initiation of the Inflammatory Response Following Injury: The Alarmins

Necrotic cells release a wide range of mediators that serve as "danger signals" and trigger an intense inflammatory reaction. These endogenous molecules, termed alarmins [6,7], can also be secreted by activated immune cells and are capable of

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

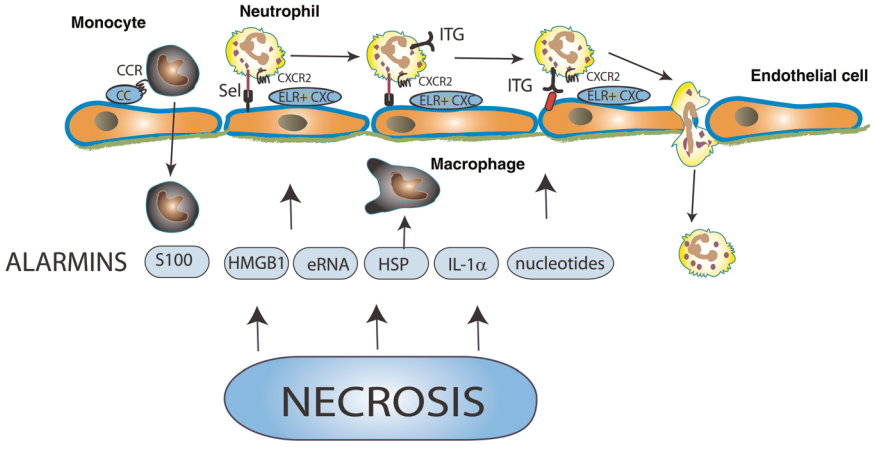

Figure 60.1 Adhesive interactions between leukocytes and endothelial cells mediate recruitment of inflammatory cells at the sites of injury. Dying cells (and some immune cell populations) secrete alarmins that activate Toll-like receptor (TLR)-dependent cascades, initiating the innate immune response. Activates endothelial cells express selectins (Sel) on their surface; these proteins interact with selectin ligands on leukocytes initiating rolling. Firm adhesion between leukocytes and endothelial cells require interactions between chemokines bound to endothelial glycosaminoglycans and their leukocyte receptors, and subsequent integrin (ITG) activation. Transmigration of the leukocytes predominantly occurs through endothelial junctions.

stimulating cellular responses that clear the injured tissue and promote a reparative program. The nuclear DNA-binding protein high-mobility group box-1 (HMGB1) is the prototypical member of the family. HMGB1 is passively released by necrotic cells, but may also be secreted by myeloid and NK cells without the need for *de novo* synthesis [8,9]. In contrast, cells dying through apoptosis do not release HMGB1. Members of the S100 family of proteins (such as S100A8/9, S100A12, and S100B), heat shock proteins, interleukin (IL)-1α, extracellular RNA or DNA, and uric acid can also act as alarmins, activating an immune response upon their release by necrotic cells (Figure 60.1) [10–12]. Alarmins target all cells implicated in tissue inflammation and repair, by activating pattern recognition receptors, such as Toll-like Receptors (TLRs) and nucleotide-binding oligomerization domain receptors (NLRs), and by binding to the promiscuous receptor for advanced glycation end-products (RAGE) [13]. Activation of TLR and RAGE signaling induces inflammatory mediator synthesis by innate immune cells, recruits antigen-presenting cells, and may be implicated in proliferation and differentiation of reparative cells, such as angiogenic endothelial cells and resident stem cells [14,15]. Moreover, prolonged secretion of alarmins may activate fibroblasts, promoting a fibrotic response [16]. Thus, alarmins have been implicated in both beneficial and detrimental actions following tissue injury. Tight spatial and temporal regulation of alarmin-mediated actions may be critical to activate a reparative program, while preventing inflammatory injury and progressive tissue fibrosis.

60.3 The Complement Cascade

The complement system is comprised by a large family of proteins, which are activated in a cascade-like fashion in response to host immunoglobulins, specific pathogens, or danger signals via three distinct pathways: (1) the classical pathway, (2) the lectin pathway, and (3) the alternative pathway. Regardless of the underlying mechanism, activation of the complement cascade ultimately leads to phagocytosis of pathogens, and ends with assembly and deposition of a membrane attack complex that kills bacteria and infected or damaged cells by disrupting their membrane integrity [17]. In addition to their cytolytic effects, components of the complement cascade also exert leukocyte chemoattractant actions [18], and trigger cytokine and growth factor release by a wide range of cell types [19–21]. Complement activation has been consistently demonstrated in healing wounds [22]. Experimental studies have suggested that activation of innate immune pathways by the complement cascade is crucial for recruitment of leukocytes [23] and may promote fibroblast proliferation and activation [24,25] in injured tissues. Moreover, evidence implicates components of the complement system in tissue regeneration. Mice lacking C3a and C5a exhibited a marked impairment in regeneration in models of hepatic resection and CCl4-induced parenchymal hepatic necrosis [26,27]. Thus, the complement cascade activates both cytotoxic and reparative processes following tissue injury.

60.4 Induction and Release of Proinflammatory Cytokines

Activation of innate immune pathways following tissue necrosis triggers the nuclear factor (NF)-κB cascade, leading to marked induction and release of proinflammatory cytokines and chemokines. Most cell types, including immune cells, vascular cells, fibroblasts, and parenchymal cells, residing in various organs are capable of producing large amounts of interleukin (IL)-1, tumor necrosis factor (TNF)-α, and IL-6 when stimulated by danger signals. Influx of abundant leukocytes with a proinflammatory profile, in response to the first wave of inflammatory mediators, further accentuates the cytokine response. Cytokines are highly pleiotropic, exerting a wide range of actions to all cell types involved in injury and repair. IL-1, the prototypical proinflammatory cytokine [28,29], is the classic endogenous pyrogen induced following inflammation, and critically modulates cellular behavior in injured tissues. Two major forms of IL-1, IL-1α and IL-1β, encoded by distinct genes have been identified and extensively characterized. Both act through the same receptor (IL-1RI) and have similar biological properties. In recent years, the IL-1 family has expanded with the discovery of several new ligands and receptor proteins.

IL-1α is constitutively expressed, and when released by necrotic cells acts as an alarmin, activating an inflammatory cascade [30]. IL-1β, on the other hand, is upregulated in immune cells following injury, and requires activation by caspase-1. Caspase-1 activation and subsequent release of active IL-1β requires assembly of a multiprotein complex, called the “inflammasome” [31]. When released in the area

of injury, IL-1 induces proinflammatory cytokine and chemokine synthesis and increases endothelial expression of adhesion molecules, mediating recruitment of leukocytes [32]. IL-1 also activates a proinflammatory program in fibroblasts, delaying myofibroblast transdifferentiation to prevent premature deposition of extracellular matrix proteins in injured areas, until the wound has been cleared from dead cells and matrix debris [33].

TNF-α synthesis is also upregulated in injured tissues and is expressed by many types of immune cells. Moreover, tissue resident mast cells may degranulate in response to complement activation, releasing significant amounts of preformed TNF-α from their granular stores [34,35]. TNF-α plays an important role in recruitment of leukocytes following injury by stimulating chemokine synthesis, by activating leukocyte integrins, and by inducing adhesion molecule expression by endothelial cells [36,37]. It should be emphasized that cytokines are highly pleiotropic and multifunctional, and have also been reported to exert prosurvival actions on resident cells in injured tissues [38].

60.5 Chemokines Regulate Leukocyte Recruitment

Chemokines are a family of small (8–12 kDa) chemoattractant proteins that plays a critical role in regulating trafficking of immune cells, both in homeostasis (during lymphoid organ development), and following tissue injury [39,40]. From a structural perspective, the chemokine family is subdivided into CC, CXC, CX3C, and XC subfamilies; this classification has important functional implications. CC and CXC chemokines are the largest subfamilies and exhibit distinct properties. Most CC chemokines function as potent chemoattractants for mononuclear cell subsets. On the other hand, CXC chemokines that contain the tripeptide motif glutamic acid–leucine–arginine (ELR) in the NH_2-terminal region (such as CXCL8/IL-8) are implicated in granulocyte recruitment [41,42]. Although chemokines predominantly target immune cells, several members of the family have been reported to function as modulators of many other cell types (such as endothelial cells, vascular smooth muscle cells, fibroblasts, neurons, and cardiomyocytes) [43,44], regulating cellular phenotype, proliferation, and survival.

On the basis of their mechanisms of regulation, chemokines can be divided into "homeostatic," which are constitutively expressed in certain tissues and may be involved in basal trafficking of leukocytes, and "inducible" chemokines that are upregulated through activation of innate immune pathways and mediate recruitment of leukocytes following tissue injury [45–47]. Clearly, this concept represents an oversimplification, as homeostatic chemokines (such as CXCL12/Stromal Cell Derived Factor (SDF-1) can be induced following immune activation [48], and inducible chemokines may also regulate trafficking of leukocyte subsets in normal tissues. However, the notion that some members of the family are predominantly upregulated in pathologic conditions and may participate in inflammatory and reparative responses following injury remains useful [43,46,49–51]. Chemokines act by binding to glycosaminoglycans on endothelial cells and on the extracellular matrix [52]. When immobilized into the microvascular endothelial surface, chemokines are presented to circulating

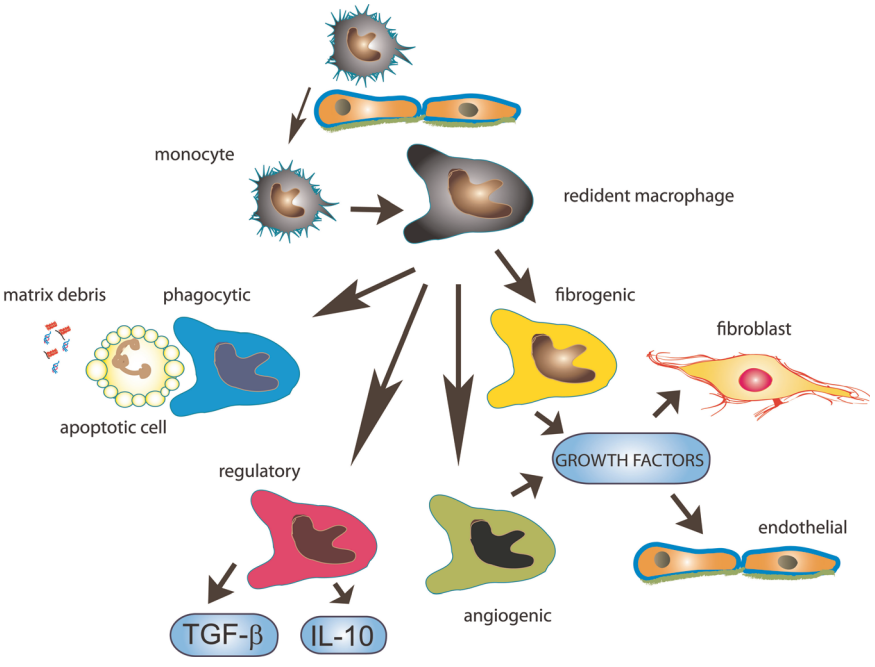

Figure 60.2 Macrophages in tissue repair. In injured tissues, macrophages do not exhibit M1/M2 polarization, but acquire nuanced phenotypes and critically regulate inflammatory, fibrogenic, angiogenic, and regenerative responses.

leukocytes expressing the corresponding chemokine receptors and can trigger an adhesive cascade that ultimately leads to extravasation of leukocytes into the area of injury (Figure 60.2).

60.6 Leukocyte Recruitment in Sites of Injury

Induction of adhesion molecules on the endothelial surface and release of chemokines and cytokines activate a multistep adhesive interaction between leukocytes and endothelial cells, ultimately leading to extravasation of leukocytes into the area of injury (Figure 60.2). First, circulating leukocytes are captured from the bloodstream through interactions that involve endothelial selectins and their corresponding ligands. Subsequently, leukocytes roll along the endothelial layer and sense chemokines bound to endothelial glycosaminoglycans. Selectin-mediated inside-out signaling and interactions between chemokines and the corresponding leukocyte ligands (chemokine receptors) induce conformational changes of leukocyte integrins [53,54], a family of adhesion proteins responsible for strong adhesive interactions and arrest of the leukocytes [55]. Leukocytes then crawl towards endothelial junctions, and migrate across the microvasculature. Experimental evidence suggests that leukocytes preferentially migrate through "matrix-poor" regions of the basement membrane [56] that often overlap with

gaps between pericytes [57]. In addition to the well-established paracellular route, leukocytes may also transmigrate via a transcellular route (through endothelial cells) [58]. Recruitment of various leukocyte subpopulations requires activation of distinct chemokine:chemokine receptor pairs and may involve a different set of integrins. In healing wounds, early release of neutrophil chemoattractants results in a first "wave" of infiltrating neutrophils, followed by upregulation of mononuclear cell-specific chemokines and recruitment of monocytes and lymphocytes [59].

60.7 The Role of Neutrophils in Injured Tissues

At the site of injury, extravasated neutrophils are activated by alarmins, cytokines, and chemokines and acquire a phagocytotic phenotype [60]. In the presence of infection, pathogen-associated molecular patterns potently activate neutrophils. Activated neutrophils generate large amounts of reactive oxygen species (ROS), and rapidly phagocytose pathogens and cellular debris. In addition, neutrophils degranulate releasing proteinases (both serine proteases and matrix metalloproteinases) and antimicrobial peptides. In order to effectively kill pathogens, neutrophils extrude networks comprised of chromatin fibers, granule-derived antimicrobial peptides, and enzymes (such as elastase and myeloperoxidase). These networks, termed neutrophil extracellular traps (NETs) play an important role in killing of pathogens [61], but may also accentuate tissue injury in sterile inflammation. A growing body of evidence suggests that neutrophils may also exert immunomodulatory actions, regulating phenotype, and function of monocytes/macrophages and lymphocytes [62].

60.8 Repression and Resolution of Inflammation: The Stop Signals

Acute inflammation triggers suppressive signals that downmodulate proinflammatory molecules and promote resolution of the inflammatory infiltrate. Suppression of inflammation following injury is accompanied by activation of reparative cells that restore tissue structure and function, or (if regeneration is impossible) repair the tissue through formation of a collagenous scar to prevent organ failure. Considering the catastrophic consequences of defects in suppression and resolution of inflammation, it is not surprising that many distinct pathways have evolved for negative regulation of inflammatory responses following injury [63]. As the wound is cleared from dead cells and debris, all cell types involved in tissue repair contribute to suppression and resolution of inflammation. Both secreted mediators (such as IL-10, and members of the TGF-β family) and intracellular cascades that inhibit innate immune signaling have been implicated in negative regulation of the inflammatory response following injury [64].

60.8.1 Negative Regulation of Cytokine Signaling

Several distinct mechanisms have been implicated in negative regulation of cytokine signaling following tissue injury. First, endogenous cytokine inhibitors may be induced to suppress the inflammatory response [65]. IL-1 receptor antagonist (IL-1Ra) is the prototypical endogenous competitive inhibitor of cytokine-driven inflammation. Second, expression of decoy receptors by inflammatory cell types may serve as a molecular sink for cytokines. Binding of IL-1 to the type II IL-1 receptor, a typical decoy receptor, does not transduce a signaling response, but serves to terminate IL-1-mediated responses [66]. Third, proteasomal-mediated degradation of signaling molecules may restrain cytokine-induced actions. Fourth, induction of inhibitory signals that terminate the JAK–STAT cascade, such as phosphatases that dephosphorylate JAKs [67] and members of the suppressor of cytokine signaling (SOCS) family [68] may play an important role in negative regulation of cytokine responses.

60.8.2 Anti-Inflammatory Cytokines

Secreted anti-inflammatory cytokines are critically implicated in suppression of the inflammatory response in injured tissues. Extensive evidence has documented the role of the interleukins IL-4, IL-13, IL-10, IL-35, IL-37, and of members of the TGF-β family in negative regulation of the immune response [69,70]. TGF-β1 restrains T-cell-mediated inflammation [71]; IL-10, on the other hand, limits immune responses to foreign antigens and suppresses inflammatory cytokine and chemokine synthesis by mononuclear cells [72]. The relative role of each anti-inflammatory cytokine in regulating inflammation following injury is dependent on the tissue studied, and on the specific type of injury. Several secreted mediators may cooperate to suppress inflammatory activation of all cell types involved in tissue repair.

60.8.3 Lipid Mediators in Resolution of Postinfarction Inflammation

A growing body of evidence suggests that resolution of inflammation may be mediated by release of specialized proresolving lipid mediators [73,74]. Four distinct families of anti-inflammatory mediators have been described: the resolvins, the lipoxins, the protectins, and the maresins. Endogenous release of proresolving lipids is associated with resolution of inflammation in a wide range of experimental models of tissue injury [75–78]. Moreover, treatment with resolvins and protectins accelerated resolution of inflammation in conditions associated with persistent and prolonged inflammatory activation, such as type 2 diabetes [79].

60.8.4 Inhibition of the Leukocyte Adhesion Cascade

Effective suppression of the inflammatory response requires inhibition of the adhesive interactions between leukocytes and endothelial cells, in order to restrain proinflammatory leukocyte influx in the tissue. Several distinct pathways may be responsible for downmodulation of leukocyte adhesion. First, induction of

anti-inflammatory cytokines (such as IL-10 and members of the TGF-β family) may repress adhesion molecule synthesis by endothelial cells. Second, chemokine-binding proteins (such as TNF-stimulated gene/protein-6 (TSG-6)) may perturb chemokine–glycosaminoglycan interactions, leading to inhibition of chemokine-driven leukocyte recruitment [80]. Third, inhibitory proteins may interfere with the early selectin-mediated steps of leukocyte rolling, decreasing the pool of leukocytes available to form strong adhesive links with the activated endothelium [81]. Fourth, endogenous endothelial cell-derived integrin ligands may be released during resolution of inflammation, serving as potent leukocyte adhesion inhibitors [82]. The integrin antagonist developmental endothelial locus (Del)-1 is an example of this mechanism: Del-1 is secreted by endothelial cells, binds to the β2 integrin CD11a/CD18, and inhibits leukocyte/endothelial cell adhesion *in vitro* and *in vivo* [83].

60.9 The Cellular Effectors of Resolution of Inflammation

Neutrophils, monocytes/macrophages, lymphocytes, vascular cells, and fibroblasts participate in suppression and resolution of inflammation following injury. Moreover, surviving parenchymal cells that reside in the injured tissue may also contribute to repression of inflammatory signaling, protecting the organ from prolonged injury.

Neutrophils are short-lived cells, programmed to undergo apoptosis. In injured tissues, ingestion of apoptotic neutrophils by macrophages triggers release of anti-inflammatory mediators (such as IL-10, TGF-β, and proresolving lipid mediators), suppressing inflammation [84,85]. Moreover, neutrophil-derived mediators, such as lactoferrin and neutrophil gelatinase-associated lipocalin (NGAL) may directly modulate macrophage phenotype, suppressing proinflammatory signaling, and stimulating a reparative program [86,87].

Recruitment of anti-inflammatory monocyte subsets may play a critical role in negative regulation of inflammation in injured tissues [88,89]. The mechanisms responsible for selective recruitment of anti-inflammatory monocytes during the transition from the inflammatory to the proliferative phase of repair remain unclear. Specific chemokine:chemokine receptor pairs may be involved. The fractalkine receptor CX3CR1 may selectively mediate recruitment of monocytes with reparative properties [90]. Moreover, Sphingosine 1-phosphate receptor 3 (S1P3) signaling has been suggested to play an important role in recruitment of anti-inflammatory monocytes in injured and remodeling vessels [91]. Several other subpopulations of immune cells have been implicated in negative regulation of inflammation following tissue injury. Dendritic cells release anti-inflammatory cytokines (such as IL-10) and may drive macrophages toward a regulatory phenotype [92]. Lymphocyte subpopulations, such as invariant natural killer T cells (iNK T cells) and regulatory T cells (Tregs), have also been implicated in negative regulation of inflammation in various models of tissue injury [93–95]. Specific chemokine:chemokine receptor interactions may be responsible for recruitment of these important lymphocyte subpopulations into sites of injury [96,97].

Macrophages are critically involved in negative regulation of the inflammatory response following tissue injury. Traditional concepts suggest that, in response to changes in their microenvironment, macrophages may acquire polarized M1 and M2 phenotypes; M1 macrophages are proinflammatory, whereas M2 macrophages exhibit anti-inflammatory and reparative properties [98]. A large body of evidence suggests that resolution of inflammation and tissue repair following injury are associated with an abundance of M2 cells [99]. Although the crucial role of macrophages in negative regulation of inflammation following injury cannot be overemphasized, the M1/M2 paradigm is oversimplified and of limited use in understanding the cell biological response responsible for tissue repair. In healing tissues, macrophages exhibit a wide range of "nuanced" phenotypes. Macrophage subpopulations with distinct properties and cytokine expression profiles may be involved in regulation of the regenerative, angiogenic, anti-inflammatory, and fibrogenic responses that cooperate in tissue repair (Figure 60.2).

60.10 The Extracellular Matrix

In injured and remodeling tissues, the extracellular matrix does not simply serve as a structural scaffold, but also plays a critical role in regulating cell phenotype. In all tissues, cells are enmeshed in a dynamic network of extracellular matrix proteins. Through interactions with the matrix, the cells sense microenvironmental changes, and respond by alteration their phenotype and gene expression profile. In injured tissues, the extracellular matrix proteins may also transduce key signals that regulate survival, proliferation, and migration of the cells. During the early inflammatory phase of tissue repair, activation of proteases generates matrix fragments with proinflammatory properties [100,101]. Ingestion of matrix fragments by professional phagocytes plays an important role in resolution of the inflammatory reaction. Moreover, the damaged matrix at the site of injury is replaced by a provisional matrix, comprised primarily of fibrin and fibronectin [102,103]. The provisional matrix serves as a conduit for migrating inflammatory and reparative cells, facilitating remodeling of the injured tissue. Alarmins, cytokines, and growth factors also induce expression of a family of structurally unrelated macromolecules, termed matricellular proteins [104,105]. These proteins are generally not part of the normal matrix network, but enrich the matrix following injury, and do not serve a structural role, but modulate cell:cell and cell:matrix interactions. Prototypical members of the matricellular family, such as thrombospondins-1 and thrombospondins-2, tenascins-C and tenascins-X, SPARC, osteopontin, periostin, and members of the CCN family, participate in the reparative response by activating growth factor and cytokine responses, by modulating protease activity, and by transducing signaling cascades that regulate cell proliferation and survival [104,106,107].

60.11 Tissue-Specific Events Leading to Regeneration

The regenerative potential of an organ following injury is dependent on the intrinsic proliferative capacity of the cellular constituents of the tissue.

Continuously dividing tissues (such as epithelia of the skin and gastrointestinal tract) exhibit continuous loss and replacement of cells, triggered by activation of progenitor cell populations that reside in the organ, or through growth factor-mediated stimulation of proliferative activity of mature cells. In these tissues, injury triggers activation of progenitor cells that restore structure and function.

In other tissues, the cells are quiescent at baseline, but maintain the ability to proliferate following injury. Parenchymal cells in the liver or kidney, fibroblasts, and vascular cells are capable of proliferation following injury. Thus, tissues comprised of these cells have the capacity to regenerate; however, the outcome is dependent on the severity of injury. Very extensive injury may overwhelm the regenerative capacity of the organ, resulting in permanent loss of function. Traditionally, certain cell types, such as cardiomyocytes and neurons, are considered terminally differentiated and nonproliferative in adult mammals. However, recent evidence suggests that cardiomyocytes in adult humans may have a (very limited) capacity for self-renewal [108]. Moreover, brain plasticity following injury suggests that neurons may also exhibit regenerative capacity, and neurogenesis has been documented in certain regions of the brain in humans [109,110]. The extremely limited regenerative capacity of these cell types is not sufficient to restore structure and function following injury in the heart or the nervous system. Thus, in these organs, injured areas heal through formation of a scar, driven by activation and proliferation of fibroblasts. In the heart, reparative fibroblasts may not be capable of performing the specialized contractile function of cardiomyocytes, but maintain the structural integrity and geometry of the organ, preventing catastrophic rupture [111].

60.12 Fibroblast Activation and Formation of a Scar

Most tissues contain resident fibroblast populations that can be activated following injury, undergoing transdifferentiation into matrix-synthetic myofibroblasts [112]. Moreover, in many cases, the local fibroblast population is enriched by cells of various origins that may acquire characteristics of fibroblasts. Thus, blood-derived progenitors, endothelial cells, epithelial cells, and pericytes have been demonstrated to contribute to the population of activated fibroblasts following injury [113].

In tissues with negligible regenerative capacity (such as the myocardium and the nervous system), fibroblasts become essential reparative cells, that deposit extracellular matrix to preserve the structural integrity of the organ. Even in regenerative tissues, fibroblasts may significantly contribute to repair, when injury overwhelms the regenerative process, or depletes the population of resident progenitor cells. Transition from the inflammatory to the proliferative phase of repair is associated with activation of abundant myofibroblasts, phenotypically modulated fibroblasts that express contractile proteins, such as α-smooth muscle actin (α-SMA). At the early stage of myofibroblast transdifferentiation, the cells may lack α-SMA expression, but have stress fibers rich in cytoplasmic actins, and exhibit mature focal adhesions comprised of β- and γ-actin microfilaments, associated with nonmuscle myosin. These cells are called “proto-myofibroblasts” [113]. Activated

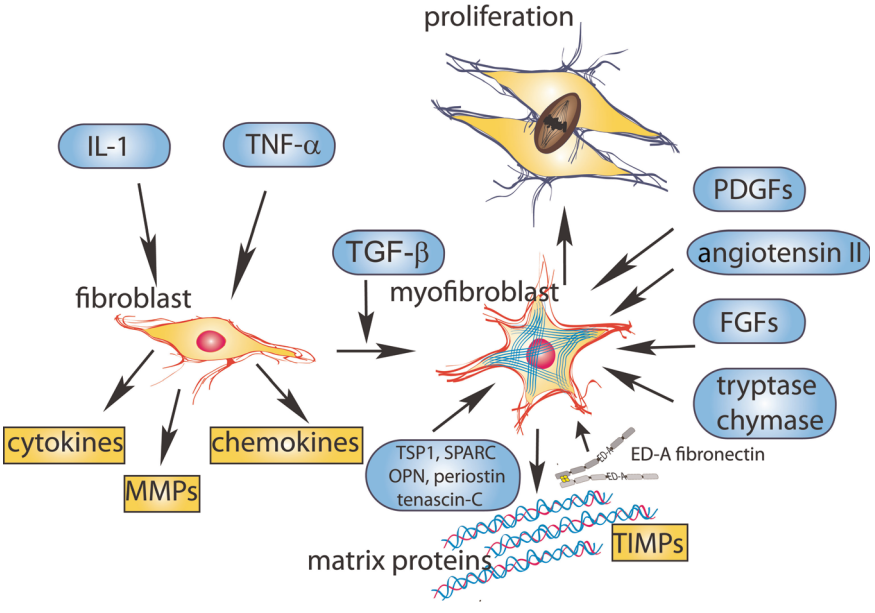

Figure 60.3 In injured tissues, fibroblasts transdifferentiate into myofibroblasts, proliferate and synthesize extracellular matrix proteins. In tissues with limited regenerative capacity, fibroblasts form a scar that serves to preserve the geometry of the organ. In the early stages of repair, fibroblasts acquire a proinflammatory and matrix-degrading phenotype, secreting cytokines, chemokines, and proteases. TGF-β activation promotes myofibroblast transdifferentiation and stimulates extracellular matrix protein synthesis. A wide range of fibrogenic mediators cooperate to stimulate fibroblast proliferation and matrix-synthetic activity. Specialized matrix proteins (such as ED-A fibronectin and matricellular proteins) contribute to fibroblast activation by transducing growth factor-mediated signals.

myofibroblasts have an extensive endoplasmic reticulum, synthesizing and secreting large amounts of extracellular matrix proteins [114–116]. Several distinct pathways cooperate to activate fibroblasts at the sites of injury (Figure 60.3):

1) TGF-β is critically implicated in myofibroblast transdifferentiation [117]. Most tissues contain significant amounts of TGF-β in a latent form that can be activated following injury. ROS, proteases, integrins, and matricellular proteins (such as TSP-1) have been implicated in activation of TGF-β in injured tissues [118,119]. Following activation, active TGF-β binds and sequentially transphosphorylates type I and type II receptors on the fibroblast surface, inducing α-SMA transcription [120]. Both Smad-dependent [121] and Smad-independent pathways have been implicated in myofibroblast activation *in vitro* and *in vivo* [122,123].
2) Alterations in the matrix environment plays critically regulate fibroblast activity. Specialized matrix proteins, such as the ED-A fibronectin variant, are upregulated in injured and healing tissues and promote myofibroblast conversion [124].
3) Release of fibrogenic growth factors (such as fibroblast growth factors, platelet-derived growth factors, and the mast cell proteases chymase and tryptase) and

activation of the angiotensin cascade may promote fibroblast activation, triggering cell proliferation, and stimulating matrix synthesis [125,126].
4) Expression of syndecans on the fibroblast surface may participate in transduction of growth factor-mediated signals that activate myofibroblasts [127].
5) Mechanosensitive signaling activates Rho/Rho kinase pathways, directly stimulates α-SMA transcription in fibroblasts [128].

Once activated, fibroblasts secrete large amounts of extracellular matrix proteins. In nonregenerating tissues (such as the heart), fibroblast-derived extracellular matrix proteins become cross-linked and form a scar that serves to prevent catastrophic failure of the organ. In both regenerating and nonregenerating tissues, fibroblast activity is restrained through poorly understood anti-fibrotic cascades.

60.13 Concluding Remarks

Tissue injury activates a superbly orchestrated inflammatory reaction that clears the wound from dead cells and matrix debris, while stimulating a reparative program. Although the cell biological characteristics of the reparative response are tissue- specific, in all cases immune cells play a critical role in wound healing [129]. In organs with regenerative capacity, macrophages may activate progenitor cells, while stimulating angiogenesis to provide blood supply, necessary for growth of new tissue. In organs with limited regenerative potential, lymphocytes orchestrate macrophage-mediated responses to activate fibroblast-derived matrix synthesis and formation of a collagen-based scar. Understanding the signaling pathways that regulate reparative responses in various tissues is critical for development of new treatment strategies for a wide range of pathologic conditions.

Sources of Funding

Biomarkers in Inflammation

Andreas Kortgen and Michael Bauer

Jena University Hospital, Department of Anesthesiology and Critical Care Medicine and Center for Sepsis Control & Care, Am Klinikum 1, 07747 Jena, Germany

A biomarker is defined as a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention [1]. Biomarkers may be used as diagnostic tools, tools for staging of disease, indicators of prognosis, or for prediction or monitoring of clinical response to therapeutic interventions [1]. They should be amenable to accurate and reproducible measurements.

Causes for inflammatory responses are numerous. However, it has become evident that more or less intraindividual response patterns are often similar particularly in acute inflammation irrespective of the inflammatory stimulus as the immune system seems to be more concerned about circumstances that do harm than those are just foreign. For instance, in infection microbial "pathogen-associated molecular patterns" (PAMPs), such as bacterial cell membrane components or bacterial or viral nucleic acids, are recognized by the innate immune system via "pattern recognition receptors" (PRRs), for example, toll-like receptors (TLRs) or retinoic acid-inducible gene(RIG)-1-like receptors (RLRs). Recognition of PAMPs by PRRs typically leads to induction of signaling cascades promoting pro- and anti-inflammatory host responses. On the other hand, disease entities of noninfectious origin, such as pancreatitis, burns, or trauma, leading to severe damages in the organism, for example, cellular necrosis, may cause release of endogenous substances functioning as danger signals or alarmins ("danger-associated molecular patterns" (DAMPs)), inducing similar pro- and anti-inflammatory cascades. However, differentiating systemic inflammation with infection from inflammatory disease entities without infection is one of the most important issues in daily intensive care allowing starting specific treatments timely to improve prognosis in these critically ill patients. Still, according to the above-mentioned similarities of inflammatory responses this differentiation is sometimes very difficult, particularly as clinical signs are typically similar, too, and microbial diagnostics often either fail to recognize causative pathogens or results are too delayed.

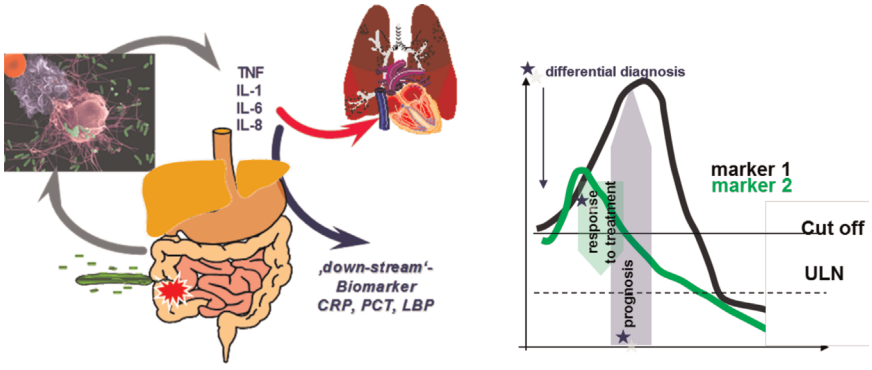

Figure 61.1 Biomarkers reflecting the host response to harmful stimuli. A perforated bowel serves as an example: Local or systemic activation of cells of the immune system will release cytokines that might contribute to remote organ injury and to induction of downstream proteins, such as CRP, PCT, or LBP, that indicate with different kinetics the underlying host response to the pathogen. Changes in expression of cytokines or downstream mediators may inform about severity and prognosis but also potentially reflect eradication or propagation of pathogens and response to treatment.

Due to the complex pathophysiology of sepsis involving a multitude of mediators of inflammation many biomarkers have been proposed. Consequently, in a review 178 different sepsis biomarkers were found in the literature [2] and the search is still ongoing. A selection of these biomarkers is presented in this chapter.

61.1 Acute-Phase Reactants

A variety of diseases and tissue damages, such as infections, trauma, burns, surgeries, or autoimmune diseases, induce inflammatory reactions mediated, for example, by interleukin-6 leading to a reprogramming most notably in liver parenchymal cells with profound changes in the plasma proteome (Figure 61.1). This highly regulated process is called acute-phase response. Changes on transcriptional and—to a lesser extent—on posttranscriptional levels lead either to reduced protein levels (negative acute-phase reactants, e.g., albumin) or higher levels of so-called positive acute-phase reactants, such as C-reactive protein (CRP), procalcitonin (PCT), serum amyloid A, or fibrinogen. While some acute-phase reactants play a distinct role in damage control, functions of other acute-phase reactants are uncertain.

61.2 Pentraxins

Pentraxins, a superfamily of evolutionary conserved proteins, act as pattern recognition molecules and play a crucial role in innate immunity. Members of this group of molecules are, for example, C-reactive protein, serum amyloid P, and pentraxin 3 [3].

61.3 C-Reactive Protein (CRP)

C-reactive protein is primarily released by the liver in response to cytokines, prototypically to Interleukin-6 (IL-6), and has pro- and anti-inflammatory effects. Pathophysiologic roles in inflammatory processes seem to be various. As a component of the innate immunity it binds to pathogens and damaged cells on the one hand and to phagocytic cells on the other hand and activates the complement system when bound to one of its ligands promoting their complement-mediated clearance [4]. Anti-inflammatory effects may be due to reduced endothelial adhesion of neutrophils, stimulation of IL-1ra synthesis, and inhibition of neutrophilic superoxide generation [5].

CRP values in healthy individuals are usually<2 mg/L. However, levels of up to 10 mg/L can be found, too. Sometimes, these patients have trivial injuries or minimally inflammatory processes but these values can also be found in patients, for example, with osteoarthritis [5,6]. After an inflammatory stimulus plasma CRP values begin to rise after (6)-12–24 h and usually peak after a single stimulus after 36–72 h. Plasma half-life is about 19 h [5,7]. In the critical care setting, CRP is often used to differentiate between presence and absence of infection [8]. It helps to differentiate patients with bacterial from viral infections or patients with exacerbated COPD and infection from those without exacerbation [9,10] and can help to predict infectious complications after gastrointestinal surgery [11,12].

In critically ill patients, CRP levels correlated in studies with multiorgan failure and mortality [13–15]. However, specificity and sensitivity of single CRP values were sometimes rather low and other studies could not demonstrate differences between survivors and nonsurvivors at onset of sepsis [15–17]. On the opposite, taking the course of CRP levels into account, decreasing CRP values over treatment time are associated with better prognosis than persistently high levels [4,18]. In the postoperative setting, absolute CRP levels and persisting high levels after the third postoperative day were associated with inflammatory complications and higher mortality [19,20], while low CRP levels on the fourth postoperative day reliably ruled out infectious postoperative complications after various gastrointestinal operations [21]. CRP levels decline when effective antimicrobial treatment is initiated [18,22,23]. However, prospective studies on CRP-guided treatment algorithms and their impact on outcome are missing [24].

61.4 Pentraxin 3

Pentraxin 3 is produced in response to TNF-α, IL-1β, and TLR signaling in several cell types, for example, macrophages, endothelial and epithelial cells, and fibroblasts, but not in hepatocytes as most other acute-phase reactants [3,25]. IL-6 does not induce pentraxin 3 hinting at a rather local than systemic function [25]. Pentraxin 3 acts as a fluid-phase pattern recognition molecule with a protective role in resistance against fungal, bacterial, and viral pathogens activating various antimicrobial effector mechanisms [26,27]. However, for alphavirus infection, a promotion of viral entry and replication was also described [26]. Pentraxin 3 contributes to opsonization of pathogens,

complement activation, and phagocytosis [3,26]. It has been proposed that pentraxin 3 exhibits a negative feedback mechanism in early neutrophil accumulation, thereby potentially limiting excessive inflammation-induced tissue damage [3]. In addition, it plays a role in tissue repair in acidic environment of tissue damage [28].

Pentraxin 3 was found to correlate with severity of disease in sepsis [29,30] and with sepsis-associated coagulation/fibrinolysis dysfunction [29]. In a study with febrile patients presenting at the emergency department, patients transferred to intensive/intermediate care had higher levels than those transferred to the ward [31]. Another study found higher level in emergency room patients with suspected infection in sepsis and organ failure than in other patients and an association with mortality. Again high levels predicted need for intensive care treatment [32]. In bacteremia both, initial pentraxin 3 values as well as high levels until day 4, were associated with mortality [33], and in patients with necrotizing soft tissue infection baseline levels were associated with need for amputation and mortality [34]. However, in another study in severe sepsis only persisting high levels were associated with mortality but not initial values [29].

61.5 Procalcitonin

The polypeptide procalcitonin (PCT) is the precursor of the hormone calcitonin. However, in inflammation and in sepsis, regulation of induction is different and independent from hormone regulation of calcitonin. PAMPs as well as DAMPs can stimulate cells in various tissues to produce and secrete PCT [35]. Peripheral blood mononuclear cells have also been shown to produce PCT *in vitro* [36]. PCT potentially augments the inflammatory response triggered, for example, by LPS, TNFα, or IFNγ and modulates gene expression of inducible nitric oxide synthase [37].

PCT exhibits faster kinetics than CRP. It becomes detectable within 3–4 h with peak serum levels usually after 24–48 h and declines by 50% within 24–36 h. Normal values are below 0.05 ng/mL. PCT appears in blood in response to bacterial infection, but also after other insults causing severe systemic inflammation, for example, after major surgery or trauma. Several studies demonstrated significant correlations between PCT levels and the diagnosis of sepsis [38]. PCT as a sepsis marker was first described in 1993 [39]. High PCT levels have a high positive predictive value for sepsis and normal or low PCT values likely rule out sepsis or severe systemic inflammation [40]. In a meta-analysis investigating PCT as a marker for separating sepsis patients from patients presenting signs of systemic inflammation due to noninfectious disease entities that included 30 studies, accounting for 3244 patients, a sensitivity of 0.77 (95% CI 0.72–0.81) and specificity of 0.79 (95% CI 0.74–0.84) and an area under the receiver operating characteristic curve (AUC–ROC) of 0.85 (95% CI 0.81-0.88) was found [41]. While bacterial infections resulting in a systemic host response seem to be a strong trigger for PCT production, in viral infections PCT induction is rather low [42–45,152]. An explanation for lower PCT values in viral infections might be that interferon γ typically released in viral infections attenuates its gene expression in response to IL1-β [46,153]. Thus, PCT

seems to be a good tool to rule out bacterial coinfection in influenza infection [47]. Nevertheless, the link between elevated PCT levels in bacterial infection is the severity of the host response [40]. Consequently, in trauma patients Wanner *et al.* found not only high PCT levels in patients with sepsis but also a correlation with severity of trauma and multiorgan dysfunction. Patients with sepsis exhibited the highest levels in the study cohort [48]. A systematic review of the diagnostic value of PCT after cardiac surgery demonstrated a correlation of PCT values not only with infection but also with the presence of organ failure and postoperative complications. Rather the course than single postoperative PCT values were informative with respect to infectious complications [49]. Nevertheless, in community-acquired low-to-moderate risk respiratory tract infections cutoff values between 0.1 and 0.25 to rule out bacterial infections seem feasible, while in critically ill patients higher cutoff values between 1 and 2 μg/l seem helpful for discrimination of patients with sepsis from other inflammatory condition [41] when the above-mentioned limitations in distinct disease entities are taken into account. In both settings repeated measurements increase diagnostic accuracy.

PCT has also been proposed for guiding antibiotic treatment with respect to both initiating as well as terminating antibiotic treatment. Such an antibiotic stewardship could be of high importance in the light of increasing antimicrobial resistance triggered at least in part by an overuse of antibiotics on the one hand and increasing mortality rates in sepsis patients with delay of appropriate antibiotic treatment on the other hand.

Several studies evaluated protocol-based decision making of initiating or withholding antibiotic treatment in patients with diagnosis of respiratory tract infection in dependence of PCT values in the primary care, emergency department, and hospital setting [38,50–58,153]. Chosen cutoff value of PCT to recommend withhold of antibiotic treatment was usually 0.25 μg/L, sometimes complemented by a strong recommendation to withhold antibiotics, if PCT value was below 0.1 μg/l. Overall, these studies demonstrated reduced antibiotic prescription rates and shorter duration of therapy without increase of adverse events.

In addition, in critically ill patients, various prospective studies have been performed evaluating PCT-guided algorithms to reduce length of antibiotic treatment. Five studies investigated a PCT-based protocol to stop antibiotic treatment in mixed ICU populations with various sites of infection [59–63], two studies in surgical ICU patients [64,65], and one in patients with ventilator-associated pneumonia [66]. The protocols used were similar, recommending discontinuing antibiotic treatment when PCT levels dropped below an absolute cutoff value (0.1–0.5 μg/L) and/or showed a relative decrease (80%–90%) from peak values. All but one study led to a decrease of initial antibiotic treatment duration of at least 2 days in the PCT-guided groups. Only one study could not demonstrate a significant reduction in antibiotic treatment duration, most likely due to a too low threshold of 0.1 μg/l as stopping rule [63]. In contrast, in the largest study including about 1500 patients using a threshold of 0.5 μg/L or a decrease of 80% demonstrated not only a decrease in antibiotic consumption, but a decrease in 28-day and 1-year mortality was also observed in the study group [60]. Thereby, in a high-risk ICU setting, a drop in PCT levels after initiation of antibiotic therapy to levels less than 0.5 or by at least 80%–90% from

baseline accompanied by a clinical improvement seems reasonable to stop antibiotic treatment [67].

61.6 Interleukin 6

The cytokine interleukin-6 (IL6), a peptide consisting of 184 amino acids, exhibits pro- and anti-inflammatory properties and has numerous biological functions in inflammatory processes, immune reactivity, oncogenesis, and hematopoiesis [68]. It is a crucial mediator in acute-phase reactions but plays also a role in chronic inflammatory processes, such as arthritis or chronic bowel disease, and in regenerative processes, such as liver regeneration after partial hepatectomy [69]. Downstream cellular reactions are induced after building a complex with cellular IL6 receptor or soluble IL6 receptor and binding of this complex to glycoprotein-130 receptor.

IL6 release is directly induced by the primary cytokines TNFα and IL1. Thereby, it appears early, that is, within 2 hours in the course of inflammatory reactions associated with infection, injury, or trauma [68]. In infection, it is mainly produced by activated macrophages and monocytes. Serum levels can increase 1000-fold. The rapid appearance of IL6 in infection seems to be an interesting characteristic.

Although in several studies IL6 levels were significantly higher in patients with infection, diagnostic accuracy was rather moderate [70–73]. In a study including 327 patients admitted to ICU, IL6 had higher AUC–ROC (0.76) than PCT, CRP and LBP to differentiate patients with infection and systemic inflammation from those without. However, it was inferior to PCT in discriminating between infected patients with or without organ dysfunction [71]. Two studies investigated patients presenting in an emergency department. In one IL6 was inferior to PCT and CRP in differentiating patients with and without infection [72], while another study found similar AUC–ROCs to differentiate patients with systemic inflammation and infection from patients neither with signs of infection nor systemic inflammation or only one of these two items [73].

Increased IL6 levels were also found in noninfectious conditions, for example, after major surgery, trauma, transplant rejection, and autoimmune disorders [24].

IL6 levels were related with severity and outcome in sepsis in several studies particularly when high levels were found in the course of disease [16,74–76]. For example, one study found that, while IL6 levels were significantly different between survivors and nonsurvivors on days 1, 3, and 7, the best discrimination was on day 3 with an AUC–ROC of 0.86 [75]. Similarly, in another study, values were different on admission, but AUC–ROC was higher on day 2 (0.799) [76]. When infection is successfully treated, IL6 decreased [16].

61.7 Lipopolysaccharide-Binding Protein (LBP)

Lipopolysaccharide(LPS)-binding protein (LBP) is 58 kD acute-phase protein synthesized in the liver. LBP transports phospholipids. It also binds to LPS, a cell

membrane component of Gram-negative bacteria, forming a complex mediating its binding to soluble CD14 and CD14 receptors on monocytes and macrophages. CD14 presents LPS to TLR4–MD2 complex leading to activation of several signaling cascades ultimately resulting in secretion of proinflammatory cytokines IL-1 and TNFα [77]. Normal values of LBP are between 1 and 20 μg/mL and can rise rapidly by severalfold in acute-phase response. High levels were demonstrated in patients with SIRS and sepsis [78,79]. In patients with suspected community-acquired infections, LBP distinguished between infected and non-infected patients [80]. However, other studies could not confirm a good discrimination between septic and nonseptic patients [71,81]. Furthermore, LBP had no prognostic significance in critically ill patients [71,81]. Interestingly LBP levels were similar in Gram-positive and Gram-negative sepsis [71].

61.8 Presepsin (Soluble CD14 Subtype)

CD 14, a glycoprotein expressed on monocytes and macrophages, functions as LPS receptor together with LBP serving as an activator of inflammatory signaling via TLR 4. Furthermore, CD14 can bind peptidoglycan and other microbial products with similar structural features and other ligands such as human heat shock protein 60 or ceramide [82]. Presepsin is a soluble *N*-terminal fragment of CD14, which is released from cell surface during monocyte activation after LPS recognition [83,84]. It can also bind LPS thereby either competing with membrane-bound CD14 for LPS binding or mediating LPS-induced activation of non-CD14-expressing cells [82]).

In a study of patients presenting at emergency department with systemic inflammation and suspected infection presepsin levels were higher in patients with sepsis with and without organ dysfunction than in patients without infection. Values tended to be higher in septic patients with organ dysfunction than in those without. However, AUC–ROC for presepsin with respect to infection was 0.7 and thereby significantly lower than for PCT (0.87) [85]. Another study in a similar setting including 859 patients found increasing presepsin levels from healthy controls over patients with systemic inflammation without infection to patients with infection and a correlation with sepsis severity with a higher AUC–ROC for predicting sepsis with organ dysfunction in septic patients for presepsin than for PCT (0.840 vs. 0.741) [86]. Other studies, however, found similar AUC–ROCs for presepsin and PCT for differentiating SIRS with and without infection (presepsin: 0.89, PCT: 0.82, CRP: 0.82) and bacteremia versus no bacteremia (presepsin: 0.750, PCT: 0.787, CRP: 0.602) [87,88].

A meta-analysis that included eight studies with a total of 1815 patients found a pooled sensitivity and specificity of 0.86 (95% CI: 0.79–0.91) and 0.78 (95% CI: 0.68–0.85, respectively. The AUC–ROC was 0.89 (95% CI: 0.86–0.92) demonstrating good diagnostic accuracy for the diagnosis of sepsis [89].

Initial high presepsin levels in patients with sepsis with and without organ failure were associated with mortality [85,90] and the number of failed organs and development of further organ failures [90]. Levels were higher within the first week in nonsurvivors [83]. In patients with appropriate antibiotic treatment and

in those with negative blood cultures presepsin levels on day 7 were moderately lower than on day 1, while they were higher in patients with inappropriate antibiotic treatment [90].

61.9 Soluble Triggering Receptor Expressed on Myeloid Cells-1 (sTREM-1)

Triggering receptor expressed on myeloid cells-1 (TREM-1), a receptor of the immunoglobulin superfamily, is expressed on the surface of neutrophils, monocytes, and macrophages [91]. It is an activating receptor of downstream signaling pathways stimulating inflammatory responses and has been demonstrated to be upregulated on cells that infiltrate human tissues infected with bacteria and on peritoneal neutrophils in microbial sepsis [92,93]. While Gram-positive and Gram-negative bacteria as well as fungi caused a strong expression of TREM-1, this was not the case in infection with mycobacteria and in noninfectious inflammatory response [92]. Upregulated TREM-1 expression is associated with increased levels of soluble TREM-1 (sTREM-1) [91].

The presence of sTREM-1 in bronchoalveolar lavage fluid strongly predicted presence of both community-acquired and ventilator-associated pneumonia (sensitivity 98%; specificity 90%) [94]. In adult patients with suspected sepsis, plasma sTREM-1 levels on admission had a sensitivity of 96% and specificity of 89% for indicating infection on a medical ICU [95] and a sensitivity and specificity of 79% each in postoperative ICU patients [96]. A meta-analysis including 13 studies with 980 patients from ICU, emergency department, and hospital ward found a sensitivity of 0.82 (95% CI: 0.68–0.90) and a specificity of 0.86 (95% CI, 0.77–0.91) for the diagnosis of infection, for example, in pneumonia, meningitis and urinary tract infection, or suspected bacterial infections, with samples drawn from blood, urine, pleural, and cerebrospinal fluid. The AUC–ROC was 0.86 (95% CI, 0.77–0.91). In urinary tract infection, diagnostic value was low [97]. However, in two later published studies either no differences were found between surgical ICU patients with inflammation of infectious and noninfectious origin and healthy controls [98] or diagnostic value for the differentiation of infectious and noninfectious origin of inflammatory response in critically ill patients was poor on the day of admission (AUC–ROC 0.62) due to a huge overlap although sTREM-1 levels were significantly different [99]. STREM-1 was associated with multiorgan dysfunction [99] and mortality in this study [99,100]. Conversely, other studies found lower serum values in nonsurvivors than in survivors in critically ill patients with infection with and without organ dysfunction [101] or no differences in surgical ICU patients [98]. While serum sTREM-1 levels decreased in survivors, there was rather an increase in nonsurvivors in a 5-day- and 14-day-period, respectively [100,101].

STREM-1 levels were also elevated in other disease entities accompanied by states of inflammation like in patients with chronic kidney disease on hemodialysis, in ulcerative colitis, and in myocardial infarction [102–105]. In the latter patient group sTREM-1 levels were an independent predictor of death [102].

61.10 Soluble Urokinase-Type Plasminogen Activator Receptor (suPAR)

Urokinase-type plasminogen activator is involved in the migration of inflammatory cells from bloodstream into tissues and can be found as a glycosyl-phosphatidylinositol(GPI)-linked protein on the cell membrane of various immune cells, for example, on monocytes and macrophages [106]. During inflammatory states it is cleaved from cell surface forming its soluble form, that is, suPAR, that plays a role in immunological functions such as cell adhesion and migration, chemotaxis, signal transduction, immune activation, proteolysis, angiogenesis, fibrinolysis, and tissue remodeling [107].

Serum/plasma levels of suPAR seem to reflect the activation of the immune system, for example, in response to infection. Increased levels can be found in various pathological conditions, including sepsis, streptococcus pneumonia bacteraemia, bacterial and viral CNS infection, active tuberculosis (TB), human immuno-deficiency virus type 1 (HIV-1)-infection, malaria, and but also in solid tumors [106]. Thus, suPAR is a nonspecific biomarker of inflammation. It has no diagnostic value with respect to the cause of inflammation. In a study evaluating patients with at least two SIRS criteria and suspected community-acquired infection, including patients with bacterial, viral, and parasitic infections, as well as noninfected patient, the AUC–ROC of suPAR for bacterial infection was 0.50 and for infection versus no infection 0.51 [108]. In another study, suPAR levels were similar in patients with and without infection, when no organ dysfunction was present but significantly higher in patients with infection and organ dysfunction, thus supporting the notion that suPAR is a marker of disease severity. Levels were higher in nonsurvivors [109]. Correlation with disease severity and prognostic value of suPAR with respect to outcome could be demonstrated in various critically ill patient cohorts including children [33,110–117].

Even in states of low-grade inflammation increased suPAR levels can be found. Higher levels were found in smokers than in nonsmokers, and in smokers higher levels were associated with increased risk to develop lung cancer [107] and elevated levels of suPAR were associated with incident chronic kidney disease and an accelerated decline in the eGFR [118].

While in tuberculosis patients suPAR levels decreased in response to therapy over an 8 months period, a similar effect could not be demonstrated in septic ICU patients during a 10- or 14-days period, respectively [112,113,119].

61.11 Adrenomedullin

Adrenomedullin (ADM) is a 52-amino acid peptide with vasodilatory effects that is secreted by the adrenal medulla and various other organs, including heart, lung, and kidney [120]. Vascular endothelial and smooth muscle cells produce ADM [121,122]. Apart from vasodilation, it has endocrine effects, affects renal function, and has antimicrobial properties [123]. In inflammation production of

ADM seems to be stimulated by TNFα, where it plays a major role in the hyperdynamic response during early sepsis [122,124]. ADM is derived from preproADM, a larger precursor peptide, from which different biologically active peptides are generated [120,125]. A reliable measurement is difficult due to short half-life, existence of a binding protein, and its physical properties [125,126]. Therefore, midregional proadrenomedullin (MR-proADM, proADM 45–92) a stable, nonfunctional peptide that is generated in stoichiometric amounts, is often measured instead [8,125].

Increased values of ADM and MR-proADm, respectively, have been described in patients with pheochromocytoma, sepsis, chronic renal failure, congestive heart failure, acute myocardial infarction, and acute cerebral hemorrhage [125–127]. In patients with suspected sepsis, MR-proADM levels showed an increase from inflammation of noninfectious origin to infectious origin with a further stepwise increase with presence of organ dysfunction and shock [128]. Higher levels in patients with organ dysfunction and/or shock were also seen in another study [124].

Elevated levels of ADM or MR-proADM seem to have a prognostic significance in a variety of disease entities with inflammatory states. In two studies including about 2000 patients with community-acquired pneumonia, initial MR-proADM levels were associated with severity of disease according to the pneumonia severity index and mortality [53,129]. Prognostic significance was also demonstrated in septic patients [124,128], but also in inflammation of noninfectious origin. For example, elevated levels of MRproADM after cardiac surgery were associated with increased mortality (AUC–ROC 0.940 after 6 h) [130]. Higher levels of MR-proADM as a predictor of complicated course of disease and mortality have also been reported in acute heart failure, myocardial infarction, and cerebral hemorrhage [127,131,132].

61.12 CD64

CD64 is a high-affinity immunoglobulin FC receptor for IgG (FC γ receptor I, FCγRI) expressed on monocytes. CD64 contains three Ig-like domains in its extracellular region, which bind both monomeric and aggregated IgG. It plays a role in antibody-dependent cellular cytotoxicity, clearance of immune complexes and phagocytosis [133].

Usually, CD64 is present on the surface of only a few circulating polymorphonuclear cells in low levels [133]. Upon activation of neutrophils it is strongly upregulated in response to IFN-γ and G-CSF [134]. CD 64 is considered to be a reliable indicator of acute inflammation. An increase in blood is seen in patients with bacterial infection but also with active autoimmune disease [134].

In a small cohort, 47 patients with infection had higher values than healthy controls with increasing values from patients without organ dysfunction over patients with organ dysfunction to those presenting with shock [135]. A meta-analysis including 13 studies with about 1900 patients demonstrated a sensitivity of 79% (95% CI: 70%–86%) and a specificity of 91% (95% CI: 85%–95%) for the diagnosis of bacterial infection. Values were even higher when only studies with

adult patients or with flow cytometry for CD64 assessment were included [136]. While one later study confirmed these results in patients where a blood culture was indicated [137], two others, however, presented conflicting results with either low sensitivity or low specificity in critically ill medical ICU patients (sensitivity: 87%; specificity: 41%) and patients presenting with fever at the emergency department (sensitivity: 63%; specificity: 89%). AUC–ROCs for the detection of infection were 0.8 or 0.66, respectively [138,139]. Only patients with microbiologically confirmed infection were included in the infection group. Patients with bacteremia had higher values than those without and values increased with severity of disease [139]. Neutrophil expression of CD64 was increased in influenza A with a higher proportion of cells expressing CD64 in complicated course of infection. It was, however, still lower than in bacterial infection [140].

After cardiac surgery with cardiopulmonary bypass, CD64 expression was enhanced. While values decreased in uncomplicated postoperative course, they remained high in patients with suspected or proven infection in the postoperative course [141].

CD64 values predicted mortality in several studies. Unfortunately, sometimes higher and sometimes lower values were associated with survival [135,138,139].

61.13 Panels of Combined of Biomarkers

As described in the previous paragraphs, single biomarkers of inflammation, albeit promising in some aspects, bear many limitations particularly in the light of distinguishing inflammatory states with infection from those without infection in critically ill patients. Furthermore, the complex pathophysiology of sepsis and the above-mentioned similarities of the host response to various infectious and noninfectious inflammatory stimuli lend support to the notion that successful diagnosis is more likely achieved by use of combinations of biomarkers and perhaps including also clinical features. The different aspects of diagnosis, prognosis, and monitoring of therapeutic interventions in different inflammatory disease entities or in different pathogens in diseases of infectious origin might obviously require different biomarker panels.

In this light, a study evaluated the combination of three biomarkers, that is, PCT, sTREM-1, and CD64 index of polymorphonuclear cells, in a two-step approach for diagnosing sepsis. In an inception cohort of 300 ICU patients, a bioscore was determined ranging from 0 to 3 with one point for each biomarker above the determined optimal cutoff value on admission. The bioscore performed better than each individual biomarker in diagnosing sepsis resulting in an AUC–ROC of 0.97. The bioscore was validated in an independent cohort of ICU patients revealing similar results (AUC–ROC 0.95) [142]. Another study evaluated neutrophil count, CRP, PCT, suPAR, sTREM-1, and macrophage migration inhibitory factor (MIF) to differentiate bacterial infection from nonbacterial causes of inflammation. Apart from sterile inflammation, the study cohort also comprises patients with viral, mycobacterial, and parasitic infections [108].

With respect to prognosis, a multibiomarker-based risk stratification model for 28-day mortality in septic shock was developed and tested in a multistep approach

in 881 patients. A decision tree was constructed that includes C–C chemokine ligand (CCL) 3 and 4, neutrophil elastase 2, granzyme B, heat shock protein 70 kDa 1B and interleukin-8. These 5 biomarkers provided maximum accuracy out of a panel 12 candidate biomarkers. They were complemented by serum lactate, age, and presence of chronic disease, as these parameters further improved predictive accuracy. When tested in the validation cohort, the decision tree resulted in a sensitivity of 85% and a specificity of 60% and an AUC–ROC of 0.726 [143]. In a similar approach, a decision tree was developed specifically for pediatric sepsis [144].

61.14 Multiplexed Molecular Markers Derived from "Omics" Technologies

There is growing evidence to suggest simultaneous activation of pro- and antiinflammatory signaling events in the host response to stress events, for example, associated with infection. As outlined above, this response is currently primarily monitored in the clinical context using single protein biomarkers restricted to the proinflammatory component of innate immunity. The advent of high dimensional biology and the ability to monitor genome-wide changes in gene expression on various levels from genome to metabolome allows for a broader assessment of both pro- and antiinflammatory signaling events and a rational selection of biomarker candidates on the different regulatory levels [8]. Applying tools of systems biology and bioinformatics, limited sets of transcripts, proteins, and/or metabolites can be selected to generate a compound biomarker that can be used for classification and diagnostics in a clinical setting. Essentially, these studies have paved the way to question the monopolar concept of SIRS proposed in the early 1990s and shed light on failure of central immune functions [145,146] that is further modulated by metabolic adaptations [147].

Due to feasibility, studies applying such an approach are currently available primarily for transcriptomic, that is, RNA-derived markers. Quantifying the systemic inflammatory response including assessment of both pro- and antiinflammatory innate and adaptive immune responses would hold great promise to identify patients at risk and to facilitate immune interventions in sepsis. Consistently, novel compound biomarkers based on genome-wide selection of candidates allow to cover the spectrum of the host response including antiinflammatory, immunosuppressive, and metabolic facets of the host response to stress.

The available data are currently restricted primarily to the transcriptome and introduce the need to corroborate them in the context of proteomics and metabolomics. Furthermore, most of the available evidence so far reflects elegant proof-of-concept while the studies typically do not fulfill rigorous criteria for diagnostic trials with independent training and confirmation cohorts under "real life" conditions across health care systems. However, the few studies available so far that fulfill criteria for validation of a molecular marker suggest that multiplexed transcriptome-based biomarkers perform superior to currently available single protein biomarkers of the host response (Figure 61.2) [148,149]. A

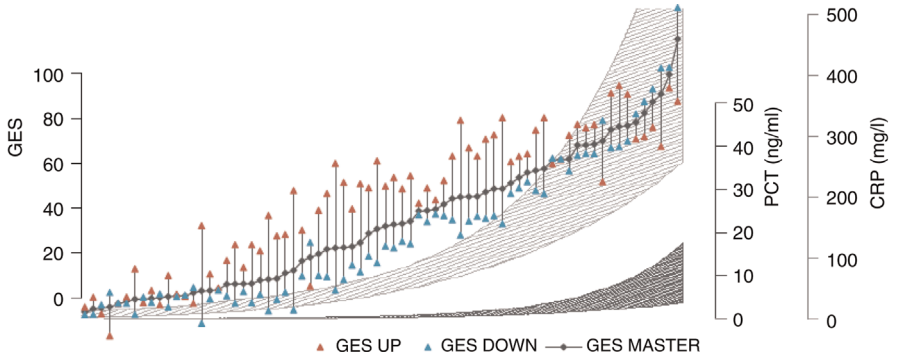

Figure 61.2 Potential of a gene expression score (GES, gray diamonds) computed based on seven transcripts that predicted the position of a given patient́s transcriptomic response in the continuum as reflected by a pangenomic assessment of the blood transcriptome. GES and its components GES UP (red triangles), that is, reflecting upregulated innate immune functions, and GES DOWN (blue triangles), that is, reflecting downregulated specific immune functions, compared to CRP (light gray shaded area) and PCT (dark gray shaded area; both represented by the 95% CI of the exponential regression fit). CRP, PCT, and downregulated adaptive immune functions (GES DOWN) are impacted significantly by disease severity. In contrast, upregulated transcripts encoding innate immune functions (GES UP) reached a plateau and were exceeded by GES DOWN in the most severe cases. The single protein biomarkers displayed broad scattering in particular with states of high-grade inflammation [148].

prerequisite to validate these compound biomarkers and assess their clinical utility requires a change of platform from research tools, such as microarrays to a feasible assay system. This can be easily achieved for both, RNA and protein markers with PCR and, for example, lateral diffusion assays respectively, while metabolites derived from metabolomic screening typically require mass spectrometry or high-resolution NMR spectroscopy [150]. The use of strategies of high-dimensional biology followed by a change in platform to a routine test system is by far the most promising avenue to develop biomarkers suitable for point-of-care testing that can classify states of severe systemic inflammation of infectious and noninfectious origin.

62.1 Introduction

Inflammation is a significant component of several chronic diseases involving the cardiovascular, metabolic, respiratory, gastrointestinal, musculoskeletal, and nervous systems. Many of these disorders are slowly disabling or fatal and account for a majority of deaths among adults in Western industrialized countries. Timely identification and localization of inflammatory foci are critical for adequate treatment of patients.

The main indications for *in vivo* imaging of inflammation are musculoskeletal disorders (e.g., painful prosthetic hip, diabetic feet and Charcot's joints, osteomyelitis, infected trauma), fever of unknown origin (FUO), abdominal infection and inflammation (e.g., sepsis, abscesses, chronic inflammatory bowel disease), vascular infection and inflammation (e.g., prosthetic valve endocarditis, vasculitis), and pulmonary infection and inflammation (particularly in immunocompromised patients).

Conventional imaging techniques (computed tomography (CT), magnetic resonance imaging (MRI), ultrasound (US)) may detect such pathology, but they only rely on anatomical changes and are not capable of discriminating active inflammatory pathology from the anatomical changes resulting from prior successful therapy or surgery. In addition, inflammatory foci cannot be detected in the early phase of development because of the lack of substantial anatomical changes at this time. Nuclear imaging with radiotracers that accumulate at the site of inflammation has become an established tool in the evaluation of several inflammatory and infectious conditions. They can reveal molecular and cellular changes associated with inflammation and provide sensitive detection of even small inflammatory foci at an early stage of disease. During the past two decades several new techniques and imaging agents have been developed for inflammation

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

imaging, but as yet no imaging agent has been found with optimal characteristics. Some characteristics of inflammation make the development of imaging agents demanding due to unspecific uptake. Locally enhanced blood flow, increased vascular permeability, and influx of white blood cells (WBCs) promote the accumulation of any imaging agents to the site of inflammation. While acute inflammation is characterized by vasodilation and changes in blood flow, increased vascular permeability with exudation of plasma (protein rich, edema), and infiltration of neutrophilic leukocytes, the chronic inflammation is characterized by proliferative response with mononuclear cell infiltration (macrophages, lymphocytes and plasma cells), increased tissue destruction (extracellular matrix degraded by matrix metalloproteinases), and attempts to heal (angiogenesis) [1].

This chapter describes the principles of different techniques used for imaging inflammation; provides an outline and examples of their clinical use in evaluation of inflammatory conditions; and discusses some of the emerging techniques that are currently being developed for imaging of inflammation.

62.2 Methods for Inflammation Imaging

In vivo imaging plays an important role in medicine facilitating detection of diseases in early stages, stratification of patients for specific treatments for example targeted therapy (personalized medicine), and monitoring treatment efficacy or progression and extent of disease. Currently, most of the clinical *in vivo* imaging protocols are based on nuclear imaging modalities, that is, positron emission tomography (PET) or single photon-emission computed tomography (SPECT). In ongoing dynamic preclinical research, new potential target molecules for different diseases are identified, and selective imaging agents are developed along with state-of-art devices, hardware, and software for sensitive and quantitative *in vivo* imaging. Beyond radionuclide-based imaging, non-radioactive techniques such as contrast-enhanced US with targeted microbubbles or optical imaging with fluorescent probes are explored as alternative strategies as they provide inexpensive, real-time imaging with high resolution. Although, several targeted-US and -optical imaging approaches are used for preclinical animal studies, we are now seeing the first applications of these methods in patients with inflammatory diseases such as arthritis.

Properties of different *in vivo* imaging modalities are summarized in Table 62.1. CT, US, and MRI methods have excellent spatial resolution, even in micrometer range, and they are best suited for imaging the structure of tissues and organs. Nuclear and optical imaging has the advantage of a high sensitivity, even up to femtomole range, and thus they are best suited to measure the function of tissues and organs.

62.2.1 Nuclear Imaging

62.2.1.1 Positron Emission Tomography

PET is noninvasive, quantitative, and repetitive imaging modality using molecules labeled with positron-emitting radionuclides to visualize and measure rates of

Table 62.1 Comparison between different imaging modalities.

	Modality	Spatial resolution	Depth	Temporal resolution	Sensitivity	Molecular probe	Common radionuclides/ contrast agents	Advantages	Disadvantage
Nuclelar imaging	PET	1–5 mm	No limit	10 s-min	pmol-fmol	ng	• ^{15}O ($t_{1/2}$ 2.04 min) • ^{11}C ($t_{1/2}$ 20.4 min) • ^{13}N ($t_{1/2}$ 9.97 min) • ^{68}Ga ($t_{1/2}$ 68 min) • ^{18}F ($t_{1/2}$ 109.8 min) • ^{64}Cu ($t_{1/2}$ 12.7 h) • ^{76}Br ($t_{1/2}$ 16.2 h) • ^{89}Zr ($t_{1/2}$ 3.27 days) • ^{124}I ($t_{1/2}$ 4.18 days)	• Unlimited depth penetration • Whole-body imaging possible • Quantitative molecular imaging • Can be fused with CT or MRI for anatomical information	• Radiation exposure • Expensive • Low spatial resolution • Long acquisition time (min to hour)
	SPECT	0.5–5 mm	No limit	min	pmol	ng	• ^{99m}Tc ($t_{1/2}$ 6.0 h) • ^{123}I ($t_{1/2}$ 13.22 h) • ^{111}In ($t_{1/2}$ 2.80 days) • ^{67}Ga ($t_{1/2}$ 3.26 days) • ^{177}Lu ($t_{1/2}$ 6.65 days)	• Unlimited depth penetration • Whole-body imaging possible • Quantitative molecular imaging • Theranostic: can combine imaging and radiotherapy • Can be fused with CT or MRI for anatomical imaging	• Radiation exposure • Low spatial resolution • Long acquisition time
Optical imaging	BLI FOI	3–5 mm 2–3 mm	1–2 mm <1 mm	sec-min sec-min	fmol pmol-fmol	μg-mg μg-mg	• Light absorbing nanoparticles • Fluorescent molecules and dyes	• No ionizing irradiation • Real-time imaging/short acquisition time (sec-min) • Relatively high spatial resolution • Can be applied externally or internally (endoscopy) • Inexpensive • Highly quantitative and sensitive • Multiplexing	• Limited depth penetration • Whole body imaging is not possible, except for small animals

(*continued*)

Table 62.1 (*Continued*)

	Modality	Spatial resolution	Depth	Temporal resolution	Sensitivity	Molecular probe	Common radionuclides/ contrast agents	Advantages	Disadvantage
Anatomical imaging	MRI	25–100 µm	No limit	min-hrs	mmol	µg-mg	• Gadolinium (Gd^{3+}) • Iron oxide particles (PSPIO, USPIO) • Manganese oxide • ^{19}F	• Unlimited depth penetration • Whole-body imaging possible • No ionizing irradiation • Excellent soft-tissue contrast • High spatial resolution	• Expensive • Long acquisition time • Limited sensitivity for detection of molecular contrast agents
	CT	50–200 µm	No limit	min	—	N/A	• Barium • Iodine • Krypton • Xenon	• Unlimited depth • High spatial resolution • Whole body imaging possible • Short acquisition time • Moderately expensive • Anatomical imaging	• Radiation exposure • Poor soft-tissue contrast
	US	50–500 µm	mm-cm	sec-min	—	µg-mg	• Contrast microbubbles	• No ionizing irradiation • Real time imaging/short acquisition time (min) • High spatial resolution • Can be applied externally or internally (endoscopy) • Inexpensive • Highly sensitive	• Whole-body imaging not possible • Contrast agents currently limited to vasculature • Operator dependency

Modified from Pysz MA1 [2].

biochemical processes in tissues of living patients. PET is based on coincidence detection of annihilation radiation. The radionuclide in the radiotracer decays and the resulting positrons subsequently annihilate on contact with electrons after traveling a short distance (~1–10 mm) within the body. Each annihilation produces two 511-keV photons traveling in opposite directions (180°), which are detected by the detectors surrounding the patient and reconstructed onto three-dimensional tomographic images as a function of time (dynamic 3D images). PET requires several persons from different disciplines to be involved in, which can make method expensive. One of the major disadvantages of PET is that most of the positron-emitting radionuclides must be produced on cyclotrons, which due to short physical half-life ($t_{1/2}$) of the PET radionuclides measured in hours must be on site. Only few PET radionuclides are made by low-cost generator systems. Typical radionuclides used in PET include ^{15}O (oxygen-15 $t_{1/2}$ 2.04 min), ^{11}C (carbon-11 $t_{1/2}$ 20.4 min), ^{13}N (nitrogen-13 $t_{1/2}$ 9.97 min), ^{68}Ga (gallium-68 $t_{1/2}$ 68 min), and ^{18}F (fluorine-18 $t_{1/2}$ 109.8 min). Some nonstandard radionuclides with longer half-lives may also be used such as ^{64}Cu (copper-64 $t_{1/2}$ 12.7 h), ^{76}Br (bromine-78 $t_{1/2}$ 16.2 h), ^{89}Zr (zirconium-89 $t_{1/2}$ 78.5 h), and ^{124}I (iodine-124 $t_{1/2}$ 4.18 days). Beyond different physical half-life, the radionuclides also differ in their β^+ decay amount and energy, which has influence on PET image quality. Radionuclides with short half-lives, such as ^{18}F and ^{11}C, are useful for rapid signal acquisition, and their use will minimize patient exposure to ionizing radiation. However, PET imaging has many advantages. Most importantly it has very high sensitivity; a typical PET scanner can detect between nmol/L to fmol/L concentrations. Beside, in principle, there are unlimited number of compounds that can be labeled with PET radionuclides as tracers. Second is its quantitative feature, which makes it attractive tool *inter alia* for drug development purposes, such as for monitoring treatment efficacy of new anti-inflammatory drugs.

A glucose analog, 2-[^{18}F]fluoro-2-deoxy-*D*-glucose ([^{18}F]FDG) facilitates *in vivo* PET imaging of inflammation with high sensitivity [3]. This is based on the fact that during inflammation, glucose consumption is elevated due to the presence of activated inflammatory cells, such as macrophages, and rapidly proliferating healing tissue. Intravenously injected [^{18}F]FDG is rapidly transported through the cell membrane to the cytosol by glucose transporters (GLUT-1, GLUT-3), phosphorylated by hexokinase enzyme, and trapped inside the cell as [^{18}F]FDG-6-phosphate. Besides *in vivo* detection of inflammatory foci, dynamic [^{18}F]FDG PET imaging with the use of graphical method, that is, Gjedde-Patlak plot [4], allows quantification of the regional glucose metabolic rate. For the analysis, plasma radioactivity concentration, plasma glucose level, and the lumped constant (LC) are required. The net influx rate ($K_i = K_1 * k_3/(k_2 + k_3)$) incorporates both net inward transport and trapping of the tracer in tissue. Although [^{18}F]FDG PET imaging is useful for inflammation imaging, the uptake of [^{18}F]FDG is not specific for inflammatory conditions. High [^{18}F]FDG uptake is also observed at site of rapidly proliferating tumor cells. [^{18}F]FDG PET cannot differentiate between cancerous growth and inflammation or between sterile inflammation and infection. New more specific imaging agents are thus needed (see paragraph 4).

62.2.1.2 Single-Photon Emission Computed Tomography

SPECT is also a functional nuclear imaging technique. The radionuclides used in SPECT have relatively long half-lives (from few hours to few days) making them easy and rather cheap to produce. Most of the SPECT radiopharmaceuticals are based on commercially available kits and a generator-produced ^{99m}Tc (technetium-99 m $t_{1/2}$ 6 h). This represents the major advantage of SPECT as an imaging technique, since it is significantly cheaper than PET. However, it lacks good spatial and temporal resolution. Additionally, due to the radiation exposure related to long half-life of radiopharmaceuticals, there are safety aspects concerning the administration of the imaging agents to the patient, especially for serial studies.

^{67}Ga-citrate (^{67}Ga $t_{1/2}$ 3.26 days), radiolabeled WBCs and ^{111}In- (^{111}In $t_{1/2}$ 2.80 days) or ^{99m}Tc-labeled anti-granulocyte antibodies or antibody fragments, chemotactic peptides, liposomes, and certain cytokines are used for SPECT imaging of inflammation, and infection [5]. At this point, it should be noted that the migration of leukocytes to sites of inflammation and infection are practically taken the same as infection always has inflammatory components. The advantage of using radiolabeled WBCs is their specificity for infection imaging. Unfortunately, their use is limited for the detection of acute inflammation. The reason is that, during acute inflammation, WBCs (mainly neutrophils) and some macrophages extravasate at the injured site, but when the inflammation becomes chronic, the amount of neutrophils reduces. The radiolabeled WBCs consist mainly of neutrophils because lymphocytes are usually damaged by radiation during the quite demanding preparation procedure, which includes the isolation of WBCs from the patient's own blood (normally comprises 59% neutrophils, 34% lymphocytes, and 2% monocytes) and *in vitro* radiolabeling of the cells. In general, the SPECT imaging with radiolabeled WBCs should be acquired at three time points ("early image" at 30 min–1 h, "delayed image" at 3–4 h, and "late image" at 20–24 h post-injection) and radionuclide decay-corrected to the time of injection. When images are displayed with the same intensity scale, any focal increase in radioactivity with time should be considered as an infection, whereas if accumulation detected at 3–4 h would decrease at 20–24 h, it is a sign of a sterile inflammation.

Intravenously administered ^{67}Ga-citrate binds to plasma transferrin. This complex extravasates at the site of inflammation due to locally enhanced vascular permeability, and in the inflammatory lesion it may transchelate to lactoferrin in activated leukocytes and bacterial siderophores. While ^{67}Ga-citrate and [^{18}F]FDG are useful for the identification of both acute and chronic inflammation, neither of them is an inflammation-specific imaging agent. ^{67}Ga-citrate SPECT imaging has largely been replaced by [^{18}F]FDG PET, as ^{67}Ga-citrate offers no advantages for imaging of inflammatory diseases.

62.2.2 Computed Tomography

CT is based on the absorption of x-rays as they pass through the different parts of a patient's body. For example, iodine-based agents enhance soft tissue or vascular contrast and facilitate anatomical delineation of numerous structures. Method is

highly reproducible, has an excellent spatial resolution, and, although more expensive than US, is still relatively inexpensive. The disadvantages include exposure of the patient to radiation and the lack of functional information. Furthermore, the use of contrast medium to enhance image contrast may be limited or impossible in patients with impaired renal function or previous allergic reactions. CT plays an important role in the evaluation of patients with a pulmonary inflammation and variety of inflammatory bowel diseases.

62.2.3 Magnetic Resonance Imaging

MRI is based on strong magnetic field and resulting nuclear magnetic resonance in tissues. The method provides very high spatial resolution, but the sensitivity is limited. To achieve molecular imaging with MRI, contrast agent-linked peptides, antibodies/antibody fragments, and small ligands have been applied. Given the imaging is relatively long and noisy, MRI may be discomfort for the patient. Furthermore, there are limitations to the scanning of patients with claustrophobia, pacemakers, implants, and other devices, and the procedure is relatively expensive. However, MRI in combination with gadolinium (Gd) enhancement is useful for evaluation of, for example, synovial inflammation, bone erosion, and edema associated with arthritis.

62.2.4 Ultrasound

US imaging is cost-effective and widely available imaging modality that can reveal anatomical changes associated with inflammation, including tissue swelling, abscess formation, and synovial effusion. Contrast-enhanced US is a promising technique for imaging of inflammation. US contrast media are composed of small (usually 1–4 μm in diameter) gas bubbles (microbubbles) that oscillate in response to US and provide strong contrast in US images. After intravenous injection, microbubbles remain mainly in the intravascular space, provide enhancement of the interface between blood and tissues, and permit assessment of tissue perfusion and vascularity. While nontargeted US contrast agents are available for clinical use, modified microbubbles covered with ligands that bind specific molecular markers (targeted microbubbles) are developed in preclinical studies. Contrast-enhanced US with microbubbles targeted to bind endothelial leukocyte adhesion molecules, such as vascular cell adhesion molecule 1 (VCAM-1), intercellular adhesion molecule 1 (ICAM-1), or E-selectin, has been studied in some inflammatory conditions as a novel approach for early detection of inflammation.

62.2.5 Multimodal and Hybrid Imaging

Hybrid imaging is defined as combination of information from two imaging modalities into one image. It has become clinical routine in inflammation imaging since most of the PET scanners and an increasing number of SPECT scanners are currently hybrid devices. It enables combination of detailed anatomical information in CT or MRI images with functional information on inflammation, such as PET or SPECT scans.

62.3 Clinical Inflammation Imaging

Nuclear medicine techniques have a well-established role or have shown promise in the evaluation of several infectious and inflammatory conditions, including systemic infections, FUO, vasculitis, sarcoidosis, rheumatoid arthritis, inflammatory bowel disease, and vascular inflammation associated with atherosclerosis [6–8].

In addition to the presence or absence of an inflammatory focus, important clinical questions related to inflammation imaging are to assess the exact localization, extent, and degree of inflammatory activity; differentiate between infection and sterile inflammation; differentiate between acute and chronic inflammation; and to assess response of inflammation to therapy. Addressing these issues requires careful planning of the test and good knowledge of the limitations of different techniques [8].

The use of [^{18}F]FDG PET has increased in the assessment of inflammatory conditions. The strengths of [^{18}F]FDG PET include high sensitivity, high resolution of images, high reproducibility of results, and relatively short duration of imaging protocols (<2 h). The main limitation is that the signal is not specific for inflammation, but it can also be related to infection, malignant tumors, and even physiological glucose metabolism in some tissues, such as the myocardium, bone marrow, and brown fat [9]. Prolonged, increased glucose uptake associated with regeneration and healing process can be a problem after surgical procedures. Furthermore, anti-inflammatory therapy can rapidly decrease the [^{18}F]FDG PET signal resulting in nondiagnostic scan. As discussed earlier, labeled WBC are more specific for infection than [^{18}F]FDG. The risks related to ionizing radiation need always to be weighed against the expected benefits of imaging, particularly in young individuals and when repeated testing is considered.

62.3.1 Suspected Systemic and Local Infections

It has been shown that in systemic bacteremia, [^{18}F]FDG PET can find clinically relevant foci of infection in a large proportion of patients [7].

FUO is a diagnostic challenge due to unspecific symptoms and wide, heterogeneous group of underlying diseases. Whole-body [^{18}F]FDG-PET/CT can often provide findings that guide to more specific investigations. A recent meta-analysis summarized the results of 15 available studies and reported that [^{18}F]FDG PET has a sensitivity of 85% for establishing the cause of FUO. A particularly challenging group of patients are immunocompromised patients in whom conventional diagnostic tests often fail to find the cause for febrile neutropenia. In such patients, many studies have shown that [^{18}F]FDG PET has high sensitivity for identification of focal pathology requiring treatment, such as opportunistic infections caused by toxoplasmosis or tuberculosis.

Infectious endocarditis is a serious infection where early diagnosis and detection of complications are important for successful management. Recent studies have shown that [^{18}F]FDG can detect paravalvular inflammation associated with prosthetic valve endocarditis (Figure 62.1). The use of [^{18}F]FDG PET significantly increases the number of definite or rejected endocarditis diagnoses as well as reduces the number of cases classified as having possible endocarditis. Recent

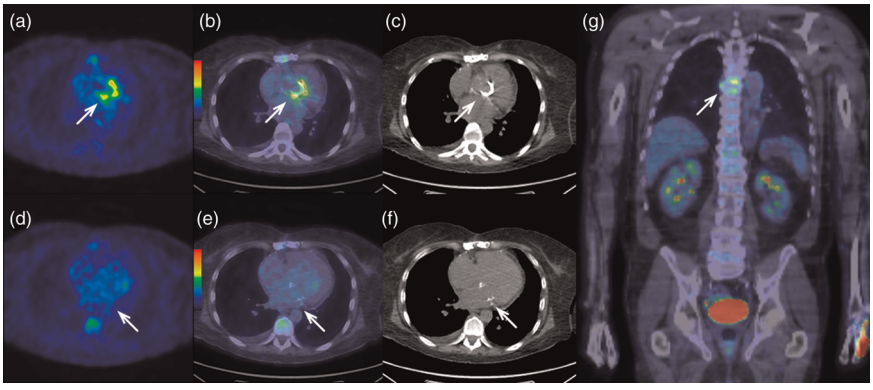

Figure 62.1 Imaging of systemic infections with 2-[^{18}F]fluoro-2-deoxy-*D*-glucose positron emission tomography/computed tomography ([^{18}F]FDG PET/CT). The patient is 67-year-old woman with aortic and mitral bioprostheses implanted several years earlier. She presented with fever, elevated C-reactive protein level (143 ng/mL), and positive blood cultures for *Staphylococcus epidermidis*. Initial transesophageal echocardiography showed no sign of endocarditis. Cardiac [^{18}F]FDG PET/CT study showed strong tracer uptake (arrow in PET image in panel (a), maximum standardized uptake value 8.4) that co-localizes with the aortic valve prosthesis (arrows in PET/CT fusion image in panel (b) and CT noncontrast CT image in panel (c). No uptake was visible in the region of mitral valve prosthesis (maximum SUV 3.6, arrows in panel (d, e and f). Myocardial uptake had been suppressed by overnight fasting and low-carbohydrate diet on the day preceding imaging. Findings were consistent with prosthetic aortic valve endocarditis that was confirmed later on and treated successfully with antibiotics. Whole-body PET images show increased [^{18}F]FDG uptake in the spine consistent with spondylodiscitis associated with endocarditis (Panel g).

European guidelines on the treatment of bacterial endocarditis indicate that the use of [^{18}F]FDG PET should be considered if the diagnosis of prosthetic valve endocarditis remains uncertain after the results of blood cultures and US examination. If the prosthesis has been implanted less than 3 months earlier, false-positive findings related to wound healing are concern.

In high-risk patients with bacteremia, such as patients with prosthetic and native valve endocarditis, [^{18}F]FDG PET and anatomical imaging tests (MRI and CT) are also important in identification of metastatic inflammatory foci, such as spondylodiscitis (Figure 62.1).

Other major clinical indications for [^{18}F]FDG PET in suspected infectious diseases include infections of joint prosthesis, spinal infections (spondylodiscitis, vertebral osteomyelitis), and peripheral bone osteomyelitis that have been reviewed in detail elsewhere [6,7].

62.3.2 Vasculitis

Vasculitis is an inflammatory disease characterized by inflammation and damage to the vessel wall. Large vessel vasculitis including giant cell arteritis and Takayasu's arteritis mainly affect the aorta and its branches. The diagnosis of vasculitis is mainly based on tissue biopsy, but the sensitivity of a single biopsy is relatively low due to the focal nature of inflammation. Several studies have shown

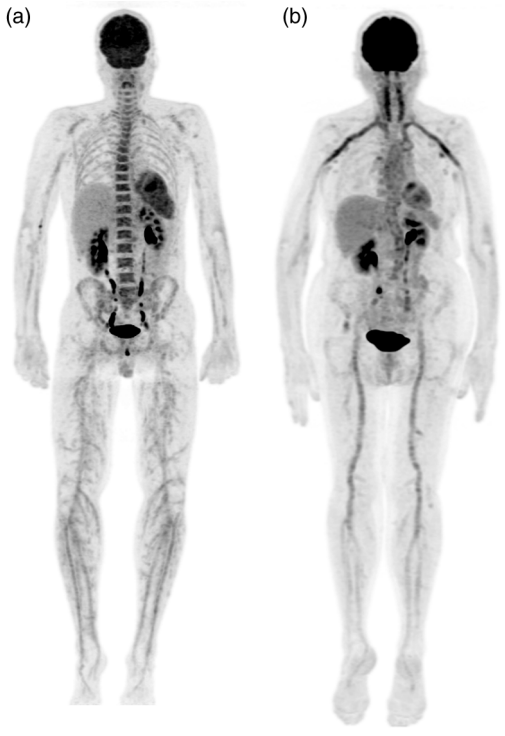

Figure 62.2 Vasculitis detected by 2-[^{18}F]fluoro-2-deoxy-*D*-glucose positron emission tomography/computed tomography ([^{18}F]FDG PET/CT). (a) A 47-year-old man had fever, fatigue, abdominal pain, and claudication due to antineutrophil cytoplasmic antibody-associated vasculitis. Whole-body PET/CT scan revealed abnormal [^{18}F]FDG accumulation in small- and medium-sized vessels of the upper extremities and in the lower extremities appearing as a tree-root-like uptake pattern. Increased [^{18}F]FDG uptake in vertebral bone marrow and the spleen was observed due to hematopoietic stimulation. (b) A 76-year-old woman had an atypical [^{18}F]FDG uptake pattern in the larger arteries, which indicated giant cell vasculitis. (Modified from Reference 9.)

that [^{18}F]FDG PET can detect inflammation in the aorta and its branches in large vessel vasculitis that can help identify a suitable biopsy site (Figure 62.2) [10]. A recent systematic review and meta-analysis concluded that [^{18}F]FDG PET appears to be a useful imaging test in the initial diagnosis and evaluation of the extent of disease in patients with large vessel vasculitis. It demonstrated a good performance (pooled sensitivity of 90% and specificity of 98%) in the detection of large vessel inflammation in giant cell arteritis patients. A potential caveat is rapid reduction in signal under immunosuppressive therapy [11]. It has been noted that standardization of image analysis and imaging protocols is still needed to optimize the use of [^{18}F]FDG PET in vasculitis [7].

62.3.3 Sarcoidosis

Sarcoidosis is a systemic granulomatous inflammatory disorder of unknown etiology. Lungs and mediastinal lymph nodes are most commonly affected, but the disease can manifest elsewhere with various presentations. Diagnosis of sarcoidosis is based on histological findings in conjunction with typical clinical and imaging findings [12]. In the absence of easily accessible tissue for biopsy, diagnosis can be very challenging.

Sarcoid lesions can be well identified by [^{18}F]FDG PET due to strong tracer uptake. [^{18}F]FDG PET is emerging as a useful diagnostic tool for sarcoidosis, especially in identifying extrapulmonic disease, such as cardiac sarcoidosis

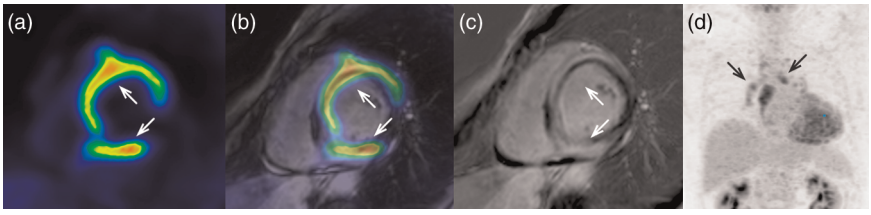

Figure 62.3 Imaging of myocardial inflammation with 2-[^{18}F]fluoro-2-deoxy-*D*-glucose ([^{18}F]FDG) positron emission tomography (PET) in cardiac sarcoidosis. Cardiac [^{18}F]FDG PET/magnetic resonance imaging (MRI) study was performed with a hybrid scanner after overnight fast to suppress physiological myocardial [^{18}F]FDG uptake. Images show cardiac PET (panel a), late-enhancement MRI approximately 5 min after intravenous injection of 0.15 mmol/kg of Gd-DTPA (panel c), and PET/MRI fusion image (panel b). There is strong [^{18}F]FDG uptake consistent with inflammation that co-localizes with late enhancement in the interventricular septum and inferior walls (arrows). Granulomatous inflammation consistent with cardiac sarcoidosis was confirmed in histological analysis of an endomyocardial biopsy obtained from the interventricular septum. In addition to myocardium, uptake of [^{18}F]FDG in mediastinal lymph nodes is typical of sarcoidosis (arrows in panel d). (Images are courtesy of Jussi Pärkkä, MD, Turku University Hospital.)

(Figure 62.3). Cardiac sarcoidosis is a serious form of sarcoidosis that is often associated with conduction abnormalities, heart failure, and ventricular arrhythmias that can even result in sudden cardiac death. To detect [^{18}F]FDG uptake associated with myocardial inflammation, a patient preparation to suppress physiological myocardial glucose utilization by fasting and avoiding carbohydrates is necessary. A typical finding consistent with cardiac sarcoidosis is focal uptake of [^{18}F]FDG co-localizing superimposed on a perfusion defect. With the recent PET/MRI hybrid scanners, [^{18}F]FDG PET findings can also be superimposed on delayed Gd enhancement, which indicates the presence of ongoing inflammation or scar tissue (Figure 62.3). [^{18}F]FDG PET can also identify extracardiac uptake in mediastinal lymph nodes that present a good target for tissue biopsy.

62.3.4 Other Applications

The use of [^{18}F]FDG PET imaging has been studied in inflammatory bowel disease showing increased [^{18}F]FDG uptake at the sites of histologically verified bowel inflammation.

Rheumatoid arthritis (RA) and psoriatic arthritis are diseases associated with synovial inflammation in often multiple joints. Functional imaging of inflammation with [^{18}F]FDG PET or ^{67}Ga-citrate SPECT has shown potential in evaluation of the degree and extent of inflammation in RA. Early detection and efficient therapy are important to prevent complications of RA and other arthritis. Some studies have indicated that [^{18}F]FDG PET may be useful to predict treatment response in RA (Figure 62.4) [13].

Inflammation plays an important role on the development of atherosclerosis and its complications. Several studies have shown visible [^{18}F]FDG uptake in atherosclerotic lesions. This may complicate detection of primary inflammatory

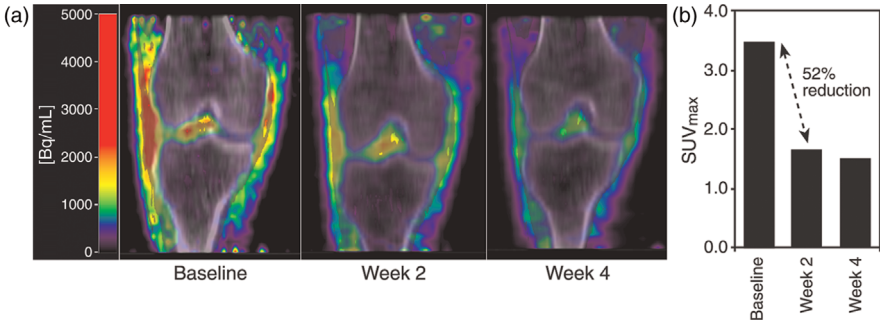

Figure 62.4 A study evaluated the potential of functional imaging to monitor disease activity and response to treatment with disease-modifying antirheumatic drugs (DMARD) in DMARD-naive patients with early rheumatoid arthritis (RA). (a) Representative [^{18}F]FDG PET/CT images of a knee in a patient with recent onset of RA presented on the same color scale, and (b) the corresponding [^{18}F]FDG maximum standardized uptake values (SUV_{max}) at baseline and 2 and 4 weeks after initiation of combination therapy. (From Reference 16.)

vasculitis but also provide significant information on the atherosclerosis risk. Some studies have shown that [^{18}F]FDG is associated with the risk of future incident cardiovascular disease that could be reduced by effective prevention strategies.

[^{18}F]FDG PET has been tested in many other conditions involving inflammation, such chronic obstructive pulmonary disease, venous thromboembolic disease, and inflammatory diseases of the central nervous system that have been discussed in detail elsewhere [7,8].

62.4 Emerging Protocols for Inflammation Imaging

In consideration of the limits of the various imaging agents currently used for inflammation imaging, the latest research has produced a series of new compounds that could increase the accuracy of functional imaging. Differentiation between bacterial and nonbacterial inflammation remains a diagnostic challenge. Although PET using [^{18}F]FDG has been introduced as a promising imaging modality for the evaluation of various infectious conditions, the diagnosis of infection remains a challenge. In general, development of new imaging agents resembles that of drugs (Figure 62.5). In general, the true value of new imaging protocols cannot be accomplished without translational studies, that is, by transforming sophisticated imaging approaches developed in experimental disease models into practical human application such as inflammation imaging for the detection of the vulnerable atherosclerotic plaques. New imaging agents that show promise after the preclinical phase will be validated in large-scale human studies.

An ideal target for *in vivo* imaging of inflammation would be a molecule that is normally absent from the endothelium of healthy tissues but is induced at the onset of inflammation. Vascular adhesion protein 1 (VAP-1) is an inflammation-

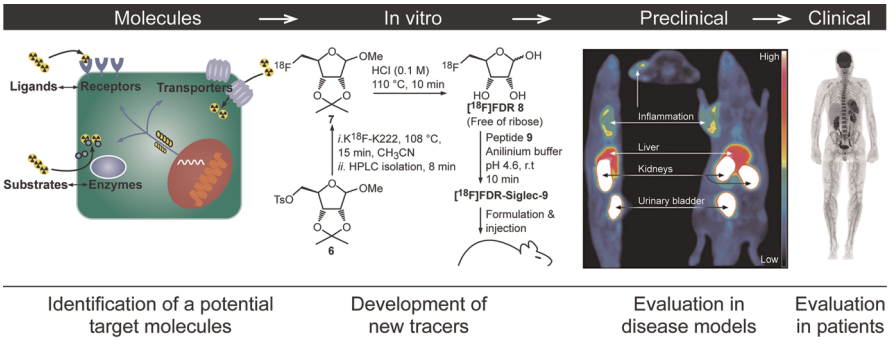

Figure 62.5 Developmental steps of the new imaging agents.

inducible endothelial cell molecule mediating leukocyte interactions with the lining of blood vessels [14]. It contributes to several steps in the extravasation cascade and controls the trafficking of lymphocytes, granulocytes, and monocytes to sites of inflammation. At the onset of inflammation, VAP-1 is rapidly translocated from intracellular storage granules to the endothelial cell surface. Besides being an adhesion molecule, VAP-1 is also a semicarbazide-sensitive amine oxidase (SSAO) enzyme (currently known as copper-containing amine oxidase AOC3, EC 1.4.3.6). The end products of the enzymatic activity are highly potent inflammatory mediators and can upregulate other adhesion molecules, such as E- and P-selectin, intercellular adhesion molecule 1, and vascular cell adhesion molecule 1. The proof of concept regarding the use of VAP-1 as an inflammation imaging target was obtained with iodinated monoclonal antibodies against VAP-1. They were used to detect skin and joint inflammation in the pig by SPECT [15]. Currently, researchers are investigating VAP-1 as a potential target for *in vivo* imaging of inflammation by means of PET. ^{68}Ga-peptides; ^{68}Ga-, ^{124}I-, and ^{18}F-labeled antibodies; and ^{11}C-labeled small molecule inhibitors of VAP-1 are being evaluated as PET tracers. Furthermore, it is assumed that the developed imaging agents may be modified for MRI (Gd-DOTA conjugation) and SPECT (^{99m}Tc-labeling), in addition to PET. Based on a phage display approach, it has been discovered that sialic acid-binding immunoglobulin-like lectin 9 (Siglec-9) is a leukocyte ligand for VAP-1 and that PET with a ^{68}Ga-labeled peptide of Siglec-9 specifically detects VAP-1 in vasculature at sites of inflammation and certain cancer [16,17]. The endothelial molecules guiding the migration of leukocytes to sites of inflammation and infection are practically taken the same as infection always has inflammatory components. Therefore, it is highly unlikely that imaging endothelial molecules one can easily discriminate between infection and inflammation.

Integrin $\alpha_v\beta_3$, a cell adhesion molecule, is overexpressed not only in various cancer cells and sprouting tumor neovasculature but also in chronic inflammatory conditions, including inflammatory bowel disease and the inflamed synovial tissue of patients with RA. The $\alpha_v\beta_3$ integrin is expressed in angiogenic vessels and mediates intercellular adhesion of all proteins in which the arginine-glycine-aspartic acid (RGD) tripeptide sequence is exposed. In recent years, numerous

RGD peptides have been developed and tested for *in vivo* imaging of various inflammatory disorders and cancers [18].

Translocator protein (18 kDa; TSPO), formerly called peripheral benzodiazepine receptor, is a ubiquitously expressed protein localizing primarily in the outer mitochondrial membrane. It is involved in numerous cellular functions, such as synthesis of steroid hormones and transport of cholesterol. The expression of TSPO is high in activated macrophages, and therefore it has been targeted for imaging of inflammatory conditions. TSPO targeting prototypic tracer, *N*-methyl-[^{11}C]-(*R*)-1-(2-chlorophenyl)-*N*-(1-methyl-propyl)-3-isoquinoline carboxamide ([^{11}C]PK11195) has been studied for PET imaging of various inflammatory disorders, but the pharmacokinetic properties and target-to-background ratio have not been optimal. Therefore, several new TSPO ligands are currently under investigation [19].

Beyond nuclear imaging, indocyanine green (ICG)-enhanced fluorescence optical imaging (FOI) has shown good results for imaging of inflammation, for example in experimental animal models of arthritis. Recently, this emerging new technology has revealed its potential for sensitive imaging of inflammatory changes in humans with arthritis (Figure 62.6) [20]. However, further development of image interpretation and quantitative analysis are still required until the technology would be useful as a clinical imaging tool.

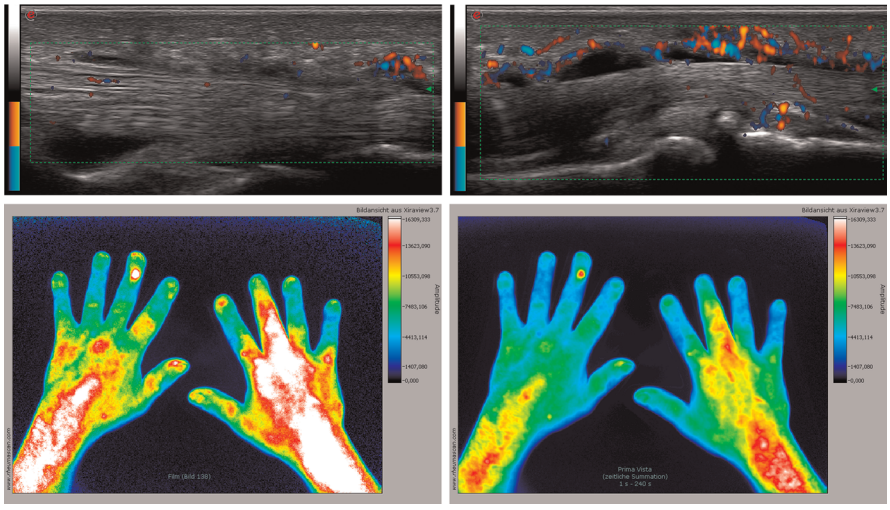

Figure 62.6 Comparison of power Doppler ultrasound (PDUS) imaging with fluorescence optical imaging (FOI) in a patient with the new diagnosis of psoriatic arthritis and clinical dactylitis of the third right finger. By PDUS (upper panels) above the third metacarpophalangeal and the third proximal interphalangeal joints (each from palmar), active tenosynovitis of the flexor tendon (and slight elevation of the MCP 3 joint capsule) is presented with the corresponding FOI images (lower panels; in phase 1 and PrimaVista mode) showing increased signal intensities especially in the third finger. Novel Targets for Drug Development

Alan S. Cross[1] *and Steven M. Opal*[2]

63.1 Introduction

Advances in our understanding of molecular components that activate and regulate the innate and adaptive immune systems have provided us with a plethora of novel targets for intervention to control the inflammatory response. Translating laboratory findings at the cellular level into effective clinical therapeutics has proven to be a major challenge. Many of these immune molecular targets have redundant pathophysiologic functions that can differ in magnitude depending upon the inciting inflammatory event, the duration of acute inflammation, and the status of immune responsiveness within the host when treatment is indicated. The capacity to do harm with immune regulators in the presence of a latent or an overt infectious process is substantial and should always be considered before initiating treatment.

The highly conserved, evolutionary balance between the advantageous survival benefits of intact host defenses and functional antimicrobial clearance mechanisms must be weighed against the potential deleterious effects of unrestrained collateral tissue damage induced by systemic inflammatory responses. This balance is highly variable in individual patients depending on their age, genetics, comorbid illnesses and medications, degree and duration of inflammatory response, and nature of injury and infectious challenge [1]. A selected group of immunomodulatory agents that are in development will be reviewed in this chapter with a focus on those drug candidates thought to be most likely to succeed as therapies for acute inflammatory disease processes. We will emphasize therapies targeting PAMPs (pathogen-associated molecular pattern molecules), DAMPs (damage-associated molecular pathogens), endothelial and epithelial barrier protection therapies, and regulators of cell apoptosis, autophagy, gene regulation, and survival. We will also highlight attempts to limit systemic inflammation with selected agents designed to terminate persistent, nonresolving

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

inflammation, and in some circumstances, provide immune reconstitution by bolstering host defenses against microbial toxins and virulence.

63.1.1 Targeting the Pathogen PAMPs, Their Toxins and Virulence Factors

Since the first discovery of microorganisms by Antonie van Leuwenhoek and Robert Hooke in the late seventeenth century and the establishment of the germ theory of disease by Pasteur and Koch in the late nineteenth century, therapies have been sought to prevent or eradicate microbial pathogens. Vaccines, serum therapy, and later antimicrobial chemotherapy culminated in the dawn of the antimicrobial era in which we now still live today [2]. This remarkable achievement seemed to place microbes inevitably and permanently under the dominion of humankind with our ever expanding access to new potent antibiotics. Regrettably, this favored status over microorganisms might be short-lived as we now find ourselves stumbling to come up with adequate antimicrobial regimens to defend against an onslaught of multidrug-resistant (MDR) bacterial pathogens [3]. Efforts to develop nonantibiotic solutions to limit the inflammatory response and to defend against the emergence of MDR pathogens are now underway and are listed on Table 63.1.

63.1.1.1 Opsonic Antibodies and Antivirulence Factor Therapies

Clearing pathogens or their toxins and removal of pathogen-associated molecular pattern molecules without antibiotics is increasingly feasible with advances in polyclonal or monoclonal antibodies, microfluidic hemoperfusion devices, or even with the return to phage therapies against bacterial pathogens. Antivirulence therapies designed to disarm bacteria and render them harmless to the host is also a future possibility [13].

63.1.1.2 Bacteriophage Therapy

Lytic bacteriophages have been used therapeutically against bacterial infections for almost 100 years and still remain an active area of research in Eastern Europe and in the Republic of Georgia, a former state of the Soviet Union. These highly lethal phage particles are highly species- and strain-specific and are therefore not well suited for early empiric treatment for septic shock. Rapid and specific diagnosis with genomic methodology might help solve this limitation but other practical issues remain such as dosing of phage, distribution to sequestered sites, biofilm penetration, development of phage resistance, and possible immunogenicity. The need to maintain ready stocks of large populations of lytic phage against every conceivable bacterial pathogen is another significant drawback. Nonetheless, phage therapy might provide an alternative to antibiotics for selected, pan-resistant, health care-associated bacterial pathogens [13]. The lytic enzyme that is utilized by phage to dissolve bacterial peptidoglycan has been identified and is undergoing preclinical studies as an alternative to standard antimicrobial chemotherapy [14].

63.1.1.3 Hemoperfusion Systems to Clear Pathogens and PAMPs

An increasing number of hemofiltration and heme absorption columns and devices are now available in clinical trials. The basic approach is to remove

Table 63.1 Agents targeting the pathogen, virulence factors, or pathogen-associated molecular patterns.

Target	Potential therapy	Mechanism(s) of action	Development status
Pathogens	Hemoperfusion columns including PMX, heparin, or MBL-bound columns	Attach and filter out pathogens and their toxins and PAMPs	Late-stage clinical trials [4–7]
Pathogens	Immunoglobulins, new vaccines and opsonic mAb	Promote host clearance of the pathogen	Late-stage clinical trials [8]
Exotoxins, LPS, and virulence factors	Monoclonal antibodies	Inhibit toxins from binding to target; WN1 222–5 binds to conserved regions on LPS	Preclinical, clinical trials [9,10]
Microbial communications	Quorum sensing inhibitors	Disrupt population sensing and coordinated virulence	Preclinical studies [11]
Pore-forming exotoxins	Engineered liposomes	Decoy membrane binders to protect host cell lysis	Preclinical studies [12]
Pathogens	Bacteriophage therapy, or lytic enzymes from phage	Lyse specific bacteria with phage injections or local delivery of phage enzymes	Ongoing preclinical and clinical studies [13–15]
MDR pathogens	Repurposed drugs, Tyrosine kinase inhibitors, combination agents	Coadministration with or without standard antibiotics	Preclinical studies [16–19]
MDR pathogens	Defensins, BPI	Antibacterial peptides that can be active against MDR pathogens	Preclinical, clinical studies [20–26]

PMX: polymyxin B; mAb: monoclonal antibody; LPS: lipopolysaccharide; PAMPs: pathogen-associated molecular patterns; MBL: mannose binding lectin; BPI: bactericidal permeability-increasing protein.

circulating microbial pathogens and/or their toxins or PAMPs and thereby reduce microbial burden and rescue patients from disseminated infection. Advances in bioengineering have provided investigators with a number of ingenious hemoperfusion systems to study in clinical trials [4–7]. These devices could prove to be a valuable adjuvant therapy in treating MDR pathogens.

63.1.1.4 Engineered Liposomes to Clear Exotoxins

In addition to hemoperfusion systems and antibody-based therapies to eliminate pathogens, their toxins, or other virulence factors [4–10], a novel strategy to adsorb circulating cytolytic toxins is currently under investigation. Empty, specially engineered liposomes can be fashioned to serve as decoys to membrane toxins and thereby preventing host membrane pore formation and cytolysis [12]. Many Gram-positive and Gram-negative pathogens produce cell membrane, pore-forming exotoxins. Administration of engineered liposomes proved to be highly effective in experimental sepsis and clinical trials is now contemplated in the near future [12].

63.1.1.5 Antivirulence Factor Therapy or Quorum-Sensing Inhibitors

Another appealing approach to controlling bacterial infections without relying upon antibiotics is to disrupt the capacity of pathogens to communicate with each other and coordinate microbial invasion of the host [11]. This is accomplished by quorum-sensing signaling systems that regulate virulence genes in a population of pathogens based upon their population density. Soluble chemical signals are generated when bacterial pathogens are gathered in high concentrations. These chemical sensors are linked to intracellular kinase systems that de-repress virulence gene expression and promote lethal infection. A large number of inhibitory molecules are under investigation that might be able to block communication systems in bacteria and limit pathogenicity [11,15]. Targeting virulence has another advantage of limiting selection pressures on bacterial populations to evolve resistance to virulence traits, as opposed to selective pressures to resist bactericidal antibiotics [8,13].

63.1.1.6 Tyrosine Kinase Inhibitors and Other Novel Antibacterial Agents

Following the success of the Abl-family tyrosine kinase inhibitor, imatinib mesylate (GLEEVEC®) in the treatment of chronic myelogenous leukemia, and other cancers (gastrointestinal stromal tumors), it was discovered that the Abl-family of tyrosine kinases is also important in the pathogenesis of diverse microbes. Kalman and colleagues show that imatinib was effective in reducing bacterial load and associated pathology in mice infected with *Mycobacterium tuberculosis*, including drug-resistant strains [16]. These antibacterial effects were detectable at doses below those used for treating cancer [17]. Unexpectedly, it induced myelopoiesis, but not lymphopoiesis, and increased the numbers of myeloid cells in blood and spleen [16].

63.1.1.7 New Antibiotic Combinations

While inhibitors of serine-beta lactamases have been employed as co-drugs to overcome beta-lactamases that inactivate carbapenems (e.g., clavulanic acid,

tazobactam, sulbactam, and avibactam), there are no equivalent inhibitors of metallo-beta-lactamases (MBL) such as NDM-1 (New Delhi metallo-beta lactamase). King *et al.* identified a natural fungal product from *Aspergillus versicolor* aspergillomarasmine that inhibits MBLs, restores meropenem antibiotic activity both *in vitro* and *in vivo* [18].

Interestingly, when the standard macrolide azithromycin, which lacks activity against Gram-negative bacilli in standard laboratory assays, was tested in tissue culture medium that mimics the host environment, there was a bactericidal effect *in vitro* and protection *in vivo* in mice. Further, it synergized with cationic antimicrobial peptides including human cathelicidin LL-37, which was otherwise inactive, and with colistin [19].

63.1.1.8 Defensins and Antibacterial Peptides

Defensins, antimicrobial peptides derived primarily from PMNs, have long been known to have immunomodulatory activity [20]. Three subfamilies of defensins, alpha, beta, and theta, have similar structure. Clinical development of defensins has been hampered by the difficulty in generating sufficient amounts for *in vivo* evaluation of their therapeutic potential, as well as their toxicity. Theta defensins were identified in rhesus macaques have an 18-residue cyclic peptide encoded by genes similar to those for alpha defensins, although a premature stop codon results in peptides with 12 residues that form cyclized nonapeptides. In humans, an additional stop codon results in a pseudogene that is express as mRNA, but the sequence has been used to resurrect the putative coding sequence. The resulting peptide has been named retrocyclin [20]. The peptide has high potency and a broad range of antimicrobial activity, including Gram-positive, Gram-negative bacteria, *B. anthracis* bacilli and spores, viruses, and fungi. Recently, Lu and colleagues developed a synthetic chemical process by which large amounts of retrocyclins, can be produced. These compounds have high stability and low toxicity [21].

Several decades ago, Peter Elsbach and Jerry Weiss discovered that a neutrophil protein which they named bactericidal permeability inducing protein (BPI) not only was bactericidal for Gram-negative bacilli but also directly neutralized endotoxin [22]. This discovery led to the development of a recombinant protein from the endotoxin-binding portion of the molecule. A clinical trial in children with meningococcal sepsis was unable to demonstrate protective efficacy but did find a reduction in gangrene among survivors. The delay in obtaining parental consent for entry into the trial most likely explained the lack of protective efficacy in this fulminant infection [23]. Interestingly, BPI is being reexamined as a potential antimicrobial agent not prone to the mechanisms of antibiotic resistance [24]. Additional LPS-binding peptides have been evaluated for LPS-neutralizing activity. Two 34-mer peptides were derived from the core LPS-binding region of Factor C from the horseshoe crab, a serine protease with multiple high-affinity LPS-binding sites [25].

63.1.2 Targeting DAMPs and the Host Response to DAMPs and PAMPs

Pathogen-associated molecular pattern (PAMPs) molecules comprise a set of highly conserved structural components of microbial pathogens such as

lipopolysaccharide (LPS), bacterial lipoproteins, flagellin, and viral, fungal, or bacterial genomic features that are distinct from human structures, and are recognized by pattern recognition receptors (PRRs). Remarkably, many of these same PRRs also recognize damaged elements arising from human tissues when released into the circulation following cell necrosis. These damage-associated molecular pattern (DAMP)-related molecules come in two basic forms: (i) conserved molecules usually confined to the intracellular or intranuclear space (e.g., histones, mitochondrial DNA, HMGB1, and actin filaments) or (ii) conserved elements within the interconnecting ground substances between cells that are disrupted during cell death (e.g., hyaluronic acid, heparan monomers, and biglycans) [26].

Collectively PAMPs and DAMPs are referred to as signal 0 of the acute inflammatory response. Signal 1 consists of antigen recognition and class I and II major histocompatibility complex; signal 2 is provided by costimulatory receptors and ligands (CD28 on T cells and CD80/86 on antigen presenting cells). Signal 3 is dendritic cell-mediated polarization of the emergent T cell response and signal 4 is differential integrin expression on activated T cells that instruct T cell trafficking into tissues during the inflammatory response [27]. Therapeutic targets and novel agents to modulate the initial host response to PAMPs and DAMPs are summarized in Table 63.2.

63.1.2.1 Statins

While the 3-hydroxy, 3-methyl glutaryl coenzyme A (HMG–CoA) inhibitors have become first line, lipid lowering agents to treat atherosclerosis and their immunomodulatory effects have been equally impressive and likely accounts for their many beneficial therapeutic effects. Statins promote the expression of eNOS (endothelial nitric oxide synthase) with its capacity to protect the microcirculation, limit neutrophil and monocyte adherence to endothelial cells, and support endothelial barrier function [28]. These anti-inflammatory effect and endothelial protective effect are mediated by statin-induced inhibition of the isoprenoid GGPP (geranyl geranyl pyrophosphate). GGPP mediates the post-translational modification of a variety of RAS-like proteins such as Rho. Decreased Rho activity improves endothelial barrier function and decreases NFκB formation [29].

Another recent finding that might explain a number of the salutary effects of statins during systemic inflammation is their capacity to activate endothelial cyclooxygenase (COX)-2 by S-nitrosylation. COX2 activation followed by extracellular 5-lipoxygenase activity catalyzes the synthesis of 13-series resolvins [30]. These host-protective, short lipid signaling molecules, along with related resolvins and protectins, promote resolution of inflammation and trafficking of inflammatory cells to regional lymphatic tissues.

A number of clinical trials have been undertaken to test the capacity of statins to provide benefit in septic patients and ARDS. The results have been mixed and generally disappointing [31]. As is always the case with anti-inflammatory agents, questions on timing, dosing and patient selection persist as to whether statins will hold promise as an adjuvant therapy in prevention and treatment of septic shock and related inflammatory states.

Table 63.2 Agents targeting host responses to DAMPs and PAMPs.

Target	Potential therapy	Mechanism(s) of action	Development status
DAMPs/PAMPs	Immunomodulatory and endothelial protection from statins	limit neutrophil binding to endothelial cells, inhibit isoprenoid synthesis and promote resolvin actions	Used clinically for cardioprotection [28–31].
Histones	Inter-alpha inhibitor protein (IaIp); non-anticoagulant heparin	IaIp and heparins possess GAGs that neutralize histones	Preclinical and clinical trials [32–34]
Histones	Soluble thrombomodulin (sTM)	sTM binds histones and blocks p rotein C activation; giving sTM repairs histone inhibition	In late clinical trials [35,36]
DAMPs and PAMPs	TLR 4 inhibitors and signaling inhibitors: innate immune response regulators	Limit signal transduction of innate immune activation from DAMPs/PAMPs	Preclinical studies [36–40]
DAMPs and PAMPs	Receptor for advanced glycation end products (RAGE) inhibitors	Soluble RAGE decoy receptors and mAbs to RAGE limit continued immune activation	Preclinical studies [41–44]
PAMPs DAMPs and actin filaments	Plasma gelsolin (pGSN)	pGSN therapy removes actin and can replete loss of circulating gelsolin during acute inflammation	preclinical and early clinical studies [45–47]
DAMPs (HMBG-1, HSPs)	Triggering receptor expressed on myeloid cells (TREM)-1 inhibitors	Soluble TREM and TLT-1s (TREM like transcript small variant) block TREM-1 potentiation of TLR signals	Preclinical studies [48–51]
High mobility group box 1 (HMGB1)	HMGB1inhibitors	block HMGB-1- mediated reduced endothelial and epithelial barrier function and might help reverse PCI	Preclinical studies [52–58]
DAMPs PAMPs	Resolvins, proctectins	Transcellular lipoxygenase products are proresolving and anti-inflammatory	Preclinical and early clinical studies [30,59]
DAMPs PAMPs	Proprotein convertase subtilisin/kexin (PCSK)-9 mAb	LPS and pathologic lipids are cleared by LDLr; PCSK9 mAb improves LDLr clearance function	Preclinical studies, clinical trials in cardiology [60–62]

GAG: glycosaminoglycans; LPS: lipopolysaccharide; mAb: monoclonal antibody; PCI: persistent critical illness; LDLr: low-density lipoprotein receptor.

63.1.2.2 Histone Inhibitors

Extracellular histones are highly injurious as DAMPs and can induce a potentially lethal inflammatory state in experimental animals [32–34,63–67]. Histones are strongly positively charged to interact closely the heavily negatively charged phosphoryl groups on DNA in tightly packed nucleosomes within chromosomes. Histones are released upon cell death by necrosis and during the extracellular release in the formation of neutrophil extracellular traps (NETs). NETs develop in the microcirculation during bloodstream infection as a final attempt to clear systemic bacterial infection [33,34,64–69].

Therapies that appear to serve as inhibitors of the inflammatory potential of histones include a family of human plasma proteins known as inter-alpha inhibitor proteins [32] and heparin [33,34], even modified forms of heparin that lack significant anticoagulant activity. Clinical trials are contemplated with such agents to limit the toxicity of extracellular histone release. Thrombomodulin (TM) will also bind to histones and can, at high histone concentrations, interfere with TMs capacity to activate protein C. A soluble form of recombinant TM is in clinical trials in sepsis at present to determine if restoring TM levels can improve survival [35,36].

63.1.2.3 Extracellular and Intracellular Signaling Inhibitors

The dramatic increase in antibiotic resistance and diminished antibiotic development pipeline, there has been considerable effort to develop host-oriented therapies, interventions directed at modifying the host response to infections. If successful, these therapeutics would have the advantage of not being subject to antibiotic resistance mechanism and not inducing such resistance. One approach is under development whereby small molecule inhibitors directed at the cytoplasmic TIR (Toll/interleukin-1 receptor) domains of Toll-like receptors (TLRs) have shown inhibitory activity in preclinical testing both *in vitro* and *in vivo* [37]. Cell-penetrating peptides comprised of the translocating segment of Drosophila antennapedia homeodomain fused with BB loop sequences of several TLR–BB peptides inhibited NFkB translocation following several TLR agonists. Since the TIR domains are highly conserved among multiple TLRs, such interventions may be more broadly applicable than small molecules directed at the TLR4 ectodomain (but not TLR3 or TNF-alpha signaling).

Following the novel finding that a peptide inhibitor of MD2, Eritoran, was protective in experimental influenza infection, these peptides were shown to improve survival in influenza-infected mice [37]. Additional peptides that inhibit MyD88 dimerization and recruitment of IRAK1 and IRAk4 have also been found to inhibit intracellular signaling [38]. High-throughput computational screening to discover inhibitors of host MyD88 protein–protein interactions implicated in the lethal immune response to staphylococcal enterotoxin identified a binding site for MyD88 on the dimeric model of Toll-interleukin receptor (TIR). Biochemical analysis and cell-based reporter assays found that the most promising compound, T6167923, disrupted MyD88 homodimeric formation, and that a single dose of this compound protected mice from lethal SEB-induced toxic shock [39]. These promising lead compounds have yet to be testing in human systemic inflammatory states.

Another class of small molecule synthetic peptides, innate defense regulators (IDR), targets intracellular signaling pathways [39]. Innate defense regulators (IDRs) are synthetic immunomodulatory versions of natural host defense peptides that mediate protection against bacterial challenge in the absence of direct antimicrobial activity. They broadly modulate a spectrum of immune responses. These antibacterial peptides that restrict excess innate immune responses are active in experimental sepsis models and might prove to be effective in clinical medicine.

63.1.2.4 Receptor for Advanced Glycation End Products (RAGE) Inhibitors

RAGE is an attractive target for therapeutic manipulation in systemic inflammatory states for a number of reasons. RAGE is the quintessential pattern recognition receptor that binds to and signals upon recognition of a myriad of endogenous DAMPs and even some PAMPs [41,42]. RAGE is a proinflammatory receptor that activates transcriptional programs for acute systemic inflammation. As opposed to many other inflammatory mediators, which have their receptors downregulated upon activation, RAGE is continuously upregulated during inflammation. RAGE and is a viable target even after systemic inflammation is established and ongoing. RAGE inhibitors include soluble decoy receptors lacking intracellular domains or monoclonal antibodies [43,44].

63.1.2.5 Recombinant Gelsolin and TREM-1

Plasma levels of gelsolin, a ubiquitous human plasma protein, fall rapidly in severe sepsis and the loss of this protein impairs actin clearance, reduces phagocytosis, and promotes inflammatory cytokine generation [45]. Actin is a DAMP molecule released into the circulation during cell injury or death. Low plasma levels are correlated directly with worsening disease severity. Recombinant gelsolin is available and could be a potential novel therapy for severe sepsis [46]. Extensive animal data and pilot studies in human sepsis with gelolsin appear promising and the potential therapeutic effects of gelsolin should be tested in septic patients [47].

Another attractive target for therapeutic manipulation during sepsis and other systemic inflammatory states is the triggering receptor expressed on myeloid cells (TREM)-1 [48]. TREM-1 belongs to a family of TREM molecules that partner with a transmembrane signaling molecule known as DNAX activation protein 12 kDa in size (DAP-12). DAP-12 possesses a ITAM (immuno-receptor tyrosine-based activation motif) that is proinflammatory signal to amplify cell activation events induced by TLR signaling. TREM-1 is a receptor for as yet not fully characterized repertoire ligands, including heat shock proteins, HMGB-1 (high mobility group box-1), and likely other DAMPs [27].

A natural inhibitor exists that effectively blocks TREM-1 potentiation of TLR signaling known as TLT-1 (triggering receptor expressed on myeloid cell-like transcript-1) [48,49]. Alternatively spliced short variants of TLT-1 that also have inhibitory activity [50]. Short sequences of peptides from the extracellular domain of TLT-1 have been identified that could be used as an inhibitory therapeutic agent [50,51]. These agents are effective in animal experiments in sepsis and could be viable candidates for clinical trials in the near future.

63.1.2.6 High Mobility Group Box 1

High mobility group box 1 (HMGB1) is a DNA binding protein found in the nucleus that is actively secreted in small amounts from activated immune effector cells and is passively released in large amounts from necrotic cells [52–54]. The disulfide form of HMGB1 signals innate immune cells through TLR4 [54]. Circulating HMGB1 in the bloodstream is a highly injurious molecule that damages endothelial barriers, and induces the release of IL-1 alpha and IL-1 beta from endothelial cells [55–57]. HMGB1 induces major defects in gut epithelial barrier function and contributes to increased mucosal permeability in prolonged shock [52]. HMGB1 also induces mitochondrial injury and cellular apoptosis during septic shock [54].

HMGB1 is now recognized as a major contributor in perpetuation of septic shock in its later phases. This pathologic state is known as persistent critical illness (PCI). PCI is a distressingly common problem in modern ICUs where prolonged need for ICU supportive care costs dearly in terms of resources and patient lives. Remarkably, HMGB1 also appears to play a role in the rather common occurrence of cognitive decline as a late complication of severe sepsis, at least in experimental mouse models [58]. Antibodies to HMGB1 and other inhibitory strategies to block HMGB1 actions are protective in experimental sepsis. Feasibilty studies with HMGB1 inhibitors should hopefully be initiated in human clinical trials in the near future.

63.1.2.7 Proresolving Agents

Serhan and colleagues have carefully investigated the biochemical signals that contribute to resolution of tissues damaged by injury and or infection and have discovered that repair and clearance of inflammatory foci is not a passive process of simply the lack of ongoing inflammatory makers [59]. Resolution of infection is an active process following an ordered sequence of lipoxygenase-mediated proresolving lipids. Many of these host-protective and proresolving lipid-mediated molecules have been identified (called resolvins, protectins, etc.) and are now in early clinical trials to increase resolution of tissue injury and improve outcomes [30].

Another remarkable recent discovery in cardiology of the role of proprotein convertases in removal of damaging phospholipids might have more general application to include systemic inflammatory states including sepsis [60]. A human protein called PCSK9 (proprotein convertase subtilisin kexin 9) has recently been shown to impair the clearance of low-density lipoproteins associated with atherosclerosis [61]. The same enzyme has been found to limit clearance of bacterial lipopolysaccharide and other pathologic lipid mediators found in sepsis [62]. Monoclonal antibodies to PCSK9 can recover the capacity to clear LPS efficiently and might serve as a novel strategy to improve the outcome in human sepsis.

63.1.3 Epithelial Membrane Barriers and Microbiome as a Target for Sepsis

Loss of epithelial mucosal barrier protection contributes to the initiation and perpetuation of the systemic immune dysfunction in sepsis [70,71]. Mucosal ischemia and inflammatory changes are commonplace is septic shock patients

and these pathologic processes alter the complex interactions between the gut mucosa and resident microflora in health and disease. Epithelial membranes play an essential role in normal physiology of separating and defending the parenchymal tissues from the external milieu. Epithelial membranes are polarized with an apical surface and a basolateral surface. This feature of selective semipermeable membranes regulates water, solute, and macromolecule flow rates, and segregate the resident microbiota from host tissues [71].

The microbiome of the gut is best known but similar microbiomes are now recognized to colonize in the lower airways, oropharynx, skin, and genitourinary tract [72–74]. The gut microbiome generates 100-fold more expressed genes than the entire complement of expressed human genes. The microbiome consists of over 10^{14} bacterial cells with is home to thousands of different species of bacteria, viruses, Archaea, fungi, and commensal protozoan parasites. The microbiome is now considered the "second human genome" that needs to be understood and accounted for in health and disease. Changes in the microbiome certainly occur in critical illness and the details and relevance of these alterations on the human host are only beginning to be unraveled. Attempts to regulate and reestablish a healthy microbiome might represent a novel strategy to promote the resolution of sepsis in patients with persistent critical illnesss (PCI) [71,72,74].

This might be feasible by probiotics, defined as the placement of favorable bacterial strains or fungi along the epithelium to reestablish a healthy microbiome. Another strategy is the use of prebiotics and the process of placing nonabsorbable complex polysaccharides or other macromolecules to alter the substrates for metabolism and structure of the microbiome [75–80]. These efforts have already produced some limited success, particularly in preventing necrotizing enterocolitis in critically ill neonates and preventing recurrent respiratory infections in children [78]. Many other possible benefits might accompany regulating or restoring a healthy microbiome. Some preliminary studies suggest that probiotics or prebiotics could be useful to prevent colonization and infections from multidrug resistant, nosocomial Gram-negative bacterial pathogens and recurrent *Clostridium difficile*-associated colitis [81–83]. However, studies designed to manipulate the microbiome to prevent ventilator-associated pneumonia have largely been unsuccessful to date [84]. Much more work will be necessary to fully understand the potential value and the limitations of regulating patient microbiomes [71,72].

Another therapeutic option is to repair damaged epithelial cells or reestablish the structure and function at the junctions between adjacent epithelial cells. In the gut epithelium, cells are held together by intercellular adhesion molecules, including occludin, ZO-1, and claudin [71,74]. Growth factors, such as granulocyte-macrophage colony-stimulating factor [85] and hepatocyte growth factor [86], support enterocyte growth and function. Specific enterocyte trophic cytokines, including interleukin-11 [87], IL-22 [88], and other epithelial growth factors [89,90], can reduce epithelial apoptosis, repair tight junctions, stimulate enterocyte growth, and retain epithelial barrier function.

Oral adminstration of protease inhibitors to prevent increased gut permeability from pancreatic enzymes are in clinical trials at present [91]. Nonabsorbed agents, such as tranexamic acid and related protease inhibitors, remain in the gut lumen

Table 63.3 Agents targeting the epithelium and the microbiome in inflammatory states.

Target	Potential agent	Mechanism(s) of action	Development status
Maintain healthy luminal microbiota	Regulate the microbiome with probiotics and prebiotics	Tightens epithelial junctions, stimulates intestinal immunity, colonization resistance, limits MDR pathogens and *C. difficile*	In clinical studies [75–84]
Epithelial membrane barriers	Hepatocyte growth factor; Interleukin-11; interleukin-22	Epithelial growth factors, cytoprotective for intestinal epithelium in acute inflammatory states	Preclinical studies, early clinical trials [85–88]
Protect epithelial barrier function	Insulin-like growth factor-1; TNFAIP3	Prevents sepsis-induced excess gut epithelial permeability and apoptosis	Preclinical studies [89,90]
Enzymatic breakdown of epithelial barrier	Orally administered pancreatic enzyme inhibitors-tranexamic acid	Prevents breakdown of tight junctions and epithelial barrier during sepsis	In clinical trials [91]

GM–CSF: granulocyte-macrophage colony-stimulating factor; MDR: multidrug resistant; TNFAIP3: tumor necrosis factor alpha-induced protein 3; I/R-ischemia reperfusion injury.

and protect the intestinal epithelium from luminal proteases that induce loss of membrane function and excess intestinal permeability during septic shock.

A summary of new epithelial barrier defensive strategies to prevent or to treat sepsis and other acute inflammatory syndromes are present in Table 63.3.

63.1.4 Targeting the Vascular Endothelium in Acute Inflammatory States

The endothelial surface is at the interface between intravascular inflammation and extravascular inflammatory responses during sepsis [71,92]. The innate immune system and coagulation pathways coevolved to collaborate in protecting the host from the simultaneous risk of exsanguination and invasive microbial infection following any break in the integument. The interface between clotting and inflammation is particularly critical in sepsis [92–94]. Dysfunction or disruption of the endothelial barrier by injury or apoptosis exposed the fluid phase of the blood compartment to subendothelial sources of tissue factor (TF), the main initiator of coagulation activation in sepsis. Activated monocytes and macrophages are major sources of TF in severe sepsis. Even activated endothelial cells themselves can express TF along their cell surface when exposed to high-levels TNF or interleukin-1β. TF binds circulating factor VII and this TF:FVIIa complex and activates factor X with generation of thrombin and fibrin. TF can also reside on microparticles (MPs) shed from hematopoietic and endothelial cells. MPs can activate both coagulation and inflammation in sepsis [92].

Platelet adhesion to activated endothelial cells is increased in sepsis by alterations in von Willebrand factor. Final assembly of von Willebrand factor multimers occurs on endothelial surfaces. Large multimers of von Willebrand factor occur in

sepsis that avidly bind to platelet glycoprotein Ibα under conditions of shear force [94]. These large von Willebrand factor multimers are normally cleaved by a protease known as ADAMTS 13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13). Sepsis induces an acquired deficiency of ADAMTS13, resulting in ultralarge von Willebrand factor multimers and platelet adhesion to injured endothelium [94–97].

Thrombin and other activated clotting factors are recognized by a set of seven-transmembrane receptors known as protease-activated receptors (PARs) [98]. Four PARs exist in humans can either promote or disrupt endothelial barrier function, depending on which G-protein-linked intracellular signaling pathway is activated. Thrombin bound to PAR1 in early sepsis contributes to endothelial dysfunction by GTPase RhoA-dependent cytoskeletal derangements in endothelial cells and induces endothelial cell contraction and rounding [98,99]. Endothelial cell contraction disables extracellular membrane barrier function thereby increasing vascular permeability. Macromolecules, such as large proteins and white cells, can now exit the circulation into the extravascular space. Over time thrombin–PAR1 complexes transactivate PAR2 and form PAR1–PAR2 heterodimers on endothelium. This reverses the net effect of thrombin generation to an endothelial barrier protection effect. This is mediated by PAR1– PAR2 switching of intracellular GTPase signaling from the RhoA-mediated barrier disruptive pathway to a PAR2-mediated Rac1 endothelial barrier protective function. This two-way competing pathway can be manipulated to a therapeutic advantage with agents that target specific PARs [98,99].

Endothelial barrier function prevents vascular leak, maintains an anticoagulant surface, and prevents macromolecules from exiting the microcirculation. Endothelial barriers are maintained by adherens junctions, consisting of vascular endothelial (VE) cadherin, and tight junctions (the zona occludens), formed by occludins and claudins [94]. Intracellular actin filament networks maintain endothelial cell apposition and this is further supported by transmembrane Robo4-slit proteins [100,101].

Several treatment options designed to retain endothelial barrier function are now under preclinical and clinical investigation. Selepressin is a vasopressin analog that is specifically targets the V1a vasopressin receptor. In addition to its vasoconstrictive properties, this vasoactive peptide limits endothelial leakage of fluid into the extra-vascular space. This drug is now in clinical trials in septic shock [102]. Another vasoactive drug strategy is monoclonal antibody to adrenomedullin [103]. Adrenomedullin is a 52-amino-acid vasodilatory peptide produced by endothelial cells that counteracts the effects of alpha adrenergic vasoconstrictive agents. Adrenomedullin antibody can restore catecholamine responsiveness and serve as an adjuvant therapy in septic shock [103].

63.1.5 Immunomodulators and Other Promising new Therapeutic Targets

63.1.5.1 Immune Reconstitution as a Molecular Target

A myriad of immunologic findings clearly demonstrate that sepsis-induced immune dysfunction occurs in many patients with prolonged sepsis and

PCI [71,104]. Reduced T-cell and B-cell functions, reduced lymphocyte proliferative capacity, excess apoptosis, T-cell exhaustion, and dysregulated innate immune responses are readily demonstrable and have significant adverse clinical consequences [105]. Reduced expression of major histocompatibility complex (MHC) class II antigens on antigen presenting cells is frequently observed in sepsis [104]. Opportunistic viral infections are reactivated in the majority of patients with severe sepsis after prolonged ICU care [106,107] and closely follow the occurrence of systemic opportunistic viral infections observed in organ transplant recipients [108]. Disseminated cytomegalovirus infection and herpes simplex infection occur regularly in severe sepsis patient. Opportunistic bacterial and fungal infections also occur at high frequency in septic patients [107].

63.1.5.2 Immune Reconstitution Strategies as a Therapy for Sepsis

A number of therapeutic strategies to limit immune dysfunction or reconstitute immune function following sepsis are now in early clinical development. These include the T-cell growth factor and thymic conditioning factor known as thymosin alpha 1 [109], inhibitors of regulatory control mechanisms such as anti-programmed cell death ligand (PDL1) antibody or anti-B and T lymphocyte attenuator (BTLA) [104], or other immune support and T-cell growth factors such as interleukin-7 and IL-15 [110,111]. Immunostimulant regimens in patients with systemic inflammation is not without risk (immune reconstitution inflammatory syndrome) and use of these therapies will need to be closely monitored in these critically ill patients [112].

63.1.5.3 Mesenchymal Stem Cells as a Therapy for Sepsis

Mesenchymal stem cells (MSC) do not express class 1 or class 2 antigens and thus are well tolerated when infused into patients with a variety of inflammatory diseases. MSCs have the remarkable capacity to traffic to sites of tissue injury and deliver anti-inflammatory cytokines in a paracrine manner to inflamed tissues. They also promote bacterial clearance and assist in remodeling and tissue repair. Their capacity to benefit patients with sepsis or acute lung injury is just beginning to be tested in clinical studies [113].

Specific immunostimulatory oligodeoxynucleotides appear capable of restoring immune competence in experimental models of sepsis by expanding the generation of endogenous MSCs. This might be another way of providing MSCs to damaged tissues in acute inflammatory states [114,115].

63.1.5.4 Mitochondrial Sparing agents and Immunometabolism as a Target for Sepsis

Other novel sepsis therapies are designed as mitochrondrial sparing agents to prevent intrinsic pathway activation of cellular apoptosis [116,117]. Sirtuins and situin activators have mitochondrial growth stimulant activity that is protective against lethality in experimental models of sepsis [118].

Considerable interest has recently developed in readily available methods of regulating the host inflammatory status by directing the immunometabolism of

Table 63.4 Immunomodulators and other potential targets in systemic inflammation.

Target	Potential therapeutic agent	Mechanism(s) of action	Development status
Sepsis-induced immune suppression	Thymosin	Thymic growth factor, supports T cell expansion and function in immune compromised patients	Currently in clinical trials for sepsis [109]
Immune reconstitution	Programmed cell death ligand-1 monoclonal antibody	Inhibit co-inhibitory signaling between lymphocytes and Antigen presenting cells	Clinical trials in oncology and pilot clinical studies in sepsis [105]
Inflammation-induced immune suppression	Interleukin (IL)-7, IL-15	T-cell growth factors that reverse lymphocyte exhaustion and promote T-cell receptor diversity	Clinical trials in oncology and pilot studies in sepsis [110,111]
Inflammation -induced organ injury	Mesenchymal stem cells (MSCs)	MSCs traffic to damaged tissue and provide local anti-inflammatory signals and promote tissue repair	Early clinical trials in acute lung injury and other indications [112]
Sepsis-induced immune suppression	Immunostimulatory oligodeoxynucleotides	Promote synthesis and release of MSCs and clear bacterial pathogens	Preclinical studies and pilot clinical studies [113]
Inhibition of apoptosis in systemic inflammation	Mitochondrial sparing agents; SIRT-1 activators	Improves cellular energetics and limits endogenous apoptosis	Preclinical investigations [74,75]
Metabolic switch to glycolysis	Immunonutrition strategies to switch to oxidative metabolism	Can induce inhibitory phenotype of macrophages	Preclinical investigations [76,77]
Macrophage activation syndrome	Interleukin-1 receptor antagonist (IL-1ra)	Blocks IL-1-induced inflammation, organ injury and cytopenias	Pilot clinical trials, phase 2 studies are contemplated

LPS: lipopolysaccharide; mAb: monoclonal antibody; HMGB1: high mobility group box 1; MDR: multidrug-resistant bacteria.

inflammatory cells [119,120]. Converting monocytes away from anaerobic glycolysis to aerobic metabolism changes the inflammatory phenotype to an anti--inflammatory functional cell type. This is an attractive mechanism to regulate the inflammatory system and will need to be testing in clinical studies to determine if it could be a clinically viable option.

63.1.5.5 CD28 Costimulatory Signal Peptide Inhibitors as a Novel Therapy for Sepsis

Short synthetic peptide inhibitors of the CD28 homodimer interface during cell activation are being developed to limit the costimulatory signals on antigen presenting cells and T lymphocytes [121]. One such peptide inhibitor looks promising in experimental studies in toxic shock syndromes and necrotizing soft tissue infections [122]. A recent phase II trial with a CD28 inhibitory peptide known as AB103 was successful in a phase II trial in patients with necrotizing fasciitis and is now in phase III trials [123].

63.1.5.6 The Return of Interleukin-1 Receptor Antagonist (IL-1ra) in Systemic Inflammation

Macrophage activation syndrome (MAS) is a component of the hemophagocytic syndromes and consists of a shock-like state with evidence of hemophagocytosis in the bone marrow, acute severe inflammation, hyperferritinemia, multiorgan failure, and poor clinical outcomes. IL-1ra has been tested in pilot studies in refractory cases of MAS with some successful treatment outcomes. A retrospective reanalysis of a phase 3 sepsis trial with examination of a subgroup of patients who met MAS criteria suggested a survival benefit when they received IL-1ra [124]. A prospective, randomized trial focused on MAS patients is planned in the near future to determine if this approach can be confirmed in a large clinical trial (see Table 63.4 for a detailed summary of immunomodulators in clinical development).

63.2 Conclusion

With the ever-increasing knowledge of the molecular and cellular mediators that contribute to sepsis pathophysiology, a new generation of therapeutic opportunities are now available for detailed investigation. Recovery and maintenance of epithelial and endothelial barriers are rational targets to assist recovery in patients with acute systemic inflammatory state, be they sterile inflammation or infection-related sepsis. Other experimental agents currently in development promote cell survival by targeting mitochondria and cellular energetics. New strategies that bolster immune defenses should be tested in this era of progressive antimicrobial resistance among bacterial and fungal pathogens. These novel agents targeting new molecular mediators need to be linked with rapid molecular diagnostic studies to identify patients likely to benefit from specific interventions [125]. Innovations in genomic medicine will bring a new generation of adjuvant therapies to the bedside to the benefit our patients.

Inflammation and Microbiota and Gut Reconditioning

Stig Bengmark

University College London, Division of Surgery & Interventional Science, 4th Floor, 74 Huntley Street, London, WC1E 6AU, UK

"Everything in excess is opposed to Nature. All disease begins in the gut."
Hippocrates

64.1 A Dramatic Increase in Incidence of Chronic Diseases

The burden of chronic diseases is steadily increasing all around the world and is forecasted to continue to do so for at least another 50 years. While the increase in chronic diseases in Western countries, although accelerating in the last 50 years, had been ongoing for more than 100 years, it is mainly in the period after the last world war that more pronounced increases in incidences of chronic diseases have occurred, especially outside the Western hemisphere. Pronounced increases are, for example, reported from Japan from the period of the first 50 years after the last world war (1948–1998) – dramatic increases in incidences of diseases such as breast, ovarian, prostatic, and testicular, much in parallel to the Japanese population adapting Western food habits, to a large extent complementing or eventually also replacing traditional horticultural and aqua-cultural foods with processed Western-type agricultural foods. During these 50 years, for example, prostatic cancer in Japan increased by no less than 25 times, much in parallel to an increase in intake of egg 7 times, meat 11 times, and dairy products 20 times [1,2]. Similar, although slightly delayed, developments are also reported both from other continents and from neighboring Asian countries to Japan [3]. Seemingly this epidemic dominated by obesity and associated diseases has its epicenter in the southern United States,[1] with states such as Alabama, Louisiana, and Mississippi having the highest incidence of obesity and chronic diseases in the United States

and the world. These diseases are rapidly spreading across the world – to the west to New Zeeland and Australia, to the north to Canada, to the west to Western Europe and the Arab world, and to the south, particularly Brazil, and Mexico.

64.2 The Epidemic Forecasted to Continue – Also in the Western World

Recent studies forecast that by 2050 at least a doubling has occurred in incidence of diabetes [4] and a tripling in incidence of attention deficit hyperactivity disorder (ADHD), Alzheimer disease [4], and cancer [5] in most countries, including both the United Kingdom and the United States, already heavily burdened by obesity and chronic diseases. A most interesting recently published study looked at the future development of disease pattern in the United States and the United Kingdom, two countries together representing approximately 5% of the world's population and two countries that already have the highest rates of obesity and chronic diseases. The study suggest that these countries combined will, by 2030, see another 76 mill obese adults, additional 6–8.5 mill cases of diabetes, 6–7 mill cases of cardiovascular disease, 492 000–669 000 new cases of cancer, leading to loss of 26–55 mill quality-adjusted life years, and a dramatic increase in costs of care – calculated to be $50–68 billion/year [6]. Other rather recent studies suggest that the increase will continue beyond 2030, if dramatic preventive measures are not instituted. While predicting future disease, especially cancer, might be fraught with uncertainty; predictions are necessary aids to health planners and others and must be done. The general experience is that the statistical models have, over the years, been refined and today these models are capable of providing accurate predictions.

64.3 Developing Countries Soon to Take Over the "Yellow Jersey"

During the last two to three decades, noncommunicable diseases (NCD) have taken over as the leading cause of death in countries such as Mexico, Brazil, Saudi Arabia, and India. Today the same development is seen in sub-Saharan Africa. It is promising that the rates of cardiovascular disease (CVD) including coronary heart disease (CHD) and stroke, have in recent years been declining in some industrialized countries, including the United States and the United Kingdom, but instead they are fast rising in most developing countries. For example the rate of mortality in stroke in urban Tanzania is, much in contrast to rural Tanzania, reported to be threefold higher than in the United Kingdom [7,8]. Recent studies suggest that 75% of the world's hypertensive population are to be found in developing countries [9] – a severe condition, which 40 years ago did not almost exist in developing countries [10]. Today more than one-third of adults living in Africa are hypertensive [11].

64.4 Hypertension Associated with Dysbiosis

Lifestyle-induced hypertension is today often accompanied by obesity and deranged sugar and fat metabolism and is today close to smoking, the leading cause of death on the Earth. Lifestyle-induced diseases are together responsible for the largest number of deaths in the United States [12] as probably in most other countries around the world, especially and certainly so in most developing countries. Increasing evidence suggests that for example hypertension is accompanied by a chronic low-grade chronic inflammation that perpetuates the hypertensive state and contributes to the often observed end-organ damage [1,13,14].

Hypertension, like most other chronic disorders, is often preceeded by and always accompanied by malfunctioning intestinal microflora – a condition named dysbiosis. A recent experimental study reports significant decrease in microbial richness, diversity, and evenness in rats with spontaneous and induced hypertension [15]. Similar observations are done in a small cohort of human hypertensive patients (n = 10), who compared to control patients (n = 7) demonstrate a much reduced richness and diversity of microflora, characterized by significant increase in the ratio of Firmicutes/Bacteroidetes but also a significant decrease in acetate- and butyrate-producing bacteria [15], important to prevent a leaky gut.

64.5 Inflammation – A Mother of Disease

A few years after having achieved the status of Professor Emeritus, I felt a strong desire to better understand the pathogenic mechanisms underpinning various chronic diseases, the incidence of each having increased significantly during my lifetime years. I did spend endless hours during almost one year to study and try to understand the pathogenesis of various diseases from ADHD, allergy and Alzheimer's disease to Zollinger–Ellison syndrome and Zuska's disease. It became a great surprise to me that the processes leading to the various diseases were almost indistinguishable – the great majority of the chronic diseases demonstrated clear signs of a most often discrete chronic inflammation accompanied by increased activation of proinflammatory cytokines such as Il-6, acute phase reactants such as C-reactive protein (CRP), PAI-1 and increased levels of free fatty acids much similar to what is seen in acute diseases, such as trauma or sepsis. This observation lead me at that time to call the process leading to the various chronic diseases "chronic phase reaction" and to publish a review entitled "Acute and "chronic" phase reaction – a mother of disease" [16,17]. Observations already in those days indicated a strong involvement of the gut and microflora in the process leading to development of chronic inflammation and associated metabolic manifestations. Among the informations early available was the observations that key proinflammatory cytokines are synthesized by enterocytes in response to the damaging endotoxin, to the largest extent produced by the gut microflora [18–20].

64.6 The Gut Harbors the Majority of the Immune System

The intestine is not only a major site for entry of pathogens, it is also an organ exposed to an enormous amounts of food antigens. It contains under normal conditions trillions of commensal bacteria and a collective genome at least 150 times larger than our own. Immunoglobulin A plays a major role in neutralization invasive pathogens and maintenance of a strong presence of noninvasive commensal bacteria, is crucial for maintaining good health. Multiple mechanisms are suggested to be involved [21,22]. The Norwegian immunologist Peter Brandtzaeg suggested in 1989 that the gut, in contrast to what was earlier believed the spleen and the lymph nodes, is the major location of "the immune system" – 70–90% of IgA immunocytes (plasma cells and plasma blasts) are found in the enteric mucosa [23].

The intestinal mucosa is densely populated by various recognition cells of which the dendritic cells (DCs) in the lamina propria (LP) are especially and strongly associated with both adaptive and innate immunity. The recognition that dietary nutrients and microbial communities in the intestine influence both mucosal and systemic immune cell development and function and development of immune-mediated disease has in recent years led to a growing interest in the functionality of intestinal recognition cells, particularly in DCs, and an explosion in information in mucosal immunology.

64.7 Strong Association Between Composition of Microbiota and Chronic Diseases

The epidemic of a plethora of chronic inflammatory NCD, all documented to have in common an underlying low-grade inflammation, constitutes a major threat to future development and particularly to the economy of modern Societies. The epidemic include early-onset NCDs, such as allergy, asthma, and some autoimmune diseases, as well as later-onset NCDs, such as CVD, metabolic disease, and neurodegenerative disorders, which all appear to share common environmental risk factors and genetic risk variants – see Reference [24] for further detail. Although the pathways to disease are multifactorial, the lifestyle and eating habits and associated severely impaired gut colonization pattern with decreasing microbial numbers and diversity are clearly central to the observed physiologic, immunologic, and metabolic dysregulations seen in most NCDs. A dysbalance between two main phyla is observed in almost all NCDs, a dysbalance observed between Bacteroidetes, comprising gram-negative bacteria, and Firmicutes, comprising gram-positive bacteria [25]. As Firmicutes and Bacteroidetes account for more than 90% of the bacterial population in the colon [26], alterations within and between these two phyla are most likely of the greatest pathogenic significance. It was originally believed that the composition of the intestinal microbiota was relatively stable from early childhood; however, recent evidence suggests that poor diet can rapidly – within 24 h – cause dysbiosis, and alterations in the composition of the microbiota could fast lead to aberrant and most negative immune responses. Studies in recent years have repeatedly demonstrated a great

sensitivity of microbiota to lifestyle changes, particularly food habits; studies performed on large supply of fat, large supply of sugar, large supply of fat and sugar, fiber-reduced, calorie-restricted, complex carbohydrates, refined sugar, vegetarian diet, high n-6 PUFA, animal milk fat, all demonstrating significant alterations in composition of microflora – for review see [27]. It is of great interest that a dysbalance in favor of gram-positive Firmicutes is associated with a significantly increased extraction of energy [28].

64.8 Paleolithic Forefathers Had a Much Different, Much More Diverse and Richer Microbiota

The microbiota of some ancient remains on the Earth with lifestyle similar to our human ancestors, having lifestyle and food habits, which in most aspects date back thousands if not millions of years are especially precious to investigate. The most representative of such groups was until recently most likely the Hadzas, living in the Rift Valley ecosystem around the shores of Lake Eyasi in north-western Tanzania, who belong to the few last remaining hunting and gathering communities in the world. The Hadza diet consists of wild foods – meat from hunted animals, berries, fruit and seeds from the baobab tree, honey, and tubers.

The Hadzas practice no cultivation or domestication of plants and animals and eat minimal amounts of agricultural products (< 5% of calories) from external sources. They consume 100–150 g of fiber each day, which is about 10 times more than typically Americans and Europeans eat. A detailed study of the microbiota of 27 Hadza, aged 8–70 years, mean age 32 years and compared to 16 urban Italians age 20–40 years, mean age also 32 years, was recently published [29]. Although Firmicutes and Bacteroidetes are the dominant phyla in both Hadza and Italian gut microbiota, Hadza are characterized by a relatively higher abundance of Bacteroidetes and a lower abundance of Firmicutes. The two gut microbiota ecosystems are remarkably different with respect to subdominant phyla (< 10% relative abundance). The microbiotas of the Hadzas are largely enriched in Proteobacteria and Spirochaetes, which are extremely rare in the Italian gut microbiota, while Actinobacteria, an important subdominant component of the Italian gut microbiota, are almost completely absent from the Hadza microbiome. It is important to stress that in addition to those mentioned above many hitherto unclassified genera belonging to Bacteroidetes, Clostridiales, and Ruminococcaceae were observed in the Hadza gut microbiota. Furthermore, it was observed that the Hadza gut microbial ecosystem is profoundly depleted in Bifidobacterium and comprises an unusual arrangement of Clostridiales. This arrangement is defined by a general reduction of well-known butyrate producers, members of the Clostridium clusters IV and XIVa22 and a corresponding increase in unclassified Clostridiales and Ruminococcaceae. Detailed recent information on the health status of Hadza is not available but early studies suggest that the Hadza have low rates of infectious disease, metabolic disease and nutritional deficiencies in comparison to other settled groups in the northern Tanzania and south-eastern Uganda region [30,31].

64.9 Different Microbiota in Infants in Hunting and Gathering Communities

Fecal microbiota of 14 healthy children, aged 1–6 years, from the Mossi ethnic group living in the small village of Boulpon in Burkina Faso (BF) were studied and compared with that of 15 healthy European children (EU) living in the urban area of Florence, Italy [32]. A significant depletion in Firmicutes accompanied by a unique abundance of bacteria from the genus *Prevotella* and *Xylanibacter*, known to contain a set of bacterial genes for cellulose and xylan hydrolysis, was observed in the BF children, but completely lacking in the EU children. A significantly greater production of short-chain fatty acids (SCFAs) was also observed in BF children in comparison to the EU children. The microbiota of the BF children was significantly richer in potentially anti-inflammatory gram-positive bacteria, while the microbiota of the EU children had a much greater component of potentially inflammation-inducing gram-negative bacteria. It was especially observed that Enterobacteriaceae (*Shigella* and *Escherichia*) are significantly underrepresented in BF compared to EU children. As concluded by the authors, gut microbiota seems to have coevolved with the polysaccharide-rich diet of BF individuals, allowing them to maximize energy uptake from fibers but also protecting them from inflammation-induced noninfectious diseases.

The gut microbiota of 44 rural Malawian 6-month-old infants was in another important study compared to that of 31 Finnish infants of the same age [33]. The Finnish children were breast-fed to 68%, the Malawian to 100% (no formula, no complementary food at 6 months of age, just as the World Health Organization (WHO) and other authorities recommend today. The Malawian microbiota comprised Bacteroides-Prevotella (17 vs. 5%) and *Clostridium histolyticum* (4.4 vs. 2.8%; P¼ 0.01), respectively. The species *Bifidobacterium adolescentis*, *Clostridium perfringens*, and *Staphylococcus aureus* were absent in Malawian but not in Finnish infants. Bifidobacteria were dominant at 6 months of age in all of the infants, although to a greater proportions in Malawian (71%) than in Finnish infants (47%). The preponderance of these special bacterial species might reflect the risk of developing allergy; it is well known that allergic infants are more often colonized by *C. difficile* and *S. aureus* and less by bifidobacteria. Higher levels of clostridial species and staphylococci, common in Western microbiota, are known to be associated with obese and overweight infants.

64.10 The Most Robust Microbiota Ever Seen

A most recent report describe the microbiome of a previously unknown group – the Yanomamis [34], a group of villagers living in complete isolation in the Amazon, and as suggested, with no contact with the outside world for an estimated 11 000 years. The Yanomami were originally mountain people, who were first contacted in the mid-1960s and who continue to live a semi-nomadic hunter-gatherer lifestyles in the Amazon jungle in the high Orinoco state of the vast mountainous Yanomami territory, Venezuela, uninfluenced by anybody from

the outside world. These villagers are observed to eat wild bananas and seasonal fruits, plantain, palm hearts, and cassava. Their hunting for food focuses mostly on birds and small mammals but also small crabs, frogs, small fish from nearby streams, and also, although very occasionally, peccary, monkey, and tapir. Samples of the microbiota of oral cavity, forearm skin, and feces were recently obtained from 34 of 54 villagers at the time of the first medical expedition in 2009 to this isolated and previously uncharted village.

The microbiotas of the villagers were analyzed and reported to have the highest diversity ever reported in humans (~40% more in Westerners), but also when compared to the rural Africans discussed above [34] – an important observation indicating that a large proportion of important ingredients of our early microbiota have become extinct during the process of Westernization. The Yanomamis harbor high amounts of *Prevotella*, *Helicobacter*, *Oxalobacter*, and *Spirochaeta* but also high levels of parasites that are absent or significantly reduced in industrialized humans. A most unexpected finding was that the gut and oral bacteria also contained genes coding for antibiotic resistance. Though these genes were inactive, they confer resistance, not only to natural antibiotics found in the soil but, and most likely, also to other chemicals including pharmaceuticals. The observations support the assumption that a large proportion of Western diseases, rare in rural Africa and South America, are results of lifestyle and profound diet changes. The medical workers reported that villagers were healthy and did not suffer from autoimmune disorders, diabetes, or high blood pressure.

64.11 Rural Lifestyle Prevents Western Diseases

The British physician Dennis Burkett should be credited for alerting the world to the need of a much higher intake of fiber to maintain health. He reported some 40 years ago a strong association between low-fiber content in the diet and a significantly higher risk of colorectal cancer, but also of other diseases such as CHD and diabetes, all based on his observations in Uganda, Africa. He reported that the shortage in plant fibers in Western diet was associated with poor gastroenteral function – both a 10 times reduction in stool weight (United Kingdom 60 g/day, Uganda 600 g/day) and a 5 times increase in transit time (United Kingdom: 100 h., Uganda: 20 h) in Western Societies (United Kingdom) in comparison to what was observed in Uganda [35–39]. The lack of fibers in diet was at that time reported especially low in special groups of the Western Societies and especially so in the foods served at hospitals – a shocking transit time of more than 14 days observed and reported in half of the investigated British geriatric patients [40].

Studies in other ancient remains of humans of the world, such as Abkhazia, Vilcabamba och especially Hunza – all living almost totally on nonprocessed plant food: Hunza och Vilcabamba 99% and Abkhazia on 90% provide most interesting results. They seem to harvest energy better than Westerners as they despite hard work seem to live and maintain weight on only 17–1800 calories, obtained from 100% nonprocessed plant foods. Obesity is said to never be seen, the incidence of disease is remarkably low and the numbers of centenarians are greater than observed in most places on the Earth – for review, see Reference [41].

64.12 Endotoxin (LPS) – A Major Inducer of Inflammation and Disease

The most obvious and harmful consequences of reduced microbiota, dysbiosis, are high levels of endotoxin in plasma (endotoxemia), which both in experimental and clinical studies are strongly associated with inflammation and risk of obesity and almost all chronic diseases. Endotoxins are integral components of the outer membrane of gram-negative bacteria such as *Enterobacteriaceae* and *Pseudomonadaceae*, and essentially composed of proteins and lipids, in addition to the toxic and inflammation-inducing lipopolysaccharides (LPS). LPS is known to have exceptionally strong ability to induce inflammation via the so-called toll-like receptors 2 (TLR2) and 4 (TLR4). Volunteers living for 1 month on a Western-style diet demonstrated, in a crossover study, a 71% increase in plasma levels of endotoxin activity (endotoxemia) when compared to those consuming, what the authors called, and a "prudent-style diet," who, in turn, demonstrate a 31% reduced level of endotoxin [42]. A positive correlation between sedentary lifestyle and higher levels of endotoxin levels, and a negative correlation to the degree of physical exercise is reported [43]. High-fat-content foods, rather than high-carbohydrate-content foods, correlate with high levels of endotoxemia. Mice fed with a high-energy diet (either high-fat diet or high-carbohydrate diet) demonstrate a significant increase in plasma LPS; however, again, a high-fat diet contributes more than a high-carbohydrate diet to a high endotoxin level [44].

64.13 Meals Rich in Long-Chain Fatty Acids Induce Endotoxemia

Fat in foods influences negatively microflora and its replication, but the most pronounced negative effects are observed with high consumption of animal-origin fat, which facilitates translocation of LPS – the chylomicrons serving as vehicle for translocation of endotoxin, through the mucosa and into the circulation, a process referred to as transcellular transportation. This process facilitates higher concentrations and a long-lasting presence of both long-chain fatty acids and endotoxin in the general circulation – see further below. Strong correlations between plasma levels of endotoxin and numbers of parameters of metabolic syndrome as well as between persistent levels of high endotoxin/plasma and "prospect of life" have been observed – especially large differences being reported between the first and fourth quartiles [42]. Among the diseases associated with increased presence of fat and endotoxin in plasma are particularly; Alzheimer's disease [45,46] and cognitive impairment [47], arteriocoronary disease [47,48] and stroke [49], diabetes 1 [50,51], diabetes 2 [52], cancer [52,53], but also allergy [54], ALS [55], autism [56], autoimmune diseases [57], bipolar disease [58], chronic fatigue syndrome [59], chronic obstructive pulmonary disease (COPD [60], minimal encephalopathy [61,62], fibromyalgia [63], HIV [64], liver cirrhosis [62,65], macular degeneration [66], nephropathies [67], obesity [68,69], osteoarthritis [70], paradontosis [71], Parkinson's disease [72,73], rheumatoid

diseases [74,75], psychiatric and cognitive disorders [47,76,77], stress [78,79], and uveitis [80].

64.14 Humans Are Especially Sensitive to Endotoxin

Humans are known to be extremely sensitive to endotoxin exposure and reported to show signs of inflammation at extremely low doses of LPS, reported to be at least 250-fold lower than what is required, for example, in mice [81]. This is especially important to remember as modern humans, much more than other primates, as an unfortunate consequence of modern living, are exposed to high amounts of LPS both at outdoor and indoor living. Tobacco smoking is a major source of LPS but also dust from home is rich in endotoxin, often occurring at home, workplace and at school. Industries such as agriculture, textile, and wood industries are especially recognized as bad environment with often extremely high levels of endotoxin exposure.

64.15 Fresh Fruits and Vegetables Contain Minimal Levels of Stimulants of Toll-Like Receptors (TLRs)

The fact that the food we eat often contains unacceptably high levels of endotoxin is often neglected. Cooking the food makes little difference as LPS is heat-resistant and both LPS and dead bacteria maintain their ability to induce inflammation. The majority of fresh and raw whole vegetables should normally contain only minimal or undetectable levels of stimulants of TLR2 or TLR4 [82]. However, certain raw and minimally processed vegetables (MPVs) are very sensitive to storage and might occasionally contain considerable quantities of bacteria and endotoxins; especially bean sprouts, diced onions, and chopped root vegetables such as carrots and onions [82]. Beef, pork and turkey increase within a few days of storage their content of TLR2- and TLR4-stimulants remarkably, even when stored at below 5 °C, especially when exposed to air [83]. The accumulation of TLR2- and TLR4-stimulants is minimized by storage of meat in intact rather than minced forms, and when stored under a modified atmosphere, rather than exposed to air [83]. Very little data exists about the health hazards of game meat, which despite its favorable nutritional profile, compared to farmed meat, is often kept hanging for weeks and, as a consequence, is especially rich in bacteria and endotoxins.

64.16 Several Proteotoxins Stimulate Also Toll-Like Receptors (TLR) and Induce/Enhance Inflammation

Different food ingredients and particularly proteins may enhance the inflammatory properties of human diets. Many peptides and proteins, to which modern humans are daily exposed, possess the ability to induce inflammation and activate

transforming growth factor-β (TGF-β) and TLRs. Among these are various lectins, especially glutenoids, and also caseins. Novel molecules, induced by heating of food or longer storage at room temperature, are collectively called Maillard products and consist in so-called "advanced glycation end products" (AGEs) and "advanced lipoxidation end products" (ALEs). The "invention of fire" in Stone Age increased dramatically the possibilities for proinflammatory food products to be produced, and the introduction of gluten-containing grains, which occurred about 10 000 years ago with the advent of agriculture, did further increase human exposure to dysfunctioning proteotoxins – proinflammatory molecules – developments, which might be regarded as unfortunate "mistakes of evolution."

The main reasons for the large exposures during human history to glutenoids might have been that it was mainly the members of the *Triticeae* grass tribe (wheat, rye, barley) and the *Pooideae* subfamily (including even oats) that grew well at higher latitudes. Modern plant breeding technology has made it worse as modern bread contains 15–20 times more gluten, compared to bread produced in the past. An unexpected consequence of high consumption of wheat, rye, and barley, is that modern will suffer from a series of highly unwanted human disorders that relate to exposure to glutenoids, particularly gluten (wheat), but also to secalins (rye) and hordeins (barley), which all have strong ability to induce inflammation and increase intestinal permeability [84]. Oats is distantly related to wheat, rye and barley, but its active peptides, the avenins, are rarely reported to give stronger reactions, either inflammation or allergy [85].

64.17 Gluten-Sensitivity a Common and Newly Detected Inflammation-Inducing Disorder

It has become increasingly apparent that "classic" celiac disease (CD) represents only "the tip of the iceberg" of an overall large glutenoid-associated disease burden. We are increasingly aware that, besides those rather few, who suffer CD and classic wheat allergy, most individuals, if not all, also suffer very discrete, but always negative reactions to glutenoids. Despite the fact that few direct and immediate allergic reactions or autoimmune mechanisms are involved with exposure to wheat, rye, or barley, consumption of these foods will almost always or always add to the general burden of inflammation in the body. A rather recently made observation has lead to recognition and acceptance of a new disorder called gluten sensitivity (GS) [86]. Although LA-DQ8 is present in almost all CD patients, these genes are only present in about half of patients with GS. Some of the individuals with GS may have no symptoms at all, others will suffer well-defined chronic diseases, and the majority "only" more ill-defined distresses; fatigue, depression, encephalopathy/"foggy mind," lack of energy, diffuse abdominal pain, bloating, diarrhea, eczema and/or rash, undefined headache, numbness in the legs, arms or fingers, joint pain and many other manifestations. More or less all affected individuals report that, when turning to gluten-free diets, increased well-being and frequently also improved clinical signs and symptoms will occur.

64.18 Gluten-Free Foods Have Led to a New and Successful Industry

Experiences such as these have made the gluten-free diet the number one health trend in the world,[2] growing faster than both low carbohydrate diets and "fat-free" diets, and rapidly fueling the gluten-free product market, which has grown in the United States with 44% in less than 3 years, from 2011 to 2013, and is expected to continue to grow further – the US market from $10.5 to $15.6 billion, and the UK market from $395 to $931 million by 2017. A parallel development is also observed in the growth of alternative milk – the global growth of soy, oat, almond, and so on based alternative milks constitute seemingly around 6% per year of the combined milk and alternative milk products.[3]

A fast increase in alternative sources of flours is also observed. Among the alternatives flours for bread-baking are ancient grains, several of them known to grow particularly, if not exclusively, well in Africa; amaranth, arrowroot, brown rice, buckwheat, chia, chickpea, corn, hemp, maize, millet, oat, potato, quinoa, sesame, sorghum, soya, tapioca, teff, and white rice, of which sorghum is the fifth most common grain in world and especially attractive due to its extremely high content of antioxidants, low content of energy [87], and ability to resist heat-induced protein glycation [88,89], but also due to its high versatility and cost-effectiveness.

64.19 Glutenoids Show Endotoxin-Mimicking Abilities

Glutenoids, which demonstrate endotoxin-mimicking abilities, are capable of lowering the threshold for immune responses, attracting leukocytes and increasing their reactive state, in a manner similar to that of endotoxin. Nearly 10 μg/mL of wheat gluten induces the equivalent effects of 1 ng/ml endotoxin LPS [90], increasing DC maturation as well as chemokine secretion [90]. A study investigating fecal samples from 76 symptom-free, nonceliac, first-degree CD relatives and compared to samples from 91 aged-matched healthy controls reported significantly lower level of acetic acid and other SCFAs) in parallel to significantly increased levels of *i*-butyric acid and fecal tryptic activity in the asymptomatic CD-relatives [91].

The information that removal of gluten from the diet of the nonobese diabetic mouse could attenuate the intensity of autoimmunity and reduce the incidence of diabetes led to a cross-over study, where 17 first-degree relatives were kept on a gluten-free diet for the first 6 months followed by another 6 months on a standard gluten-containing diet [92]. The acute insulin response to intravenous glucose tolerance test rose significantly in 12/14 patients after the first 6 months of gluten-free diet when complying with the diet ($P = 0.04$) and decreased again in 10/13 during the following 6-month period on a standard gluten-containing diet ($P = 0.07$) [92].

3 http://blog.euromonitor.com/2014/09/whitewaves-acquisition-of-so-delicious-dairy-free-should-cement-its-lead-in-non-dairy-milk-alternati.html.

64.20 Similar Effects Observed on Gluten Restriction in Individuals with ADHD

A similar outcome is reported from a crossover study in which 100 individuals suffering ADHD, aged 4–8 years, who were randomly assigned to 5 weeks on a restricted elimination diet (not planned as but in fact a gluten-restricted diet) or to what was referred to as a healthy diet, followed by another 5 weeks on the alternative diet. All parameters' total score, inattention, hyperactivity, and abbreviated Connor scale scores (ACS) improved significantly on the restricted diet but deteriorated again during the subsequent period on a "normal," although supposedly healthy diet [93]. Another study focused on thirty-four individuals with irritable bowel syndrome, 56% of them with human leukocyte antigen (HLA)-DQ2 and/or HLA-DQ8 genes, during 6 weeks on a gluten-free diet [94]. Statistically significant improvements, compared to controls, were reported in the gluten-free group in 3/6 parameters studied: abdominal pain ($P = 0.02$), satisfaction with stool consistency ($P = 0.03$), and tiredness ($P = 0.001$), but no improvement being observed in overall symptoms ($P = 0.15$), wind ($P = 0.08$), and nausea ($P = 0.69$), and no differences observed between individuals with or without DQ2/DQ8 genes [94]. Another rather recent study reported disappearance of signs of malabsorption and intractable therapy-resistant seizures in three young girls (ages 18, 19, 23) when placed on gluten-free diet [95]. Similarly, individuals with symptoms of neuropsychiatric diseases; Alzheimer's disease/cognitive decline [96], autism [97], and schizophrenia [98] are reported in the literature as symptom-free on a gluten-free diet.

64.21 Gluten Sensitivity Associated with Severe Dysbiosis, Leaky Gut and Increased General Inflammation

Typical symptoms of nonceliac GS are fatigue, sleep disturbances (insomnia and/or nonrestorative sleep), morning stiffness and cognitive problems, but also gastrointestinal symptoms are frequent – a clinical picture almost identical to fibromyalgia, 50–70% of patients with fibromyalgia are reported to suffer nonspecific gastrointestinal symptoms such as abdominal distension (59%), dyspepsia (50%), nausea (21%), alternating diarrhea-constipation (63%), constipation (12%), and diarrhea (9%) [99].

All gluten-sensitive diseases as mentioned above are strongly associated with severe dysbiosis, leaky gut and permanent general chronic inflammation. A recent study was aimed to clarify how cultured peripheral blood mononucleated cells (PBMC) obtained from nonceliac gluten-sensitive (NCGS) patients responded to contact with wheat proteins. Wheat protein was observed to induce an overactivation of the proinflammatory chemokine CXCL10 and decrease the transepithelial resistance of monolayers of normal colonocytes by diminishing the mRNA expression of cadherin-1 (CDH1) and tight junction protein 2 (TJP2), two primary components of the tight junction strands. Furthermore, the induction of

inflammation was greater with proteins extracted from modern compared to when extracted from ancient wheat genotypes [100].

64.22 Proteotoxin-Induced Low Threshold for Immune Response

Inclusion of industrially made foods ingredients and particularly those of protein nature might both enhance and diminish the inflammatory properties of the diet. This is also true for various lectins and frequently observed with various bovine milk-derived proteins, and particularly with powdered milk. The synthesis in the brain of serotonin (5HT) and melatonin is dependent on access to their precursor amino acid, the essential amino acid L-tryptophan (TRP), normally released in the gut by microbial fermentation of plants rich in this amino acid [101]. As it is believed that some food proteins might block release of some amino acids such as L-tryptophan, an animal study was undertaken to compare the effects of five different such proteins: zein (corn), gluten (wheat), soy protein isolate, casein, lactalbumin or no protein. An eightfold variation was observed in levels of cortex tryptophan: a marked decline followed zein ingestion, slightly more modest reductions were observed after casein or gluten application, all paralleled by reductions in cortical and hippocampal hypothalamic 5-hydroxytryptophan (5HTP) [101].

Fermented milk such as Kefir contains more than 250 peptides, mainly released from β-casein, of which several have significant biological effects: ACE-inhibitory, antioxidant, antithrombotic, mineral binding, antimicrobial, immunomodulating, and opioid activity [102]. It is most likely that the same peptides are released during microbial fermentation in the gut, which might explain why intake of various dairy products are associated with dysbiosis, increased general inflammation and also why dairy-free diet often leads to reduced general inflammation and clinical improvements, and also explain the observed association between larger intake of dairy and increased incidence of diseases including Alzheimer's disease and dementia [103–107].

64.23 Heat- and Storage-Induced Inflammation-Inducing Proteins

Heat- and storage-induced dysfunctioning proteins are of special interest, as they are shown to have strong ability to induce inflammation [108,109]. It is thought that certain dietary AGEs are indigestible by human gut enzymes and most likely enter the colon, where they will act as a growth substrate for detrimental bacteria such as some Clostridium and Bacteroides species [110,111]. Therefore, it is most conceivable that individuals who consume highly processed diets (which contain large quantities of AGEs) may adversely alter their colonic microbial composition and potentially enhance the risk for the development of metabolic diseases such as obesity and type 2 diabetes [112].

Among foods rich in AGEs and ALEs are dairy products, especially powdered milk (frequently used in enteral nutrition and baby formulas, as well as in numerous other industrially produced foods), and also especially rich in high-temperature prepared fried and grilled meat and poultry, but also fish (especially deep-fried and oven-fried), drinks including coffee and colas, Asian sauces, such as Chinese soy sauces, balsamic products as well as smoked and cured foods in general [113–115]. Consumption of such foods, often main constituents of fast foods, has increased dramatically in recent decades, much in parallel to the endemic of chronic diseases. Higher levels of AGEs such as methylglyoxal derivatives in serum (sMG) and/or other AGEs are strongly associated with a faster rate of cognitive decline in elderly individuals [116], neurodegenerative diseases [113], premature aging and cognitive decline [114], diabetes type 1 and 2 [115], diabetic nephropathy [116], obesity [117], liver disease, particularly liver steatosis and liver fibrosis [118], lung disease, particularly COPD [119], various cancers especially breast cancer [120], colorectal cancer [121], esophageal [122], gastric [123], lung [122], ovarian [122], pancreatic [124], prostatic [125], renal [126], and leukemia [127].

64.24 Numerous Proinflammatory Mediators Involved

A wide range of proinflammatory mediators, including TNF-α, IL-1b, IL-6, IL-8, and the nuclear protein high mobility group box-1 (HMGB1), are implicated in the pathogenesis of the above-mentioned chronic diseases. HMGB1 is one of the important mediators known to signal effects of the AGEs, particularly RAGEs, and through the TLR2 and TLR4. Activation of these receptors will ultimately result in activation of NF-κB, known to induce up-regulation of leukocyte adhesion molecules and production of proinflammatory cytokines and angiogenic factors in both hematopoietic and endothelial cells, thereby promoting inflammation [128]. A recent review suggests that particularly HMGB1, TLR and RAGE constitute a functional tripod with high ability to promote inflammation [129].

64.25 Short-Chain Fatty Acids – A Magic Bullet?

The gut microbiota is, as already discussed, the key to gut/immune homeostasis and health to the host. Increasing evidence suggests that this is achieved, at least to a large extent, through the release SCFAs, which are the main microbial metabolites produced by specific colonic anaerobic bacteria in the gut fermentation of dietary fiber and resistant starches. Deficiencies in SCFAs will strongly affect the pathogenesis of a diverse range of diseases, from allergies and asthma to cancers, autoimmune diseases, metabolic diseases, and neurological diseases.

Therapeutic manipulation of the gut microbiota and restoration of normal microbiota (a condition called eubiosis) could potentially reduce the levels of circulating AGE levels and improve the metabolic health of individuals at risk for the development of type 2 diabetes or other metabolic syndrome-associated diseases. Regular consumption of fiber-rich/prebiotic-rich foods to promote the growth of beneficial gut bacterial flora is a most promising possibility. Prebiotics/

nondigestable plant-derived carbohydrates confer health benefits to the host by acting as a fermentation substrate in the colon, stimulating the preferential growth and activity of a limited number of beneficial microbial species [130]. Prebiotic-induced stimulation of gut fermentation increases the levels of intestinal Bifidobacterium species, known to attenuate the production of ROS and markers of inflammation in individuals consuming high fat diets [131]. Supplementation of the human diet with prebiotic fructans such as inulin or fructo-oligosaccharides alters the bacterial composition of the large intestine and favors a selective proliferation of beneficial lactic acid-producing species such as bifidobacteria and lactobacilli.

64.26 Consumption of Plant Fibers Crucial to Eubiosis and Good Health

It is increasingly understood that different fibers have different impacts on microbiota composition and metabolism. When the effects on human fecal microbiota of six dietary fibers: pectin, guar gum, inulin, arabinoxylan, b-glycan, and resistant starch was investigated, pectin was found to induce increases in Actinobacteria (more specifically bifidobacteria), guar gum increased levels of Bacteroidetes and reductions in Firmicutes and Proteobacteria, resistant starch increased levels Bifidobacterium adolescentis type-2 and Blautia wexlerae, while inulin increased Actinobacteria [132]. Supplementations of guar gum and inulin resulted in the largest production of butyrate [132]. Apple pectin is reported to be an effective apple component improving the fecal Environment – stimulating growth of Bifidobacterium, Lactobacillus, Enterococcus, and the Bacteroides fragilis group but not microbes such as *Escherichia coli*, *Collinsela aerofaciense*, *Eubacterium limosum*, and *C. perfringens* [133].

Fibers such as pectin and guar gum are known to inhibit weight gain, adiposity, fatty liver, and high blood glucose levels in experimental animals fed a high-fat diet. A recent study demonstrated significantly increased levels of butyric acid in cecum and blood after supply of guar gum with medium and high viscosity as well as of high methoxylated pectin [134]. These fibers reduce to varying extent levels of blood cholesterol, liver steatosis, and blood glucose levels – much depending on the degree of methoxylation and viscosity of the particular fiber. The medium viscosity guar gum was the most effective fiber to prevent a diet-induced hyperlipidemia and liver steatosis. Guar gum is shown to have distinct bifidogenic effects independent of viscosity, and increases the cecal abundance of bifidobacterium about 10-fold [134].

64.27 Prebiotic Fibers Generally Resistant to Digestion in the Small Intestine

It is characteristic of prebiotic fibers that they, to the greatest extent, are resistant to digestion in the human small intestine and that they consequently will largely

pass intact into the colon, where they increase viscosity and bulking of the fecal matters. It is preferably in the proximal half of the large intestine that the dietary fibers undergo fermentation by the resident anaerobic colonic microbiota and produce SCFAs. SCFAs consist in a subset of saturated fatty acids containing six or less carbon molecules that include formic acid(C1), acetate (C2), propionate (C3), butyrate (C4), pentanoic (valeric) acid (C5), and hexanoic (caproic) acid (C6). Recent advances in the information about SCFAs, favorably acetate, propionate, and butyrate, highlight their much important effects on metabolism at both cellular and molecular levels.

Butyrate is mainly utilized by colonic mucosa, while acetate and propionate reach the liver solely through the portal vein. Propionate is fastly metabolized by hepatocytes, while acetate will either remain in the liver or be released to the peripheral venous system and tissues. Of the SCFAs only acetate can be detected as circulating in the body.

64.28 It Is the Luminal Levels of SCFAs, Which Make the Difference

A significant association exists between composition of the microbiota and luminal levels of SCFAs. Higher luminal concentrations and lower colonic pH are observed in proximal colon where fermentation is highest (pH = 5.5–6.5), compared to the distal colon with its significantly higher pH (pH = 6.5–7.0). SCFAs, especially butyrate – the primary energy source for the colonic mucosa – is credited for its unique and important ability to inhibit growth of ptotential pathogens, gram-negative Enterobacteriaceae, especially pathogens such as *Salmonella* spp. and *E. coli* [135,136].

Diets containing low amounts of dietary fibers are strongly associated with distinct long-term negative effects on composition of the intestinal microbiota and production of SCFAs. All SCFAs have significant anti-inflammatory and antiproliferative properties. Consumption of a diet rich in meat and low in fiber promotes proteolytic fermentation and production of uremic compounds and branched-chain fatty acids, which all are proinflammatory and increase the risk of development of disease, particularly cancer.

64.29 Not only SCFAs but MCFAs Have Strong Ability to improve Immunity and Prevent Disease

The documented strong ability of SCFAs to control inflammation, reduce excessive production of radical oxygen species and mitochondrial dysfunction [137], and to regulate immune functions particularly regulating T-cell functions [138] should offer hope for various therapeutic applications, not only by SCFAs (1–6 carbon atoms) but also by medium-chain fatty acids (MCFAs) (6–12 carbon atoms), which are more easy to administer. However, attempts to infuse various SCFAs and MCFAs have not been met with the success,

which was primarily expected. The most significant benefits obtained this far were obtained by direct application of bioactive fibers – administer to facilitate derived production of SCFAs at the mucosal surface. However, intake of plant fibers is not always possible, especially in critically ill, which somewhat limits the applicability of this otherwise successful treatment alternative.

64.30 Stress Increases Microbial Growth and Virulence

It is well documented that the immune system and central nervous system are involved in cross-talk to maintain homeostasis under normal and disease conditions. Acute and chronic stress induces release of a variety of hormones, neurochemicals, and neuropeptides, which directly or indirectly lead to severe impairment of immune functions [139]. Nearly all types of cells, especially immune cell possess receptors for the stress-related neurohormones adrenaline and noradrenaline. Sympathetic nerve fibers do also extensively innervate "immune"/lymphoid organs, such as the bone marrow, thymus, spleen and lymph nodes, and terminate in close proximity to lymphocytes [139]. The large intestine has by far the greatest number of nerve fibers when compared to other organ in the body – the total number of enteric neurones estimated to be at least 500 million [140]. Stress hormones such as norepinephrine and dopamine are shown to dramatically increase the virulence of pathogenic hormones [141]. Noradrenaline, adrenaline, dopamine, and the synthetic catecholamine inotropes dobutamine and isoprenaline are all able to increase virulence and microbial growth by up to 100 000-fold over controls [142].

64.31 Early-Life Conditions Influence Long-Term Health

Early-life conditions play important role in the establishment of microbiota and immune functions, which often influences stress reactions: allergic and immunological response neurodevelopmental later in life. Babies born via cesarean section are born by mothers with high levels of stress. Meta-analyses suggest a 20% increase in incidence of asthma among babies born with cesarean section [143]. Cesarean section, especially unplanned cesarean section, is perceived as severely stressful [144,145] with significantly increased glucorticoid and catecholamine neuroendocrine hormone levels [146,147]. Breast-fed babies, fed by a different and unique prebiotic human milk fibers, oligosaccharides [148], acquire maternal intestinal bacteria from breast milk [149] to digest the fibers and have during this period a much different, more "beneficial" gut microbiota [150,151]. Maternal separation, a common early-life stressor, has been shown to cause a significant decrease in fecal lactobacilli on day 3 post separation, returning to normal by day 7 [152]. It is suggested that early-life stress might have long-term effects on the microbiome [153]. Analysis of the 16 S rRNA diversity in adult rats exposed to maternal separation for 3 h/day from post-natal days 2–12 reveal a significant and permanently altered fecal microbiome, when compared to nonseparated control animals [154].

64.32 Psychological Stress Impairs Microbiota

Psychological stress has long been known, both clinically and experimentally, to cause significant bowel problems. In a study published in 1976 the fecal contents of three astronauts were examined during a 5-month period, when housed under significantly stressful conditions isolated in Skylab [155]. Bacteroides fragilis subspecies thetaiotaomicron was found to be significantly increased in all three astronauts investigated. A slightly later similar study in astronauts reports a distinct decrease in the numbers of Bifidobacterium and of Lactobacilli and a substantial increase in numbers of the pathogens E. coli and of Enterobacteria during preparation for flight, particularly significant within the period immediately before take-off. The numbers of potentially pathogenous Enterobacteria and Clostridia were substantially increased and numbers of Lactobacilli decreased also after the flight. Other studies at the same time conclude that preparation for flights is associated with about 50% reduction in beneficial bacteria, lactobacilli and Bifidobacteria [156]. A detailed analyses of the microflora of 24 Russian astronauts during preparation for flight performed a few years later reported dramatic reductions in various Lactobacilli and significant increases in potentially pathogens [157]. The composition of intestinal [157], oral [158,159] and nasal [158] microbiota was significantly deranged after spaceflights, changes that remained at least for weeks after spaceflights [160], and most likely also for months if not years. See further a recent review [161]. Another interesting study collected saliva samples and fecal samples from 23 healthy undergraduate students during two separate 1-week periods: during the beginning of semester (low-stress baseline condition) and during the first week of exams (high-stress condition). The density of microbes in feces fell in connection with exams from a baseline level of 6×10^7–1×10^7 and remained at this low level during the following 5 days [162].

64.33 Physical Exercise Increases Microbiota Numbers and Diversity

Numerous studies report that physical activity decreases the risk of many chronic diseases and increases longevity. Current US, UK, Australian, and WHO guidelines recommend that significant health benefits can be obtained through about 150 min of moderate activity or 75 min of vigorous activity per week – see further a recent review [163]. Large meta-analyses of cohort studies have reported an app 30% difference in mortality when comparing groups with the lowest and highest amount of physical activity [164,165]. Both volume and intensity of physical exercise have been shown to exert significant influence on gastrointestinal health status. It is demonstrated that exercise reduces the transient time of foods in the gastrointestinal tract, hereby reducing the prolonged contact of pathogens with the gastrointestinal mucus layer and also with circulatory system [166]. Exercises have been shown to have capacity to change gut microbiota diversity both quantitatively and qualitatively and a significant increase of butyrate concentrations is reported in animals after voluntary running exercise [167]. A recent study

in elite rugby players reports significant increases in gut microbiota richness and diversity after physical exercise [168].

It is clearly demonstrated that the diversity of gut microbiota correlates positively with protein intake and creatine kinase concentrations, suggesting that diet and exercise are drivers of biodiversity in the gut. As expected, athletes and controls differ significantly in levels of plasma creatine kinase (a marker of extreme exercise), as in levels of inflammatory and metabolic markers. Furthermore, athletes are shown to have significantly higher diversity of gut microorganisms, representing 22 distinct phyla, which in turn positively correlate with protein consumption and creatine kinase. These results provide evidence for a beneficial impact on gut microbiota diversity of exercise, but it is most likely also influenced by the better diet, often rich in fibers characteristic to elite athletes. For further information – see recent review [169].

64.34 Exercise Has Positive and Negative Effects on Immunity Depending on Its Intensity

Exercise might though have both positive and negative effects on immune function and also health, much depending on intensity. Regular moderate-intensity exercise enhances immune functions significantly above those typically found in sedentary individuals [170]. These functions include the potentiation of T-cell-mediated immunity, natural killer (NK) cell cytotoxicity, proinflammatory cytokine production, and a stronger Th1 reaction as demonsdtrated both in human and animal models. Very prolonged strenuous bouts of exercise with periods of intensive, very strenuous training and strong competition may, however, impair immune functions and increase susceptibility to acute disorders such as upper respiratory tract infections (URTI) by decreasing saliva secretory immunoglobulin A (S-IgA) secretion, NK-cell activity, and proinflammatory cytokine production. Comparisons were recently made between patients, who reported that they exercised 3–6 h/week (LOW), 7–10 h/week (MED) or 11 or more h/week (HIGH). The HIGH and MED groups had more URTI episodes than the LOW group (2.4 ± 2.8 and 2.6 ± 2.2 vs. 1.0 ± 1.6, respectively: $P < 0.05$) [171]. The HIGH group demonstrated approximately threefold higher levels of interleukin (IL)-2, IL-4 and IL-10 (all $P < 0.05$) in antigen-stimulated whole blood cultures compared to the LOW group while the MED group showed a twofold higher IL-10 levels than the LOW group ($P < 0.05$) [170]. Although to my knowledge no studies exist on alterations in composition of microbiota in immediate connection with strenuous exercise, it is likely that increasing load of exercise is accompanied by increasing exhaustion also of the microbiome.

64.35 Postprandial Inflammation a "Deadly" Threat to Long-Term Health

Postprandial lipemia has emerged as a potential candidate to induce postprandial inflammation. It is well demonstrated that ingestion of a high-fat meal causes

systemic increases in a wide range of inflammatory mediators. Frequent episodes of postprandial inflammation has for years been recognized as a key factor behind the development of arteriosclerosis [172] and various other chronic diseases, especially metabolic syndrome [173], diabetes [174], and hepatosteatosis [171]. Every meal rich in fat is associated with significant derangement of microbiota [27], cascades of markers of inflammatory and oxidative stress [175], particularly tumor necrosis factor-α (TNF-α) [176] and significant endothelial dysfunction [177]. Plasma endotoxin levels were studied in 12 healthy men (20–58 years, mean age: 32 years) after exposure to no meal, three cigarettes, a high-fat meal, or a high-fat meal plus three cigarettes [176]. The high-fat meal with or without cigarettes, but not the no meal or only smoking, reduced significantly ($P < 0.05$) the plasma endotoxin neutralization capacity – an indirect measure of endotoxin exposure The levels of endotoxin/plasma increased with a mean of 50% ($P < 0.05$) and remained significantly elevated for about one and a half-hour, while the triacylglycerol concentrations remained statistically significantly elevated as long as 4 h after the meal [176]. This study provides strong support to the hypothesis of endotoxemia and postprandial inflammation as major contributors to endothelial activation and to the development of atherosclerosis. It is also observed that simultaneous intake of sugars significantly potentiates the postprandial inflammation induced by a high fat meal [177]. The inflammatory responses of the vascular endothelial cells are shown to vary directly and much in parallel to the patient's postprandial serum triglyceride level and waist circumference [178].

64.36 Abdominal/Visceral Obesity Enhances Postprandial Inflammation

Visceral obesity was extremely rare among our forefathers and remained so until only a few decades ago. When anthropometric studies using NMR were performed in 54 otherwise healthy female volunteers with BMI ranging from 19 to 57 kg/m^2, it was demonstrated that visceral fat content can vary from only a few ml in lean individuals to over 6 L in morbidly obese [179]. A strong correlation exists between visceral amount of fat, waist circumference and waist-to-hip ratio [179]. It is of the greatest interest that when in stress, visceral adipocytes will per time unit, compared to subcutaneous fat cells, secrete significantly more of free fatty acids and also about three times as much of proinflammatory factors such IL-6 and PAI-1 per gram tissue, observations that might well explain the high risk of acute disease episodes in individuals with visceral obesity [180]. As a matter of fact, the stress-induced load on the vascular endothelium and particularly those the brain, heart and lungs can be extreme, as proinflammatory and procoagulant molecules can vary up to 1000 times in blood concentrations. Observations such as these provide strong support to what has been called the "portal theory," proposing that the liver when exposed to larger amounts of free fatty acids and proinflammatory factors, released from visceral depots of fat into the portal vein especially in obese patients, promotes development of liver steatosis, hepatic insulin resistance, and enhances the development of metabolic

syndrome, and subsequent development of type 2 diabetes [181]. Dysbiosis and metabolic endotoxemia is strongly associated with obesity and insulin resistance both in mice and humans, supporting the strong linkage between gut microbes, gut barrier function, acute and chronic inflammation, adipose tissue inflammation, endothelial inflammation and dysfunction, diet-induced obesity, chronic inflammation and insulin resistance and various chronic diseases.

64.37 Postprandial Inflammation Are Induced by Long-Chain but Not Medium-Chain Fatty Acids

The metabolism in the body of consumed MCFAs (C6–C12) is fundamentally different from that of long-chain fatty acids (LCFAs) (C12–C21) – observations that have not yet received enough interest. Medium-chain triglycerides (MCT) are, much in contrast to long-chain triglycerides (LCT), much more readily hydrolyzed. MCFAs are known to be absorbed from the small intestine by a more direct and much more rapid pathway, the portal vein than that of LCFAs. Since several decades ago it is well known that MCTs undergo a rapid hydrolysis by the gastric, salivary or pancreatic lipases, most likely due to much better solubility and motility of the MCT lipid droplet. MCFAs are therefore rapidly transported as nonesterified fatty acids into the portal blood stream to reach the liver, while LCFAs after long-lasting transport as chylomicrons via the thoracic duct and after hours remaining in the general circulation are redistributed as LCTs by hepatic lipoproteins to nonhepatic tissues – see References [182,183] and Figure 64.1 for further detail.

The clinical effects of chain length were studied in a most interesting experimental study. Wale Wistar rats were fed isocaloric high-fat diets containing triacylglycerols composed of either MCFAs or LCFA. Insulin sensitivity was

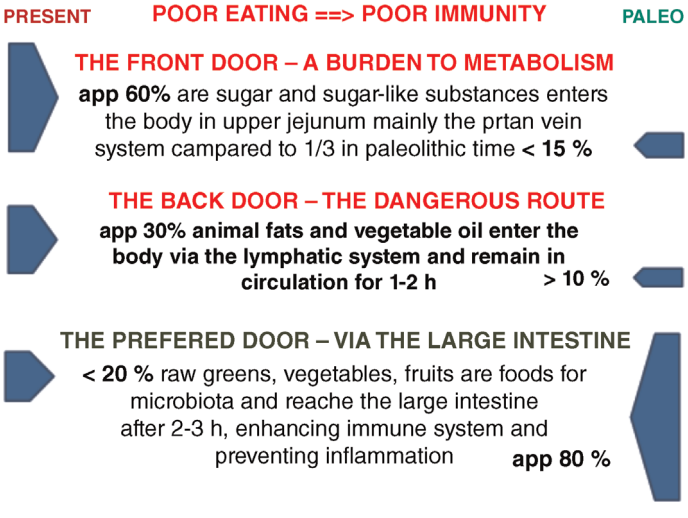

Figure 64.1 Comparing overview of eating habits and immune system.

demonstrated to already after 4 weeks be reduced by 30% in the LCFA group, while it remained nonaffected in the MCFA group [184]. Triacylglycerol concentrations in muscle were higher in both the high-fat groups in comparison to controls. No diet-induced changes were found in acyl-CoA oxidase (ACO) activity (liver and muscle) in the MCFA group, while feeding LCFAs significantly raised carnitine palmitoyltransferase activity. It was concluded that the chain length of saturated fatty acids clearly affect whole-body insulin sensitivity and mitochondrial fatty acid uptake even in absence of obesity. It was also observed that MCT compared to LCT feeding resulted in lowered fasted and post-prandial triglyceride concentrations [184]. Feeding sows with diets containing 15% MCTs resulted in a significantly lower mortality of newborns and promoted development, particularly of underweight piglets [185,186].

64.38 Reduced Intake of LCFAs and Increased Intake of MCFAs Good for Microbiota and Health

Numerous studies have demonstrated significant beneficial impacts of feeding MCFAs on both composition of the intestinal microbiota and inhibitory effects on bacterial concentrations in the digesta, mainly of Salmonella and coliforms. Apart from the specific nutritional and metabolic effects of MCTs and MCFA, their rapid digestion, passive absorption and obligatory oxidation, provide these fatty acids with especially strong immunomodulary effects. While LCTs and LCFAs have meat and dairy as their dominating food source, MCTs and MCFAs are typical plant fats. The content of thesefats is especially high in coconut oil – caprylic acid (C8), 3.2–15% of capric acid (C1), and 41–56% of lauric acid (C12). High contents of caprylic (2.4–6.2%), capric (2.6–7.0%), and lauric acid (41–55%) are also found in palm kernel oil. Cuphea seeds (family of loosestrife) have a broad species-dependent diversity in MCFAs. Oils from Cuphea seeds are known for their extraordinarily high content of MCFAs; Cuphea lanceolata and Cuphea ignea oils containing over 80% capric acid and are often used for nutrition of domestic animals, particularly piglets [186].

This far too few studies are undertaken in humans. One study reports impressive effects in patients with severe hypertriglyceridemia after 7-day treatment with a formula diet rich in omega-3 fatty acids and medium-chain triglycerides: plasma triglycerides decreased from a mean of 1601–554 mg/dL ($P < 0.05$), total cholesterol levels reduced from 417 to 287 mg/dL ($P < 0.001$), and slight decreases also observed in fasting glucose (−8%) and uric acid levels (−12%) [187]. Significant improvements of supplementation of MCTs och MCFAs are also reported in conditions such as:

- Obesity with significantly reduced body weight, waist line and insulin resistance [188,189]
- Mild to moderate dementia in Alzheimer [190] – improved cognition without adverse effects, and improvements in adrenergic or symptomatic responses to hypoglycemic
- Type 1 diabetic patients [191]

- Premature aging and arteriosclerosis [192]
- Inherited cardiomyopathy [193,194]
- Chronic pancreatitis [195]

64.39 Gut Reconditioning – An Important Tool to Maintain Optimal Health

Supplementing live bioactive bacteria constitutes in addition to eating large amounts of raw plant fibers a powerful instrument to control inflammation and protect health. It is important to stress that only a small minority of bacteria sold as probiotics on the market have any significant probiotic clinical effects, even if they sopmetimes carry the same name as one demonstrated to be effective. Only a few products on the market have done proper preclinical and clinical studies – the three leading being, in addition to my own synbiotic product, Synbiotic 2000 – see below – are Lactobacillus GG (Valio Ldt), Lactobacillus reuteri (Biogaia Ltd), and VSL 3 (Sigma-Tau Ltd.). Exciting results are obtained when probiotics, which are properly tested preclinically; *in vitro*, in experimental animals are tried in controlled clinical trials. About two dozens human controlled studies, most of them published in the last few months are presented below. They demonstrate statistically significant and impressive clinical effects: improved gut colonization and immune system [196], reduced allergic manifestations [197], reduced risk of ADHD [198], reduced disease activity in rheumatoid arthritis [199], reduced clinical symptoms and improved quality of life in colorectal cancer survivors [200], reduced diarrhea in children with tropical diarrhea [201], clinical improvement in full-term infants with critical illness [202], improved safety and clinical effects in very low-birth-weight infants (VLBW) [203], reduced translocation and inflammation in HIV patients [204], reduced insulin sensitivity, blood lipids, and inflammation in metabolic syndrome [205], relief of symptoms in irritable bowel syndrome (IBS) [206,207], improved eradication of *Helicobacter pylori* when used as supplement to antibiotic therapy [208], reduced inflammation in CD [209], reduced negative effects when exposed to hepatotoxins and carcinogens [210], reduction in fatty infiltration and inflammation in non-alcoholic fatty liver disease (NAFLD) [211], reduced accumulation of urea in chronic kidney disease [212], reduced inflammation in dialysis patients [213], increased reduction of uremic waist products in patients undergoing renal dialysis [214], reduced number of days with URTIs [215,216], reduced degree of inflammation in cystic fibrosis (CF) [217], and prevention of toxic effects of environmental toxic metal exposure [218] – just to mention a few of very many nteresting studies presented in the litterature.

Here follows brief summaries of these selected studies.

64.39.1 Allergies

Improved gut colonization and development of the immune system – 241 mother-infant pairs with history of allergic disease and atopic sensitization were randomly

assigned to receive either (1) *Lactobacillus rhamnosus* LPR and *Bifidobacterium longum* BL999 (LPR + BL999), (2) *L. paracasei* ST11 and *B. longum* BL999 (ST11 + BL999), or (3) placebo, beginning 2 months before delivery and continuing during the first 2 months of breast-feeding [216]. Altogether 205 infants completed the follow-up up to 24 months and were included in the analyses. The risk of developing eczema during the first 24 months of life was significantly reduced in infants of mothers who received LPR + BL999 ($P < 0.001$) and ST11 + BL999 ($P < 0.001$), the odds ratios (ORs) for chronically persistent eczema described to be 0.30 ($P = 0.016$) and 0.17 ($P = 0.003$), respectively [196].

Reduced allergic manifestations –48 patients were randomized to receive for 12 weeks a combination of two probiotics: *Lactobacillus salivarius* LS01 and *Bifidobacterium breve* BR03 or maltodextrin as placebo and studied at baseline, at the end of therapy, and 2 months later [197]. The patients receiving probiotics showed a significant improvement in clinical parameters, Severity Scoring of Atopic Dermatitis Index (SCORAD) ($P < 0.0001$) and in Dermatology Life Quality index (DLQ) ($P = 0.021$). The probiotics reduced significantly microbial translocation ($P = 0.050$), immune activation ($P < 0.001$), improved T-helper cell – regulatory T cell (Treg) ($P = 0.029$) and Th1/Th2 ($P = 0.028$) ratios. None of these changes were observed in the placebo group [197].

64.39.2 ADHD

Reduced risk of developing/elimination of ADHD – 75 infants were randomized to receive *L. rhamnosus* GG (ATCC 53103) or placebo during the first 6 months of life and were thereafter followed for 13 years [198]. The children were reinvestigated at the age of 13 years by specialist in child neurology or child psychiatry. ADHD and Asperger's syndrome (AS), based on ICD-10 diagnostic criteria, were found in 6/35 (17.1%) of the children in the placebo-treated and in *none* in the perinatally probiotic-treated children ($P = 0.008$). The mean numbers of *Bifidobacterium* species bacteria in feces during the first 6 months of life was found to be significantly lower in the children who developed ADHD and AS – 8.26 (1.24) log cells/g compared to healthy children 9.12 (0.64) log cells/g; ($P = 0.03$) [198].

64.39.3 Autoimmune Diseases

Reduction in disease activity in Rheumatoid arthritis – 46 female patients with established rheumatoid arthritis (RA) for more than 1 year, and on stable medication for at least 3 months, were in a randomized double-blind clinical trial randomly allocated to receive for 8 weeks either 10^8 colony-forming units (cfus) of *L. casei* 01, or a placebo. Twenty-two patients received the probiotic and 24 patients the placebo [199]. *L. casei* 01 supplementation decreased significantly serum high-sensitivity C-reactive protein (hs-CRP) levels, and reduced tender and swollen joint counts, and improved global health (GH) score and Disease activity score-28 (DAS28) ($p < 0.05$). Significantly more patients in the *L. casei* 01 group, at the end of the study, as based on the European League Against Rheumatism (EULAR) criteria, demonstrated clinical response to the probiotic treatment ($P < 0.01$). Statistically significant differences in favor of the probiotic

group were also demonstrated in activity of IL-10, IL-12, and TNF-α ($P < 0.05$) [199].

64.40 Cancer

Reduction of bowel symptoms and improving quality of life in colorectal cancer survivors – A double-blind, randomized, placebo-controlled trial was undertaken with 32 participants receiving twice daily for 12 weeks Lacidofil (Institut Rosell's *L. helveticus* and *L. rhamnosus.*) and 28 participants receiving placebo [200]. Lactofil did significantly decrease the numbers of patients suffering from irritable bowel-like symptoms ($P = 0.03$), improve cancer-related quality of life ($P = 0.04$), and improve fatigue-related quality of life ($P = 0.02$) as well as patients' health-9 (PHQ-9) scores ($P = 0.01$) [200].

64.41 Childhood Diarrhea

Reducing tropical childhood diarrhea – An open-labeled, randomized controlled trial was undertaken in 2000 children with acute severe watery diarrhea, aged between 6 months and 5 years [201]. The children received for 5 days either *Lactobacillus* GG (LGG) in dose of 10 billion cfus/day or no probiotic medication. Median duration of diarrhea was significantly shorter in children in LGG group (60 vs. 78 h, $P < 0.001$) and the consistency of stool returned to normal significantly faster than in the control group (36 vs. 42 h, $P < 0.001$). Furthermorre, significant reduction in the average number of stools per day was observed in the treated children ($P < 0.001$). The benefits of probiotics were also seen rotavirus-positivite children [201].

64.41.1 Critical Illness

Improved safety and clinical effects in critically ill neonates – A double-blind, randomized controlled trial was conducted in 100 full-term critically ill infants, assigned at birth to duriong 8 days three times daily receive a total of 30 billion of L casei, *L. acidophilus*, *Bacillus subtilis*, and *Enterococcus faecalis* or placebo [206]. Significant reduction in the rate of nosocomial pneumonia (18 vs. 36%) and in multiple organ dysfunction syndrome (6 vs. 16%) was observed in the probiotic-treated group compared with the placebo group ($P < 0.05$). Significantly higher levels of IgA than the placebo group was observed in the probiotic-treated infants ($P < 0.05$). Furthermore, a significantly reduced hospital stay was reported in the probiotic-treated group ($P < 0.05$) [202].

Prevention or reduction of disease activity in necrotizing enterocolitis (NEC) in VLBW – A multicentre, prospective, randomized, controlled trial was conducted in 400 VLBW infants, who during 8 weeks and until discharge or death were supplemented either *B. lactis*, the prebiotic inulin, or a combination of *B. lactis* and inulin (= synbiotics) [203]. Maternal exposure to antibiotics increased significantly the risk of the babies developing NEC. The rate of NEC was lower

in both *L. lactis*-treated (2.0%) and *L. lactis* plus inulin-treated (4.0%) compared to only inulin (12.0%) or placebo (18.0%) treated children ($P < 001$). The time to reach full enteral feeding was significantly shorter ($P < 0.001$), the rate of clinical nosocomial sepsis was lower ($P = 0.004$), the stay in the neonatal intensive care unit shorter, ($P = 0.002$), and the mortality rate lower ($P = 0.003$) in the infants receiving active treatments compared to controls [203].

64.41.2 HIV – Virologic Suppression

Reduce translocation and inflammation in HIV patients – double-blind, randomized, placebo-controlled trial was conducted in 44 nonconsecutive HIV-1-infected patients with viral load of <20 copies/mL during the last 2 years, who received either Saccharomyces boulardii or placebo [204]. A significant decrease in lipopolysaccharide-binding protein (LBP) was observed (57.9 vs. 6.2% $P = 0.002$) and also in IL-6 (−0.60 vs. +0.78 pg/mL, $P = 0.002$) [204].

64.41.3 Metabolic Syndrome and Diabetes

Reduced insulin sensitivity, blood lipids, and inflammation – A probiotic composition consisting in 112.5×10^9 cfus of three strains of bifidobacteria (*B. longum*, *B. infantis*, and *B. breve*), four strains of lactobacilli (*L. acidophilus*, *L. paracasei*, L. delbrueckii subsp. bulgaricus, and *L. plantarum*), and one strain of *Streptococcus salivarius* subsp. thermophilus. (VSL 3) with or without added omega-3 fatty acid was tried in 60 overweight (BMI > 25), healthy adults, aged 40–60 years, who for 6 weeks received either placebo, only omega-3 fatty acid, only probiotic VSL 3, or combination of omega-3 and VSL 3 [205]. Patients with low HDL, higher insulin resistance, and high hsCRP had significantly lower total lactobacilli and bifidobacteria count and higher *E. coli* and bacteroides count. VSL 3 supplementation resulted in significant reductions in total cholesterol, triglyceride, LDL, and VLDL, and increase in HDL ($P < 0.05$). The VSL 3 treated patients demonstrated significantly improved insulin sensitivity ($P < 0.01$), decreased hsCRP, and an improved gut microbiota. Also the Omega-3 treated demonstrated significant effect on insulin sensitivity and hsCRP, but no effects on gut microbiota. Combination of VSL 3 with omega-3 fatty acid attenuated the effects on HDL, insulin sensitivity, and hsCRP [205].

64.41.4 Gastrointestinal Disorders

Relief of symptoms in patients with irritable bowel syndrome (IBS) – 50 patients suffering from IBS were randomized to receive daily for 4 weeks either *L. casei rhamnosus* LCR35 in a dose of 6×10^8 cfus (n = 25) or placebo (n = 25) [206]. No general improvements were reported, but the subgroup dominated by diarrhea demonstrated significant improvement with LCR35 treatment (reduction with 37%) compared to placebo (freduction with 3%) and also significant reduction in abdominal pain severity score (reduction with 36%). On the other hand, a slight improvement in favor of placebo was observed in patients with severe constipation; more reduced with placebo reduction with 41%) than in the LCR35-treated

(reduction with 20%) [206]. Another randomized, double-blind, placebo-controlled trial was undertaken in adult patients with symptomatic IBS with a probiotic composition consisting in *L. rhamnosus* NCIMB 30174, *L. plantarum* NCIMB 30173, *L. acidophilus* NCIMB 30175, and *Enterococcus faecium* NCIMB 30176 or placebo (1 mL/kg/day), administered for 12 weeks [207]. Total 152 patients completed the study. The mean reduction in IBS scores was 63.3% in the probiotic-treated versus 28.3% in placebo ($P = 0.019$). No improvements in IBS quality of life scores could, however, be seen [207].

Improved clinical effects as supplement to antibiotic therapy to eradicate H. pylori. – A multicenter, prospective, randomized, placebo-controlled, and double-blind study in totally 650 patients, who received for 14 days, twice a day, at least 2 h prior to or after the administration of antibiotics, capsules with probiotics containing either 10^8–10^{10} of *L. rhamnosus* GG (LGG®) and *Bifidobacterium (*BB-12®) or placebo capsules [208]. A significantly larger proportion of successfully cured patients were observed with probiotics added to the antibiotic treatment than without (87.38 vs. 72.55%; $P < 0.001$). The average intensity for symptoms induced by the antibiotic therapy was significantly reduced when probiotics were added (0.76 vs. 0.55; $P < 0.001$). Supplementation of probiotics reduced in average 7 of the following 10 symptoms: presence and intensity of epigastric pain, bloating, flatulence, taste disturbance, loss of appetite, nausea, vomiting, heartburn, rash, and diarrhea [208].

Significant reduction of inflammation in CD – The potential effects of *B. longum* CECT 7347 in children with newly diagnosed CD were evaluated in a double-blind, randomized, placebo-controlled trial in 33 children, who received daily for 3 months in addition to a gluten-free diet either10^9 cfus *B. longum* CECT 7347 or placebo [209]. The *B. longum* CECT 7347 treated demonstrated compared to placebo greater height percentile improvements ($P = 0{\cdot}048$), decreased peripheral $CD3^+$ T lymphocytes ($P = 0{\cdot}004$), and slightly reduced TNF-α concentration ($P = 0{\cdot}067$). Significant decreases in $CD3^+$ ($P = 0{\cdot}013$), in human leukocyte antigen (HLA)-DR^+ T lymphocytes ($P = 0{\cdot}029$), and slightly reduced TNF-α concentration ($P = 0{\cdot}085$) were also reported in the *B. longum* CECT 7347-treated patients [209].

64.41.5 Liver Disease

Reduced uptake of hepatotoxins and carcinogens – 90 healthy young men were enrolled in a study aimed to determine whether administration of probiotic bacteria could block the intestinal absorption of a dangerous poison aflatoxin B(1) and reduce urinary excretion of aflatoxin B(1)-N(7)-guanine (AFB-N(7)-guanine), a marker of aflatoxin exposure [210]. The patients received for 5 weeks twice daily either a mixture of *L. rhamnosus* LC705 and *Propionibacterium freudenreichii* subsp. shermanii strains or a placebo. The percentage of samples with negative AFB-N(7)-guanine values were after the 5-week intervention higher in the probiotic group than in the placebo group period ($P = 0.052$), and the decrease in urinary AFB-N(7)-guanine was statistically significantly reducecd in the probiotic-treated group compared to placebo ($P < 0.05$). The observed reduction was as high as 36% after 3 and 55% after 5 weeks – the geometric means for the

probiotic and placebo groups reported to be 0.24 and 0.49 ng AFB-N(7)-guanine/mL respectively ($P = 0.005$) [210].

Reduced fatty infiltration in NAFLD – A double-blind clinical trial supplementing a probiotic composition consisting in 112.5×10^9 cfus of three strains of bifidobacteria (*B. longum*, *B. infantis*, and *B. breve*), four strains of lactobacilli (*L. acidophilus*, *L. paracasei*, *L. delbrueckii* subsp. *bulgaricus*, and *L. plantarum*), and one strain of *Streptococcus salivarius* subsp. *thermophilus*. (VSL 3) or placebo, supplemented to obese children with biopsy-proven NAFLD [211]. Fourty-four patients (22 VSL 3 and 22 placebo) completed the study. At baseline, moderate and severe NAFLD were present in 64% and 36% of placebo children and in 55% and 45% of VSL 3 children. The probability that children supplemented with VSL 3 had in comparison none, light, moderate, or severe fatty liver at the end of the study was 21 versus 0%, 70 verus 7%, 9 versus 76%, and 0 versus 17% group ($P < 0.001$). No differences were detected in triglycerides, homeostasis model assessment (HOMA) and alanine transaminase (ALT) while BMI decreased and glucagon-like peptide 1 (GLP-1) and activated GLP-1 (aGLP-1) increased in the VSL 3 group ($P < 0.001$ for all comparisons) [211].

64.41.6 Renal Disease

To reduce the accumulation of urea in chronic kidney disease – Patients with chronic kidney disease (CKD) show an increase in bowel aerobic bacteria that produce uremic toxins and decreased anaerobic bacteria as bifidobacteria and lactobacillus [212]. Two different strains of *L. casei shirota* (LcS) were tried for 8 weeks in CKD patients in aimple randomized, controlled clinical trial in two doses: Group A: 8×10^9 cfu and group B: 16×10^9 CFU. The larger dose was most effective, inducing a statistically significant no less than 10 times reduction in blood urea concentrations [212].

To reduce inflammation in dialysis patients – Peritoneal dialysis (PD) patients received daily for 6 months one capsule of a probiotic composition containing 10^9 cfu Bifobacterium bifidum A218, 10^9 cfu Bifidobacterium catenulatum A302, 10^9 cfu *B. longum* A101, and 10^9 cfu *L. plantarum* A87, or maltodextrin as placebo [213]. 39 patients completed the study. The serum levels of proinflammatory cytokines TNF-α, IL-5, IL-6, and endotoxin were significantly decreased after 6 months of treatment, while serum levels of anti-inflammatory cytokine IL-10 were significantly increased, whereas no significant changes in levels of serum cytokines and endotoxin were observed in the placebo group. Most importantly, the residual renal function was well preserved after 6 months in patients receiving probiotics [213].

To reduce uremic waist products in patients with in patients with chronic kidney disease – In a 6-month crossover trial 46 outpatients were supplemented a probiotic formulation consisting in a gel capsule containing a mix of L. acidophilus KB27, B. longum KB31, and S. thermophilus KB19, totally 1.5×1010 CFU/day [214]. Significant improvements were observed: enhanced well-being (quality of life – QLT) ($P < 0.05$), absence of serious adverse effects and impressive reductions in blood urea nitrogen (BUN) ($P < 0.05$ – BUN levels reported to be decreased by 63%, creatinine levels by 43% and uric acid levels by 33%. The improvement in QOL was estimated to be no less than 86% ($P < 0.05$) [214].

64.41.7 Respiratory

To reduce the number of days with URTI in academically stressed students – Randomized, double-blind, placebo-controlled study examined the effect of three potentially probiotic bacteria on the proportion of healthy days over a 6-week period in academically stressed undergraduate students (n = 581) who received one of the following probiotics; Lb helveticus R0052, *B. longum* ssp. infantis R0033, *B. bifidum* R0071 or placebo [215]. The percentage of participants reporting ≥ 1 day of cold/flu during the 6-week intervention period was significantly lower only with *B. bifidum* ($P < 0{\cdot}05$), while no effects were observed with supplementing *B. infantis* or *L. helveticus* [215]. The efficacy of daily dietary consumption of *L. brevis* KB290 (KB290) to prevent against influenza also in elementary schoolchildren, was studied in an open-label, parallel-group trial conducted 8-week periods [216]. The incidence of influenza was 16% with probiotic protection and 24 without ($P < 0{\cdot}001$). The reduction in the incidence of influenza by KB290 consumption was especially pronounced in nonvaccinated individuals [216].

To reduce inflammation in CF patients – 22 children with CF children were enrolled in the study. The CF children were found to suffer severe intestinal dysbiosis with significant reductions in *Eubacterium rectale*, *Bacteroides uniformis*, *Bacteroides vulgatus*, *B. adolescentis*, *B. catenulatum*, and *Faecalibacterium prausnitzii* [217]. Significant elevations in fecal calprotectin (CLP: 184 vs. 52 ± 46 μg/g, $P =< 0.01$) and in rectal nitric oxide (rNO) levels (184 vs. 52 ± 46 μg/g, $P =< 0.01$)) were reported in children with CF compared to healthy controls. The degree of dysbiosis was especially increased in children with CF, who were taking antibiotics. A significant correlation was observed between the treated groups in favor of the probiotic-treated group both in degree of inflammation and increase of microbial richness of intestinal microbiota. Administration of 6×10^9 cfus of Lactobacillus GG (LGG) reduced significantly fecal CLP and restored, at least partially, the intestinal microbiota [217].

64.41.8 Toxic Exposure

To prevent effects of environmental toxic metal exposure – A study in Tanzania investigated the efficacy of probiotic foods to prevent consequences of high local toxic metal exposures. A group of 44 school-aged children was followed over 25 days, and 60 pregnant women were followed over their last two trimesters until birth [218]. A yogurt containing 10^{10} CFU *L. rhamnosus* GR-1 per 250 g was administered, while control groups received either whole milk or no special foods. Changes in blood metal levels were assessed, and the gut microbiomes of the children were profiled by analyzing 16 S rRNA sequencing via the Ion Torrent platform. The children and pregnant women at the beginning of the study found to have significantly higher blood levels of lead and mercury when compared to age- and sex-matched Canadians. Consumption of probiotic yogurt provided a statistically significant tool to protect against increases in blood levels of both mercury (3.2 nmol/L; $P = 0.035$) and arsenic (2.3 nmol/L; $P = 0.011$) particularly in the pregnant women, a trend, which was not statistically significant in the children, at least not after only treated for 25 days [218].

64.42 Fecal Microbiota Transplantation (FMT) – A Giant Step Forward

Reconditioning of the gut by transfer of microbiota from a healthy individual to an often very sick patient, marks a new époque in the history of restitution a healthy gut and attempts to reduce the burden of disease. It is unfortunate that in the Western world most, if not all of the donors, also suffer a much reduced microbiota, compared to those still living a rural forefather-like lifestyle such as the Hadzas [29], the Burkina Fasons [32], the Yanomamis [34], whose microbiota demonstrate around 50% higher diversity – and worse, recent data suggest that the deterioration of human microbiota is a continuous process [219]. It seems reasonable to assume that the most effective health-promoting bacteria are already extinct in Western population due to lack of proper foods. Maybe one day such rich stools from groups such as those may be available deep-frozen for FMT. Under all circumstances it will not last long before deep-frozen stools are a reality – to begin with stools from the individual saved already at an early age. It must be emphasized though that the best results from reconditioning of the gut is obtained when combined with a dramatic change in lifestyle and food habits – and that forever. Recent studies demonstrate that it takes less than 24 h to destroy microbiota if the microbes do not receive for them suitable nutrients [220]. For information about recent progress with FMT – please read some recent excellent reviews [221–225].

64.43 Synbiotics – A Less Invasive Alternative

Oral or rectal supplementation of a synbiotic formula offers simple and less cumbersome alternatives – constitutes attempts to produce "synthetic feces."

For the most recent 15 years my personal focus has been on trying:

1) To identify lactobacilli (LAB) on growing plants that might have unique inflammation-reducing abilities, based on the belief that the strongest anti-inflammatory microbes might be extinct in human microbiome.
2) To provide strong fibers with documented ability to serve as substrate for microbial fermentation (favored nutrients for microbes) and in doses of at least 10 g – adding about 40% more fiber to the average fiber consumption, which is very low in Westyerners.
3) To provide large doses of LAB than commonly used (exemption VSL 3).

I took initiative in 1999 to develop and produce a synbiotic formula based on these principles Since 1999, all my efforts in this field have concentrated on a four LAB/four fiber composition, consisting of either a mixture of either 4×10^{10} (40 billion LAB in a Standard version – Synbiotic 2000™) or a mixture of 10^{11} (400 billion, Forte version – Synbiotic 2000 Forte™). From studies of about 500 lactobacillus species (about 200 collected from plants) the following four LAB, which demonstrating unique anti-inflammatory abilities [226,227] were chosen for the composition: *Pediococcus pentosaceus* 5–33:3, *Leuconostoc mesenteroides* 32–77:1, *Lactobacillus paracasei* subsp paracasei 19, and *Lactobacillus plantarum* 2362. To the four LAB was added 10 g of documented bioactive fibers:

4 × 2.5 g of each of the following four fermentable fibers: betaglucan, inulin, pectin and resistant starch, a formula that is currently a product produced by Synbiotic AB, Sweden.

Below is summarized the experience from some of the human randomized controlled studies, using Synbiotics 2000:

To prevent postoperative sepsis in extensive pancreatic surgery – A prospective, randomized, double-blind trial was performed in 80 patients undergoing pylorus-preserving pancreatoduodenectomy (PPPD) who received, twice daily, either Synbiotic 2000™ (2 × 40 billion LAB, i.e., 80 billion LAB/day) or only the fibers in composition from the day before surgery and during the first seven post-operative days [228]. A highly significant difference in infection rate ($P = 0{,}005$) was observed – only 5/40 patients (12.5%) in the Synbiotic 2000-treated group suffered infections (4 wound and one urinary tract infection) in sharp contrast to 16/40 (40%) in the fiber-only group (6 wound infections, 5 peritonitis, 4 chest infections, 2 sepsis, and 1 of each of urinary tract infection, cholangitis, and empyema). The number of infecting microorganisms were also statistically significantly reduced ($P = 0{,}005$) as was the use of antibiotics (mean: Synbiotic 2000; 2 ± 5 days, only fibers; 10 ± 14 days) [228].

To prevent postoperative sepsis in abdominal cancer operations – 45 patients undergoing major surgery for abdominal cancer were randomized into three treatment groups: 1. enteral nutrition (EN) supplemented with Synbiotic 2000 (LEN), 2. EN supplemented with only the fibers in the same amounts (20 g) (20 g) as in Synbiotic 2000™ (FEN) and 3. Standard parenteral nutrition (PN). All treatments lasted for 2 preoperative and 7 days postoperative days. The incidence of postoperative bacterial infections was 47% with PN, 20% with FEN and only 6.7% with Synbiotic 2000-based LEN ($P < 0.05$). The numbers of infecting microorganisms were statistically and significantly reduced. Significant improvements were observed with both Synbiotic 2000 and only-fiber-based treatments (LEN, FEN), in prealbumin, CRP, serum cholesterol, serum endotoxin, and with only Synbiotic 2000 in white cell blood count and in IgA (Han Chun Mao, personal information).

To prevent postoperative sepsis in orthotopic liver transplantation – 66 human orthotopic liver transplant patients were randomized to either receive Synbiotic 2000 or selective bowel decontamination (SBD) [229]. The treatment continued from the day before surgery until 14 days after surgery. The Synbiotic 2000 treatment did almost extricate postoperative sepsis. After 1-month follow-up had only one patient in the Synbiotic 2000-treated group developed an infection – a benign *E. faecalis*-based asymptomatic catheter-induced urinary infection 1/33 (3%) compared to 17/33 (51%) in the SBD-treated patients [229]. The use of antibiotics was on average 0.1 ± 0.1 days in the Synbiotic-treated patients and 3.8 ± 0.9 days in the SBD-treated patients [229].

To reduce infections and complications to severe acute pancreatitis – 62 patients with severe acute pancreatitis (SAP) were supplemented twice daily during the first 14 days after arrival at the hospital with Synbiotic 2000™ (80 billion + 20 g fibers) or the same amounts of fibers (totally 20 g/day) as in Synbiotic 2000™ [230]. 9/33 patients (27%) in the Synbiotic 2000-treated group and 15/29 patients (52%) in the fiber-only treated group developed infections.

8/33 (24%) of the Synbiotic 2000-treated and 14/29 (48%) of the fiber-only treated patients developed SIRS, MOF or both ($P < 0.005$). A total of seven pathogenic microorganisms were detected in the Synbiotic-treated group compared to seventeen in the fiber-only group [230] Another study supplemented Synbiotic 2000 Forte (400 billion Lab + 10 g fibers) from within 24–48 hrs of symptoms of sickness to patients with severe acute pancreatitis and compared to 32 patients on a control formula considered as anti-inflammatory [231]. Synbiotic-2000 Forte treatment lead to a lower infection rate including less pancreatic and peripancreatic necroses; secondary infections (2 vs. 9, $P = 0.0001$), septicemia (2 vs. 7, $P = 0.03$), lower rate of surgical interventions, (3 vs. 12, $P = 0.005$), shorter stay in ICU (8 vs. 16 days $P = 0.05$), shorter hospital stay (23 vs. 36 days, $P = 0.03$), and reduced mortality (0 vs. 17 patients, $P = 0.02$) [231].

To reduce infections and complications to major trauma – Two prospective randomized trials with either Synbiotic 2000™ or Synbiotic 2000 Forte™ were undertaken. In the first study [232] 52 patients were randomly allocated into 4 groups with different commercial nutrition formulas: Group A: Alitraq (Abbott-Ross) B: Nova Source (Novartis) Group C: Nutricomp peptide (*B. braun*) plus Synbiotic 2000) Group D: Nutricomp standard (*B. braun*) plus Synbiotic 2000. Nova Source and Nutricomp peptide did not reduce the levels of proinflammatory cytokines at all, while Alitraq and Nutricomp standard + Synbiotic 2000 significantly down-regulated Il-6, but not Il-8 and TNF- α. The groups containing Synbiotic 2000 demonstrated significant reductions in both total infections and in chest infections; the total number of infections being reduced with about two thirds ($P < 0.005$) and the number of chest infections being reduced to about half ($P < 0.005$) [232]. In a series of studies 65 polytrauma patients were randomized to receive once daily for 15 days following major trauma, either Synbiotic 2000 Forte (400 billion LAB + 10 g of fibers) or maltodextrine as placebo [233–235]. Significant reductions were observed between the groups in the number of deaths (5/35 vs. 9/30, $P < 0{,}02$), severe sepsis (6/35 vs. 13/30, $P < 0.02$), chest infections (19/35 vs. 24/30, $P < 0.03$), central line infections (13/32 vs. 20/30, $P < 0.02$), and days on artificial ventilation (average 15 vs. 26 days). A total of 54 pathogenic microorganisms were cultivated in the Synbiotic treated group compared to 103 in the placebo group. Repeat analyses revealed that serum levels of endotoxin (LPS) were significantly decreased and the time to occurrence ofbloodstream infection significantly prolonged in patients treated with Synbiotic 2000 Forte $P < 0.02$) [233–235].

64.44 Less Suffering for the Patients – Great Savings for Society

Figure 64.2 summerizes the gains in reduced numbers of infections obtained after Synbiotic 2000 treatment in various severe conditions – reductions varying between 60 and 94% depending on disease/trauma/surgical treatment demonstrated. Figure 64.3 summarizes the savings in use of costly antibiotics, savings varying between 80 and 97%, savings on costly artificial respiration of about 20% savings on reduced time in costly ICUs vaying between 14 and 67% and also savings on the average in hospital time varying from 3 to 24% depending on treated condition.

REDUCTIONS IN INFECTIONS/POSITIVE BLOOD CULTURES

Liver transplantation – 66 patients[236]	
Patients with postop. infections	16 => 1 = 94%
Patients with pos. blood cultures	11 => 1 = 91%
Pancreatdoudenectomy for cancer – 80 patients[235]	
Patients with postop. infections	16 => 5 = 69%
Patients with pos. blood cultures	27 => 5 = 82%
Severe pancreatitis – 62 patient[237]	
Patients with infections	15 => 9 = 40%
Patients with pos. blood cultures	17 => 7 = 59%
Severe trauma, treated with synbiotic 2000 standard – 52 patients[239]	
Patients with infections	23/30 (77 %) => 17/35 (49 %)
Severe trauma, treated with synbiotic 2000 Forte – 72 patients[239-241]	
Patients with post-trauma infections	13 => 5 = 62%
Patients with pos. blood cultures	13 => 5 = 62%

Figure 64.2 Reduction in infections/positive blood cultures after Synbiotic 2000 treatment.

REDUCTIONS IN USE OF ANTIBIOTICS, ARTIFICAL RESPIRATION, TIME IN ICUs, AND IN HOSPITAL

Liver transplantation – 66 patients[236]	
Days on Antibiotics	3.8 => 0.1 = 3.7 (97 %)
Days in ICUs	10.2 => 8.8 = 1.4 (14 %)
Days in Hospital	27.9 => 27.8 = 0.1 (3 %)
Pancreatdoudenectomy for cancer – 80 patients[235]	
Days on Antibiotics	10 => 2 = 8 (80 %)
Days in ICUs	6 => 2 = 4 (67 %)
Days in Hospital	22 => 17 = 5 (23 %)
Severe acute pancreatitis – 62 patient[237]	
Days in Hospital	19.7 => 14.9 = 4.8 (24 %)
Severe trauma treated with synbiotic 2000 Forte – 65 patients[239-241]	
Days on Artificial Respiration	24 => 19 = 5 (21 %)
Days in ICUs	41.3 => 27.7 = 13.6 (33 %)

Figure 64.3 Reduction in use of antibiotics, artificial respiration, time in ICUs, and in hospital after Synbiotic 2000 treatment.

64.45 Ecobiological Functions – Same but Different Response Compared to So-Called Biological Drugs

Inflammation is said to involve about 1200 genes and affecting an enourmously wide range of effector molecules; proinflammatory cytokines such as IL-1β, IL-6, TNF-α and IL-18, chemokines such as IL-8, IP-10, MCP-1, MIP-1 and RANTES, MMPs such as MMP-1, -3, -9, and -13, and metabolic proteins such as Cox-1, Cox-2, and iNOS, and many more. The so-called biological drugs are made to target exactly the same genes, but mainly one at the time. Ecobiologicals;

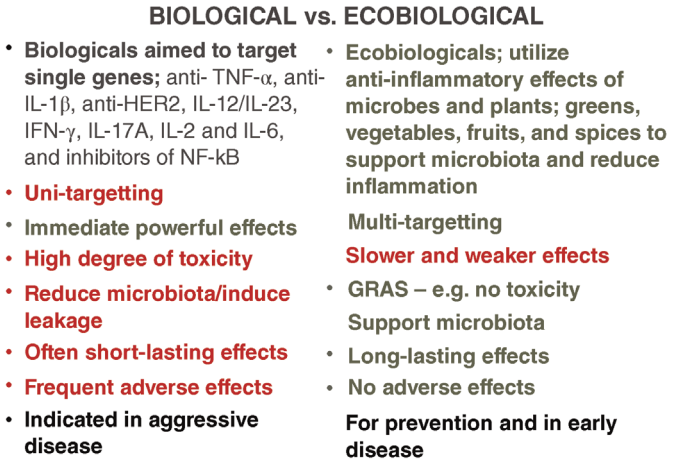

Figure 64.4 Comparison of effects of biologicals versus ecobiologicals.

probiotic bacteria, plant fibers, plant antioxidants and so on produce an accumulated response targeting all the genes much in parallel but slower and weaker (Figure 64.4).

Especially affected are the two special tissues, strongly involved in inflammation; the intestinal mucosa and the vascular endothelium organ, both effective barriers, effective metabolic, effective endocrine, and also important immune organs, both covering similarly wide surfaces: the intestinal mucosa that of a soccer field – greater than 7000 m^2 and consisting in greater than 10 000 billion cells and weighing greater than 1 kg each and both intimately involved in inflammations such as postprandial inflammation [171–185]. The total endothelial tissue of the body, which cover a similarly sized surface, has the unique ability to activate extraordinary many genes and factors involved in inflammation such as VCAM-1, ICAM-1, E-selectin, PDGF, TGF-β, TNF-α, IGF-1, MCP-1, CTGF, Il-6, PAI-1, RAGE, VEGF, ANG II-dependent cell activation factors, type IV collagen expression factors, toll-like stimulatory factors, cell cycle progression factors, and fibronectin [236].

Natural Products as Source of Anti-Inflammatory Drugs

Shivaprasad H. Venkatesha,[1] Bodhraj Acharya,[1] and Kamal D. Moudgil[1,2]

65.1 Introduction

Natural products have been an invaluable resource for drug discovery over centuries [1–5]. Most information on medicinal properties of natural products is based on the traditional systems of medicine such as traditional Chinese medicine (TCM), Ayurveda, and other forms of complementary and alternative medicine (CAM) [6–10]. This knowledge was derived from the use of indigenous natural products, such as crude plant extracts, by local healers/practitioners as recipes for the maintenance of health and treatment of diseases. Subsequently, application of advanced methodologies to natural products research allowed the fractionation of crude extracts and isolation of bioactive molecules from them. This, in turn, paved the way for drug discovery from natural products obtained from plants, microbes, and animals [2,6,10,11].

Over the past few decades, scientific developments in the characterization and quality control, in defining the mechanism of action, and in improving the efficacy and safety of natural products have broadened the scope of natural products research [1–5,12]. Typically, drug discovery from natural products involves the following steps: the screening of natural products using *in vitro* cell culture models and/or *in vivo* experimental animal models for their therapeutic effects; the identification of a lead multi component product and determining its chemical constituents; the screening of bioactive compounds under controlled conditions and studying their mechanisms of action; the refining of drug delivery approaches for selected compounds; and the testing of one or more lead compound(s) in clinical trials in patients with a particular disease [2,10–13]. This approach is similar to the mainstream "forward pharmacology" in which a

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

large library of synthetic compounds is screened to identify a lead compound having the desired functional attributes and then taking it through different steps to final testing in the clinic. In contrast to this, a reverse approach ("reverse pharmacology") is increasingly being applied to natural products, such as medicinal plants in the traditional systems of medicine (e.g., TCM), whose extracts are already known to be effective against various diseases [14,15]. Such products are first thoroughly characterized for their bioactive principles, and then the structure-function relationships and toxicity profiles of select compounds are further improved in the laboratory before testing the modified compound(s) back in a clinical setting.

Natural products also offer an opportunity for multitarget drug discovery [6–11]. The multiplicity of therapeutic targets of natural products is an asset, and it can be viewed in context of multiple bioactive components in a mixture, for example, compounds in an extract from the leaves of a medicinal plant, as well as of more than one target of a compound purified from that mixture. The availability of a well-defined bioactive compound from a natural product offers certain advantages, for example, the ease of both quality control and examination of its mechanism of action, when compared with a crude extract. In some cases, a single bioactive compound can replicate a vital biological activity or therapeutic benefit of the whole extract, and therefore in those situations such a compound can be pursued further for development of a pharmaceutical lead compound/drug. However, there are some likely disadvantages to consider as well. When a bioactive compound is removed from other compounds in the same crude extract, it can display unexpected effects in terms of its tolerability, bioavailability, toxicity, and even biological activity. These effects, in turn, can be attributed to the additive/synergistic versus counterbalancing activity of the accompanying compounds. Awareness of these issues can guide the process of drug discovery to meet the goals of improved therapeutic efficacy coupled with reduced toxicity. In addition, the knowledge of bioactive compounds from different natural products and the use of these compounds in specific combinations can be exploited for developing an effective multitarget natural product for inflammatory diseases [16].

Regarding the source of natural products for drug discovery, different plants, animals, and terrestrial microorganisms have contributed significantly to the pool of products for this purpose [2,6,10,11]. However, the potential of the microorganisms from the marine environment as well as that of underexplored terrestrial microbial species remains to be fully tapped for diversifying the sources of natural products [5,6]. Advancements in biotechnology and other areas of research including, high-throughput screening, combinatorial biosynthesis, metabolic engineering, microarrays, systems pharmacology, and nanotechnology-based drug delivery systems (Figure 65.1) are making a significant impact on the process of drug discovery from natural products [2,4]. Furthermore, hopefully the recent awarding of the 2015 Nobel Prize in Physiology or Medicine to William C. Campbell, Satoshi Ōmura, and Youyou Tu for the discovery of avermectins and artemisinin for anti-parasite therapy

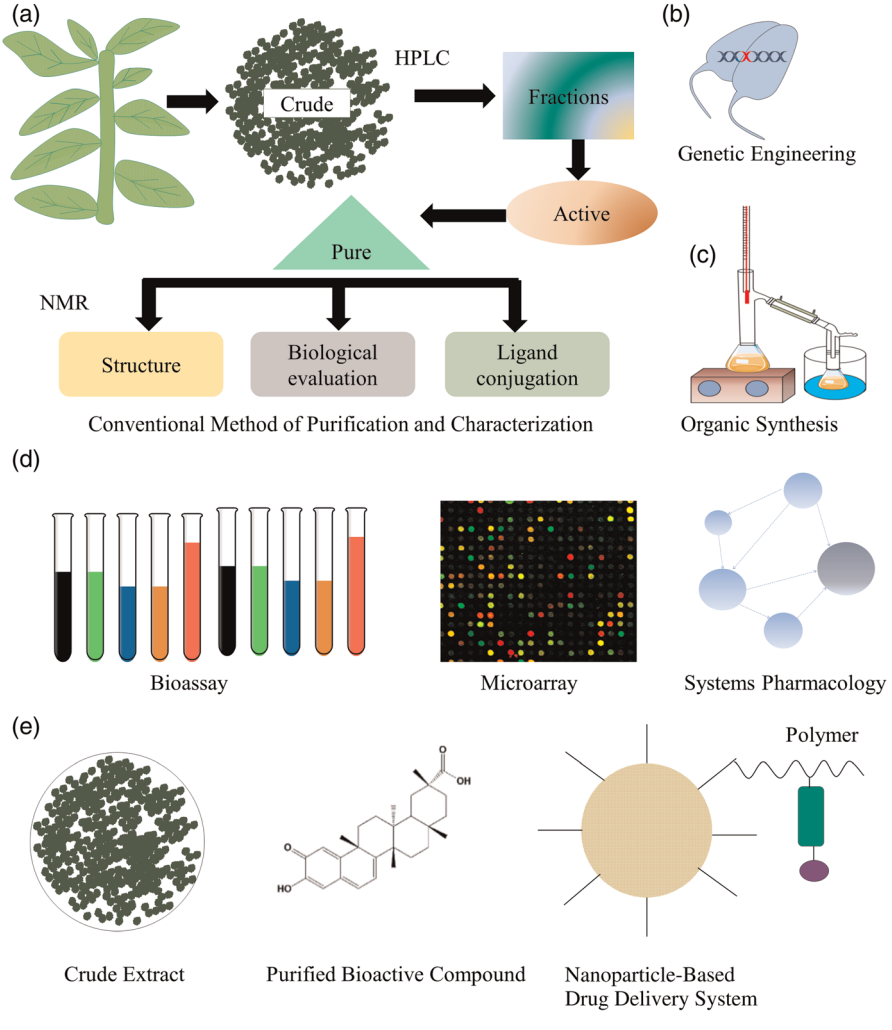

Figure 65.1 Advancements in the methods for the production, characterization, and delivery of natural products. (a) Conventional scheme for the fractionation and purification of bioactive compounds from crude extracts of natural products; (b) genetic engineering; (c) organic synthesis; (d) common screening methods (e.g., bioassays), microarrays, and systems pharmacology; and (e) nanotechnology for delivery of natural products.

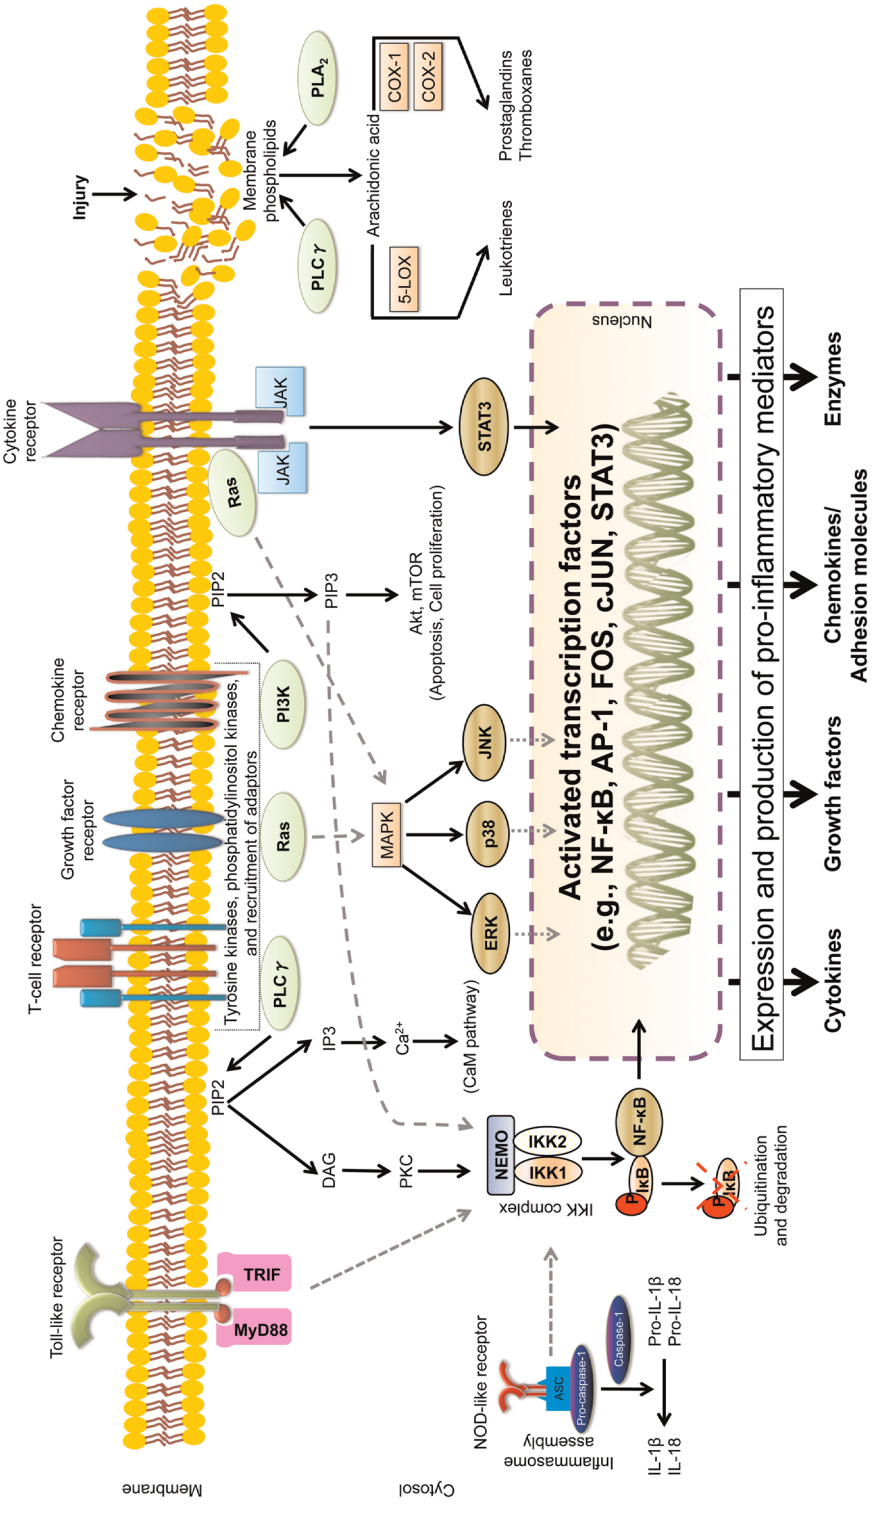
would further rejuvenate interest in, and research efforts into, natural products drug discovery.

In this chapter, we have presented a brief summary of the key pathways involved in the process of inflammation; of natural products as the source of compounds/drugs with anti-inflammatory activity for use in the treatment of inflammatory, autoimmune, and other immune-mediated diseases; and of the

modern approaches for, and recent advancements in, the production, characterization, and delivery of natural products. (Although inflammation is also linked with cancer, but that aspect of natural product therapy is not covered here.)



65.2 Cellular, Molecular, and Biochemical Pathways of Inflammation

Inflammation is a complex process involving a variety of cellular, molecular, and biochemical mediators that are activated/induced in response to inflammatory stimuli. The mechanisms of induction and amplification of the key inflammatory events are briefly described below. Anti-inflammatory drugs, including those derived from natural products, combat inflammation by targeting one or many of these pathways (Figure 65.2).

65.2.1 Inflammation Triggered by Innate Immune Responses

Macrophages, dendritic cells, fibroblasts, and mast cells are among the cellular components of the innate immune system. Pattern recognition receptors (PPRs) expressed on these cells recognize pathogen-associated molecular patterns (PAMPs), such as microbial lipoproteins, carbohydrates, and nucleic acids. Another category of PRRs is the damage-associated molecular patterns (DAMPs) released from injured cells [17]. The description below is mainly for PAPMs, although certain DAMPs can also use these pathways. Toll-like receptors (TLRs) are the major PPRs expressed on the cell surface (Figure 65.2). More than 10 different TLRs have been identified in humans and mice. Specific ligand-induced activation of TLRs, which interact with adapter molecules such as myeloid

Figure 65.2 A schematic representation of major cell signaling pathways associated with inflammation that are targeted by natural products. Activation of cell surface receptors such as the toll-like receptors (TLRs) and receptors for antigens, cytokines, chemokines, and growth factors occurs following the binding of respective ligands. This results in the activation of receptor complex-associated tyrosine kinase activity, the recruitment of adapter proteins, and/or the activation of other enzymes. These early events in turn lead to the activation of various intracellular signaling cascades culminating in the production of various mediators of inflammation. Similarly, injury and tissue damage initiate a cascade of reactions that lead to the production of various biochemical mediators of inflammation such as prostaglandins, thromboxanes, and leukotrienes. A number of agents derived from natural products are known to interact with one or more of these pathways and exhibit anti-inflammatory activity (Tables 65.1 and 65.2). differentiation primary response gene 88 (MyD88) and TIR-domain-containing adapter-inducing interferon-β (TRIF) at their cytosolic domain, activates MyD88- and TRIF-dependent signaling pathways. Activation of these pathways then results in the activation of transcription factors nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) and the activator protein 1 (AP-1) [18,19]. Nucleotide oligomerization domain (NOD)-like receptors (NLRs) are cytosolic PRRs. Activation of NLRs by microbial products or aberrant self components of the host leads to NF-κB activation [20] and may also induce inflammasome activation. Inflammasome assembly typically consists of a sensor (an NLR), an adapter (apoptosis-associated speck-like protein (ASC) containing an N-terminal pyrin domain (PYD) and a C-terminal caspase activation and recruitment domain (CARD), and an effector (CARD and caspase) component [21]. Activation of the inflammasome leads to the activation of caspases, which play an important role in the induction and propagation of inflammation [22]. For example, activated caspase-1 causes the maturation of proinflammatory cytokines such as IL-1β and IL-18 by proteolytic cleavage of pro-IL-1β and pro-IL-18, respectively (Figure 65.2) [23,24]. These cytokines and other biochemical and immunological mediators contribute to the initiation and propagation of inflammation. The above-mentioned PRRs are attractive targets for the control of diseases associated with inflammation including, infections, autoimmunity, and cancer. Several agents targeting TLRs [25–28] and NLRs [29,30] are undergoing preclinical/clinical evaluation for the prevention and treatment of these disorders.

65.2.2 Inflammation Triggered by Adaptive Immune Responses

The T cells and B cells are vital components of the adaptive arm of the immune response. An imbalance in adaptive immune responses may lead to inflammation and autoimmunity. Activation of the antigen receptors (T-cell receptor (TCR)/B-cell receptor (BCR) on T/B cells, respectively, occurs following antigen recognition [31–35]. (In the case of T cells, TCR recognizes an antigenic peptide presented by the major histocompatibility complex (MHC). The signal transduction by the TCR and BCR has broad similarities and involves the activation of protein kinases, phospholipase C-gamma (PLCγ), and of small G proteins (Figure 65.2) [31–35]. The binding of antigen to cell surface receptors activates receptor-associated protein kinases at the inner surface of the cell membrane, which leads to the activation of other cytosolic targets including the enzyme PLCγ. PLCγ cleaves phosphatidylinositol bisphosphate (PIP2) to yield diacylglycerol (DAG) and inositol triphosphate (IP3). IP3 then increases intracellular Ca^{2+} concentration, activates calcineurin pathway, and results in the activation of nuclear factor of activated T cells (NFAT) and related transcription factors. Similarly, DAG and Ca^{2+} activate protein kinase C (PKC), which then leads to activation of NF-κB and other transcription factors. In addition, the kinase activity associated with the activated TCR/BCR complex recruits and activates guanine-nucleotide exchange factors (GEFs) with the help of adapter proteins. GEFs then activate small G proteins, which in turn trigger MAPK pathway. MAPK pathway then activates AP-1 and related transcription factors. All these activated transcription factors

move into the nucleus and regulate gene expression of a variety of mediators of inflammation (Figure 65.2).

65.2.3 Cell Signaling Pathways involved in inflammation

65.2.3.1 The Nuclear Factor Kappa-Light-Chain-Enhancer of Activated B Cells (NF-kB) Pathway

Mediators such as proinflammatory cytokines, growth factors, and enzymes play a central role in the induction and amplification of inflammation. The NF-κB pathway is a master regulator for the synthesis of these mediators, which then participate in inflammation associated with infection or autoimmunity [36–38]. Initial signals for activation of the classic NF-κB pathway come from the binding of specific ligands to their respective cell surface receptors such as receptors for cytokines, growth factors, or microbial products. The downstream event of these interactions is the activation of the IKK complex, which consists of I kappa B kinase 1 (IKK1), I kappa B kinase 2 (IKK2) and NF-κB essential modulator (NEMO) (Figure 65.2). The activated IKK complex phosphorylates IκB, a component of the inactive cytosolic NF-κB complex, which consists of inhibitory IκB and a heterodimeric NF-κB/RelA complex. The phosphorylated IκB undergoes ubiquitination and proteasomal degradation. The degradation of IκB in turn activates NF-κB, which then translocates into the nucleus, binds to DNA, and induces the expression of specific target genes [37,38]. Phosphorylation and subsequent degradation of IκB is critical for the activation of NF-κB. Agents that inhibit either the activation of the IKK complex or the phosphorylation of IκB or enhance the proteasomal degradation of IκB can thereby help retain NF-κB in an inactive state in the cytoplasm. Such NF-κB inhibitors are one of the prominent groups of anti-inflammatory agents capable of controlling inflammation in a wide variety of diseases [39]. Many natural product-derived molecules have been shown to inhibit NF-κB pathway in various *in vitro*, preclinical, or clinical settings. These include aspirin, curcumin, resveratrol, quercetin, celastrol, and others (Tables 65.1 and 65.2).

65.2.3.2 Mitogen-Activated Protein Kinase (MAPK) Pathway

MAPKs are a family of serine/threonine protein kinases, which are activated by the activation of small G proteins in response to various proinflammatory stimuli [108,109]. Extracellular signal-regulated kinase (ERK), c-Jun N-terminal kinase (JNK), and p38 MAPK represent three defined MAPKs (Figure 65.2) [108]. Activation of ERK leads to the activation of transcription factors such as c-Jun, c-Fos, and activating transcription factor 2 (ATF-2). Similarly, JNK activation in turn activates c-Jun and ATF-2. The p38 MAPK mediates both anti-inflammatory and proinflammatory processes, and its action involves transcription factors cAMP response element-binding protein (CREB) and ATF-2 [108,110,111]. The inhibition of ERK and JNK pathway has been shown to have greater efficiency than p38 MAPK in attenuating inflammation associated with autoimmune/inflammatory diseases [112–115]. Examples of natural product-derived agents that regulates MAPK pathway, and which have been tested *in vitro* and in preclinical/clinical settings, are given in Tables 65.1 and 65.2.

Table 65.1 Natural product-derived bioactive compounds with anti-inflammatory activity.

Lead agent	Chemical class	Natural source category	Targets: cellular/molecular mediators and pathways	Health maintenance/ therapeutic applications used/tested	References
Acetylsalicylic acid (aspirin) (modified, synthetic)	2-(acetoxy) benzoic acid	Based on salicylic acid	COX-1, COX-2, MAPK signaling, NF-κB pathway, adenosine release	Pain, fever, RA and other types of inflammation, cardiovascular disease prevention	[16,40–42]
Salicylic acid (natural)	Beta hydroxy acid	Plant (*Salix alba*)			
Curcumin	Diarylheptanoid	Plant (*Curcuma longa*)	NF-κB pathway, Nrf2, STAT3 signaling, COX-1, 5-LOX, protein kinase C, glycogen synthase kinase-3P, histone acetyltransferases, p53	RA, OA, and other types of inflammation	[16,43–46]
Epigallocatechin-3-gallate (EGCG)	Catechin	Plant (*Camellia sinensis*)	NF-κB pathway, JAK/STAT, PI3K/Akt, COX-1, 5-LOX, proteasome, CDK, dihydrofolate reductase, MMPs	RA, MS	[16,47–49]
Resveratrol	Stilbenoid	Plant (*Vitis vinifera, Polygonum cuspidatum*)	PI3K/Akt signaling, NF-κB pathway, MAPK signaling, 5-LOX, COX-1, Nrf2, PPARy, AMPK, Wnt/p-catenin signaling, SIRT signaling	Diabetes, metabolic disorders, coronary artery disease, skin diseases	[16,50–52]
Quercetin	Flavonol	Plant (Many fruits, vegetables, grains)	PI3K/Akt signaling, MAPK signaling, NF-κB pathway, JAK3, P-catenin signaling, CDK, serine/threonine protein kinases, PDGF receptor	OA, RA, prostatitis	[16,53–56]
Capsaicin	Capsaicinoid	Plant (*Capsicum sps*)	TRPV1 agonist	Local pain, OA	[57,58]
Myriocin (ISP-1)	Amino fatty acid	Fungus (*Mycelia sterilia, Isaria sinclairii*)	Serine palmitoyltransferase, T cell proliferation, immunosuppression		[59]
Fingolimod (FTY720)	Modified myriocin	Based on myriocin	Phosphorylated drug acts as an agonist of G protein-coupled receptor for sphingosine-1-phosphate (S1P) and blocks egress of lymphocytes from thymus and secondary lymphoid tissues, immunosuppression	MS	[60,61]

Mizoribine (MZB)	Imidazole nucleoside	Fungus (*Eupenicillium brefeldianum*)	Inosine monophosphate (IMP) dehydrogenase and guanosine monophosphate (GMP) synthetase, purine biosynthesis, T- and B-cell proliferation, immunosuppression.	RA, SLE, and other rheumatic and renal diseases	[62,63]
Cyclosporine A (CsA)	Cyclic peptide (with a single D-amino acid)	Fungus (*Tolypocladium inflatum*)	Calcineurin inhibitor, NFAT, IL-2, T-cell activation, immunosuppression	Organ transplant rejection, psoriasis, RA, keratitis, uveitis	[64–69]
Tacrolimus (FK506)	Macrolide lactone	Bacteria (*Streptomyces tsukubaensis*)	Calcineurin inhibitor, NFAT, IL-2, T-cell activation, immunosuppression	Organ transplant rejection, inflammation associated with ulcerative colitis, eczema	[67,69,70]
Sirolimus (Rapamycin)	Macrocyclic lactone	Bacteria (*Streptomyces hygroscopicus*)	mTOR, IL-2, T- and B-cell activation, immunosuppression	Organ transplant rejection, ocular diseases, atopic dermatitis	[71,72]
Mycophenolic acid	Small molecule, antibiotic	Fungus (*Penicillium Roquefort* and other penicillium species	Purine nucleotide biosynthesis, IMP dehydrogenase, T- and B-cell proliferation, immunosuppression	Organ transplant rejection, pemphigus vulgaris, psoriasis,	[73,74]
Mycophenolate mofetil (MMF)	Mofetil ester of mycophenolic acid	Based on mycophenolic acid		SLE	[75–77]

Examples of lead compounds in their native or derivatized/modified form that have proved beneficial following preclinical and clinical testing are listed with their source, chemical composition, molecular targets, and therapeutic applications. (*Abbreviations*: AMPK, Activated protein kinase; CDKs, Cyclin-dependent kinases; COX, cyclooxygenase; ERK, extracellular signal-regulated kinase; HIF, hypoxia-inducible factor; IBD, inflammatory bowel disease; IL-2, interleukin 2; iNOS, inducible nitric oxide synthase; JAK, janus kinase; JNK, c-Jun N-terminal kinase; LOX, lipoxygenase; MAPK, mitogen-activated protein kinase; MMPs, matrix metalloproteases; MS, multiple sclerosis; NFAT, nuclear factor of activated T cells; NF-κB, nuclear factor kappa-light-chain-enhancer of activated B cells; NO, nitric oxide; NOS, nitric oxide synthase; Nrf-2, nuclear factor erythroid 2-related factor 2; OA, osteoarthritis; PI3K, phosphatidylinositol-3-kinase; p-JNK, phospho c-Jun N-terminal kinase; PDGF, Platelet-derived growth factor; PPAR, Peroxisome proliferator-activated receptor; RA; rheumatoid arthritis; SLE, systemic lupus erythematosus; STAT, signal transducer and activator of transcription 3; Th17, T helper 17; TNFα, tumor necrosis factor alpha; TRPV1, transient receptor potential vanilloid receptor; Treg, regulatory T cell.)

Table 65.2 Medicinal herbs, nutraceuticals, and endogenous products possessing anti-inflammatory activity.

Natural product	Active component(s) identified	Targets: cellular/ molecular mediators and pathways	Therapeutic applications	References
A. Extracts of medicinal herbs				
Tripterygium wilfordii Hook F (Thunder God Vine)	Triptolide, Celastrol	NF-κB pathway, MAPK signaling, iNOS	RA, SLE, other inflammatory diseases	[78–83]
Boswellia serrata (Indian frankincense)	Boswellic acids	5-LOX, proinflammatory cytokines	RA, OA, bursitis, tendinitis inflammatory bowel disease (IBD), asthma	[84–86]
Urtica dioica (Stinging nettle)	Flavonoid glycosides, terpenoids	PLA2, NF-κB pathway	OA, RA, colitis, allergies	[86,87]
Harpagophytum procumbens (Devil's claw)	Harpagoside, harpagide	NF-κB, MAPK signaling, COX-2, NO	OA, back pain	[86,88,89]
Uncaria tomentosa (Cat's claw)	Mitraphylline	NF-κB pathway, proinflammatory cytokines, antioxidant	OA	[90,91]
Rosa canina (Dog rose)	Carotenoids, organic acids	COX-1 and COX-2	OA	[92,93]
B. Commonly used nutraceuticals				
Curcuma longa (Turmeric)	Curcumin	NF-κB, MAPK signaling, JAK/ STAT, arachidonic acid pathway, and iNOS	RA, OA, other autoimmune diseases	[43,86,94]
Zingiber officinale (Ginger)	Zingerone, gingerol	NF-κB pathway, COX-2	OA and RA	[95,96]
Fish oil	Omega-3 fatty acids	Inflammatory cytokines and prostaglandins	RA, SLE, psoriasis, other inflammatory conditions	[91,97,98]
Perna canaliculus (New Zealand Mollusc)	Omega-3 fatty acids	5-LOX, Leukotrienes production	RA and OA	[91,99,100]

Table 65.2 (*Continued*)

Natural product	Active component(s) identified	Targets: cellular/ molecular mediators and pathways	Therapeutic applications	References
C. Naturally occurring compounds in the body				
S-adenosyl-L-methionine	S-adenosyl-L-methionine	ERK and STAT3 pathway	OA, fibromyalgia, bursitis, tendinitis, chronic low back pain	[101,102]
Dehydroepiandrosterone	Dehydroepiandrosterone	Pro-inflammatory cytokines	SLE, RA, MS	[103–105]
Melatonin	Melatonin	NF-κB pathway, MAPK signaling, HIF, Nrf2 signaling	Fibromyalgia, irritable bowel syndrome (IBS)	[106,107]

Examples of different categories of natural products that have anti-inflammatory effects are listed along with their source, chemical composition, molecular targets, and therapeutic applications. Abbreviations are same as in Table 65.1.

65.2.3.3 The Janus Kinase (JAK)-Signal Transducer and Activator of Transcription (STAT) Pathway

Inflammatory signals from the activated NF-κB and MAPK pathways result in the production of various effector molecules, including cytokines. The binding of certain cytokines to their receptors rapidly transduces signals through the Janus kinase (JAK)-signal transducer and activator of transcription (STAT) pathway. JAK enzymes are associated with the cytoplasmic domain of cytokine receptors. Cytokine-cytokine receptor interaction leads to phosphorylation of JAKs and STATs. Activated STATs form a dimer, and these dimers then translocate into the nucleus (Figure 65.2). Within the nucleus, the STATs differentially modulate the expression of specific cytokine-responsive genes [116]. The seven mammalian STATs have distinct roles [117], for example, in the differentiation of naïve T cells into a specific T-cell subset (e.g., Th1, Th2, Th17, and Treg). The inhibition of JAK-STAT pathway, particularly the Th17-related STAT3-dependent signaling, is important to control Th17-associated inflammation in autoimmune diseases such as rheumatoid arthritis (RA), multiple sclerosis (MS), and others [118–120]. Several natural product-derived agents, including curcumin, sirolimus, epigallocatechin-3-gallate (EGCG), quercetin, and celastrol, have been shown to modulate the JAK/STAT pathway (Table 65.1) [121–126].

65.2.3.4 The Phosphatidylinositol-3-Kinase (PI3K)/Akt/Mammalian Target of Rapamycin (mTOR) Pathway

The PI3K/Akt/mTOR pathway is another regulator of events of cell metabolism and cell survival, and it plays a role in the pathogenesis of immune-mediated disorders [127–133]. This pathway can be activated by environmental changes, including growth factors, cellular stress, and other inflammatory stimuli. Furthermore, this pathway has been shown to regulate angiogenesis, cell proliferation, and cell survival in cancer [134]; insulin resistance, adipogenesis, and T-lymphocyte activation in type 2 diabetes (T2D) [134]; and osteoclast differentiation, and survival and proliferation of synovial fibroblast-like cells in rheumatoid arthritis [135,136]. Several natural products such as sirolimus, EGCG, resveratrol, and quercetin have been shown to inhibit PI3/Akt/mTOR pathway, and this inhibition contributes to their anti-inflammatory and immunosuppressive/immunomodulatory activities (Tables 65.1 and 65.2).

65.2.3.5 The Arachidonic Acid Pathway

Prostaglandins, thromboxanes, and leukotrienes are biochemical mediators that act as short-lived hormones to induce inflammation and pain at the local site [137,138]. These mediators regulate vasodilation, platelet aggregation, and clot formation to increase inflammatory responses. Arachidonic acid is released by the action of activated phospholipase A2 (PLA2) on membrane phospholipids following mechanical trauma or tissue destruction (Figure 65.2). Arachidonic acid is then transformed into prostaglandins and thromboxanes by a series of enzymatic reactions following the action of cyclooxygenases (COX) [137]. Similarly, 5-lipoxygenase (5-LOX) activity results in the transformation of arachidonic acid into leukotrienes [139]. Two isoforms of COX, COX-1 and COX-2, have been identified. COX 1 is constitutively expressed in the gastrointestinal tract (GIT), whereas COX-2 is inducible and primarily expressed at sites of inflammation. This information has led to the development of selective inhibitors of COX-2 to limit some of the side effects associated with inhibitors of COX-1 only or of both enzymes [137,140]. Inhibition of the arachidonic acid pathway has the potential to suppress inflammation and pain by blocking the generation of downstream mediators [141]. Aspirin, an esterified compound of salicylic acid isolated from the bark of the Willow tree (*Salix Alba*), is a well-known drug that inhibits the synthesis of prostaglandins and thromboxanes. It irreversibly inhibits both COX-1 and COX-2, with a predominant effect on COX-1 compared with that on COX-2. Subsequently, several other inhibitors of arachidonic acid pathway have been found to be beneficial following preclinical/clinical testing (Tables 65.1 and 65.2).

65.2.3.6 Nitric Oxide (NO), Inducible Nitric Oxide Synthase (iNOS), and Inflammation

Free radicals are a group of highly reactive species, which can differentially display beneficial or deleterious effects depending on the environmental conditions [142]. NO is one of the free radicals and plays a role in inflammatory reactions [143]. NO is synthesized from the guanidino group of L-arginine during its conversion to L-citrulline by NO synthases (NOS) [144]. Under normal conditions, NO is continually generated by constitutively expressed endothelial cell NOS (eNOS)

and brain NOS (bNOS), and it has beneficial effects [145]. However, NO is produced at higher rates under inflammatory conditions by the activity of inducible NOS (iNOS), which is expressed in macrophages, neutrophils, granulocytes, and many other cells in response to proinflammatory signals [146]. NO produced under these conditions helps propagate inflammatory responses [147]. The role of NO in inflammatory conditions including autoimmune disorders has been studied extensively [148–150], and the inhibition of NO has been shown to mediate anti-inflammatory effects. Tacrolimus and cyclosporine A are examples of inhibitors of iNOS and NO production [151], and both these drugs have been shown to be effective in treating immune-mediated inflammation (Table 65.1). Similarly, other natural products such as *Curcuma longa*, *Tripterygium wilfordii* Hook F., and *Harpagophytus procambuns* have been shown to inhibit NO production (Table 65.2).

65.2.3.7 Other Pathways Associated with Inflammation

Inflammation alters multiple cellular functions as well as the response of cells to environmental conditions. Furthermore, there is a cross-talk between different cellular pathways that are operative concurrently in an inflammatory milieu. The pathways that mediate cell proliferation, cell migration, cell apoptosis, glucose metabolism, hypoxia, and oxidative stress also contribute, directly or indirectly, to the process of inflammation and in turn are affected by it. Therefore, the mediators and regulators of these pathways also constitute additional targets for therapeutic control of inflammation. Many of the natural products targeting such mediators are described below (Tables 65.1 and 65.2). For example, the nuclear factor erythroid 2–related factor 2 (Nrf2), which upregulates cytoprotective genes to restore redox homeostasis, is regulated by curcumin and resveratrol [152,153]; cyclin-dependent kinases (CDKs), which regulate cell cycle, are targeted by EGCG [154]; and serine palmitoyltransferase (SPT), which is involved in sphingolipid metabolism, is inhibited by Myriocin [59].

65.3 Natural Products from Diverse Sources Possess Anti-Inflammatory Activity

Inflammation is an integral component of the pathological processes in a variety of diseases. During inflammation, there is a cross-talk among many of the effector molecules produced in different pathways described above, and these interplays can further augment inflammation. In this regard, natural products and synthetic compounds that can modulate one or more of these pathways have been used as anti-inflammatory agents for the control of inflammation and management of symptoms associated with it. Most natural products that have been used for medicinal purposes for their anti-inflammatory activity have originated from plants, terrestrial microorganisms such as fungi and bacteria, and marine animals. Such products include purified bioactive compounds in their native state or in synthetically modified forms (Table 65.1), extracts of medicinal herbs (Table 65.2A), commonly used nutraceuticals (Table 65.2B), and those that occur naturally in the body (Table 65.2C). Collectively, the chemical structures of

the major bioactive principles that endow anti-inflammatory activities to these natural products are vastly diverse. These natural products have been used for the treatment of a variety of chronic diseases including, inflammatory and autoimmune diseases (e.g., rheumatoid arthritis (RA), multiple sclerosis (MS), systemic lupus erythematosus (SLE) (also known as lupus), psoriasis, pemphigus vulgaris, uveitis); pain and swelling associated with other rheumatic diseases (osteoarthritis (OA), chronic low back pain, tendinitis, bursitis, fibromyalgia); inflammation and related immune-mediated events in organ transplant rejection (e.g., liver or kidney transplant), inflammatory bowel disease (IBD), colitis; other conditions associated with inflammation (e.g., dermatitis, prostatitis, keratitis); and other diseases such as T2D, metabolic disorders, irritable bowel syndrome, cardiovascular disease, and cancer.

The above-mentioned examples represent the potentially broad scope of the use of natural products, in one form or another, as anti-inflammatory agents. Of these products, synthetically modified compounds based on natural compounds (e.g., aspirin from salicylic acid, fingolimod from myriocin, mycophenolate mofetil from mycophenolic acid) and the unmodified bioactive compounds derived from natural products (e.g., cyclosporine A, tacrolimus, sirolimus, mizoribine) are already approved drugs for therapeutic use (Table 65.1). Another group of natural compounds (e.g., curcumin, resveratrol, EGCG, quercetin, capsaicin) includes promising anti-inflammatory drug candidates (Table 65.1). They have extensively been tested in clinical studies by different investigators. However, additional scientifically controlled clinical trials and comparative studies with established mainstream anti-inflammatory drugs are required before one or more of these candidates are approved for therapeutic use. Similarly, besides extensive experience through the traditional systems of medicine (e.g., TCM and Ayurveda), the extracts of medicinal herbs (e.g., *T. wilfordii* Hook F, *Boswellia serrata*, *Urtica dioica*, *Harpagophytum procumbens*, *Uncaria tomentosa*, *Rosa canina*) have been subjected to extensive testing in several clinical trials for their efficacy and safety (Table 65.2A). The results of these trials have been promising, yet additional studies are warranted before approval is granted for therapeutic use of one or more of these herbal products. For example, *T. wilfordii* Hook F (Thunder God Vine) has shown promising results in patients with rheumatoid arthritis, and the effects of this herbal preparation were comparable to, or better than, those of the mainstream drugs sulfasalazine and methotrexate [78–81,155]. However, the toxicity profile still remains a concern for the therapeutic use of this product.

The remaining groups of natural products (Table 65.2B and C) being explored for their anti-inflammatory activity include commonly used nutraceuticals (e.g., turmeric and ginger that are used as spices in food; fish oil; and New Zealand mollusk), and naturally occurring substances (e.g., hormones such as dehydroepiandrosterone and melatonin, and other compounds such as S-adenosylmethionine). (Turmeric contains *Curcumin longa*, the source of curcumin discussed above.) These products are widely consumed for general maintenance of health and prevention of inflammation, but additional controlled studies are needed to fully assess their utility for the treatment of inflammatory and immune-mediated diseases.

65.4 Technological Advancements in the Production, Characterization, and Delivery of Natural Products

Using a typical conventional scheme, the processing of a plant extract involves drying, grinding, boiling, and distillation or sublimation. The mixture of compounds thus obtained is subjected to fractionation using high-performance liquid chromatography (HPLC) and mass spectrometry (MS). Select compounds are then tested for their functional activity using bioassays. Bioassays are used for the detection, isolation, and functional characterization of new or unknown compounds in a mixture [2,12,156]. Such bioassays include those that measure enzyme activity, the activity of transcription factors, or the interaction of specific molecules with inflammatory cells [156,157]. However, certain limitations exit. For example, extracts of some natural products may emit endogenous fluorescence or possess certain components that may bind to proteins and form complexes with them, or denature them, and thereby interfere with the readout of the bioassays [158]. Following functional validation, a pure compound of interest can be subjected to nuclear magnetic resonance (NMR) to elaborate its structural features. Technological advances have significantly improved the efficacy of isolation and purification of natural compounds from a crude extract of a natural product (Figure 65.1) [2,5,12].

65.4.1 Semisynthesis, Combinatorial Biosynthesis, and Metabolic Engineering

Isolation of bioactive compounds from natural sources such as plants is influenced by soil conditions and seasonal variations. Depending on the structural complexity, the synthesis of a compound originally derived from a natural product can be undertaken in the laboratory using "total synthesis" or "semisynthesis" (partial synthesis) method. The latter method uses pre-existing natural product intermediates as templates for generating the final products that replicate the original, functional natural product-derived compounds. These synthetic approaches have successfully been used for the production of a variety of natural products, for example, rottnestol and herboxidiene [159], alkyne-containing jadomycin [160], aeruginosin [161,162], and epicoccin [163].

Combinatorial biosynthesis and metabolic engineering represent advanced techniques to produce complex organic compounds using genetically modified organisms (GMO), such as bacterial strains that have been genetically engineered to produce sets of compounds. Combinatorial biosynthesis is aimed at producing a library of structurally diverse compounds, including hybrid structures, by genetically introducing into an organism a set of genes, or sets of different combinations of genes, from specific biosynthetic pathways [164,165]. Furthermore, deliberate modifications introduced into enzymatic domains and the use of different enzyme-substrate combinations can produce structurally diverse compounds. Products of combinatorial biosynthesis are then subjected to screening procedures described below to identify functionally relevant compounds. In metabolic engineering, a similar approach is used to deliberately modify a particular biosynthetic

pathway for a structurally complex compound to generate a single compound, or few variants of that compound, with functional attributes that represent improvements over the original natural compound. Another application of this approach is to enhance the yield of a known product. The leads for targeting particular pathways or enzymes are derived from mathematical modeling of chemical networks of biosynthetic pathways and by identifying sites where changes are required. Thereafter, appropriate genetic modifications are introduced to alter the reaction pathway or to overcome any constraints.

Synthesis of alkynes such as polyketides [166,167] and terpenoids such as tetrahymanol [168] has been achieved using above methods. It is anticipated that these approaches would permit biosynthesis of several natural products of medicinal value, such as resveratrol, curcumin, paclitaxel, and artemisinin, in microbial hosts, in large amounts and in a consistent manner to minimize batch-to-batch variations for clinical testing and eventual therapeutic use.

65.4.2 High-Throughput Screening (HTS) and Virtual Screening

HTS, a laboratory-based method, uses automation to simultaneously examine a collection (library) of a large number of compounds against a set of defined targets with the purpose of identifying compounds that induce inhibition or activation of a specific biological target, for example an enzyme or a cell-surface receptor [169–171]. In addition, such a screening procedures can be used to determine the pharmacokinetic and pharmacodynamic attributes of a compound. *In vitro* and cell-based bioassays and microarray analysis are among the commonly used methods for screening of natural products and for defining their mechanism of action. Virtual screening, an *in silico* approach using defined computer algorithms for protein docking or ligand-protein interactions, is now increasingly being used in conjunction with, or in place of, actual laboratory-based screening of a large number of compounds of interest [2,8]. Compounds identified via virtual screening are then validated using appropriate *in vitro* and *in vivo* laboratory methods.

65.4.3 Microarrays

Microarray technology platform can also be utilized as a bioassay, besides its use for high throughput screening or biosynthesis. Microarrays use a chip-based platform to test the reactivity of a biological sample with a vast number of molecules (proteins, DNA or RNA) in a single screen. The readouts of such assays can directly or indirectly provide information about the expression level of RNA/DNA or the measurement of the biological activity of proteins, for example enzyme activity [172], anti-mitotic effects [170], or toxicological profile [171].

65.4.4 Systems Pharmacology

Systems pharmacology extends the application of the principles of systems biology to the study of drug actions, responsiveness to drugs, adverse effects of drugs, and identification of new targets (Figure 65.1). These aspects are examined in the context of network of interactions of drugs with other molecules

(e.g., proteins, genes, signaling components, etc.) within cells; with different types of cells within an organ; with different organs; and with the whole organism. These analyses use computational networks in combination with functional readouts of cellular metabolites (metabolomics), transcripts (transcriptomics), genes (genomics), or proteins (proteomics) [173–176]. In addition, bioinformatics and statistics are integral parts of these interpretations. Besides advancing our knowledge of drug actions, systems pharmacology can contribute significantly to better understanding of differences in therapeutic efficacy as well as risk of adverse effects, and to developing polypharmacy for complex diseases, including inflammatory and autoimmune disorders.

65.4.5 Use of Nanotechnology to Deliver Natural Products for Therapeutic Purposes

Nanoparticles are of nanoscale (up to 100 nm) size and are used to deliver hydrophilic drugs, hydrophobic drugs, proteins, and other biological products [177]. Nanoparticles are comprised of a drug tagged with a polymer and a targeting ligand, which together help in the targeting, delivery, solubility, bioavailability, and *in vivo* stability of that drug (Figure 65.1) [178–180]. Poly (lactic-co-glycolic acid) (PLGA) and polyglycolic acid (PGA) are examples of polymers that are often used as carriers of drugs [177,181]. PLGA has been approved by the Food and Drug Administration (FDA) for use with a therapeutic agent. The polymers can be designed so as to make them responsive to pH, temperature, or specific metabolites to further optimize drug delivery [177,181]. The main objective of developing nanoparticles for the delivery of natural products include improved targeting and delivery, enhanced bioavailability, reduced toxicity, and maintained or enhanced therapeutic effects [178–180]. Several natural products possessing anti-inflammatory properties have been formulated as nanoparticles, and these include, curcumin, EGCG, *Tripterygium wilfordii*, triptolide, quercetin, and ginger [180,182–185].

65.5 Concluding Remarks

The period between the 1940s and 1960s represented the "golden age" of drug discovery from natural products [5]. By 1990, approximately 80% of drugs for various categories of diseases had been estimated to be from natural products or their analogs [4]. However, over the past two decades, there has been a gradual decline in interest and effort on the part of major pharmaceutical companies in the process of drug discovery based on screening of natural products. Nevertheless, over 100 drugs based on natural products are being tested in clinical studies for many different diseases, and about 18 are at different stages of development for inflammation and related diseases [2,4,11]. Hopefully advancements in technology and applications of *in silico* approaches; expansion of the search of natural product-based drugs to marine microorganism and other underexplored microbes; and the recognition of the contribution of natural products research to drug discovery by the 2015 Nobel

Prize in Physiology and Medicine would reinvigorate the field of natural product drug discovery [4,5,16].

system 863
thresholds 864
thermosensors 864
thiazolidinediones (TZDs) 1210
adipose effects of 1236
insulin sensitizing effect 1236
thioredoxin (TRX) 138
thiyl radicals (R-S•) 706
threonine amino acid residues 440
threshold temperatures 863
thrombelastography (TEG) 846

thrombin 733, 1595
activatable fibrinolysis inhibitor (TAFI) 840
thrombocytopenia 425, 426, 800, 995
thrombocytosis 425
thrombolysis agent 1317
thrombomodulin (TM) 840, 1590
bound thrombin 841
TM-1 1525
thrombotic microangiopathies 801
thromboxane A2 (TxA2) 459
induced vasoconstriction 461
synthase 460
TP signaling 663
Thr308, phosphorylation of 1381
Thr^{37} residue of Rho 88
thymic DC 1062
thymic regulatory T cells (tTreg) 298, 1378
thymic self-ligands 1378
thymic stromal lymphopoietin (TSLP) 996
thymocytes 224
thymus 1057, 1065
derived T_{REGS} (tT_{REGS}) 1379
thyroid hormones 915, 916
thyroxine (T4; 3,5,3′,5′-tetraiodothyronine) 915
tie-2-mediated phosphorylation 467
timeline of autoantibody-positive rheumatoid arthritis (RA) 1108
TIR. *see* toll-interleukin receptor (TIR)
TIR-containing adapter protein (TIRAP) 1370
tissue damage 787, 915, 1363
tissue factor (TF) 464
eomesodermin 341
inhibitors 1316
pathway inhibitor 732, 837
protease inhibitor (TFPI) 739, 841
tissue ILCs homeostasis 345
tissue inhibitor of metalloproteinase 1 (TIMP1) 1208
tissue injury 629
tissue metaplasia 663
tissue remodeling 663
tissue repair 1355, 1517
anti-inflammatory cytokines 1523
cellular effectors of resolution 1524
chemokines regulate leukocyte recruitment 1520
complement cascade 1519
extracellular matrix 1525
fibroblast activation/scar formation 1526
inflammatory response 1517
leukocyte adhesion cascade 1523
leukocyte recruitment 1521
macrophages 1521
negative regulation of cytokine signaling 1523
pathways 790
postinfarction inflammation 1523
proinflammatory cytokines 1519
repression/resolution of inflammation 1522
role of neutrophils 1522
tissue-specific events leading to regeneration 1525
Tityus serrulatus venom 106
TL1A/DR3 interaction 534
TLR. *see* toll-like receptors (TLR)
TNF. *see* tumor necrosis factor (TNF)
tocilizumab 407, 580, 1343
tofacitinib 1343
tolerance 1159
and accommodation of blood group mismatched transplants 1160
tolerogenic dendritic cells 596, 825, 1062
toll-interleukin receptor (TIR) 479, 1430, 1590
toll interleukin-1 receptor domain-containing adapter-inducing interferon-β (TRIF) pathway 59
toll-like receptors (TLR) 24, 105, 138, 150, 176–181, 220, 275, 441, 468, 551, 594, 796, 821, 974, 997, 1097, 1152, 1232, 1281, 1282, 1315, 1351, 1423, 1488, 1518, 1541, 1590, 1664
agonists 144

cell surface-bound TLRs 177
endosomal TLRs 178
humans TLR4 expression 1153
ligands 145, 296, 479, 602, 916
