Table of Contents

Preface *xlv*

Volume I

1 Inflammation through the Ages: A Historical Perspective *1*
Jean-Marc Cavaillon
1.1 Introduction *1*
1.2 The First Treatments *1*
1.3 The Definitions *3*
1.4 Fever *3*
1.5 Phagocytosis *4*
1.6 Diapedesis *6*
1.7 Chemotactism *7*
1.8 Infection and Inflammation *8*
1.9 Usefulness of Inflammation for Adaptive Immune Response *9*
1.10 Mediators of Inflammation *10*
References *12*

Part One Inducers and Sensors of Inflammation *17*

2 Pathogen-associated Molecular Patterns *19*
Jean-Marc Cavaillon
2.1 Definition *19*
2.2 Endotoxin *20*
2.2.1 Brief Historical Background *20*
2.2.2 Biochemical Characteristics *21*
2.2.3 Detection *23*
2.2.4 Natural Ligands *24*
2.2.5 Cell Activation *25*
2.2.6 Tolerance *26*
2.3 Other Bacterial PAMPs *26*
2.3.1 Lipoproteins *26*
2.3.2 Lipoteichoic Acid *27*
2.3.3 Flagellin *28*

2.3.4 Peptidoglycan *28*
2.3.5 Fimbriae *30*
2.3.6 Glycogolipids *30*
2.3.7 Heat Shock Proteins *30*
2.3.8 Bacterial DNA *31*
2.3.9 Bacterial RNA *32*
2.4 Viral PAMPs *33*
2.5 Parasitic PAMPs *35*
2.6 Fungal PAMPs *36*
2.7 Synergy *37*
References *38*

3 Damage-associated Molecular Patterns *57*
Jean-Marc Cavaillon
3.1 Definition *57*
3.2 Necrosis versus Apoptosis *58*
3.3 Receptors of Danger Signals *58*
3.4 Main DAMPs *60*
3.4.1 High-mobility Group Box 1 *60*
3.4.2 Heat Shock Protein *61*
3.4.3 RNA and DNA *62*
3.4.4 Mitochondria *62*
3.4.5 Histones *62*
3.4.6 Uric Acid Crystals *63*
3.4.7 ATP *63*
3.4.8 S100A8/S100A9 *64*
3.4.9 Interleukin-1α and Interleukin-33 *64*
3.4.10 Heme *65*
3.4.11 Hyaluronan *65*
3.4.12 Biglycan *66*
3.4.13 Heparan Sulfate *66*
3.4.14 Eosinophil-derived Neurotoxin *66*
3.4.15 Peroxiredoxins *67*
References *67*

4 Bacterial Toxins *81*
Marina de Bernard and Cesare Montecucco
4.1 Introduction *81*
4.2 Toxins Modulating the Activity of Inflammatory Caspases and Inflammasomes *82*
4.3 Toxins Modulating the Intracellular cAMP Levels *84*
4.4 Toxins Modulating MAPK Signaling *85*
4.4.1 Synergy between ET and LT *86*
4.5 Toxins Affecting Host Cell Motility *87*
4.6 Toxins Blocking Protein Synthesis or Protein Folding *88*
4.7 Conclusions *89*
References *90*

5 Venoms *99*
Catarina Teixeira, Vanessa Moreira, and José María Gutiérrez
5.1 Introduction *99*
5.2 Inflammation Induced by Snake Venoms *100*
5.3 Inflammation Induced by Scorpion Venoms *105*
5.4 Inflammation Induced by Spider Venoms *107*
5.5 Inflammation Induced by Venoms of Bees, Vespids, and Ants *110*
5.6 Conclusions *112*
References *113*

6 Hypoxia as an Inducer of Inflammation *129*
Ariel Brandwein and Clifford S. Deutschman
6.1 Introduction *129*
6.2 Oxygen Sensing *130*
6.3 Mitochondrial Oxygen Sensing *131*
6.4 The Role of Transcription Factors *132*
6.4.1 Hypoxia-Inducible Factor *133*
6.4.2 Nuclear Factor κB *135*
6.5 The Warburg Effect *135*
6.6 Acute versus Chronic Hypoxia *136*
6.7 Inflammasome Activation *137*
6.8 Summary and Conclusions *139*
References *139*

7 Vaccine Adjuvants *143*
Dennis M. Klinman and Hidekazu Shirota
7.1 Introduction *143*
7.2 Adjuvants Approved for Human Use *144*
7.3 Aluminum Compounds: The Gold Standard *144*
7.4 AS04 *145*
7.5 Calcium Phosphate *145*
7.6 Emulsions *146*
7.6.1 IFA and CFA *146*
7.6.2 MF59 *146*
7.6.3 AS03 *147*
7.7 Nano/microparticles Including Liposomes and Virosomes *148*
7.8 Immune Stimulating Complexes *148*
7.9 Cytokines *149*
7.9.1 IL-12 *149*
7.9.2 IL-2 *149*
7.9.3 IL-15 *150*
7.9.4 GM-CSF *150*
7.10 Adjuvants that Target Toll-like Receptors *150*
7.10.1 Introduction *150*
7.10.2 TLR2 *151*
7.10.2.1 Overview *151*
7.10.2.2 TLR2 ligands *151*

7.10.2.3 Clinical Activity *151*
7.10.2.4 Safety *152*
7.10.3 TLR3 *152*
7.10.3.1 Overview *152*
7.10.3.2 TLR3 Ligands and Their Immunogenicity *152*
7.10.3.3 Safety *153*
7.10.4 TLR4 *153*
7.10.4.1 Overview *153*
7.10.4.2 TLR4 Ligands *153*
7.10.4.3 Clinical Activity *153*
7.10.4.4 Safety *154*
7.10.5 TLR5 *154*
7.10.5.1 Overview *154*
7.10.6 TLR7/8 *154*
7.10.6.1 Overview *154*
7.10.6.2 TLR7/8 Ligands and Their Preclinical Activity *155*
7.10.6.3 Clinical Activity *155*
7.10.6.4 Safety *155*
7.10.7 TLR9 *156*
7.10.7.1 Overview *156*
7.10.7.2 TLR9 Ligands *156*
7.10.7.3 Clinical Activity *156*
7.10.7.4 Safety *157*
7.11 Adjuvant Combinations *157*
7.12 Future Directions *157*
References *158*

8 Pattern Recognition Receptors *175*
Lauren Whitehead and Gordon D. Brown
8.1 Introduction *175*
8.2 Toll-like Receptors *176*
8.2.1 Cell Surface-bound TLRs *177*
8.2.2 Endosomal TLRs *178*
8.2.3 TLR Signaling *179*
8.2.4 MyD88-dependent Signaling Pathway *179*
8.2.5 TRIF Signaling Pathway *179*
8.3 C-type Lectin Receptors *181*
8.3.1 DC-SIGN *181*
8.3.2 Mannose Receptor *182*
8.3.3 Surfactant Protein D *182*
8.4 Natural Killer Gene Complex-associated CLRs *183*
8.4.1 Activation Receptors *183*
8.4.2 Inhibitory Receptors *185*
8.4.3 CLR Signaling *186*
8.5 RIG-1-like Receptors *187*
8.5.1 RLR Signaling *188*
8.6 NOD-like Receptors *189*

8.6.1 NOD1 and NOD2 *191*
8.6.2 NOD1 and NOD2 Signaling *192*
8.6.3 NLRC4 *192*
8.6.4 NLRPs *192*
8.7 DNA-sensing Molecules *193*
8.7.1 Signaling Components of DNA-sensing Molecules *194*
8.7.2 Cross-talk between PRRs *195*
8.8 Conclusions *195*
Acknowledgments *196*
References *196*

Part Two Inflammatory Cells *217*

9 Monocytes and Macrophages *219*
Irina N. Shalova, Shilpi Saha, and Subhra K. Biswas
9.1 Introduction *219*
9.2 Origin and Differentiation *219*
9.3 Activation and Polarization *221*
9.4 Functions *222*
9.4.1 Cytokine Production and Inflammation *223*
9.4.2 Phagocytosis *224*
9.4.3 Antigen Presentation *226*
9.4.4 Migration *227*
9.4.5 Immunoregulation *228*
9.4.6 Vascular Functions *229*
9.5 Molecular Pathways and Mechanisms Regulating Response *230*
9.5.1 Signaling Pathways *230*
9.5.2 Epigenetic Regulation *232*
9.5.3 Micro-RNAs *234*
9.6 Conclusions *235*
Acknowledgment *235*
References *236*

10 Neutrophils *253*
Salvatore Cuzzocrea
10.1 Characteristics *253*
10.2 Hematopoiesis *254*
10.3 Adhesion and Migration *255*
10.3.1 Traffic and Margination *255*
10.3.2 Adhesion to the Endothelial Wall *256*
10.3.3 Transendothelial Migration *257*
10.4 Phagocytosis and Degranulation *258*
10.4.1 Phagocytosis *258*
10.4.2 Degranulation *259*
10.5 Cytokine Synthesis *260*
10.5.1 TNF-α *260*

10.5.2 IL-1 and IL-1 Receptor Antagonist *260*
10.5.3 IL-8 as a Model of Chemokines *261*
10.5.4 Modulation of Cytokine Expression and Production by Neutrophils *261*
10.6 Neutrophil Apoptosis *261*
10.7 Neutrophils in Pathology *262*
10.7.1 Bacterial Infection *263*
10.7.2 Tissue Injury-induced Inflammation: Ischemia-reperfusion Injury *263*
10.7.3 Crystal-induced Inflammation *263*
10.7.4 Cytokine-induced Inflammation: Rheumatoid Arthritis *263*
10.7.5 Autoimmunity Against Neutrophil Components: Antineutrophil Cytoplasmic Antibodies and Vasculitis *264*
10.7.6 Genetic Disorders of Neutrophil Regulations: Hereditary Periodic Fever Syndromes *264*
10.7.7 Cystic Fibrosis: Neutrophil-mediated Tissue Damage and Concomitant Persistence of Infection *265*
10.8 Conclusions *265*
References *266*

11 Mast Cells: Master Drivers of Immune Responses against Pathogens *273*
W.X. Gladys Ang and Soman N. Abraham
11.1 Introduction *273*
11.2 Biology of Mast Cells *273*
11.3 Role of Mast Cells in Immune Surveillance *275*
11.3.1 Strategic Peripheral Location *275*
11.3.2 Direct Recognition of Pathogens *275*
11.3.3 Indirect Recognition of Pathogens *276*
11.3.4 Activation by Endogenous Danger Signals *276*
11.3.5 Degranulation and Secretory Responses to Pathogens *277*
11.4 Mast Cells in Innate Immunity *278*
11.4.1 Direct Bactericidal Activity of Mast Cells *278*
11.4.2 Resistance to Exo- and Endotoxins *278*
11.4.3 Induction of Immune Cell Trafficking to Sites of Infection *279*
11.5 Mast Cells in Adaptive Immunity *279*
11.5.1 Mast Cells as Effectors of Adaptive Immunity *279*
11.5.2 Recruitment of DCs and Effector T Cells to Sites of Infection *280*
11.5.3 Recruitment of Dendritic Cells and T Cells to Draining Lymph Nodes *280*
11.5.4 Antigen Presentation *280*
11.6 Enhancement of Immunity by Boosting Mast Cell Activity *281*
11.6.1 Mast Cell Activators as Novel Vaccine Adjuvants *281*
11.6.2 Synthetic Mast Cell Granules *281*

11.7 Potentially Detrimental Roles of Mast Cell Activation during Immune Responses *282*
11.7.1 Overactivation of Mast Cells *282*
11.7.2 Negative Modulation of Immunity by Mast Cells *283*
11.8 Concluding Remarks *283*
Acknowledgments *284*
References *284*

12 Dendritic Cells in Inflammatory Disease *289*
Bart N. Lambrecht, Martin Guilliams, and Hamida Hammad
12.1 What Defines a Dendritic Cell? *289*
12.2 Dendritic Cell Subsets *290*
12.3 Dendritic Cells and T-cell Polarization *291*
12.4 Dendritic Cells in Allergic Inflammation *292*
12.4.1 Dendritic Cells are Necessary and Sufficient for Induction of Th2 Immunity *292*
12.4.2 Different Subtypes of DCs Induce Th2 Immunity *293*
12.4.3 Dendritic Cells are Also Required for Effector Th2 Immune Responses to Allergens *294*
12.4.4 DCs Get Activated Directly after Exposure to Allergen *295*
12.4.5 Lung DCs Activated Indirectly by Epithelial Cells *296*
12.5 Inflammatory DCs' Role in Human Allergy *298*
12.6 Dendritic Cells in Autoimmune Inflammatory Disease *298*
12.7 Conclusions *299*
References *300*

13 Roles for NK Cells and ILC1 in Inflammation and Infection *315*
Christian A.J. Vosshenrich and James P. Di Santo
13.1 Introduction *315*
13.2 Distinguishing Group 1 ILC and NK Cells *316*
13.3 NK Cell and ILC1 Activating and Inhibitory Receptors *317*
13.3.1 Natural Cytotoxicity Receptors *317*
13.3.2 NKG2D *318*
13.3.3 DNAX Accessory Molecule-1 (DNAM-1, CD226) *318*
13.3.4 MHC Class I-specific Receptors and NK Cell "Education" *318*
13.3.5 Are ILC1s "Educated" Similar to Convention NK Cells? *319*
13.4 Evidence for Distinct Subsets of NK Cells and ILC1 *319*
13.5 Effector Functions of NK Cells and ILC1 *320*
13.6 NK Cells and Group 1 ILCs in Inflammation and Infection *322*
13.6.1 Mouse Cytomegalovirus *322*
13.6.2 Influenza Virus *323*
13.6.3 NK Cells and Other Viral Infections *324*
13.6.4 Salmonella *324*
13.6.5 Listeria monocytogenes *325*
13.6.6 Mycobacteria and Other Bacteria *325*
13.7 NK Cell and ILC1 Memory *326*

13.8 Concluding Remarks: NK and ILC1 as Partners in a Type 1 Network *327*
References *329*

14 Group 2 and 3 Innate Lymphoid Cells: New Actors in Immunity and Inflammation *341*
Nicolas Serafini and James P. Di Santo
14.1 ILCs: A New Family of Innate Effector Cells *341*
14.2 ILC2 and ILC3 Heterogeneity and Homeostasis *342*
14.3 ILC2 in Acute and Chronic Inflammation *345*
14.4 ILC3 in Acute and Chronic Inflammation *348*
14.5 Therapeutically Harnessing ILC2 and ILC3 *351*
14.6 Concluding Remarks *352*
References *353*

15 Th9 Cells: From the Bench to the Bedside and Back Again *365*
Benjamin J. Ulrich, Matthew M. Hufford, and Mark H. Kaplan
15.1 The History of T Helper Cells *365*
15.2 Introduction to Th9 Cells *367*
15.2.1 Development *367*
15.2.2 Additional Th9-inducing Cytokines *368*
15.2.3 Th9-inducing Cell Surface Ligands *369*
15.2.4 The Function of Th9 Cells *369*
15.3 Th9 Cells in Disease: The Helpful and Unhelpful *371*
15.3.1 Tumor Immunity *372*
15.3.2 Helminth Immunity *372*
15.3.3 Inflammatory Bowel Disease *373*
15.3.4 Allergic Inflammation *374*
15.3.5 Dermatitis *376*
15.3.6 Food Allergy *377*
15.4 Targeting Th9 Cells Therapeutically *377*
15.4.1 Th9 Differentiation *377*
15.4.1.1 Cytokines and Costimulators Required for Differentiation *377*
15.4.1.2 Transcription Factors for Differentiation *379*
15.4.1.3 Factors Required for Promotion of Th9 Biology *380*
15.4.2 Th9-associated Effector Molecules *381*
15.5 Summary and Future Directions *382*
References *382*

16 Th17 Cells *395*
Mélissa Noack and Pierre Miossec
16.1 Introduction *395*
16.2 Differentiation of Th17 Cells *396*
16.2.1 Th17 Cell Differentiation in Mice *396*
16.2.2 Th17 Cell Differentiation in Humans *397*
16.2.3 Pathogenic Th17 Cells *398*

16.2.4 Circulating versus Tissue Phenotypes *398*
16.3 Cytokines and Chemokines Related to Th17 Cells *399*
16.3.1 Major Cytokines and Chemokines Produced by Th17 Cells *399*
16.3.1.1 IL-17A (IL-17)/IL-17F *399*
16.3.1.2 IL-21 *400*
16.3.1.3 IL-22 *400*
16.3.1.4 CCL20 *400*
16.3.2 Major Cytokines Acting on Th17 Cells *401*
16.3.2.1 IL-23 *401*
16.3.2.2 IL-27 *401*
16.4 Th17 and Inflammatory Diseases *401*
16.4.1 Psoriasis *402*
16.4.2 Arthritic Diseases *402*
16.4.3 Multiple Sclerosis *403*
16.4.4 Inflammatory Bowel Diseases *403*
16.5 Mechanisms in Chronic Inflammation *403*
16.5.1 Differentiation, Recruitment, and Maintenance of Th17 Phenotype during Chronic Inflammation *403*
16.5.2 Secretion of IL-17 and its Activity *404*
16.6 Plasticity of Th17 Cells *405*
16.7 Clinical Targeting of Th17 Cells *407*
16.8 Conclusions *408*
Acknowledgment *408*
References *408*

17 Platelets *419*
Jack Levin
17.1 Introduction *419*
17.2 Expression of Toll-like Receptors *422*
17.3 Interactions between Platelets and Bacteria *422*
17.4 Interactions between Platelets and White Blood Cells *423*
17.5 Platelet Integrins *424*
17.6 Role of Platelets in Immune Responses *425*
17.7 Platelets and Inflammatory Disorders *425*
17.8 Malaria *426*
17.9 Systemic Lupus Erythematosus *426*
17.10 Conclusions *426*
References *427*

18 Epithelial Cells *437*
Jill M. Hoffman and Charalabos Pothoulakis
18.1 Introduction *437*
18.2 The Intestinal Epithelium: An Archetypal Epithelial Barrier *438*
18.3 Choosing a Cell Fate: The Absorptive Lineage *438*
18.4 Choosing a Cell Fate: The Secretory Lineage *439*
18.4.1 Goblet Cells *439*

18.4.2 Paneth Cells *441*
18.4.3 Enteroendocrine Cells *441*
18.5 The Epithelium: The Sum is Greater than its Parts *442*
18.6 Epithelial Homeostasis: Maintaining the Balance *443*
18.6.1 Wnt Signaling *443*
18.6.2 Notch Signaling *444*
18.6.3 Inflammation-induced Alterations in Epithelial Cells *445*
18.7 Concluding Remarks *447*
References *447*

19 Inflammation: The Role of Endothelial Cells *457*
J. Steven Alexander, D. Neil Granger, and Norman R. Harris
19.1 Introduction *457*
19.2 Vasomotor Dysfunction *458*
19.2.1 Mechanism of Vascular Smooth Muscle Contraction/relaxation *459*
19.2.2 Endothelial Cell-dependent Vasoactivity *459*
19.2.3 Endothelium-dependent Vasoactivity in IBD *460*
19.2.3.1 Leukocyte– and Platelet–endothelial Cell Adhesion *461*
19.2.3.2 Enhanced Thrombosis *463*
19.2.3.3 Angiogenesis/vasculogenesis *465*
19.2.3.4 Junctional and Vascular Permeability *468*
19.3 Conclusions *470*
References *471*

Volume II

Part Three Inflammatory Mediators *477*

20 IL-1 Superfamily and Inflammasome *479*
Charles A. Dinarello
20.1 Introduction *479*
20.1.1 The IL-1 Family of Cytokines and the Innate Immune System *479*
20.1.2 The Family of IL-1 of Receptors *481*
20.1.3 The IL-1 Family Consensus Sequence *481*
20.1.4 The IL-1 Family as Therapeutics *482*
20.2 IL-1α *483*
20.2.1 Historical Background *483*
20.2.2 Systemic Effects of IL-1α in Humans *483*
20.2.3 IL-1α is a Dual-function Cytokine *484*
20.3 Cell Sources, Production, and Secretion *484*
20.3.1 Large Amounts of Constitutive IL-1α in Healthy and Disease Cells *484*
20.3.2 IL-1α as a Growth Factor *485*
20.3.3 Membrane IL-1α *485*
20.3.4 Studies in IL-1α-deficient Mice *486*

20.4 IL-1β *486*
20.4.1 Historical Background *486*
20.5 Systemic Effects of IL-1β in Humans *487*
20.5.1 Transcription, Translation, and Synthesis of IL-1β *487*
20.5.2 Regulation of IL-1β Production *487*
20.5.3 The NLRP3 Inflammasome-dependent Processing and Secretion of IL-1β *488*
20.5.4 P2X7 and the Activation of the Inflammasome *489*
20.5.5 Noncaspase-1 Processing of IL-1β *489*
20.5.6 Effects in Mice Deficient in IL-1β *490*
20.6 IL-18 and IL-18-binding Protein *490*
20.6.1 Processing of the IL-18 Precursor by Caspase-1 *491*
20.6.2 Signal Transduction by IL-18 *491*
20.6.3 Role of IL-18 in the Production of IFNγ *492*
20.6.4 IL-18, IL-17, and Gamma/delta T-Cell Activation *492*
20.7 IL-18 and Inflammation *493*
20.7.1 Proinflammatory Properties of IL-18 *493*
20.7.2 IL-18 in Heart Disease *494*
20.8 IL-18 as a Protective Cytokine *495*
20.9 IL-18-binding Protein *495*
20.9.1 Background on IL-18BP *495*
20.9.2 The Concept of Free IL-18 *496*
20.9.3 Regulation of IL-18BP *496*
20.9.4 Viral IL-18BP *497*
20.9.5 Hemophagocytic Lymphohistiocytosis and Macrophage Activation Syndrome *497*
20.9.6 IL-18 in the Hemophagocytic Syndromes *497*
20.10 IL-33 *498*
20.10.1 The Discovery of IL-33 *498*
20.10.2 Processing of IL-33 *498*

Preface

Inflammation is older than humanity itself. Indeed, the earliest signs of inflammatory processes can be found on the bones of dinosaurs. Inflammation has always been integral to humans as the key process that protects against sterile or infectious insults. By the end of the eighteenth century, John Hunter was among the first to define inflammation as a salutary function, a concept endorsed 100 years later by Elie Metchnikoff. To limit the side effects of inflammation, the use of herbal anti-inflammatory was introduced in China (2800 BC) and Egypt (1520 BC), well before Hippocrates. Bloodletting was another therapeutic approach widely supported for some 2000 years. While natural products remain an important source of new anti-inflammatory drugs, bloodletting has been recognized to be powerless!

Nowadays, the beneficial effects of inflammation are well recognized when associated with the overlapping innate immune response. In recent years, molecular and cellular players have been well characterized and their precise interactions better understood. New molecular mechanisms have been deciphered such as the inflammasome and epigenetics. However, the word inflammation remains mainly associated with disease. Indeed, many chronic inflammatory disorders have been identified as severe debilitating diseases that may even favor the emergence of certain cancers. Deciphering the molecular and cellular events underlying inflammation has enabled development of new drugs that have revolutionized treatment and outcomes of some of these disorders.

Major achievements have been made in the last few decades allowing new understanding of the cross-talk between immune and nonimmune cells (e.g., cytokines, neuromediators, and eicosanoids) and in the resolution of inflammation (e.g., control by the neuronal system, new lipid mediators). Well-recognized

leaders in the field have contributed their specific expertise to this book, thus making it most comprehensive overview of inflammatory processes and associated diseases.

Inflammation through the Ages: A Historical Perspective

Jean-Marc Cavaillon

Institut Pasteur, Unit Cytokines & Inflammation, 28 rue Dr. Roux, 75015 Paris, France

1.1 Introduction

Inflammation is older than humanity itself and the earliest signs of inflammatory processes can be found on the bones of dinosaurs. Of course, inflammation has always been accompanying humans since they are on Earth as it can be seen on the bones of the first humanoids and of *Homo sapiens*. The first precise diagnoses of inflammatory disorders were made on Egyptian mummies by *Sir Marc Armand Ruffer* (1859–1917). Accompanying the first British Egyptologists, he gave birth to a new science: "paleopathology." He made a pioneer post-mortem diagnosis of arthritis and spondylitis, and by studying the mummy of Ramses II, he diagnosed that the pharaoh had suffered from atherosclerosis. In fact, long before inflammatory processes could be understood or even defined humans had proposed various therapeutic approaches to treat different types of inflammatory diseases.

1.2 The First Treatments

According to Chinese mythology, herbology or the use of plants to cure diseases was introduced by Emperor *Shennong* in 2800 BC, and the first ever book on medicinal plants was published in China in 300–200 BC. Other testimonies of interest on plants to cure diseases or at least to relieve pain and fever were provided by *Edwin Smith* and *Georg Moritz Ebers*, two Egyptologists who obtained fascinating papyruses. These papyruses (around 1520 BC) were copies of even older ones (3400 BC). Not only did they describe case reports of injuries but also listed different plants to be used against various types of injuries (crocodile bites, burns, fractures, bowel diseases, joint pains, etc). For example, infusion of dried myrtle was recommended for rheumatic pain. The interest to use plants to cure inflammatory diseases was perpetuated by the Greeks, and *Hippocrates* (450–370 BC) used extracts from willow bark to relieve pain and

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.
Edited by Jean-Marc Cavaillon and Mervyn Singer.

fever. The study of willow bark ended with the discovery of aspirin in the nineteenth century.

Hippocrates also advocated bloodletting as another therapeutic approach to cure most diseases, including inflammatory disorders. Its use was supported by other erudite Greeks such as *Erasistratus*, *Asclepiades of Bithynia*, or *Galen of Pergamon* and later by the Roman scholar *Aulus Cornelius Celsus*, the Persian medical doctor *Avicenna* (tenth century), or the Spanish Jewish doctor *Moïse Maïmonide* (twelfth century). All physicians of the kings of France were great supporters of bloodletting. *Ambroise Paré* (1509–1590), the physician of Charles IX, explained why he bled a young man 27 times in four days: "I liked to mention this event, so that the young surgeon will not be too shy to draw blood when confronted to large inflammation." *Laurent Joubert* (1529–1583), the physician of Henri III, claimed that it was a way to get rid of the "bad blood" while the best was retained. *Charles Bouvard* (1572–1658) had probably prescribed 47 bloodlettings during the last 10 years of Louis XIII who died of Crohn's disease at the age of 42 years. They used it even when their patients were still young. For instance, *François Vaultier* (1590–1652) bled the young Louis XIV at the age of 9 years when he had smallpox. *Guy Patin* (1601–1672), the dean of the School of Medicine in Paris for a brief period, declared: "There is no remedy in the world that does so many miracles. I have bled my wife twelve times for a pleurisy, twenty times my son for a continuous fever and myself seven times for a cold." [1] Even on the American continent, bloodletting was popular. Thus, on December 14, 1799, Georges Washington, probably suffering from pneumonia, died when 3.7 l of blood was drained out of his body in one single day. The first doctor to question the usefulness of bloodletting was *Pierre Charles Alexandre Louis* (1787–1872) who in 1835 considered this approach to have had very limited advantages. But pitted against him were leading doctors such as *François Broussais* (1772–1838) who was alleged to have had spilled more blood than Napoleon on all battlefields! If the lancet was commonly used to remove blood from patients, then the use of leeches was another method. According to an estimate, 35 million leeches were used in France in 1830 alone. This trend went unabated until *François-Vincent Raspail* (1794–1878) questioned the method in 1845 saying: "But why resort to violent and bloody means? Do you wish to calm fever? You will not succeed by bleeding [. . .] So leave your lancet there, it has made enough troubles since Hippocrates" [2]. In 1856, in Great Britain, *John Hughes Bennet* (1812–1875) also concluded that there was no proven therapeutic advantage of bloodletting.

The other method used to prevent a severe inflammation and infection after a wound was cauterization supported by doctors such as *Giovanni da Vigo* (1450–1525) in Italy and *Paracelsus* (1493–1541) in Switzerland until Ambroise Paré, comparing the relative advantages of cauterization and the use of antiseptics, concluded that the latter were the best. But the word "antiseptic" was coined only in 1750 by *John Pringle* (1707–1782), a Scottish physician, who studied numerous substances able to prevent putrefaction. In 1854, *Florence Nightingale* (1820–1910) advocated hygiene as a means to prevent infection during the Crimean war in order to limit the mortality of wounded soldiers. Of

course, the main advocate of hygiene was *Ignaz Semmelweis* (1818–1865) who succeeded in 1847 to reduce mortality due to puerperal sepsis.

1.3 The Definitions

One of the very firsts to define the parameters of inflammation was *Aulus Cornelius Celsus* (25 BC–50 AD), a Roman encyclopedist to whom we owe the famous statement: "*Notae vero inflammationis sunt quatuor: rubor et tumor cum calore and dolore*" (The signs of inflammation are four: redness, swelling, fever and pain). A fifth element was later added "loss of organ function." Erroneously attributed to Galen of Pergamum, it could have been proposed by either *Thomas Sydenham* (1624–1689) or *Rudolf Virchow* (1821–1902). Of course, inflammation has for a long time been considered a morbid response of the host to any types of insults. However, *John Hunter* (1728–1793), a Scottish surgeon, appropriately defined inflammation in his book published one year after his death: "*Inflammation in itself is not to be considered as a disease, but as a salutary operation, consequent either to some violence or some disease*" [3]. Despite this appropriate definition, one could still read in 1865 in the French dictionary of medicine that "Inflammation is a complex morbid phenomenon, particularly associated with the function of blood circulation." In his lecture on inflammation, *Elie Metchnikoff* (1845–1916) stated in 1891 that phagocytes were the participant of the inflammatory process and that inflammation should no longer be seen as only being deleterious [4]. Since Metchnikoff, many mechanisms accompanying inflammation have been further deciphered and mediators have been characterized.

1.4 Fever

For a while it was believed that fever was consecutive to some obstructions within the blood vessels leading to an accelerated movement within the free vessels. At the beginning of the eighteenth century, a defender of this concept was the Italian physician *Lorenzo Bellini* (1643–1704). *Herman Boerhaave* (1668–1738), a Dutch physician, also thought that increased heartbeats were the source of the accelerated circulation and fever. In 1744, *François Boissier de Sauvages de Lacroix* (1706–1767), while translating in French the book on "haemastatic" written by *Stephen Hales* (1677–1761), added his personal view on fever, confirming the prevailing concept that inflammation was associated with increased blood flow. Thanks to scientists and doctors such as *John Davy* (1790–1868) in the United Kingdom who made the first sets of temperature measurements in different humans and in different environments (1816–1818), *Antoine Becquerel* (1852–1908) in France who invented the pyrometer to measure human temperature (1835), *Thomas Clifford Allbutt* (1836–1925) who invented the clinical thermometer (1866), and *Reinhold August Wunderlich* (1815–1877) of Germany who made more than one million measurements on more than 25 000 patients (1868), normal temperature and fever could be definitively and precisely defined. *William H. Welch* (1850–1934), the first dean of the

Johns Hopkins School of Medicine, offered a wonderful definition of fever in his 1888 Cartwright lecture:

> The real enemy in most fevers is the noxious substance which invades the body, and there is nothing to prevent us from believing that fever is a weapon employed by Nature to combat assaults of this enemy. According to this view, the fever-producing agents light the fire, which consumes them. It is not incompatible with this conception of fever to suppose that the fire may prove injurious also to the patients and may require the controlling hand of the physician [5].

What could be these "noxious substances?" The same year, *Nikolai Fedorovich Gamaleïa* (1859–1949), who worked in Odessa and Moscow, spent some time with Metchnikoff at the Institut Pasteur and reported that an injection of dead bacteria could induce fever in rabbits and sheep. Most fascinatingly, he showed that filtered alcoholic extracts of spleen from pyretic sheep could induce fever within 30 min in rabbits [6]. The following year (1889), Marc *Armand Ruffer*, who joined Elie Metchnikoff and Louis Pasteur shortly after the Institute was set up, published a paper with *Albert Charrin* (1856–1907) who was a professor at the prestigious College de France. They reported that the filtered culture of pyocyanic bacillus (*Pseudomonas aeruginosa*) could induce fever in rabbits, in the absence of alive or dead bacteria [7]. Of note, this report was published three years before the German physician and bacteriologist *Richard Pfeiffer* (1858–1945) coined in 1892 the word "endotoxin" that is nowadays widely used. Most fascinating, the authors wrote, although did not prove, that fever was the consequence of the activation of macrophages. In 1894, *Eugenio Centanni* (1863–1942), an Italian pathologist, recognized the intimate relationship between the pyrogenic and toxic properties of the bacterial poison, which he found to be chemically inseparable. This led him to name his material "pyrotoxina" [8]. In 1890, *Hans Ernst August Buchner* (1850–1902) had shown that this material was also pyogenic [9].

Valy Menkin (1901–1960) was the first to attempt to purify the endogenous mediator that could be responsible of fever. In 1943, he isolated a mediator called "pyrexin" [10]. Unfortunately, further analysis of his work suggested that his factor was contaminated with endotoxin [11]. So, in 1953, *Ivan L. Bennet Jr.* (1922–1990) and *Paul Beeson* (1908–2006) were the first to extract a fever-producing substance from rabbit polymorphonuclear leukocytes [12]. In 1955, *Elisha Atkins* (1921–2005) and *W. Barry Wood Jr.* (1910–1971) isolated a circulating endogenous pyrogen in the blood after the injection of typhoid vaccine [13]. In 1984, Charles Dinarello cloned the human interleukin-1β, known to be the endogenous pyrogen among many other activities [14].

1.5 Phagocytosis

In 1882, *Elie Metchnikoff* (1845–1916), when he was in Messina (Sicilia) with his family-in-law, made his key observation. He stuck rose thorns into starfish larvae

and was surprised to see that many phagocytic cells in the hemolymph of the starfish surrounded the "foreign object." He also observed the process in Daphnia, which he infected with yeast. These cells were able to move, ingest, and destroy the yeast cells within the water fleas. He then understood that this process was an important mechanism of host defense against infectious agents. When he met his Austrian friend Karl Claus in Vienna, he was offered to publish his observation in a Viennese journal and Karl Claus coined the word "phagocyte" (1883) [15]. It is worth mentioning that this discovery that finally led to a Nobel Prize (1908) was not published in a high-profile journal (happy times!). Interestingly, he was not the first one to observe the phenomenon. In 1847, *Alexander Ecker* (1816–1887) in Germany had described erythrocytes inside rabbit spleen cells, an observation confirmed in 1870 by *Nathanael Lieberkühn* (1821–1887) who reported that leukocytes could ingest erythrocytes. In 1871–1873, *Giulio Bizzozero* (1846–1901) provided the first drawings of macrophages that had ingested erythrocytes. He stated that reticular cells could ingest infective particles that were carried by the lymphatic liquid. He made this farsighted statement: ". . . this fact is, perhaps, the cause of the stoppage of some infections to the lymphatic glands which are connected to the part covered by the infection through the lymphatic vessels" [16]. In 1875, *Sir William Osler* (1849–1919) reported that alveolar macrophages of coal miners were full of carbon particles. In 1881, *Alexander Ogston* (1844–1929) published cartoons of groups of cocci, mostly free, but sometimes in or on large nonnucleated masses of protoplasm of leukocytes [17]. While Metchnikoff was in Messina trying to understand the aim of phagocytosis, *Robert Koch* (1843–1910) identified anthrax bacilli within white blood cells. Yet, Koch had interpreted his finding to mean invasion of the host by bacterial pathogens. The discovery of phagocytosis by Metchnikoff was not easily accepted, however. He recalls: ". . . The controversy about the phagocytosis could have killed me, or sooner permanently weakened me. Sometimes, (I remember such attacks of Lubarsch in 1889, and those of Pfeiffer in 1894) I was ready to get rid of life" (Oct. 1913). But some other scientists were fully convinced. For instance, Sir Marc Armand Ruffer was an ardent advocate of phagocytosis in the UK. In 1892, he wrote in the *British Journal of Medicine* [18]: "Should anyone meet a dead lion and find a lamb inside, he, knowing the habits of the lion would not conclude that the lamb had taken refuge in that. True, after a surfeit of lamb, the lion might die of indigestion but the chance of the lamb ever getting out alive would be very small."

Other sources of phagocytes were also discovered. *Nicolas Tchistovitch* (1860–1926) described that what were then considered epithelial cells were in fact alveolar macrophages [19]. *Carl Wilhelm Kupffer* (1829–1902) described stellate cells in the liver. He incorrectly believed that these cells were an integral part of the endothelium of the liver's blood vessels. In 1898, *Tadeusz Browicz* (1847–1928), a Polish pathologist, correctly identified them as macrophages, now known as Kupffer cells. In 1922, *Karl Albert Ludwig Aschoff* (1866–1942) introduced the term "reticulo-endothelial system" that included endothelial cells, fibrocytes, histiocytes, and splenocytes, monocytes and Kupffer cells [20]. However, this concept was of limited help since it mixed cells that undergo pinocytosis and cells that are able to achieve phagocytosis.

In 1903, *Sir Edward Almroth Wright* (1861–1947), a British bacteriologist and immunologist who discovered an effective vaccine for typhoid fever, coined the word "opsonisation" from Greek "οπσονο" meaning "I prepare victuals for . . ." He nicely explained: "The body fluids modify bacteria in a manner which renders them a ready prey to phagocytes" [21]. But the observation had been first reported in 1895 by Joseph Denys (1857–1932), a professor of bacteriology and anatomy at Louvain University. He stated: "In vaccinated rabbit, leukocytes get from sera their power to engulf and destroy *Streptococcus* pyogenes" [22]. In 1904, *Friedrich Neufeld* (1869–1945), a physician and bacteriologist, director of the Robert Koch Institute in Berlin, described the exactly same phenomenon, only based on much more solid experimental works [23]. But the word, "bacteriotropin," he coined did not survive the effects of time, and was not used after 1930.

In 2003, *Aimee M. deCathelineau* and *Peter M. Henson* coined the word "efferocytosis" derived from the Latin prefix *effero*, meaning "to take away, to put away, to carry to the grave, or to bury" [24]. However, Metchnikoff already knew the process as he had observed: "[. . .] many of phagocytes perish and are taken in by other phagocytes, as can be seen in every case a few days after the onset of the inflammation" [25]. But it was described for the first time by Giulio Bizzozero in 1871–1872, studying eye inflammation: "In summary, my observation showed the presence of big cells able to engulf white blood supurative cells or red blood cells in their contractile protoplams. This represents a way through the pus or blood is absorbed from the anterior chamber" [26]. Marc Armand Ruffer, while working with Metchnikoff, described in 1890: "Macrophages are able to swallow microphages (neutrophils) and to destroy and digest them" [27].

1.6 Diapedesis

Galen of Pergamon had considered that the formation of pus was part of the healing process ("*pus bonum et laudabile*," good and commendable pus). Pus was supposed to facilitate the removal of the unhealthy mood of the injured body. Galen's theory prevailed for more than a millennium until *Ugo Borgognoni of Lucca* (1160–1257), a surgeon and the founder of the Faculty of Medicine of Bologna, and his son *Theodorico Borgognoni of Lucca* (1205–1298), clergyman and surgeon, critiqued the doctrine in a four-volume work entitled "Chirurgia" (1267). In 1810, *Alexandre François Ollivier* (1790–1844), a physician accompanying Napoleon's campaign, injected himself with the pus from a wound of a severely injured soldier dying from putrid fever and was the first one to demonstrate its contagiousness [28].

In 1845, two scientists studied pus under the microscope and observed that the cells present in the pus were similar to the cells found in blood. *Alfred Donné* (1801–1878), a French bacteriologist and physician, studied blood from a leukemic patient and thought that it might contain pus cells, although he observed a clear-cut difference between these cells [29]. In contrast, *William Addison* (1802–1881), the physician to the Duchess of Kent, appropriately understood that pus cells were derived from white blood cells (or colorless as they called them): "Colorless blood cells are deposited all over the interior of the vessels;

[. . .] and at length pass into the tissue; [. . .] These facts are all independent of any orifices, rupture or pores in the vessels, allowing the escape of cells" [30]. Yet, the observation of diapedesis was not made. *Augustus Volney Waller* (1816–1870), a British neurophysiologist, was the first to observe natural leukocyte emigration in 1846, using the frog tongue. Hence, the origin of pus cells was not fully demonstrated [31]. In 1858, *Rudolf Virchow* (1821–1902), a medical doctor at Charité Hospital in Berlin, the father of the cell theory, erroneously believed that pus cells were derived from tissue elements following cell division [32]. But his assistant and two of his students made the final demonstration. In 1863, *Friedrich Daniel von Recklinghausen* (1833–1910), a physician and pathologist who left Virchow for a position of professor at the University of Würzburg before joining the University of Strasbourg, induced an experimental keratitis in frogs with silver nitrate. He characterized the pus cells in humor aqueous during acute inflammation and made the seminal observation of the contractility and mobility of colorless cells [33]. In 1867, *Julius Friedrich Cohnheim* (1839–1884) used a combination of colloidal aniline blue injections and microscopy to prove, what Addison had hypothesized, that white blood cells crossed blood vessels to become pus cells [34]. And in 1875, *Julius Arnold* (1835–1915), using an injection of cinnabar to demonstrate the borders of endothelial cells, came to the conclusion that leukocytes moved across blood vessel walls (diapedesis) by passing between endothelial cells at either points of dense staining, "stigmata," or circles of stain, "stomata" [35]. Quite surprisingly, 33 years after Addison's work, *Louis Pasteur* (1822–1895) wrote in 1778: "For us currently, it would be the red blood cells that would be the pus cells from a simple transformation from the first into the second" [36]. This illustrates that great scientists can also make wrong statements!

1.7 Chemotactism

Nowadays, it is well understood that diapedesis of circulating cells toward tissues is under the control of chemoattractant signals. Interestingly, the concept came from an observation made with bacteria. In 1884, *Wilhelm Pfeffer* (1845–1920), a botanist at the University of Tübingen, Germany, observed bacteria swimming toward the vicinity of the tip of a capillary tube filled with nutrient sugar that had been dipped into a bacterial culture broth. He coined the word "chemotaxis" [37]. The *in vivo* phenomenon was first reported in 1889 by *Cornelis Adrianus Pekelharing* (1848–1922), a Dutch physician and professor of physiological chemistry and histology at the University of Utrecht [38]. He put cotton wool soaked with anthrax bacilli in the peritoneal cavity of a frog. Retrieving this cotton wool some time later, he showed that it contained significantly more leukocytes than those that had been soaked with neutral liquid. He came to the conclusion that bacteria produce chemoattractant factors. The following year, in 1890, *Georges Gabritchevsky* (1860–1907), a Moscovite researcher who spent some time with Elie Metchnikoff, drew the same conclusion [39]. He inserted under the skin of frogs, rabbits or axolotl, small capillary tubes filled with alive or dead bacteria. Twenty-four hours later, the capillary tubes were full of leukocytes,

whereas this was not the case if the capillaries had been filled with saline. The same year in Belgium, *Jean Massart* (1865–1925), a doctor in sciences and medicine working with *Charles Bordet*, the brother of the famous Jules Bordet who got the Nobel Prize for his discovery of the complement, was the first to demonstrate that the host can make chemoattractant factors [40]. He injected bovine bile subcutaneously in a frog. Then, he sampled the transudation liquid and transferred it in a capillary tube into the abdominal cavity of another frog. Twenty hours later, the capillary tube was full of leukocytes, whereas this was not observed with a capillary tube filled with normal lymph. Thus, he had demonstrated that chemoattractant factors were produced by the frog. In 1891, the same team performed another elegant demonstration [41]. They injected s.c. bacteria (*Micrococcus prodigiosus*, nowadays known as *Serratia marcescens*) in a rabbit. Thirty-five minutes later, they sampled the blood, prepared the serum, placed it in a capillary tube and finally transferred it into the peritoneal cavity of another rabbit. Eight hours later, the capillary tube was full of leukocytes, whereas this was not the case when the tubes were filled with normal serum. For the first time, they had demonstrated that chemoattractant factors were produced in response to infection. In 1938, *Valy Menkin* (1901–1960) purified a substance from inflammatory exudates that induced an increased capillary permeability followed by a migration of polymorphonuclear leukocytes. He called his factor "leukotaxine" [42]. Unfortunately, like the case for pyrexin, despite all his efforts, he could not succeed and further studies revealed no convincing evidence that "leukotaxine" existed as a distinct chemical entity [43]! The discovery of well-identified chemoattractant factors, later called chemokines (the word was coined in 1992), was made in 1987 and 1988 with the description of interleukin-8 and macrophage inflammatory protein (MIP), renamed CXCL8 and CCL3 according to the revised nomenclature of chemokines [44].

1.8 Infection and Inflammation

The link between microbes, infection, and inflammation was made during the nineteenth century. But some genius had outstanding intuition. This is the case of *Marcus Terentius Varro* (116–27 BC), a Roman scholar who wrote: "There are certain minute creatures which cannot be seen by the eyes, but which flоat in the air and enter the body through the mouth and nose and cause serious diseases." In 1822–1823, *Bernard Gaspard* (1788–1871) and *François Magendie* (1783–1855) showed a link between putrefaction and severe diseases, fever, and death [45,46]. In 1863, *Casimir J. Davaine* (1812–1882) was the first one to convincingly demonstrate the link between bacteria and infectious disease, transmitting anthrax with the blood of a sheep containing the bacteria into rabbits which then died following this injection [47]. The same year, Louis Pasteur established that the first six bacteria identified by *Christian Gottfried Ehrenberg* (1795–1876) in Germany, 30 years earlier, were the ferments of putrefaction [48]. Of note, Ehrenberg had coined the word "bacterium" in 1828. Some infectious diseases were not immediately recognized as such. For example, *Antoine de Jussieu* (1686–1758), a French botanist and physician, claimed that puerperal sepsis

was an inflammation of the uterus. He proposed to use extracts of bark of quassia to reduce fever. Interestingly, this plant was well known to Brazilian Indians who used to relieve pain and fever. *Thomas Denman* (1733–1815) in his book, the first ever to be entirely devoted to puerperal sepsis, mentioned that in addition to an inflammation of the uterus, it could be also an inflammation of the bowel [49]. In 1795, *Alexander Gordon* (1752–1799), a Scottish physician who studied the epidemic puerperal sepsis in Aberdeen, also described inflammation of the abdomen, but he was the very first to claim that it was a contagious disease spread by the hand of the physicians [50]. A similar observation was also made in the United States of America by *Oliver W. Holmes* (1809–1894) in 1843 [51]. Nevertheless, the final demonstration was achieved in 1847 by *Ignaz Semmelweis* (1818–1865), a Hungarian doctor working at the maternity clinic of the Vienna General Hospital. He successfully demonstrated that if medical students cleaned their hands after practicing autopsies before helping women in childbirth, the mortality due to puerperal sepsis was significantly decreased. Yet, doctors were not convinced, and he was asked to leave the maternity clinic. He published his key demonstration 10 years later in Hungarian [52]. However, a short note was published in *The Comptes Rendus* of the French Academy of Sciences on February 21, 1848. Ten years after his demonstration, in Paris, *Paul Dubois* (1795–1871), a professor of obstetrics, claimed that the contamination was due to miasma [53]. Eighteen years after Semmelweis' observation, *Carl Mayrhofer* (1837–1882) was asked by Prof. Carl Braun (1862), the head of the same maternity clinic in Vienna, to demonstrate that airborne organisms were the source of childbed fever. After publishing works in agreement with the ideas of his boss, his following works supported Semmelweis' work, concluding that infection was usually the result of contaminated hands [54]. He was fired! In 1869, *Victor Feltz* (1835–1893) and *Léon Coze* (1819–1896), two Strasbourg physicians, were the first to identify the presence of bacteria in the blood of a lady who died of puerperal sepsis [55]. Ten years later, on March17, 1879, Feltz republished a similar observation [56]. The following day, on 18th March, Louis Pasteur confirmed the observation [57], but challenged the work of Feltz, arguing that his patient had died of anthrax after deliverance.

1.9 Usefulness of Inflammation for Adaptive Immune Response

Gaston Ramon (1886–1963), a veterinary doctor, was hired by the Institut Pasteur to prepare horse immune sera against diphtheria toxin and tetanus toxin. He observed that the antibody titers were quite different from one horse to another. He made a link between these titers and the presence of an inflammatory reaction at the site of injection of the antigen as illustrated by the appearance of an abscess. Then, he purposely created an inflammatory reaction at the site of injection using different substances such as tapioca or lanolin. In 1926, he realized that there was a need to involve an inflammatory reaction at the site of injection of the antigen to enhance immune response, and he had discovered the

concept of adjuvant [58]. Many others used different inflammatory substances, such as lipids. For example, *Jules T. Freund* (1890–1960), an Austria-Hungarian born American immunologist, proposed to create a water oil emulsion to which he added inactivated mycobacterium tuberculosis. In search of the smallest bioactive part that allows the adjuvant properties, the biochemist *Edgar Lederer* (1908–1988) and the immunologist *Louis Chedid* joined forces and discovered the muramyldipeptide [59]. The adjuvants, the so-called "little dirty secrets of the immunologists" led *Charles Janeway* (1943–2004) to redefine the immune response [60]. Since then, what used to be defined as nonspecific immunity was renamed innate immunity. Innate immunity and inflammation are more or less two names for a similar mechanism, namely, the defense of the host against infectious or sterile insults.

1.10 Mediators of Inflammation

If nowadays the complement system is known to contribute to inflammation, particularly through the release of anaphylatoxins, its first identification was associated with its capacity to induce bacteriolysis as shown in 1894 by *Richard Pfeiffer*. In 1898, *Jules Bordet* (1870–1961), who received Nobel Prize in 1919, identified that hemolysis was similarly induced by serum components, but the word "complement" was coined by *Paul Ehrlich* (1854–1915), who shared the 1908 Nobel Prize with Metchnikoff. Surprisingly, when the word anaphylatoxin was employed in a paper reporting a model of anaphylatoxic shock, its existence was denied. Indeed, an unanticipated severe reaction had been observed in 1901 when *Charles Richet* (1850–1935, Nobel Prize 1901) and *Paul Portier* (1866–1962) involuntarily killed dogs after the second injection of a hypnotoxin from physalia. One of the main mediators of anaphylatoxic shock is histamine. The molecule was synthesized for the first time in 1907 by *Adolf O.R. Windaus* (1876–1959, Nobel Prize 1928), and *Henry H. Dale* (1875–1968, Nobel Prize 1936) who discovered its activity on smooth muscle and on endothelium. In 1937, *Anne-Marie Staub* (1914–2012), who worked in the laboratory of *Daniel Bovet* (1907–1992, Nobel Prize 1936) at Institut Pasteur, was the first scientist to save an animal from a shock induced by histamine. However, the employed antihistaminic drug was toxic, and the first antihistaminic to be used in humans (Antergan) was developed by *Bernard Halpern* (1904–1978).

In 1930, *William S. Tillett* (1892–1974) and *Thomas Francis Jr.* (1900–1969), working at the Rockefeller Institute in New York, identified in the serum of a rabbit injected with *Streptococcus pneumoniae* an interaction activity with a carbohydrate extract of the bacteria (called "fraction C"). The C-reactive protein (CRP) was thus discovered and shown to be present in the inflammatory settings independent of any *S. pneumoniae* infection [61]. CRP was purified by *Colin M. MacLeod* (1909–1972) and *Oswald T. Avery* (1877–1955) in 1941 [62] and crystallized in 1947 by *Maclyn McCarty* (1909–1972) [63]. All these investigators were working at the Rockefeller Institute. The pentameric structure was determined in 1977 and its liver origin was demonstrated the following year.

Nowadays, CRP is one of the most common biomarker to confirm the presence of an inflammatory reaction.

In 1935, *Ulf von Euler* (1905–1983) discovered the prostaglandins. This Swedish physiologist and pharmacologist, who also discovered noradrenalin and substance P, was awarded the Nobel Prize in 1970. His father, *Hans von Euler-Chelpin* (1873–1964) was also awarded the Nobel Prize in 1929 for his contribution to the fermentation of sugar and his mother, *Astrid Cleve* (1875–1968), a botanist, geologist, and chemist at Uppsala University, had been the first woman in Sweden to obtain a doctoral degree of science. For their studies on prostaglandins, related biologically active substances, and the discovery that aspirin prevented the production of prostaglandins, the Swedish *Sune K. Bergström* (1916–2004) and *Bengt I. Samuelsson* (1934–) and the British *Sir John R. Vane* (1927–2004) were awarded the 1982 Nobel Prize.

Glucocorticoids was discovered in 1936–1941 by three scientists who were awarded the Nobel Prize in 1950 for their discoveries related to the hormones of the adrenal cortex, their structure, and biological effects. In the United States, *Philip Showalter Hench* (1896–1965) postulated that a natural mediator, which he called substance X, was involved in the improvement of arthritis when patients developed jaundice. He collaborated with *Edward Calvin Kendall* (1886–1972), who purified a large number of substances from adrenals. Among those, was the compound E (dehydrocorticosterone) that was finally considered as substance X [64]. In Switzerland, *Tadeusz Reichstein* (1897–1996), who was born in Poland, also produced numerous substances from adrenals, of which few were bioactive. In 1937, he reported the production of desoxycorticosterone and its first clinical essays [65].

After the identification of the endogenous pyrogen in 1953 as aforementioned, the next cytokine being described was the interferon. In 1954, two Japanese scientists *Yasuichi Nagano* (1906–1998) and *Yasuhiko Kojima* (1928–) noticed that rabbit skin or testis previously inoculated with UV-inactivated virus exhibited inhibited viral growth when reinfected at the same site with live virus. They hypothesized that this was due to some inhibitory factors. They made two major mistakes. The first one was to publish in a French-speaking journal and the second one was not to create a neologism [66]. This explains why the British *Alick Isaacs* (1921–1967) and the Swiss *Jean Lindenmann* (1924–2015), who published three years later in English and coined the word "interferon," have been regularly considered as the discoverers of this cytokine.

In 1966, a new cytokine was discovered by Bloom and Bennett who illustrated the capacity of the supernatants of T cells involved in delayed type hypersensitivity to prevent macrophage migration (macrophage migration inhibitory factor, MIF) [67]. Most fascinatingly, this cytokine was rediscovered later as a product of the pituitary gland. Interestingly, MIF brought Stanley Cohen to create in 1974 his neologism "cytokine" [68]. The words lymphokine and monokine were commonly used, but Cohen had shown that fibroblasts infected with viruses could release MIF. Then, it was obvious that these mediators were not only the products of immune cells but also a universal language of the cells.

Endogenous pyrogen, osteoclast activating factor, hemopoietin-1, catabolin, lymphocyte-activating factor (LAF), epidermal cell-derived thymocyte-activating

factor (ETAF) are various mediators identified between 1953 and 1981, which appeared to be the diverse biological properties of one molecule, namely, interleukin-1. It was later categorized into IL-1α and IL-1β, which are members of a family of 11 molecules, including agonists and antagonists [69]. IL-1 bioactivity was the first to be identified in an inflammatory fluid. In 1982, a French dentist working in Joost Oppenheim's laboratory demonstrated the presence of IL-1 in the gingival fluid of patients with periodontal inflammation [70]. In 1986 in Norway, Waage *et al.* reported for the first time the presence of tumor necrosis factor in the plasma of patients with severe meningococcal sepsis [71]. Later on, all pro- and anti-inflammatory cytokines could be detected in the plasma of patients with severe sepsis or sterile systemic inflammation. These measurements illustrate the cytokine storm observed in many severe inflammatory settings, but those are just the tip of the iceberg [72]. Most fascinating is this statement made by William Osler in 1904: "Except on few occasions, the patient appears to die from the body's response to infection rather than from it."

Inducers and Sensors of Inflammation

2

Pathogen-associated Molecular Patterns

Jean-Marc Cavaillon

Institut Pasteur, Unit Cytokines & Inflammation, 28 rue Dr. Roux 75015 Paris, France

2.1 Definition

For a while, the immune system was defined by its capacity to distinguish between self and nonself, thanks to the specific immunity achieved by B and T lymphocytes with the help of accessory cells. A nonspecific immunity was also recognized but was not considered to be of great interest by the leaders in the field of immunology. Not until in 1989, Charles Janeway (1943–2003) asked: "Why do we need to add adjuvant (noxious substances like mineral oil, mycobacteria, or aluminum hydroxide) in order to get a decent response to a vaccine?" The self–nonself model neither predicted nor explained the need for adjuvant [1]. And he called the adjuvants, the "immunologists' dirty little secret." Then, he proposed that the self–non-self model had reached its end, arguing that the innate immune system was the real gatekeeper. He also argued that the innate immune system used ancient pattern recognition receptors" (PRRs) to recognize a pathogen by its unchanging characteristics. Thereafter, the concept of "pathogen-associated molecular pattern" (PAMPs) was born. PAMPs are compounds present among microorganisms but absent in host cells. They possess rather conserved structures that are required for the survival of pathogens. Often, authors appropriately prefer the term "microorganism (or microbe) associated molecular patterns (MAMPs)." Indeed, the molecular determinants recognized by the "pattern recognition receptors" of the host are not specific to pathogens but are found in any microorganisms being nonpathogenic, pathogenic, or commensal. Indeed, human body is made of 3×10^{13} cells, while it hosts $4 \times 10E^{13}$ commensal bacteria in the throat, nose, gut, or skin. All of these commensal bacteria express similar compounds that can also be found among the pathogenic ones. For example, all Gram-negative bacteria express endotoxin (lipopolysaccharide, LPS) on their surface, and all Gram-positive bacteria display lipoteichoic acid anchored within the peptidoglycan (PGN). Of interest, PAMPs can be expressed on the surface of or inside the pathogens. This means that some PAMPs can be released following the action of the complement system or released within an endosome or the cytoplasm of the phagocytic cells or the

target cells. Then, these PAMPs will be sensed by intracellular PRRs present either within endosomes or within the cytoplasm.

Of interest is the capacity of the host both to sense these different PAMPs and to specifically adapt its response. This specific recognition and adapted response is not only found in mammals but also exists in insects, which can release antimicrobial peptides adapted to fungal and Gram-negative or Gram-positive bacterial infection. In mammals, the response is different depending on the type of pathogen, and the host can discriminate between viral, bacterial, parasitic, or fungal infections and adapt its response. To illustrate this adapted responsiveness, let us mention the plasticity of dendritic cells, which display different gene expression in response to a bacterium, a virus, or a fungus, while their respective PAMPs, LPS, viral double-stranded RNA, and mannan partially mimic the gene expression induced by the whole pathogen [2]. While Polly Matzinger defined the concept of "damage-associated molecular patterns" (DAMPs) as endogenous alarm signals, which initiate the immune response, it is interesting to note that the concept of exogenous alarm signal was previously proposed by Legrand in his review on the response of the host to endotoxin, undoubtedly the most potent PAMP [3].

2.2 Endotoxin

2.2.1 Brief Historical Background

The basis of contagious diseases was first associated with the presence of miasma in the close environment, before the source of infection was suspected to have been derived from putrid matter. In 1822, *Bernard Gaspard* (1788–1871), a physician in Châlon/Saone, showed that indeed the injection of purulent material could induce death in animals. In 1856, *Peter Ludvig Panum* (1820–1885), a Danish physiologist, showed that the "putrid poison" leads to symptoms and signs similar to those observed in sepsis. Although he initially rejected the possibility that bacteria could play a causative role, in his last publication he hypothesized that "putrid poison" could be a bacterial product. Indeed, his "putrid poison" had striking similarities with endotoxin. In 1888, *Nicolai Gamaleia* (1859–1949), an Ukrainian bacteriologist, after his training with Elie Metchnikoff, reported that heat-killed bacteria injected in rabbits could induce fever. Most fascinatingly, he showed that filtered alcoholic extracts of spleen from pyretic sheeps could induce fever within 30 min when injected into rabbits. In the following year, *Sir Marc Armand Ruffer* (1859–1917), a famous British physician, when working in Paris with *Albert Charrin* (1856–1907), a professor of medicine, showed that the filtered culture of pyocyanic bacillus (*Pseudomonas aeruginosa*) could induce fever in rabbits, in the absence of alive or dead bacteria. Amazingly, the authors proposed, although did not prove, that fever was the consequence of the activation of macrophages. In 1890, *Hans Ernst August Buchner* (1850–1902), a German bacteriologist, showed that bacteria were pyogenic. In 1892, *Richard Pfeiffer* (1858–1945), a German physician and bacteriologist, proposed that toxic properties of bacteria were due to a factor released by lysed bacteria, and coined

the term "endotoxin." In 1894, *Eugenio Centanni* (1863–1942), an Italian pathologist, recognized the intimate relationship between the pyrogenic and the toxic properties of the poison, which he found to be chemically inseparable. This caused him to name his material "pyrotoxina." In 1894, *Giuseppe Sanarelli* (1864–1940), an Italian physician and bacteriologist, observed that animals injected twice with a bacterial endotoxin experience massive disseminated intravascular coagulation with blood clots in the vessels of the kidneys. His observation, called Sanarelli reaction, is also known as the Schwartzman reaction described later in 1928. In 1898, *William B. Coley* (1862–1936), an American surgeon, published that a mixture of dead *Streptococcus pyogenes* and dead *Serratia marcescens* could protect against tumor. On January 24, 1893, the first patient to receive Coley's treatment (known as Coley's toxins) was John Ficken, a 16-year-old boy with a massive abdominal tumor. Every few days, Coley injected his vaccine directly into the tumor mass. By August 1893, the remains of the tumor were barely perceptible. In 1906, *Alexandre Besredka* (1870–1940), an Ukrainian doctor working with Elie Metchnikoff, reported the very first anti-endotoxin antibodies when the German school was claiming that it was impossible [4]. In 1930, *Fritz Kauffmann* (1899–1978) published the first antigenic schema for *Salmonellae*. Based on antibodies against the polysaccharidic region of LPS, 44 serotypes were then listed. In 1935, *Lydia Mesrobeanu* (1908–1978), a scientist at the Cantacuzino Institute in Bucharest, and *André Boivin* (1895–1949), her mentor, reported the first demonstration that endotoxin was made of sugars and lipids. They called it "antigène glucido-lipidique," before it was renamed lipopolysaccharide in the English speaking journals. In 1946, *Paul Beeson* (1908–2006) showed that repeated exposure to typhoid vaccine in rabbits led to a state of tolerance, identified as a reduced fever. The concept was soon called "endotoxin tolerance." In 1952, *Otto Westphal* (1913–2004) described the most popular method to prepare LPS from Gram-negative bacteria by a hot aqueous phenol extraction [5]. In 1956, LPS was shown to be an adjuvant [6] and the same year was demonstrated to be a B-cell mitogen [7]. In 1968, Louis Chedid was the first to propose the concept of a universal antibody, which could neutralize endotoxin during sepsis [8]. Although it was initially shown to be successful [9], this approach was abandoned. In the 1970s, LPS was reported to induce interleukin-1 (IL-1) [10] and tumor necrosis factor (TNF) [11], and TNF was shown to mediate the lethal effects of LPS in 1985 [12]. In the 1980s, the biological characterization of the lipidic moiety (lipid A) and its properties were further deciphered and a synthetic lipid A was produced [13]. In 1990, CD14 was identified as part of the LPS receptor [14], and in 1998 TLR4 was identified to be the other essential moiety of this receptor [15]. In 2009, the US Food and Drug Administration (FDA) approved the monophosphoryl lipid A (MPLA), a subunit of LPS, to be used as an adjuvant in vaccines.

2.2.2 Biochemical Characteristics

Endotoxins are specific of Gram-negative bacteria. The LPS constitutes 75% of the outer membrane of the bacteria and the number of molecule per bacteria is estimated to be around 4 million. They are made of a lipidic moiety called "lipid

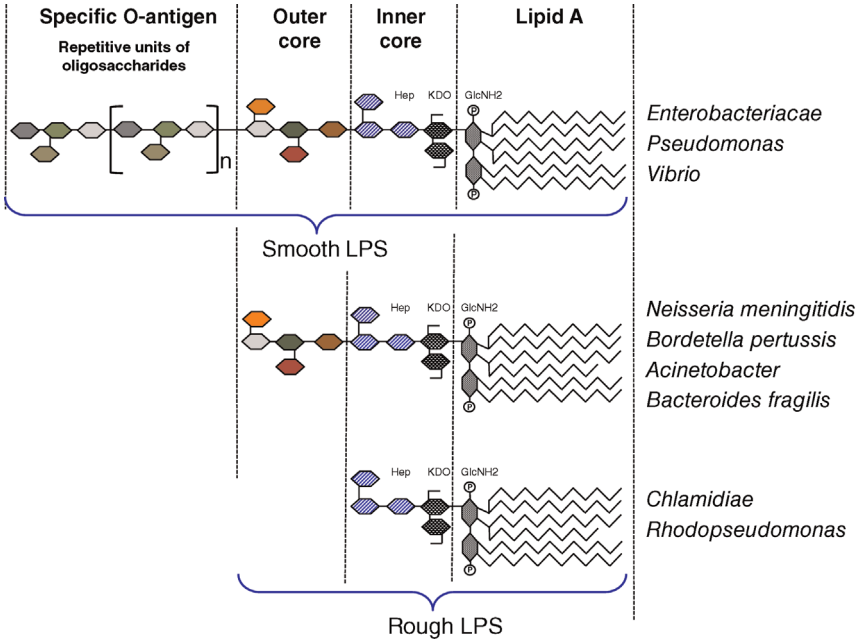

Figure 2.1 Chemical structures of the endotoxins (LPS) of Gram-negative bacteria. Of note, the complete structure (lipid A + core + O-antigen) corresponding to smooth LPS can be shortened in certain rough (R) bacteria. Hep = heptose; KDO: keto-deoxy-octonate; GlcNH2: glucosamine.

A" and a polysaccharidic moiety (Figure 2.1). The lipid A is made of four to seven fatty acids bound to a dimer of phosphorylated D-glucosamine. The length of the fatty acid varies between 10 and 18 carbons. The lipid A is bound to the polysaccharide through one specific eight-carbon acidic sugar (3-deoxy-D-manno-oct-2-ulopyranosonic acid, KDO). The KDO and few heptoses often substituted by phosphate, pyrophosphate, or diphosphoethanolamine are part of the "inner core." The "outer core" region usually consists of neutral or amino-hexoses such as D-glucose, D-galactose, D-glucosamine, D-galactosamine, or *N*-acetyl derivatives. The O-chain structure is made of repeating units (up to 50 ×) consisting of one to eight sugars, and confers the serotype specificity. Enterobacteriacae (e.g., *Escherichia*, *Salmonella*, etc.), *Pseudomonas*, and *Vibrio* display such a complete structure, which is associated with smooth colonies (S LPS). Structures that miss the oligosaccharidic repetitive units are found in mutants of enterobacteriacae and naturally in other bacteria (e.g., *Neisseria*, *Bordetella*, etc.). LPS from some bacteria (*Chlamidiae, Rhodopseudomonas*, etc.) further misses the outer core region. When the repetitive polysaccharidic units are missing, the colonies of the bacteria are rough (R LPS). Because the bacteria are permanently making their LPS, the preparations of LPS are extremely heterogeneous with a mixture of R and S molecules and with intermediate molecular weights reflecting different degrees of polymerization of the repetitive units.

Numerous studies have been carried out to decipher the relationship between structures and activities. Most bioactivities have been regularly linked to the lipid

A moiety. Certain charged structures (i.e., phosphate groups, KDO) enhance the strength of the molecule to activate phagocytes [16] and R LPS are more potent than the purified or synthetic lipid A [17]. The number of fatty acids interferes in the potency of LPS to activate immune cells. Usually, hexa-acylated LPS are the most active ones (e.g., *Neisseiria, Salmonella, Escherichia*, etc.), while lower numbers of fatty acids ($n = 4–5$) are associated with less active LPS (e.g., *Bordetella*). Different degrees of acylation can be found in the same strain of bacteria, depending either on their origin (e.g., laboratory strains versus cystic fibrosis clinical isolates of *P. aeruginosa* [18]) or on their culture conditions (e.g., culture at 37 °C versus 27 °C of *Yersinia pestis* [19]). Similarly, cultures of bacteria in planktonic or biofilm forms affect the exact nature of the LPS [20].

2.2.3 Detection

The hemolymph of horseshoe crab (*Limulus polyphemus*) contains amebocytes of which granules content can be released after contact with endotoxin, resulting in a coagulation cascade. The first available *in vitro* limulus amebocyte lysate (LAL) tests led to a process of jellification within the tube. Nowadays, colorimetric assays are commonly used. Because of the great sensitivity of the assays, they have to be performed with endotoxin-free water and materials. Usually, the calibration curve is performed with *Escherichia coli* LPS and the results are expressed as endotoxin units (EUs). The sensitivity is around 0.1 EU/ml, which corresponds to 10 pg/ml of *E. coli* LPS. Of note, unsurprisingly, because of the great heterogeneity of the LPS structures from bacteria to bacteria, the reactivity within the LAL varies greatly between the LPS of different origins, from 0.14 to 16.7 EU for a similar amount of LPS (1 ng) [21]. Similarly, the capacity of polymyxin B to neutralize LPS activities varies depending on the origin of the LPS [22]. The presence of endotoxin is universal, from drinking water to tobacco leaves and from dust to environmental air. It was reported that a high environmental contamination in farms had been associated with the reduced risk of young children to develop asthma [23]. Interestingly, LPS has also been identified as the main PAMP in filarial nematode as a consequence of the presence of endosymbiotic *Wolbachia* bacteria [24]. Furthermore, LPS contaminants are present in numerous elements employed in *in vitro* culture (fetal calf serum, proteins, monoclonal antibodies, etc.) and have been the source of a large number of published artifacts.

Circulating endotoxin can also be detected in the blood of sepsis patients. The first demonstration was made in 1963, using a rabbit skin test associating subcutaneous injection of epinephrine [25]. The possible presence of endotoxin was then confirmed with the Limulus assay in 1970 [26]. The highest levels were associated with the poorest outcome [27]. In patients with meningococcal infection, plasma levels of LPS were shown to correlate with circulating chemokines [28], and bacterial DNA [29]. Of interest, its presence was also found in patients with Gram-positive bacterial or fungal infection, suggesting that part of its origin can derive from gut translocation [27]. Indeed, circulating endotoxins have been found in many clinical settings as an illustration of endotoxin translocation from the gut (Table 2.1).

Table 2.1 Clinical settings associated with the presence of circulating endotoxin.

2.2.4 Natural Ligands

A great number of natural ligands have been identified in plasma, saliva, and lungs and in granules of neutrophils (Table 2.2). Some have been reported to be acute-phase proteins (LPS-binding protein, LBP; soluble CD14) and further enhance cell activation by LPS [49,50]. LBP has been shown to behave as a shuttle molecule, catalyzing its interaction with CD14. Membrane CD14 is a glycosyl-phosphatidylinositol (GPI)-anchored protein with leucin-rich repeats like those found in the extracellular domain of TLR (Toll-like receptor) molecules. Not only CD14 is a key molecule in the activation of cells by LPS but it is also involved in the interaction of host cells with different PAMPs such as lipoteichoic acid, fimbriae, sugar polymers (e.g., *P. aeruginosa* poly β-1-4-D-mannuronic acid; Streptococcal rhamnose-glucose polymer), bacterial lipoproteins, mycobacterial lipomannan, and trehalose-dimycolate. Apart from being an acute-phase protein, sCD14 can also be released by monocytes/macrophages. Soluble CD14 allows CD14-negative cells, which express TLR4, such as the endothelial cells, to

Table 2.2 Natural LPS ligands.

LPS-binding protein Soluble CD14 Soluble MD2 Albumin Lipoproteins (HDL and LDL) Antibodies Complement HSP60 Transferrin Hemoglobin Serum amyloid P Lactoferrin	Bactericidal/permeability increasing protein (BPI) Cationic antimicrobial peptides (CAP18 and CAP37) Gangliosides Acyloxylacyl hydrolase	Lysozyme Histatins	Surfactant protein A

respond to LPS. Similarly, LBP binds other PAMPs than only LPS, including glycolipids, lipoteichoic acid, triacylated lipopetide, peptidoglycan, and mycobacterial lipomannan. LBP is a 60 kDa glycoprotein produced by hepatocytes. Its normal concentration in serum is 3 μg/ml and can reach 200 μg/ml in acute-phase serum. LBP can either shuttle the LPS to plasma high-density lipoprotein for its neutralization or to CD14 for initiation of activation [51]. Interestingly, both anti-LBP and anti-CD14 antibodies protect mice against a lethal challenge with LPS, but these antibodies are deleterious when used during a Gram-negative infection [52]. In agreement with the latter observation, LBP-deficient mice are more sensitive to bacterial infection [53].

In contrast, other ligands inhibit LPS activating properties (e.g., cationic antimicrobial peptide CAP 18 and CAP37; bactericidal/permeability increasing protein, BPI). As reflected in the different LPS structures, their inhibitory potency varies from LPS to LPS [54]. BPI share 44% homology with LBP, mainly present in granules of neutrophils, and it can be found in low amounts in human plasma (0.2–2 ng/ml). In abscess fluids, its concentration exceeds that of LBP [55]. BPI is protective against bacterial infection, but its protective efficiency depends on the nature of the bacteria [56]. A recombinant fraction of BPI was shown to significantly reduce the neuroinjury and the need for amputation in patients with severe meningococcal sepsis [57]. Plasma lipoproteins prevent LPS to interact with its receptor, hence limiting its capacity to activate cytokine release [58]. Robert Munford's team has described that the acyloxyacyl hydrolase, which is an enzyme present in macrophages and neutrophils, removes secondary acyl chains from the lipid A, thus detoxifying the endotoxin molecule [59].

2.2.5 Cell Activation

Among the various TLR ligands, LPS is the one, which induces or represses the largest number of genes in macrophage cell line [60]. After its interaction with the MD2 molecule associated with surface TLR4, LPS induces a MyD88-dependent

signaling cascade that leads to the nuclear translocation of the transcription factor NF-κB that acts on the promoters of numerous genes involved in inflammation. In addition, in a CD14-dependent fashion, LPS can be internalized and initiates the TRIF signaling pathway. Of note, human caspase 4 and its murine homolog caspase 11 have also been identified to be the intracellular receptor of LPS [61]. B-lymphocytes, dendritic cells, neutrophils, and monocytes/macrophages are the main LPS responsive leukocytes. Activation of human neutrophils by 100 ng/ml LPS activates or represses 385 genes [62]. A study performed on human monocytes revealed that among the LPS-inducible genes, 25% were identified to encode cytokines and chemokines, followed by proteins related to metabolism (11%), cell surface antigens (9%), nuclear proteins (8%), proteases (6%), proteins related to extracellular transport (4%), and intracellular transducers (4%) [63]. Of interest, in addition to a common core of 415 modulated genes, the gene expression profile in LPS-activated bone marrow-derived macrophages is specific to each mouse strain [64]. *In vivo*, LPS is a potent inducer of cytokines particularly TNF, of which the production that can be detected in the bloodstream is contributed by many tissues, including, heart [65], spleen [66], kidneys [67], brain, and liver [68]. Once again, the plasma levels of TNF depend on the mouse strains [69]. Similarly, in experiments performed with human peripheral blood mononuclear cells, the LPS-induced TNF levels vary from individual to individual [70]. Humans are highly sensitive to endotoxin, and as little as 30 ng/kg induces fever, chills, drop in leukocyte counts, and lower blood pressure, and it also induces interferon expression as shown after a self-injection of LPS [71]. Another self-injection of 15 μg/kg induces a major cytokine storm and a multiple organ failure in humans [72]. In contrast, mice can be injected with 5 g/kg without major deleterious effects. Plasma factors present in murine serum are responsible for the great resistance of mice to LPS [73].

2.2.6 Tolerance

A first activation by LPS up- or downregulates numerous genes, but a second dose soon after does not lead to the same profile of gene modulation. This phenomenon, which is known as endotoxin tolerance, was first claimed not to be specific to endotoxin [74] before being recognized to be common in most TLR ligands, including PAMPs and DAMPs. The terms "leukocyte reprogramming" illustrates this natural event occurring to prevent an overzealous activation that would be deleterious and to initiate mechanisms that aim to dampen the inflammatory reaction. This topic is specifically addressed in Chapter 60.

2.3 Other Bacterial PAMPs

2.3.1 Lipoproteins

In vivo, no cell will ever interact with the purified molecule of endotoxin since its extraction needs a phenol-water extraction that does not occur in any living host. An interesting approach had been undertaken by Shaw Warren's group to identify

how LPS looks like in the host after bacteria have been killed with the complement system. They showed that LPS was associated with a few other PAMPs, including the outer membrane protein A (OmPA), the peptidoglycan-associated lipoprotein (PAL) and the Braun's lipoprotein or murein lipoprotein [75]. OmpA is a small ion channel transmembrane β-barrels protein. OmpA-deficient mutants display markedly decreased virulence [76]. Braun lipoprotein is with LPS the most abundant component of the outer membrane. Together with the PAL molecule, they contribute to maintaining the integrity of the bacterial cell envelope. PAL is highly conserved among enteric Gram-negative bacteria and is a 18–21 kDa lipoprotein of which the protein moiety (152 amino acids) is expressed within the periplasmic domain (i.e., between the outer and the inner membrane). PAL is released into the bloodstream in a mouse cecal ligation and puncture (CLP) model used to induce sepsis and can be lethal in the sensitized D-galactosamine mice[1] [77]. Lipoproteins can be exposed on the bacterial outer membrane and are also expressed by Gram-positive bacteria. For example, PpmA (putative proteinase maturation protein A) and SlrA (streptococcal lipoprotein rotamase A) are lipoproteins belonging to a family of peptidyl isomerases (PPIases) and have been demonstrated to contribute to the virulence of *S. pneumonia* [78]. Synthetic dipalmitoylated lipopeptide (Pam2-Cys-Ser-Lys-Lys-Lys-Lys; Pam2CysSK4) and tripalmitoylated lipopeptide (Pam3-CysSK4) are often used to mimic bacterial lipopeptides and are used as TLR2/TLR6 and TLR2/TLR1 agonists, respectively. Another synthetic derivative of the macrophage-activating lipopeptide (MALP-2) from *Mycoplasma fermentans* is also available as a TLR2/6 agonist.

2.3.2 Lipoteichoic Acid

Lipoteichoic acid (LTA), an ubiquitous cell wall component of Gram-positive bacteria, represents a potent immunostimulatory molecule. LTA is anchored in the bacterial membrane via a diacylglycerol and projects through the peptidoglycan. LTA activates immune cells via TLR-2, requiring CD14 [79]. LTA and its receptor molecules accumulate in lipid rafts and subsequently target the Golgi apparatus after internalization [80]. A complete LTA molecule containing six glycerophosphate units carrying four alanine plus one *N*-acetyl-glucosamine substituents has been synthesized, which displayed the same potency to activate monocytes as native LTA [81]. LTA without any alanine is 100-fold less active than the native molecule [82]. When the molecule is delivered to the lungs in murine models, it induces neutrophil recruitment and inflammatory cytokine expression. Surprisingly, the process does involve not only TLR2 but also TLR4 and the platelet activating factor receptor [83]. On the contrary, when it is delivered to human lungs, LTA elicits neutrophil recruitment but fails to activate them as well as the alveolar macrophages [84]. Indeed, the studies on the capacity of LTA to activate neutrophils led to controversial reports.

1 D-galactosamine is a hepatotoxic agent used to render the mice far more sensitive to endotoxin and other PAMPs.

2.3.3 Flagellin

The bacterial flagellum is a rotary nanomachine that spins at hundreds of revolutions per second. The flagellum is composed of ~30 different proteins. Flagellin, a highly conserved protein of 33–40 000 Da, is the major structural component of the filament of the flagellum. It is recognized in host cells by cell surface receptor TLR5 [85], the cytoplasmic nucleotide-binding oligomerization domain (NOD)-like receptor (NLR) family members NLRC4 (*NLR family caspase-activating and recruitment domain (CARD) domain-containing protein 4*) [86], and NAIP (*neuronal apoptosis inhibitory protein*) [87]. TLR5 is expressed exclusively on the basolateral surface of intestinal epithelia, thus providing a molecular basis for the polarity of this innate immune response. Therefore, the detection of flagellin by basolateral TLR5 mediates epithelial-driven inflammatory responses to Salmonella [88]. Flagellin not only activates monocytes/macrophages but can also directly stimulate human NK cells, inducing interferon-γ (IFN-γ) production [89].

Intravenous injection of flagellin in mice induces a strong pulmonary inflammation as assessed by leukocyte recruitment and the high levels of cytokines in bronchoalveolar lavages [90]. Chignard's team showed that flagellin was with LPS the main PAMP of *P. aeruginosa* [91]. Of note, some bacteria (e.g., *Helicobacter pylori*, *Campylobacter jejuni*, etc.) display mutated flagellin in 89–96 region that is known to be important for TLR5 recognition, allowing them to escape the innate immunity [92]. Of interest, flagellin could be detected in the serum of sepsis patients and its level correlates with the duration of shock and the lung injury score [90]. Flagellin is also found in the sputum of cystic fibrosis patients [93].

2.3.4 Peptidoglycan

Peptidoglycan is a constituent of both Gram-negative and Gram-positive bacteria. In Gram-negative bacteria, the peptidoglycan area is thin and present between the outer and the inner membranes. In Gram-positive bacteria, the peptidoglycan is thick and constitutes the external structure of the bacteria. PGNs are polymers of β-(1,4) linked *N*-acetylmuramic acid (N-AcMur) and N-acetylglucosamine (N-AcGlc) linked by peptide bonds (Figure 2.2). In Gram-negative bacteria, the peptide bridges are short and contain a very specific amino acid, the diaminopimelate (DAP) or its epimer (mesoDAP). In Gram-positive bacteria, the peptide bonds are longer and contain repeated sequence of glycine. In all cases, alanine is bound to N-AcMur. By attempting to characterize the smallest active moiety of the peptidoglycan displaying adjuvant property, Louis Chedid and Edgar Lederer identified in 1976 the N-acetylmuramyl-L-alanyl-D-isoglutamine (or muramyl dipeptide, MDP) as the smallest active moiety [94]. In 1984, Claude Leclerc showed that intracellular delivery of MDP with the help of antibodies increased 10 000-fold its adjuvanticity [95]. She then postulated that "specific receptors for MDP exist inside the macrophage [96]. To be active, MDP has to be present inside the cells in sufficient concentration" [97]. Seventeen years later, this statement was confirmed with the discovery of NOD1 and NOD2 as the receptor for Gram-negative peptidoglycan-derived minimal structure (N-AcGlc – N-AcMur – L-Ala – D-Glu – mesoDAP), and for both types of bacteria

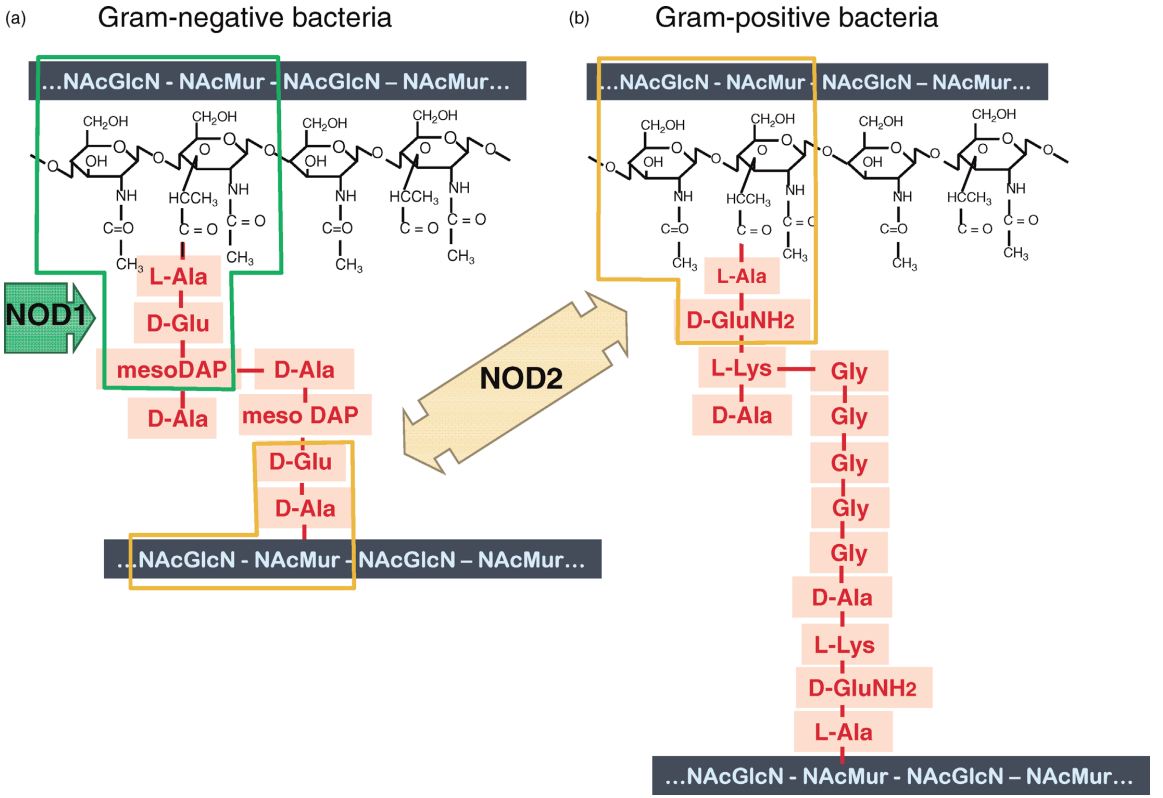

Figure 2.2 Chemical structure of peptidoglycan (PGN) from Gram-negative (a) or Gram-positive (b) bacteria. Of note, a specific amino acid (meso-diaminopimelate) is found mainly in PGN of Gram-negative bacteria, and the peptide bridge is longer in PGN of Gram-positive bacteria. The PGN area recognized by the NOD1, and NOD2 cytoplasmic pattern recognition receptors are shown. NAcGlcN: *N*-acetyl-glucosamine; NAcMur: *N*-acetyl-muramic acid.

(N-AcGlc – N-AcMur – L-Ala – D-Glu) [98,99]. Of note, human and murine NOD1 and NOD2 do not recognize the same minimal structures [100]. If TLR2 can also recognize PGN remains debatable [101,102]. CD14 and LBP also concur to the activation of host cells by PGN [103,104]. Furthermore, peptidoglycan recognition proteins (PGRPs) are PRRs known to interact with PGN. Thirteen PGRP have been described in *Drosophila melanogaster* and four in mammals (PGLYRP-1,2,3,4). The latter are found in different tissues and produced by different cells [105]. Human PGRPs form disulfide-linked homodimers and heterodimers. PGLYRP-1, 3, 3:4, and 4 have antibacterial and bactericidal activities [106] and PGLYRP-2 is an amidase [107].

2.3.5 Fimbriae

Fimbriae are short appendages up to 2 μm long that are exposed on the entire bacterial surface and allow the bacteria to adhere to different types of surfaces. They are made of staking of 500–3000 FimA subunits with additional molecules (FimF, FimG, and FimH) attached on the top. The studies on the interaction of complete fimbriae with epithelial cells, monocytes, dendritic cells, or transfected cells identified TLR2 as the major PRR [108,109]. CD14 and CD11b/CD18 were also shown to interact with fimbriae [109]. The isolated subunit FimA failed to activate epithelial cells [110], but it was shown to weakly activate the macrophage cell line THP-1 via TLR2 [111]. FimH was found to activate macrophages and NK cells via TRL4 [112], and the major fimbrial subunit CsgA of thin curled fimbriae of *Salmonella enterica* serotype Typhimurium is recognized by TLR2 [113].

2.3.6 Glycogolipids

Although the widespread distribution of glycolipids among bacteria is well established, those of mycobacteria have received considerable attention. In particular, mycobacterial dimycolate is a potent macrophage modulator and has been used as an adjuvant. Different receptors have been identified including a C-type lectin named Mincle [114], and the scavenger receptor MARCO, which cooperates with CD14 and TLR2 [115].

Glycosphingolipids (GSLs) are membrane components of every eukaryotic cell. *Sphingomonas* species, *Borrelia burgdorferi*, *S. pneumoniae*, and *H. pylori* have been shown to possess such glycolipid antigens. In contrast, Gram-negative bacteria, if they do, poorly express these molecules [116]. These glycolipids are presented by CD1d molecules of dendritic to the invariant T cell antigen receptor of NKT cells resulting in IFNγ production [117,118].

2.3.7 Heat Shock Proteins

Heat shock proteins (HSPs) are found in both eukaryotic and prokaryotic cells. Of interest, this family of molecules can be classified as PAMPs when derived from pathogens and also as DAMPs when released by damaged host cells. HSPs are intracellular molecular chaperones and play a cytoprotective role when cells are exposed to stressful stimuli. Released into the extracellular milieu, they display

immunoregulatory properties. *Chlamydia pneumoniae* HSP60 activates smooth muscle cells, endothelial cells, monocytes/macrophages, and dendritic cells [119–121]. The specific involvement of TLR2 and TLR4 depends on the cells studied. The *in vivo* role of TLR4 was demonstrated when acute pulmonary inflammation was induced in mice [122]. *H. pylori* HSP60 activates human epithelial cells via both TLR2 and TLR4 [123], and human monocytes via TLR2 [124]. While other studies using *E. coli* HSP (DnaK) and *Mycobacterium tuberculosis* HSP71 suggested that their capacity to enhance antigen processing and presentation was TLR independent [125]. Indeed, the stimulatory properties of *M. tuberculosis* HSP71 were confirmed *in vivo* to be TLR2 and TLR4 independent [126]. However, another *M. tuberculosis* HSP (HSP60) was shown to interact with both TLR2 and TLR4 [127]. Finally, *Francisella tularensis* HSP "DnaK" activates dendritic cells in a TLR4-dependent fashion [128].

2.3.8 Bacterial DNA

Immunostimulating properties of bacterial DNA and oligodeoxynucleotides (ODNs) were first reported when the antitumoral property of *M. bovis* was investigated [129]. Then, the capacity of bacterial DNA and oligodeoxynucleotides to stimulate B-lymphocytes in terms of proliferation and immunoglobulin production was reported [130]. Short ODNs containing an unmethylated cytosine triphosphate deoxynucleotide, phosphodiester bound to a guanine triphosphate deoxynucleotide (CpG), are bioactive. In contrast to eukaryotic DNA, the dinucleotide motif 5′-CpG-3′ is mostly hypomethylated in bacterial DNA. In galactosamine-sensitized mice, bacterial DNA causes lethal shock and induces the production of TNF by macrophage cell line [131]. TLR9 was identified as one of the PRRs for bacterial DNA [132] (Figure 2.3). Bacterial DNAs differ in the percentage of CpG content, and their capacity to activate TLR9 transfected HEK cells is proportional to the CpG content within the bacterial genome. For example, CpG represents 12.2% of the genome in *P. aeroginosa*, whereas it is only 2.2% in *Staphylococcus epidermidis* [133]. In RAW 264.7 macrophage cell line, CpG ODN activated 190 genes at 4 h and 105 genes at 12 h, while Poly (I:C) treatment led to the stimulation of 574 genes at 4 h and 1051 at 12 h [134]. Of interest, some genes that were upregulated neither by CpG nor by Poly (I:C) were significantly upregulated when the combination of both agonists was used. High-mobility group box 1 (HMGB1) is a DAMP that favors DNA delivery to the cells [135]. The cationic antimicrobial peptide LL37/CAP18 allows cells to sense self-DNA [136]. In contrast, some ODN sequences display inhibitory activities [137].

AIM2 (*absent in melanoma 2*) constitutes with ASC (*apoptosis-associated speck-like protein containing CARD*) and procaspase-1 in an inflammasome aiming to sense dsDNA. It is a 343 amino acid protein with an N-terminal pyrin domain and an HIN200 (*hematopoietic interferon-inducible nuclear antigens with 200 amino acid repeats*) domain. The inflammasomes are molecular platforms that lead to the activation of caspase-1, the maturation enzyme required for the cleavage of IL-1β and IL-18 precursors. It has been regularly reported that AIM2 binds bacterial dsDNA resulting in the release of IL-1β and IL-18 (Figure 2.4) [138–140].

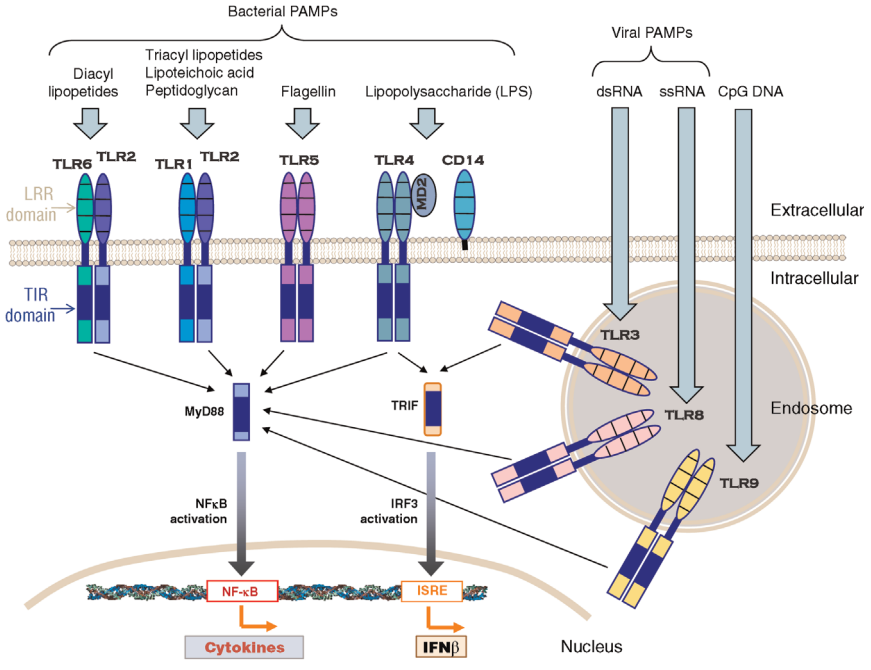

Figure 2.3 Membrane and endosomal Toll-like receptors (TLR) sensing bacterial and viral PAMPs and the two main pathways dependent on adapter molecules MyD88 (myeloid differentiation primary response gene 88) or TRIF (TIR domain-containing adapter-inducing interferon-β). 2.3.9 Bacterial RNA

Bacterial RNAs are important stimuli of the innate immunity [141] and their sensing can indicate to the host the presence of live bacteria [142]. The immunostimulatory properties of bacterial mRNA was first identified by its capacity to induce the release of IL-12 by human dendritic cells [143] before it was reported that macrophages could also be activated by bacterial RNAs to produce cytokines. Human and murine endosomal TLR7 can sense bacterial RNA and favor the release of type I interferon. In mice, endosomal TLR13, which does not exist in humans, specifically recognizes 23S ribosomal RNA [144]. In humans, endosomal TLR8 was reported to recognize bacterial RNA [145,146]. More precisely, TLR8 recognizes two degradation products of single-strand RNA: uridine and a short oligonucleotide. Uridine binds the site on the dimerization interface and the short oligonucleotide binds a site on the concave surface of the TLR8 horseshoe structure. Both binding sites were essential for activation of TLR8 by ssRNA [147] (Figure 2.4).

Retinoic acid-inducible gene-I (RIG-I) is a cytoplasmic PRR with two CARD domains and a helicase subunit initially recognized to bind 5′-triphosphate viral ssRNA. Different investigations have also reported the capacity of bacterial RNA to activate type I IFN response via RIG-I [148], a process that occurs during

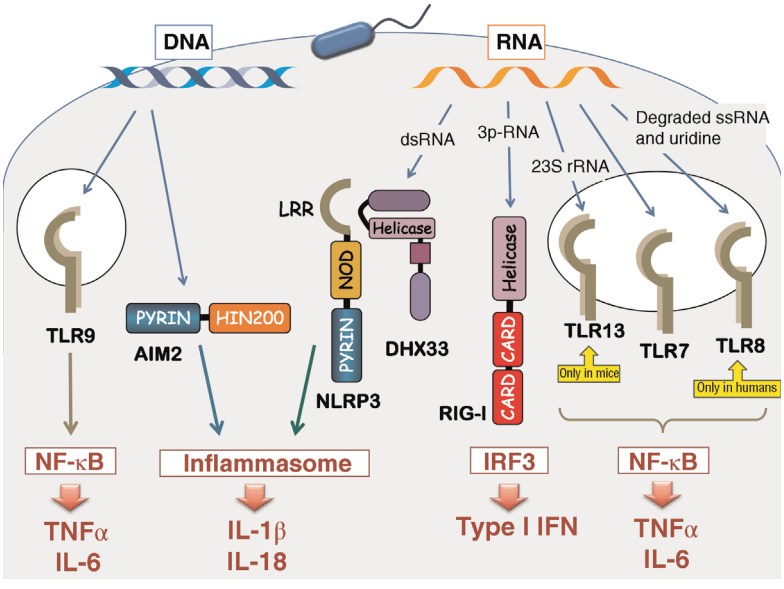

Figure 2.4 Bacterial DNA and RNA can be sensed by endosomal or cytoplasmic receptors, resulting in signaling cascades that end in cytokine production. dsRNA: double-strand RNA; ssRNA: single-strand RNA; NOD: nucleotide-binding oligomerization domain; AIM2: absent in melanoma 2; NLRP: NOD-like receptor family, pyrin domain containing DHX33 (DEAH (Asp-Glu-Ala-His) box polypeptide 33); RIG: retinoic acid-inducible gene; CARD: caspase-activating and recruitment domain; IRF3: interferon regulatory factor 3; NF-κB: nuclear factor-κB.

bacterial infection in immune and nonimmune cells [149]. The specificity of eukaryote mRNA is a 2′O-methyl group at N1. This methylation prevents the RIG-I molecule from being activated by self RNA [150]. Of interest, flaviviruses exploit this tolerance mechanism to escape from the immune system sensing.

The third signaling pathway is consecutive to the capacity of bacterial double-stranded RNA to bind via the helicase domain to DHX33, a nucleolar RNA helicase, allowing the assembly of a DHX33-NLRP3 (*NLR pyrin-domain containing 3*)–ASC–caspase-1 complex that mediates processing and secretion of IL-1β and IL-18 [151].

2.4 Viral PAMPs

Of course, the variety of viral PAMPs is far lower than that of bacteria. Viral PAMPs can be expressed on virus surface structures, be part of the capside or its genomic material and replication products (Figure 2.5). Whole virus such as yellow fever virus used for vaccine activates dendritic cell via TLR2, TLR7, TLR8, and TLR9 to elicit the proinflammatory cytokines [152]. Isolated viral components interact with either TLR2 or TLR4. For example, mouse mammary tumor virus or murine leukemia virus envelope proteins coimmunoprecipitated with TLR4 when expressed in HEK cells [153]. Hepatitis C virus core and

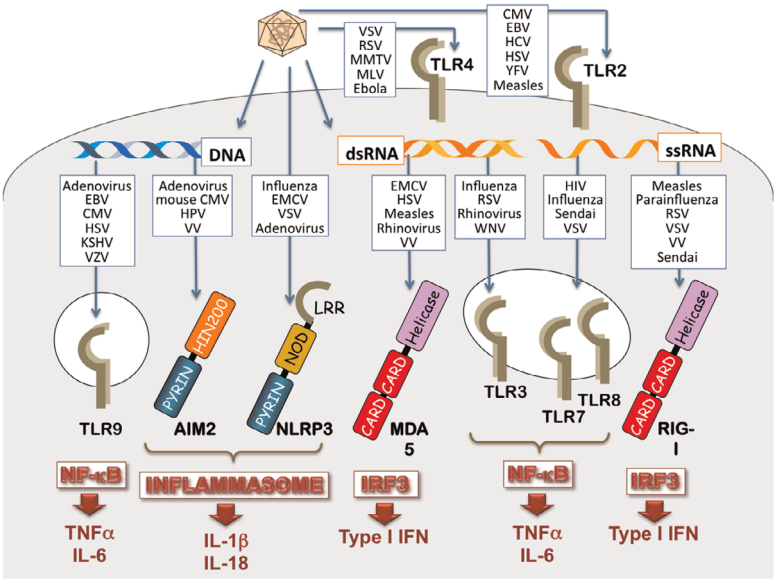

Figure 2.5 Viral DNA and RNA can be sensed by endosomal or cytoplasmic receptors. VSV: vesicular stomatitis virus; RSV: respiratory syncytial virus; MMTV: mouse mammary tumor virus; MLV: murine leukemia viruses; CMV: cytomegalovirus; EBV: Epstein–Barr virus; HCV: hepatitis C virus; HSV: herpes simplex virus; YFV: yellow fever virus; KSHV: Kaposi's sarcoma-associated herpes virus; VZV: Varicella zoster virus; HPV: human papilloma virus; VV: vaccinia virus; EMCV: encephalomyocarditis virus; HIV: human immunodeficiency virus; TLR: Toll-like receptor; AIM2: absent in melanoma 2; NLRP: NOD-like receptor family, pyrin domain containing MDA5 (melanoma differentiation-associated protein 5); RIG: retinoic acid-inducible gene.

nonstructural 3 (NS3) protein activate inflammatory pathways in monocytes via TLR2. TLR2-mediated cell activation was dependent on the conformation of core and NS3 proteins and required sequences in the regions of a.a. 2–122 in core and a.a. 1450–1643 in NS3 [154]. Wild-type measles virus but not vaccine strains activate cells via both human and murine TLR2, and this is a property of the hemagglutinin protein. Its ability to activate cells via TLR2 is abolished by a mutation of a single amino acid, asparagine at position 481 to tyrosine, as found in attenuated strains [155]. Glycoproteins of herpes simplex virus (HSV) and human cytomegalovirus (CMV) are TLR2 ligands, whereas the glycoprotein of vesicular stomatitis virus (VSV) is a TLR4 ligand [156]. Interestingly, Ebola virus leads to a glycoprotein expression on the surface of infected cells, which is shed from the surface by TNF-alpha-converting enzyme (TACE). This glycoprotein is a potent TLR4 agonist that triggers the release of inflammatory cytokines and increases vascular permeability [157].

Genomic ssRNAs of human immunodeficiency virus (HIV), influenza virus, Sendai virus, Coxsackievirus, and VSV are TLR7/8 ligands. 5′-triphosphate ssRNA of flaviviridae, paramyxoviridae, orthomyxoviridae, rhabdoviridae, and filoviridae are recognized by RIG-I. Double-stranded RNA derived from HSV, Epstein–Barr virus (EBV), influenza virus, respiratory syncytial virus (RSV), HIV, and rhinovirus are TLR3 ligands. MDA5 (*melanoma differentiation-associated*

protein 5) is a RIG-I-like receptor of dsRNA generated by the replication of the viruses. MDA5 does not recognize the genomic ssRNA but is the key sensor for the dsRNA replicative intermediate form of positive sense ssRNA viruses [158]. Of note, polyinosinic:polycytidylic acid (poly I:C) is a useful synthetic tool commonly used to mimic dsRNA. Poly I:C is a mismatched double-stranded RNA with one strand being a polymer of inosinic acid and the other being a polymer of cytidylic acid. Finally, viral DNA from HSV, CMV, EBV, Varicella zoster virus, Kaposi sarcoma-associated herpes virus, and Vaccinia virus are TLR9 ligands [156], while others act through AIM2. More surprising was the report that ssRNA of RSV could activate an antiviral innate immune response via NOD2 [159]. Indeed, NOD2-deficient mice were more sensitive to the viral infection and produced a limited amount of IFNβ.

2.5 Parasitic PAMPs

Although the use of different PRR-deficient mice has allowed the identification of some of the innate immune receptors involved in sensing parasitic infections, PAMPs of parasites remain far less characterized than those of bacteria.

In the case of *Plasmodium falciparum*, the malaria parasite digests hemoglobin and converts it into insoluble and chemically inert β-hematin crystals, called hemozoin. This hemozoin favors the recognition of plasmodial DNA by TLR9 [160]. *Plasmodium* glycosylphospatidylinositol (GPI)-anchored glycolipids play an important role in the innate immunity. They are synthesized exclusively at the mid to late trophozoite stages. The parasite's GPI glycolipid consists of four mannoses, one glucosamine, and one inositol. The carbohydrate moieties contain one or two extra phosphoethanolamine. The inositol residue is usually di- or triacylated with C14 to C22 fatty acids, predominantly palmitic and myristic acids. In humans, the GPI glycolipids are mainly recognized by the TLR2/1 heterodimer. In mice, they seem to be recognized by both TLR2/1 and TLR2/6 [161]. CD36, a scavenger receptor, is also involved in the recognition of the GPI glycolipid [162]. The fact that TLR7 was identified as a key sensor of *P. chabaudi* suggests that ssRNA of the parasite also behaves as a PAMP [163]. The observation that *Plasmodium* RNA is a PAMP and is capable of activating a type I IFN response was further demonstrated *in vivo*, and MDA5 was recognized as its cytosolic pattern recognition receptor [164].

Trypanosoma cruzi infections were shown to involve TLR2, TLR4, and TLR9 receptors [165]. GPI-anchored mucin-like glycoproteins distributed at the cell surface membrane of *T. cruzi* trypomastigotes, and glycoinositolphospholipids (GIPLs), which are a subset of GPI anchors from the epimastigote stage of *T. cruzi*, activate cells via TLR2 [166]. The GPI-anchored mucin-like glycoproteins also bind to CD1d, but this interaction with NKT cells does not seem to play a major role in the innate immunity against *T. cruzi* [167]. The *T. cruzi*-released protein, Tc52, has been identified as a potent inducer of TLR2 activation in human and mouse innate immune cells. The *T. cruzi* Tc52-released protein induces human dendritic cell maturation, signals via TLR2 [168]. *T. brucei rhodesiense* and *T. brucei gambiense* express a unique surface coat comprising GPI-anchored variant

surface glycoprotein (VSG) molecules that activates macrophages through scavenger receptor [169]. Other PRRs have been shown to contribute to the innate immune response to *Trypanosoma* (i.e., NOD1, C-type lectin receptor), but the precise nature of the parasitic ligands has not yet been identified. Similarly, the activation of inflammasome by *T. cruzi* has been well established, but the exact nature of the ligand and its receptor remains to be defined [170].

A soluble tachyzoite antigen prepared from *Toxoplasma gondii* induces IL-12 and CCL2 in bone marrow-derived macrophages in a TLR2-dependent fashion [171]. *T. gondii*-derived heat shock protein 70 (*Tg*HSP70) is a tachyzoite-specific virulent molecule expressed before the death of hosts. A vaccine with *Tg*HSP70 was shown to be TLR4-dependent [172]. *T. gondii* activates NLRP1 and NLRP3 inflammasome, but no defined PAMP has yet been identified [173].

Soluble egg antigen (SEA) of *Schistosoma mansoni* is a complex mixture that activates immune cells and others such as endothelial cells. Accordingly, different PRRs have been reported to be involved including TLR2 [174], C-type lectin (i.e., Dectin-2, DC-SIGN, and L-SIGN) [175–177], and the mannose receptor [178]. Glycans and a T2 ribonuclease are part of the SEA. Multifucosylated glycosphingolipids constitute the major egg glycolipids and can behave as other putative PAMPs of *S. mansoni* [179]. In addition, schistosomal lysophospatidylcholine has been reported as a TLR2 agonist [180], a larval preparation has been shown to stimulate macrophages through TLR4 [181], and finally, *Schistosoma* egg-derived double-stranded RNA activate dendritic cells via TLR3 [182].

Lipophosphoglycan is a prominent member of the phosphoglycan-containing surface glycoconjugates of *Leishmania*. When two different lipophosphoglycan biosynthetic genes were knocked out from *L. major*, there was a clear loss of virulence in several steps of the infectious cycle, but no effect on virulence was found with *L. mexicana* [183]. *Leishmania* lipophosphoglycan interacts with TLR2, but contradictory works have been reported on the protective role of this interaction [184–186]. *L. major* specific glycan structure is characterized by a poly-β-galactosyl epitope of which galectin-3 and -9 are the main PRRs [187,188]. Other lectins such as Dectin-1, mannose receptor, and DC-SIGN are other sensors of glycosylated surface antigens [189]. Other PRRs such as NLRP-3 [190] or TLR4 [191] have been identified to sense *Leishmania*, but their corresponding ligands remain to be deciphered. An important PAMP of *Leishmania* is its DNA, which activates dendritic cells via TLR9 [192]. Of interest, the fact that specific activating motifs are present in *Leishmania* and other trypanosomatidae DNA allows human and murine TLR9 to differentiate between parasites and host DNAs [193].

2.6 Fungal PAMPs

The fungal cell wall is the main source of PAMPs. Its composition varies depending on the fungi and their growth stage. Three major cell wall components are found in all medically important fungi. β-glucans, polymers of glucose, are distinct entities [194,195]. For example, the cell wall of *Aspergillus fumigatus* contains β-1,3- and β-1,4-glucan, and α-1,3-glucan, while *Candida albicans*

contains β-1,3- and β-1,6-glucan. Chitin, a β-1,4-linked homopolymer of *N*-acetylglucosamine, provides a protective thin rigid layer on the fungal surface. Finally, mannose-containing structures mannoprotein, mannan (which are chains of several hundred N- or O-linked mannose molecules), and phospholipomannan are expressed mainly on the outer cell wall. Most of these substances are capable of inducing the release of inflammatory cytokines by macrophages. Many PPRs have been reported to recognize these fungal PAMPs. This is the case of C-type lectins that interact with the different forms of mannan (e.g., Galectin-3, Dectin-2, mannose receptor, and DC-SIGN) [195]. Dectin-1 and a scavenger receptor (CD36) have been shown to interact with β-glucan. Glucuronoxylomanann has been demonstrated to interact with TLR4 [196] and phospholipomannan with TLR2/6 [197]. Chitin has been shown to dampen inflammation through its interaction with the mannose receptor and more surprisingly with TLR9 and NOD2 [198]. Finally, as seen for the other pathogens, fungal DNA from *Candida, Cryptococcus*, or *Aspergillus* activates cells via TLR9 [199–201]. Fungal RNA could possibly be a PAMP as suggested in a study on *C. albicans* using TLR7-deficient mice [202]. Of interest, the authors demonstrated a protective role of type I interferon during fungal infection.

2.7 Synergy

One of the key features of the innate immune response to pathogens is the amazing synergy that exists not only between PAMPs but also between PAMPs and host mediators, leading to an increased production of proinflammatory cytokine, nitric oxide, and prostaglandin, dendritic cell maturation, NF-κB activation, and gene expression [203]. These synergies can contribute to enhance probabilities to develop multiple organ failure and lethal shock during severe infections. *In vitro* synergies have been demonstrated between TLRs ligands in terms of cytokines production by macrophages, dendritic cells, or epithelial cells [204–208]. Similarly, this synergy can be observed in human whole blood samples as shown by mixing LPS and PGN [209]. Furthermore, a synergy has been established between TLR agonists and NOD1 or NOD2 ligands [210–212]. Of interest, such a combined effect can be associated with the induction of the expression of certain genes, which are not induced by each PAMP individually [134]. *In vivo*, the injections of two PAMPs such as PGN and LTA synergize to cause a systemic tissue injury (i.e., liver, kidney, heart, pancreas, and lungs) and multiple organ failure [213]. In the galactosamine murine model, another synergy between LPS and bacterial lipoproteins has been shown to increase the incidence of death [214]. This observation was associated with an increased level of circulating TNF. A similar effect was reported between LPS and the *S. aureus* toxic shock syndrome toxin-1 [215]. Interestingly, the increased level of TNF was lowered by anti-IFNγ antibodies, which also protected against lethal shock.

Indeed, once produced, cytokines act in synergy with PAMPs within auto amplificatory loops. IFNγ, initially characterized as a macrophage activating factor, synergizes with LPS [216] as does IL-3 [217]. These results explain the deleterious effects of these cytokines reported in murine models of sepsis [218,219]. The

autocrine loop involving IL-1 and TNF has been nicely demonstrated in the induction of IL-8 in LPS-activated human whole blood samples [220]. The production of IL-12 by dendritic cells requires IFNβ in addition to the activation by different TLR ligands [221]. Similarly, IFNγ and GM-CSF production by NK cells induced by TLR4, TLR2, and TLR9 agonists is amplified by the presence of different cytokines [222]. Anti-inflammatory cytokines can also favor the activation of cells by LPS. For example, IL-4 enhances the IL-1 receptor antagonist (IL-1Ra) production by neutrophils [223] and paradoxically, in the absence of adherence, IL-10 boosts TNF production by LPS-activated human monocytes [224]. Synergy between cytokines has also been reported for NLR ligands as illustrated by the enhanced production of MDP-induced IL-1β and IL-6 by IL-32 [225]. The *in vivo* consequence of such synergies is an increased mortality after LPS injection by IFNγ [226] or TNF [227]. Granulocyte macrophage colony-stimulating factor (GM-CSF) also amplifies the LPS bioactivities *in vivo* [228].

Among the other host mediators produced during the inflammatory process, which act in synergy with LPS, let us mention the anaphylatoxin C5a [229], hemoglobin [230], neurotensin [231], substance P [232], adenosine [233], elastase [234], H_2O_2 [235], or platelet activating factor [236]. Membrane compounds can also amplify the effect of LPS such as triggering receptor expressed on myeloid cells-1 (TREM-1) [237]. Viral infection [238], hypoxia [239,240], ischemia/reperfusion [241], and mechanical ventilation [242] are exogenous signals that enhance the response to LPS and most probably to many other PAMPs.

Institut Pasteur, Unit Cytokines & Inflammation, 28 rue Dr. Roux, 75015 Paris, France

3.1 Definition

After Charles Janeway had revisited the current definition of immunology [1], introducing the concept of pathogen-associated molecular patterns (PAMPs) (see Chapter 2), there was still room for further brainstorming in order to conceptualize the aim of the immune system and, more importantly, to define the triggering signals needed to maintain homeostasis and host integrity. In 1994, Polly Matzinger offered a new definition of immunology. For her, the immune system does not discriminate between self and nonself, but recognizes and responds to danger signals. She postulated that any stress undergone by healthy tissues generates danger signals that initiate the activation of the immune response. She proposed the concept of danger as an internal signal, when pathogens are recognized by the tissue damage they generate. She postulated 4 "D"s of her danger model: "Distress, Damage, Destruction, and Death" [2]. While this postulate was fully correct for sterile inflammation, it was only partially true for pathogen-initiated innate immune responses (Figure 3.1). Nevertheless, endogenous danger signals are generated during both sterile and infectious inflammation. These signals – "damage-associated molecular patterns" (DAMPs) – are released by damaged tissues and necrotic cells. They can also be produced and released by activated live cells but not by apoptotic cells. Another term, "alarmins," proposed by Joost Oppenheim [3], was initially restricted to antimicrobial proteins. However, this was later extended to the early warning signals able to activate innate and adaptive immune systems, particularly in recognition of their role in mobilizing the immune system with chemoattractant and immunostimulating properties [4]. In particular, these include enhancing dendritic cell differentiation and maturation, facilitating antigen uptake, processing, and presentation. Evolution has incorporated into the mammalian genome genes encoding receptors aimed at sensing these danger signals. Interestingly, most DAMP receptors are similar to those sensing PAMPs.

3.2 Necrosis versus Apoptosis

Apoptosis was defined as a silent physiological death aimed at avoiding the triggering of immune cell activation. By contrast, necrosis reflects an unintentional death following insults threatening host integrity. The insult can be of microbial origin or be sterile, for example, burns, trauma, ischemia/reperfusion, hypoxia, radiation, chemicals, and inflammatory particles. The effects of necrotic versus apoptotic cells on macrophages and dendritic cells revealed the capacity of necrotic cells to favor antigen presentation, antitumor activity, NF-κB activation, and cytokine production [5–8]. Of note, a synergy was shown between endotoxin (lipopolysaccharide, LPS) and necrotic cell lysate [9]. In trauma patients, the release of DAMPs is extremely rapid; levels of circulating nuclear DNA, mitochondrial DNA, and HSP70 are increased even at the scene of the trauma [10]. In patients with chronic obstructive pulmonary disease, the extracellular lung fluid levels of several DAMPs (including S100 proteins and high-mobility group box-1) are also increased.

3.3 Receptors of Danger Signals

The nature of the pattern recognition receptors (PRRs) sensing necrotic cells was identified *in vitro* to be Toll-like receptor 2 (TLR2) [11], TLR3 [12], and Nod-like receptor family, pyrin domain containing 3 (NLRP3) [13] (Figure 3.2). Of

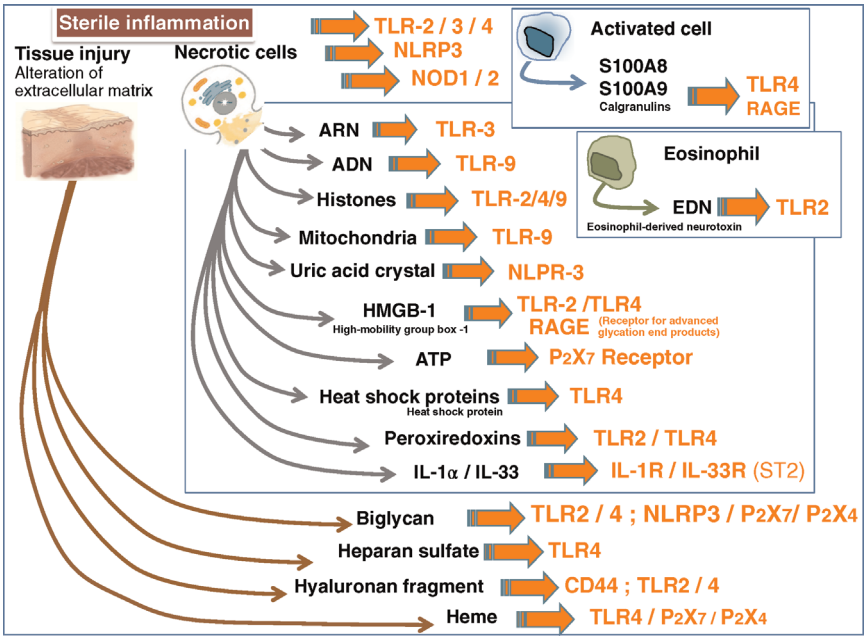

Figure 3.2 Some of the damage associated molecular patterns and their corresponding pattern recognition receptors.

particular interest, the injection of necrotic cells into the peritoneal cavity revealed a minor role for TLR2 and TLR4 but a major role for IL-1α, its IL-1 receptor, and the MyD88-associated pathway [14]. In different *in vivo* models of sterile inflammation, using different types of PRR-deficient mice, liver [15], and kidney [16], myocardial [17] and brain [18] ischemia/reperfusion injuries were found to be TLR4-mediated. Inflammation associated with trauma generated by bone fractures [19], gut injury following trauma-hemorrhagic shock [20], and acute lung injury [21] were also found to be TLR4-dependent. In the latter case, oxidized phospholipid was identified to induce lung injury and cytokine production by lung macrophages via the TLR4-dependent Toll interleukin-1 receptor domain-containing adapter-inducing interferon-β (TRIF) pathway [21]. The same pathway was also shown to be involved in a model of liver ischemia/reperfusion [15]. TLR2-dependent signaling was also identified in a model of myocardial [22] and kidney [23] ischemia/reperfusion. More surprisingly, knowing the initial specificity of the peptidoglycan ligand of nucleotide-binding oligomerization domain (NOD) molecules, NOD1 and NOD2 were demonstrated to be intracellular sensors during kidney ischemia/reperfusion [24]. CD24-Siglec-10 is a receptor that discriminates DAMPs and PAMPs and negatively regulates the stimulatory activity of DAMPs [25]. CD24 associates with HMGB1 and other DAMPs (HSP70 and HSP90), and inhibits NF-κB activity, at least in part through its association with Siglec-10 in humans.

3.4 Main DAMPs

3.4.1 High-mobility Group Box 1

High-mobility group box 1 (HMGB1) (also known as amphoterin) was identified in 1975 as a nuclear protein [26]. Present in all nucleated cells, it binds to DNA, bends it to facilitate the transcription of many genes, and can also interact with nucleosomes. HMGB1 led to the publication of numerous papers in most prestigious journals. The story started in 1999, when Kevin Tracey's group found HMGB1 in the serum of LPS-treated mice, with a late peak at 15 h post-injection [27]. Mice injected with a lethal dose of LPS could be protected by anti-HMGB1 antibodies as HMGB1 acted synergistically with LPS. They also reported HMGB1 in the serum of septic patients, with the highest levels found in nonsurvivors. Similarly, elevated levels of HMGB1 were reported in the sera of patients with hemorrhagic shock [28], trauma [29], and pneumonia [30].

HMGB1 was considered a DAMP when it was reported that necrotic cells release HMGB1, leading to inflammation [31]. However, HMGB1 can also be released by live activated cells in response to inflammatory cytokines [32] or LPS [33]. Other stimuli include polyinosinic-polycytidylic acid (poly I:C) [34], influenza infection [35], or neutrophil NADPH oxidase induced by hemorrhagic shock [36]. During sepsis, a major source of HMGB1 appears to be the spleen [37]. Cardiomyocytes were also found to be a source of HMGB1 after LPS injection [38].

Tracey's group showed that HMGB1 could induce release of inflammatory cytokines by human monocytes [39]. However, it was subsequently shown that highly purified HMGB1 by itself does not induce monocyte activation [40]. Rather, HMGB1 activities are influenced by its redox state: reduced cysteine makes HMGB1 a chemoattractant, whereas a disulfide bond makes it a proinflammatory cytokine, while further cysteine oxidation abrogates both activities [41]. This molecule also has a great capacity to stick to many other microbial agonists such as LPS [42], CpG DNA [43], all immunogenic nucleic acids [44], cytokines, and chemokines such as IL-1β [45] and CXCL12 [46]. Depending on the nature of the complex formed by HMGB1, the nature of the receptor can be TLR2, TLR4, TLR7/8, TLR9, the IL-1 receptor, or CXCR4 [47]. In addition, HMGB1 can be bound by the receptor for advanced glycation end products (RAGE) [48]. HMGB1 promotes recruitment of leukocytes across the endothelial barrier, activates endothelial cells with increased expression of adhesion molecules, disrupts both the endothelial barrier and that of enterocytes, enhances dendritic cell maturation, and acts in synergy with other cytokines to induce production of interferon-gamma by NK cells [49]. It also favors release of prostaglandin E2 by vascular smooth muscle cells [50]. Targeting HMGB1 with specific antibodies protected against acute lung injury [51], experimental models of arthritis [52], remote organ injury following trauma [53], and sepsis [54]. The use of glycyrrhizic acid, which binds and inhibits HMGB1, in a rat model of diffuse axonal injury ameliorated motor and cognitive deficits, reduced neuronal apoptosis, protected the integrity of the blood–brain barrier, reduced axonal injury, and limited the expression of proinflammatory cytokines [55]. siRNA treatment targeting HMGB1 was effective in a cecal ligation and puncture (CLP) model of

sepsis in humanized mice [56]. Human hematopoietic stem cells transferred to immune-deficient nonobese diabetic mice (NOD/SCID/IL2R$\gamma^{-/-}$) contributed to sepsis-induced mortality. Delivery of HMGB1 siRNA targeted at human macrophages reduced the cytokine storm and lymphocyte apoptosis, and rescued humanized mice from CLP-induced mortality. In a mouse model of acute and chronic seizures, antagonists of HMGB1 and TLR4 reduced the clinical symptoms. Together with the observation that increased expression of HMGB1 and TLR4 was found in human epileptogenic tissue, a role for the HMGB1-TLR4 axis in human epilepsy has been suggested [57].

3.4.2 Heat Shock Protein

Heat shock proteins (HSP) are abundant and ubiquitous intracellular proteins. They were initially discovered in 1962 in drosophila exposed to heat. They represent around 5% of total intracellular proteins, but under stressful conditions (high temperature, toxins, oxidative stress, glucose deprivation, etc.), their concentration can rise significantly [58]. Intracellularly, they act as chaperone molecules that are involved in the folding and unfolding of other proteins. They are grouped into families according to their molecular weights (small HSPs, HSP40, HSP47, HSP60, HSP70, HSP90, and HSP100). They also share similarities with their bacterial counterparts. They can activate T-lymphocytes, B-lymphocytes, NK cells, dendritic cells, macrophages, and endothelial cells. A puzzling observation is their capacity to activate cells via TLR2 and TLR4 in a CD14-dependent fashion [59], exactly as endotoxin does. Indeed, numerous investigations came to the conclusion that the macrophage-activating properties of HSP60 [60], HSP70 [61–63], and gp96 [64] were secondary to endotoxin contamination. LPS binds to cell membrane forms of HSP70 and HSP90 [65]. HSPs are released by necrotic but not by apoptotic cells [7], and produced in response to LPS [66,67], to CpG oligonucleotide [68], and in experimental models of hemorrhage [69]. HSP70 levels were increased in the sera of patients with trauma [70], in resuscitated patients after cardiac arrest, and in brain death [71]. In sepsis, HSP70 is enhanced not only in plasma but also in circulating neutrophils [72].

Of great interest are the arguments of van Eden *et al.* [73], who consider that HSPs are not DAMPs but rather "dampers." They state that HSPs exist at homeostasis both at the cell surface and as freely circulating molecules. High concentrations of highly purified HSPs have no stimulatory effects but rather are highly immunogenic and stimulate Treg. Of interest, as noted for HMGB1, they favor the action of PAMPs [74].

HSPs may all not share the same properties. For example, intracellular HSP70 is directly hepatoprotective during liver ischemia–reperfusion injury while extracellular HSP70 does not contribute significantly to the injury response in this model [75]. Indeed, heat stress protects rats and mice against endotoxin shock [76,77]. Similarly, HSP70 was reported to ameliorate experimental acute respiratory distress syndrome [78] and to offer protection in a heart ischemia–reperfusion model [79]. *In vitro*, overexpression of HSP-70 was able to inhibit lipopolysaccharide-induced production of cytokines in human monocyte-derived macrophages. By contrast, HSP90 inhibitors prevented LPS-induced endothelial

barrier dysfunction [80], reduced lung injury, and prolonged survival in a murine model of sepsis [81]. Also in favor of a role for HSPs as DAMPs, a model of myocardial ischemia reperfusion revealed significantly attenuated apoptosis and cytokine expression in wild-type mice treated with anti-HSP60 antibody and in TLR4-deficient mice compared with wild-type controls [82].

3.4.3 RNA and DNA

Hypomethylated CpG sequences among bacterial DNA contrast with the high frequency of methylation in human DNA. This major difference explains why bacterial DNA can activate human TLR9, while human DNA cannot. Similarly, trypanosomatidae DNAs contain 6–13 more agonist sequences than human DNA, as well as fewer inhibitory telomeric motifs [83]. Accordingly, mammalian DNA is, by itself, not a major DAMP. However, when combined with antimicrobial peptide LL37 [84] or HMGB1 [85], self-DNA could activate cells.

Similarly, there are mechanisms that prevent self-RNA to be recognized by the retinoic acid-inducible gene 1 (RIG-I) PRR. A conserved amino acid in the RNA binding pocket prevents recognition of endogenous RNA bearing a N1 - 2′-*O*-methyl group as a marker of "self," flaviviruses exploit this tolerance mechanism to escape the immune system [86]. Double-stranded RNAs are recognized by melanoma differentiation-associated protein 5 (MDA5) and by TLR3. RNA escaping from damaged cells could serve as en endogenous ligand for TLR3 [87]. For example, RNA released from necrotic synovial cells activates rheumatoid arthritis synovial fibroblasts via TLR3 [88]. RNAs are also ligands of TLR7 and TLR8 [89]. As for DNA, the antimicrobial peptide LL37 can bind RNA and the complexes can activate cells through TLR7 and TLR8 [90]. Of note, self-RNA-LL37 complexes are present in psoriatic skin lesions [90].

3.4.4 Mitochondria

Because of the bacterial origin of this organelle, it is not surprising that mitochondria released following the disruption of cells behaves as a DAMP. *In vitro*, they can activate neutrophils while injection of mitochondria causes systemic inflammation and organ injury [91]. As mitochondrial DNA contains hypomethylated CpG DNA repeats similar to bacterial DNA, it is the main activator within the mitochondria via TLR9 [91]. Of note, TNF-induced cell death is associated with release of mitochondria that act as a danger signal [92]. Importantly, mitochondria and mitochondrial DNA can induce cross-tolerance with LPS and, most probably, with any other TLR agonist [93].

3.4.5 Histones

Extracellular histones released in response to inflammatory challenges contribute to endothelial dysfunction, organ failure, and death during endotoxemia and sepsis [94]. This was illustrated by the capacity of antihistone antibody to rescue mice after a lethal injection of LPS or in a peritonitis model. Injection of histones induces massive accumulation of neutrophils in the alveolar vasculature and can

lead to death. During sterile inflammation following liver ischemia/reperfusion, histones activate Kupffer cells via the NLRP3 inflammasome [95]. In trauma patients, histones are found within the bloodstream at concentrations that are toxic for endothelial cells [96]. Histones can trigger cytokine release with the lungs being the predominantly affected organ showing edema, hemorrhage, microvasculature thrombosis, and neutrophil recruitment [96].

3.4.6 Uric Acid Crystals

The cytosol of UV-treated fibroblasts and liver cells contain uric acid. As this is relatively insoluble, high concentrations favor the formation of monosodium urate (MSU) crystals. These activate dendritic cells when released by dying cells [97]. This endogenous adjuvant has been shown to contribute to the adjuvant property of alum [98]. MSU crystals are the etiological agent causing gout. Their capacity to induce IL-1β production reflects their capacity to activate the NLRP3 inflammasome [99]. In this context, it is worth recalling the beneficial effects of IL-1 receptor antagonist treatment in patients with gout [100]. In a bleomycin-induced lung injury model, uric acid released from injured cells activated the NLPR3 inflammasome and contributed to lung inflammation repair and fibrosis [101]. Of note, other crystals, such as cholesterol crystals, act as endogenous danger signals due to their capacity to activate the NLRP3 inflammasome [102].

3.4.7 ATP

Adenosine triphosphate (ATP) is not only an intracellular nucleoside triphosphate utilized by energy-requiring cellular processes but can also serve as a danger signal in inflammatory processes. ATP can be released both by apoptotic cells or autophagic dying cells through pannexin hemichannels and by activated inflammatory cells via connexin hemichannels. ATP also acts as a DAMP in plants [103]. ATP can be released by cells exposed to inflammatory substances such as uric acid crystals, silica, and alum [104]. Anaphylatoxin C3a, which favors IL-1 release [105], also favors ATP release [106]. ATP acts in synergy with LPS to amplify release of IL-1β and IL-18. ATP activates cells via the purinergic P2X7 receptor on macrophages and dendritic cells. High concentrations of ATP are lethal for T-lymphocytes [107]. ATP also contributes to NLRP3 inflammasome activation and the release of IL-1β and IL-18 [108]. Its role, via the P2X7 receptor, has been illustrated in experimental lung inflammation and in patients with idiopathic pulmonary fibrosis [109]. In a murine model of autoimmune encephalomyelitis, alkaline phosphatase, an enzyme that dephosphorylates ATP to ADP thence to AMP and adenosine, significantly reduced neurological signs [110]. Ectonucleoside triphosphate diphosphohydrolase-1 (also known as CD39) is a cell surface molecule expressed on numerous immune cell types; this also contributes to the hydrolysis of ATP to ADP and AMP. In patients with multiple sclerosis, CD39 is increased on microglial cells in white matter lesions [110]. Of note, AMP itself can be converted by CD73 (Ecto-5′-nuclotidase) to adenosine, which possesses anti-inflammatory properties.

3.4.8 S100A8/S100A9

S100 proteins are calcium-binding proteins; more than 20 members of this protein family have been described. S100A8 (also named myeloid-related protein-8, MRP8, or Calgranulin A – 8 kDa) and S100A9 (MRP14/Calgranulin B – 14 kDa) are two abundant cytoplasmic proteins in monocytes and neutrophils comprising 30–60% of total cytosolic protein in neutrophils. They exist as homodimers and, preferentially, as a heterodimer (24 kDa) or a heterotetramer also known as calprotectin (S100A8/A9). Calprotectin contains zinc-binding domains that are involved in its antibacterial activity. Intracellular S100A9 is a critical regulator of TLR3 trafficking, and it acts as a regulator of TLR3 signaling and functions. It colocalizes with TLR3 following poly I:C treatment and facilitates maturation of TLR3 containing early endosome to late endosome [111]. S100A8/A9 is secreted by macrophages and neutrophils activated by TLR agonists, C5a, fMLP, LPS, TNF, or IFNγ. Their increased presence within tissues reflects the inflammatory process as seen in inflamed skin and colon [112,113]. They bind to heparan sulfate proteoglycans, CD36, RAGE, and TLR4. In a murine model, bone marrow cell activation by S100A8, as assessed by TNF production, was absent in cells derived from TLR4-deficient mice [114]. LPS-induced TNF production was lower in S100A9 KO cells, while S100A8 KO mice were more resistant to the lethal effect of LPS + galactosamine [114].

In humans, TLR4 may play a dominant role. Interestingly, the transcriptome analyzed in human monocytes triggered by LPS or S100A8 revealed a common core of 653 modulated genes, while 768 genes specific to S100A8 were modulated [115]. Other experiments identified an association between S100A8 and S100A9 with RAGE in connection with a decrease in cardiomyocyte contractility [116]. S100A8 and S100A9 also contribute to leukocyte migration [117]. Enhanced levels of serum S100A8 and S100A9 were reported in sepsis patients and in human volunteers injected with LPS [118]. Following injection of *Escherichia coli* in mice, liver injury was less severe in S100A9-deficient mice suggesting that S100A9 released during sepsis contributes to its severity and tissue injury [118]. Similarly, during viral infection, S100A9 was released from undamaged virus-infected cells and contributed to the exacerbation of the inflammatory response, cell death, and virus pathogenesis [119]. S100A8/S100A9 has been used as a sensitive biomarker of local (irritative and allergic contact dermatitis) or systemic inflammation (collagen-induced arthritis), with detection even at subclinical activity [120]. Of note, some protective functions of S100A8 and S100A9 molecules have been reported, such as their capacity to enhance bactericidal activity of human neutrophils [121] or to induce IL-10 that initiates a feedback loop that attenuates acute lung injury [122]. Similar to other DAMPs, S100A8/S100A9 can induce cross-tolerance [123].

3.4.9 Interleukin-1α and Interleukin-33

Interleukin-1α is a cytokine that can be normally present within certain cells such as keratinocytes. In addition to its intracellular form, IL-1α also exists as a membrane form. It binds to the same receptor as IL-1β and shares similar

activities. In contrast to IL-1β and IL-33, the precursor form of IL-1α (30 kDa) is biologically active [124]. However, its production and release are independent of the inflammasome, and it possesses intracrine properties, which allows it to act directly within the nucleus. For example, it can induce release of IL-8 within *Chlamydia*-infected cells [125] without being released. In fact, intracellular accumulation of intracellular IL-1 occurs at extremely low concentrations of LPS, far lower than those required for its release [126]. The capacity of necrotic cells (endothelial cells, macrophages, etc.) to stimulate cytokine and chemokine release and an immune response can be counteracted by anti-IL1α and IL-1RA, and was abolished using cell lysates from IL-1α-deficient mice [127,128]. Another study reported that necrotic cells could also stimulate IL-1α release by macrophages [14]. IL-1α released from damaged epithelial cells and during sterile inflammation plays a key role in triggering tissue inflammation, for example, in brain [129], lungs [130,131], skin [132], and heart [133]. Interestingly, IL-1α can stimulate release of other DAMPs such as S100A8/A9 [134].

Similar to IL-1α, IL-33 displays transcriptional regulatory properties that allow it to act as an intracellular nuclear factor in an intracrine fashion [135]. Endothelial cells constitute a major source of IL-33 in chronically inflamed tissues from patients with rheumatoid arthritis and Crohn's disease [135]. Constitutive nuclear expression of IL-33 has also been reported in fibroblasts, epithelial cells, and keratinocytes [136]. IL-33 appears to be an important amplifier of innate immunity, particularly in pulmonary and digestive mucosa [137]. Once released by damaged cells, cathepsin G and elastase released by activated neutrophils contribute to its cleavage and its processing to its active form [138].

3.4.10 Heme

Heme is composed of an atom of iron linked to four ligand groups of porphyrin. Heme is a main component of hemoglobin and is also found in other hemoproteins such as myoglobin and cytochrome catalase. As a free molecule, elevated heme level in blood is a characteristic feature of diseases with increased hemolysis, myolysis, or extensive cell damage. It causes oxidative damage and amplifies the inflammatory response by its capacity to activate macrophages and neutrophils. Heme is scavenged by hemopexin and catabolized by heme oxygenase-1. Heme induces TNF secretion, but neither IL-6 nor CXCL10, by murine peritoneal macrophages in a TLR4-dependent manner [139]. Heme also activates the production of inflammatory proteins by cardiac cells through NF-κB activation [140] and vascular smooth muscle cells via reactive oxygen species [141]. Another study found that heme could activate the NLRP3 inflammasome and IL-1β release via P2X7 and P2X4 receptors [142].

3.4.11 Hyaluronan

Hyaluronan, a major component of extracellular matrix, is a high molecular weight polymer ($>10^6$ Da) glycosaminoglycan composed of the repeating polymeric disaccharides, D-glucuronic acid, and *N*-acetyl glucosamine. After tissue injury and inflammation, it undergoes cleavage, resulting in accumulation of low

molecular weight hyaluronan fragments. Those initiate an inflammatory response in a TLR4- and TLR2-dependent manner [143–145]. TLR4-associated MD2 molecule and CD44 are associated with sensing of hyaluronan fragments [146]. CD44 can promote endocytosis of hyaluronan, which can be further degraded into small saccharide fragments that can trigger the NLRP3 inflammasome and release of IL-1β [147]. Low molecular weight fragments of hyaluronan could trigger the release of β-defensin-2 in keratinocytes [148] and intestinal epithelial cells [149]. Accordingly, hyaluronan fragments contribute to protection of the skin and gut against microorganisms. Furthermore, their presence in human milk, and their capacity to induce production of β-defensin-2 in the gut, contributes toward protective antimicrobial defenses in the newborns [150].

3.4.12 Biglycan

Biglycan is a proteoglycan consisting of a 42-kDa leucine-rich protein core substituted at its N-terminal with two chondroitin/dermatan sulfate side chains. In its matrix-bound form, biglycan cannot activate any PRRs. However, upon tissue stress or damage, biglycan becomes soluble, primarily by partial proteolysis of the extracellular matrix [151]. In this form, biglycan interacts with TLR2 and TLR4, generating a rapid inflammatory response by macrophages [152] in terms of TNF and chemokine production. Biglycan-deficient mice are more resistant to LPS-induced lethality than wild-type mice, illustrating the synergy between PAMPs and DAMPs. Biglycan also induces release of IL-1β following activation of NLRP3 and P2X4 and P2X7 receptors [153]. Biglycan-deficient mice display lower levels of IL-1β in the kidney, lung, and circulation than wild-type mice in response to LPS.

3.4.13 Heparan Sulfate

Heparan sulfate (HS) is a polysaccharide ubiquitously expressed as a proteoglycan in extracellular matrices and on cell surfaces. Heparan sulfate binds to many proteins and contributes to the inflammatory response, particularly by its involvement in the initial adhesion of leukocytes to the inflamed endothelium, and the subsequent chemokine-mediated transmigration through the vessel [154]. HMGB1 is one of its ligands with HS favoring its binding to the RAGE receptor [155]. β-D-endoglucuronidase heparanase is an endoglycosidase that cleaves HS, releasing 4–7 kDa fragments that can activate the release of NF-κB-dependent inflammatory cytokines in a TLR4-, MyD88-dependent manner [156]. Soluble HS is found in the serum of septic shock patients and contributes toward an increased production of mitochondrial reactive oxygen species [157].

3.4.14 Eosinophil-derived Neurotoxin

Eosinophil-derived neurotoxin (EDN) is an eosinophil granule-derived secretory enzyme (RNASE2) belonging to the family of RNase A-type ribonucleases. EDN has broad antiviral activity, targeting RNA viruses. It also displays some chemoattractant activities for dendritic cells, stimulating maturation. It also boosts the production of inflammatory cytokines via TLR2 [158].

3.4.15 Peroxiredoxins

In humans, peroxiredoxin (PRDX) is a family of six antioxidant cytosolic enzymes whose major functions are to regulate hydrogen peroxide signaling through their peroxidase activity and to act as protein chaperones. PRDX are abundant proteins in many cells, particularly erythrocytes. PRDX1 recombinant protein stimulated inflammatory cytokine release in a TLR4-dependent signaling pathway [159]. Their release in ischemic brains contributed to the inflammatory reaction through both TLR2 and TLR4 [160]. In this model, targeting PRDX rather than HMGB1 was more neuroprotective. Of note, LPS and TNF can induce PDRX release by macrophages [161]. Circulating PRDX1 could be measured in cardiogenic shock patients needing extracorporeal membrane oxygenation [162]. Levels correlated with lactate and high levels were predictors of poor outcome. Hypoxia favors release of PRDX1 by human monocytes, while recombinant PRDX1 acted in synergy with hypoxia to induce inflammatory cytokine release of by monocytes [162].

4.1. Introduction

Coevolution between host and pathogen is the major determinant of genetics and pathobiology of infections and associated diseases. It is a complex process of reciprocal, adaptive genetic change in two or more species. Changes in gene structure and nuclear organization, driven by selection in one species, generate novel life styles and behaviors that, in turn, select genetic and epigenetic changes in species that share their ecological niche with the first species. Coevolution occurs among any interacting populations: prey and predator, plant and herbivores, competitors or mutualists, but it is expected to be particularly important in host–pathogen systems because of the intimate nature of their association and the strong selective pressures that one species can exert on the other. Pathogen infectivity and host resistance as well as ability of the host to clear an infection versus the strategies of the pathogen to evade or suppress host defenses are examples of reciprocal traits that are potentially involved in the host–pathogen coevolution. In each of these pairings, the effects on the fitness of the host and of the pathogen act in opposite directions: what is advantageous for the pathogen is frequently noxious for the host and vice versa. This paradigm applies to all infectious diseases, even those in which the pathogen, instead of suppressing the host immune response, elicits a strong inflammation as strategy for draining nutrients. In this case, the microorganism usually takes advantage of other mechanisms to escape the host defenses.

The second general mechanism of development of pathogenicity by microorganisms is the one deriving from the generation of proteins that support the growth of the producing species in one environment and that turn out to behave as protein toxins in occasional hosts. This is exemplified by the case of fungi [1].

In this chapter, we will focus on recent advances in the knowledge of the mechanisms evolved by bacteria to face and counteract the inflammatory response; such an action can profoundly impact the survival and spreading of the microorganisms within the host, from the host into other hosts and into the

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

environment. More in particular, we will focus on those microbial virulence factors that are released in the host or in the environment and are generally termed bacterial toxins or exotoxins, and will not consider the so-called bacterial effectors that are introduced into target cells by secretion systems.

4.2 Toxins Modulating the Activity of Inflammatory Caspases and Inflammasomes

Caspases are ancient and evolutionarily conserved proteases that play essential roles in development, homeostasis, and immunity. Some caspases are involved in apoptosis, an immunologically silent form of programmed cell death. In contrast, the inflammatory caspase, caspase-1, following its activation initiates a form of lytic cell death termed pyroptosis, which releases inflammatory mediators (cytokines and danger signals), removes the replicative niche of cytosolic bacteria, and exposes intruders to extracellular defenses and neutrophils. In addition, caspase-1 mediates the maturation and secretion of pro-IL-1β and pro-IL-18, two pleiotropic inflammatory cytokines best known for inducing fever and interferon (IFN)-γ secretion, respectively. The canonical inflammasomes, a class of cytosolic pattern recognition receptors (PRR), activate caspase-1 in response to specific signatures of infection. Initially characterized in myeloid cells, inflammasomes are present also in epithelial cells [2].

Recently, a new noncanonical inflammasome pathway has been described that activates another inflammatory caspase, namely, caspase-11 (or the presumed human orthologs caspase-4 and caspase-5) [3]. Caspase-11 lacks the ability to cleave pro-IL-1β and pro-IL-18, but it can promote the release of the mature form of the cytokines by interacting and activating NLRP3 [4]. Similar to caspase-1, it induces lysis of the host cells, but the caspase-11-dependent cell death has features that distinguish it from caspase-1-induced pyroptosis and it was suggested to promote the spreading of intracellular bacterial pathogens [3] rather than contributing to their clearance as in the case of caspase-1-dependent cell death [5]; however, this remains a controversial issue [6]. In addition, it is disputed that caspase-11 rather than caspase-1 may be the critical effector of deleterious inflammatory responses [7].

Listeria monocytogenes is a Gram-positive saprophyte and facultative pathogen that causes self-limited gastroenteritis in immunocompetent individuals. In immunocompromised hosts, *L. monocytogenes* infection can progress to cause sepsis, encephalitis, and death. After internalization into epithelial cells and macrophages by exploiting the two bacterial surface proteins internalin A and B [8], *L. monocytogenes* readily escapes from phagosomes into the cytosol using listeriolysin O (LLO) that assembles transmembrane pores at acidic pH values [9]. LLO is a member of a large group of pore-forming toxins produced by a variety of pathogenic bacteria that includes perfringolysin, streptolysin, pneumolysin, and so on [10]. These toxins bind to cholesterol-containing membranes and form transmembrane pores of large diameter that rapidly quenches ion gradients across membrane causing osmotic imbalance. The pore-forming activity of

purified LLO protein is sufficient to trigger NLRP3 activation, probably via perturbations of the intracellular K^+ levels. Macrophages cultured with *L. monocytogenes* deficient for the toxin LLO do not secrete IL-1β [11].

Streptococcus agalactiae or group B streptococcus (GBS) is a highly pathogenic extracellular Gram-positive bacterium that causes life-threatening infections in neonates, pregnant women, and the elderly [12]. GBS produces two membrane-damaging exotoxins, namely, β-hemolysin/cytolysin and CAMP factor. These bacteria are capable of activating both the signals required for the synthesis and release of IL-1β. Stimulation of pro–IL-1β synthesis by GBS requires an as yet unidentified MyD88-dependent receptor, internalization of whole bacteria, and phagosomal acidification, while the secretion of the mature cytokine is consequent to the activation of the NLRP3 inflammasome by the β-hemolysin [13]. β-hemolysin is an oxygen-stable, nonimmunogenic, pore-forming cytolysin; it has not been purified to homogeneity yet and its precise molecular nature remains unknown [14]. It activates the cytosolic inflammasome platform not only because it permits the efflux of K^+ through the plasma membrane but also because it alters the membrane integrity of phagolysosomes, thus allowing bacterial RNA to escape and to interact with and activate NLRP3 [15]. IL-1β plays a central role in eliciting host defenses against GBS and this action is mediated by the increased production of the neutrophil chemokines CXCL1/CCL3 and the consequent recruitment of neutrophils to infection sites [16]. It was shown that GBS produces a serine protease that cleaves CXCL1 *in vitro* [17]; however, the *in vivo* relevance of such an activity remains to be demonstrated.

Pneumolysin, the thiol-activated cytolysin of Streptococcus pneumoniae, displays a complex action on host defense, not only by inducing necrosis or apoptosis of human neutrophils but also by triggering IL-8 production and stimulating neutrophil transendothelial migration [18]. Pneumolysin also activates the NLRP3 inflammasome and the activation of the inflammatory platform is determinant for the host defense to *S. pneumoniae* [19]. Therefore, pneumolysin can either stimulate or disable host defense depending on expression levels, site, and magnitude of infection and this dichotomy likely applies to all pore-forming toxins [18].

NLRP3 is activated also by the α-hemolysin of *Staphylococcus aureus* but inflammasome activity does not influence the clearance of bacteria during pulmonary infection, while, on the contrary, it plays an important role in pulmonary injury: the latter is independent of IL-β signaling but relies on NLRP3-induced cell death [20]. Similarly, the leukocidin PVL of *S. aureus* triggers the release of IL-β by macrophages upon the activation of the NLRP3 inflammasome [21].

Some extracellular Gram-negative bacteria activate the noncanonical inflammasome pathway and among them *Escherichia coli*, *Vibrio cholerae*, and *Salmonella typhimurium*, a facultative intracellular pathogen. In the case of *V. cholerae*, the toxin responsible for the activation of this pathway is cholera toxin B (the pentameric ganglioside GM1-binding protomer, abbreviated CTB), component of the AB5 holotoxin complex. CTB not only promotes the secretion of IL-1β/IL-18 by activating NLRP3 and caspase-1 but it also induces macrophage cell death in a caspase-11-dependent, NLRP3-independent manner [7].

4.3 Toxins Modulating the Intracellular cAMP Levels

The cAMP signaling pathway, the MAPK pathway, and the cytosolic [Ca^{2+}] are the major signaling systems in mammalian cells, including those of the immune system. Moreover, these three signaling pathways cross-talk among each other at several sites. Therefore, it is not surprising that many bacterial pathogens produce exotoxins that enter into host cells inducing an increase of intracellular cAMP or producing cAMP themselves. This is an effective and powerful strategy of immune evasion as it impacts many different cells of the immune system. The elevation of the cAMP content can be achieved by the activation of the Gsα subunit of heterotrimeric G-proteins coupled to cellular adenylate cyclases, such as in the case of CT and *E. coli* heat-labile enterotoxin (LT). Alternatively, bacteria such as *Bacillus anthracis* or *Bordetella pertussis* release and deliver into target cells an adenylate cyclase toxin: the edema factor (EF) and CyaA, respectively.

CT and LT have been extensively studied because of their strong adjuvant activity and the consequent potential application in human mucosal vaccination protocols [22]. Nevertheless, the molecular mechanisms responsible for their ability to affect the induction of mucosal immune responses have remained ill-defined. Recently, it was shown that the adjuvant activity of CT and of LT is mediated mainly by effects on antigen presenting cells (APCs) and it occurs via the cAMP-dependent protein kinase A and caspase-1/inflammasome-dependent IL-1β signaling [23].

EF produced by *B. anthracis* has a crucial role in disarming the host immune response, an event that occurs early during infection; however, as the activity of EF frequently synergizes with that of the other anthrax toxin (the lethal factor, LF), this topic is dealt with in a dedicated section below.

Interestingly, EF has been reported to enhance the migration of intoxicated macrophages by inducing the activation of cAMP signaling and the transcription factor CREB that, in turn, increases the expression of the proteoglycan syndecan-1 [24], crucial in cell adhesion and migration [25]. The bacterium would take advantage of the modified migratory behavior of macrophages to reach regional lymph nodes wherefrom it enters into the blood circulation, where it rapidly proliferates [24]. The same effect is achieved when edema toxin (ET) is applied to macrophages and it is recapitulated in dendritic cells [26]. On the other hand, ET was also shown to inhibit macrophage migration [27], and it is conceivable that ET may have differential effects on macrophages depending on their phenotypic programming. ET is composed of edema factor and the cell-binding protein, known as protective antigen (PA), which is released as a separate entity. Its name refers to the fact that it is sufficient, by itself, to generate protective immune response to anthrax disease when used as a vaccine [28]. PA binds to two different receptors widely expressed among vertebrate cell types [29,30] and it is processed on the cell surface by removal of a 20 kDa portion. The remaining 67 kDa PA forms a heptamer or octamer that binds either EF or LF [31]. The toxin complex is then internalized via the endocytic route [32] and, at the acidic pH values of late endosomes, PA forms a transmembrane pore with a structure similar to that of α-hemolysin, which mediates the translocation across the membrane into the cytosol of the unfolded EF or LF [31].

The adenylate cyclase toxin CyaA produced by *B. pertussis* is another toxin capable of elevating intracellular cAMP to supraphysiological levels. Upon the translocation of the adenylate cyclase domain across the phagocyte plasma membrane and its activation by binding the cytosolic calmodulin, the enzyme catalyzes the unregulated conversion of ATP to cAMP. Notably, live imaging of cAMP production revealed that EF and CyaA cause cAMP elevation in different compartments of the cell. EF acts mainly in the perinuclear region causing a cAMP gradient of decreasing value from the nucleus to the plasma membrane, while CyaA induces an opposite gradient [33]. CyaA causes a subversion of the bactericidal superoxide and nitric oxide production and neutrophil extracellular trap release (NET) [34–36]. Recently, it was shown that the elevation of intracellular cAMP concentration induced by CyA in macrophages activates the mitochondrial apoptotic pathway in macrophages. This is due to the accumulation of the Bax-activating protein BimEL in the cell cytosol; the stabilization of the proapoptotic protein takes place via its phosphorylation at the Ser^{83} residue by the cAMP-activated protein kinase A [37]. It is also involved in the activity of the tyrosine phosphatase SHP-1 that inhibits ERK1/2 thus preventing phosphorylation of BimL at the Ser^{69} residue that commits to proteosomal degradation [38]. Moreover, the CyA-triggered cAMP signaling upregulates the expression of BimEL through the activation of the transcription factor FOXO3A, leading to a persistent increase in proapoptotic BimEL levels in cell cytosol [39].

4.4 Toxins Modulating MAPK Signaling

Accumulating evidence suggest that p38MAPK plays an essential role in inflammation. In fact, it is involved in the expression of proinflammatory mediators in macrophages such as IL-1β, TNF-α, PGE2, and IL-12 as well as COX-2, IL-8, IL-6, IL-3, IL-2, and IL-1, and for this reason it is considered a good target in the treatment of inflammation-based diseases [40]. However, p38MAPK may also exert an anti-inflammatory role: sublytic concentrations of β-hemolysin of GBS were shown to drive the expression of the anti-inflammatory cytokine IL-10 by triggering the activation of p38MAPK in infected macrophages. This, in turn, results in the inhibition of macrophage killing activity and repression of the expression of IL-12 and NOS2, both critical factors in antibacterial host defense. In accordance, targeted deletion of p38MAPK in macrophages increases resistance to invasive GBS infection *in vivo*. The β-hemolysin capability of activating p38MAPK is shared by two other large pore-forming toxins, streptolysin O and LLO produced by *Streptoccus pyogenes* and *L. monocytogenes*, respectively, and is independent of the osmotic stress induced by membrane permeabilization and of the engagement of a TLR [41].

LF of *B. anthracis* is a zinc-dependent metalloprotease that cleaves the N-terminus of mitogen-activated protein kinase kinases (MAPKKs or MEKs) [42–44]; the impact of interfering with this signaling pathway on the functions of the immune system is tremendous, starting from macrophages that represent the first line of defense irrespective of the port of entry of the bacterial spores [45]. One of the most prominent effects of LT (the binary complex formed

by LF and PA) on macrophages is the induction of apoptosis. At variance from initial studies showing that LT induces apoptosis of activated macrophages via inhibition of the p38MAPKs activation, due to the cleavage of the upstream kinase [46], more recent studies revealed that LT-induced death pathways are more complex than it was initially thought. Indeed, LT also acts at the crossroads of the mitochondria [47], the proteasome and, more importantly, the inflammasome pathways [48,49] to trigger macrophage apoptosis; it is not clear yet whether LT acts by direct physical interactions with components of these pathways or through indirect consequences of MEK cleavage. Mice are killed by LT over days in a manner independent of their macrophage sensitivity to toxin, suggesting that other cell types play a more important role in LT-induced lethality [50,51]. By contrast, rats are killed in a manner directly correlated to the sequence of the NLRP1 inflammasome sensor and thus to the sensitivity of their macrophages to toxin [52]. Notably, the toxin-induced macrophage cell death concerns rodent macrophages and not the human ones that are resistant to LT [49].

LT inhibits the sporicidal and bactericidal activities of macrophages [53–56]. LT also disrupts the production of phospholipase A2 group IIA by alveolar macrophages, which is crucial for their anthracidal activity, by interfering with the MAPK-NF-κB activation pathway [57]. Moreover, while ET enhances spontaneous macrophage migration [24], both LT and ET inhibit macrophage chemotaxis through the respective enzymatic activities [27]. This function is likely to result in suppression of the migratory response of macrophages toward inflammatory chemokines. LT also inhibits the expression of several proinflammatory cytokines in macrophages, both *in vitro* and *in vivo*, thus compromising the recruitment of other immune cells [45,58,59].

4.4.1 Synergy between ET and LT

Beyond the inhibition of macrophage chemotaxis, activity shared by LT and ET, these two toxins act in a concerted way to impair the bacterial clearance by phagocytes and by *B. anthracis*-specific responses. This synergy derives from the intense and multilevel cross-talk that occurs among the cAMP and the MAPK signaling pathways [60]. This permits *B. anthracis* to economize greatly on the amount of protein toxin to be synthesized. This strategy may have evolved under the pressure of amino acid availability inside the phagosomes where *B. anthracis* is located after the first interaction with alveolar or intestinal macrophages. Double and synergic toxin production strategy may have been used by other bacteria: the concomitant production of pertussis toxin and CyaA by *B. pertussis* and of botulinum neurotoxin C1 and toxin C2 by some strains of *Clostridium botulinum* is well known [61,62]; however, the fact that these couples of toxins act in concert remains an ill-defined issue. Although comparatively little has been reported on the effects of LT and ET on the potent antimicrobial defenses provided by PMNs, there is compelling evidence that *B. anthracis* uses both toxins to evade killing by these cells. ET and LT inhibit the oxidative burst elicited by lipopolysaccharide or muramyl dipeptide [63], and ET also inhibits phagocytosis [64]. Moreover, ET impairs neutrophil chemotaxis and when combined with

LT its inhibitory effect is potentiated [65,66]. Collectively, these effects may explain the poor neutrophil response that accompanies early stages of systemic anthrax.

Given the crucial role of DCs in the immune response, it is not surprising that anthrax toxins are capable of crippling DC functions [67,68]. LT and ET impair cytokine secretion by mouse-derived DCs, human monocytes-derived DCs, or primary blood DCs [69,70]. ET also disrupts DC functions [68], alone or in cooperation with LT. Moreover, anthrax toxins may finely tune the balance between signals delivered by DCs, inducing terminal differentiation of T cells toward a Th2 rather than a Th1 immune response. As the Th1 immune response is crucial for host survival, its inhibition by the two toxins may be a major aspect in the pathogenesis of anthrax [71].

4.5 Toxins Affecting Host Cell Motility

The actomyosin cytoskeleton of eukaryotic cells plays a pivotal role in host–pathogen interactions. It is essential for epithelial and endothelial barrier functions, which prevent and limit the invasion and dissemination of pathogens in tissues [72,73]. It also has key roles in different processes carried out by immune cells, including migration and phagocytosis [74], formation of the immune synapse and immune cell signaling [75,76]. Owing to its paramount importance in cell structure, physiology, and movement, the dynamic assembly, disassembly, and orientation of the actomyosin polymers are regulated at various levels by multiple factors among which the Rho GTPases family plays a major part [77]. Therefore, it is not surprising that bacterial toxins targeting the actomyosin cytoskeleton are the second largest family of exotoxins produced by bacterial pathogens, after that of the pore-forming toxins. These bacterial toxins display a number of different biochemical activities and target different GTPases, thus interfering with the corresponding host signaling pathways [78]. A growing number of bacterial protein toxins affects host GTPase activity by catalyzing covalent modifications of the target proteins [78]. The C3 exoenzyme of *C. botulinum* (C3bot) was the first toxin shown to modify Rho-family GTPases [79]. Further, C3 proteins were identified in *Clostridium limosum* (C3lim) [80], *Bacillus cereus* (C3cer) [81], as well as in *S. aureus* (C3stau) [82]. These toxins are small enzymes that transfer the ADP-ribose moiety from cytosolic NAD^+ to different target proteins; interestingly, they consist of only a catalytic domain and do not possess any specific modules for membrane translocation. Accordingly, the cell accessibility of C3-like toxins is often very low except for C3stau (also known as Edin) of *S. aureus* that does not need to be translocated to reach its target, as the bacterium invades the host cell; once within the host cytoplasm, it secretes the toxin that ADP-ribosylates Rho, resulting in the reorganization of the actin cytoskeleton [83]. Monocytes and macrophages take up C3bot and C3lim very efficiently, suggesting that these host cells are preferred targets for the toxin [84]. The same could be true also for C3cer, but no such evidence is yet available. Similarly, the impact of C3stau on phagocytic cells remains unexplored. On the contrary, clostridial C3 enzymes have been extensively studied. These

toxins specifically mono-ADP-ribosylate the isoforms Rho-A, -B, and -C at Asn^{41} rendering them inactive [85]; as a consequence, the subsequent activation of the various cellular Rho-effector molecules is compromised. In monocytes/macrophages, the C3-catalyzed Rho-inhibition prevents migration [86], adhesion [87,88], and phagocytosis [89], suggesting a specific pathogenic role of the C3 protein toxins toward such immune cells [90].

Clostridium difficile, the most common cause of nosocomial antibiotic-associated diarrhea and the etiologic agent of pseudomembranous colitis, produces two large multidomain toxins, TcdA and TcdB, which are capable of entering cells via the endosomal route and membrane translocation into the cytosol similar to the anthrax toxins. Once inside the cytosol, their N-terminal domain displays the glucosyl-transferase activity directed to the Thr^{37} residue of Rho [91]. This covalent modification results in the functional inactivation of the GTP-ase that ultimately culminates in the disruption of the intestinal epithelial barrier [92,93]. In addition to this effect, TcdA and TcdB stimulate the release of inflammatory mediators by immune cells and this relies on two mechanisms, one dependent on the enzymatic activity of the two toxins and the other mediated by the inflammasome [94–96]. There has been considerable debate as to whether TcdA or TcdB is responsible for the inflammatory response and tissue damage associated with the *C. difficile* infection; recent reports suggest that TcdB may synergize with TcdA, enhancing its ability to trigger intestinal inflammation and cause tissue damage [97].

Various cytotoxic necrotizing factors (CNFs) such as CNF1, CNF2, and CNF3 from *E. coli* and CNF from *Yiersinia pseudotuberculosis* persistently activate proteins of the Rho family by deamination of a glutamine residue (Gln^{61} or Gln^{63}) [78] and this is followed by the degradation of the GTPase by proteasomal cleavage [98]. Although the impact of disrupting Rho proteins on the host immune response has been poorly investigated, it may result in a decreased inflammatory response favoring bacterial infection [99].

4.6 Toxins Blocking Protein Synthesis or Protein Folding

Shiga toxins (Stxs) compose a family of structurally and functionally related cytotoxic proteins expressed by enteric pathogens *Shigella dysenteriae* 1 and enterohemorrhagic *E. coli* (Shiga-toxigenic *E. coli*, STEC). Following ingestion of small numbers of Shiga toxin-producing bacteria, humans develop bloody diarrhea and risk the development of life-threatening systemic complications including the hemolytic uremic syndrome and neurological abnormalities [100]. STxs are AB_5 holotoxins, with a structural architecture similar to that of cholera toxin, but capable of inhibiting protein synthesis. These toxins bind the glycolipid globotriaosylceramide at the cell surface and are endocytosed via a retrograde trafficking system from early endosomes to the Golgi stacks and finally to the endoplasmic reticulum (ER). In the ER, toxin A subunits are proteolitically cleaved and a 27 kDa fragment translocates into the cytoplasm via the reverse translocon [101]. In the cytosol, the fragment displays an *N*-glycosidase activity specific for a specific adenine base of the 28 s RNA, thereby blocking protein

synthesis [102]. The treatment of monocytic cells with Shiga toxin type 1 (Stx1, produced by enterohemorrhagic *E. coli*) leads to the activation of the ER stress sensors IRE1, PERK, and ATF6 [103] that are responsible for the initiation of the unfolded protein response (UPR) [104]; with the exception of IRE1 activation that does not require the enzymatic activity of the toxin, the latter is necessary for the optimal activation of PERK and ATF6. ER stress response induced by Stx1 leads to increased cytosolic Ca^{2+} levels, activation of calpain and of caspases-8 and -3 leading to apoptosis [105]. However, it remains to be established whether apoptosis of monocytes occur *in vivo* and whether this is part of a bacterial strategy aimed at evading the host immune response.

Cell life is dependent on the correct folding of proteins taking place in the ER. A central player in this process is the chaperone BiP, which is the target of a toxin produced by Shiga-toxigenic *E. coli* (STEC). The toxin is an AB_5 cytotoxin and it is named subtilase cytotoxin (SubAB); it is extremely cytotoxic *in vitro* for a range of cell types and it is lethal for mice when injected intraperitoneally [106]. SubAB acts by binding via its pentameric B protomer to cell surface glycan receptors terminating in α2–3-linked N-glycolylneuraminic acid [107]. This triggers internalization and retrograde transport to the ER [108], where the A subunit, a highly specific serine protease, cleaves the chaperone BiP [106]. BiP is a conserved ER chaperone essential for the survival of eukaryotic cells. It also maintains the permeability barrier of the ER membrane and plays a crucial role in the UPR. Accordingly, SubAB treatment rapidly triggers the three ER stress-signaling pathways [109]. The toxin also causes a major redistribution of leukocytes and increases leukocyte apoptosis *in vivo* suggesting that it has relevant immunosuppressor effects [110]. Moreover, SubAB was shown to lower the secretion of interleukin-8 (IL-8) and monocyte chemoattractant protein 1 (MCP-1) in human macrophages, colonic epithelial cells, and brain microvascular endothelial cells. The downregulation of secreted chemokines is dependent on the cytotoxic activity of SubAB, as it was not observed in cells treated with an inactive mutant. Thus, SubAB-mediated suppression of secreted chemokines is dependent on the toxin capacity to cleave the ER chaperone BiP [111].

4.7 Conclusions

The study of the impact of bacterial toxins on the innate immune system has revealed important insights into the pathogenesis of several microbial diseases and has highlighted the strategies evolved by bacteria to survive and spread, under the selective pressure exerted by the defense mechanisms of the host. Moreover, deciphering the molecular mechanisms by which the toxins hamper the immune system contributes to implementation of the already large group of toxins that, because of their ability in knocking down or altering a specific cell target and function, represent an excellent tool for unraveling signaling pathways and physiological aspects of the cells, including those belonging to the immune system.

5.1 Introduction

Venom systems are key evolutionary innovations in a broad phylogenetic range of animal lineages, and are used for defense, competitor deterrence, or predation. Venomous animals include the extensively studied and medically important clades (snakes, scorpions, and spiders), and sea anemones, jellyfish, sea snails, cephalopods, centipedes, several insect orders, echinoderms, fishes, lizards, and even some mammals, such as platypus and shrews.

Venoms across the Kingdom Animalia are complex mixtures of substances that include variable combinations of proteins, ranging from multiunit globular enzymes to small peptides, salts, and organic molecules such as polyamines, amino acids, and neurotransmitters [1–6]. Different venom components act synergistically, thus enhancing their deleterious effects [7]. Modes of venom delivery are diverse and include barbs, beaks, fangs or modified teeth, harpoons, neumocysts, pinchers, proboscises, spines, sprays, spurs, and stings.

Targets of venom action include virtually all major physiological pathways and tissues. The targeting of mammalian species by animal venoms has presumably introduced evolutionarily relevant selective pressures to either avoid or minimize the toxic effects of envenomation in a coevolutionary "arms race" [8,9]. In general, animal venoms are potent inducers of tissue damage and inflammation. Understanding the mechanisms involved in venom-induced inflammation has been useful not only to understand the mechanisms of envenomation but also in the more general characterization of inflammatory pathways. The aim of this chapter is thus to describe the present status of the knowledge on the inflammatory response to animal venoms with emphasis on those of medically important animal clades.

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

5.2 Inflammation Induced by Snake Venoms

Venomous snakes belong to four main families: Elapidae, Viperidae, Atractaspididae, and Colubridae (*sensu lato*); their venoms contain a vast array of molecules with different biochemical properties and biological activities. The study of snake venom proteomics has unveiled the biochemical complexity of these toxic secretions [10]. Some of these molecules present enzymatic activities, whereas several others are nonenzymatic proteins and polypeptides. The most common enzymes in snake venoms are phospholipases A_2 (PLA_2s), serine proteinases, metalloproteinases, acetylcholinesterases, L-amino acid oxidases, nucleotidases, and hyaluronidases [11,12]. Among these components, PLA_2s [13], metalloproteinases [14–16], and L-amino acid oxidases [17,18] have been described as venom components responsible for triggering inflammatory responses. In addition to enzymatic components, other nonenzymatic venom proteins induce inflammatory events, such as cytotoxins, vasoactive peptides, and C-type lectin-like components [10].

Snakebite envenoming constitutes a serious health problem mainly in the tropical regions of the world that might lead to irreversible sequelae and mortality and affects thousands of individuals every year [19–21]. Snakes of the family Viperidae, which encompasses many different genera, account for the majority of cases of death and morbidity worldwide. In general, viperid snakebite envenomation causes systemic cardiovascular alterations associated with coagulopathy and systemic bleeding, which may evolve into cardiovascular collapse and death. Furthermore, it induces prominent local manifestations, which include myonecrosis, blistering, hemorrhage, and inflammation. Local inflammation is a major characteristic of envenomation by snakes of viperid species [22,23]. Although still fragmentary, a significant body of information has been gathered on the local inflammation induced by venoms of snakes of the genus *Bothrops*, which are responsible for the vast majority of cases in Latin America. Thus, emphasis will be placed in the description of the inflammatory events induced by *Bothrops* sp. venoms (see Figure 5.1).

Bothrops sp. snake venoms induce a set of inflammatory events, including plasma exudation, edema, leukocyte migration, and the synthesis and release of a complex network of mediators that induce multiple actions. These events can progress to resolution, if the amount of injected venom is low, or to an excessive and uncontrolled inflammatory response when a high volume of venom is injected. Prominent local edema is a common clinical finding in viperid snake-bitten victims [22,24] that may cause ischemia and neural compression, leading to permanent tissue loss, disability, and/or amputation [25–27]. In addition, the displacement of vascular fluid to the interstitial space in cases of widespread edema contributes to the pathogenesis of cardiovascular shock. Thus, edema is a relevant clinical manifestation in viperid snakebite envenomation, considering the partial inefficacy of the classical antivenom therapy in the neutralization of viperid venom-induced local manifestations both in humans and in experimental animals [22,28].

It has long been demonstrated that *Bothrops* snake venoms have the ability to induce inflammatory response at the site of their injection in experimental

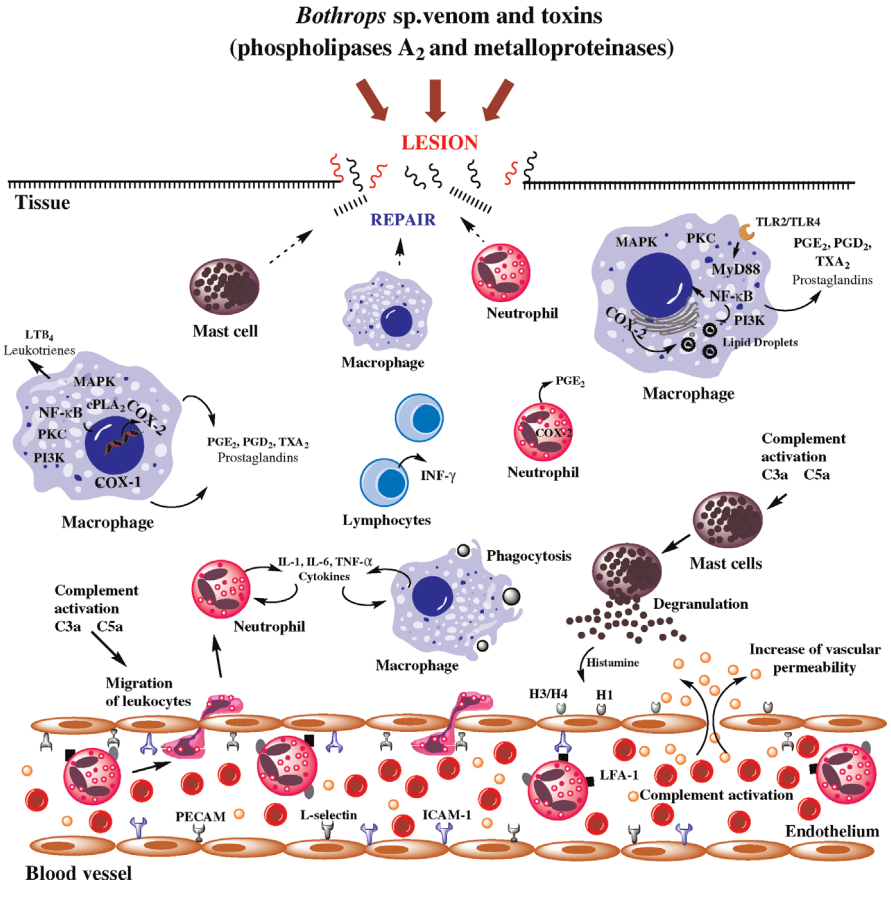

Figure 5.1 Schematic representation of the inflammatory actions of snake venoms. The local inflammatory events caused by *Bothrops* venoms and toxins are summarized.

animals. Many reports have shown that injection of venom of several *Bothrops* species into the mouse and rat foot paw causes edema of rapid onset that can be sustained up to 24 h, depending on the dose of venom. Moreover, it has been shown that edema induced by low dose of venom is not related to the hemorrhagic activity of venom [29–35]. Studies on the dynamics of the local inflammation caused by *Bothrops asper* venom have demonstrated an early plasma extravasation from small venules and adjoining capillary segments after 2 min of exposure to venom, associated with stasis in the microcirculation and dense packing of erythrocytes in the microvasculature [36]. In addition, the ability of this venom to contract collecting lymphatic vessels of mouse mesentery, associated with a halting in the flow of lymph, was demonstrated, thus suggesting that altering of lymphatic system may contribute to the development of edema in envenomed tissues [37].

Regarding the mediators of snake venom-induced edema, despite some variability of data among the available reports, due to the use of different venoms, doses and experimental animal species in the studies, it has been described that

viperid snake venom-induced vascular permeability and edema depend on the local release of well-known synergistic inflammatory mediators, which cause increased vascular permeability and/or vasodilation. Among these mediators are histamine, serotonin, bradykinin [38], platelet activating factor [39], prostaglandins (PGs) [31,39,40], derived from both cyclooxygenase 1 and 2 pathways, mast cell-derived neurokinins, opioid mediators [41], and anaphylatoxins, including the complement components C3 and C5 [42–46]. In addition, participation of both α-1 and -2 adrenergic, but not β-adrenergic mediators, was shown in mouse paw edema induced by *B. asper* venom [29]. In the case of other species, such as *B. lanceolatus*, participation of lipoxygenase rather than cyclooxygenase-derived mediators has been demonstrated [47]. The role of cytokines, such as IL-β, IL-6, and TNF-α, has also been suggested for edema induced experimentally by the venoms of *B. jararaca* [48], *B. asper* [86], *B. jararacussu* [49], *B. bilineata* [50], and *B. atrox* [40], since increased levels of these mediators were detected at the site of venom injection.

Activation of mammalian tissue mast cells contributes to the local edema and inflammation induced by snake venoms, including those from the family Viperidae. Mast cells are tissue-resident effector cells that play key roles in inflammation. Once activated, they rapidly secrete and produce a vast array of inflammatory mediators, which trigger the earliest inflammatory events such as edema [51,52]. The ability of *B. jararaca* and *B. moojeni* venoms to induce degranulation of mast cells was demonstrated by both *in vivo* and *in vitro* experimental models [35,53], and mast cell-derived histamine, acting via H1 and H3/4 receptors, is involved in edema induced by *B. moojeni* snake venom [35]. Among venom components, PLA_2s are potent inductors of mast cell degranulation [54,55]. Apart from the contribution of mast cells in triggering the early events of venom-induced inflammation, some reports have shown that mast cells significantly enhance the resistance of mice to the venom of the snake *Atractaspis engaddensis* (family Atractaspididae), at least in part by releasing carboxypeptidase A and other proteases, which can degrade venom components [56,57]. However, no similar studies are available in the literature with regard to the venoms of species of the family Viperidae.

Besides edema, an important cellular component characterizes the local inflammation induced by the majority of snake venoms. Leukocytes play essential roles in the host defense against offending agents. Upon stimulation by injurious agents, these cells respond with phagocytosis followed by generation and release of microbicide products and mediators. In this regard, several studies have demonstrated that venoms from *Bothrops* sp., as well as from other viperid genera, induce a time-related infiltration of leukocytes into the site of injection. Similar to many other exogenous inflammatory agents, *Bothrops* snake venoms evoke an early neutrophil influx followed by a late mononuclear cell infiltrate, which accumulate at the site of venom injection and adjacent tissues [30,40,58–61]. During the innate immune response, neutrophils are the first cells to migrate into the inflammatory site. This process involves the action of chemotactic mediators and expression of distinct subsets of adhesion molecules by both neutrophils and microvascular endothelium. Studies on the mechanisms involved in *Bothrops* snake venom-induced leukocyte recruitment have provided

contrasting results. Whereas whole *B. jararaca* venom neither triggers oriented cell locomotion nor modifies the intrinsic ability of neutrophils to migrate *in vitro* in response to a chemotactic factor [62], *B. jararacussu* venom has the ability to induce neutrophil chemotaxis *in vitro* by a direct mechanism [49]. This was explained by the presence of a lectin in *B.jararacussu* venom that recognizes glycoligands on the neutrophil surface leading as a consequence to polarization and chemotaxis of neutrophils [63,64]. Further, the ability of *Bothrops* venoms to stimulate *in vivo* the expression of the adhesion molecules L-selectin, LFA-1, ICAM- 1, PECAM-1, and CD-18 by endothelium and leukocytes was described in an experimental model in mice [48,86]. This effect was attributed to a direct action of venom on vessel walls and leukocytes, followed by the release of chemotactic cytokines, chemokines, and leukotrienes [68].

The involvement of cytokines and chemokines in *Bothrops* venom experimentally induced infiltration of leukocytes has been suggested by many authors due to the potent activity of these mediators to induce leukocyte activation, chemotaxis, and expression of adhesion molecules, and to the increased levels of Th1 cytokines IL-1-β, IL-6, IL-8, and TNF-α detected at the site of injection of *Bothrops* venoms in experimental models [39,58,65,66]. This is in agreement with increased levels of IL-6, IL- 8, TNF-α, MIP-1β, and RANTES, also described in the serum of patients bitten by *Bothrops* snakes [67]. In addition, complement system-derived chemotactic fractions have a role in leukocyte infiltration induced by *Bothrops* venoms, and the ability of several venoms to activate the complement system, such as C5a fraction, generating chemotactic fractions, has been demonstrated [69,70]. Furthermore, studies using isolated toxins have demonstrated that PLA_2s and metalloproteinases from *Bothrops* venoms are able to induce leukocyte infiltration into the site of their injection. The effects of PLA_2s were attributed to the action of eicosanoids and cytokines, and those induced by venom metalloproteinases were associated with the release of chemotactic cytokines and complement C5a fraction, as well as with the direct stimulatory action of the metalloproteinase disintegrin-like domain on neutrophils [69,71–73].

Bothrops venoms are also able to activate inflammatory functions of leukocytes as they (1) induce the release of inflammatory mediators that amplify and/or lead to resolution the inflammatory process, (2) induce phagocytosis, and (3) trigger microbicide functions of these cells. Release of cytokines, chemokines, eicosanoids, and nitric oxide by neutrophils and macrophages, as well as neutrophil extracellular traps (NETs) by neutrophils induced by *Bothrops* snake venoms, has been demonstrated in a number of studies [74–77]. Although inflammation induced by *Bothrops* venoms is characterized by a complex network of chemical mediators, the eicosanoids represent major players of this venom-induced response. There is evidence of the involvement of prostaglandins and leukotrienes in edema, hyperalgesia, and leukocyte infiltration induced by the venoms of several species of *Bothrops* [34,39,40,65,68,77,78]. In accordance, *Bothrops* venoms have the ability to induce the expression of COX-2 by peritoneal leukocytes in an *in vivo* experimental model [77] *in vitro* by macrophages and neutrophils in culture, indicating that these cells are relevant sources of eicosanoids under inflammatory conditions triggered by these venoms. Furthermore, venom PLA_2 and metalloproteinases are involved in this effect, since their ability to induce

protein expression of COX-2 enzyme system in macrophages has been described, being the effect of venom PLA_2 dependent on activation of NF-κB and downstream kinase proteins [79–82]. These venom components may thus act synergistically within the context of the whole venom.

In addition, there are studies showing that *B. jararaca* and *B. asper* venoms increase the capacity of phagocytosis by both peritoneal polymorphonuclear and mononuclear leukocytes at the site of their injection. This effect was dependent on the engagement of the phagocytosis complement receptor [83]. Further, it was shown that a PLA_2, named MT-III, from *B. asper* venom increases the phagocytic capacity of macrophages, through mannose and β-glucan receptors [84], whereas a metalloproteinase, named HF3, from *B. jararaca* venom, activates phagocytosis of opsonized-zymosan particles by macrophages via $\alpha M\beta_2$ integrin [85].

With regard to the leukocyte microbicide activities, the ability of *Bothrops* venoms to induce generation of reactive oxygen species (ROS) in macrophages and peritoneal leukocytes has been demonstrated [74,75,83,87]. Moreover, increased production of hydrogen peroxide and nitric oxide by macrophages followed by the generation of the nitric oxide reactive intermediate (RNI) peroxynitrites induced by *Bothrops* venoms [83,86] and the ability of the venom of *Daboia russelli*, another viperid snake of medical importance in Asia, to activate the production of ROS in neutrophils were also described [88,89]. It is known that prolonged or excessive release of leukocyte-derived peroxynitrites and ROS could intensify the inflammatory process and enhance venom-induced tissue damage. However, studies attempting to block the damaging effects of either *B. asper* or *Daboia russelli* snake venoms, by using inhibitors of NO production and/or different antioxidant compounds, showed contrasting results [90,91]. Therefore, the role of leukocytes, mainly neutrophils and their microbicide products, in the host defense against envenomation by snakes remains to be better understood. The beneficial role of neutrophils in the host defense against noxious effects of snake venoms was demonstrated by studies showing that experimentally induced neutrophil depletion in mice reduced skeletal muscle regeneration after myonecrosis induced by *B. asper* snake venom and a myotoxic PLA_2 isolated from this venom. The hindering of arrival of these phagocytic cells to the damaged site impaired their functions related to tissue regeneration, such as the late recruitment of macrophages into the damaged areas and the clearance of necrotic debris [92].

The inflammasome is a large multiprotein complex responsible for the activation of caspase-1, leading to secretion of the proinflammatory cytokines IL-1β and IL-18 and to the onset of a proinflammatory cell death termed pyroptosis. Despite the relevance of inflammasome in the development of inflammation, studies on participation of this multiprotein complex in the inflammatory responses to snake venoms are scarce. In this regard, the ability of *Crotalus atrox* snake venom to activate inflammasome was recently demonstrated [93]. This activation was related to a protective host response to envenomation, since caspase-1-deficient mice were more sensitive to venom-induced pathology. Further studies with other venoms are required to assess the role of the inflammasome in inflammation triggered by snake venoms.

The signaling pathways leading to each specific function of the host defense cells are triggered by pattern recognition receptors (PRRs) that recognize either pathogen-associated molecular patterns (PAMPs) or damage-associated molecular patterns (DAMPs) [94,95]. Toll-like receptors (TLRs) are PRRs expressed in a variety of leukocytes that sense diverse exogenous and endogenous stimuli and activate signaling pathways that result in inflammatory events, such as the synthesis of inflammatory mediators, including cytokines and eicosanoids [96–98]. Adapter proteins, such as myeloid differentiation factor 88 (MyD88), mediate TLR-activated intracellular signaling pathways. Although the impacts of TLRs in triggering inflammation are well appreciated, their participation in snake venom-induced inflammation is less known. Participation of TLRs via MyD88 adapter molecule in inflammation induced by *Bothrops* snake venom-induced inflammation was demonstrated in MyD88 knockout mice, which showed impaired inflammatory response to *B. atrox* snake venom, with reduced infiltration of leukocytes into the site of venom injection, and failure to produce Th1 and Th17 cytokines, CCL-2, PGE_2, and LTB_4 [99]. Similarly, galatrox, a C-type lectin isolated from *B. atrox* snake venom, induced the generation of proinflammatory mediators IL-6, TNF-α, and keratinocyte-derived chemokine from bone marrow-derived macrophages, by a mechanism dependent on activation of the TLR4-MyD88 signaling pathway [100]. In addition, the involvement of TLR2 via engagement of MyD88 adapter molecule in the release of inflammatory mediators (PGE_2, IL-1 β, and IL-10) by macrophages in response to MT-III, a PLA_2 isolated from *B. asper* venom, has been demonstrated [101]. Engagement of TLR2 pathway by this PLA_2 was attributed to its ability to release fatty acids, such as the palmitic and oleic acids, which are TLR2 agonists, from macrophage membranes.

5.3 Inflammation Induced by Scorpion Venoms

Scorpions are arthropods belonging to the class Arachnida. These animals are found everywhere in the world, mainly in subtropical and tropical regions. Envenomation by scorpion stings is considered an important public health issue worldwide, affecting mainly children. Venomous scorpions of medical importance belong to Buthidae family and include the genera *Androctonus, Buthus*, *Mesobuthus*, *Buthotus*, *Parabuthus*, and *Leiurus* in North Africa, Asia, and the Middle East. Species of the genus *Centruroides* are found in North America (United States of America and Mexico) and Central America, and the genus *Tityus* is common both in Central America and South America [102,103].

The venom of scorpions consists of a complex mixture of mucopolysaccharides, hyaluronidase, serotonin, histamine, enzyme inhibitors, and a variety of low molecular mass proteins, most of which are neurotoxic, which target primarily ion channels, mainly voltage-gated Na^+, K^+, or Cl^- channels of excitable cells, such as neurons and muscles. The uncontrolled depolarization of postganglionic nerve terminals by scorpion neurotoxins leads to continuous release of neurotransmitters [104,105], which contribute to the onset of various systemic manifestations of scorpion envenomation. Clinical manifestations of this

envenomation include hyperthermia, psychomotor agitation, local pain, and systemic manifestations resulting from cardiovascular, respiratory, gastrointestinal, genitourinary, hematological, and metabolic alterations [106–109]. The scorpion sting also triggers a strong inflammatory systemic response in the victims, characterized by increased levels of circulating inflammatory mediators such as cytokines, eicosanoids, and platelet-activating factor (PAF), nitric oxide (NO), and kinins, as well as leukocytosis, which are involved in the worsening of clinical symptoms after scorpion stings [110]. The occurrence of multiple organ failure has been documented in severe scorpion envenoming, and this condition is usually accompanied by systemic inflammatory response syndrome (SIRS) [102,106,111–113].

In patients with moderate to severe systemic manifestations, leukocytosis and high plasma levels of the inflammatory cytokines IL-6, TNF-α, IL-8, IL1-β, INF-γ, GM-CSF, and RANTES, as well as the anti-inflammatory cytokines IL-10 and IL-4, are observed [113–117]. A positive correlation between increased levels of cytokines and the severity of scorpion envenomation in humans was described [113]. In this context, studies with experimental models of severe scorpion envenomation have demonstrated that multiple organ dysfunction and death were associated with an increased production of inflammatory cytokines [110,118–123]. The role of IL-6 and TNF-α in hyperglycemia and metabolic deregulation described in severe envenomation by scorpion stings was evidenced after injection of *Androctonus australis hector* venom in mice [124]. Injection of scorpion venom *Tityus serrulatus* causes hyperthermia in rats via release of IL-1 with pyrogenic activity [121]. Moreover, increased brain levels of TNF-α were found in mice injected with tityustoxin (TsTX), a neurotoxin isolated from *T. serrulatus* venom, which were correlated with increased rolling and adhesion of leukocyte in the brain microvasculature [122].

Eicosanoids constitute another group of mediators involved in the systemic inflammatory response and to scorpion venom sting. Participation of eicosanoids derived from the cyclooxygenase (COX) pathway in hyperthermia caused by the scorpion *Leiurus quinquestriatus* sting in children has been shown, since treatment of patients with nonsteroidal anti-inflammatory drugs ameliorated the venom-induced effect [125]. In line with this report, experimental studies have demonstrated that prostaglandins released by the scorpion venom also have a role in the cardiorespiratory, edematogenic, and nociceptive effects induced by the injection of this venom in experimental animals [126–129]. Release of PGE_2 and LTB_4 induced by neurotoxins Ts2 and Ts6 isolated from *T. serrulatus* venom, as well as participation of these mediators in the leukocyte infiltration into the site of injection of these toxins, has been described [123]. With regard to the molecular mechanisms underlying the biosynthesis of eicosanoids, the role of peroxisome proliferator-activated receptor gamma (PPAR-γ) was experimentally shown in macrophages stimulated by *T. serrulatus* venom [130].

In addition, experimental studies have shown that the injection of crude venom or toxin of the scorpions *T. serrulatus*, *Centruroides noxius*, and *Androctonus australis hector* in murine models reproduces the severe symptoms associated with local and systemic inflammatory response and prominent inflammatory cell recruitment similarly to those observed in envenomed humans [114,131–136].

Although leukocytes are recognized as a major source of inflammatory mediators, the stimulatory mechanisms of these cells by the scorpion venom are not completely understood. It is currently accepted that neurotoxins present in the scorpion venom can directly stimulate ion channel receptors on the surface of immune cells, such as macrophages and lymphocytes, thus triggering the production of inflammatory mediators [110,137–142].

Acute pulmonary edema is an important systemic manifestation frequently resulting from scorpion sting, with risk of death due to high propensity of cardiorespiratory arrest [107]. The pulmonary edema induced by scorpion venom is attributed both to an excessive stimulation of the adrenergic system, leading to cardiogenic edema, and to the activation of an inflammatory cascade, which leads to noncardiogenic edema. A number of experimental studies have indicated that lung edema evoked by scorpion venom is due, at least in part, to the release of several inflammatory mediators, with vasodilator and increased vascular permeability activities, such as PAF, nitric oxide, kinins, prostaglandins, and leukotrienes [126,129,131,142–153].

Moreover, stimulation of inflammatory cells, such as mast cells, and neuronal fibers by venom neurotoxins, with release of neuropeptides, including substance P, which activates NK1 receptor, facilitates the release of inflammatory mediators [110,137–141] and contributes to the development of pulmonary edema [145,153–155]. The ability of scorpion venoms to induce degranulation of mast cell and release the vasoactive mediator histamine has also been reported [134,156–161]. In line with these experimental findings, the involvement of the kinin system in the induction of clinical effects caused by *T. serrulatus* envenomation in humans, including pulmonary edema, was demonstrated [161]. Besides edema, a conspicuous leukocyte infiltrate was observed in the lungs of experimental animals injected with this venom (see Figure 5.2). This inflammatory event was dependent on the production of PAF and KC, as well as on the activation of CXCR2 on neutrophils [131].

Studies on the recognition of scorpion venoms by the innate immune cells are scarce. It was experimentally shown that Toll-like receptors 2 and 4 (TLR2 and TLR4) are engaged by *T. serrulatus* scorpion venom and its toxin, toxin 1, in macrophages, playing a role in the synthesis of cytokines IL-6 and TNF-α, which occurs via MyD88-dependent NF-κB phosphorylation [162].

5.4 Inflammation Induced by Spider Venoms

Spiders are arthropods belonging to the class Arachnida. These animals are distributed everywhere in the world, except in the Antarctic region. These arthropods live in a wide variety of ecosystems, including aquatic environments. At present, the World Health Organization considers only four major genera of spiders causing severe envenomation in humans, that is, *Loxosceles*, *Phoneutria*, *Latrodectus*, and *Atrax* [163]. In general, bites of these venomous spiders promote local effects such as edema, erythema, and intense pain associated with acute inflammation [163–165]. Some factors may influence the severity of injuries caused by spider venoms, such as the developmental stage of the spider, the

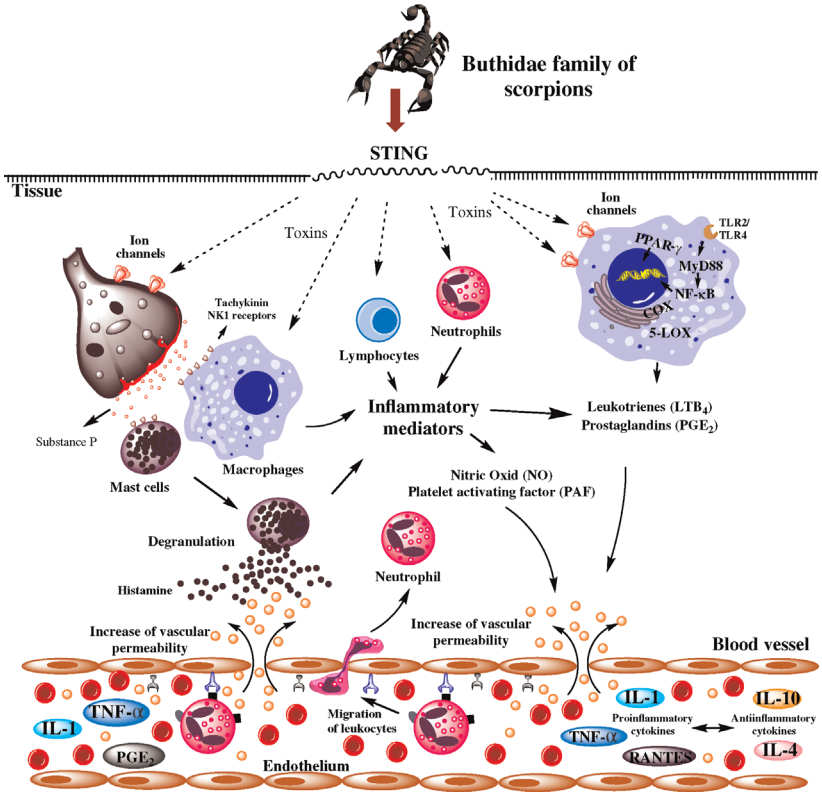

Figure 5.2 Schematic representation of the inflammatory action of scorpion venoms. The local and systemic inflammatory events triggered by venoms of scorpions of the family Buthidae are summarized.

amount and composition of injected venom, and the physiological features of the patient, such as age and physical conditions, among others. In addition, the clinical consequences and the role of inflammatory events are different for each genus of spider of medical importance. Among the medically relevant spiders, the inflammatory effects caused by *Loxosceles* and *Phoneutria* are the most studied and reported in the scientific literature.

Despite being found in four continents, the accidents caused by species of the genus *Loxosceles*, known as brown spiders, are particularly serious in South America [166]. *Loxosceles* ssp. venoms promote classical dermonecrosis at the site of injection, which is a characteristic feature of loxoscelism. This clinical sign is the result of the direct action of venom components, which include proteases, hydrolases, lipases, peptidases, sphingomyelinases, hyaluronidases, metalloproteinases, phospholipases, and collagenases, and is also associated with a prominent inflammatory response in the tissues. Sphingomyelinases are particularly important in the generation of local necrosis. Eventually, in severe cases, systemic symptoms such as intravascular hemolysis and acute kidney injury can lead to death [166–171]. The initial interaction between *Loxosceles* spp. venoms and tissues activates components of the inflammatory process, thus leading to

migration of leukocytes, platelet aggregation, and release of inflammatory mediators, such as lipid mediators, cytokines, chemokines, and growth factors. These elements contribute to pain, disruption of microvasculature integrity, increased vascular permeability, and erythema [166,172]. Following 24 h, the damaged tissue area becomes pale with a white halo, which is caused by ischemia around the affected dermal region. Between 3 and 7 days after *Loxosceles* bites, the lesion may ulcerate and, in some cases, due to failure of healing, surgical removal and grafting in the local damaged skin are necessary [170–173].

Studies have revealed that the intense infiltration of polymorphonuclear leukocytes into the tissue, and the secretion of proteolytic enzymes from the granules of these cells, participate in the pathogenesis of tissue damage caused by *Loxosceles* ssp. envenomation [171]. Some investigations have demonstrated that the upregulation of leukocyte influx induced by *Loxosceles* ssp. spider venoms is a consequence of activation of other cell types, including endothelial cells and fibroblasts. Stimulation of human endothelial cells (HUVEC) in culture with *L. reclusa* and *L. deserta* venoms induces the expression of E-selectin adhesion molecule and the release of leukocyte chemoattractant mediators, such as interleukin-8 (IL-8) and granulocyte colony-stimulating macrophage (GM-CSF), and the monocyte chemoattractant protein-1 (CCL-2) [174,175]. In this context, cultured human fibroblasts stimulated with *L. reclusa* recombinant sphingomyelinase D upregulated gene expression of IL-6, IL-8, CXCL1, CXCL2, and CCL5, which are relevant mediators for chemotaxis of leukocytes. From these observations, it has been postulated that, in addition to activation of endothelial cells of the microvasculature, *Loxosceles* venom acts on fibroblasts present in the dermal region, activating a dysregulated inflammatory leukocyte influx, which in turn contributes to the development of dermonecrosis. The action of *L. gaucho* spider venom on primary cultures of keratinocytes, which are cells that protect skin against external aggressions, was followed by secretion of tumor necrosis factor (TNF-α). The presence of TNF-α, a potent cytotoxic mediator, together with ceramide, which is a lipid generated from the venom sphingomyelinase action on sphingomyelins of endothelial cells, activates mechanisms that culminate in cellular apoptosis or necrosis around the spider bite site [176,177]. The ability of *L. deserta* venom to induce the release of vascular endothelial growth factor (VEGF) from keratinocytes has been demonstrated. Besides inducing angiogenesis, VEGF, by regulating vascular permeability of endothelial cells, can contribute to development of erythema and edema observed after *Loxosceles* ssp. envenomation [178]. Furthermore, the involvement of mast cells and the participation of histamine and serotonin, released from their granules, in the increased vascular permeability and edema induced by *Loxosceles* sp. venom has been demonstrated [179].

Envenomations caused by spiders of the genus *Phoneutria* known as armed-spider, have been described mainly in South America and Costa Rica, in Central America [164]. *P. nigriventer* envenomation causes local symptoms in patients that include intense pain, erythema, and edema. In severe envenomation, systemic effects can be manifested by autonomic effects such as tachycardia, hypertension, diaphoresis, salivation, diarrhea, visual disturbs, tremors, priapism, and lung edema. Occasionally, the evolution of severe cases can lead to death [180,181].

In experimental animals, *P. nigriventer* venom causes paralysis of the upper and lower limbs, convulsion, agitation, neuromuscular blockade, and flaccid paralysis, resulting from the action of neurotoxins present in this venom [182,183]. This spider venom also contains substances that are responsible for edema formation, as demonstrated in rat and rabbit skin [184]. Although the venom contains histamine and serotonin in its composition, these components are not the main culprits of edema formation [184,185]. Edema induced by *P. nigriventer* injection has been related to activation of complex systems linked to the increase in vascular permeability. Early studies demonstrated the participation of bradykinin via B2 receptors in the genesis of edema by this venom [186]. Further studies have evidenced an important role of neurogenic mediators in the inflammatory response to *P. nigriventer* venom. Activation of tachykinin NK1 receptors by vasoactive neuropeptides released from sensory nerve terminals have been shown [187,188]. Moreover, it has been demonstrated that activation of vanilloid receptor and purinergic P2 receptor of ATP and ADP is an important mechanism of the increased vascular permeability induced by *P. nigriventer* venom [189].

Similar pathways, involving activation of peripheral tachykinin NK1 and NK2 receptors in addition to receptors NMDA and AMPA, were described for the nociceptive effect of *P. negriventer* venom [190]. Moreover, 5-HT receptors were demonstrated to be involved in the activation of nociceptive sensory nerve fibers by *P. nigriventer* venom. The exaggerated sense of pain is the most evident manifestation provoked by the venom of this spider. This effect was demonstrated to result from neurotransmitter release in the dorsal horn of the spinal cord, a region of integration of synaptic transfer of sensory inputs from the periphery to the central nervous system. Transmitters such as substance P (SP), neurokinin A, calcitonin gene-related peptide (CGRP), and amine glutamate, contribute to dorsal horn hyperexcitability and pain transmission induced by *P. nigriventer* venom. In addition, nitric oxide (NO) mediates this phenomenon as well as TNF-α, IL-1β, and prostaglandins from the COX-2 pathway. There is evidence that prostaglandins promote an increased release of neurotransmitters in the dorsal horn, including excitatory amino acids, SP, and CGRP. Prostaglandins, in turn, are modulated by glutamate, SP, CGRP, cytokines, and NO, indicating a cooperative link between spinal prostaglandins and neurotransmitters for pain evoked by *P. nigriventer* bite [191]. Interestingly, the neurogenic mechanisms evoked by this spider venom are linked to leukocyte migration, as it has been shown in experimental models that bradykinin is involved in both activation of sensory nerves and leukocyte migration, reinforcing the importance of neurogenic inflammatory mechanisms stimulated by this venom [192].

5.5 Inflammation Induced by Venoms of Bees, Vespids, and Ants

Arthropods from the order Hymenoptera include species of venomous insects capable of promoting accidents in humans. Among them, species of bees and vespids (wasps, yellow jackets, and hornets) belonging to Apidae and Vespidae

families, respectively, are of public health interest. Ants of medical importance, in turn, are included in the Formicidae family [193]. The injuries caused by venomous insects have in common the occurrence of local inflammatory response (erythema, heat, and edema), pain, and hyperalgesia. Rarely, in severe cases, stings may cause more extensive local inflammatory reactions with both erythema and edema signs involving the whole extremity. On the other hand, in some cases, hymenoptera stings can result in the development of an anaphylactic reaction, due to individual hypersensitivity to some components of the venoms, which may be fatal. As local reactions usually disappear within 24 h after being stung, few studies have been conducted to demonstrate the mechanisms governing the inflammatory events promoted by venomous wasps, bees, and ants [194]. Hymenoptera venoms are complex mixtures of pharmacologically active substances that comprise enzymes (phospholipases A_1 and A_2, hyaluronidase), nonenzymatic proteins (antigen 5), peptides (neuropeptides, chemotactic peptides, antimicrobial peptides, apamin, and mast cell degranulating peptides (MCDP), such as melittin and mastoparans), and biogenic amines (histamine, epinephrine, and dopamine) [194–198]. Experimental studies have demonstrated that the components of hymenoptera venoms are responsible for their biological actions, including the inflammatory response, nociception and hyperalgesia. Some of these substances are responsible for massive release of vasoactive amines through degranulation of mast cells. Mast cell degranulating (MCD) peptides such as melittin and mastoparans promote the release of histamine and other vasoactive amines from mast cells. These mediators increase vascular permeability, leading to edema characteristic of the inflammatory response or hypersensitivity reactions caused by these venoms. Honey bee venom contains two polypeptides with MCD activities: (1) melittin, the major component of the venom, and (2) MCDP. Vespid venoms have a type of MCD peptide group named mastoparans, the major components of wasp venom. These peptides exert a detergent action that results in the lysis of cell membranes and the release of biogenic amines from neuronal cells, inflammatory mediators from neutrophils, or vasoactive amines from mast cells [194,199,200]. Beside these peptides, hymenoptera venoms contain pharmacological components, such as histamine, histamine-releasing activity, kinins, and kinin-like components, as described in *Myrmecia genus* ant venom [195,201], in *Apis mellifera* bee venom [202], and in vespid venom [194,203], which may contribute synergistically to local inflammation. The edema induced by venoms of the social wasps *Polybia paulista* and *Polistes lanio lanio* is due to histamine release through a mechanism dependent on the engagement of H1 histamine receptor [204,205]. On the other hand, it has been demonstrated that *P. lanio lanio* wasp venom increases vascular permeability by activating tachykinin NK1 receptors. These receptors may be activated by venom tachykinin-like peptides or by endogenous neuropeptides, such as substance P, released from activation of sensory fibers in response to that venom [205].

It is well known that, besides inflammatory response, melittin also a role in production of pain after bee stings [206]. On the other hand, melittin is not found in wasp venom and the intense pain caused by vespid stings is attributed to

serotonin, kinins, and specific peptides [194,206], as well as to the activation of capsaicin-sensitive afferent fiber and spinal protein kinases pathways [207–211]. Other studies have demonstrated the participation of inflammatory lipid mediators in the genesis of pain induced by melittin. Leukotrienes, lipid mediators derived from lipoxygenases (LOX) pathway, were proved to modulate nociceptive effect induced by injection of melittin and other peptides isolated from social wasp *P. paulista* and *P. sylveirae* venoms in mice [197,203]. This phenomenon was demonstrated to be independent of mediators derived from cyclooxygenases pathway. Further, the involvement of secretory PLA_2 from bee venom in the production of leukotrienes and in hymenoptera venom-induced pain was also demonstrated. Besides mediating the wasp venom nociceptive effects, LTs derived from 5-LOX were proved to mediate polymorphonuclear cell migration into the inflammatory site in tissue injected with *P. paulista* wasp venom [204]. In the case of the jumper ant venom (*Myrmecia pilosula*), there is evidence that, in addition to histamine, eicosanoids are released by factors present in this venom, and potentiate pain and inflammatory response induced by this arthropod sting [212]. In this context, it was shown that a phospholipase-activating protein and melittin from *A. mellifera* bee venom stimulated the release of prostaglandin E_2 (PGE_2) from macrophages [213]. Melittin has been suggested to activate PLA_2. In addition, the ability of mastoparan and PLA_1, from the yellow jacket *Vespula vulgaris* venom, to induce the release of PGE_2 from macrophages in culture was demonstrated [199]. Since PGE_2 is a potent mediator of inflammation and plays an immunomodulatory role, this mediator was associated with the diverse range of biological activities of *V. vulgaris* venom, including enhanced vascular permeability, vasodilation, and nociception [214].

5.6 Conclusions

Inflammation is a general characteristic of envenomation caused by diverse animal species. Complex networks of inflammatory mediators regulating the inflammatory events generated by the actions of animal venoms have been described, but for the majority of venomous animal species the available information is limited or absent; there is, therefore, a need to investigate the inflammatory pathways and mediators involved in the tissue reaction to a variety of animal venoms. Despite the evidence on the ability of some venoms to activate leukocytes, the role of each type of recruited leukocyte in the evolution and resolution of the inflammatory response remains to be clarified. Moreover, the cell receptors sensing venoms that lead to engagement of downstream inflammatory signaling pathways are poorly known, as is the role played by the inflammasome complex in animal venom-induced inflammation. A much better understanding of the mechanisms of inflammatory actions of animal venoms and their toxins, with characterization of the factors and signaling pathways that regulate the inflammatory response to animal venoms could provide important clues to develop novel therapeutic strategies to efficiently treat the dysregulated inflammation commonly resulting from envenomation by many animal species.

6.1 Introduction

Despite the proliferation of therapies to treat the critically ill, administration of oxygen is perhaps the most commonly used and cost-effective modality available. Further, at some level, defective oxygen delivery or utilization underlies most severe threats to the well-being of the organism. Therefore, it is not surprising that cell and oxygen deficit constitutes a threat to normal cellular activity. As such, hypoxia constitutes a "danger signal" that is a potent activator of inflammation. This chapter will review the cellular and molecular mechanisms that detect oxygen availability and how these mechanisms activate inflammation.

Cellular hypoxia can be caused by systemic factors and local factors (Table 6.1). On a systemic level, hypoxia is due to (1) decreased fraction of inspired oxygen (i.e. high altitude), (2) ventilation and perfusion mismatch, (3) right to left intracardiac shunting, (4) low cardiac output, (5) anemia, and (6) derangements in the function of the electron transport chain (ETC) (i.e. cyanide poisoning). Locally, hypoxia is due to changes in the vascularity of a tissue bed and the ability of a particular organ to utilize oxygen appropriately (histotoxic hypoxia). The responses to hypoxia include erythropoiesis, increased cardiac output, increased ventilation, and changes in vascular tone.

At its most basic, oxygen utilization is tied to substrate metabolism (Figure 6.1). Oxygen is used by the mitochondrial enzyme complex cytochrome c oxidase (complex IV of the ETC) as the final electron acceptor in oxidative phosphorylation. Thus, oxygen availability is essential to drive the production of ATP and to reestablish, by reduction, sufficient stores of NAD and FAD to support postglycolytic carbohydrate metabolism – the tricarboxylic acid cycle – and utilization of fatty acids.

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

Table 6.1 Causes of hypoxia.

Extracellular	Pericellular	Intracellular
Ambient atmosphere	Blood flow	Mitochondrial defect
Pulmonary function	Microcirculation	Exogenous inhibitors (poisons)
Cardiac shunting	Acid-base abnormalities	Electron transport chain defects
Hemoglobinopathy	Extracellular fluid accumulation	
Circulatory failure		

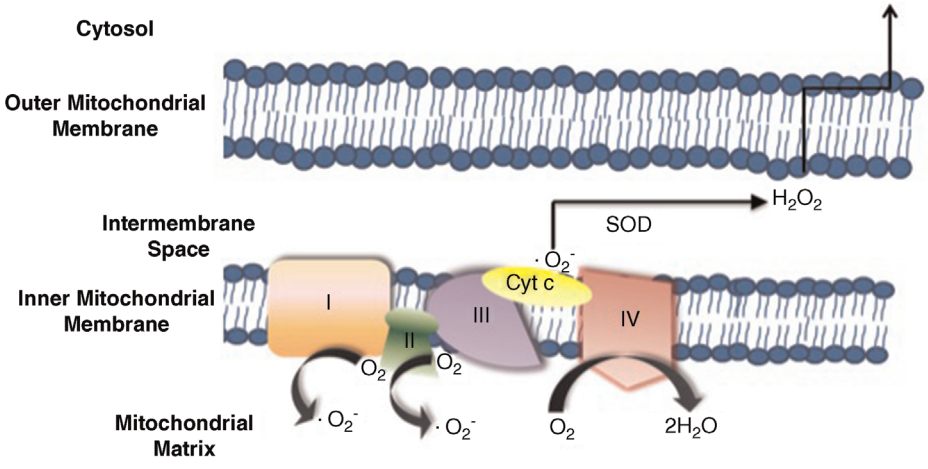

Figure 6.1 Formation of reactive oxygen species by the electron transport chain. Superoxide is formed by mitochondrial complexes I–III of the ETC. At complexes I and II, superoxide (O_2^-) tends to accumulate in the mitochondrial matrix. However, at complex III, O_2^- preferentially diffuses toward the intermembrane space. Superoxide dismutase converts superoxide into hydrogen peroxide (H_2O_2) that diffuses into the cytosol and acts as a trigger for oxygen sensing.

Inadequate oxygen availability/utilization impairs the ETC. Energy production thus comes to rely on glycolysis and not oxidative phosphorylation.

The precise mechanisms by which a transition from oxidative to glycolytic metabolism occurs have been extensively studied over the past 50 years. The link to inflammation has emerged more recently. In this chapter, we will examine oxygen sensing and the molecular response to hypoxia and discuss how hypoxia activates the inflammatory response.

6.2 Oxygen Sensing

It was initially believed that oxygen sensing involved only chemoreceptors in the carotid and neuroepithelial bodies. Hypoxia stimulates these cells to release neurotransmitters that induce cardiovascular and respiratory changes directed

toward restoring oxygen content to steady state levels [1]. However, what constitutes hypoxia varies from tissue to tissue and organ to organ. For example, cells in the lung are most often exposed to oxygen tensions in the 100 mm Hg range. In contrast, renal cortical cells see PO_2 levels around 60 mm Hg, while PO_2 in skeletal and cardiac muscle is much lower at rest and decreases to 10 mm Hg during exertion [2]. A system that regulates oxygen tension in one location only would not be capable of responding to the differing needs of different tissues, let alone cells. As noted by Schumacker, it appears that individual cells have the ability to modulate the PO_2 level at which mechanisms to increase oxygen availability are activated [3]. Researchers have, therefore, sought to identify cellular or subcellular processes that sense perturbations in local oxygen concentration and activate signaling pathways that can restore oxygen tension to a steady state. Most appear to originate in mitochondria.

6.3 Mitochondrial Oxygen Sensing

As oxygen is inhaled, it travels from large airways to smaller airways and ultimately to the millions of alveoli in the lung. It then diffuses from the alveoli into the adjacent capillaries from which it is carried to tissues throughout the body. Via specialized membrane oxygen channels, oxygen diffuses into cells and migrates toward the mitochondria. This process is facilitated by a pressure gradient; the partial pressure of oxygen at the large airways is 150 mmHg and at the mitochondria is 5 mmHg [4]. In addition, oxygen is a highly lipophilic molecule, allowing it to pass through cell membranes. Once inside the mitochondrion, O_2 binds to cytochrome oxidase (complex IV of the ETC) and is reduced to form water [5]. When oxygen tension is adequate this process nets 38 ATP molecules from one molecule of glucose.

Cytochrome oxidase had been touted as the "molecular sensor" signaling hypoxia [6]. However, this enzyme has a very high affinity for oxygen ($K_m < 1\,\mu M$), allowing cellular respiration/oxygen consumption to function at basal rates until the PO_2 falls below 5–7 mmHg [7]. The rate of O_2 consumption by a cell does not fall until a threshold is reached (~1% O_2). The reason that O_2 consumption is maintained is because the redox status in the complexes of the ETC remains constant over a wide range of O_2 concentrations. Even when oxygen tensions are low, cytochrome c, the electron donor for cytochrome oxidase, can be fully reduced right up until the point where the critical threshold – 1% O_2 – is reached. Thus, cytochrome oxidase will continue to consume oxygen at a normal rate even at oxygen tension levels that constitute hypoxia. Oxygen acts to limit the function of cytochrome oxidase only when hypoxia is extreme – where cellular survival is in question [3]. Thus, an alternate mechanism for sensing hypoxia must be operative.

ETC activity, with the transfer of electrons, in the presence of oxygen, can generate the free radical superoxide (O_3^-). Superoxide produced at complex I, complex II, and the ubisemiquinone site of complex III (Figure 6.1) crosses the inner mitochondrial membrane where it can be converted into hydrogen peroxide (H_2O_2) that then exits the mitochondrion [8]. During periods of normal oxygen tension, superoxide formation, and thus H_2O_2 generation, is limited by the immense capacity of cytochrome oxidase to use the majority of mitochondrial oxygen. However, when

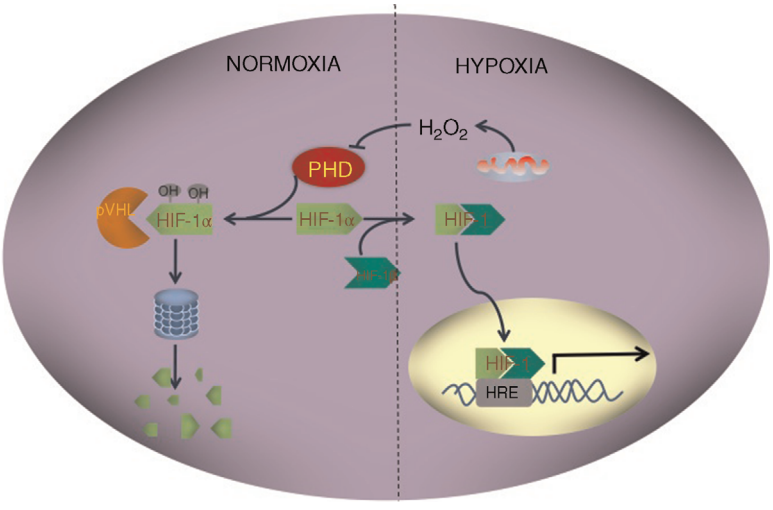

Figure 6.2 Influence of PHD on HIF. Under normoxic conditions, Prolyl hydroxylase dehydrogenase hydroxylates HIF-1α creating a binding site for the Von Hippel–Lindau protein (pVHL). This causes HIF-1α to be degraded by the proteasome. During hypoxia, PHD is inhibited by ROS. This allows HIF-1α and HIF-1β to dimerize, relocate to the nucleus, and lead to the transcription of various genes by binding with the hypoxia response element.

oxygen tensions fall, the ability of cytochrome c oxidase to transfer all the electrons generated by electron transport may become limited. As a result, there is an increase in the transfer of superoxide and other reactive oxygen species (ROS) produced by complexes I–III across the inner mitochondrial membrane onto the matrix, across the outer membrane, and into the cytoplasm. Under normal circumstances, mitochondrial mechanisms (such as mitochondrial superoxide dismutase, mtSOD) can eliminate ROS. However, hypoxia may change this effect [9,10].

ROS are produced during hypoxia and hyperoxia. Studies looking at oxygen tension within the mitochondria demonstrated that, under mildly hypoxic conditions, oxidation in the cytosol and intermembrane space of the mitochondria *increased*, whereas oxidation in the matrix of the mitochondria *decreased*, perhaps reflecting saturation of mtSOD. This effect leads to the development of an ROS gradient between the cytosol and matrix that may drive ROS migration through the intermembrane space and into the cystosol [5]. When coupled with the increase in free electrons in the intermembrane space that occurs as the ability of complex IV to accept electrons is exceeded, free radical transfer into the cytosol can increase substantially in response to relatively small changes in oxygen tension. These free radicals are now believed to activate inflammatory processes, including those that reverse hypoxia [8].

6.4 The Role of Transcription Factors

Cytosolic free radicals alter cellular response via two primary mechanisms. The first involves release of intracellular calcium and the opening of cell membrane

Table 6.2 Transcription factors involved in oxygen sensing.

Hypoxia-inducible Factor
Nuclear factor κ-B
Cyclic AMP response element-binding protein
Activating protein-1

Growth arrest and DNA damage-153

calcium channels [6]. The second is the activation of transcription. The myriad transcription factors that have been identified as potential mediators of cellular responses to hypoxia are listed in Table 6.2 [11]. For some of these factors, the pathways involved in oxygen sensing have been intensely studied. Others have been less well investigated.

6.4.1 Hypoxia-Inducible Factor

Hypoxia-inducible factor (HIF) is perhaps the best-studied transcription factor involved in oxygen sensing. The designation *HIF*, in fact, represents a group of molecules that fall into three classes: HIF-1, HIF-2, and HIF-3. HIF-1 is a heterodimer consisting of HIF-1α, a basic helix–loop–helix protein, and HIF-1β, an aryl hydrocarbon receptor nuclear translocator (ARNT) [12]. HIF-1α and HIF-1β have been identified in almost all cells of the human body. HIF-2α and HIF-3α are structurally similar to the HIF-1 subunits but are not as ubiquitous [13,14].

Active HIF-1 can alter the expression of hundreds of genes (Table 6.3) [14]. However, only the HIF-1α/HIF-1β dimer has transcriptional activity. Thus, elimination of one of the two subunits inactivates HIF-1. Studies performed a number of years ago demonstrated that the abundance of the HIF-1α/HIF-1β dimer increases as the FiO_2 decreases and that this effect is reversed when ambient oxygen tension is restored [15]. Additional reports have identified an enhanced, but still incomplete, picture of the mechanism modulating these changes. These findings implicate elimination of the HIF-1α subunit as the key step leading to inactivation of the transcriptional activity of HIF-1. Thus, normoxia stimulates the ubiquitination and proteasomal degradation of HIF-1α. However, under hypoxic conditions, the dimer remains intact and transcription is accelerated [15,16].

Table 6.3 HIF-1 Target genes.

Adenylate kinase 3	α_{1B}-Adrenergic receptor
Adrenomedullin	Aldolase A
Aldolase C	Endothelin-1
Enolase 1	Erythropoietin
Glucose transporter 1	Glucose transporter 3
Glyceraldehyde phosphate dehydrogenase	Heme oxygenase-1
Hexokinase 1	Hexokinase 2
Insulin-like growth factor (IGF)II	IGF binding protein 1
IGF binding protein 3	Lactate dehydrogenase A
Nitric oxide synthase 2	P21
P53	Phosphofructokinase L
Phosphoglycerate kinase 1	Pyruvate kinase M
Transferrin	Transferrin receptor
Vascular endothelial growth factor (VEGF)	VEGF receptor FLT-1

HIF-1α is targeted for ubiquitination and degradation when specific amino acids are hydroxylated, acetylated, or phosphorylated. Hydroxylation involves one of the two enzymes: prolyl hydroxylase dehydrogenase (PHD) and factor-inhibiting HIF (FIH). PHD acts by removing prolyl residues on the α subunit of HIF-1, creating a binding site for the von Hippel–Lindau protein (VHLP) (Figure 6.2). VHLP is a component of the E3 ubiquitin ligase that ultimately causes degradation of HIF-1 [17,18]. The absence of the VHLP tumor suppressor gene is associated with elevated levels of the HIF-1α/HIF-1β dimer in cultured renal carcinoma cells [19]. There are three PHD enzymes: PHD1, PHD2, and PHD3. Of these, PHD2 is predominantly involved in the oxygen-dependent regulation of HIF [20].

FIH hydroxylates asparagyl residues in HIF-1α, decreasing the interaction between the HIF-1 complex and the several essential coactivators. As with PHD, FIH is fully active in normoxic states, but its activity decreases with decreasing oxygen tension. The resultant increase in the interaction of HIF-1 with its cofactors ultimately leads to the transcription of target genes [21].

HIF-1 acetylation at lysine residues is mediated by the enzyme acetyltransferase arrest-defective-1 (ARD1). As with PHD and FIH, ARD-1 provides a site for interaction with VHLP. In contrast to the actions of PHD and FIH, ARD1 activity is not directly affected by changes in oxygen concentration; acetylation may occur even under normoxic conditions. However, the transcription and translation of ARD1 are decreased during hypoxia, providing another mechanism by which the HIF-1α/HIF-1β dimer can be preserved when oxygen availability is low [22].

HIF-1α phosphorylation is mediated by members of the mitogen-activated protein kinase (MAPK) family and involves phosphate binding to both HIF-1α and HIF-2α, increasing transcriptional activity on target genes [23].

PHD activity is oxygen dependent. However, the K_m for oxygen of PHD is higher than that of complex IV. Thus, under hypoxic conditions complex IV will

preferentially consume oxygen, reducing PHD activity and HIF-1α degradation, thus stabilizing the HIF-1α/HIF-1β dimer and enhancing transcription [4]. A number of theories to explain how the activity of PHD, FIH, and ARD-1 are modified by changes in oxygen tension have been proposed. Sabharwal *et al.* demonstrated that mitochondrial scavenging of hydrogen peroxide by peroxiredoxin-5 decreased HIF-1α stabilization in association with a change in PHD activity [24]. It has been suggested that PHD itself senses changes in oxygen tension. Others postulate that PHD is subject to post-translational modification by ROS [25]. An additional hypothesis posits that the activity of PHD is reduced when ROS oxidize cysteine residues on the enzymes [26]. Similar pathways have been proposed to explain the O_2 dependence of FIH, ARD1, and MAPK [17].

6.4.2 Nuclear Factor κB

In addition to effects on HIF-1, PHD also plays a role in the regulation of the nuclear factor kappa B (NF-κB) family of transcription factors. Like HIF-1, NF-κB subspecies (p65, cRel, RelB, p50, p52, etc.) function as homo- and heterodimers whose activity has been linked to inflammation, infection, and cancer. NF-κB species are maintained in an inactive state in the cytoplasm via a complex with IκBα. Phosphorylation by the IκB kinase (IKK) complex targets IκB for ubiquitination and degradation. The released NFκB is free to translocate to the nucleus and stimulate transcription of genes encoding a variety of proinflammatory, anti-inflammatory, apoptotic, and cell cycle enzymes [11,27]. Chandel *et al.* showed that ROS act as a stimulus for the release of NFκB from IκB [28]. NF-κB signals the upregulation of HIF-1α mRNA under both hypoxic and nonhypoxic conditions [29]. Further, the gene for HIF-1α contains an active NF-κB binding site [30,31] and the IKK complex stimulates increased transcriptional activity of HIF-2α [31].

6.5 The Warburg Effect

When oxygen availability decreases, either as a result of global or local tissue hypoxia, ATP production by mitochondria may be impaired. This situation is not uncommon in tumors where rapid growth may exceed oxygen delivery, producing local hypoxia. In 1927, Otto Warburg and colleagues described a phenomenon in tumor cells in which lactate production increased as a result of an enhanced reliance on glycolysis over oxidative phosphorylation [32]. It has been shown that HIF-1 is one of the main regulators of this process, now known as the Warburg effect. The shift from oxidative to glycolytic metabolism preserves ATP production despite hypoxic conditions. While glycolysis produces ATP in a manner that is less efficient than oxidative phosphorylation, an HIF-1-mediated upregulation of glycolytic enzymes via enhanced gene transcription results in an increased rate of glycolysis so that cellular energy provision remains sufficient [33].

Is the Warburg effect a global response to hypoxic conditions or something that is unique to neoplasia? To address this question Cramer *et al.* studied macrophages that were isolated from mice and exposed to a hypoxic environment. These studies

demonstrated that lactate levels were decreased in mice with a knockout of the gene encoding HIF-1α. ATP production in these animals was approximately 15–20% of that found in wild-type mice [34]. These data suggest that HIF-1 has a strong regulatory role over the glycolytic pathway. This conclusion is consistent with the known ability of HIF-1 to enhance the transcription of a number of genes encoding the glycolytic enzymes (Table 6.3) [35]. In addition, the promoters of these genes contain potential HIF-1 binding sites. Further clarification was provided by Zhang *et al*., who exposed both wild-type mouse embryonic fibroblasts and cells with a knockout of the gene encoding HIF-1α to either 1 or 20% oxygen. These studies demonstrated that, even under 1% oxygen, ATP production was preserved in knockout cells, a finding suggesting that the shift from oxidative phosphorylation to glycolysis reflects an HIF-1-mediated response to oxygen content [36]. Further investigations revised our understanding of metabolomics. While hypoxia seems to drive changes in energy production and utilization, these changes appear to reflect the generation of ROS during states of hypoxia. Hypoxia increases ETC production of ROS, which in turn can be toxic to cells and even trigger mitochondrial autophagy. When oxygen concentrations are low, HIF- 1 mediates a metabolic switch to glycolysis, limiting ROS production [37].

6.6 Acute versus Chronic Hypoxia

Different disease states result in varying degrees of hypoxia. For example, an episode of choking may result in hypoxia lasting less than a minute; patients with obstructive sleep apnea (OSA) may have numerous periods of hypoxia, each lasting only a few seconds; those with severe acute respiratory failure may have prolonged hypoxia lasting hours or even days. Although we have thus far described the importance of HIF-1 and NFκB as substantial mediators of gene transcription during hypoxia, studies have shown that they are of lesser importance when hypoxia is not sustained.

Wang *et al*. compared HIF-1 RNA expression in hepatoblastoma cells exposed to 20 or 1% oxygen. Hypoxia was associated with increased levels of HIF-1. Peak expression occurred at 1–2 h with a secondary increase at 16 h. If normoxia was restored, HIF-1 levels returned to baseline within 5 min [12]. These findings suggest that acute, nonrecurrent hypoxia does not result in long-term changes in HIF-1-mediated gene transcription.

To further characterize the activity of the HIF family of transcription factors during intermittent hypoxia, Yuan *et al*. studied rat pheochromocytoma (PC-12) cells. These experiments revealed that intermittent hypoxia increased expression of both HIF-1 and HIF-2α. In addition, lengthening the duration of the hypoxic episode proportionally increased HIF-1 transcriptional activity. During sustained hypoxia, MAPK and phosphoinositol-3 (PI-3) transactivated the activity of the HIF-1 complex. Inhibitors of these enzymes attenuated this response. However, these findings were not replicated during intermittent hypoxia, where gene activation via the HRE continued unfettered [38]. Gene profiling experiments identified two clusters of genes that were activated by intermittent, but not sustained, hypoxia: one was downregulated, the other upregulated [39]. Taken

together, these findings suggest that intermittent and sustained hypoxia both increase HIF-1 activity, but these effects may be mediated via different pathways.

Studies by Ryan *et al*. focused on intermittent hypoxia secondary to OSA. HeLa cells subjected to increasing cycles of hypoxia/reoxygenation were compared to cells cultured in sustained hypoxia. Activation of NFκB, but not HIF-1, was predominantly increased during intermittent hypoxia. Conversely, sustained hypoxia more profoundly increased HIF-1 relative to NFκB [40]. Thus, differences in the activation of the NFκB and HIF-1 pathways may be responsible for the differing responses to intermittent and sustained hypoxia.

6.7 Inflammasome Activation

Mitochondrial and cytoplasmic activities initiated by hypoxia participate in the modulation of inflammation. Most often, hypoxia or other detrimental stimuli stimulate pathways that do not require activation of extracellular mechanisms or the recruitment of others cells, such as those of the immune system. Free radicals are scavenged by endogenous, systems, most notably superoxide dismutase (SOD) molecules in the cytoplasm or mtSOD found in the mitochondrial matrix. In addition, dysfunctional cell components or proteins can be sequestered in the endoplasmic reticulum. In some cases, molecular chaperones such as heat shock proteins (HSPs) facilitate repair. At other times, cellular debris can be confined to *autosomes*, discrete membrane–enclosed "bubbles" that can fuse with similar structures containing digestive enzymes and free radicals – lysosomes – to form an *autophagosome*. Among these contents are senescent or dysfunctional mitochondria [41]. The process by which these contents are deconstructed is *autophagy*. Complete autophagy results in fragments that can be released into the cell and reused or the autophagosome can undergo exocytosis, releasing its contents into the extracellular matrix. Noxious stimuli can increase the generation of ROS and enhance autophagy [41–43]. At times, however, these events can produce ROS and cellular debris in quantities that overwhelm the capacity of the SOD and autophagy systems. In such instances, ROS can accumulate in the cytoplasm, and autosomal contents, including free radicals, may enter into the same space prior to full autophagy (see Figure 6.3). Cellular breakdown products of this type constitute danger-associated molecular patterns (DAMPs) that activate the *inflammasome*. In addition, incomplete autophagy followed by exocytosis of DAMPs into the extracellular space can activate additional components of the inflammatory pathway.

The inflammasome is a primary component of a complex signaling cascade that is activated by intra- or extracellular DAMPs such as molecules that are usually structurally isolated from the cytoplasm (e.g., DNA, RNA, transcription factors, ATP, free radicals, etc.) or microbe/pathogen-associated molecular patterns (MAMPs/PAMPs) such as bacteria or microbial toxins (e.g., LPS). Ultimately, this process activates intracellular defense mechanisms, innate immunity, and inflammation. The inflammasome is the intracellular component of the response system. Its assembly is initiated by ligand binding to a pattern recognition receptor of the NOD-like receptor (NLR), RIG-like receptor (RLR), or Absent

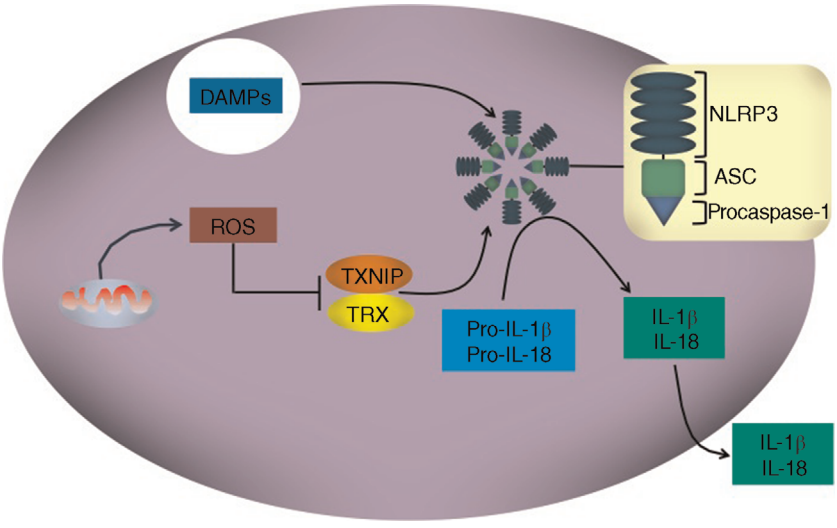

Figure 6.3 Inflammasome activation. The inflammasome is formed when stimulated by intracellular elements containing DAMPs and ROS. Activation of the inflammasome converts procaspase -1 to caspase-1 and then cleaves pro-IL-1b and Pro-IL-18 to their active form for secretion.

in Melanoma-2 (AIM2) types. Upon activation, NLR proteins (NLRPs), RLRPs, or AIM2Ps recruit and assemble a complex that includes an apoptosis-associated speck-like protein (ASC) and procaspase-1. Formation of the complex activates the caspase that, in turn, cleaves pro-IL-1 and pro-IL-18. These cytokines are, in turn, released into the extracellular space and, by interacting with Toll-like receptors (TLRs) on the cell surface, activate additional production of IL-1 and IL-18, as well as other cytokines such as TNFα and IL-6 [41,44–47]. In addition, by a poorly understood mechanism, inflammasomes also initiate a process of cell destruction called *pyroptosis*, in which cells are destroyed by an intense inflammatory reaction [48]. Pyroptosis is characterized by cellular plasma membrane rupture, edema, and ultimately cell lysis accompanied by the release of intracellular components that function as extracellular DAMPs [47].

As discussed above, cellular debris, such as the products of incomplete autophagy that leak into the cytoplasm, activate the inflammasome. In addition, a number of studies indicate that inflammasome activation can be initiated by ROS accumulation in the cytoplasm [47,49]. Zhou *et al*. used inhibitors of ETC complexes I and II in human macrophages to compare wild-type cells and NLRP3 knockout cells. These studies demonstrated that the ROS production induced by ETC inhibition correlated with an enhanced cytoplasmic presence of NLRP3 and increased levels of IL-1β [46]. Bauernfeind *et al.* found that inhibitors of ROS production prevented the activation of NLRP3 [50].

The activation of NLRP3 by ROS is incompletely understood. One proposal involves the action of thioredoxin (TRX), an antioxidant [51]. When in a reduced state, TRX is held inactive by binding to TRX interacting protein (TXNIP) [52]. When electron donation from ROS oxidizes TRX, TXNIP is released, and its binding to NLRP3 activates the inflammasome [53].

6.8 Summary and Conclusions

Based on the material presented, it is possible to construct a model that explains how hypoxia activates inflammation. Decreased O_2 availability limits the transfer of electrons from complex III to IV. These electrons generate ROS that accumulate in the mitochondrial matrix. When the ability of mtSOD to reduce ROS is exceeded, they are transported to the cytoplasm. In the cytoplasm, ROS activate a number of pathways that result in the nuclear translocation of transcription factors, the best studied of which are NF-κB and HIF-1. These in turn stimulate the expression of genes that encode proteins involved in oxygen transport and utilization, as well as those encoding the proteins of the glycolytic pathway. However, ongoing production of free radicals may overwhelm this system as well. Resultant damage to mitochondria can activate autophagy, deconstructing the damaged mitochondria for recycling. Once again, this mechanism may be insufficient. The result will be accumulation of ROS and DAMPs in the cytoplasm. This leads to activation of the inflammasome and ultimately secretion of IL-1 and IL-18. These cytokines stimulate TLRs and, therefore, innate immunity.

Identifying appropriate therapeutic targets is problematic. Our proposed paradigm postulates that initial responses to hypoxia are adaptive, increasing oxygen carrying capacity and redirecting metabolism, via a Warburg-like effect, favoring glycolysis over oxidative phosphorylation. Even stimulation of the inflammasome and, via extracellular mechanisms and TLR on the cell surface, inflammation, results in activation of innate and adaptive immunity. However, activation of the inflammasome can result in pyroptosis and excessive immune activity can be damaging. The only conclusion possible is that additional information about the factors that initiate pyroptosis and the point at which immune activation becomes maladaptive is needed before targeting of the cellular response to hypoxia can be considered as a therapeutic option.

7.1 Introduction

Vaccines represent one of the greatest successes of modern medicine. Widespread vaccination has dramatically reduced the frequency of infectious diseases among both the susceptible individuals and the general population [1]. In addition to preventing innumerable childhood illnesses, vaccination has led to the eradication of smallpox and freed most of the world from polio. Since not all individuals can be vaccinated and vaccination is not 100% effective, breakthrough infections can and do occur. To prevent such illnesses from spreading, public health officials recognized the importance of establishing "herd immunity." This is achieved by vaccinating such a large fraction of the population that an infected individual is unlikely to come into contact with another susceptible target who could spread the disease further. Herd immunity requires widespread prophylactic vaccination of otherwise healthy individuals (frequently children), a strategy that demands vaccines be extremely safe and well tolerated [1].

Early vaccines were produced from attenuated or heat-killed pathogens. Those preparations primarily induced Th1 biased immune responses that culminated in the production of protective neutralizing Abs. We now know that those early vaccines contained not only pathogen-derived antigenic determinants against which the host developed immunity but also immunostimulatory ligands derived from the pathogen that bolstered the induction of vaccine-specific responses (e.g., endogenous adjuvants) [2]. Today, separately prepared adjuvants are added to vaccines to enhance their immunogenicity. Newer vaccines typically combine purified pathogen-derived Ag with a purified adjuvant designed to boost the immune system. Such formulations have superior safety profiles and can be manufactured with unparalleled consistency [3]. The ability of an adjuvant to enhance vaccine immunogenicity may take a variety of forms, from altering the nature of the response (Th1 versus Th2 versus Th17, cellular versus humoral) to increasing its magnitude and/or

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

duration. Adjuvants have two general mechanisms of action. The first involves improving the delivery of the vaccine so as to enhance the uptake, persistence, and/or processing of Ag by professional antigen-presenting cells (APCs) [4–6]. Examples of adjuvants in this category include alum, emulsions, calcium phosphate, liposomes, and "immune stimulating complexes" (ISCOMs). The second category involves agents that directly stimulate immune cells (including elements of the innate and/or adaptive immune systems) to boost their response to the vaccine Ag. Included in this category are the ligands of innate immune receptors such as TLRs, NOD-like receptors (NLRs), C-type lectins, RIG-I-like receptors and cytokines.

Despite the success of licensed vaccines, historically effective strategies have been unsuccessful in confronting the challenges posed by cancer, allergy, and chronic infections such as malaria, TB, and HIV. It is widely believed that vanquishing those diseases will require an enhanced Th1 (or mixed Th1/Th2) response capable of generating large numbers of cytotoxic T cells (CTL). Adjuvants that trigger the innate immune system are of particular interest in this regard as they excel at inducing Th1 biased immunity. This review will provide a general overview of adjuvants in widespread clinical use. It will then describe those in advanced clinical testing, focusing on the development of TLR agonists as vaccine adjuvants.

7.2 Adjuvants Approved for Human Use

Vaccines and the adjuvants they contain have been in widespread use for many decades. Despite this long history and considerable research effort, few adjuvants have been approved for use in humans. These include aluminum-based compounds and monophosphoryl lipid A (MPLA) (licensed for use in the United States and Europe), calcium phosphate, and oil-in-water emulsions (including MF-59, AS03, and AF03) the latter two having been licensed in Europe. Adjuvants currently undergoing clinical testing include a number of TLR ligands, a limited number of cytokines, saponin and its derivative QS-21, ISCOMATRIX, Montanide ISA, and the biopolymer Advax.

7.3 Aluminum Compounds: The Gold Standard

Aluminum compounds including aluminum hydroxide and aluminum phosphate (referred to collectively as alum) are the oldest and most widely used exogenous adjuvants incorporated into human vaccines. Alum is included in vaccines targeting hepatitis A virus (HAV), hepatitis B virus (HBV), diphtheria-tetanus-pertussis (DTP), haemophilus influenza type b (Hib), human papillomavirus (HPV), and pneumococcus. A long history of safety and efficacy combined with low cost make alum the "gold standard" to which other adjuvants are compared [7].

Alum elicits a strong humoral immune response biased toward the production of the Th2-associated IgG1 subclass of Abs [8,9]. This makes alum particularly suitable for use in vaccines that confer protection by stimulating

the production of neutralizing Abs. Conversely, the induction of cellular immune responses by alum is relatively weak, rendering it ineffective for vaccines targeting cancer and chronic infectious diseases [8,9]. Alum does not directly activate cellular elements of the innate immune system, reducing its utility for vaccines composed of poorly immunogenic Ags such as small peptides or recombinant proteins. To compensate for this deficiency, alum can be administered in combination with TLR ligands (reviewed below) to improve the induction of protective immune responses.

Alum's mechanism of action is widely believed to involve acting like a matrix onto which Ag can be adsorbed and stabilized. The slow release of Ag from alum at the inoculation site was postulated to support the induction of a longer lasting immune response. A recent series of studies dispute this interpretation, instead suggesting that alum deposition is not required for adjuvant activity since subsequent removal of the alum did not reduce the induced immune response [10]. Rather, it is proposed that alum stimulates the innate immune system via the inflammasome pathway by interacting with NLRP3, triggering a signaling cascade that proceeds through the recruitment of ASC and caspase-1 to induce inflammasome assembly [11]. The subsequent activation of caspase-1 allows processing of pro-IL-1ß and pro-IL-18 into their active forms. Consistent with such a mechanism, alum-induced innate and adaptive immune responses including alum-dependent Ag-specific IgG1 Ab production were abrogated in NLRP3 and ASC knockout (KO) mice. Unfortunately, other groups have been unable to reproduce these findings such that the overall mechanism(s) of action of alum adjuvants remains uncertain [12].

7.4 AS04

AS04 is a combination adjuvant composed of monophosphoryl lipid A (MPL) and alum. MPL is an immunostimulatory agent that mimics the ability of LPS to trigger cells via TLR4 but with considerably lower toxicity. The activity of MPL is discussed in a subsequent section focusing on TLR4 agonists. AS04 is part of the GSK vaccine against hepatitis B (Fendrix) and is approved in Europe for use in high-risk patients. This adjuvant is also used in GSK's licensed HPV vaccine (Cervarix). In terms of mechanism, the alum component of AS04 is believed to prolong the cytokine responses induced by MPL at the injection site [13,14].

7.5 Calcium Phosphate

Calcium phosphate is being evaluated as an adjuvant for human vaccines against polio, TB, yellow fever, measles, HepB, and in combination with the DTP vaccine in Europe [15,16]. Its mechanism of action is believed to be similar to alum, creating a depot of Ag in particulate form that facilitates and prolongs the uptake of Ag by APCs. When compared to alum, calcium phosphate generally elicits a more potent IgG response but virtually no IgE response in humans [17]. These are important advantages for vaccines that provide protection based on humoral

immunity and for which it is important to avoid an allergic response. As calcium phosphate is a natural constituent for human body, this adjuvant is well tolerated and readily absorbed.

7.6 Emulsions

7.6.1 IFA and CFA

Incomplete Freund's adjuvant (IFA) is the classic example of a water-in-oil emulsion. It is prepared by mixing a water-based solution containing Ag with paraffin oil and mannide monooleate. Extensive animal studies show that IFA induces a predominantly Th2 biased immune response. Although its precise mechanism of action is unknown, IFA creates a depot at the injection site from which Ag is slowly released. This serves to attract and trigger APCs that support the stimulation of Ab secreting plasma cells.

Early clinical trials of IFA involving an influenza vaccine showed that superior protection was achieved due to a higher and more sustained antibody response compared to alum [18–20]. The same improved immune response was observed when IFA was added to a tetanus toxoid vaccine [21]. However, in the latter studies severe side-effects were observed including local swelling, granulomas, and abscesses [21]. Induration was also observed when IFA was used to adjuvant a whole-cell Vibrio cholerae vaccine [22]. Histopathological examination of tissue from the site of these reactions showed that they were caused by a combination of foreign-body reactions and local hypersensitivity. Further development of IFA for clinical use was halted due to the development of granulomas and sterile abscess at the site of injection combined with autoimmune reactions in a small subset of volunteers [23].

Complete Freund's adjuvant (CFA) is made by adding heat-killed *Mycobacterium tuberculosis* to IFA. The mycobacterium expresses ligands for TLRs 2, 4, and 9 and its effect can be replicated by adding these TLR ligands to IFA. The inclusion of mycobacteria boosts activation of the innate immune system, thereby enhancing the development of adaptive immune responses. CFA is highly immunogenic, excels at inducing Th1-dominated immunity, and has been used to elicit strong Ab responses in animals. Unfortunately, the high degree of reactogenicity triggered by CFA makes it unacceptable as an adjuvant in humans. Indeed, even its use in animals has been highly restricted. Side effects include severe pain, swelling, skin ulceration, and necrosis at the injection site [24].

7.6.2 MF59

Extensive efforts to identify safer oil-based emulsions found that the short hydrocarbons present in some oils caused toxicity by disrupting the lipid membrane of tissues at the injection site. Less reactogenic emulsions that were more suitable for human use were subsequently developed. These include mineral oil and the squalene-based adjuvants MF59, AF03, and AS03. All are potent stimulators of both cellular (Th1) and humoral (Th2) immune responses.

Clinical studies showed that MF59 significantly enhanced the potency of an influenza vaccine in young children and the elderly when compared to alum [25–27]. The inclusion of MF59 also led to a broader immune response that protected against heterovariant strains of influenza. Of equal importance, the safety and tolerability profiles of the MF59 adjuvanted flu vaccine were excellent [25–27]. MF59 became the first oil-in-water emulsion licensed for use in Europe, initially as an adjuvant for seasonal flu vaccine and later for pandemic flu vaccines.

MF59 was a more potent adjuvant than alum for the induction of both Ab and CD4 T cell responses [28,29]. MF59, unlike IFA oil-in-water emulsions, did not form a long-lived depot at the injection site [30]. Rather the Ag and emulsion were cleared rapidly but with different kinetics. This might explain the lower toxicity of MF59 when compared to IFA emulsions. MF59 operates through multiple mechanisms, including the induction of a prostimulatory environment at the injection site. MF59 attracts dendritic cells and macrophages to the site of vaccination, thereby facilitating Ag uptake that further supports immune cell recruitment [31,32].

The possibility that oil-in-water emulsions might be combined with other immunostimulatory agents, such as TLR ligands, was investigated in animal models. Adding TLR9 or TLR4 agonists to MF59-adjuvanted vaccines shifted the ensuing response toward Th1 immunity. For example, a tumor vaccine adjuvanted with MF59 plus the TLR9 agonist CpG ODN had superior antitumor activity compared to MF59 alone. The combination inhibited tumor growth and significantly prolonged survival in a melanoma model, whereas the same vaccine lacking CpG ODN promoted melanoma growth [33].

7.6.3 AS03

Adjuvant system 3 (AS03) is composed of α-tocopherol (a bioavailable form of vitamin E) plus squalene in an oil-in-water emulsion. AS03's mechanism of action is likely similar to that of MF59. The inclusion of α-tocopherol is reported to have several benefits: it increases the production of cytokines (particularly IL-6), improves antigen-loading by monocytes, and enhances the recruitment of granulocytes to the draining LNs. This culminates in AS03 inducing an Ab response an order of magnitude higher than nonadjuvanted vaccines [34]. As a result, AS03 was approved for use in Europe and Canada as part of an H1N1 pandemic flu vaccine.

Unfortunately, phase 3 clinical trials suggested that recipients of AS03 suffered from an increased incidence of narcolepsy during the 2009 H1N1 influenza pandemic [35,36]. This was first observed among children and adolescents in Nordic countries [37,38] and subsequently confirmed by findings elsewhere in Europe [39,40]. Clinical results suggested that Pandemrix (an AS03-containing vaccine given to more than 30 million Europeans) could trigger an autoimmune reaction leading to narcolepsy in genetically predisposed individuals. Yet no increase in narcolepsy was observed in Canada or Brazil despite the widespread use an AS03-adjuvanted H1N1 vaccine in those countries [40]. Recent evidence suggests that antibodies to the 2009 A(H1N1)

nucleoprotein antigen cross-reacts with human hypocretin receptor 2, which may provide an possible explanation for the association of this particular influenza vaccine with narcolepsy [41].

7.7 Nano/microparticles Including Liposomes and Virosomes

There is considerable interest in using lipid-based vesicles as vaccine adjuvants. The safety and tolerability of liposome-based delivery systems was established in clinical trials involving the delivery of antifungal and anticancer drugs [42]. In the field of vaccinology, liposomes are commonly produced from a combination of stabilized membrane lipids plus viral fusion proteins to create an antigen delivery system termed virosome [42]. As an example, the hepatitis A vaccine Epaxal is composed of inactivated Hep A viral antigens carried within a virosome composed of highly purified influenza virus surface proteins plus phospholipids and cephalin. These particles retain the receptor binding capacity and specificity conferred by the flu proteins and deliver their Ag payload into the cytosol of target cells [43,44]. In addition to Epaxal, the Inflexal virosome-based influenza vaccine has been approved for use in Europe [45]. Both vaccines show excellent immunogenicity and tolerability profiles. Additional virosome-based vaccines are undergoing clinical trial for use in HIV/AIDS and malaria [46,47]. Preclinical studies suggest that virosomes with a mean diameter of 150 nm may be effective after intranasal or mucosal delivery.

7.8 Immune Stimulating Complexes

ISCOMs are cage-like particles that form spontaneously when a solution of Ag in water is mixed with cholesterol, phospholipids, and Quillaia saponins [48]. The antigen is incorporated into microparticles whose size (typically ≈40 nm) facilitates recognition and uptake by professional APC [48]. ISCOMs promote both humoral and cellular immune responses as characterized by the production of Ab and the activation of cytotoxic T lymphocytes [49]. The saponins in these complexes serve to boost the immunostimulatory activity of the ISCOM. Although ISCOMs were found to improve vaccine immunogenicity in animal studies, there was a problem with toxicity: the saponin component was associated with the development of hemolysis. These and other adverse reactions were observed after human use.

A less toxic derivative of saponin, QS-21, is undergoing clinical evaluation as an adjuvant for several vaccines. These include phase 3 trials of MPL plus QS21 for use in a malaria vaccine and phase 2 and 3 trials in which QS21 is included as a component of AS01, AS02, liposomes, and oil-in-water emulsions for vaccines targeting influenza, HIV, malaria, and cancer. Available results suggest that QS21 supports the immunogenicity of these vaccines without inducing the adverse events associated with saponin [50–52].

7.9 Cytokines

Numerous cytokines influence the nature and strength of vaccine-induced immune responses. Preclinical studies show that depleting cytokines such as IL-2, IL-12, IL-15, and GM-CSF adversely affects vaccine immunogenicity, whereas coadministering such cytokines enhances the induction of Ag-specific immune responses by stimulating T cells and/or APCs. Since recombinant cytokines generally have very short *in vivo* half-lives (on the order of minutes), efforts to use them as adjuvants complicates the method, site, and dose of vaccine delivery. Various strategies have been explored in clinical trials of vaccines designed for use in cancer patients.

7.9.1 IL-12

IL-12 is a major Th1 cytokine. It induces NK, T, and B cells to produce IFNg and plays a key role in supporting the generation of Th1 cells and CTL [53,54]. These abilities support the development of IL-12 as an adjuvant for vaccines targeting chronic infection and cancer. The ability of IL-12 to enhance Th1 immunity was initially demonstrated in a model of *Leishmania* infection in mice [55]. IL-12 was shown to increase IgG2a and decrease IgG1 Ag-specific Ab production compared to Ag alone [56,57], consistent with its induction of a Th1 biased immune response.

In clinical trials, the efficacy of recombinant IL-12 was found to be inconsistent, perhaps being influenced by the route of administration and type of vaccine. Most studies document that it increases Ag-specific CD8 and CD4 T cell responses [58–60]. In terms of safety, when IL-12 was administered systemically at high doses as monotherapy in cancer patients, it was found to be toxic [61]. If IL-12 is to find use as a vaccine adjuvant, it will need to be effective at much lower doses to avoid such toxicity [58–60].

7.9.2 IL-2

IL-2 plays an important role in T-cell proliferation, the induction of regulatory T-cell responses, and the initiation and maintenance of Ag-specific immunity. As such, it can be used to support the generation of CTLs and improve Ab production. In a variety of preclinical models, IL-2 was shown to be effective as a vaccine adjuvant, findings that supported the initiation of clinical trials [62,63]. Moreover, IL-2 was studied and approved as monotherapy for metastatic renal-cell carcinoma and metastatic melanoma in the 1990s [64]. Those early trials helped identify the toxicities associated with IL-2, which include flu-like symptoms, nausea/vomiting, and others.

The first clinical trial evaluating the administration of systemic IL-2 following vaccination reported an improved objective response rate in melanoma patients from 5% in subjects receiving vaccine alone to 42% in recipients of vaccine plus IL-2 [65,66]. Unfortunately, subsequent clinical trials failed to reproduce that outcome. A meta-analysis found that coadministering IL-2 with melanoma vaccine was no more effective than IL-2 alone [67–69]. Given the importance

of IL-2 for the induction and maintenance of T-cell responses, only through studies evaluating the method, dose, and timing of IL-2 delivery may the potential benefits of this cytokine as a vaccine adjuvant be determined.

7.9.3 IL-15

IL-15 is structurally similar to IL-2 and has similar functions [70,71]. In addition to promoting NK and T-cell development/proliferation (especially of CD8 T cells), IL-15 can augment the production of antibodies by B cells [70,71].

The use of a plasmid encoding IL-15 as a vaccine adjuvant was evaluated in a number of infectious disease models [72–74]. Oh *et al.* demonstrated that mice injected with a Vaccinia-based vaccine encoding IL-15 induced long-term CD8 T-cell-mediated immunity, while a vaccine encoding IL-2 was short-lived [75]. These results are consistent with those obtained in rhesus macaques immunized with tetanus and influenza vaccines [76]. Several clinical trials utilizing IL-15 plus chemotherapy or vaccination in cancer patients are ongoing with results expected in the near future [77,78].

7.9.4 GM-CSF

GM-CSF induces the proliferation of macrophages and the differentiation of DC [79,80]. The adjuvant properties of GM-CSF were explored in numerous preclinical tumor models where enhanced Ag-specific Ab and CTL responses were observed [81,82]. Several strategies for administering GM-CSF were examined including coadministration with vaccine [83,84], injection at the vaccination site [85], systemic administration [86,87], and administration as a plasmid/viral vector [88]. Unfortunately, results from clinical trials have been disappointing [83,85,88,89]. As in the case of IL-2, achieving greater activity may depend on improving the dose, route, method, and schedule of GM-CSF administration.

7.10 Adjuvants that Target Toll-like Receptors

7.10.1 Introduction

The innate immune system is responsible for rapidly detecting and responding to viral, microbial, and fungal pathogens. Cells of the innate immune system express pattern-recognition receptors including Toll-like receptors that bind to and are stimulated by molecules expressed by a diverse array of infectious agents. Inducing immunity via TLR triggers the production of proinflammatory cytokines/chemokines as well as type I IFNs that increase the host's ability to eliminate the pathogens [6,90–92]. This innate response supports the subsequent development of adaptive immunity and can be harnessed to accelerate and enhance the induction of vaccine-specific responses [93]. Given the importance of TLR agonists as potential vaccine adjuvants, what follows is a detailed description of the responses they elicit and their safety as determined by clinical trial.

7.10.2 TLR2

7.10.2.1 Overview

TLR2 interacts with a broad and structurally diverse range of ligands, including molecules expressed by microbes and fungi. There is evidence that natural and synthetic lipopeptides, peptidoglycans, various types of polysaccharides, and lipopolysaccharides (LPS) can all act as TLR2 agonists [94,95]. Yet uncertainty exists concerning the mechanisms by which TLR2 could recognize such a wide array of ligands and it seems likely that contamination with lipopeptides (which trigger TLR2 at picomolar levels [94]) may underlie some of the activity attributed to other moieties [96–98]. This section will focus on the use of lipopeptides as vaccine adjuvants, as available data suggest they are certainly agonists for TLR2.

7.10.2.2 TLR2 ligands

Since TLR2 is expressed in many different cell types (including dendritic cells, macrophages, and lymphocytes), the mechanisms by which bacterial lipopeptides manifest their adjuvant properties are diverse. Preclinical testing indicates that lipopeptides coadministered with or physically linked to Ag can (i) induce DC maturation and cause the upregulation of costimulatory signals and Ag-presenting molecules (e.g., MHC class II, CD80, CD83, IFN-γ, and IL-12) [99–101], (ii) stimulate macrophages to release cytokines (e.g., TNF, IL-1, and IL-6) [102,103], (iii) promote the maturation and activation of B cells leading to increased production of Ag-specific IgG and IgM Abs [104,105], and (iv) boost the generation of antigen-specific CD8 T-cell (CTL) responses [106–108]. Animal studies demonstrate that the immunogenicity of peptide-based vaccines can be significantly improved by conjugating them to either bacterial lipopetides or palmitic acid moieties.

7.10.2.3 Clinical Activity

The lipopeptide adjuvant that has undergone the most extensive clinical testing is Pam3Cys. It has been used in a vaccine containing the outer-surface protein A (OspA) of *B. burgdorferi* (the spirochete that causes Lyme disease). This vaccine was tested in over 20 000 volunteers [109,110]. Protective immunity correlated with IgG anti-OspA titers >1400 EIA units/ml. This lipopeptide adjuvanted vaccine (LYMErix™) was licensed by the FDA in 1998 but withdrawn by the manufacturer due to reports of autoimmune side effects [111,112]. Of note, neither the FDA nor the CDC found a connection between the vaccine and the development of autoimmunity.

The same adjuvant was tested in combination with peptide vaccines targeting malaria, HIV, and HBV. The addition of Pam2Cys typically improved or broadened the immunogenicity of these vaccines and boosted humoral responses to peptide-based vaccines in normal healthy volunteers [113,114]. However, their effect on CTL responses was less impressive and they were not effective in postexposure settings. Thus, their utility for the prevention/treatment of chronic infectious diseases (such as HPV or HIV) is uncertain.

7.10.2.4 Safety

Clinical trials indicate that lipopetide vaccines are generally safe with transitory local erythema being the most common adverse event and most systemic reactions being mild [114]. LYMErix™ was well tolerated in clinical trials involving >20 000 individuals followed for up to 6 years. Local adverse events were generally mild or moderate and lasted 2–3 days. Less than 4% of the vaccinees reported systemic complaints, primarily mild myalgia or fever [109,110,115]. In all, 1.4 million doses of LYMErix were administered postlicensure and the Vaccine Adverse Events Reporting System database shows 905 reports of mild self-limiting reactions and 59 reports of arthritis associated with vaccination [116]. This incidence of arthritis did not differ from the background rate in unvaccinated individuals. These findings suggest that lipopeptides interacting with TLR2 can be used safely as vaccine adjuvants.

7.10.3 TLR3

7.10.3.1 Overview

TLR3 is expressed within the endosomal compartment of conventional dendritic cells and macrophage [90]. TLR3 is triggered by double-stranded RNA (dsRNA) generated during the life cycle of most infectious viruses. The interaction of TLR3 with dsRNA initiates a TRIF-dependent signaling cascade that progresses through the activation of NF-kB, MAP kinases, and IRF3 and culminates in the production of inflammatory cytokines and type 1 IFNs [117,118]. Thus, TLR3 is distinct from all other TLRs in not using the MyD88-dependent pathway for signaling.

A potential advantage of TLR3 agonists is that triggering via this signaling cascade facilitates Ag cross-presentation, in which CD8 T cells are primed by exogenous Ag presented in the context of MHC class 1 molecules, improving the generation of cytotoxic T cells [119,120]. Cross-presentation is also enhanced by the type 1 IFNs induced following TLR3 stimulation [121]. Thus, TLR3 ligands are considered excellent candidates as adjuvants for vaccines targeting the induction of a strong cellular immune response [122].

7.10.3.2 TLR3 Ligands and Their Immunogenicity

Poly I:C (polyriboinosinic: polyribocytidylic acid) is a synthetic analog of dsRNA that triggers via TLR3 [123]. In a murine model of influenza virus infection, intranasal administration of poly I:C with an HA-based influenza vaccine induced a strong and protective IgA anti-HA response in the nasal mucosa and IgG response in serum, whereas vaccination without poly I:C was nonprotective [124]. Other studies document that poly I:C enhances the efficacy of peptide-based cancer vaccines by promoting tumor antigen-specific T-cell responses in murine models [125–128].

Despite promising findings in mice, the utility of poly I:C in primates (including man) is limited due to the susceptibility of this adjuvant to degradation by serum nucleases [129,130]. High doses of poly I:C were unsafe, causing shock, renal failure, and coagulopathies in phase 1–2 clinical trials of cancer patients [131]. The FDA has

not approved the use of alternative TLR3 agonists that have shown promise in animal studies but are of uncertain safety and efficacy in humans [132,133].

7.10.3.3 Safety

Initial clinical studies involving poly ICLC showed that high-dose therapy was associated with mild to severe side effects including hypotension, fever, and anemia. Once the dose and frequency of delivery were optimized, this TLR3 agonist was well tolerated in humans [134–141]. Several phase 1–2 clinical trials evaluating the activity and safety of poly ICLC as a cancer vaccine adjuvant are ongoing.

Poly I:C12U was well-tolerated in several long-term phase 1–2 clinical trials involving cancer patients [142]. The reduction in toxicity compared to poly I:C may reflect the accelerated hydrolysis and shorter plasma half-life of polyI:C12U [142,143]. Available data suggest that this agent is the most promising TLR3 ligand under clinical development. Studies of poly I:C12U as monotherapy against viral infection and phase 2 and 3 clinical trials examining its use in HIV and chronic fatigue syndrome are underway [144,145]. Clinical use of this TLR3 ligand as an adjuvant will begin with studies involving a vaccine targeting ovarian cancer [146].

7.10.4 TLR4

7.10.4.1 Overview

TLR4 is expressed by cells of the innate immune system, including conventional dendritic cells and macrophages. It is also expressed by many nonimmune cells including fibroblasts and epithelial cells [90]. Triggering via TLR4 induces a signaling cascade that utilizes both the MyD88- and the TRIF-dependent pathways, leading to NF-kB and IRF3/7 activation, respectively. TLR4 activation generally induces robust IL-12p70 production and strongly enhances Th1 type cellular and humoral immune responses [147,148].

7.10.4.2 TLR4 Ligands

Virtually all clinical trials of TLR4 adjuvants involve derivatives of lipopolysaccharide. LPS is a complex molecule whose lipid A portion mediates interactions with TLR4 [149,150]. Although the immunostimulatory capacity of LPS has been known for decades the intact molecule is highly toxic, preventing its use as a vaccine adjuvant [7]. The monophosphoryl lipid A component is considerably less toxic while maintaining immunostimulatory activity [151–154].

7.10.4.3 Clinical Activity

MPLA can boost vaccine-induced serum Ab titers by 10–20-fold compared to vaccine alone [154]. MPLA preferentially induces the production of IgG2a Abs and supports the generation of Th1 immunity in mice [155,156]. Human vaccine trials indicate that MPLA has a safety profile similar to that of alum [147,156]. Even very high doses of MPLA (up to 100 mg/m^2 delivered i.v.) are safe, inducing neither renal nor hepatic toxicity [157].

As described above, extensive clinical studies were conducted using MPLA absorbed onto aluminum salts [158,159]. Combining the hepatitis B vaccine with MPLA (Fendrix®) improved the speed and magnitude of the resulting anti-HBs Ab response [160]. MPLA was also used as an adjuvant with Cervarix®, a conjugate vaccine that uses virus-like particles to induce immunity against HPV-16 and HPV-18 [158]. Compared to the same vaccine adjuvanted with alum, Cervarix® induced higher anti-HPV16 and HPV18 L1 Ab responses (1.6–3.2-fold, $p < 0.05$) was approved for use in the European Union and the United States [161,162]. MPLA was also tested as an adjuvant for cancer vaccines. A modest enhancement in survival was observed in phase II trials, but further development was not pursued. Instead, a new class of synthetic lipid A mimetics, the aminoalkyl glucosaminide 4-phosphates (AGPs), was developed [148,156]. Clinical trials of the HepB vaccine coadministered with AGP RC-529 demonstrated superior immunogenicity and seroprotection. Based on those findings plus an acceptable safety profile, the RC-529 conjugated HBV vaccine was approved for use in Argentina [163].

7.10.4.4 Safety

In general, adverse events (typically mild to moderate) were more frequent in subjects receiving MPLA or RC-529 adjuvanted vaccines than vaccines adjuvanted with alum. Local reactions were typically mild to moderate and resolved in 1–3 days. The incidence of systemic adverse events was low and did not differ significantly between groups. No serious systemic adverse events related to vaccination were reported.

7.10.5 TLR5

7.10.5.1 Overview

TLR5 recognizes the protein ligand bacterial flagellin [164,165]. TLR5 is expressed on the surface of many types of immune cell, including monocytes, mDCs, Langerhans cells, T cells, and NK cells [166–168]. The adjuvant properties of flagellin have been tested by generating fusion proteins in combination with recombinant Ag. In that form, flagellin induced DC maturation leading to the upregulation of costimulatory signals and Ag-presenting molecules (CD80, CD83, CD86, MHC class II, TNF-α, IL-8, IL-1β, CCL2, and CCL5) [169]. Flagellin also stimulated monocytes to produce IL-10 and TNFa, NK cells to produce IFNγ and α-defensins, T cells to proliferate and produce cytokines/chemokines (e.g., IL-10, IL-8, and IFN-γ), and B cells to increase Ab production by up to 10-fold [165,170,171]. Little is known of the immunogenicity or safety of flagellin-based vaccines in humans.

7.10.6 TLR7/8

7.10.6.1 Overview

TLRs 7 and 8 are phylogenetically and structurally related and will be handled together in this section [172]. Both recognize single-stranded RNA sequences

containing poly-U or GU-rich sequences and are activated by synthetic imidazoquinolines and guanosine analogs [172–175]. TLR 7/8 molecules are localized to the endosomal compartments of human immune cells including DC, monocytes, macrophage, lymphocytes, Langerhans cells, and NK cells [176–178].

The interaction between TLRs 7/8 and their cognate ligands triggers DC to (i) enhance expression of costimulatory molecules (e.g., CD80, CD86, and CD40) [179], (ii) migrate [180], and (iii) produce proinflammatory cytokines including IFN-α, TNF-α, and/or IL-12 (the latter facilitating induction of Th1-type responses). In this context, TLR7-specific activation preferentially triggers IFN-α secretion by pDC, whereas TLR8-specific activation preferentially induces IL-12 production by mDCs [176,181].

TLR 7/8 agonists also stimulate B cells to produce cytokines (e.g., IL-6, TNF-α, etc.) and secrete Ig [182], trigger NK cells to produce IFNγ and T cells to proliferate and produce cytokines including IFNγ, IL-2, and IL-10 [183]. Memory T cells are particularly sensitive to this form of TLR-mediated activation, and TLR7/8 ligands may reduce the immunosuppression mediated by CD4 T regulatory cells [167,184].

7.10.6.2 TLR7/8 Ligands and Their Preclinical Activity

Preclinical studies indicate that imidazoquinolines can improve both the magnitude and the quality of Ag-specific T-cell and Ab responses. In mice and macaques, TLR7/8 agonists enhanced Ag-specific IgG and CTL responses, particularly when the adjuvant was conjugated to Ag [185–187]. TLR7/8 agonists have also been used as adjuvants with cancer vaccines. In a genetically engineered mouse model of breast cancer, a DNA vaccine encoding HER2/neu adjuvanted with imiquimod significantly delayed the development of spontaneous mammary tumors and reduced their incidence by 65% compared to the DNA vaccine alone. These effects were accompanied by a significant increase in Ag-specific Ab production (threefold, $p < 0.05$), a switch from IgG1 to IgG2a Ab isotype, and a 30% increase in CTL activity ($p < 0.05$) [188].

7.10.6.3 Clinical Activity

Imiquimod (Aldara, 3 M) is the only TLR7/8 agonist currently approved for clinical use, having proven efficacious as a topical ointment for the treatment of anogenital warts caused by HPV, for basal cell carcinoma, and for actinic keratosis [189,190].

Topical use of TLR 7/8 in patients with other types of cancer resulted in only modestly enhanced Ag-specific Ab and CD4 responses, although it is unclear whether this was sufficient to impact disease progression.

7.10.6.4 Safety

Topical administration of imiquimod is well tolerated. In contrast, severe side effects were reported after oral and systemic delivery of imidazoquinoline as monotherapy in humans [191,192]. Novel formulations are being developed to overcome this limitation, but their utility awaits the outcome of clinical trials designed to assess their activity and safety.

7.10.7 TLR9

7.10.7.1 Overview

TLR9 is expressed by human B cells and plasmacytoid dendritic cells (pDC). The receptor is localized within endolysosomal compartments and detects the unmethylated CpG motifs present at high frequency in bacterial DNA [193]. Activation of cells expressing TLR9 has broad effects on the immune system, eventually leading to the maturation, differentiation, and/or proliferation of NK cells, T cells, B cells, monocytes, and macrophages [177,193–200]. The resultant immune response is characterized primarily by the production of proinflammatory and Th-1 biased cytokines (including IL-1, IL-6, TNF-α, IFN-γ, and IL-12 [193,194,201–205].

7.10.7.2 TLR9 Ligands

The immunostimulatory activity of bacterial DNA is mimicked by synthetic oligonucleotides (ODNs) expressing CpG motifs [206–208]. While several different "classes" of CpG ODN have been described, "K" type ODN (also referred to as "B" type) are the most widely studied of the lot. They strongly support B-cell activation and induce the maturation of pDCs and monocytes [209–211].

Preclinical studies demonstrate that CpG ODN can accelerate [212], increase the magnitude [212–214], and prolong the duration of vaccine-specific Ab and CTL responses [214–216]. CpG ODNs promote vaccine immunogenicity by improving Ag uptake by professional APC (particularly pDC), triggering the functional maturation of APC, and generating a cytokine/chemokine microenvironment supportive of Ag-specific immunity [217]. These effects are optimized when vaccine and adjuvant are presented to the immune system in close spatial and temporal proximity [213,218,219].

7.10.7.3 Clinical Activity

Clinical trials examined the adjuvant activity of "K" type ODN combined with a number of human vaccines. CpG ODN plus the HBV vaccine boosted anti-HBs Ab titers by 13-fold after primary and 45-fold after secondary immunization [220–222]. When tested in combination with the licensed anthrax vaccine, "K" ODN boosted anthrax-specific Ab titers by six-eight-fold and accelerated the induction of immunity [223]. The effect of adding CpG ODN to the Fluarix influenza vaccine was less impressive. In that trial, CpG ODN had a dose sparing effect, but it did not increase the magnitude of the Ab response [224].

CpG ODNs were tested as adjuvants with a number of cancer vaccines. Improved CTL responses were generally observed, but these had little effect on outcome. Thus, available clinical data indicate that CpG ODNs are most likely to find use as adjuvants for vaccines targeting infectious diseases. This reflects the consistent ability of CpG ODNs to boost Ag-specific humoral immunity in naive subjects. The utility of CpG ODNs as tumor vaccines adjuvants is less clear, as the magnitude of the CTL response needed to clear an established tumor may exceed that which can be induced by the current generation of vaccines.

7.10.7.4 Safety

CpG ODNs have been well tolerated when administered as vaccine adjuvants. However, the frequency and severity of local adverse events (injection site reactions such as pain, swelling, induration, pruritus, and erythema) and systemic symptoms (including flu-like symptoms) were elevated, consistent with the immunostimulatory properties of CpG ODN. Most adverse events were mild to moderate, appeared within 24 h of dosing, and persisted for only a few days. In general, no significant difference in the frequency or severity of AEs was reported for patients receiving vaccine alone versus vaccine plus CpG ODN.

7.11 Adjuvant Combinations

As described in the introduction, vaccine adjuvants generally fall into two broad categories: those that stimulate specific elements of the immune system and those that improve vaccine uptake/persistence/presentation. Not surprisingly, there is considerable interest in combining these two approaches to achieve superior results. It is also hoped that improved safety and lower cost might be achieved if the dose of an immunostimulatory adjuvant could be decreased by pairing it with a delivery system that improved uptake and targeting.

As an example of this approach, TLR agonists such as CpG ODNs have been co-encapsulated with Ag in microparticle delivery systems. Animal studies suggest that this use of microparticles significantly increased the generation of CTL compared to preparations in which Ag, CpG ODN, and microparticles were delivered independently [225–227]. There have been clinical trials in which CpG ODN was paired with alum to adjuvant a novel HBV vaccine "HEPLISAV-B." The addition of the TLR9 agonist was expected to overcome the hyporesponsiveness of some individuals to the commercially available HBV vaccine. Similarly, phase 2 clinical studies indicate that a vaccine composed of the combination adjuvant AS15 (which includes MPL, QS21, CpG ODN, and liposomes) plus the MAGE-3 tumor antigen improves disease-free intervals in a subset of melanoma patients better than the same antigen formulated with AS02 [228].

Also being examined are combination adjuvants designed to modify the Th1: Th2 balance by targeting immunostimulatory ligands to specific receptors. Preclinical studies support the hypothesis that synergy between different TLR agonists can be exploited to improve vaccine efficacy. For example, a vaccine containing a mixture of TLR4 and TLR9 agonists was more efficient than a vaccine containing adjuvants targeting TLR4 or TLR9 alone [229,230]. Similarly, the combinations of TLR7 and TLR9 agonists were more effective against tumor targets than either ligand alone [231].

7.12 Future Directions

There is considerable interest in developing vaccines with improved activity against cancer and chronic infectious diseases. Concepts including combining

immunostimulatory adjuvants with immune checkpoint inhibitors such as anti-CTLA4 or anti-PD-1 are of interest to the oncology community. They hypothesize that checkpoint inhibitors can reduce tumor growth while vaccines enhance adaptive antitumor immunity. Central to any immunologic approach to cancer treatment is the need to overcome the suppressive microenvironment that protects established tumors from immune elimination.

As described in the introduction, novel adjuvants that enhance the generation of the CTL are considered key to the next generation of vaccines that target chronic infectious diseases. Such adjuvants must not only have excellent safety profiles but also induce stronger, longer lasting and/or qualitatively improved immune responses while simultaneously being amenable to consistent manufacture. These multiple requirements highlight the challenges associated with the development of novel vaccine adjuvants.

Pattern Recognition Receptors

Lauren Whitehead and Gordon D. Brown

University of Aberdeen, Institute of Medical Sciences, Ashgrove Road West, Aberdeen, AB25 2ZD, UK

8.1 Introduction

The innate immune system is the first line of defence and is crucial for the initial sensing of microbial infection or tissue injury. Innate immune cells within the body constantly sample the extracellular and intracellular environment through a broad class of proteins known as pattern recognition receptors (PRRs). These germ-line encoded receptors recognize highly conserved motifs known as pathogen-associated molecular patterns (PAMPs) that are associated with microbial pathogens or damage-associated molecular patterns (DAMPs) that are associated with cellular stress. PRRs dictate the initiation of an appropriate and effective innate immune response as well as activation of the adaptive immune response in the face of an infection or sterile inflammation. At present, four major classes of PRRs have been identified, namely, Toll-like receptors (TLRs), C-type lectin-like receptors (CLRs), nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs), and retinoic acid-inducible gene-1-like (RIG-1) receptors (RLRs), as shown in Figure 8.1. In addition, several other classes exist, including DNA-sensing molecules (Figure 8.1). These families of receptors are expressed in a wide variety of cells where they enact functions tailored to the cell and its functional role in the immune system.

Sensing of PAMPs or DAMPs by PRRs triggers specific signaling cascades resulting in transcription of genes involved in the inflammation response. These genes mediate several processes such as release of cytokines, chemokines, antimicrobial peptides, and cell proliferation [1]. Some of these PRRs enable direct phagocytosis of the bound antigen or can enhance the cells' phagocytic ability. Another key mechanism for antimicrobial killing is the generation of reactive oxygen species (ROS), and in the case of neutrophils, neutrophil extracellular trap (NET) formation. Activation of these signaling cascades may also upregulate or downregulate the expression of other PRRs and costimulatory molecules, thus modulating the responsiveness of the cell to stimuli. More recently, there is a growing interest in the contribution of PRRs in mediating the development of adaptive immunity.

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

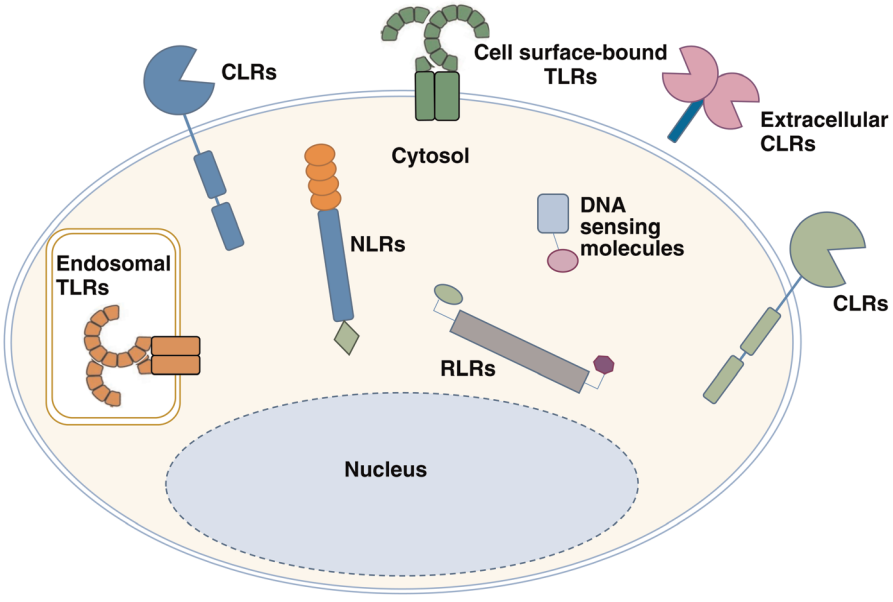

Figure 8.1 Overview of PRR distribution within the cell. TLRs and CLRs can be extracellular or membrane bound that are expressed either at the cell surface or in the endosome. NLRs, RLRs, and DNA sensing molecules are expressed in the cytosol.

In this chapter, we briefly describe the structure and expression of the four major classes of PRRs as well as DNA-sensing molecules and their respective signaling cascades. In addition, we highlight their functional role with selected receptor–ligand examples and their contribution to immunity.

8.2 Toll-like Receptors

The family of Toll-like receptors, initially discovered in *Drosophila*, consists of 10 transmembrane glycoproteins in humans (12 in mice) that recognize a wide range of pathogens. They are highly conserved and share both structural and functional similarities across humans and mice [2]. Structurally, they are characterized by N-terminal leucine-rich repeats (LRRs), a transmembrane region, and a cytoplasmic Toll/IL-1R homology (TIR) domain. Description of the TLR crystal structure revealed that the ligand-binding LRR region gives TLRs their characteristic horseshoe shape. TLRs are monomeric but can form hetero- or homodimers upon ligand binding, thus adapting ligand specificity. They are expressed in a wide variety of cells such as innate immune cells, T and B cells, epithelial cells, fibroblasts, and endothelial cells; however, not all cell types express every TLR [3]. For example, plasmacytoid dendritic cells express a limited repertoire of TLRs, predominantly TLR7 and TLR9, making them particularly responsive to viral and bacterial nucleic acids [4]. Based on their cellular localization, TLRs can be divided into two classes: cell surface-bound and endosomal TLRs.

8.2.1 Cell Surface-bound TLRs

The cell-surface bound TLRs consist of TLR1, TLR2, TLR4, TLR5, and TLR6 and detect lipoproteins with the exception of TLR5. TLR2 recognizes the broadest range of ligands due to its dimerization with either TLR1 or TLR6. TLR2/TLR1 and TLR2/TLR6 heterodimers detect triacyl and diacyl lipoproteins, respectively [5,6]. These lipoproteins can be found on various components of bacteria, fungi, and viruses. TLR2, for example, recognizes lipoarabinomannan from mycobacteria [7–9]. Secreted isoforms of human TLR2 in plasma, saliva, and breast milk may act independent of TLR6 or TLR1 and negatively regulate TLR2 signaling through ligand-binding competition [7,10,11].

TLR5 forms homodimers upon detection of bacterial flagellin and is highly expressed in dendritic cells (DCs) of the lamina propia in the small intestine [12–14]. This ligand specificity and location enable TLR5 to respond to invasive pathogenic flagellated bacteria in the gut [15–17]. In addition, TLR5-deficient mice exhibit uncontrolled microbiota-induced gut inflammation [17]. Due to the increasing importance of the gut microbiota in the development of autoimmune diseases, TLR5 may play an important role in the onset of these diseases [18]. Indeed, TLR5 polymorphisms in humans have already been linked to ulcerative colitis and Crohn's disease [17,19,20]. Sensing of the microbiota by TLR5 may also be important for vaccine responses as the required antibody response cannot be triggered without the initial priming of the innate immune system by either an adjuvant or the microbiota [21].

TLR4 in combination with myeloid differentiation factor 2 (MD2) recognizes lipopolysaccharide (LPS), a component of the outer membrane of Gram-negative bacteria and the cause of septic shock [22]. The crystal structure revealed that upon ligand binding a TLR4-MD2-LPS complex assembles and then interacts symmetrically to form a TLR4 homodimer [23]. MD-2 contains a hydrophobic pocket formed by two antiparallel β sheets that directly binds LPS [23]. Polymorphisms in TLR4 have been linked to increased susceptibility to parasitic infections, malaria, leishmaniasis, and typhoid fever [24]. As is expected, TLR4 plays a seminal role in immune responses to bacterial infections; however, there is contradicting evidence when attempting to draw associations between human polymorphisms and bacterial infections [25]. TLR4 is also involved in antiviral innate immunity through the recognition of viral envelope proteins or DAMPs generated during infection [26,27]. For example, infection with H5N1 avian influenza resulted in acute lung injury and the production of endogenous oxidized phospholipids that stimulate TLR4. This recognition is key to avian influenza-induced lethality. Another example, HMGB1, a ubiquitous nuclear protein actively secreted by innate cells or released from damaged cells as a result of sterile tissue injury has been identified as a ligand of TLR4 [28]. It functions as DAMP thereby linking tissue injury and infection. During sepsis, HMGB1 levels are persistently elevated during the later stage of disease [29]. This release of DAMPs can result in a cytokine storm and organ failure, and neutralizing antibodies against HMGB1 was shown to protect against sepsis-induced mortality [30,31].

8.2.2 Endosomal TLRs

This group of TLRs is localized on the endosomal membrane within the cell and is comprised of TLR3, TLR7, TLR8, and TLR9. They predominantly recognize nucleic acids derived from viruses and bacteria but can also recognize self-nucleic acids degraded by DNAses. In order to prevent self-recognition, these TLRs are compartmentalized on the endoplasmic reticulum and translocate to the endolysosome in a regulated manner [32–34]. The multipass membrane protein UNC93B1 loads the TLRs into COPII vesicles that then pass through the Golgi complex to their final destination, the endolysosome [34]. In addition, there is evidence showing that this group of TLRs must be cleaved by various proteases before they are capable of downstream signaling; however, this process is still controversial [35]. These regulatory mechanisms are crucial in preventing autoimmunity.

TLR3 detects viral double-stranded RNA (dsRNA) formed during the replication of positive stranded viral RNA in the cytosol [36]. Double-stranded RNA binds to both N and C terminals of TLR3 and induces dimerization via its cytoplasmic TIR domain [37,38]. A synthetic analog of this ligand, polyinosinic polycytidylic acid (poly I:C) can be used to induce TLR3-driven responses. Inoculation of mice with poly I:C induces the production of Type 1 interferon cytokines essential for viral clearance [39]. Furthermore, TLR3-deficient mice have been shown to be susceptible to a number of viruses including poliovirus and encephalomyocarditis virus [40–43]. TLR7 and TLR8 both recognize viral single-stranded RNA (ssRNA) [44,45]. TLR8 is expressed as a dimer with two ligand-binding sites, situated in a concave face and the other in the dimerization interface [46,47]. TLR7 and TLR9 have both been implicated in the development of lupus through detection of self-nucleic acids [48,49]. TLR9 recognizes bacterial DNA rich in unmethylated CpG motifs [50]. The crystal structure of TLR9 revealed that upon ligand binding, TLR9-CpG-DNA forms a symmetric dimer [51]. TLR9 agonists are increasingly being explored as vaccine adjuvants for several infectious disease vaccines [52].

While the ligand for TLR10 remains unknown, there is evidence that this TLR is indeed functional in humans. Recently, it has been implicated in the recognition of *Helicobacter pylori* by gastric epithelial cells and may act as a heterodimer with TLR2 [53,54]. Further studies are required to elucidate this receptor's biological function.

TLR11 and TLR12 are both present in mice but not in humans. TLR11 is expressed on macrophages, dendritic cells as well as liver, kidney, and bladder epithelial cells. It plays a crucial role during parasitic and urinary tract bacterial infection [55,56]. In addition, TLR11 has been shown to prevent intestinal infection during a murine model of *Salmonella* infection [57]. Similar to TLR11, TLR12 also plays a role in parasitic infection with *Toxoplasma gondii* through recognition of *T. gondii* profilin protein [55,58]. Interestingly, TLR12-deficient mice succumb rapidly to *T. gondii* infection, while TLR11-deficient mice are partially resistant. This difference may be partially attributed to the expression patterns of these two TLRs. TLR12 is expressed on plasmacytoid dendritic cells and, therefore, promotes their function during *T. gondii* infection. In contrast, TLR11 and TLR12 may form heterodimers and are both required for IL-12

production by macrophages and conventional dendritic cells during infection with this pathogen [58].

8.2.3 TLR Signaling

TLR signaling can be roughly divided into two distinct pathways based on the TIR domain-containing adapter molecules recruited to the activated TLR, namely, MyD88-dependent signaling or TIR-containing adapter -inducing IFNβ (TRIF)-dependent signaling. MyD88-dependent signaling leads to activation of the transcription factor NF-κB while TRIF-dependent signaling results in both NF-κB and interferon regulatory factor 3 (IRF3) activation [59,60]. The activation of these transcription factors results in the expression of subsets of genes responsible for proinflammatory immune responses.

8.2.4 MyD88-dependent Signaling Pathway

The MyD88 signaling pathway, summarized in Figure 8.2, is initiated by ligand binding, following which TIRAP (TIR domain-containing adapter protein) is recruited to the TIR domain of the ligand-bound TLR and is activated. In turn, TIRAP activates MyD88, composed of a death domain (DD) and TIR domain. MyD88 is an essential adapter for the downstream signaling of TLRs with the exception of TLR3. This has been demonstrated in both humans and mice; MyD88 knockout (KO) mice exhibit a high mortality rate during bacterial infection, while MyD88-deficient children suffer from recurrent bacterial infections [61]. MyD88 interacts via its N-terminal death domain with IL-1R-associated kinase (IRAK-4) that subsequently recruits other members of the IRAK family and TNFR-associated factor 6 (TRAF6) to form a complex [62]. TRAF6 acts as a ubiquitin ligase and catalyzes the formation of a lysine-63 (K63) ubiquitin chain on itself and an unconjugated ubiquitin chain with the help of ubiquitin ligase enzymes: ubiquitin-conjugating enzyme 13 (UBC13) and ubiquitin-conjugating enzyme E2 variant 1 (UEV1A) [63]. TRAF6 ubiquitination activates the TGF-β-activated kinase 1 (TAK1), TAK1-binding protein (TAB1), TAB2, and TAB3 complex. This complex promotes the phosphorylation of the IκB kinase (IKK) complex, MAP kinase 6, p38, Jun N-terminal kinase (JNK), and extracellular signal-regulated kinase (ERK). The IKK complex, composed of IKK-α, IKK-β, and NF-κB essential modulator (NEMO), then phosphorylates IKK-β, a NF-κB inhibitory protein. Subsequently, IKK-β is degraded by the ubiquitin-proteasome system releasing NF-κB to translocate to the nucleus and activate transcription of proinflammatory genes. Phosphorylation of MAP kinase 6 results in a MAP kinase cascade and activation of the transcription factor AP-1.

8.2.5 TRIF Signaling Pathway

TLR3, which recognizes dsRNA, induces a MyD88-independent signaling cascade through the recruitment of the adapter molecule TIR domain-containing adapter-inducing IFN-β (TRIF) instead of MyD88. This pathway is summarized in Figure 8.2. Binding to dsRNA induces dimerization of the TIR domain in the TLR

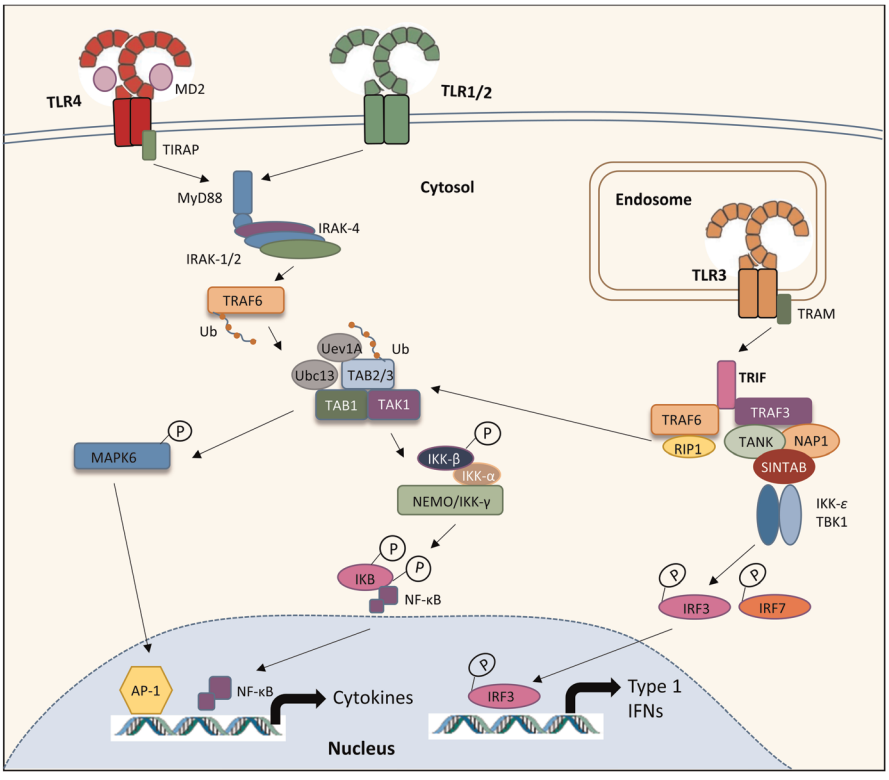

Figure 8.2 TLR signaling pathway. TLR4 and TLR1/6 signal via the MyD88-dependent pathway. MyD88 signaling leads to activation of TAB1-TAB2/3-TAK1 complex, which promotes the phosphorylation and activation of the IKK complex leading to NF-κB activation. The TAB1-TAB2/3-TAK1 complex also activates the MAP kinase pathway leading to activation of the transcription factor AP-1. TLR3 signals via the TRIF-dependent pathway. Following activation of TRIF, TRAF6 and RIP1 activate NF- κB, while TRAF3 activate the transcription factors IRF3 and IRF7 via IKK-ϵ/TBK1 complex.

and interaction with TRIF. TRAF3 and TRAF6 associate with TRIF through TRAF-binding motifs present in its N-terminal portion, while receptor interaction protein (RIP) 1 interacts via its C-terminal RIP homotypic interaction motif (RHIM). TRIF activates NF-κB either by direct interaction with TRAF6 or through RIP-1. TRAF3 is required for activating TANK-binding kinase 1 (TBK1) and IKK-ϵ [64,65]. TBK1 and IKK-ϵ phosphorylate IRF3 and IRF7 that subsequently form homodimers and translocate to the nucleus to initiate transcription of proinflammatory genes. In addition, IKK-ϵ also phosphorylates the transcription factor STAT1 [66]. TLR4 stimulation can trigger both MyD88 and TRIF signaling cascades; however, TLR4 requires TRIF-related adapter molecule (TRAM) to activate TRIF and initiate the cascade [67].

Several proteins modulate the TRIF signaling cascade at various steps. The TNFR-associated death domain protein (TRADD) forms a complex with RIP1 and FAS-associated death domain-containing protein (FADD), thereby mediating RIP1 ubiquitination [68,69]. Activation of TBK1 and IKK-ϵ is modulated by TRAF

family member-associated NF-κB activator (TANK), TBK1 adapter (SINTBAD), and NAK-associated protein 1 (NAP1) [70–72]. In humans, the sterile-alpha and armadillo motif-containing protein (SARM) acts as a negative regulator of TRIF signaling [73].

While TLR-mediated microbial recognition is essential for the host defence, in contrast, exaggerated responses to TLR ligands can induce lethal septic shock syndrome and TLR recognition of self-peptides can result in autoimmunity. Therefore, appropriate and regulated activation of TLRs is crucial for clearance of an invading pathogen and repair of tissue injury with minimal host damage.

8.3 C-type Lectin Receptors

C-type lectin receptors (CLRs) are a large class of proteins characterized by the presence of a C-type lectin-like domain (CTLD) responsible for ligand recognition [74]. CLRs can be found as both soluble and transmembrane proteins that are able to recognize a wide variety of PAMPs and/or DAMPs as well as endogenous ligands. They have traditionally been regarded as carbohydrate-binding receptors; however, they can also bind lipid and protein ligands. Classical carbohydrate-binding CLRs can be divided in two broad groups based on motifs present in the CTLD; those that bind mannose-type carbohydrates via their EPN motif and those that bind galactose-type carbohydrates via their QPD motif [75,76]. For clustering purposes, CLRs have been divided into 17 groups based upon domain organization and phylogeny [76]. Here, we describe a few of the more well-known CLRs, most primarily originating from groups II and V and also from group III, which have established roles in antimicrobial innate immunity and emerging roles in adaptive immunity.

8.3.1 DC-SIGN

One of the most intensively studied CLRs is DC-specific ICAM3-grabbing nonintegrin (DC-SIGN) within group II. As the name suggests, it is expressed in dendritic cells and recognizes fucose and mannose structures via a single extracellular CTLD. Structurally, it is a transmembrane protein with an extracellular stalk of seven complete and one partial tandem repeat with a CTLD and a short cytoplasmic domain with several sorting motifs [77]. Functionally, it exists as a tetramer. DC-SIGN is able to bind a wide variety of pathogens such as HIV-1, *Aspergillus fumigatus*, *Candida albicans*, *Mycobacterium tuberculosis*, and *H. pylori*, for example [78]. It signals through dileucine (LL) and triacidic (EEE) motifs in its cytoplasmic tail. In addition, this receptor can tailor the immune response depending on the pathogen encountered through the formation of the DC-SIGN complex. This complex consists of several proteins including, Raf-1, and scaffold proteins, LSP1, KSR1, and CNK. Raf-1, a serine/threonine MAP kinase, is activated by DC-SIGN and is involved in the acetylation of p65, an NF-κB subunit, which enables prolonged transcription of the IL-10 gene [79]. Recently, triggering of DC-SIGN by fucose and not mannose was shown to activate IKK-ϵ and induce the polarization of T follicular helper cells through the

production of IL-27 [80]. T follicular helper cells play an important role in the induction of the humoral immune response against invading pathogens. Several human polymorphisms in DC-SIGN have been described and, for example, have been shown to increase susceptibility to potentially lethal invasive pulmonary aspergillosis caused by *Aspergillus* infection [81].

8.3.2 Mannose Receptor

The mannose receptor (MR) is a calcium-dependent endocytic receptor within group I that has established roles in homeostasis and immunity. Structurally, it is composed of an extracellular region containing a cysteine-rich (CR) domain, a domain containing fibronectin type two repeats (FNII) and multiple CTLDs, a transmembrane domain, and a short cytoplasmic tail. The cysteine-rich and fribronectin domains recognize endogenous ligands [82]. In addition, it binds and internalizes glycoproteins and immune complexes that contain mannose, fucose, and *N*-acetylglucosamine residues. These residues can be found in glycoproteins on the cell surface of various pathogens including *C. alibicans*, *Leishmania donovani*, *Pneumocystis carinii*, and *Mycobacterium* species [83–88]. Mannose-capped lipoarabinomannan (ManLAM), a major component of the mycobacterial cell wall, is an example of a MR ligand. Recognition of ManLAM by MR results in mediation of phagocytosis and subsequent phagolysosome fusion in macrophages. However, MR-deficient mice exhibit no change in antibacterial activity indicating the redundancy of PRRs in pathogen detection [88–90]. More recently, two studies have demonstrated that MR deficiency results in reduced allergen uptake by mouse and human antigen presenting cells suggesting a possible role in allergy development [91,92]. In addition to the recognition of microbial ligands, MR also detects endogenous self-ligands produced during the inflammatory response such as lysosomal hydrolases [93]. Removal of these potentially detrimental serum glycoproteins enables maintenance of tissue homeostasis and resolution of inflammation.

8.3.3 Surfactant Protein D

Surfactant protein D (SP-D) is a hydrophilic C-type lectin protein present in the lung mucosa. It falls within group III of the CLR superfamily and is characterized by four domains: an N-terminus involved in interchain disulfide bonding, a collagen-like domain, a coiled coil neck domain, and a carbohydrate-recognition CTLD. Each SP-D monomer assembles to form a triple helix at the collagen-like domain that further assembles into a dodecamer. A subpopulation of SP-D can also form an oligomer through interaction of their N-termini. SP-D can bind various ligands present on the cell surface of microbes including lipoproteins, glycoproteins, and phospholipids [94]. Its primary function is interaction and subsequent agglutination of the microbe, thereby preventing dissemination. This interaction also enhances phagocytosis due to opsonization of the microbe with SP-D [94–96]. SP-D has also been shown to play an important role in NET formation. During this process, SP-D binds both the NET and the microbial surface, thus promoting neutrophil killing [97]. In

addition, there is evidence suggesting a direct inhibitory effect on the growth of some microbes [98].

8.4 Natural Killer Gene Complex-associated CLRs

The natural killer gene complex, a genetic locus located on chromosome 12p13.1 in humans and 6F3 in mice, encodes several group II and group V CLRs. In mice, members of two receptor families are encoded by this locus, the NKRP1 and Ly49 families. The ly49 family includes activating receptors such as Ly49D and Ly49YH (Klra8) that recognize epitopes of H2-D and H2-K MHC Class I molecules. Recognition of these epitopes plays an important role in regulating NK cell cytotoxicity. Cells expressing reduced levels of MHC Class 1 molecules are targeted for cell death [99]. The Ly49 family also includes inhibitory receptors such as Ly49Q. These receptors suppress NK cytotoxicity and allow for regulated killing of virus-infected or malignant cells [100–102]. In humans, the equivalent of the Ly49 family is known as killer cell Ig-like receptors (KIRs) and recognizes the human leukocyte antigens, HLA-A, HLA-B, and HLA-C.

Several group V CLRs are also encoded by this locus and can be divided into two distinct clusters: the "Dectin-1" and "Dectin-2" clusters. The Dectin-1 cluster includes receptors such as Dectin-1, myeloid inhibitory C-type lectin-like receptor (MICL or CLEC12A), CLEC1, CLEC2, and CLEC9A, while the Dectin-2 cluster encodes receptors such as Dectin-2, CLECSF8 (CLEC4D or MCL), Mincle (CLEC4E), and DCIR (CLEC4A) [103]. The CLRs encoded by these clusters have been studied primarily in the context of antifungal immunity and also play a role in other pathogen infections, immune homeostasis, and autoimmunity. Several of these receptors are expressed in multiple myeloid lineage cells and natural killer cells but are not restricted to these subsets. Structurally, they consist of an extracellular CTLD, a stalk, a transmembrane region, and a cytoplasmic tail that may contain either an immunoreceptor tyrosine-based activation-like motif (ITAM) or its inhibitory counterpart, immunoreceptor tyrosine-based inhibitory-like motif (ITIM). Functionally, CLRs can be clustered into two groups: activation receptors that signal via their cytoplasmic ITAM or via an association with ITAM-bearing adapter molecules such as FcRγ, DAP10, or DAP12 and inhibitory receptors that signal through their cytoplasmic ITIM. The interplay of these two groups enables the fine balance required for immune homeostasis.

8.4.1 Activation Receptors

Upon ligand binding, the ITAM in the cytoplasmic tail of these receptors or associated ITAM bearing adapter molecules are phosphorylated at tyrosines within the consensus sequences, canonical (YxxI/L (6–12)YxxI/L) and hemITAM (YxxI/L), by Src family kinases. Subsequently, spleen tyrosine kinase (Syk) or zeta chain-associated protein kinase 70 (Zap70) are recruited to the phosphorylated ITAM and activate downstream signaling [104].

Natural killer group 2, member D (NK2GD), is an activating receptor expressed on the surface of natural killer (NK) cells as well as some NKT cells, CD8+

cytotoxic T cells, and γδ T cells [105]. Structurally, it is expressed as a disulfide-linked homodimer on the cell surface as either two isoforms, long or short. NK2GD lacks a signaling motif in its intracellular tail and instead associates with signal-transducing proteins DAP10 or DAP12 via charged residues in its transmembrane domain [100,105,106]. Subsequent activation of these proteins results in Syk, PI3YK, Zap70, and growth factor receptor-bound protein 2 (Grb2) signaling cascades [105]. NK2GD has a remarkable range of ligands due to its ability to recognize distantly related homologues of MHC Class I proteins that include proteins like MHC class-I-chain-related protein A (MICA) and B (MICB) [106]. These ligands are expressed at a low level in all cells but are upregulated during infection or malignant transformation [107]. This recognition of "self-induced" ligands is vital for the NK cytotoxic response to a viral-infected or cancerous cell.

Dectin-1 (CLEC7A) recognizes β-1,3-glucans present in the cell wall of several fungal species as well as undefined ligands on mycobacteria and endogenous ligands [108,109]. It has a typical group V type II tansmembrane receptor structure, as described earlier, with a hemITAM sequence [YxxL] and triacidic [DED] motifs present in its cytoplasmic tail [108,110]. Ligand binding induces signaling through the CARD9-Bcl10-MALT1 complex and results in production of key cytokines necessary for the Th1 and Th17 antifungal response as well as other key cellular effects including actin-mediated phagocytosis, production of reactive oxygen species, endocytosis, and DC maturation [111–113]. Stimulation of dectin-1 with β-1,3-glucans on antigen presenting cells induces the differentiation of Th17 and Th1 Cd4+ T cells through the enhanced production of cytokines IL-6, IL-23, IL-1β, and inhibition of IL-12 [78,114,115]. The importance of dectin-1 is demonstrated by the susceptibility of humans with a dectin-1 deficiency to recurrent candida infections, for example [116]. In addition, dectin-$1^{-/-}$ mice are susceptible to *C. albicans*, *A. fumigates*, and *P. carinii* infection [111,117,118]. Dectin-1 also plays an important regulatory role in NET formation by acting as a microbial size sensor. Through this mechanism, neutrophils are able to clear fungal pathogens while minimizing tissue damage caused by aberrant NETosis [119]. In the gut, dectin-1 has also been shown to be essential for the transcytosis of glycosylated secretory IgAs by intestinal microfold (M) cells, which provide protection for the intestinal epithelium against gut pathogens [120].

In addition to its key proinflammatory role during fungal infections, dectin-1 has also been demonstrated to play a role in homeostasis and autoimmunity. Recently, vimentin, a DAMP secreted during inflammation, was identified as an endogenous ligand of dectin-1. Thiagarajan *et al.* demonstrated colocalization of vimentin and dectin-1 in areas of active inflammation and superoxide anion production in human atherosclerotic plaque sections [121]. However, another study has demonstrated that dectin-1 does not play a role in the development of atherosclerotic plaques [122]. In the context of antitumour innate responses, dectin-1-mediated recognition of tumour cells by macrophages and dendritic cells is vital for the induction of an effective tumourcidal response by NK cells [123]. Interestingly, a human polymorphism in the gene for dectin-1 has been linked to a severe form of ulcerative colitis further highlighting the role of dectin-1 in homeostasis [124].

Dectin-2 (CLEC4N) is also fundamental in antifungal immunity and recognizes α-mannans and glycoproteins containing O-linked mannobiose-rich glycans [125,126]. Moreover, dectin-2 has been shown to play a role in the recognition of various fungi including, *C. albicans*, *A. fumigates*, and *C. neoformans* [127,128]. Dectin-2 can recognize the aeroallergen house dust mite extract, a major allergen during asthma. Activation of this receptor on dendritic cells and alveolar macrophages is crucial for induction of airway inflammation via the Th2 response and the development of severe asthma [129–131]. Mechanistically, triggering of dectin-2 results in the generation of cysteinyl leukotrienes and Th2 cytokines, such as IL-10 and IL-23, which drive Th2 pulmonary inflammation to the major allergen, house dust mite [131]. Signaling occurs through the CARD9-Bcl10-MALT1 complex, similar to dectin-1, but requires an FcRγ signaling adapter bearing an ITAM motif to initiate the cascade [125,132]. Interestingly, several groups have demonstrated that dectin-2 and not-dectin-1 is crucial for the induction of Th17 cell differentiation, important for the defence against fungal infections in humans [128,132].

Mincle (CLEC4E) is predominantly involved in the recognition of mycobacteria but has also been shown to recognize *Candida*, *Malassezia*, and *Fonsecaea* species [133,134]. Several Mincle ligands have been identified including α-mannose, mannitol-linked glyceroglycolipid, mannosyl fatty acids, and trehalose dimycolate (TDM). Furthermore, Mincle acts as a heterotrimeric complex with CLECSF8 (otherwise known as CLEC4D or MCL) and FcRγ to bind mycobacterial cord factor (TDM), for example [135–137]. While Mincle knockout mice do not exhibit an obvious defect during mycobacterial infection, loss of CLECSF8 results in increased inflammation, bacterial burdens, and mortality [138–140]. In humans, a CLECSF8 polymorphism has been identified and is associated with an increased risk of pulmonary tuberculosis [138]. Mincle is also involved in the sensing of damaged cells through recognition of SAP130 providing a homeostatic role for this receptor [141]. Recently, elevated levels of Mincle and SAP130 in the brain and cerebrospinal fluid following traumatic brain injuries were suggested to contribute to inflammation-induced pathology associated with this injury [142].

8.4.2 Inhibitory Receptors

Inhibitory CLRs such as myeloid inhibitory C-type lectin (MICL) and dendritic cell immunoreceptor (DCIR) have been shown to play fundamental roles in autoimmunity and immune homeostasis. These receptors are identified by the presence of ITIMs (I/V/L/SxYxxI/L/V) in their cytoplasmic tails and inhibit cellular activation through a dephosphorylation cascade.

MICL (CLEC12A) is expressed on myeloid cells and recognizes the endogenous ligand, monosodium urate microcrystals (MSU) [143,144]. MSU, the causative agent of gout, is formed when soluble uric acid is released into the extracellular matrix following disruption of the cell membrane. MICL is, therefore, the first inhibitory CLR identified that can bind dead cells [145]. It has been identified as a biomarker in acute myeloid leukaemia but more recently been implicated in rheumatoid arthritis and may control myeloid cell activation during this disease [146,147].

DCIR (CLEC4A) is primarily expressed on antigen presenting cells and is believed to play an immune inhibitory function. Although the ligand for this receptor has not been identified, studies have demonstrated several negative regulatory effects on other receptors including TLR8, TLR9, and B cell receptor [148,149]. In addition, DCIR has been shown to be crucial in the induction of regulatory T cells as well as limiting tissue injuring during Chikungunya virus-induced inflammation, for example [150,151]. Recently, DCIR has been used as a target to improve vaccine responses induced by a HIV Gagp24 protein fused to a DCIR monoclonal antibody. In nonhuman primates, this approach yielded a strong anti-Gagp24 antibody response and may be a promising strategy for HIV vaccines [152]. In the case of autoimmune diseases, DCIR polymorphisms in humans have been associated with both rheumatoid arthritis, systemic lupus erythematosus (SLE), and primary Sjogren's syndrome in the Chinese population [153,154]. Moreover, there is evidence of an immune regulatory role for DCIR in the development of experimental autoimmune encephalomyelitis (EAE), an autoimmune disease model for multiple sclerosis [155]. This receptor may prove to be very useful in the study of the pathology of several autoimmune diseases as well as in future vaccine strategies.

8.4.3 CLR Signaling

C-type lectin receptors in the dectin-1 and dectin-2 cluster signal via Syk-dependent and Syk-independent pathways summarized in Figure 8.3. These pathways lead to the activation of several transcription factors including NF-κB, NFAT, and AP-1 [156]. In the case of activation receptors, phosphorylation of tyrosine residues within the ITAM induces the recruitment of Syk. Following activation, Syk phosphorylates phospholipase C (PLC)γ2 leading to activation of protein kinase C (PKCδ). In turn, PKCδ phosphorylates the heterotrimeric CARD9-Bcl10-MALT1 complex to induce NF-κB translocation to the nucleus. PLCγ2 also promotes calcium release from the endoplasmic reticulum that drives the calcineurin-NFAT pathway.

Syk also causes the noncanonical activation of NF-κB through NK-κB-inducing kinase (NIK) [157,158]. Dectin-1 also mediates a Syk-independent pathway via activation of Raf-1 by Ras (Figure 8.3). Ras interacts with the triacidic motif (DED) in the cytoplasmic tail of dectin-1. Activation of Ras leads to activation of Raf-1 that in turn phosphorylates p65, a subunit of NF- κB. Phosphorylation of p65 results in the formation of p65-RelB dimer that sequesters active RelB and promotes Th1 cytokine gene transcription [79].

In the case of inhibitory receptors, ligand binding induces phosphorylation of tyrosine residues in the consensus sequence of the ITIM by Src kinases. This results in the recruitment of SH2 domain-containing protein tyrosine phosphatises, including SHP-1 and SHP-2, which are able to directly regulate signaling downstream of ITAM motifs through inhibition of Syk [103].

Similar to TLR signaling via MyD88, there is a convergence of downstream signaling of CLRs via the CARD9-Bcl10-MALT1 complex. Humans with a CARD9 deficiency are extremely susceptible to invasive candidiasis and other fungal infections highlighting the central role of CARD9 [159]. In addition,

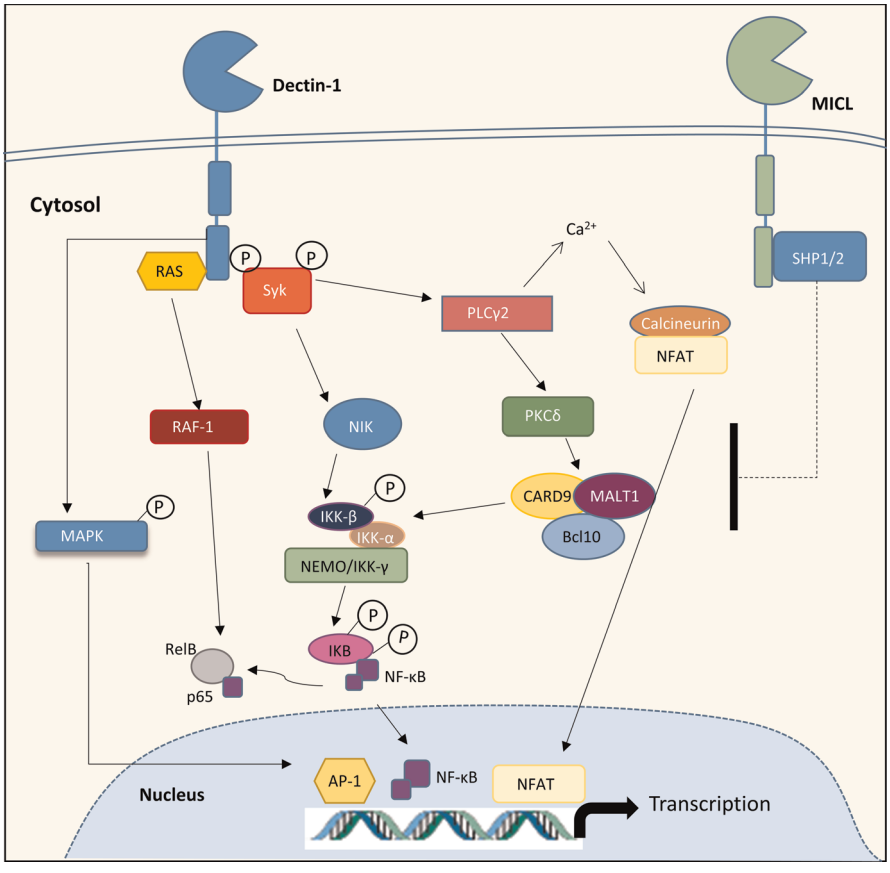

Figure 8.3 CLR signaling pathway. Activation receptors such as dectin-1 signal via Syk. This leads to activation of the CARD9-MALT1-Bcl10 complex via PLCγ2 and PKCδ. CARD9 promotes phosphorylation of the IKK complex resulting in NF-κB activation. Syk can also activate NF-κB via the noncanonical NIK pathway. PLCγ2 promotes calcium release from the endoplasmic reticulum that drives the calcineurin-NFAT pathway. Dectin-1 also signals via the Syk-independent activation of RAF-1. Activation of the RAF-1 pathway results in the formation of a RelB-p65 dimer and modification of gene transcription. Inhibitory receptors such as MICL phosphorylate SHP-1 and SHP-2 enact their downstream inhibitory function.

CARD9-deficient mice exhibit a high mortality during mycobacterial infection due to exacerbated neutrophilic pulmonary inflammation and uncontrolled bacterial replication [160].

8.5 RIG-1-like Receptors

The RIG-1-like receptor family consists of RNA-binding proteins that are expressed in almost all cells and are predominantly responsible for viral recognition in the cytoplasm. Family members include RIG-1, melanoma

differentiation-associated gene 5 (MDA5), and laboratory of genetics and physiology 2 (LGP2) [3]. Structurally, RLRs are RNA helicases characterized by two N-terminal caspase recruitment domains (CARDs), which LGP2 lacks, a central DEAD box helicase/ATPase domain and a C-terminal regulatory/repressor domain. They recognize dsRNA as a replication intermediate of ssRNA viruses and genome content of dsRNA viruses [161].

RIG-1 detects short dsRNA that is 5′ triphosphorylated and lacks a 7′ methylguanosine cap [162–164]. In contrast, MDA5 recognizes long dsRNA (more than 2Ykb), and the synthetic analog, poly I:C. [165–168]. Although LGP2 possess the ability for RNA binding, it has not been shown to be crucial for viral RNA recognition and is rather thought to act as a regulator of RIG-1 and MDA5 signaling [169]. RIG-1 and MDA5 signal via activation of IRF3 and NF-κB through the adapter, mitochondrial antiviral signaling protein (MAVS) (also known as IPS-1). Subsequently, transcription of antiviral type 1 interferon genes is upregulated and leads to an antiviral Th1 immune response. RIG-1 and MDA5 have been reported to play a role in immune defense against viruses such as Ebola, measles, dengue, hepatitis C, and many more [170–174].

Recently, a key mutation in the RLR MDA5 rendered this receptor unresponsive to dsRNA but induced lupus-like symptoms in mice [175]. This link between RLR activation and autoimmunity was further confirmed through the discovery of several mutations in humans with three different autoimmune diseases: Aicardi–Goutieres syndrome (AGS), SLE, and Singleton–Merten syndrome (SMS) [176–178]. Interestingly, these mutations all lie within the conserved RNA helicase domain of either MDA5 or RIG-1. A common theme in these diseases and several other autoimmune diseases is the presence of elevated type 1 interferon cytokines, termed the "interferon signature," which drive disease pathogenesis and have since become the target of several therapies [179,180].

8.5.1 RLR Signaling

In uninfected cells, RLRs are maintained in a "closed" conformation with the repressor and CARD domains folded over the PAMP-binding helicase domain as shown in Figure 8.4 [181]. Upon RNA binding, RIG-1 and MDA5 hydrolyze ATP, thereby releasing the CARD domain for oligomerization and enhancing the interaction with MAVS/IPS-1 [182–185]. This oligomerization is further promoted by ubiquitination at N-terminal sites by TRIM25 proteins [186,187]. RIG-1 then translocates from the cytoplasm to the mitochondrial-associated membrane (MAM) where it interacts with IPS-1 [188]. Interaction with IPS-1 leads to activation of TBK1 and IKK-ϵ via TRAF3, TANK, and TRADD. Activated TBK1 and IKK-ϵ subsequently activate the transcription factors IRF3 and IRF7 leading to their translocation to the nucleus [189,190]. Simultaneously, IPS-1 activates NF-κB via RIP1, FADD, and caspase-8/-10. In addition, IPS-1 activates the MAP kinase cascade and subsequent AP-1 activation. As a result, antiviral type 1 interferon genes and proinflammatory cytokines are upregulated and the immune response is initiated.

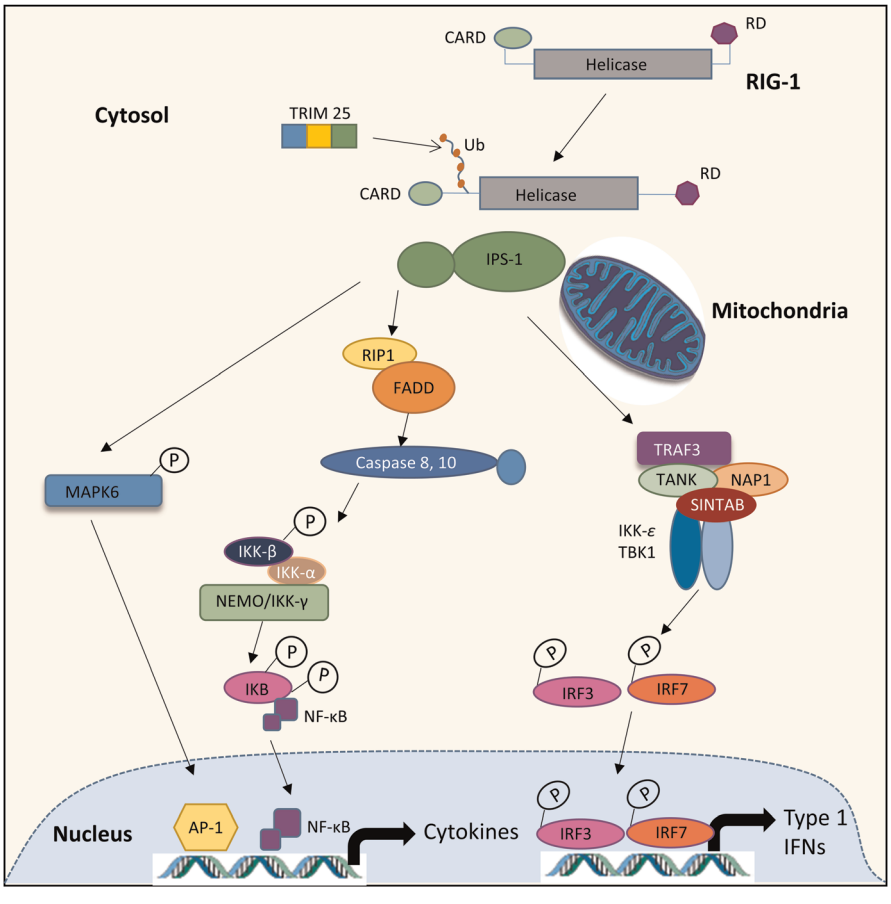

Figure 8.4 RLR signaling pathway. Activation and ubiquitination of RIG-1 induces a conformational change releasing its CARD domain and enhancing interaction with IPS-1. Resultant activation of IPS-1 leads to activation of NF-κB through RIP-1-FADD and caspase-8/-10. IPS-1 simultaneously activates the transcription factors IRF3 and IRF7 via TRAF3.

8.6 NOD-like Receptors

The NLR family consists of 20–30 (34 in mice) cytosolic receptors that have been categorized structurally into five subsets based on their N-terminal effector domain: NLRA, NLRB, NLRC, NLRP, and NLRX. Structurally, NLRs possess a C-terminal leucine-rich repeat domain, a central nucleotide oligomerization domain (NOD), and an N-terminal effector domain used for classification as summarized in Figure 8.5a [191]. NLRA contains an acidic transactivation domain, NLRB, with a baculovirus inhibitor of apoptosis protein repeat, NLRC, with a CARD domain, NLRP, with a pyrin domain and NLRX, has an uncharacterized N-terminal domain (Figure 8.5a) [192]. Traditionally thought to counteract intracellular pathogens by recognition of microbial ligands in the

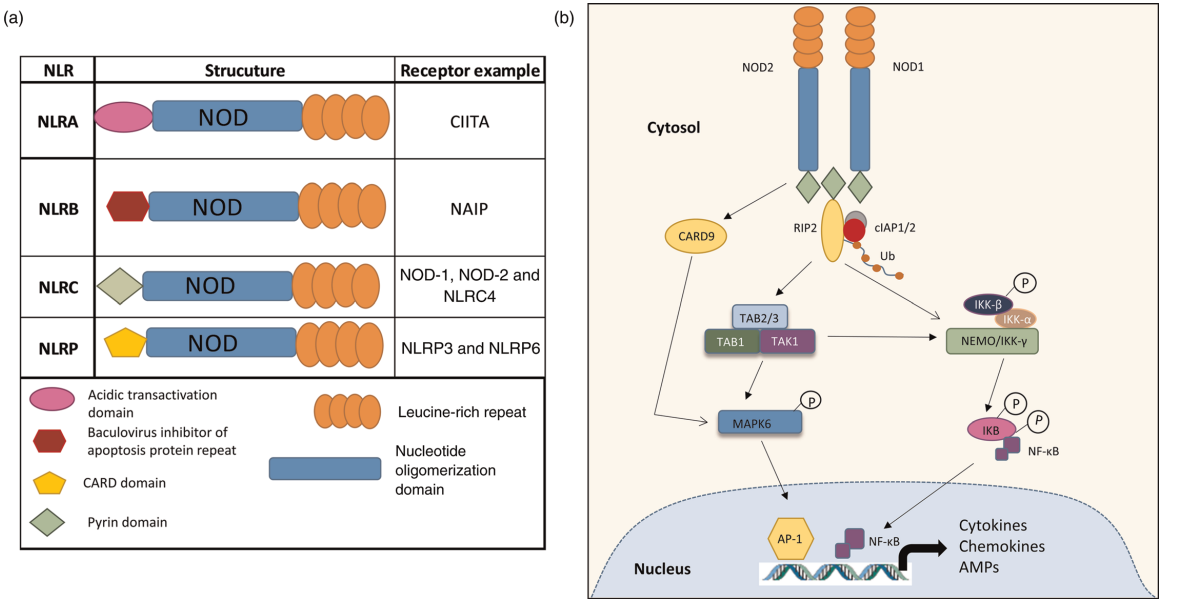

Figure 8.5 NLR classification and signaling pathway. (a) NLR structural classification and receptor examples. (b) NOD1 and NOD2 initiate signaling via activation of RIP2. Ubiquitinated RIP2 activates the IKK complex directly or the TAB1-TAB2/3-TAK1 complex, both of which result in NF-κB activation. Simultaneously, the TAB1-TAB2/3-TAK1 complex activates MAPK6 and initiates the MAPK cascade resulting in AP-1 activation. NOD2 also mediates AP-1 activation via CARD9.

cytosol, NLRs have also been implicated in sensing metabolic changes in the cell, cell death, embryo development, and modulation of inflammation [193–198]. Here, we briefly discuss selected receptor examples from the NLRC and NLRP families.

8.6.1 NOD1 and NOD2

NOD1 and NOD2 within the NLRC family are perhaps the most intensively studied, while NLRPs follow closely behind. NOD1, first identified through sequence homology searches, is expressed in a wide variety of cells including phagocytic cells, dendritic cells, intestinal epithelial cells, lung epithelial cells, and endothelial cells [199–203]. This receptor recognizes mainly Gram-negative and certain Gram-positive bacteria, through peptidoglycan (PGN) fragments from the cell wall containing the *N*-acetlyglucosamine-*N*-acetlymuramic acid tripeptide motif with diaminopimelic acid (DAP) [204–206]. NOD2, closely related to NOD1, contains an extra CARD domain and is also expressed in phagocytic cells, paneth cells, and stem cells within the small intestine and bronchial cells in the lung [207–210]. It detects muramyl dipeptide (MDP), a motif of PGN from both Gram-negative and Gram-positive bacteria [205].

NOD1- and NOD2-deficient mice show enhanced susceptibility to several pathogens [211–214]. Expression of NOD1 and NOD2 in the intestinal epithelium is crucial in the control of enteric bacterial infections caused by *Shigella*, *Salmonella*, *Listeria*, *Yersinia*, pathogenic *Escherichia coli* strains and *Mycobacterium* species [205,212,215–217]. Meanwhile in the lung, NOD1 responds to pathogens such as *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Chalmydophila pneumoniae*, and *Legionella pneumophilia* [218–222]. In contrast, NOD2 detects *Streptococcus pneumoniae*, *S. aureus*, *E. coli*, *C. pneumoniae*, and *M. tuberculosis* [8,215,223–227]. Ultimately, NOD1 and NOD2 ligation triggers NF-κB activation and subsequent production of proinflammatory cytokines and antimicrobial molecules [228,229]. As such, bacterial pathogens have evolved mechanisms to evade detection and clearance by the NLR-mediated host defense. One of these ways has been described for *L. monocyogenes* and *H. pylori* that evade detection by NOD1 through modification of cell wall PGNs [191,230].

In addition to their role in innate immune response, NOD1 and NOD2 signaling has been implicated in adaptive immune responses. The NOD2 ligand, MDP has been identified as an adjuvant of antigen-specific IgG responses [228,231]. Furthermore, NOD2 and NOD1 stimulation alone induces a predominantly Th2 adaptive immune response in mice [195,232].

Interestingly, human polymorphisms in NOD2 have been linked to Crohn's disease [207,233]. Individuals with genetic variants in NOD2 have a significantly increased risk of developing Crohn's disease, up to 40-fold [234,235]. The mechanisms by which these variants contribute to disease development are controversial; however, it is thought that impaired bacterial recognition and clearance leads to uncontrolled inflammation through NOD2-independent pathways [236].

Although the exact mechanism by which bacterial PGN fragments enter the cytosol is unknown, several routes of entry have been reported. Most recently,

Nakamura *et al.* demonstrated that MDP is transported across the membrane of phagosomes via two peptide transporters, SLC15A3 and SCL15A4 [237]. This is supported by reports demonstrating decreased NOD1-mediated cytokine production in SLC15A3-deficient mice [238]. Other routes of entry include endocytosis, endosomal membrane transporters, bacterial secretion systems, or outer membrane vesicles.

8.6.2 NOD1 and NOD2 Signaling

NOD1 and NOD2 bind cytosolic peptidoglycans and initiate an antibacterial proinflammatory response via the signaling pathways depicted in Figure 8.5b. Following ligand binding, receptor-interacting serine/threonine protein kinase 2 (RIP2) is recruited to the CARD domain of NOD and undergoes ubiquitination by cellular inhibitor of apoptosis protein 1 and 2 (cIAP1 and cIAP2) [199,239,240]. Polyubiquitinated RIPk-2 then interacts with the TAK-1-TAB2/TAB3 complex and the IKK complex [241,242]. TAK-1 is phosphorylated and activates MAPKs p38/JNK and NF-κB pathways. This leads to IKK complex activation and subsequent phosphorylation of IκB that then undergoes polyubiquitination and degradation through the proteasome. Degradation of IκB allows for NF-κB translocation to the nucleus. NOD2 can also induce the noncannonical NF-κB pathway through interaction with NF-κB-inducing kinase (NIK) that in turn activates the p100/p52-dependent NF-κB pathway [243].

8.6.3 NLRC4

NLRC4 is a cytosolic NLR that triggers inflammasome formation in response to bacterial flagellin or components of type 3 bacterial secretion systems (T3SS). It is expressed in myeloid cells as well as intestinal epithelial cells [244]. Similar to the function of TLR5, NLRC4 plays not only an important role in control of the intestinal microflora but also a protective role in the airways. It has been shown to protect mice during pulmonary infection with several bacteria such as *K. pneumoniae* and intestinal infection with *Salmonella typhimurium*, for example [245,246]. Recently, a missense mutation identified in the NLRC4 gene in humans has been linked to a hereditary autoinflammatory disease, familial cold autoinflammatory syndrome (FCAS). This mutation resulted in aberrant NLRC4 inflamasome activation and subsequent IL-1β production leading to uncontrolled inflammation [247]. This study highlights the importance of this receptor not only in bacterial infections but also in the development of autoimmunity.

8.6.4 NLRPs

NLRPs are involved in the formation of the inflammasome that consists of one or two NLR proteins, apoptosis-associated speck-like containing a CARD domain (ASC) adapter molecule and procaspase-1 [191,248]. The NLRP3 inflammasome, expressed in myeloid cells, formed with NLRP3 as its scaffold, mediates the conversion of pro-IL-1β and pro-IL18 to their active forms, IL-1β and IL-18 [249]. These potent proinflammatory cytokines are involved in a mechanism of cell

death termed pyroptosis [249]. NLRP3 is activated by several pathogenic lung microorganisms such as *S. pneumoniae*, *M. tuberculosis*, *A. fumigatus*, influenza virus, and many more [210,250–252]. In addition, there is an emerging role in defense against enteric pathogenic *Clistridium difficile* and *Citrobacter rodentium* [217]. However, there is no evidence for direct ligand binding to NLRP3 in any of these infections. Interestingly, NLRP3 inflammasome production of IL-18 and its subsequent signaling has a protective role against intestinal inflammation during a colitis murine model [253]. The NLRP3 inflammasome is also required for chemotherapy-mediated antitumor response during colorectal cancer. During chemotherapy, dying cells release ATP, thereby activating the NLRP3 inflammasome. This results in IL-1β secretion and subsequent activation of IFNγ producing cytotoxic T lymphocytes that target malignant cells [254].

Aberrant activation of the inflammasome has also been linked to multiple autoimmune diseases. Genetic activation of NLRP3 is associated with multiple autoimmune cryopyrinopathies such as cryopyrin-associated periodic fever syndromes (CAPS), FCAS, MWS (Muckle–Wells syndrome), and NOMID (neonatal onset multisystem inflammatory disorder) [255]. Symptoms of these cryopyrinopathies include periodic fevers, rashes, and arthralgia and can be treated with IL-1β-targeted therapies [256].

NLRP1, a less characterized inflammasome, is activated by the lethal toxin of *Bacillus anthracis* and induces rapid cell death [248,257]. NLRP1 is expressed in myeloid cells, lymphoycytes, and respiratory epithelial cells [258]. As a more recent example, *T. gondii* infection of mice and rats has been shown to activate the NLRP1 inflammasome [259].

NLRP6-deficient mice are resistant to infection with several pathogens such as *L. monocytogenes*, *S. Typhimurium*, and *E. coli* due to enhanced production of proinflammatory cytokines [260]. It is thought that this inflammasome is essential for homeostasis and restriction of commensal bacterial [261]. Despite evidence for these roles, the exact ligand for this receptor remains to be determined.

NLRPs can also negatively control the inflammatory response by reducing NF-κB activation and IFNβ production [262,263]. As an example, NLRP6 inhibits downstream TLR signaling [260,264]. This response may be important in regulating the immune response to gut microflora [264]. NLRP12, another negative regulator of inflammation, expressed in myeloid cells, regulates TLR- and TNFα-induced signaling [265,266]. These roles are crucial for immune and metabolic homeostasis.

8.7 DNA-sensing Molecules

Pathogen DNA or RNA is an important PAMP released during infection with DNA viruses, RNA viruses, or with intracellular bacteria such as *L. monocytogenes* and *L. pneumophila*. Following the discovery of TLR9, there has been a search for alternative foreign nucleic acid receptors. As such, several DNA sensors have been discovered and have been shown to be pivotal in multiple viral and bacterial infections as well as autoimmunity. Although not a formal PRR family, some of these proteins share structural similarity and have since been termed the AIM2-

like receptors (ALRs). These receptors all result in the transcription of type I interferon genes and subsequent proinflammatory phenotype. Here, we briefly mention a few examples of ALRs and others with their respective ligands and signaling mechanisms.

DNA-dependent activation of IFN regulatory factors (DAI) was the first TLR9-independent sensor to be identified [267]. DAI interacts directly with DNA and can signal via the receptor interacting proteins, RIP1 and RIP3, to facilitate NF-κB activation [268,269]. In addition, DAI can also signal via TBK-1 in a STING-dependent manner. The current proposed ligand is AT-rich B form DNA [267].

RNA polymerase III is an indirect sensor of AT-rich DNA. It performs this function by transcribing AT-rich dsDNA into 5′ triphosphate-containing dsRNA, a ligand of RIG-1 [161,270]. Activation of RIG-1 induces signaling via MAVS/IPS-1 and finally the transcription of interferon genes as described above. The RNA polymerase III-dependent pathway has been implicated in sensing of ligands such as Epstein–Barr virus (EBV) RNA as well as HSV-1, adenovirus, and *L. pneumophila* DNA, for example [271,272]. However, it is difficult to fully elucidate the contribution of this enzyme as it is essential for cell survival.

The leucine-rich repeat-containing protein (LRRFIP-1) recognizes AT-rich B-form dsDNA as well as GC-rich Z-form dsDNA. Stimulation of this receptor results in the production of IFN-β through β-catenin rather than NF-κB or IRF3 activation [273]. LRRFIP-1 triggers phosphorylation of β-catenin, which then binds to the C-terminal domain of the transcription activator IRF3 and induces IFN-β expression [273]. This response can be induced through infection of macrophages with vesicular stomatitis virus (VSV) and *L. monocytogenes*, thereby suggesting a role for this receptor during these infections [273].

More recently, a new PRR family has emerged, termed the AIM2-like receptors or more specifically the pyrin and HIN domain (PYHIN) family. This family consists of four members AIM2, MNDA, IFI16, and IFIX. AIM-2 (Absent in Melanoma 2), a cytosolic dsDNA sensor, activation results in the assembly of the inflammasome [274]. Upon activation, AIM2 interacts with ASC, a common adapter of inflammasomes, which leads to cleavage of caspase-1 and production of IL-1β and IL-18 [275]. This receptor plays a central role in the sensing of pathogens including *Francisella tularensis*, vaccinia virus, and mouse cytomegalovirus, for example [275–277]. IFI16 is proposed to sense viral DNA in the nucleus and mediates inflammasome activation of AIM2 as well as IFN-β induction [278]. Following activation, IFI16 recruits stimulator of interferon genes (STING) to activate a TBK1-IRF3-dependent signaling cascade as well as NF-κB activation to intiate an inflammatory response. This response can be induced by DNA oligonucleotides or HSV-1 infection.

8.7.1 Signaling Components of DNA-sensing Molecules

STING is a transmembrane protein present on the endoplasmic reticulum that induces the expression of IFN-β following detection of DNA ligands. It acts as a crucial signaling molecule downstream of DNA sensors such as DAI and upstream of the signaling adapters, TBK1 or IKKβ [279]. STING-dependent signaling has been shown to be crucial for the recognition of viruses such as HIV-

1 and bacteria such as *F. tularensis* [280]. TBK1 directly phosphorylates and activates the transcription factor IRF3, while STING induces the phosphorylation and subsequent degradation of IKKβ resulting in NF-κB activation. IRF3, NF-κB, and IRF7 activation all result in the transcription of type 1 interferon genes crucial for the antiviral or intracellular antibacterial response.

8.7.2 Cross-talk between PRRs

In addition to cross-talk between PRRs within a specific family, there is also cross-talk across PRR families. It is important to note that under physiological conditions there is participation of several PRRs that may act in a collaborative effort to increase the efficiency of the immune response. As microbes can be sensed by multiple PRRs, it is not surprising that in most cases, a loss in one PRR has only modest effects on pathogen clearance *in vivo*. The collaborative effort during bacterial infection has been demonstrated through costimulation experiments of multiple cell subtypes with NOD1/2 and TLR2/4/9 agonists. Costimulation induces a synergistic effect on the expression of proinflammatory cytokines such as TNFα, IL-12p40, and IL-6 [281–283]. As an additional example, NOD1 and TLR4 cooperate to mobilize mature hematopoetic stem cells in the spleen in response to an *E. coli* infection [284].

In the case of viral infection, TLR3 and RLRs can function together leading to enhanced antigen presentation by dendritic cells [285]. RNA viral infection may also induce inflammasome activation through the RLR signaling protein MAVS/IPS-1 [286]. This cross-talk may be particularly important in prevention of viral spread by inflammasome-induced pyroptosis.

During antifungal immunity, dectin-1, a CLR, has been shown to collaborate with TLR4 and TLR2 [287]. In addition, there is evidence to support a functional interaction between dectin-1 and DC-SIGN [288]. Chromoblastomycosis, a chronic skin infection caused by the fungal pathogen *F*onsecaea *pedrosoi*, occurs due to a lack of PRR costimulation. *F. pedrosoi* is recognized only by CLRs and not TLRs, thus resulting in defective proinflammatory cytokine production and chronic infection [289]. Notably, when patients suffering from a chronic chromoblastomycosis infection were treated with imiquimod, a TLR agonist, all four recipients exhibited a marked improvement in their skin lesions [290]. This finding highlights the importance of the collaborative action of CLRs and TLRs in the initiation of an effective innate immune response. In contrast, in order to maintain homeostasis, it is equally likely that there is a negative regulatory effect both within and across the PRR families as mentioned above. However, in many cases, this area is almost completely unstudied.

8.8 Conclusions

Activation of PRRs by PAMPs or DAMPS is essential for the initiation of the innate immune response and triggering of the adaptive immune response. Identifying these innate immune sensors has drastically improved our

understanding of not only how the host defends itself against pathogens but also the development of autoimmunity and immune homeostasis. The implications of this research are not only for the enhancement in the knowledge of basic immunology but also therapeutically with advances in vaccine responses through adjuvant studies and novel drug treatments for infection, autoimmunity, and even cancer. Defining the ligands for these PRRs as well as the dynamic cross-talk of PRRs will continue to aid the clinical aspects of this field of research. In addition, identifying the association of diseases and human PRR polymorphisms and mutations provides valuable insight into the role of these receptors.

Acknowledgments

We thank the University of Aberdeen, Wellcome Trust, and MRC (UK) for funding this study.

Part Two

Inflammatory Cells

9

Monocytes and Macrophages

Irina N. Shalova, Shilpi Saha, and Subhra K. Biswas

9.1 Introduction

Monocytes and macrophages are not only immune cells that serve as the first line of host defense but also key players in organogenesis and development [1]. To perform these distinct roles, monocytes and macrophages show immense functional diversity: triggering inflammation, killing pathogens, tissue remodeling and repair, and immunoregulation [2]. Thus, understanding how these cells perceive different microenvironmental cues and translate them into a "tailored" response as well as how a dysregulation in this process might lead to pathogenic outcomes is of paramount importance. In this chapter, we present a brief account of monocytes and macrophages, focusing on their ontogeny, activation, function, and the molecular mechanism regulating their functional plasticity and diversity.

9.2 Origin and Differentiation

Monocytes differentiate from macrophage/dendritic cell precursor (MDP) in the bone marrow and are released into the circulation from where they are recruited to the tissues under homeostatic or pathological conditions [3]. Based on the differential expression of chemokine receptors CCR2 and CX3CR1, two main subsets of monocytes have been described in mouse: the $Ly6C^{hi/+}CCR2^{+}CX3CR1^{int}$ inflammatory monocytes and the $Ly6C^{lo/-}CCR2^{-}CX3CR1^{hi}$ patrolling monocytes [4]. Corresponding to these murine subsets, inflammatory monocytes in humans correlate to the $CD14^{+}CD16^{-}$ and $CD14^{+}CD16^{+}$ monocytes, whereas patrolling monocytes correlate to the $CD14^{dim}CD16^{+}$ monocytes [5]. Inflammatory monocytes are recruited to the sites of inflammation and infection where they release proinflammatory cytokines to mediate the inflammatory process. In contrast, patrolling monocytes patrol the vasculature, sensing and scavenging cellular

debris [6,7]. Patrolling monocytes are particularly good at sensing danger signals that stimulate Toll-like receptors (TLRs) 7 and 8 as compared to the inflammatory monocytes that are better at sensing bacteria-related danger signals [5]. Interestingly, a temporal recruitment of respective monocyte subsets has been reported by Auffray *et al.* 2007 [6] during *Listeria* infection, with the patrolling monocytes being recruited first to the sites of inflammation and subsequently inducing the recruitment of inflammatory monocytes (see Section 9.4.4 for further details). More recently, inflammatory and patrolling monocytes have also been shown to have important functions in cancer, with the former contributing to cancer-related inflammation and tumor progression [8–10], while the latter in preventing tumor progression by helping in the natural killer (NK) cell-mediated clearance of metastatic cancer [11]. It was suggested that in the absence of inflammation, mouse inflammatory monocyte subset home back to the bone marrow, where they possibly give rise to the patrolling monocytes [3]. Recent data with fate mapping experiments have indicated $Ly6C^{+}CCR2^{+}CX3CR1^{int}$ monocytes serve as short-lived, obligate precursors for $Ly6C^{-}CCR2^{-}CX3CR1^{hi}$ monocytes under steady state and regulate their life span [12].

For long, it was believed that under steady-state conditions, blood monocytes enter the tissues and differentiate into tissue-resident macrophages. However, fate mapping approach in the last few years has challenged this idea. Except for inflammatory conditions and certain tissue macrophages (e.g., intestinal macrophages), monocytes do not substantially contribute to the differentiation and maintenance of adult tissue macrophages. It is now well accepted that embryonic precursors seed tissues prior to birth and give rise to most adult tissue macrophages, which maintain themselves thereafter by self-renewal [13]. Furthermore, different tissue macrophages have been shown to have different origins, with some derived from yolk sac macrophages (e.g., microglia), fetal monocytes (e.g., alveolar macrophages and Kupffer cells), or from both of these embryonic progenitors (e.g., Langerhans cells), or from adult blood monocytes (e.g., gut) [1]. It is now known that yolk sac erythro-myeloid progenitor (EMP) serve as the embryonic precursor of yolk sac macrophages and fetal monocytes [14,15]. An early wave of c-Myb-independent EMP gives rise to yolk sac macrophages followed by a later wave of $c\text{-}Myb^{+}$ EMPs that gives rise to fetal liver monocytes that following recruitment to the fetal tissues differentiate into the majority of the adult tissue macrophages. However, gut is the only exception that relies exclusively on adult blood monocytes to give rise to intestinal macrophages. In contrast to these steady-state situations, blood monocytes serve as the main precursors of macrophage during infection and inflammation. An exception to this condition is helminth infection as well as adipose tissues, where the macrophages self-renew [16,17].

Colony-stimulating factor-1 (CSF-1) and its receptor (CSF-1R), which is expressed in monocytes and macrophages, is the major regulator of macrophage differentiation. More recently, interleukin-34 (IL-34) was also suggested to contribute to macrophage differentiation, especially in the brain (microglia) and skin (Langerhans cells) [18,19]. Similarly, granulocyte-macrophage colony stimulating factor (GM-CSF) was found to be essential for the differentiation of alveolar macrophages [20], while vascular endothelial growth factor (VEGF)

contributed to the development of osteoclasts [21]. Besides these, the tissue microenvironment also plays an important role in shaping the phenotype of tissue resident macrophages. This is supported by experiments where embryonic-derived macrophages were replaced by adult bone marrow-derived cells upon infection or inflammation, with the latter recapitulating the phenotypic, gene expression, and functional features of the preexisting population [22–24]. As explained above, our understanding of the origin and differentiation of monocytes and macrophages have undergone phenomenal changes in the past few years. However, several issues such as the relationship between monocyte subsets and macrophages differentiated thereof, the identification of specific microenvironmental factors that shape the differentiation and phenotype of different tissue macrophages, and the relative contributions of tissue resident versus monocyte-derived macrophages during pathological conditions await future investigations.

9.3 Activation and Polarization

Monocytes and macrophages are equipped with the ability to respond to their local microenvironmental cues and danger signals by eliciting a functional phenotype that helps them to adapt to or mitigate these conditions. Often, such responses are tailored according to the stimuli these cells encounter. For example, Gram-negative bacterial pathogens (or its product like lipopolysaccharide, LPS) would induce macrophages to produce inflammatory cytokines and antimicrobial products aimed at inducing a full-fledged immune inflammatory response and killing of the pathogen. In contrast, upon encountering tissue microenvironmental stimuli like CSF-1, macrophages trigger an anti-inflammatory phenotype that helps in tissue remodeling and development [2]. Since microenvironmental cues can be immensely diverse and dynamic, these cells can also respond by displaying equally diverse phenotypes as well as switch from one phenotype to the other, paralleling the dynamic changes in their microenvironmental cues. Thus, diversity and plasticity of phenotype and function is a characteristic feature of the monocytes and macrophages [25,26].

Although the functional phenotypes of macrophages can be diverse, early investigators identified two broad activation phenotypes. These include the classical and alternative activation states of macrophages. Classical activation is triggered by inflammatory stimuli such as LPS and interferon gamma (IFNγ) that induces the expression of proinflammatory cytokines (e.g., IL-12, TNF, etc.) and release of reactive nitrogen and oxygen intermediates (RNI and ROI) in macrophages that promotes Th1 effector response and mediates antimicrobial and tumoricidal properties [27,28]. In contrast, alternative activation is triggered by anti-inflammatory cytokines IL-4 or IL-13 wherein macrophages show decreased ability to express proinflammatory cytokines, preferentially metabolize arginine to ornithine via arginase I (Arg1) expression, and show increased scavenger receptor expression and phagocytosis activity [29]. Such alternatively activated macrophages are crucial for the control and clearance of nematode infection [30]. Mills *et al.* [31] noted that macrophages from Th1 mice strains

(C57/B6) and Th2 mice strains (e.g., Balb/c) utilized distinct modes of nitrogen metabolism. Based on this, he proposed that analogous to the Th1 versus Th2 response, macrophages too could display an M1 versus M2 response. Subsequently, this concept was extended by Mantovani *et al.*, who proposed LPS and Th1 cytokines like IFNγ polarized macrophages to the M1 activation state, while those stimulated with anti-inflammatory Th2 cytokines like IL-4, IL-13, or IL-10 polarized them to the M2 activation state, paralleling the Th1 and Th2 nomenclature [32]. Distinct phenotypic and functional characteristics were proposed for M1 and M2 macrophages (see review by Biswas and Mantovani, 2010) [25]. Although different anti-inflammatory stimuli such IL-4, IL-13, IL-10, dexamethasone, or a combination of immune complexes plus LPS can polarize macrophages to a IL-12^{low}IL-10^{high} M2 phenotype, these cells show subtle variations in their phenotypes depending on the particular M2 stimuli used. This led to the proposal of subdivision of M2 phenotype into M2a, b, and c [33] and more recently into M2 (IL-4-polarized macrophages) and M2-like (IL-10-, glucocorticoid or immune complex+LPS-polarized macrophages) phenotypes [25].

The polarized phenotype of macrophages is also evident *in vivo* [34]. For example, M2-like characteristics have been observed for macrophages in the placenta and embryo and macrophages associated with helminth infection, endotoxin tolerance, and cancer [32,35–38]. Under some pathological conditions such as lean versus obesity, allergic skin, myocardial infarction, sepsis progression, or *Listeria* infection, a transition between M1 and M2 phenotypes has also been documented [2,6,39–41]. However, accumulating evidence now reveals further complexity under *in vivo* settings where monocytes and macrophages often fail to show a clear-cut polarized phenotype and even display a mixture of M1 and M2 characteristics [10,42–44]. Recent transcriptome and epigenetic analysis of macrophages support such complexity. For example, human macrophages stimulated with 28 different stimuli demonstrated a transcriptomic profile that suggested these cells to display a spectrum of phenotypes that could not be explained by a simplistic M1–M2 dichotomous model but by a multidimensional model, where macrophage phenotypes are dictated in an input-specific manner [45]. In line with this, a tissue-specific transcriptional and epigenetic regulation was demonstrated in murine tissue macrophages by a recent study [23]. In support of this growing complexity, a stimulus-specific nomenclature system of macrophage activation has been recently suggested. Macrophage phenotypes will be designated by their activating stimuli, for example, M1(LPS), M2(IL-4), and so on so that a common and unambiguous language of defining macrophage activation states can be achieved [46].

9.4 Functions

Monocytes and macrophages play a plethora of functions that relate to host defense, development, and maintenance homeostasis [47], For example, spleen red pulp macrophages help maintain iron homeostasis [48,49], peritoneal cavity macrophages control production of gut immunoglobulins A (IgA) [50], and macrophages in the brain engulf and remodel developing synapses [51]. Some of

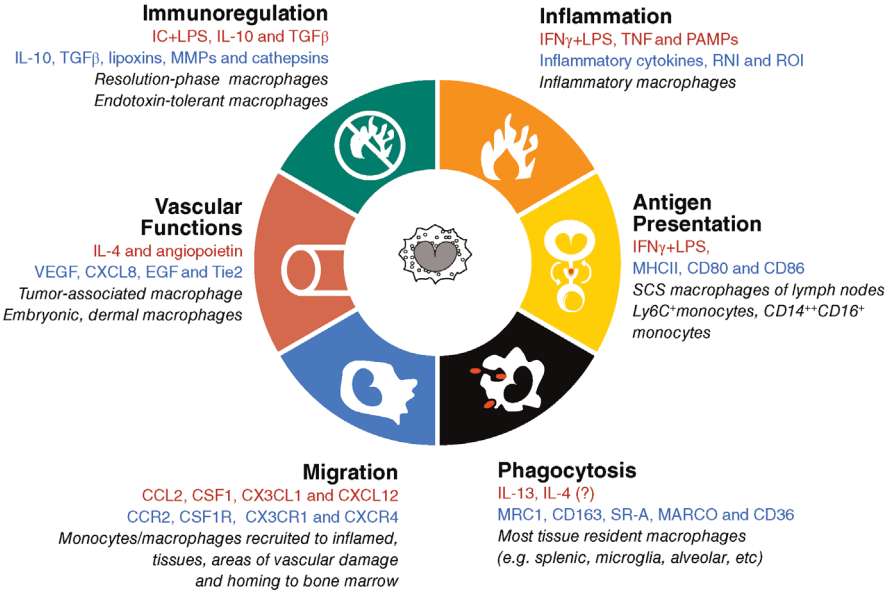

Figure 9.1 Hallmarks of macrophage functional diversity. A schematic representation of the key functions associated with these cells. Red: stimuli inducing the particular functions in macrophages; Blue: the effectors produced by macrophages associated with the particular function; italics: examples of macrophages showing these specific functions. Note: Although IL-4 induces expression of phagocytosis-associated receptors and enhanced endocytosis in macrophages, it impairs phagocytosis of microbes [205]. Tissue repair and remodeling functions of macrophage are integrated into the "immunoregulation" heading.

the hallmark functions of monocytes and macrophages include cytokine production and inflammation, antigen presentation, phagocytosis, migration, vascular functions, and immunoregulation (Figure 9.1). These are further discussed below.

9.4.1 Cytokine Production and Inflammation

Blood monocytes and tissue macrophages act as the first line of host defense against infections. These cells through the expression of pattern recognition receptors (PRRs) on their surface can "sense" pathogens or their products (also referred to as pathogen-associated molecular patterns, PAMPs). For example, TLRs are one of the main classes of PRRs expressed in these cells and can sense a variety of microbial components. Recognition of microbes by TLRs trigger intracellular signaling pathways that activate transcriptional factors such as nuclear factor kappa B (NF-κB) [52] that induce the expression of proinflammatory cytokines such as TNFα, IL-8, IL-6, IL-1, and microbicidal mediators like RNI and ROI. Proinflammatory cytokines and chemokines released by these cells induce the recruitment and activation of other immune cells like T and B cells, promoting a full-fledged immune response. Such an immunoinflammatory response coupled with the release of microbicidal mediators is ultimately instrumental for destruction of the pathogen. However, too much or too long release of

such inflammatory cytokines ("cytokine storm") may lead to serious deleterious effects such as septic shock and organs failure [53]. Indeed, we and other have shown a proinflammatory gene expression profile for monocytes during sepsis [39,47]. In contrast to these acute inflammatory conditions, obesity and cancer are examples of chronic inflammation. Accordingly, obese adipose tissues show increased infiltration of macrophages (ATMs) that are characterized by an M1-like phenotype, expressing high level of TNFα and inducible nitric oxide synthase (iNOS) [54,55]. Similarly, many cancer tissues are characterized by the recruitment of monocytes and macrophages, which by releasing inflammatory cytokines like TNF, IL-1β, and IL-6 contribute to cancer-related inflammation and tumor progression [25,56].

Since an uncontrolled or prolonged release of inflammatory cytokines by monocytes/macrophages can cause serious damage to the surrounding tissues, a tight regulation of this mechanism is necessary. Thus, concomitant with the expression proinflammatory cytokines, these cells also express anti- inflammatory cytokines such as IL-10 and IL-1RA. The tuning down of macrophage inflammatory response is well-documented during resolution of inflammation [57]. This and other immunoregulatory properties of macrophage will be discussed under in Section 9.4.5.

9.4.2 Phagocytosis

Phagocytosis refers to the process by which a cell engulfs a particulate matter (> 0.5 μ) with its plasma membrane to form a vacuole-like structure called the phagosome, within which the target is degraded by acidification and exposure to proteolytic enzymes. Both monocytes and macrophages are "professional" phagocytes. These cells survey their microenvironments for danger, kill potentially harmful microbes, and clear apoptotic cells and tissue debris as part of normal tissue homeostasis and repair [58]. Indeed, tissue-resident macrophages are highly phagocytic. For example, splenic macrophages during erythropoiesis ingest erythrocyte nuclei and contribute to iron recycling. Consequently, PU.1-deficient mice, which lack macrophages, have defective erythropoiesis resulting in lethality [59]. Likewise, resident microglia and recruited monocytes in the brain clear apoptotic neurons [60], thymic macrophages clear apoptotic thymocytes, and Kupffer cells in the liver clear microbial ligands from blood and lymph.

However, not all macrophages are constitutively phagocytic, for example, the $F4/80^{-}CD169^{+}$ sialic acid-binding immunoglobulin (Ig)-like lectin 1 (SIGLEC1)-expressing metallophilic macrophages in the rodent spleen are poorly phagocytic. Similarly, monocytic subsets also differ in their phagocytic ability [61].

The process of phagocytosis is a complex and dynamic cascade of events that initiates with recognition and physiochemical interaction between the particle and its cognate receptors (on the phagocyte), its attachment to the cell surface, its internalization into the phagosomes, and finally its destruction in the phagosome via acidification and proteolytic enzymes [62]. A variety of nonself-entities like microbes or their related molecules as well as self-entities like apoptotic or necrotic cells can be recognized by phagocytic receptors present on the cells surface. Either such receptors can directly recognize these particles (e.g.,

nonopsonizing, microbial ligand receptors) or indirectly recognize via opsonins coated on the surface of these particles (opsonic receptors). Examples of microbial ligand receptors are C-type lectin receptors (CLRs) (e.g., mannose receptor, dectin 1) and scavenger receptors (e.g., SR-A, MARCO, and CD36). Lectin receptors recognize carbohydrate motifs on microbial cell walls or in the side chains of microbial proteins and lipids, as well as those associated with apoptotic cells and extracellular matrix components. In particular, a lot of attention has been focused toward identifying the receptors that recognize and clear dying cells. Receptors like brain-specific angiogenesis inhibitor 1 (BAI1) directly bind to phosphatidyl serine present on apoptotic cells [63]. Similarly, the Tyro3, Axl, and Mer-TK receptors on monocytes and macrophages can recognize Gas 6 and Pros1 (vitamin K-dependent protein S) expressed on the apoptotic cells, thereby initiating a phagocytic cascade [64]. Recently, a C-type lectin receptor CLEC9A was implicated in the clearance of apoptotic and necrotic cells [65]. Foreign materials such as titanium particles and native beads are recognized by scavenger receptors MARCO [66] and SR-A1 [67], respectively, and elicit distinctive gene expression profile in macrophages [68]. However, whether phagocytic receptors can differentially recognize apoptotic versus necrotic cells and how this couples to differential immune response is still not clear.

Opsonin receptors include the immunoglobulin Fc receptors (FcγRI, II, and IIIA) and complement receptors (CR1, CR3, CR4, CRIg, and C1qRp) [58,69]. These receptors recognize opsonins such as immunoglobulins (IgG in the serum, IgA in the mucosal surface, etc.), C-reactive proteins, complement proteins C1q and C3b, mannose-binding lectins, fibronectin, and milk fat globulin (MFG)-E8 (lactadherin) [70].

Besides these phagocytic receptors, several accessory receptors can contribute to the efficiency of phagocytosis by either helping in the tethering of particles to the cell surface or modulating the intracellular signaling pathways. For example, TLRs can cooperate with other phagocytic receptors to regulate phagocytic uptake and signaling. Uptake and processing of particles in the phagosome can trigger various responses that orchestrate actin cytoskeletal remodeling, cell migration, inflammatory response, and microbial killing, many of which are mediated by signaling via TLRs, NOD-like receptors (NLRs), and inflammasome activation [71]. Interestingly, a recent study demonstrated that autophagy can regulate phagocytosis in macrophages as implicated by increase in the expression of both SR-A1 and MARCO receptors in autophagy-related gene 7-deficient ($Atg7^{-/-}$) macrophages [72].

Modulating phagocytosis can have important consequence in diseases. Pathogens and malignant cells exploit different mechanisms to evade removal by innate immune cells. One such mechanism is to display "don't eat me" signals that include CD47 and the signal regulatory protein-alpha (SIRPα) [73]. Blocking CD47-SIRPα axis was shown to increase tumor cell phagocytosis by innate cells including macrophages in a broad range of malignancies [74] as well as regulate response to therapeutic antibodies [65]. Similarly, response to anti-CD20 therapy was shown to involve macrophage-mediated phagocytosis of anti-CD20-bound tumor cells [75]. Besides cancer, phagocytosis is also being actively explored as a possible therapeutic target for other pathological conditions. In diabetes, reduced

phagocytic activity, which may have lead to increased susceptibility of patients to infection, can be improved by insulin treatment [76]. However, in-depth insights into the mechanisms underlying the relationship between phagocytosis, inflammation, and immunosuppression will be necessary before phagocytotic targets can be tested for modulating dysregulated macrophage function in disease.

9.4.3 Antigen Presentation

Macrophages are antigen-presenting cells and, therefore, have the ability to uptake, process, and present antigens to $CD4^+$ and $CD8^+$ T cells to trigger their activation and effector functions [77,78]. However, *in vitro* studies have shown that macrophages are much less efficient in stimulating naïve T cells than dendritic cells (DCs). A possible reason for this is that macrophages rapidly and completely degrade internalized proteins, while DCs do this more slowly and subtly, thereby preserving antigen epitopes for effective T-cell activation [79]. *In vivo* studies did not show such a compelling difference, wherein DCs and bone marrow-derived macrophages upon direct injection into mice showed comparable ability to migrate to the lymph node and activate $CD8^+$ T cell proliferation [80]. However, Moser and Loetscher [81] showed *in vivo* antigen-pulsed macrophages could prime T cells but, compared to DCs, selectively activated Th2 response. Peritoneal macrophages stimulated with CSF-1 have been shown to induce antigen-specific T-cell suppression [82]. Since CSF-1 is more associated with homeostatic functions than inflammatory activation, if using this factor induced such a Th2 or immunosuppressive phenotype is not known. The cytokine milieu definitely dictates the ability of macrophage antigen presentation, as discussed below.

A two-way relationship between macrophage and T-cell subsets has been proposed. For example, IFNγ released by Th1 or cytotoxic T cells can drive macrophages to an M1 phenotype wherein these cells upregulate inflammatory cytokines like IL-12 and TNF, *major histocompatibility complex* class II (MHC class II), and costimulatory molecules, T-cell-specific chemokines (CXCL10), all of which contribute to antigen presentation, activation, and polarization of T cells to a Th1 response [25,83]. In contrast, IL-4 released from Th2 cells or IL-10 from Tregs polarizes these cells into an immunosuppressive M2 phenotype that abundantly express IL-10, promotes an immunosuppression and Treg phenotype [25,84]. In autologous cocultures, antigen-loaded human macrophages when activated with LPS or LPS/IFNγ preferentially induced Th17 or Th1 responses, respectively, whereas those stimulated with IL-4 failed to induce a T-cell response [85,86]. Evidence supporting the role of macrophages in driving polarized T-cell response and vice versa can be found in various *in vivo* settings like bacterial infection, helminth infection, and tumors [25]. Moreover, human lamina propria $CD14^+$ macrophages exhibit antigen-presenting ability, enhancing Th1 response and contributing to Th17 differentiation under Crohn's disease settings [87].

Macrophages can also deliver antigens to B cells. A subset of specialized macrophages located at the subcapsular sinus (SCS) of lymph nodes were shown to be involved in the delivery of antigens to B-cell follicles [88–90]. These were

involved not only in inactivating viral particle-associated antigens [88] but also in delivery of particulate antigens and antigen in the form of immune complexes to B cells [89,90]. Furthermore, macrophages are also known to cooperate with DCs to present dead cell-associated antigens to trigger optimal $CD4^+$ T cell responses.

Human monocytes also show antigen-presenting capacity. The $CD14^+CD16^+$ monocytes have stronger antigen presentation capacity than the classical ($CD14^+CD16^-$) and nonclassical ($CD14^{dim}CD16^+$) monocytes [91]. Elevated expression levels of genes related to MHC class II molecules, antigen processing, and protein turnover in the $CD14^{++}CD16^+$ subset correlated with their stronger antigen presentation and T-cell proliferation capacity. Recently, mouse $Ly6C^+$ monocytes were suggested to carry soluble antigen from tissue to the draining lymph nodes where they presented them to the $CD4^+$ and $CD8^+$ T cells [92]. These monocytes had the intrinsic capacity to uptake dying cells and cross-present cell-associated antigen to $CD8^+$ T cells [93].

9.4.4 Migration

Migration, recruitment, and homing of monocytes between blood, peripheral tissues, and bone marrow is essential for immune surveillance and maintaining homeostasis. For example, blood monocytes are recruited to sites of tissue damage and inflammation, wherein they differentiate into macrophages or DCs, release cytokines and chemokines, and orchestrate an immune response [94,95]. Similarly, sequestering these cells at these sites is critical for eliciting effective immune response as well as avoiding collateral tissue damage. Recruitment and trafficking of monocytes and macrophages between blood, peripheral tissue, and bone marrow is largely guided by the expression of chemokine (or growth factor) receptors in these cells and their cognate ligands in the microenvironment. For example, classical ($CD14^+CD16^-$) monocytes in humans or the inflammatory ($Ly6C^{hi}$) monocytes in mice show high expression of CCR2 but low expression of CX3CR1. Accordingly, these cells respond to the CCR2 ligand CCL2, a key chemoattractant for monocytes [96], which contributes to their migration from blood to tissue and bone marrow to blood. In fact, during a variety of inflammatory conditions including obesity, cancer, and atherosclerosis, CCL2 production by adipocytes, cancer cells, and vessel walls orchestrate the recruitment of inflammatory monocytes into these sites [9,95,97,98]. However, in the absence of inflammation, $Ly6C^{hi}$ monocytes are reported to home to the bone marrow, where they are believed to differentiate into $Ly6C^{lo}$ monocytes [3,99].

Patrolling ($Ly6C^{lo}$) monocytes in mice and $CD16^+$ human monocytes show a $CCR2^{lo}CX3CR1^+$ phenotype [100,101]. These monocytes patrol the vascular endothelium where they help in the scavenging and clearance of cellular debris as well as removal of metastatic tumor cells [7,11,102]. In a recent study, $CX3CR1^+$ patrolling monocytes were suggested to migrate to sites of vascular damage in response to CX3CL1, the ligand for CX3CR1. Upon reaching these sites, these cells express chemokines like CCL3 and CCL5, which recruit NK cells for the removal of blood-borne tumor cells. CX3CR1 is also reported to support the survival of $Ly6C^{lo}$ monocytes [95,103–105]. In a *Listeria* infection model in

mice, patrolling monocytes were shown to arrive rapidly at the site of infection where they released chemokines that subsequently attracted the inflammatory monocyte subset [6]. Similarly, during exercise, $CD16^{+}$ monocytes were reported to increase in number within minutes [106,107], which is conceivable considering their localization to the vascular epithelium that allowed them to rapidly emigrate into the tissue during inflammation.

Recruitment of monocytes and macrophages into inflamed tissues, atherosclerotic lesions, and tumor tissues is also regulated by other receptors such as CX3CR1, CCR5, CSF1R, VEGFR1, and CXCR4 in response to their respective ligands (including hypoxia) in their microenvironment [95,97]. Similarly, adhesion molecules and integrins are important players in the migration of monocytes. For example, inflammatory monocytes use L-selectins, lymphocyte function-associated antigen-1 (LFA-1), macrophage-1 antigen (MAC1), and platelet/endothelial cell adhesion molecule 1 (PECAM1) for migration and adhesion, whereas patrolling monocytes use LFA-1 for their endothelium patrolling functions.

Monocytes and macrophages also undergo trafficking constitutively under homeostatic conditions. This may include homing to bone marrow or seeding to specific tissues. However, how or which chemokines and their receptors play a role in such homeostatic trafficking of these cells still remains poorly understood. Further characterization of tissue macrophages and their ontogeny may shed light on their homeostatic trafficking.

9.4.5 Immunoregulation

In contrast to their inflammatory functions, monocytes and macrophages play an important role in immunoregulation [108,109]. M2-like macrophages have been generally attributed to immunoregulatory activity, although several variations occur within this theme. Some examples of such activity are discussed in this section. A very good example of immunoregulatory function of macrophage is observed during resolution of inflammation. Macrophages during resolution engulf apoptotic cells (e.g., apoptotic neutrophils) as part of clearance of debris and switch to a phenotype characterized by impaired proinflammatory cytokine expression but heightened expression of TGFβ, IL-10, and lipoxins, which relates to proresolving, antifibrotic, and wound repair functions [110–112]. Further study of such cells during resolution of inflammation in mice suggested the existence of $CD11b^{hi}$ and $CD11b^{lo}$ macrophages with phenotypic variations [113]. The $CD11b^{hi}$ macrophages expressed high levels of M2 markers (Arg1), low to intermediate levels of inflammatory markers like NOS2, cyclooxygenase 2 (COX2), matrix metalloproteinase 9 (MMP9), and 12/15-lipoxygenase and were highly phagocytic. These cells resembled the resolution-phase macrophages reported by Stables *et al.* [44]. In contrast, $CD11b^{lo}$ macrophages did not express Arg1, showed lower levels of inflammatory markers than $CD11b^{hi}$ macrophages, high levels of TGFβ, and possessed no phagocytic ability. These cells have been suggested to be involved in antifibrotic and immune regulatory functions [114]. During helminth infection, M2-like macrophages were shown to drastically contribute to rapid resolution of tissue damage [115]. More recently, polarization

of macrophages with TLR ligands in the presence of high-density immune complexes, prostaglandin E2 (PGE2), or adenosine was reported to yield three distinct populations of macrophages with immunoregulatory activity [116]. These cells shared the common characteristics of high expression of IL-10, growth factors, and angiogenic factors, whereas showing reduced levels of inflammatory cytokines (IL-1β, IL-6, and IL- 12). However, the *in vivo* relevance of these populations need further study.

Another variation of immunoregulatory macrophages is the endotoxin-tolerant macrophage. During sepsis, exposure to overt inflammatory cytokines renders monocytes/macrophages to an endotoxin-tolerant phenotype characterized by their inability to respond to further endotoxin challenge [47,117]. Endotoxin-tolerant monocytes/macrophages display downregulated inflammatory cytokines and upregulated anti-inflammatory cytokines along with increased phagocytic activity and tissue remodeling characteristics, suggesting a M2-like phenotype [38,118]. Indeed, monocytes from sepsis patients show such a phenotype [39]. Possibly such an immunoregulatory phenotype is a protective adaptation to the excess inflammation. Tumor-associated macrophages (TAMs) also share immunoregulatory properties since they promote immunosuppression and tissue remodeling processes that are essential for cancer immune evasion, tumor angiogenesis, and metastasis [56,119]. In addition, many of the developmental functions of tissue and embryonic macrophages recapitulate elements of immunoregulation and tissue remodeling [120]. Further discussion on such macrophage functions may be found in Section 9.4.6.

Lastly, it may be emphasized that the monocytes and macrophages show dynamic plasticity switching between inflammatory and immunoregulatory phenotypes. This is not only seen during *Listeria* infections, where patrolling monocytes initially show an inflammatory phenotype and later switch to a tissue resolving M2 phenotype, but also in monocytes during skeletal muscle injury and sepsis [6,39,42]. However, the mechanism of the microenvironmental signals that switch these cells to an immunoregulatory phenotype is still not well understood.

9.4.6 Vascular Functions

Angiogenesis involves the process of new blood vessel formation. Typically, new vessels arise from preexisting ones by sprouting and ultimately fusing (anastomosis) with other vessels. Macrophages play a key role in regulating angiogenesis during development as well as postnatal organ remodeling. By directly secreting proangiogenic factors (VEGF, EGF, CXCL8, and CXCL12) or via secretion of tissue remodeling proteases (e.g., MMPs) that release ECM-bound proangiogenic factors, these cells promote vascular growth as well as contact-dependent anastomosis [121–123]. Indeed, cytokines secreted by activated monocytes and/or macrophages have been long known to induce endothelial cell activation, proliferation, migration, and survival, thereby supporting angiogenesis. At the same time, macrophages are also known to secrete proapoptotic or antiangiogenic factors that induce endothelial cell apoptosis, enabling vascular patterning, and remodeling during development [124–126]. For example, macrophages both support retinal angiogenesis and contribute crucially to hyaloid vessel

regression [122,124–126]. Similarly, in developing neural tissues, fetal macrophages promote as well as restrict the formation of vascular intersections [121–125,127]. It may be pointed out that the vascular modulating role of macrophages ranges from developmental (e.g., retina, brain, etc.) settings to disease settings like wound healing, cancer, retinopathies, and endometriosis [123,128–132]. The role of monocytes and macrophages has been extensively studied in tumor angiogenesis (reviewed in detail elsewhere [133]). Monocytes as well as macrophages by releasing various factors like VEGF, epidermal growth factor (EGF), TNF, and IL-1β can induce tumor angiogenesis [133]. Interestingly, a subset of monocytes/macrophages that express an endothelial marker, Tie2, and localize to perivascular areas in the tumors was shown to possess strong proangiogenic effect as well as regulate tumor response to chemotherapy [134,135]. At a mechanistic levels, macrophage–endothelial cell interaction has been ascribed to interactions involving receptor Tie2 and its ligand angiopoietin 2 (TIE2/ANG2) [136], CXCL12/CXCR4 [137], CSF-1/CSF-1R [138], NOTCH, and delta-like ligand 4 (NOTCH/DLL4) [139] molecules. In addition, embryonic, dermal, and tumor macrophages have also been shown to promote lymphangiogenesis [128,140–143]. Many of these macrophages released VEGFC and VEGFD. Monocytes and macrophages also have an important contribution in arteriogenesis [144,145].

9.5 Molecular Pathways and Mechanisms Regulating Response

In the last decade, our knowledge on macrophage activation, function, and ontogeny has improved immensely. However, information on the molecular mechanisms that connect the impinging microenvironmental stimuli to the diverse gene expression profiles and functions of macrophages is relatively limited. We summarize below the existing information on the molecular mechanisms regulating macrophage activation, polarization, and response, focusing on the signaling, epigenetic, and post-transcriptional mechanisms (Figure 9.2).

9.5.1 Signaling Pathways

Macrophages possess a variety of transmembrane and cytosolic PRRs such as TLRs, CLRs, RIG-I-like receptors (RLRs), and NLRs through which they can sense various danger signals of microbial (e.g., LPS, zymosan, and flagellin) or host origin (e.g., endogenous molecules released from damaged or altered cells) [146]. Upon sensing such a danger signal, the PRRs trigger signaling cascades that lead to a gene expression program that ultimately drives the macrophage functional response to that particular stimulus. In general, macrophage response to Gram-negative bacteria and the classical activating agent, LPS, is mediated through TLR4 [147,148]. Signaling downstream of TLR4 pathway is mediated by two distinct adaptors, Myeloid differentiation primary response 88 (MyD88) and TIR domain-containing adapter-inducing interferon-β (TRIF) [146] (Figure 9.2). The

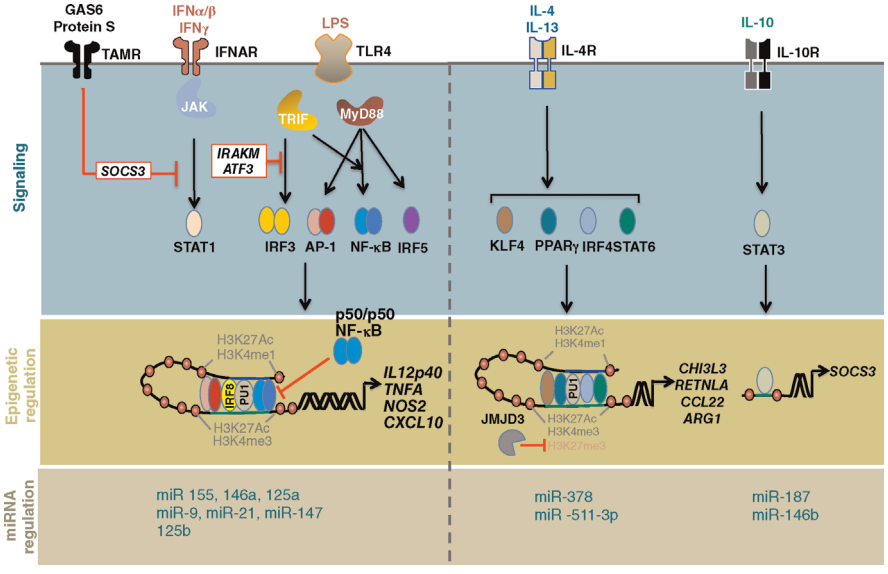

Figure 9.2 Multilevel molecular mechanism regulates the polarized response of macrophages. The figure depicts signaling, epigenetic changes, and miRNA-mediated regulation of macrophage response to polarizing stimuli. Only key pathways are indicated. Not all transcription factors that bind to enhancers and promoters are shown due to space constraints. Note that in basal or unstimulated macrophages, lineage-specific transcription factors such as PU.1 first bind to enhancers making them accessible or "poised" (via histone modifications) for the binding of other stimuli-specific transcription factors such as NF-κB, AP1, IRFs, and so on. Transcription factor binding and epigenetic marks on M2 genes are not well understood, a possible schematic view is presented. Enhancer: blue line; promoter: green line; Gray font: histone modifications. Red "T" sign depicts inhibition.

MyD88-dependent pathway leads to the activation of the master transcription factor NF-κB, which induces the expression of inflammatory cytokine genes such as TNFA, IL1B, IL6, and IL12A. The TRIF-dependent pathway activates the transcription factor interferon regulatory factor 3 (IRF3) that via IFNβ expression activates the transcription factor, signal transducer and activator of transcription 1 (STAT1) [149]. Type I (IFNα/β) and Type II IFNs (IFNγ) through STAT1 activation induces the expression interferon-inducible genes such as NOS2, CCL5, and CXCL10 [150,151]. Thus, M1 polarization of macrophages by IFNγ+LPS induce the activation of various transcription factors such as NF-κB, activator protein 1 (AP-1), IRF5, IRF3, and STAT1 that drives the expression of inflammatory (M1) cytokines like TNF, IL12A, and CXCL10 (Figure 9.2). In particular, IRF5 was demonstrated to be an integral transcription factor in regulating the expression of M1-related inflammatory genes [152].

In contrast to the above, anti-inflammatory stimuli like IL-4 or IL-13 through the IL-4 receptor activates various transcription factors like STAT6, Kruppel-like factor 4 (KLF4), IRF4, c-Myc, and peroxisome proliferator-activated receptor gamma (PPARγ) that induce expression of M2 phenotype-related genes such as ARG1, CCL17, CCL22, and IRF4 (Figure 9.2) [153–155]. The anti-inflammatory

cytokine IL10 via STAT3 activation induces its target genes as well as negative regulators of inflammation such as suppressor of cytokine signaling 3 (SOCS3) in macrophages, promoting immunosuppression. SOCS1 and SOC3 can also be induced via the TAM receptors (e.g., Axl, Tyro3, and Mer), which are known to mediate immunosuppression in sepsis patients [156]. It may be pointed out that many molecules such as p50/p50 NF-κB, hypoxia-inducible factor 1 alpha (HIF1α), negative regulators of TLR signaling (e.g., IRAKM, ATF3, and A20), and pyruvate kinase isoenzyme type M2 (PKM2) that are initially induced by inflammatory stimuli can also switch macrophages to an anti-inflammatory phenotype over time [157–160]. Supporting this concept, IFNβ in some instances can induce IL-4, IL-13, IL-4Rα, and TAM receptors, which facilitates the polarization of inflammatory macrophages into an immunosuppressive, M2-like phenotype [161]. In sepsis, accumulation of p50/50 NF-κB homodimer and HIF1α activation was shown to reprogram macrophages from an inflammatory to an M2-like immunosuppressive phenotype [38,39,162]. However, divergent roles of HIF isoforms, HIF1α, and HIF2α in macrophage polarization have been reported [163–165]. A more detailed account of the various innate signaling pathways and molecular mechanism of macrophage polarization are reviewed elsewhere [25,146]. More recently, another level of complexity to macrophage signaling has emerged with the involvement of signaling molecules and transcription factors such as AMPK, mTOR, PI3 K/AKT, p53, and HIF1α that regulate macrophage response to nutritional and immune–metabolic stimuli [166].

9.5.2 Epigenetic Regulation

Chromatin immunoprecipitation-sequencing (ChIP-Seq), iChIP and RNA-Seq studies in macrophages have advanced our understanding of how the gene expression profile of these cells is regulated at an epigenetic level. Transcription of a gene is often controlled by the participation of multiple transcription factors that assemble at the *cis* regulatory elements like enhancers and promoters for that particular gene (Figure 9.2). However, the accessibility of the chromatin to transcription factors depends on its coiling status that is regulated by nucleosome remodeling and modification of the histone tails associated with the chromatin. Nucleosome remodeling, among many factors, is dictated by cytosine and guanine (C/G) content of the DNA sequence. Thus, areas with extreme C/G content (e.g., "CpG islands") favor nucleosome depletion, thereby giving rapid accessibility to transcription factors [167]. For example, promoters of inflammatory genes coincide with such CpG island and hence have active chromatin that is poised for further stimulus-driven activation [168]. In general, two broad types of transcription factors can be envisaged in macrophages: lineage-specific transcription factors that guide basal gene transcription and stimuli-specific transcription factors that drive gene expression in response to stimuli. In macrophages, lineage-specific transcription factors like PU.1 bind to genomic enhancers and favor nucleosome depletion, thereby making them accessible to other stimuli-specific transcription factors [169,170]. Interferon regulatory factor 8 (IRF8) plays a role in both basal (constitutive) and stimuli-induced (inducible) gene expression in macrophages [171]. In the former case, it cooperates with PU.1

to bind under basal conditions, whereas in the latter case it cooperates with AP1 family members to bind to AP1 consensus sequences.

Histone modification is a key regulatory mechanism that controls the accessibility of chromatin for transcription factors binding. Accordingly, acetylation of histone H3 at lysine-9 and -27 (H3K9ac and H3K27ac) and histone H4 at lysine-5, -8, and -12 (H4K5ac, H4K8ac, and H4K12ac) is associated with active promoters and enhancers. Similarly, methylation of histones is associated with activation or repression depending upon the site of lysine residue. Methylation of histone H3 at lysine-4, -36, and -79 (H3K4, H3K36, and H3K79) associates with active transcription. Promoters exhibit high levels of H3K4me3, whereas enhancers display H3K4me1 (Figure 9.2). Accordingly, PU.1 binding to gene enhancers causes H3K4me1, which facilitates access to other transcription factors like NF-κB, IRF8, IRF5, IRF4, and C/EBPβ in response to activation stimuli (Figure 9.2) [157]. Moreover, some of these transcription factors also cause recruitment of histone acetyltransferase p300 to the enhancer and facilitate transcription [169]. In contrast to the above histone modification, methylation of histone H3 at lysine-9 and -27 and histone H4 at lysine-20 (H3K9, H3K27, and H4K20) promotes transcription repression [172,173]. A good example of gene repression is LPS tolerance. Two classes of genes were identified in a study on LPS tolerance in murine macrophages [174]. These include LPS-responsive nontolerant and LPS-unresponsive tolerant genes. Promoters of both gene classes showed histone methylated, but those of the nontolerant genes displayed histone reacetylation and RNA polymerase II (RNA polyII) recruitment and transcription, when restimulated with LPS. Such differential epigenetic modification has also been proposed to explain "trained immunity" in human monocytes in a recent study [175]. On similar lines, the temporal regulation of macrophage inflammatory gene expression also involves epigenetic regulation. This typically consists of early response genes that have permissive promoters that allow for immediate transcription factor binding. These gene regulatory regions are characterized by nucleosome depletion, CpG-rich islands, relatively high levels of H3K4me3 and acetylated histones, and RNA Pol II recruitment in unstimulated macrophages. Thus, they are poised for rapid transcription upon LPS treatment. In contrast, secondary response genes have nonpermissive promoters that require nucleosome remodeling before transcription factors can bind. In line with these facts, secondary response genes show low-level H3K4me3 [176] and are enriched with H3K27me3 [177].

While most studies have concentrated on the epigenetics of inflammatory genes associated with M1 macrophages, relatively little is known about the regulation of the genes related to the M2 macrophages. In this regard, Jumonji domain containing-3 (Jmjd3), a H3K27 demethylase, was shown to be upregulated in IL-4-polarized macrophages, where it decreased H3K27 methylation at the promoters of M2 genes such as ARG1, YM1 (CHI3L3), and FIZZ1 (RETNLA) to activate their transcription (Figure 9.2) [178]. JMJD3 was also reported to induce the expression of the M2-associated transcription factor IRF4 [179]. Further investigation into the gene regulatory mechanism of M2 macrophages and those involved in homeostatic functions in various tissues is now needed.

9.5.3 Micro-RNAs

Micro-RNAs (miRNAs) or small noncoding RNAs are important regulators of gene expression in immune cells at a post-transcriptional level [180–182]. miRNAs modulate monocyte/macrophage response [182]. Different micro-environmental factors (LPS, IL-4, IL-10, helminth infection, and endotoxin shock) can either induce or downregulate the expression of particular miRNA species in these cells, which in turn act on their target genes to modulate the downstream functional response (Figure 9.2). An excellent review of this topic is presented by Squadrito *et al.* [182].

Inflammation modulates a large number of miRNAs. One of the earliest miRNA studies have shown LPS to rapidly upregulate miR-146a in monocytes [183]. This miRNA acts as a negative regulator of TLR signaling via downregulating the expression of important upstream molecules like TRAF6 and IRAK1 [181,183]. miR-146a also inhibits TNFα at a transcription and translation level during inflammation in monocytes/macrophages [184]. These observations support the role for miR-146a inducing endotoxin tolerance in macrophages [47,185,186]. LPS also upregulates miR-155 in monocytes and macrophages, but the effect is complex. miR-155 inhibits components of TLR4 signaling pathway, but stabilizes TNFA transcripts, thus playing both positive and negative regulatory roles [187,188]. In fact, miR-155 knockin mice show high levels of TNFα [188,189]. Interestingly, LPS differentially regulates the miR-125 family with the upregulation of miR125a and dowregulation of miR-125b in macrophages [190,191]. Both these miRs induced enhanced NF-κB activation [192], while downregulation of miR-125b was required for TNFα production (via stabilization of its gene transcript) [188]. Coordinated regulation of miR-155, miR-146a, and miR-125b has been suggested in pathological settings like endotoxin shock and tolerance [186,188,193]. TLR agonists induce a number of other miRNAs such as miR-9, miR-21, and miR-147, which inhibit proinflammatory response in monocytes/macrophages by downregulation of the NF-κB signaling pathway [194–196]. A recent study showed that miR-10a secreted by endothelial cells could suppress monocyte activation by targeting components of the NF-κB pathway, such as IRAK4 [197].

Anti-inflammatory stimuli may also activate particular miRNAs resulting in the regulation of monocytes/macrophages [182]. Thus, IL-10 alone or with LPS induces miR-187 expression in human monocytes [198]. This miRNA downregulates IL-6 and IL12p40 expression favoring an anti-inflammatory response. IL-10 also induces miR-146b expression in human monocytes that negatively regulates TLR4 signaling and tunes down the inflammatory response [199]. Another anti-inflammatory stimulus, IL-4 induces several miRs in macrophages such as miR-125b and -378 [200]. In this study, miR-378 was shown to target Akt1 signaling serving as negative feedback loop for M2 activation of macrophages. miR- 511-3p is encoded in the fifth intron of the M2 macrophage marker gene, MRC1 (CD206) [201]. miR-511-3p was found to be upregulated *in vitro* and *in vivo* in various M2 macrophages like IL-4-polarized bone marrow-derived macrophages, adipose tissue macrophages, and TAMs. Importantly, this miRNA

was shown to regulate the protumor phenotype of TAMs and hence tumor growth. miR-511-3p serves as a negative feedback loop for M2 macrophages, by targeting ROCK2 that is required for activation of the M2 transcription factor, IRF4 [201].

These examples together with the differential miRNA expression in M1 and M2 macrophages suggest an important role for miRNAs in regulating the M1/M2 macrophage phenotype. This concept is demonstrated *in vivo* in mice with a myeloid-specific gene knockout of Dicer 1 (the key enzyme regulating miRNA processing in mammalian cells) [202]. These authors showed that myeloid-specific Dicer1 deletion in tumor-bearing mice switched the protumor phenotype of the tumor-associated macrophages to a strongly antitumor M1 phenotype that led to robust cytotoxic T-cell response and tumor regression. In fact, Dicer1 deletion led to better outcome of immune checkpoint therapy with anti-PD1 and anti-CD40 in these mice. Surprisingly, Dicer1 deletion specifically affected miRNAs in macrophages, with the Let7-5p family, in particular. It was suggested that under wild-type conditions, Dicer upregulated Let7-5p expression, which targeted the costimulatory molecule CD86, thereby thwarting the activation of an antitumor T-cell response. These results constitute *in vivo* evidence for the role of Dicer (and the miRNA machinery) in driving an immunoregulatory phenotype in tumor macrophages and hence open options for targeting the miRNA machinery for "rewiring" macrophage-mediated antitumor response [203].

9.6 Conclusions

The study of macrophages using fate-mapping approach, transcriptome, ChIP-Seq, and single-cell analysis in last few years has shed unprecedented light on the ontogeny, activation, and functional diversity of these cells. These findings coupled with the characterization of these cells in disease models and patients have established their central role in a large number of pathologies such as obesity, cancer, allergy, liver diseases, and so on. Based on this, strategies modulating monocyte/macrophage lineage such as those targeting CSF-1R are entering into clinical trials [204]. A new area of investigation revolves around the homeostatic roles of these cells and distinguishing between the biology of tissue resident macrophages versus those differentiated from blood monocytes and/or recruited in response to microenvironmental cues. Future multidimensional approaches should provide further insights into these issues [1].

Neutrophils

Salvatore Cuzzocrea

University of Messina, Biological & Environmental Sciences, Viale Stagno d'Alcontres 31, 98166 Messina, Italy

10.1 Characteristics

The original report of neutrophils was made in 1865 by Max Johann Sigismund Schultze, who first defined the four different types of blood leukocyte corresponding to what are now documented as the lymphocyte, the monocyte, the eosinophil, and the neutrophil [1]. Paul Ehrlich, on the basis of their characteristic nuclear morphologies, called neutrophil "cells with polymorphous nuclei" [2]. In 1905, Elie Metchnikoff renamed these cells and the term "polymorphonuclear leukocytes" is still used today.

Neutrophils are uniform in dimension with a diameter between 9 and 15 μm. When analyzing neutrophils in a medium, neutrophils have a typical diameter of 8.85 μm [3]. They have copious cytoplasm with a tiny Golgi apparatus, where mitochondria and ribosomes are sparse and the rough endoplasmic reticulum is absent. Two most important morphological characteristics of the neutrophils are the form of their nucleus and their granules. Nucleus is divided into three to five lobules. The evolutionary advantages of having a lobulated nucleus are still unclear. Neutrophils have three varieties of granules: *azurophilic granules* (or "primary granules") that contain myeloperoxidase, bactericidal/permeability-increasing protein (BPI), defensins, and the serine proteases neutrophil elastase and cathepsin G; *specific granules* (or "secondary granules") that contain alkaline phosphatase, lysozyme, NADPH oxidase, collagenase, lactoferrin, and cathelicidin; and *tertiary granules* that contain cathepsin and gelatinase [2]. In normal adult blood, the relative percentage of neutrophils is 60–75% or 4200–5200 mm^{-3}; low neutrophil counts are termed *neutropenia* and it can be hereditary, as in the case of aplastic anemia or some kinds of leukemia, it can also be a side effect of medication or it can be the result of colonization by intracellular neutrophilic parasites [4]. Neutrophils survive 1–4 days once they leave the blood stream. They traverse the connective tissues by ameboid movement and are the most active phagocytes of the three granulocytes. Ameboid movement and, to a lesser degree, phagocytosis is seen moreover in eosinophils and basophils. When

circulating in the bloodstream and unactivated, neutrophils have a spherical structure. Once activated, they change shape and become more amorphous or ameba-like and can extend pseudopods as they hunt for antigens [5].

10.2 Hematopoiesis

Blood cells are commonly classified into three cell lines: erythrocytes, granulocytes, and megakaryocytes. Hematopoiesis is the process by which blood cells are created.

Hematopoietic stem cells (HSCs) are usually found in the bone marrow, where they self-renew and begin their tour of differentiating into all the singular blood cell types. In the bone marrow, pluripotent stem cells distinguish into either the lymphoid progenitor cells, which are induced to differentiate into B- or T-derived lymphocytes, or the myeloid stem cell (CFU-GEMM) line, which are further induced to become erythrocytes, granulocytes, (neutrophils, eosinophils, or basophils), macrophages, or megakaryocytes (platelets) [6].

Neutrophils are formed within haematopoietic cords interspersed within the venous sinuses of the bone marrow. The bone marrow of a normal adult produces around 100 billion neutrophils daily. The original cells destined to become neutrophils and macrophages that distinguish from the pluripotent stem cells are called granulocyte macrophage progenitor (CFU-GM) cells. The CFU-GM cells are affected by colony-stimulating factors and become either CFU-G or CFU-M cells. The principal regulator of granulopoiesis is granulocyte colony-stimulating factor (G-CSF), whose effects comprise commitment of progenitor cells to the myeloid lineage [7], production of granulocytic precursors, decrease in transit time through the granulocytic compartment [8], and release of mature cells from the bone marrow. G-CSF is made of cells such as monocytes, macrophages, and bone marrow stromal cells, and its action almost entirely concerns with the proliferation of neutrophils. Therefore, CFU-GM cells are encouraged by G-CSF in the bone marrow, pass through the CFU-G stage, and become myeloblasts, which are the greatest primitive neutrophils that can be morphologically distinguished. Myeloblasts continue to divide and differentiate, and they mature into neutrophils, which then lose their ability to divide. Mature neutrophils are not directly released into the blood, but rather are accumulated within the bone marrow. In fact, the neutrophil population in the bone marrow can be subdivided into three pools: the stem cell pool, the mitotic pool, and the postmitotic pool. The stem cell pool contains undifferentiated haematopoietic stem cells (HSCs); however, the mitotic pool refers to committed granulocytic progenitor cells that are undergoing proliferation and differentiation. Finally, fully differentiated complete neutrophils make up the postmitotic pool, which forms the bone marrow reserve, available for release. Neutrophils that have been released into the blood reside in the marginal granulocyte pool or the circulating granulocyte pool, and they later egress into tissues [9]. Studies that have used cells labeled with ^{32}P or ^{2}H have reported that in humans, the transit time through the postmitotic pool is 4–6 days [10,11].

Similarly, the bone marrow reserve of granulocytes in humans has been estimated at 6×10^{11} cells; given this, and the assumption of a 5-day lag between DNA labeling of cells in the marrow and their appearance in blood, the daily turnover of granulocytes through the blood should be 1.7×10^9 cells/kg [7,12,13].

Like M1 versus M2 in macrophages, neutrophils are grouped into either N1 or N2, the former being proinflammatory, whereas the latter being anti-inflammatory. N1 was stimulated under a mild burn injury, whereas N2 was induced under a severe burn damage. N1 was $CD49d^+$ and $CD11b^-$, whereas N2 was $CD49d^-$ and $CD11b^+$.

Burn injury caused systemic infection after subcutaneous infection of a wild-type *P*seudomonas *aeruginosa*. Such mice presented a significant elevation in serum of IL-10 and polarization of neutrophils into an N2 phenotype (IL-10+ IL-12) in the spleen. The surface phenotype of N2 was $Gr1^+$ and $CD11b^+$. Administration of a TLR5 agonist, flagellin, after burn injury, on the other hand, reestablished the neutrophil reply toward a N1 phenotype, resulting in an improved clearance of a wild-type strain of *P. aeruginosa*.

CD177, a GPI-anchored neutrophil antigen, is present in 0–100% of neutrophils, but the portion of CD177-positive neutrophils looks to be constant in all individual [15,16]. CD177 is contained primarily in the membrane of specific granules and in the plasma membrane. Its expression is determined by polymorphisms of the gene.

Olfactomedin 4 (OLFM4), a definite granule protein, is present in roughly 20–25% of neutrophils. Its presence is not regulated at the level of transcription [17]. Both OLFM4-positive and -negative neutrophil subpopulations undergo apoptosis and phagocytose bacteria similarly. Both subpopulations were employed equally to inflammatory positions *in vivo*. OLFM4 was liberated upon NET formation in response to PMA. It was distinguished in only a fraction of the NETs [18].

The relation of these subpopulations with N1 and N2, however, is not known at present. Actually, researchers have not examined cytokine production in these subpopulations [19].

10.3 Adhesion and Migration

10.3.1 Traffic and Margination

Neutrophils are in equilibrium in the blood with a circulating pool, present in large blood vessels, in the axial stream of small vessels, and in a marginating pool. Under physiological conditions, the marginating pool, better called "physiological regional granulocyte pool" [20], comprises granulocytes transiently arrested in narrow capillaries. This retention of neutrophils in capillaries appears to be a mechanical process due to the stiffness of neutrophils compared to the high deformability of erythrocytes and does not involve cell adhesion [21,22].

10.3.2 Adhesion to the Endothelial Wall

On the other hand, during inflammation, neutrophils roll along the endothelial wall of postcapillary venules and integrate inflammatory signals. The recruitment of neutrophils out of blood vessels into injured tissue proceeds in a coordinated series of steps [23]. The traditional three steps of rolling, activation, and firm adhesion have recently been augmented and refined. Slow rolling, adhesion strengthening, intraluminal crawling, and paracellular and transcellular migration are now recognized as separate, additional steps [24]. Capturing is the first contact between neutrophils and the endothelium of postcapillary venules, mediated by selectins and their counterreceptors. During this initial step, neutrophil traffic involves a selectin- and integrin-dependent sequestration in capillaries and postcapillary venules [25]. Intravascular injection of inflammatory mediators results in rapid sequestration that involves a decrease in neutrophil deformability, followed by long-lasting accumulation of neutrophils and by a process involving integrins and L-selectin [21,26]. Reversible interactions of leukocytes with P- and E-selectin on endothelial cells mediate tethering and rolling of leukocytes in inflamed vascular beds, the first action in their recruitment to sites of injury [27]. P-selectin binds with higher affinity to an N-terminal region of P-selectin glycoprotein ligand-1 (PSGL-1) located at the tip of leukocyte microvilli and rolling subsequently involves E-selectin, which appears on endothelial cells 1–2 h after cell stimulation by chemokines or LPS. Furthermore, rolling facilitates binding of neutrophil-expressed chemokine receptors to their chemokines presented on the luminal endothelial surface [28]. Different from P- and E- selectins, L-selectin is constitutively present on leukocytes and directs the migration of naive and central memory T cells to lymph nodes through identification of glycoproteins expressed in high endothelial venules [29]. In addition to its binding to endothelial ligands, PSGL-1 is a counterreceptor for leukocyte L-selectin and there is evidence that neutrophils roll, via L-selectin, on previously adherent neutrophils. This secondary tethering would synergistically enhance neutrophil accumulation on inflamed endothelium [30]. During this tethering step, neutrophils respond to ligands dispatched on the endothelium surface by tissue mediators releasing cytokines that attract free-flowing neutrophils in the bloodstream [31]. These chemokines, tumor necrosis factor-α (TNF-α), interleukin (IL)-1, and (IL)-8 specifically attract neutrophils [32] and their receptors mediate intracellular signaling cascades through activation of two superfamilies of G proteins, the heterotrimeric G proteins and the RAS superfamily of small monomeric GTPases [33]. IL-8 is a major neutrophil chemoattractant, as shown by the complete inhibition of neutrophil recruitment in inflammation sites by anti-IL8 monoclonal antibodies in animal models [34]. While selectins are the key molecules that allow neutrophils' capture and rolling, adhesion mainly depends on molecules of the β_2 integrin family (CD11α, CD11β, and CD11c/CD18) [35]. Ligand binding of β_2 integrins leads to integrin clustering and subsequent outside-in signaling, which contributes to adhesion support and cell motility by controlling cytoskeletal rearrangements [36]. Integrins transmit signals triggered by their clustering and multiple activities with adhesion substrates. Neutrophils integrate these signals and those delivered simultaneously by

inflammatory cytokines or chemoattractants to activate a cascade of intracellular events resulting in cell spreading, locomotion, degranulation, and oxidative burst.

10.3.3 Transendothelial Migration

Neutrophil transmigration happens mainly at the borders of endothelial cells and involves specific neutrophil interactions with endothelial adhesion, through both paracellular and transcellular mode molecules, including P-selectin, ICAM-1, and platelet-endothelial cell adhesion molecule-1 (PECAM-1) [37]. P-selectin has been shown to be concentrated along endothelial borders and may target there neutrophil adhesion. However, extravasation requires modifications of endothelial cell-to-cell adherent junctions. Indeed, disorganization of the junctional components VE-cadherin and β-catenin has been observed in neighborhood regions of mainly adhesion between neutrophils and endothelial cells [38]. PECAM-1, a tyrosine phosphoprotein highly expressed in endothelial cells' junction and on neutrophil surface, modulates neutrophilic transmigration via homophilic PECAM-1/PECAM-1 interaction, but the mechanisms underlying endothelial PECAM-1 function are unknown. Proposed mechanisms consist of (1) formation of a gradient that "guides" neutrophils to the cell–cell border, (2) service as a "passive ligand" for neutrophil PECAM-1, mediating activation of neutrophil β integrins, (3) regulation of endothelial calcium influx, and (4) mediation of SH2 protein association [39]. Two cell adhesion molecules of the Ig superfamily (CAMs) have been shown to be involved in leukocyte transmigration, PECAM-1 and, more recently, the junctional adhesion molecule (JAM) [40]. JAMs are members of an immunoglobulin subfamily, composed of JAM-A, -B, -C, JAM-4, ESAM (EC-selective adhesion molecule), and CAR (coxsackie virus and adenovirus receptor) that localize to cell–cell contacts and are specifically present in tight junctions implicated in leukocyte transendothelial cell migration [41]. JAM-C is unique in terms of its expression and functional profile, and increased luminal expression of JAM-C may promote migration of leukocytes to endothelial cells junctions through increased intravascular crawling, a response that appears to support efficient leukocyte transmigration [42]. Neutrophils move about tissues by haptotaxis rather than through soluble chemoattractants [43]. These chemoattractants, produced by bacteria, dying cells, or epithelial cells of inflamed tissues, are bound to extracellular matrix components because of their negative charge. Cross-talks between chemoattractant receptors and their signaling pathways result in desensitization to one chemoattractant by another, allowing leukocytes recruited by endothelial-derived chemoattractants to migrate source toward their final target [44]. Neutrophils display multiple structurally related receptors for chemoattractants that can generate adhesion, direct cell migration, and promote degranulation and oxidative responses. The link of chemoattractants to such receptors activates phospholipases, via heterodimeric G proteins, resulting in intracellular Ca^{2+} release and activation of proteine kinase C isoforms, tyrosine kinases, and the GTP-binding protein Ras [45]. Chemoattractant receptors, via their coupled G protein heterodimers, activate PI3-kinase, which support the migration of neutrophils; its activation is essential for reorganization of cytoskeleton and membrane organization in response to such agonists, events

resulting in cell polarity and pseudopodia extension [46]. In main inflammatory diseases (gastrointestinal, respiratory, and urinary), neutrophils finally transmigrate across a polarized epithelium to accumulate within a lumen. The initial stage of neutrophil transepithelial migration is characterized by adhesion of the neutrophils to the epithelial membrane. Further, the neutrophils that arrive at the epithelium have a "hystorical previous" in as much as they have just crossed the endothelium and migrated through interstitial tissues before arriving at the base of the epithelium. These accession priorities and migratory events, in conjunction with exposure to the chemoattractants that have stimulated this movement, result in an alteration in the state of activation of the migrating neutrophils [47]. Finally, after traversing the epithelial barrier, neutrophils emerge on the apical surface of the epithelium and adhere to this surface for variables periods of time. During these events, multiple and sequential adhesive interactions must happen in order for the neutrophils to completely traverse the epithelial monolayer. Neutrophil transepithelial migration is mediated by β2 integrin CD11β/CD18 interaction with unknown epithelial ligands, which might include members of the proteoglycan family. Integrin-associated protein CD47 appears to be implicated in neutrophil transepithelial migration as shown by the delayed neutrophil recruitment to inflammation sites in the presence of anti-CD47 blocking antibodies [48]. During transepithelial neutrophil migration, neutrophils seek to migrate in clusters following in the "footsteps" of the leading leukocytes [49]. Migration of great numbers of activated neutrophils results in the formation of large epithelial lacerations due to the mechanical separation of epithelial cells at the site of the interepithelial junction. These wounds represent precursors of the macroscopic areas of denuded epithelium (ulcerated lesions), features of inflammatory mucosal diseases.

10.4 Phagocytosis and Degranulation

10.4.1 Phagocytosis

Phagocytosis is the main microbicidal function of neutrophils, which with macrophages represent the professional phagocytes that are able to engulf and thereby eliminate pathogens and environmental debris [50,51]. Phagocytes are provided with specialized receptors to recognize their targets; this complex machinery mediates internalization and initiates an assortment of degradative mechanisms that culminate in killing of the engulfed particles. Neutrophil phagocytosis can be caused in response to binding of opsonized targets (e.g., immunoglobulin (Ig)- or complement-coated) or by direct bond of target components [52], and it involves two different receptor classes: Fcγ receptors and complement receptors, CR1 (CD35) and CR3 (or CD11β/CD18 integrin). While several different types of receptors are involved in phagocytic uptake of particulate targets [53], a true phagocytic receptor is complicated to define. Among these, the functional phagocytic receptors are FcγRII and CR3, while CR1 and FcγRIIIB appear mostly as coreceptors facilitating the function of the former receptors. Signaling pathways triggered by these two classes of receptors are

different, so are the phagocytic processes. Fcγ receptors are receptors binding IgG-opsonized targets [53]. So, when a small particle is opsonized with IgG, the Fc regions of the IgG molecules may bind to FcR in the neutrophil plasma membrane and trigger a phagocytic reaction. The ingestion of IgG-coated targets is promoted by the aggregation of Fc**γ**RII receptors and the phosphorylation of their cytoplasmic ITAMS (immunoreceptor tyrosine-based activation motifs), through the activation of Src-tyrosine kinases; downstream signaling is propagated by the recruitment of the tyrosine kinase Syk. Syk recruitment is followed by the mobilization of adapter molecules that promote lipid modifications (PLCγ and PI3-kinase), actin remodeling (Cdc42 and Rac1), and Rho protein activation, leading to a localized reorganization of the membrane and the cytoskeleton [54]. This results in an extension of membrane protrusions over the surface of the opsonized particle to form a "phagocytic cup" that engulfs the particle.

CR3-mediated phagocytosis requires an additional signal, resulting in integrin activation, and involves a different process: complement-opsonized targets sink into the cell producing little protrusions [55]. Adhesion of neutrophil CR1 and CR3 to particles exclusively coated with C3b/iC3b is not sufficient to promote phagocytosis, except that neutrophils are activated by formyl-peptides and a contact with fibronectin or laminin [56]. These stimuli result in the phosphorylation of CR1 and trigger the way that activates CR3 binding capacity. Cooperativity between Fcγ and complement receptors occurs when C3b/iC3b-bearing targets are also opsonized by antibodies or display glycosylated CR3 ligands. CR3 can be activated by "inside-out" or "outside-in" mechanisms to generate high-affinity binding sites on the integrin [57].

10.4.2 Degranulation

Neutrophils are specialized killers of invading pathogens to the human organism [58]. Various antimicrobial and cytotoxic proteins are synthesized by neutrophils, packed into different types of granules and released upon cell activation. The phagosome in neutrophils acquires its antimicrobial effects through fusion with secretory vesicles and granules, endomembrane organelles produced from vesicles that bud off the trans-Golgi network and contain a surprisingly heterogeneous and powerful store of microbicidal peptides and proteolytic enzymes that contribute to pathogen elimination [59]. Granule biogenesis follows the granulocyte differentiation pathway, so in different stages of neutrophil growth, azurophil granules are formed first, followed by specific granules containing lactoferrin and collagenase, then it is the turn of gelatinase granules, and finally secretory vesicles appear at the stage of mature neutrophil [60]. Granules are characterized to be readily mobilized upon an inflammatory stimulus at the plasma membrane in reverse order to their formation [61]. Instead, secretory vesicles are endocytic vesicles that represent a reservoir of membrane-associated receptors needed at the earliest phases of the neutrophil-mediated inflammatory response; vesicles are mobilized in response to a wide variety of inflammatory stimuli [62].

The release of granule-derived mediators from neutrophils occurs by tightly controlled receptor-coupled mechanisms, leading to exocytosis. It is known that

exocytosis happens in four discrete steps [63]. The first step is granule recruitment from the cytoplasm to target membrane, which depends on actin cytoskeleton remodeling and microtubule assembly, and it is followed by vesicle tethering and docking, leading to contact of the outer surface of the lipid bilayer membrane surrounding the granule with the inner surface of the target membrane. Translocation and exocytosis of neutrophil granules and secretory vesicles require increases in intracellular Ca^{2+} [64].

10.5 Cytokine Synthesis

Neutrophils are a "factory" of *de novo* synthesized cytokines and also express cytokines at a basal level from preformed stores [61]. Different proinflammatory cytokines and chemokines often exert their proinflammatory functions via an autoregulatory pathway. Neutrophils are favorite targets of proinflammatory cytokines, IL-1 and TNF-α, chemokines such as IL-8, and growth factors such as granulocyte/monocyte colony stimulating factor (G-CSF and GM-CSF). The pattern of cytokines produced by neutrophils also greatly differs depending on the agonist. Also, the production of cytokines by neutrophils can easily be modulated by immunomodulatory cytokines such as IFN-γ, IL-4, IL-10, and IL-13, suggesting that T helper-1 (Th-1) or Th-2 cells may influence neutrophil cytokine production [65].

10.5.1 TNF-α

TNF-α is a pleiotropic cytokine belonging to the superfamily of membrane-anchored and soluble cytokines that are remarkably involved in T cell-mediated immunity. Although it inhibits the growth of tumor cells and it has an enhancing effect on the proliferation of normal cells [66], TNF-α takes part in septic shock, autoimmunity, and inflammatory diseases. Its potent proinflammatory effects mainly results from its capacity to increase expression of endothelial cell adhesion molecules and subsequently support neutrophil adherence to vascular endothelium. Neutrophils are exquisite targets of TNF-α that, under certain conditions, strengthens their expression of adhesion molecules, induces their degranulation and successive release of lysosomal enzymes, causing the production of highly reactive oxygen species (ROS). TNF-α-induced transcellular migration of neutrophils through the production of soluble protein synthesis-dependent chemotactic factors, including IL-8. This testifies cytokine networking involvement in inflammatory cell recruitment and an active role in inflammation [67].

10.5.2 IL-1 and IL-1 Receptor Antagonist

Neutrophils indeed express the mRNA of both IL-1α and IL-1β and release IL-1 proteins [68]. On the other hand, the quantity of IL-1β is greater than IL-1α. Interestingly, it is demonstrated that antineutrophil cytoplasm autoantibodies (ANCA) induce IL-1α mRNA expression in neutrophils, usually released in

concert with TNF-α [69]. The demonstration of a constitutive secretion of IL-1 receptor antagonist (IL-1Ra) by neutrophils using GM-CSF combined with TNF-α as agonists [68] has been followed by the demonstration that neutrophil-derived cytokines have an inhibitory activity on IL-1 production [70].

10.5.3 IL-8 as a Model of Chemokines

IL-8 is a prototype of the C-X-C chemokines family [71]. IL-8 is a potent neutrophil chemoattractant and activator expressed in response to LPS, cytokines, or aggregated immune complexes. Interestingly, IL-8 is the most abundantly secreted cytokine by neutrophils and, on the other hand, neutrophils are the primary cellular target of IL-8 [72].

10.5.4 Modulation of Cytokine Expression and Production by Neutrophils

Proinflammatory cytokines and chemokines upregulate microbicidal activity of neutrophils. All are considered additional immunomodulatory agents to treat serious or refractory infections in humans [73]. Cytokine expression by neutrophils can be easily modulated by the T-cell-derived regulatory cytokines: positively by Th1-type cytokines such as IFNγ and negatively by Th2-type cytokines such as IL-10, IL-4, and IL-13 [74].

IFN-γ exerts a strong enhancing effect on the production of cytokines, upregulating both the production of IL-1Ra and the accumulation of IL-1Ra mRNA. Contrary to IFN-γ, IL-10 exerts an inhibitory effect on neutrophil cytokine production, particularly TNF-α, IL-1-β, and IL-8 production [75]. IL-4 also induces an upregulation of IL-1Ra synthesis in neutrophils and a priming effect on neutrophil production of TNF-α and IL-8 induced by LPS.

One of the important findings is the ability of stimulated neutrophils to release TNF-a, IL-lβ, IL-8, and IL-lRa, and the fact that the type of triggering stimulus determines not only the amplitude but also the intrinsic characteristic of this response [76]. Moreover, recent studies have shown that a wide variety of agonists induce the nuclear accumulation of NF-κB/Rel proteins, the main way of cytokines activation [77]. In contrast, numerous studies have shown that cytokine gene expression can be regulated at the level of mRNA stability and this mechanism explains the upregulation of IL-1β mRNA. The inhibitory effects of IL-10 on neutrophil IL-8 production also result from both an inhibition of IL-8 gene transcription and an enhanced IL-8 mRNA degradation. Finally, a control at the translational level has also been suggested for IL-1Ra under specific experimental conditions [78].

10.6 Neutrophil Apoptosis

Neutrophils live for less than 24 h in the circulation and are characteristically preprogramed to die by constitutive apoptosis. Recent studies suggest that this process is planned by intracellular signaling and changes in gene expression that

define an "apoptosis differentiation program" [79]. Neutrophil apoptosis is a essential, early component of efficacious resolution of inflammation and is likely delayed or defective in nonresolving chronic inflammatory states [80]. This is linked to the loss of expression of adhesion molecules and greatly decreases responsiveness to external stimuli, so that these cells become functionally isolated from their environment. In contrast with necrosis, apoptosis is related with preservation of plasma membrane integrity, so that relieving of harmful neutrophil contents is incomplete, and the inert neutrophils are phagocytosed by local macrophages. Also, phagocytosis of apoptotic neutrophils by human macrophages *in vitro* destroys release of macrophage-derived proinflammatory mediators. Like this, by downregulating neutrophil functions and triggering "silent" clearance by phagocytes, apoptosis provides an instrument for the safe disposal of possibly destructive inflammatory cells [81]. Throughout apoptosis, receptors for proinflammatory signals from the cell membrane are not involved, while phosphatidylserine residues, recognized by phagocytes, are involved. A standard tool for the affinity of apoptotic cells implicates annexin-V binding to phosphatidylserine residues. Interestingly, a putative phagocyte receptor for PS has been found difficult to describe, and three recently identified receptors (Tim4, stabilin2, and BAI1) designate that the complication of this process might have been undervalued. Phagocytosis should be nonphlogistic, suggesting that a professional phagocyte such as the macrophage on recognizing an apoptotic cell is planned to upregulate the production of anti-inflammatory intermediaries such as transforming growth factor (TGF)-β and interleukin (IL)-10 [82]. Developing an understanding of granulocyte behavior has been a study priority and has indicated that a pharmaceutically tractable method to the modulation of granulocyte functional responsiveness might be to influence the longevity of these cells by inducing apoptosis. In addition, research is engendering an increasingly detailed picture of the apoptotic machinery at a molecular level [82,83]. A better appreciation of the processes that drive and delay neutrophil apoptosis will support the development of new drugs appropriate for the management of granulocyte-mediated diseases [84,85].

10.7 Neutrophils in Pathology

The major role of neutrophils is a rapid response to invading microorganisms. On the other hand, neutrophils do not differentiate efficiently between foreign and host antigens without the help of soluble components of the immune system [86]. The host-damaging power of the neutrophils is limited by elimination of the primary event that initiates inflammatory sequences and by mechanisms that inactivate neutrophils such as apoptosis. The blocking of neutrophil influx involves inactivation of mediators and temporal change in the model of chemokines produced. When regulatory mechanisms are impaired or when the acute insult cannot be resolved, neutrophils become the predominant contributor to tissue injury and induce lesions [87]. To exemplify the role of neutrophils in pathology by different diseases, it is appropriate to assess the stimulus or type of mechanism that activates neutrophils.

10.7.1 Bacterial Infection

The ability of neutrophils to sense bacteria and/or their components and migrate across epithelia along a chemotactic gradient is interesting. Neutrophil sequestration is an essential antibacterial defense, but excessive neutrophil infiltration and activation in the infected tissue may partly cause tissue damage. Thus, several life-threatening bacterial lung diseases are caused by excessive neutrophil-mediated inflammation [88]. During pyelonephritis, microscopic examination of infected kidneys shows intensive degranulation of neutrophils containing phagocytosed bacteria, causing severe tubular destruction and occlusion of small capillaries by leukocyte plugs [89]. Indirect evidence suggests that uropathogenic bacterial strains, which induce excessive neutrophil activation, contribute to tissue damage and renal scarring [90]. The bacterial load at the initiation of the inflammatory response and the phenotypic expression of bacteria, determining their ability to cause neutrophil activation and to resist neutrophil phagocytosis, are important factors contributing to neutrophil-induced tissue damage during bacterial infection.

10.7.2 Tissue Injury-induced Inflammation: Ischemia-reperfusion Injury

Tissue injury after ischemia appears to be a consequence not only of tissue hypoxia but also of the process of reperfusion that leads to an inflammatory response. Infiltrating neutrophils are a potential source of reactive oxygen species, proteolytic enzymes, and cytokines, which during reperfusion may play a damaging role; also, capillaries could become clogged by aggregated neutrophils, causing reperfusion of the microcirculation [91]. Several studies have shown a pathogenetic role for neutrophils in ischemic insult to the myocardium [92], liver [93,94], and kidney. Inhibition of leukocyte adhesion with anti-ICAM-1, such as therapeutic approaches on antiadhesion strategies, could be beneficial in ischemia–reperfusion injury.

10.7.3 Crystal-induced Inflammation

Neutrophils appear to be the major effector of certain forms of crystal-induced inflammation, as a consequence of their accumulation in the joint fluid where they actively ingest urate crystals, aggregate, and degranulate. One consequence of this neutrophil action is acute gouty inflammation, due to deposition of monosodium urate crystals in joints [95]. Precipitated urate crystals activate humoral mediator cascades such as complement and contact activation systems; also, urate crystals induce the production of inflammatory mediators by neutrophils (TNF-α and IL-8), amplifying the leukocyte influx [96]. Acute gouty inflammation may be prevented by neutrophil depletion or leukocyte chemotaxis inhibition.

10.7.4 Cytokine-induced Inflammation: Rheumatoid Arthritis

Neutrophils are prominent participants in the joint inflammation of human rheumatoid arthritis (RA) [97]. RA is a predominantly T-cell/macrophage-driven process in the early stage of the disease, but the cell with the greatest capacity to inflict damage within joints is the neutrophil, which is numerous in the synovial

fluid and joint tissues during the early stages of RA and during acute exacerbation of the disease. Neutrophils concentrate at the pannus–cartilage junction, which is the site of early cartilage erosion, contributing directly to the cartilage damage, both through serine and metalloproteases and through the production of ROS and chlorinated oxidants. Neutrophil-mediated cartilage injury is modulated by cytokines such as TNF-α and IL-8 [98]. TNF-α is likely to be an important stimulator of neutrophils within the joints of RA patients, resulting in amplification of the inflammatory response and contributing to the tissue damage caused by neutrophils, while, although IL-8 alone does not exert a direct effect on cartilage, it induces a rapid cartilage destruction [99].

10.7.5 Autoimmunity Against Neutrophil Components: Antineutrophil Cytoplasmic Antibodies and Vasculitis

The neutrophil plays a central role in the pathogenesis of many inflammatory disorders of the vasculature. The presence of neutrophils in vasculitic lesions, including those of Wegener's granulomatosis, leukocytoclastic vasculitis, and others, bears witness to this. Although the effector functions of neutrophils are central to the vascular injury associated with vasculitis, neutrophils must be present at the site in order to contribute to the vasculitic lesion [100]. Neutrophil granule proteins are recognized as target antigens for antineutrophil cytoplasmic antibodies (ANCA) [101]. ANCA can be divided into a group displaying a cytoplasmic staining pattern (C-ANCA) and a second group displaying perinuclear staining (P-ANCA). It appears that the majority of C-ANCA react with PR3 and the correlation between clinical expression of Wegener's granulomatosis and ANCA reactivity has established that PR3 is the target autoantigen, while the major target antigen of P-ANCA is myeloperoxidase; anti-MPO was originally described in patients with microscopic polyangiitis and idiopathic necrotizing crescentic glomerulonephritis [102].

10.7.6 Genetic Disorders of Neutrophil Regulations: Hereditary Periodic Fever Syndromes

The hereditary periodic fever syndromes are a group of disorders characterized by self-limited episodes of fever accompanied by localized inflammation. Of these syndromes, familial Mediterranean fever (FMF) has been the longest recognized [103]. FMF is an autosomal recessive disease characterized by recurrent febrile episodes in association with peritonitis, pleuritis, and arthritis and has ongoing subclinical inflammation during attack-free period [104]. The inflammatory episodes of FMF affect mainly the serosal or synovial membranes, characterized by massive influx of neutrophils into the affected tissues. The FMF gene has been identified by positional cloning and it encodes a transcript expressed predominantly in neutrophils [105]. Other tissues such as mucous membranes that are more exposed to trivial injury are not affected by the inflammatory episodes of FMF, showing that the regulatory dysfunction of neutrophils from these patients is not implicated in all pathways leading to neutrophil stimulation.

Familial Hibernian fever (FHF) is an autosomal dominant disease consisting in recurrent attacks of fever with abdominal pain and severe localized myalgia; the presence of erythematous skin lesions, conjunctivitis, unilateral periorbital edema, and scrotal pain are observed with high frequency, while pleuretic and nonpleuretic chest pain may occur [106]. Mutations that cause this disease are point substitutions within cystein-rich motifs of the extracellular domains of the 55 kDa TNF-α receptor [107].

10.7.7 Cystic Fibrosis: Neutrophil-mediated Tissue Damage and Concomitant Persistence of Infection

Cystic fibrosis (CF) is characterized by chronic progressive bronchiectasis, exocrine pancreatic insufficiency, sterility in males, and abnormally high concentrations of sodium chloride in the sweat. Water reabsorption from the CF airway lumen outweighs limited Cl^- secretion resulting in the airway secretions becoming viscid and clearance of secretions is impaired causing airway obstruction [108]. This is further compounded by colonization of the airway with organisms such as *P. aeruginosa* [109]. The most characteristic feature of inflammation in the CF lung is the persistent infiltration of massive numbers of neutrophils into the airways. Neutrophils are considered responsible for the early onset and the promotion of the inflammatory process in CF, which starts within the first year of a CF patient's life [110]. Proinflammatory chemoattractants have been found to be elevated in bronchoalveolar lavage fluid(BAL) from CF, including IL-8, IL-1, IL-6, and TNF-α and bacterial products, which also act as potent chemoattractants for neutrophils. Also, neutrophil elastase (NE) induces gene activation and secretion of IL-8 and digestion of C3b receptors on neutrophils, which limits the phagocytosis of pathogens [111]; studies in CF patients have shown increased numbers of elastase [112]. With regard to neutrophil functions, myeloperoxidase-dependent activities appear to be significantly higher also in heterozygote parents of CF patients [113], providing some evidence for a genetic component in the altered neutrophil function in CF. Also, there is a decrease in the changing role of L-selectin in stimulated CF neutrophils, which was not observed in either stable or acutely infected non-CF bronchiectasis patients, thus suggesting a disturbed control of the migration process in CF neutrophils [114]. Clinical management of CF presents a paradox because CF involves chronic active inflammation and recurrent infections requiring a therapy combining antibiotherapy and anti-inflammatory drugs [115].

10.8 Conclusions

Polymorphonuclear neutrophils include two-thirds of peripheral blood leukocytes and they are leaders of the innate immune cells that migrate to the place of infection or inflammation for suppression and clearance of infectious elements [58]. Until approximately two decades ago, neutrophils were considered as short-lived cells having a destructive hardware but no software. This notion has

been revised since it became clear that neutrophils were capable to integrate complex arrays of adhesion, chemoattractant, and cytokine driven signs. Neutrophils also were able to synthesize cytokine in reply to inflammatory stimuli. The neutrophil itself acts to be well equipped with an uncommon combination of contrasting molecules: ROS, ubiquitous and short-lived molecules and proteases, and macromolecules with specific long-lasting inactivity. Neutrophil safely keeps them apart through independent intracellular compartmentalization under physiological conditions. These mediator activities regulate pathophysiological processes not exclusively designed at the destruction of invading microorganisms. Finally, neutrophils are activated by anabundant variety of stimuli and are convoluted in different disorders.

11.1 Introduction

The unique properties of mast cells were first noticed by Paul Ehrlich, who described the distinct morphological appearance and metachromatic staining of these cells in his seminal 1878 doctoral thesis [1]. Now, over 130 years later, we are beginning to gain a full appreciation for the multifaceted capabilities of the mast cell in orchestrating immune responses, particularly in the context of infectious diseases.

Once only thought to serve as part of the defense against parasitic infections and the noxious effectors of allergic disease, it is now becoming apparent that this cell type plays a varied and tunable role in orchestrating immunity to pathogens. As we will describe in this chapter, mast cells have several intrinsic properties that allow them to be such effective drivers and conductors of immune responses. Specifically, mast cells are strategically located at host–environment interfaces, where their expression of a wide range of receptors allows them to respond promptly to extrinsic challenge through degranulation of prestored mediators with both degranulation and secretion of *de novo* synthesized mediators. This leads to potent induction of both innate and adaptive immune responses, which can be exploited in to boost immune responses to vaccines. However, mast cells do not always play protective roles against pathogens. Under certain contexts, mast cell-mediated inflammation may even worsen the disease state. Mast cells also may prematurely trigger anti-inflammatory effects, which can inhibit productive immune responses against pathogens.

11.2 Biology of Mast Cells

Tissue located mast cells originate from bone marrow haematopoetic progenitors that circulate in the blood [2]. Upon entering tissues, these progenitors

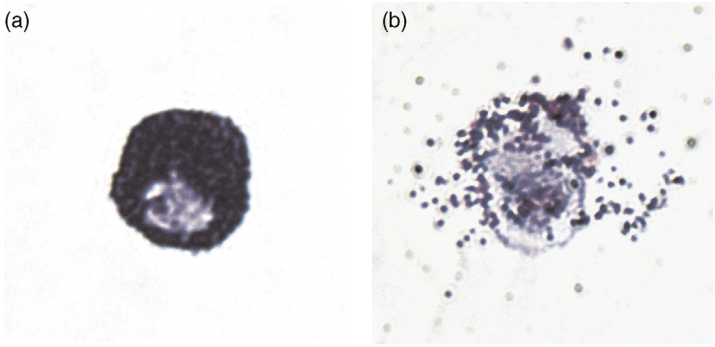

Figure 11.1 Mast cells release prestored granules upon activation. Peritoneal lavage from IgE-sensitized mice injected i.p. with (a) PBS or (b) antigen was stained with Toluidine blue, which stains heparin-containing granules a deep purple. Note the densely packed granules in (a) and the extensive exocytosis of granules in (b).

differentiate into mature mast cells that may live for months [3]. These long-lived cells are capable of several cycles of degranulation and regranulation and are able to proliferate in tissue in response to appropriate signals despite being terminally differentiated [4,5].

The most distinct feature of mast cells is their numerous, electron-dense secretory granules, which occupy a large proportion of the mast cell cytoplasm and upon activation, can be discharged rapidly within seconds to minutes (Figure 11.1). These granules contain high amounts of anionic proteoglycans [6,7] that result in the characteristic metachromatic staining when visualized with cationic dyes such as Toluidine blue. The major constituent of granules are mast cell-specific proteases, which are tightly complexed with sulfated proteoglycans such as heparin and chondroitin sulfate, the specific combinations of which vary with mast cell phenotype. Mast cell granules are also rich sources of biogenic amines, the most notorious of which is histamine, the compound responsible for many of the symptoms of allergic inflammation. The neurotransmitter, serotonin, is also highly expressed in rodent mast cells but less so in human MCs. In addition, as part of their unique function, mast cells also store preformed cytokines and growth factors within granules, such as tumor necrosis factor (TNF) and vascular endothelial growth factor (VEGF) [8].

Notably, mast cells are phenotypically heterogeneous at different anatomical sites, as well as between different animal species. Broadly, rodent mast cells can be categorized into mucosal mast cells, which are present in the epithelia of mucosal tissues such as the gut and lung, and connective tissue mast cells, which are found in the submucosae and muscle layer. Based on their anatomical location, these subtypes of mast cells differ notably in the protein and proteoglycan components of their granules [9]. Connective tissue mast cells express both tryptases and chymases complexed with heparin, while mucosal mast cells express only chymases, complexed with chondroitin sulfate. A similar dichotomy is present in human cells, which are classified into tryptase and chymase-positive (MC_{TC}) and tryptase-positive (MC_T), though there is less stringency in tissue-type specificity [10]. Individual mast cells may also vary with regard to granule

contents, as different environmental stimuli can result in the upregulation of specific granule components. For instance, human mast cells cultured *in vitro* can increase the chymase content of their granules in the presence of IL-4 [11]. In mouse mucosal mast cells, IL-10 can modulate the transcription of the protease mMCP2 [12]. Thus, mast cells can potentially have very heterogeneous responses even to the same stimulus depending on their granule contents.

11.3 Role of Mast Cells in Immune Surveillance

11.3.1 Strategic Peripheral Location

Mast cells are found in most connective tissues throughout the body, but they are most concentrated at interfaces between the host and the environment, such as the skin, gastrointestinal tract, and respiratory tract. Thus, they are ideally situated to be one of the first responders to pathogens and other extrinsic challenges that breach the epithelial barrier of the host [13].

In addition, mast cells are located proximal to blood vessels, lymphatics [14], and nerve fibers [15], suggesting that they are also ideally situated to quickly relay information regarding invading pathogens by releasing mediators in the vicinity of these structures. Interestingly, a recent report suggests that perivascular mast cells may even directly acquire IgE antibodies circulating in the blood by extending cellular processes across blood vessel walls [16]. This ability to sample vascular contents may also apply to detecting pathogens or pathogen-associated molecules in the circulation, and the ability of mast cell products to affect vascular permeability could further facilitate their ability to access microbes and other antigens in the blood.

11.3.2 Direct Recognition of Pathogens

Mast cells express a wide variety of pattern recognition receptors (PRRs) that allow them to directly recognize pathogen-associated molecular patterns (PAMPs). This includes Toll-like receptors (TLRs), C-type lectins (e.g., dectin-1), and other surface molecules such as CD14 [17]. Expression of most TLRs has been described for mast cells at least at the mRNA level, and they have been shown to be either constitutively expressed or are upregulated based on cues from the microenvironment. TLR4 expression in human mast cells derived from cord blood, for example, is inducible by *in vitro* culture in the presence of IFNγ or IL-4, but it is not expressed constitutively [18,19]. Certain pathogen-associated ligands can also activate mast cells by a combination of TLRs and other surface molecules, such as fungal zymosan, which is recognized by a combination of TLR2 and dectin-1 [20], and LPS, which is recognized by TLR4 and CD14 [21].

Differential ligation of different TLRs alone or in combination with other receptors can result in distinct mast cell activation outcomes, such as degranulation or secretion of specific cytokines. TLR2 activation via bacterial peptidoglycan, for instance, results in both mast cell degranulation and cytokine production, while TLR4 ligation via LPS only results in cytokine release [22].

However, different groups have reported conflicting results regarding the ability of various TLRs to stimulate mast cell degranulation or cytokine synthesis, suggesting that the specific responses of mast cells to TLR stimulation may depend on mast cell phenotype. In addition, simultaneous ligation of both TLR and other activating receptors, such as the high-affinity receptor for IgE, FcεRI, can enhance the release of cytokines [23], adding a further dimension to TLR-mediated responses.

Conversely, TLR signaling may influence the phenotype of mast cells, such as by downregulating FcεRI expression, by altering protease composition of granules, and by influencing cytokine secretion [17]. Prolonged interaction of mast cells with pathogens and their associated PAMPs, such as in a chronically inflamed tissue, could therefore further shape mast cell-directed immune responses.

11.3.3 Indirect Recognition of Pathogens

Mast cells express receptors for IgG and IgE on their cell surface, allowing them to become sensitized to antigen previously encountered by the host by binding antigen-specific immunoglobulins. These bound antibodies enable mast cells to specifically recognize and vigorously react to previously encountered pathogens. The high-affinity receptor for IgE, FcεRI, is highly expressed in mast cells and is responsible for protective IgE-mediated responses to metazoan parasites such as roundworms [24]. However, they are also responsible for misdirected IgE-mediated hypersensitivity reactions to harmless antigens. Rarely, IgE can also be produced in response to bacterial antigens [25]. In addition to FcεRI, mast cells also express the FcγR family of receptors for IgG [26], of which FcγRI and FcγRIII are activating and FcγRIIB is inhibitory. Human mast cells express FcγRII constitutively, while FcγRI expression is induced by the presence of IFNγ [27] and FcγRIII is not expressed. In mouse mast cells, FcγRI is not expressed, FcγRIIB is constitutively expressed, and FcγRIII is induced only in the presence of stem cell factor (SCF), such as when bone marrow-derived mast cells (BMMCs) are cocultured with fibroblasts [28]. Cross-linking of activating FcγR by IgG immune complexes or IgE-bound FcεRI by multivalent antigen results in mast cell activation, degranulation, and cytokine secretion. Coligation of FcεRI and the inhibitory FcγRIIB, however, results in the downregulation of FcεRI signaling [26]. Bacterial superantigens such as *Staphylococcus aureus* protein A, which binds certain classes of antibodies independent of their antigen specificity, can also trigger mast cell degranulation through FcR [29].

11.3.4 Activation by Endogenous Danger Signals

During infection many endogenous "danger signals," which are host-derived proinflammatory mediators, are elaborated by stressed or dying cells. These signals, such as complement, antimicrobial peptides, substance P, and endothelin-1, can also activate mast cells [13]. Human mast cells express the G protein-coupled receptor Mrgx2, which can be activated by the antimicrobial peptide LL-37 [30]. This receptor has also been implicated in mast cell-dependent anaphylactoid reactions to ciprofloxin and other irritants [31]. Endothelin-1,

which is produced during sepsis by endothelial cells, can activate mast cells via the receptor ET-1 [32]. Notably, components of the complement system, in particular C5a, can also activate mast cells, inducing their chemotaxis and degranulation and production of cytokines through complement receptors on mast cells [33].

11.3.5 Degranulation and Secretory Responses to Pathogens

The rapid exocytosis of mast cell granules and their associated preformed contents allows for their prompt response to pathogens or other insults within seconds to minutes. This is hugely advantageous, as other immune cells, such as skin-resident DCs or epithelial cells, require considerably more time to mount a response due to the requirement for *de novo* synthesis of mediators. However, mast cells also have a potent second-phase response occurring hours after the initial stimulus, where they *de novo* synthesize and secrete mediators such as cytokines, prostaglandins, and other inflammatory molecules. It is well known that different stimuli, or even intensity of stimuli, can trigger differential production and secretion of these mediators. This two-phase response allows for great plasticity in the duration, nature, and specificity of mast cell-directed responses to pathogens.

During the first phase of mast cell activation, mast cell granules, which are stored as insoluble particles within the cytoplasm, are exocytosed into the extracellular milleau. While some granule-associated mediators, such as histamine, become immediately soluble, most of the membrane-free structure remains insoluble, due to tight electrostatic interactions formed between positively charged proteins (mostly proteases) and negatively charged heparin or chondroitin sulfate. Preformed cytokines such as TNF are entrapped within these particles and are released slowly over time once the particle is exocytosed [34]. In this way, mast cells are able to prolong the half-life of their mediators, as they are extremely susceptible to dilution and degradation in the extracellular medium. In addition, exocytosed granules can drain into the lymphatics and traffic to the draining lymph nodes to modulate cellular infiltration at this distal site [34]. This represents a highly effective way for peripherally placed mast cells to modulate immune responses initiated in the draining lymph nodes.

Within minutes of stimulation, mast cells begin to *de novo* synthesize mediators such as cytokines and eicosanoids. Eicosanoids, which comprise prostaglandins and related compounds such as leukotrienes, can be rapidly enzymatically converted from arachidonic acid to an active form [35]. Once secreted, they function as proinflammatory mediators that enhance vascular permeability and cellular recruitment. Mast cells also produce a wide array of chemokines and cytokines depending on type and strength of stimulus, which have varied effects including cellular recruitment, enhanced bacterial killing, and promotion of antigen presentation. Thus, mast cells can follow up an immediate degranulation response with the synthesis of additional factors that are tailored to the stimulus, allowing for both rapid activation of nearby immune cells and changing the microenvironment to direct immune cells toward appropriate responses to pathogens.

11.4 Mast Cells in Innate Immunity

Mast cells are increasingly being recognized as a pivotal modulator of the innate immune system. Other than directly contributing to degradation of bacteria or other noxious substances, they can also direct the activation and recruitment of appropriate immune cells to the site of infection to facilitate early clearance of the pathogen.

11.4.1 Direct Bactericidal Activity of Mast Cells

Mast cells have been observed to display direct antimicrobial activities, which is in part due to the presence of antimicrobial peptides such as cathelicidins [36] within their granules. In addition, mast cells are able to endocytose enterobacteria, such as *Escherichia coli*, which express type I fimbrae, by binding the fimbral component FimH through the cell surface molecule CD48 [37,38]. Endocytosed bacteria are then killed through oxidative burst and acidification of vacuoles. There is also evidence that mast cells, like neutrophils, are able to trap and kill bacteria via extracellular trap formation (mast cell extracellular traps) [39]. These extracellular traps are composed of nuclear histones, antimicrobial peptides, and tryptases and are released in a reactive oxygen species (ROS)-dependent cell death mechanism. However, due to their low numbers at sites of infection, relative to the large numbers of recruited professional phagocytes and other immune cells, it is unlikely that mast cells contribute significantly to direct bacterial killing *in vivo*.

11.4.2 Resistance to Exo- and Endotoxins

Mast cell granules contain large amounts of active proteases that could potentially cleave and inactivate protein substrates in the microenvironment, including peptide toxins. It has been demonstrated that in a cecal ligation and puncture rodent model of bacterial sepsis, high levels of inflammatory peptides such as neurotensin and endothelin are released, which contribute to mortality of the host. In this model, mast cell-derived carboxypeptidase A3, and possibly other proteases, digested these toxins and increased host survival [32]. Exotoxins present in insect or reptile venoms can cause pathology by mimicking the structure of endogenous inflammatory peptides, and in recent years, mast cells have been hypothesized to play an important role in the defense against these toxins. Mast cell carboxypeptidase has been shown to be protective against sarafotoxin, a component of viper venom that is a homologue of the endogenous inflammatory peptide endothelin [40]. This exotoxin can induce mast cell degranulation through the ET-1 receptor. Interestingly, IgE/antigen-mediated activation of mast cells, even when the antigen was not a component of the venom tested, could enhance immunity to viper venom, perhaps by enhancing immune cell trafficking [41].

11.4.3 Induction of Immune Cell Trafficking to Sites of Infection

Mast cells secrete a wide variety of chemoattractants and cytokines that promote leukocyte trafficking to sites of infection, where they can contribute to pathogen clearance or amplify inflammation by secretion of proinflammatory cytokines. One of the most important cytokines secreted is TNFα, which plays an important role in the trafficking of neutrophils to sites of mast cell activation in order to initiate bacterial clearance [42]. Mast cell granule proteases, released upon degranulation, are also known to have chemotactic activity for leukocytes. Specifically, mouse mast cell protease 6 (mMCP6), but not mMCP7, has been shown to induce neutrophil migration in mice [43,44]. mMCP6 may also contribute to eosinophil recruitment and cytokine production in response to parasitic infection [45]. Mast cells also synthesize leukotrienes (LT), such as LTB4 and LTC4, in response to bacterial challenge, which upregulate P-selectin on endothelial cells, enhancing the rolling phase of the leukocyte adhesion cascade [46]. This activity of mast cell leukotrienes has been demonstrated to facilitate neutrophil recruitment and bacterial clearance in an infectious peritonitis model [47]. Mast cells can also induce cell trafficking in response to viral challenge, presumably after stimulation of TLRs during infection of the cell by virus. Respiratory syncytial virus, while only poorly infective for human mast cells, was able to induce the secretion of multiple chemotactic factors for leukocytes, such as CCL4, CCL5, and CXCL10 [48]. In a mouse model of dengue infection, mast cells upregulate the chemokines CX3CL1, CXCL12, and CCL5, which recruit NK cells to the site of viral infection [49]. This role of mast cells to recruit appropriate pathogen-clearing immune cells to sites of bacterial, viral, and parasitic infections is arguably the most important innate immune activity mediated by these immune surveillance cells.

11.5 Mast Cells in Adaptive Immunity

As previously discussed in Section 11.3.3, mast cells are well known effectors of adaptive immunity by binding immunoglobulin through their Fc receptors. The best known instance of this is in IgE-mediated immunity against helminth parasites. However, mast cells also have critical roles in enhancing and shaping the adaptive immune responses.

11.5.1 Mast Cells as Effectors of Adaptive Immunity

Mast cell and IgE-associated responses are thought to contribute to host defense against helminths and other parasites that are too large to be endocytosed. Mast cell products such as their proteases secreted upon IgE/FcεRI activation and directed at parasite surfaces are believed to contribute to killing and expulsion of parasites [50]. Prior sensitization to insect and reptile venoms can also induce the production of specific IgE. Mast cell-derived carboxypeptidase secreted in response to subsequent challenge with these venoms has been demonstrated to be protective [51].

11.5.2 Recruitment of DCs and Effector T Cells to Sites of Infection

Dendritic cells (DCs) are professional antigen-presenting cells that bridge the innate and adaptive immune systems. DC activation and trafficking to lymph nodes is a hugely important event in the initiation of adaptive immunity. During infection by bacteria such as *E. coli*, mast cells recruit large numbers of DCs into infected tissues, which then go on to migrate into draining lymph nodes [52]. This trafficking was caused by the upregulation on E-selectin on endothelial cells facilitated by mast cell-derived TNF. This mast cell-dependent recruitment of DCs was essential for primary humoral responses against bacteria. In addition, mast cells may also promote the trafficking of effector T cells to sites of infection. In a model of viral peritonitis, mast cell secretion of CXCL10 and CCL4 promoted the recruitment of CD8+ T cells [53].

11.5.3 Recruitment of Dendritic Cells and T Cells to Draining Lymph Nodes

Draining lymph nodes are dynamic lymphoid structures that can entrap large numbers of circulating lymphoctyes during infection, causing them to swell dramatically in size. During infection, T cells recruited to the node interact with antigen-loaded antigen-presenting cells that have trafficked from sites of infection, initiating the adaptive immune response. It is now clear that mast cells can regulate lymph node hypertrophy. Mast cell secretion of TNF recruits T cells and DCs to draining lymph nodes within 24 h after bacterial infection or activation with 48/80, a mast cell activator, a process that involves the upregulation of VCAM-1 on endothelial cells [54]. Interestingly, peripherally located mast cells can also direct distal responses in lymph nodes by the release of stable particles containing inflammatory mediators. These insoluble particles drain via the lymphatics to local lymph nodes, transporting mast cell-derived TNF where it is slowly released [34]. Mast cells may also induce DC migration to the lymph node in a TNF-independent histamine and IL-6-dependent manner when stimulated with bacterial peptidoglycan [55]. Thus, following infection at peripheral sites, mast cells serve to kick-start adaptive immunity by promoting the coordinate trafficking of professional APCs from infection site into the draining lymph nodes and simultaneously sequestering T lymphocytes to facilitate optimal antigen presentation.

11.5.4 Antigen Presentation

While not regarded as professional APCs, mast cells can directly present antigen to T cells and stimulate their response [56]. Constitutively, they express MHC class I, while mast cells isolated from infected tissues have been observed to express MHC class II [57]. They also express costimulatory molecules such as OX40 ligand [58]. Mast cell-mediated MHC class I-dependent antigen presentation to T cells has been reported to promote the activation and proliferation of CD8+ T cells, as well as enhance their production of IL-2 and granzyme B in autoimmunity, suggesting that this modulation of CD8+ T cell function could also possibly occur during infection [59]. However, the contribution of MHC class II-dependent antigen presentation by mast cells *in vivo* is still unclear, as mast cells are comparatively few compared to professional APCs in tissue. Rather, mast

cells are likely to enhance antigen presentation by APCs. Mast cell products can influence DC activation and antigen presentation. For instance, histamine has been suggested to enhance DC uptake of antigen and cross-presentation and the upregulation of costimulatory molecules. Mast cell-derived cytokines can also prime immune responses toward Th2, such as during responses to helminth infection, by the secretion of type 2 cytokines [50].

11.6 Enhancement of Immunity by Boosting Mast Cell Activity

The potent ability of mast cells to drive adaptive immunity, as outlined above, has inspired studies directed at harnessing this activity to improve immune responses to vaccine antigens. One approach is to coadminister small-molecule mast cell activators as adjuvants in vaccine formulations. These mast cell activators, upon administration, would activate local mast cells, greatly enhancing antigen uptake and trafficking of immune cells to the draining lymph node. The second approach is to utilize mast cell granule-inspired synthetic granules loaded with immunomodulatory cytokines such as TNF and incorporate them as adjuvants in vaccine formulations. When injected at a peripheral site, the synthetic granule forumulation, just like natural mast cell granules, would traffic via the lymph to the draining lymph node and release their cargo of immunodulatory cytokines. The resulting cytokine burst should markedly enhance immune cell trafficking into this organ from both the peripheral site of vaccination and the blood, culminating in an enhanced immune response to the vaccine. Both of these approaches are described below.

11.6.1 Mast Cell Activators as Novel Vaccine Adjuvants

The addition of compound 48/80 (C48/80), a mast cell activator, to vaccine formulations has been shown to markedly enhance humoral immunity in an anthrax lethal toxin challenge. Importantly, using this adjuvant resulted in a balanced Th1/Th2/Th17 response without evoking IgE-mediated responses [60]. In addition, intranasal vaccination with C48/80 adjuvant activated mast cells in the nasal-associated lymphoid tissue (NALT) and promoted antigen-specific IgA, a goal considered especially important for evoking effective immunity at mucosal surfaces. Recently, intranasal coadministration of C48/80 with a pneumococcal vaccine has also been demonstrated to be protective against lethal challenge and even nasal pneumococcal colonization compared to a classic mucosal adjuvant, cholera toxin [61]. These reports suggest that it is safe to intentionally activate mast cells in a local fashion in order to promote immunity.

11.6.2 Synthetic Mast Cell Granules

Current vaccine strategies have mostly attempted to enhance immune responses to antigen. However, the nature of the resulting immune response must be carefully tuned to target the specific pathogen. Mast cells evoke predominantly

Th2-type responses, defined by enhanced antibody production and cytokines such as IL-4. These responses are helpful for the production of neutralizing antibodies against pathogens. By contrast, Th1-type responses, characterized by cytotoxic T cell activity and cytokines such as IL-12 and IFNγ, are more effective against intracellular pathogens. Thus, it is important to tailor adjuvants to evoke the type of response that is most effective against a particular pathogen. As discussed previously, mast cell granules contain inflammatory mediators tightly complexed with proteoglycans to form stable particles that can potently induce immune responses at distal sites [34]. Mimicking these particles and including different cytokines to polarize immune responses as needed could, therefore, be a viable strategy in vaccination. Mast cell granule-inspired particles can be readily synthesized by encapsulating cytokines within heparin–chitosan complexes at acidic pH, forming nanoparticles between 200 and 1000 nm in diameter. Indeed, such synthetic mast cell granules containing TNF could protect against lethal flu challenge with efficacy on par with conventional alum adjuvant. Conversely, when particles were loaded with IL-12, a Th1-associated cytokine, this promoted Th1-polarized responses toward an experimental antigen, OVA [62]. Thus, the use of synthetic granules loaded with immunomodulatory cytokines to target lymph nodes in order to enhance and/or polarize immune responses is potentially a powerful new strategy for enhancing immunization. In addition, this approach provides tremendous flexibility in vaccine design by tailoring the specific cytokines encapsulated to the desired immune response.

11.7 Potentially Detrimental Roles of Mast Cell Activation during Immune Responses

While local mast cell activation at mucosal or skin sites is generally beneficial during early infection, these mast cell responses can become harmful if pathogens or pathogen-derived products gain entry into the blood, where they can simultaneously activate mast cells through out the body. Even if the pathogen does not enter the circulation, prolonged activation of mast cells at the site of infection can also lead to significant pathology. Paradoxically, at certain body sites, mast cell activation by microbes can lead to inhibition rather than promotion of immune responses, resulting in impaired clearance of the pathogen.

11.7.1 Overactivation of Mast Cells

Prolonged activation of peripheral mast cells and release of mediators can result in chronic inflammation and tissue remodeling. The best-known examples of this are in allergic diseases such as asthma, where chronic activation of mast cells can result in remodeling of airways [63]. In atopic dermatitis, where most patients are colonized with *S. aureus*, peptidoglycan derived from *S. aureus* can activate mast cells through TLR2, stimulating proinflammatory cytokine production [22]. The *S. aureus* delta-toxin can also potently induce mast cell degranulation directly [64]. Costimulation of FcεRI and TLRs can also enhance cytokine

secretion in mast cells [23], suggesting that viral or bacterial infections have the ability to exacerbate IgE and mast cell-associated disorders. Systemic activation of mast cells can occur either when pathogens bypass the mucosal or skin barrier and reach the bloodstream or when infections are so overwhelming that bacteria or bacterial products enter the circulation, such as during sepsis. In rodent models of sepsis, while local activation of mast cells in the peritoneum can be protective, they can also aggravate inflammation and increase mortality, a complication associated with systemic activation of mast cells and release of IL-6 [65]. In dengue hemorrhagic fever, systemic activation of mast cells and elevated serum protease has been associated with vascular leakage and higher morbidity in human patients [66]. Interestingly, blocking of mast cell degranulation with mast cell-stabilizing drugs such as ketotifen and cromolyn during severe sepsis [65] or dengue hemorrhagic fever [66] has been markedly protective. Mast cells thus seem to be a double-edged sword in immunity, where acute local responses, such as at mucosal surfaces, enhance the clearance of pathogens, while sustained or systemic activation is associated with harmful sequelae.

11.7.2 Negative Modulation of Immunity by Mast Cells

While many mast cell mediators have significant proinflammatory effects, mast cells are also capable of downregulating the immune response. In particular, mast cells secrete IL-10, an anti-inflammatory cytokine. IL-10 can suppress the production of proinflammatory cytokines and chemokines and enhance the ability of DCs to decrease T cell proliferation and cytokine secretion. Mast cell-derived IL-10 has been shown to inhibit proinflammatory responses and limit skin pathology in mouse models of contact hypersensitivity (CHS) and chronic, low-dose exposure to ultraviolet B (UVB) [67]. In these models, tissue swelling and recruitment of leukocytes to the affected skin was reduced in mast cell and IL-10 sufficient mice. In bacterial cystitis, which is an inflammation of the bladder, IL-10 secreted by mast cells limits humoral responses to the pathogen, despite vigorous innate immune responses, resulting in the persistence of bacteria in the bladder, a phenomenon that could contribute to the high rates of recurrence of urinary tract infections. It was found that this limitation was tissue-specific, as bacterial infection of the kidneys (pyelonephritis) did not show the same defect in humoral responses [68]. Other mediators secreted by mast cells are also likely to have negative immunomodulatory effects. One study demonstrated that the ability of UVB to suppress CHS responses to the hapten 2,4,6-trinitrochlorobenzene was dependent on mast cells and histamine [69]. Thus, mast cells have the capability to significantly limit inflammatory responses *in vivo*, potentially hindering the clearance of pathogens.

11.8 Concluding Remarks

Mast cells are one of the first responders to pathogenic insult at host–environment interfaces. The speed of their responses and their ability to evoke both vigorous innate immune responses and long-lasting immunological memory

suggests that they are critical to successfully controlling infections. Therefore, harnessing these properties of mast cells through using adjuvants that stimulate mast cell activity or mimicking the long-distance immunomodulatory effects of their granules are attractive strategies for enhancing productive immune responses to pathogens. However, chronic or systemic activation of mast cells also occurs in some diseases, where they can be severely detrimental to the host. In such cases, inhibiting mast cell activation with specific stabilizers such as ketotifen or cromolyn can have beneficial effects. Thus, understanding the role of mast cells in different contexts is invaluable in order to manipulate their functions to combat infections or reduce inflammation.

Dendritic Cells in Inflammatory Disease

Bart N. Lambrecht, Martin Guilliams, and Hamida Hammad

University of Ghent, VIB Inflammation Research Centre, Technologiepark 927, 9052 ZwiJ naarde, Belgium

12.1 What Defines a Dendritic Cell?

Dendritic cells (DCs) are professional antigen-presenting cells that play an essential role in the initiation and the regulation of T-cell responses [1]. By bridging innate and adaptive immunity, they control the balance between tolerance and immunity. They are a relatively newly described cell type, only discovered in 1973 by Nobel laureate Ralph Steinman [2]. From his work, as well as the work of many others, a DC is now described as a cell that has the potential to take up antigen, process it in small peptides for presentation to naïve T cells, and present the antigen in an immunogenic manner, meaning that T-cell costimulatory molecules like CD80 and CD86 and cytokines like IL-12 are made for stimulation of naïve T cells. Another defining characteristic of a dendritic cell (and an important discriminator with macrophages) is the potential of the DC to migrate from the periphery of the body (skin, lung, and intestine) to the T-cell area of draining nodes. Again, there are important exceptions to this conundrum, as some DCs are very sessile, and even called "lymph node resident" DCs, to contrast them with "migratory" DCs. It is also clear now that DCs do more than just stimulate naïve CD4 and CD8 T cells. It was shown that DCs can also stimulate memory T cells, and can transfer unprocessed antigen to B cells [3–5]. In addition, we now realize that DCs can also tolerize and dampen T-cell responses [6]. DCs are considered as promising targets for next-generation immunotherapies aimed at boosting or dampening T-cell responses in inflammatory diseases [7]. This chapter deals with the contribution of DCs in inflammatory disease, beyond the role that these cells have in the initiation of immunity, but focusing mainly on their role in allergic inflammation, the area of our specific expertise.

12.2 Dendritic Cell Subsets

Initially considered as a single family of cells, distict from macrophages, we now know that there are many subsets of DCs [8,9]. Conventional DC (cDCs) are found in almost all tissues and lymphoid organs and act as sentinels capable of integrating multiple environmental signals and conveying them to CD4 and CD8 T lymphocytes. Plasmacytoid DC produce type I interferons and can also develop into antigen-presenting cells, particularly when stimulated by virus or self DNA [10]. Finally, monocytes can also develop into a cell type called monocyte-derived DC or moDC that not only shares many functional aspects with DCs but also closely resembles macrophages (e.g., they are poorly migratory) [11,12]. moDCs are, however, the form of DCs that has been most exploited for clinical immunotherapy purposes as many cells can be generated *in vitro* from PBMCs or monocytes grown in GM-CSF and IL-4 [13]

The analysis of the various forms of DC is surrounded by complexity. This stems from the fact that DCs are not very abundant in tissues and greatly resemble macrophages and that historically many phenotypes and functions of tissue DCs were described before the development of these cells was properly understood. It has been recently proposed to first classify DCs based on their ontogeny prior to subdividing them based on their microanatomical location or specific functional specialization [14]. This would yield only three subsets of DC: conventional type 1 DC (cDC1), conventional type 2 DC (cDC2), and plasmacytoid DC (pDC). Human and mouse conventional (c)DCs are derived from committed DC precursors (pre-cDC) produced in the bone marrow (BM), distinct from macrophage precursors [8,9]. These pre-cDCs migrate from the BM into the blood and then seed the various tissues where they develop into the two distinct lineages of cDCs. The idea of two distinct lineages is supported by the identification of lineage-defining transcription factors required for development and/or function of cDC1 (IRF8, BATF3, and ID2) and cDC2 (IRF4, ZEB2, Notch2, and KLF4) [14–21]. A separate E2-2-dependent progenitor with prominent pDC potential was recently described [22]. Mature pDCs express Siglec-H, the bone marrow stromal antigen-1, B220, and Ly6C and they can produce large amounts of type I interferons in the presence of viral infection.

With these new molecular insights, it is now clear that cDC belonging to the same lineage are present in various tissues and species and that these cells have been historically characterized by different surface markers (e.g., the marker CD207 has been used to define cDC1 in the mouse skin, CD8α has been used to define cDC1 in the mouse spleen, CD103 in the mouse intestine and lung, and CD141 (BDCA3) in human peripheral blood). In hindsight, it is clear that these markers are not specific to a particular lineage but are imprinted by tissue-specific cues, such as TGF-β or GM-CSF. In addition, monocytes, monocyte-derived cells/moDCs, and macrophages have often contaminated cDC populations in past studies. This is due to the fact that mouse cDCs were typically identified as $CD11c^{+}MHCII^{+}$ cells, while macrophages were identified as $F4/80^{+}$ cells. We now know that many macrophages can express CD11c or MHCII and conversely that cDC2 can express intermediate levels of F4/80 [19,23–27]. The best markers do delineate mouse macrophages from DCs appear to be CD64 and MerTK on

macrophages, whereas CD26 is expressed in cDCs. Distinguishing DCs from macrophages in human tissues has been equally challenging [28–30]. Finally, the lack of conserved markers to identify DCs hampered communication between mouse and human experts within the DC community and was detrimental for fostering translational medicine. The advent of multicolor flow cytometry, allowing unprecedented characterization of these cells through the addition of many novel cellular markers, has even made matters worse by yielding a seemingly ever-growing list of novel DC subsets based on new markers. Therefore, a rational approach simplifying the classification of DC subsets across tissues and species, while still permitting the introduction of new markers to study tissue- and disease-specific activation states, is urgently needed. Generally speaking, within CD64-negative cells (nonmacrophages) expressing CD11c and CD26 ("conventional dendritic cells"), one can use XCR1 (or CADM1) to delineate cDC1s and CD172 (Sirpa) to delineate cDC2 in virtually every tissue and species [31,32].

The different functions of DCs are thought to be performed by different subsets. cDC1s are effective cross-presenters of exogenous antigens to $CD8^+$ T cells and in generating short-lived T effector memory cells [33–35]. The cDC2s excel in presentation to CD4T cells and in generation of T central memory responses (T_{cm}). These DC subgroups with their specific functions are present during the steady state, but during inflammation monocytes migrate to the local tissue to form mo-DCs (inflammatory DCs); this changes the picture as moDCs and cDC2s can also crosspresent antigens quite efficiently uner conditons of inflammation [8,36,37]. Plasmacytoid DCs are mainly proficient in producing type I interferons and can stimulate CD4 and CD8 T-cell responses, particularly to virus [38]. Their antigen-presenting functions are further more boosted by the presence of antigen-specific IgGs [39,40].

12.3 Dendritic Cells and T-cell Polarization

One of the major ways by which DCs influence the inception and maintenance of inflammatory disease is by causing the polarization of naïve CD4 Th0 cells into Th1 cells (making IFNg), Th2 cells (making IL-4, IL-5, and IL-13), Th17 cells (making IL-17 and IL-22), and Treg cells (making IL-10 and TGFβ). The developmental driving force for this has been the tuning of T-cell responses to help clearing infectious threats, but the various extremes of Th-cell polarization are also often associated with allergic (Th2) and autoimmune (Th17) inflammatory diseases. To cause this polarized Th response, DCs express particular costimulatory molecules and produce Th-polarzing cytokines such as IL-1, IL-6, and IL-23 for Th17 development; IL-12 for Th1 development; and TGFβ and IL-10 for Treg development. The precise signals that determine Th2 development are much less clear.

Just like DCs control many aspects of immunity, it is equally important that tolerance mechanisms be installed for ubiquitous environmental antigens such as food antigens or commonly inhaled antigens such as allergens (derived from animal dander, plant pollen, etc.). These are intrinsically inert proteins to which an immune response would be futile and potentially harmfull to the host, causing

inflammation. It has been shown that intestinal DCs are major determinants of oral tolerance mechanisms. First of all, it was shown that intestinal DCs continuously migrate from the lamina propria of the small and large intestine to the mesenteric lymph nodes, where self- and food allergens are presented to naïve T cells that subsequently develop into $Foxp3^+$ iTregs [41–46]. The intestinal CX3CR1+ macrophages of the intestinal villi probe the oral antigens and hand them over to intestinal $CD103^+$ cDCs via gap junctions [47,48]. Intestinal $CD103^+$ cDCs employ various mechanisms to instruct iTreg development in naïve T cells, the most important one being the production of retinoic acid through the enzyme aldehyde dehydrogenase (RALDH), which instructs iTreg development, and a program that ensures that these cells return to the gut mucosa, as well as a differentiation program in B cells that ensures IgA production [49–57]. This program in CD103+ cDCs is driven largely by contact with commensal microbiota [58,59].

In the lung, similar mechanisms of tolerance to commonly inhaled antigens are operative. It was shown that exposure of mice to harmless antigens like ovalbumin is able to subsequently suppress vaccine response to OVA in adjuvant and even prevent the onset of allergic asthma initiated by OVA [60,61]. This induction of tolerance was initially shown to be mediated by DCs, expressing ICOS ligand and producing IL-10 [62]. It was subsequently shown that plasmacytoid DCs are necessary and sufficient to induce inhalation tolerance via induction of Treg cells [63–65]. On the other hand, CD103+ cDCs of the lung that produce RALDH are also able to induce tolerance to inhaled allergens, via induction of Tregs [48,66].

12.4 Dendritic Cells in Allergic Inflammation

12.4.1 Dendritic Cells are Necessary and Sufficient for Induction of Th2 Immunity

The contribution of DCs to the induction of Th2 immune responses has mainly been studied in models of asthma and allergic rhinitis [67], as well as in models employing the proteinase papain [68–70]. Allergic asthma is caused by continuous inhalation of allergens, which leads to chronic eosinophil-rich inflammation, goblet cell hyper/metaplasia, and bronchial hyperreactivity. The end result of these alterations is airway obstruction. Typically, IgE synthesis, eosinophil expansion and activation, mucus overproduction, and hyperreactivity of smooth muscle cells are driven by the cytokines IL-4, IL-5, and IL-13 that are produced by Th2 lymphocytes [71–73]. A crucial contribution for DCs in allergy induction is not so surprising as allergy is dominated by an adaptive Th2 lymphocyte response. When bone marrow DCs or DCs obtained from the spleen were cultured with GM-CSF and pulsed with antigen and then injected into the lungs of mice, they caused sensitization and led to eosinophilic inflammation and asthma features when the mice were challenged with the antigen [74,75]. Some induction of Th17 cells also occurs in this adoptive transfer model, refflecting the mixed Th2/Th17 profile seen in human

asthma [75]. Moreover, repeated injection of DCs into the lungs induces irreversible airway remodeling involving subbasement membrane deposition of components of the extracellular matrix [76]. Likewise, when DCs from the lungs of mice exposed to allergen are transferred to naive recipients, they can induce sensitization and features of asthma [77–79].

The studies described above demonstrate the ability of DCs to induce Th2 immunity in the lung. Recent studies have also demonstrated that induction of Th2 immunity, bronchial hyperreactivity, and goblet cell metaplasia in response to allergens all require lung DCs. These manifestations were abolished when lung DCs were depleted in CD11c-DTR transgenic mice when they were first exposed to the inhaled allergen, house dust mite (HDM) [77]. Studies using sensitization models based on the use of the enzymatic model allergen papain or on helminth allergens indicate that DCs are required for a proper Th2 immune response [68–70,80]. Whether innate ILC2 and DCs interact functionally in asthma has not been studied. In two recent papers, Halim *et al.* showed that in *Rorα*$^{sg/sg}$ mice or ICOS-T mice (lacking ILC2s but not Th2 cells), both the early innate and the late Th2-mediated heightened eosinophilic and IgE responses to inhalation with papain were abolished, pointing to an enforcing role for ILC2s in adaptive Th2 immunity [81,82]. The most striking observation of the study is that ILC2s promote Th2 immunity not through IL-4 (which they hardly produce) but by provision of IL-13. Th2 immunity to papain in *Rorα*$^{sg/sg}$ mice is restored by wild-type ILC2s but not by IL-13-deficient ILC2s. IL-13 stimulates migration of activated DCs to the lung draining nodes, pointing for the first time that ILC2s and DCs cooperate to promote adaptive Th2 immunity [81].

In the context of allergy, it has been repeatedly suggested that basophils and eosinophils are also capable of antigen presentation and that they alone might be able to induce allergic responses [70,83–85]. However, an antibody to the high-affinity IgE receptor FcεRI was used in these studies to deplete basophils, and it is possible that DCs were depleted as well [77]. Direct evidence for the ability of human basophils to present antigen and trigger Th2 immune responses is scanty [86]. More likely, basophils cooperate with DCs to prime for Th2 immunity, possibly by providing IL-4 at an early stage [77,87]. When lung eosinophils were directly compared with DCs, they did not demonstrate a strong antigen presentation function, except maybe for primed Th2 cells [88,89].

12.4.2 Different Subtypes of DCs Induce Th2 Immunity

There has been interest in recent years to know if lung DC subsets induce Th1, Th17, or Th2 responses in different ways. Subsets of CD103$^+$ and CD11b$^+$ cDC sorted *ex vivo* and stimulated with the model allergen OVA induced Th1 and Th2 responses, respectively [90]. This issue was also investigated *in vivo*, but sorting subsets during inflammation is daunting. Monocyte-derived DCs are rapidly recruited to the inflammation site in a CCR2-dependent way. The monocytic marker Ly6C is commonly used to differentiate between CD11b$^+$ Mo-DCs and CD11b$^+$ cDCs. But because Ly6C is downregulated when mo-DCs enter inflamed

tissue, conventional surface marker staining could not distinguish between mo-DC and CD11b cDCs. Better markers are needed, and we and other researchers recently reported that mo-DCs express FcεRI (recognized by MAR-1), CD64, and MerTK, but CD11b cDCs do not [79]. This approach was used to sort DC subsets from the LN of HDM-sensitized mice. Both $CD11b^+$ cDCs and $CD64^+$ moDCs could sensitize acceptor mice after adoptive intratracheal transfer, but $CD103^+$ DCs could not. Mice deficient in Flt3L lacked all cDC subsets and also failed to induce Th2 immunity to low doses of HDM allergen. However, *Flt3l*$^{-/-}$ mice still mounted Th2 immunity when a high dose of HDM was used, thus recruiting moDCs to the lung. Depletion of $CD103^+$ in langerin-DTR mice did not abolish the hallmarks of asthma, confirming the redundancy of the role of CD103+ DCs in the HDM-driven asthma model [79]. The fact that $CD11b^+$ cDCs seem to be necessary for Th2 immunity was also recently confirmed in *CD11c*Cre x *Irf4*$^{fl/fl}$ mice that selectively lack this subset of cDCs. These mice failed to mount Th2 immunity driven by OVA and the Th2 adjuvant alum [91].

Following injection of papain in the skin, basophils collaborate with DCs to induce Th2 immunity [70,84]. Papain is captured by $CD11b^+$ cDCs that also express macrophage galactose-type C-type lectin 2 (CD301b) in the skin and various mucosae [92]. Using the promotor of this gene to drive expression of the diphteria toxin receptor, it was shown that conditional depletion of $CD301b^+$ $CD11b^+$ cDCs abolished the early generation of IL-4 producing Th2 cells to papain as well as to alum and to *Nippostrongylus brasiliensis*, although IgE responses to the parasite were intact [69]. Similarly, *CD11c*Cre x *Irf4*$^{fl/fl}$ mice lack PDL-1^+ $CD301b^+$ cDCs in the skin draining lymph nodes and there was a defect on Th2 response generation to papain [68]. Despite these reports, others have shown that DCs are not necessary to mount Th2 immunity to papain. The most likely explanation is that with very high doses of allergen, there might be other APCs that come into play [84]. For most allergens, including spores of the fungus *Alteraria* or cockroach allergens, there might be a spectrum of innate immune cells that come into play at various time points after allergen exposure. The relative contribution of these innate immune cells to induction of Th2 immunity in the lung depends a.o. on the dose of extract used, the presence of contaminating microbial products in the allergen extracts, and the timing of the experimental obervations. This has created a lot of confusion in the field.

12.4.3 Dendritic Cells are Also Required for Effector Th2 Immune Responses to Allergens

It has been adequately demonstrated that dendritic cells are both necessary and sufficient for inducing Th2 immunity in naive animals, but studies in mice from which DCs can be conditionally depleted have shown that they are also crucial during the allergen challenge period and when primed mice repeatedly encounter inhaled allergens [3,76,93]. In areas of eosinophil-rich type 2 infammation, DCs have an activated phenotype expressing higher levels of costimulatory molecules OX40L, CD80, CD86, PDL-1, and PDL-2 [93]. In a secondary immune response, DCs are found very close to effector T cells and T resident memory (T_{rm}) cells in

the regions of airways and large blood vessels [71–73,94–96]. At these sites, they might secrete chemokines to attract effector T cells or they might restimulate T_{rm} cells by providing costimulatory molecules [79,97]. Allergen-specific IgE and IgG1, by stimulating FcεRI and FcγRIII, respectively, provide strong enhancement because they target inhaled allergens to DCs in primed mice; this further boosts Th2 immunity [98,99].

Though adoptively transferred moDCs can induce Th2 immunity, they more likely play a more important role during the effector phase of the immune response. MoDCs do not express CCR7 and thus do not migrate well to the draining nodes, although a subset of moDCs might upregulate CD209a (DC-SIGN) and migrate efficiently [11]. So, they likely interact with effector Th2 cells that migrate back to the lung or with T_{rm} cells [100]. The observed attraction of effector Th2 cells by chemokines produced by moDCs provides support of this model [79,97,101]. They are also the predominant APC expressing FcεRI and RcγRIII. The exact role of PDL-2 expression on DCs is currently unclear. PDL-2 was identified as a marker for the IRF-4-dependent Th2 inducing DCs of the skin [68].

12.4.4 DCs Get Activated Directly after Exposure to Allergen

Steady-state DCs are immature and must be activated and undergo maturation before they can migrate to the LN (in a CCR7-dependent manner) and initiate an immune response. DCs sense their environment via PRR, such as TLRs, NOD-like receptors, RIG-I-like receptors, and C-type lectin receptors [102,103]. PPRs can detect various molecular patterns on microbes, called pathogen-associated molecular patterns (PAMPs), as well as molecules released by necrotic cells, called damage-associated molecular patterns (DAMPs). DCs also produce different cytokine receptors that can induce activation after they are secreted in an autocrine or paracrine manner. There is evidence that most allergens can activate different classes of PRRs, but the actual Th immune response might depend on the allergen, again creating some confusion in the field [102,103]. For example, glycans in the peanut glycoallergen ara h 1 can mediate DC activation and Th2 induction through DC-SIGN; in contrast, triggering DC-SIGN by the HDM allergen Der p 1 promotes Th1 immunity instead [104,105]. The mannose receptor on DCs mediates the uptake of various allergens through their carbohydrate moieties, leading to Th2 polarization [106]. Triggering of the C-type lectin receptor dectin-2 on DCs by HDM induces the production of cysteinyl-leuktrienes (CysLT), Th2 attractive chemokines, and costimulatory molecules [101,107]. CysLTs then affect DC functioning in an autocrine manner through positive effects on the CysLT(1)R receptor and negative effects through CysLT(2)R. Mice deficient in CysLT(2)R developed a considerably stronger Th2 immune response to HDM, and adoptive transfer of DCs lacking CysLT(2)R had a similar effect. One of the main HDM allergens, Der p 2, is a functional homologue of MD-2, the lipopolysaccharide (LPS)-binding component of the Toll-like receptor (TLR) 4 signaling complex, and so it amplifies TLR4 signaling and DC activation [108].

It is not quite clear how activated DCs, after migrating to the draining nodes, prime for Th2 immune responses because IL-4, which drives Th2 differentiation, is not produced by DCs. The situation is different for cytokines involved in Th1 and Th17 differentiation, namely, TGF-β, IL-6, IL-12, and IL-23. It is possible that Th2 differentiation is the default pathway unless DCs produce Th1 or Th17 polarizing cytokines. Otherwise, ligands interacting with Notch receptors on Th cells might provide a direct polarizing signal for induction of Th2 immune responses [109,110]. Also, the B7 family costimulatory molecule PDL2 was identified as a marker of Th2-inducing DCs, although it remains to be shown if signaling via PD1 on T cells boosts Th2 immunity [68]. It is believed that after migrating to the draining lymph nodes, DCs move to the T-cell zone, where they activate T cells. But based on experiments in a model of *H*eligmosomoides *polygyrus* infection, Leon *et al.* [111] recently challenged the applicability of this proposition to Th2 immunity. They showed that B cells in the draining lymph nodes of infected mice secreted CXCL13 and recruited CXCR5-expressing DCs and T cells, resulting in DC–T interactions outside the T-cell zone. Mice lacking CXCR5 on T cells or on DCs had impaired Th2 immunity against *H. polygyrus* infection, indicating that these interactions are required for optimal Th2 development [111]. It is not known if this model is valid for all Th2-dependent immune responses. Polarizing pro-Th2 cytokines might also be delivered in trans from innate immune cells like basophils, mast cells, or ILC2s (as for IL-13 in the papain response).

12.4.5 Lung DCs Activated Indirectly by Epithelial Cells

Although DCs express PPRs that can directly sense the environment, recent studies have shown that the epithelium is as important for activation of DCs following exposure to allergens [112]. This is certainly true for environmental adjuvants such as diesel particles, fine dust particles, and toxic gases like NO_2, all of which can promote Th2/TH17 sensitization by DCs. Epithelial cells provide more than a physical barrier, because they express TLRs, C-type lectin, and protease-activated PARs [113]. We and others have recently shown that DC activation requires TLR4 triggering on epithelial cells. In radiation-chimera mice lacking TLR4 on radiosensitive hematopoietic cells or radioresistant epithelial cells, the activation and migration of DCs depended on signals emanating from the radioresistant cells following HDM administration. On the other hand, HDM-driven allergic asthma could not be induced in epithelial cells lacking TLR4 [110,114]. Similar effects have been described for other TLR ligands like flagellin acting on TLR5 [115]. The effects of triggering TLR4 seem to depend on the dose, because a high dose of endotoxin can also suppress the development of an allergic response to HDM [116]. Airway epithelial cells produce the cytokines TSLP, IL-33, IL-25, and GM-CSF in a TLR4-dependent manner. These cytokines are essential for DC activation and allergic Th2 sensitization. The relative importance of these cytokines is related to the type of allergen or respiratory adjuvant, which has caused some confusion in the field [117,118]. TSLP is made not only by epithelial cells but also directly by DCs, and it acts on DCs and T cells to promote Th2 immunity [119]. In mice lacking STAT5 (a crucial intermediary

of TSLP signaling) only in DCs, Th2 immune response induction is severely defective. This phenotype resembles that of TSLPR-deficient mice, indicating that TSLP acts mainly through its effects on DCs that require STAT5 to respond to it [120]. IL-33 too affects mainly the activation DCs and ILC2. Production of IL-33 by lung epithelial cells is strictly regulated; under homeostatic conditions, it is suppressed by the recognition and clearance of apoptotic cells [121]. When epithelial cells are exposed to allergen, they also produce trefoil factor 2 (TFF-2), which further increases the production of IL-33 in DCs and epithelial cells [122]. Necrotic cells too can release IL-33, but there is not much in the literature about substantial necrotic cell death in asthma. Moreover, lung macrophages and DCs can also produce IL-33, and allergen-specific IgG1 immune complexes triggering the FcγRIII receptor greatly enhance this process [99].

Besides the well-known role of innate pro-Th2 cytokines, we and others recently demonstrated a central role for IL-1α in the cross-talk between epithelial cells and DCs in HDM allergy. In a manner that was dependent on the NLRP3 inflammasome and caspase-1, HDM triggered epithelial cells to produce IL-1α, and in an autocrine fashion led to the release of IL-33, TSLP, and GM-CSF. Cytokines downstream of IL-1α, for example, GM-CSF and IL-33, also played a role in DC activation. Consequently, mice-deficient in IL-1R were resistant to the asthma caused by HDM [123]. In contrast to this predominant Il-1α role in DC activation, others reported that IL-1β and caspase-1 mediated the adjuvant effects on DC activation and Th2 development in a model of NO_2-enhanced airway inflammation.

There are many studies on how the innate pro-Th2 cytokines are produced in response to various allergens. ECs do produce cytokines, but they may also activate DCs by producing DAMPS in response to allergens. For example, ECs can induce DC activation by producing uric acid (UA), which is released in response to inhaled HDM in both mice and humans and plays a role in increasing cytokine production [124]. UA crystals are classical activators of the NLRP3 inflammasome, but mice deficient in *Nlrp3* or *Asc* had normal HDM and UA-induced Th2 responses in the lung. Another inflammasome believed to negatively regulate other inflammasomes is NLRP10. This inflammasome was found to have a function in the induction of Th2 immune responses by regulating the ability of DCs to migrate to the draining nodes [125].

If epithelial cells are so decisive in controlling the activation of DCs, one can speculate that the threshold for recognition of allergens by epithelial cells is an important check point in the development of Th2 sensitization to inhaled allergens. Many of the receptors expressed by the epithelila cells are TLRs and IL-1R family members, whose signaling cascades are also controlled by negative feedback mechanisms. One such mechanism involves the deubiquitinating molecule TNFAIP3, also known as A20. This enzyme turns off activating lysine-63 (K63) ubiquitin tags from key signaling intermediates in the TLR and IL-1R signaling pathway. Overexpression of A20 and of its binding partner ABIN1 (TNIP1) in the lungs of mice was sufficient to suppress all the salient features of asthma [126,127]. Recently, a genetic polymorphism in TNIP1 and in TNFAIP3 was found to be associated with development of asthma [128,129]. It will be interesting to see how this molecule is regulated and how it affects

epithelial-DC biology. Children growing up on farms are protected from developing allergy. We recently found that farm dust extract induces the expression of TNFAIP3 in lung epithelial cells of mice, and has the potential to suppress HDM allergic asthma in a TNFAIP3-dependent manner. Strikingly, children growing up on farms and still developing asthma had a single nucleotide polymorphism in the TNFAIP3 gene that led to lower levels of the protein, and epithelial cells of asthmatics produced lower levels of TNAIP3 protein [129].

12.5 Inflammatory DCs' Role in Human Allergy

Monocyte-derived DCs have been grown *in vitro* for decades, but they have been hard to trace in human samples. Nevertheless, a recent study identified and characterized inflammatory (Infl)DCs in general terms. Besides expressing CD11c and HLA-DR, (Infl)DCs expressed CD206, CD11b, Sirpα, CD14, CD1a, and FcεR1. Analysis by microarray showed that the inflDCs were enriched for an *in vitro* mo-DC gene signature. This indicates that these inflDCs were derived from monocytes and that they were the *in vivo* counterparts of moDCs. The infDCs produced Th17 polarizing cytokines and preferentially induced Th17 cells. Whether the nature of the pathologic condition affects infDCs T helper lymphocyte polarization is not yet known [37].

Inflammatory FcεR1$^+$ DCs are present not only in allergic lungs but also in the skin of atopic dermatitis patients, in which case they are named inflammatory dendritic epidermal cell [130]. A phenotypically similar cell type has also been observed in the lungs of humans undergoing lung surgery, but we do not know if larger numbers of these moDCs exist in asthma patients [131]. But it is known that circulating and tissue resident DCs of patients with asthma or allergy have higher levels of FcγRI armed with IgE [132,133].

12.6 Dendritic Cells in Autoimmune Inflammatory Disease

Developing autoreactive CD4$^+$ T cells are normally deleted during negative selection in the thymus, yet many tissue antigen-specific autoreactive T cells escape from the negative selection check point, emerging as anergic cells, thymic regulatory T cells (tTreg), or ignorant conventional T cells (Tconv) [134–136]. Dendritic cells have been implicated in controlling negative selection of developing thymocytes, as expression of MHCII exclusively on CD11c+ cells is enough to delete self-reactive cells [137]. Activation of self-reactive CD4 T cells that escape negative selection is a major culprit in organ-directed autoimmune disease, and therefore T cell tolerance to some tissue-restricted self-antigens is shaped entirely by nondeletional processes outside the thymus [138]. The suppression of potentially pathogenic autoreactive CD4$^+$ T helper cells is dependent on peripheral DCs that present tissue-restricted self-antigens derived

mostly from turnover of cells that die by apoptosis [139,140]. In the absence of inflammation, self-antigen presentation by immature DCs results in T cell anergy, the further expansion of natural tTregs or the generation of induced (i) Tregs from Tconv cells, thus promoting peripheral tolerance to the self-antigen [6,141,142]. Not surprisingly, the constitutive lack of steady-state DCs results in a loss of functional Tregs and the subsequent activation of autoreactive Th1/Th17 effector $CD4^+$ T cells, while a constitutive increase in the numbers of immature DCs results in increased iTreg numbers, which prevent autoimmunity [143,144]. It is, however, equally important that DCs presenting self-antigen remain in a quiescent state, devoid of costimulatory molecules or cytokine production that can break peripheral tolerance [145–151]. Removal of inhibitory NF-κB signaling intermediates and inhibitory apoptotic cell receptors on DCs, or artificial extension of DC lifespan, is sufficient to break self-tolerance [152–158]. As only one example, the loss of the deubiquitinating enzyme TNFAIP3 (also known as A20) selectively in CD11c+ dendritic cells leads to spontaneous activation of DCs throughout the body and a failure of DCs to be suppressed by apoptotic cells. Normally, apoptotic cell-derived self-antigen is not presented in an immunogenic maaner to T cells. In DCs lacking A20, apoptotic cell-derived self-antigen was presented to CD4T cells that developed into Th17 producing effector cells. Not surprisingly, mice lacking A20 in DCs developed signs of severe autoimmunity resembling lupus, with development of membranoproliferative glomerulonephritis, thrombocytopenia, and habitual abortion, in conjunction with double-stranded DNA antibodies and antibodies to the phospholipid cardiolipin [154].

Despite these experiments clearly implicating DCs in the regulation of peripheral tolerance and induction of autoimmunity, the precise triggers that can cause activation of DCs and potentially break tolerance to self are incompletely understood [6]. Certain organ-directed infections trigger tissue-specific autoimmunity by promoting the activation of DCs either through direct infection, the triggering of pattern recognition receptors such as Toll-like receptors on DCs, or release of cytokines that causes full DC maturation [159–161]. It has also been proposed that endogenous danger signals like uric acid, ATP, or HMGB1 can lead to activation of DCs in response to sterile tissue injury [162]. These danger signals can be actively secreted from inflammatory cells recruited to the site of sterile injury or directly released from dying cells. It was also shown that exposure of DCs to necrotic cells, but not apoptotic cells, is sufficient to drive DC maturation *in vitro* [163]; however, it is not known if and how sterile inflammation caused by tissue ischemia and necrosis is a driver of tissue restricted autoimmunity *in vivo*.

12.7 Conclusions

It is now clear that there are many subsets of DCs that do much more than just induce primary CD4 and CD8 T-cell immunity. As we review here, DCs are major drivers of autoimmune and allergic inflammation, but it is very likely that they are

at the basis of basically every form of chronic and persistent inflammation. In the future, the challenge will be to selectively target key functions of DCs without undermining the induction of antimicrobial immunity. Alternatively, exploiting the tolerogenic potential of DCs might offer long-term cure for allergic and autoimmune inflammatory disease.

Roles for NK Cells and ILC1 in Inflammation and Infection

Christian A.J. Vosshenrich[1,2] and James P. Di Santo[1,2]

[1]*Institut Pasteur, Innate Immunity Unit, 25 rue du Dr. Roux, 75724 Paris, France*
[2]*Inserm U1223, 25 rue du Docteur Roux, 75015 Paris, France*

13.1 Introduction

For roughly three decades (1975-2008), NK cells occupied a unique space in the hierarchy of immune defense being the only lymphoid cell subset that retained a close developmental relationship with B and T cells of the adaptive immune system, but could develop independent of the antigen receptor recombinase machinery. This changed recently when several independent reports described peculiar, rare innate lymphocyte populations with "hardwired" effector functions, similar to NK cells [1]. It was subsequently shown that all of these cells comprise a related family of lymphoid lineage cells now referred to as innate lymphoid cells (ILCs) [2,3]. ILCs can be classified into three distinct groups: group 1 ILCs comprise cells that express the transcription factor (TF) T-bet and produce the cytokine interferon gamma (IFNγ). Group 2 ILCs produce type 2 cytokines IL-5, IL-9, and IL-13 and require the TFs GATA-binding protein 3 (GATA3) and retinoic acid orphan receptor alpha (RORα) for their development and function. Finally, group 3 ILCs comprise cells expressing the TF RORγ and producing the cytokines IL-17A and/or IL-22 [4].

All ILCs require cytokines of the γ_c-family (especially IL-2, IL-7, and IL-15) for their development and homeostasis. Nevertheless, NK cells have special features, including granule-mediated cytotoxicity and a capacity to recirculate throughout the body in contrast with other ILCs that appear as tissue-resident [5,6].

NK cells are proposed both to participate in the immune responses to a variety of infectious agents, including viruses, bacteria, and parasites, and to act as modulators of autoimmunity and chronic inflammation [7]. Still, the precise role played by NK cells in these different disease situations remains poorly defined. Over the years, diverse mouse models have been proposed as tools to study the biology of NK cells *in vivo* [8]). Still, many of these models suffer from incomplete NK cell depletion or show effects on other non-NK hematopoietic cell types, thereby clouding interpretations. While more recent studies have allowed for direct targeting of NK cells using "NK cell-specific" gene expression (i.e., NKp46

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

expression using the Ncr1 locus), we now know that this gene is also expressed in some γδ T cells, in a subset of intestinal ILC3 and in ILC1 [9,10] that share many properties with "conventional" NK cells. With the identification of ILC1s as a distinct effector subset, it will be important to reassess previous conclusions about NK cell biology. Being able to distinguish between NK cell functions and ILC1 functions in immune responses, however, will be challenging given the phenotypic and functional similarity of NK cells to ILC1s [4,6,10-12].

13.2 Distinguishing Group 1 ILC and NK Cells

Rag-independent innate lymphocytes that are $Tbet^{+}IFN\gamma^{+}$ include previously characterized NK cells and ILC1 in both mice and man. Mouse NK cells are recognized as $CD3^{-}NKp46^{+}$ cells or as $CD3^{-}NK1.1^{+}$ cells (in C57BL/6 or C57BL/10 mice). While the antibody DX5 recognizing CD49b (integrin α2) has also been used to identify NK cells [13], a subset of hepatic NK cells lacks this marker [14]. Liver $DX5^{-}$ NK cells were initially proposed as immature NK cells [14], although recent evidence suggests that they represent a distinct NK subset lacking Eomesodermin (Eomes) [11,12]. A similar $Eomes^{-}$ $NKp46^{+}$ cell subset exists in the mouse intestinal tract and bone marrow [10] with lower cytotoxic activity but stronger cytokine production [10,15]. As such, they resembled thymic $IL\text{-}7R^{+}$ NK cells [16] and were termed "ILC1" to distinguish them from classical NK cells. NK cells and ILC1s express NKp46 (along with NK1.1 in B6 mice) as well as NKG2D, DNAM-1 (CD226), 2B4 (CD244), and NKG2A [6,11,17,18]. In some tissues, mouse NK cells and ILC1s show differential expression of IL-7R, CD49b, and CXCR6 (Figure 13.1).

Human NK cells are $CD3^{-}CD56^{+}$ cells and can be divided into $CD56^{bright}CD16^{-}$ and $CD56^{dim}CD16^{+}$ subsets [19]. $CD56^{dim}$ NK cells predominate in the blood, while $CD56^{bright}$ prevail in lymphoid tissues, especially LN [19]. Atypical $CD3^{-}CD56^{+}$ subsets exist ($NKp44^{+}CD103^{+}$ and $NKp44^{-}CD103^{-}$) in human tonsils that produced IFNγ upon stimulation with IL-12 and IL-15 *in vitro*,

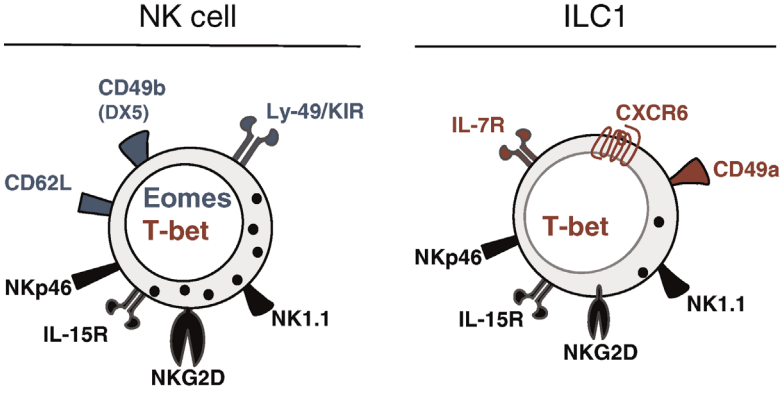

Figure 13.1 Cell surface markers and signature transcription factors expressed by NK cells and ILC1s. Relative expression level is indicated by the size of the corresponding receptor.

but were unresponsive to IL-18 [15]. Based on their expression of CXCR6 and their mucosal location, these cells were termed ILC1s, although they clearly expressed the TF Eomes [15]. These human ILC1 expressed NKG2D, CD244, and CD94, but only $KIR^{-/lo}$, DNAM-1^{lo}, and $NKp44^{+}CD103^{+}$ cells expressed NKp30, distinguishing them from blood NK cells [15]. Unlike other ILC subsets, these atypical $CD3^{-}CD56^{+}$ cells lack IL-7R expression.

More recently, human hepatic $CD56^{bright}$ NK cells have been described expressing CD49b (a2 integrin) and T-bet but lacking Eomes expression. Liver $CD49b^{+}$ NK cells expressed activating receptors (NKp46, NKp30, NKG2D, and DNAM-1) and produced IFNγ, TNF, and GM-CSF upon stimulation [20]. As such, these cells could represent the human counterpart to hepatic ILC1s in the mouse.

Finally, a human $CD161^{+}$ ILC1 subset has been identified that expresses IL-7R but lacks most NK cell markers (CD56, NKp46, NKp44, CD16, and CD94); these cells produce IFNγ but do express neither perforin nor granzyme B, the prototypical cytotoxic molecules expressed by circulating NK cells [21]. Human $CD161^{+}$ ILC1 express T-bet but not Eomes, and *in vitro* culture experiments suggest that they may derive - at least in part - from ILC3s under the influence of the proinflammatory cytokines IL-12 and IL-18 [21].

13.3 NK Cell and ILC1 Activating and Inhibitory Receptors

NK cells express a wide array of germ line-encoded surface receptors that convey either activating or inhibitory signals upon ligand binding. The balance between these opposing pathways "tune" the reactivity of NK cells to have optimal capacity to react to infected, "stressed," "foreign," or transformed cells while remaining tolerant of normal, healthy cells. Engagement of these different activating or inhibitory pathways may occur during development: this process of NK cell "education" has been extensively studied in the context of MHC class I inhibitory receptors (see below) but may also apply to activating receptors.

13.3.1 Natural Cytotoxicity Receptors

Natural cytotoxicity receptors (NCRs) represent a major group of activating receptors expressed by NK cells. Human NK cells express three NCRs, NKp46 encoded by *NCR1*, NKp44 encoded by *NCR2*, and NKp30 encoded by *NCR3* [22]. Of note, NK cells express NKp44 only upon activation [19]. Mouse NK cells express only NKp46. NCRs belong to the immunoglobulin (Ig) superfamily and signal via adapter proteins containing immunoreceptor tyrosine-based activation motifs (ITAMs) [22].

NCRs have been shown to bind viral hemagglutanins (HA) from various viruses, including influenza A (IFA) virus [23-25], vaccinia virus (VV), and ectromelia virus [26], as well as antigens from other viruses, including HCMV [27,28] and West Nile virus (WNV) [29]. Moreover, nonviral NCR ligands can be expressed following infection by *Mycobacteria* [30-32] or *Fusobacterium nucleatum* [33]. NKp46 activation induces cytokine production in NK cells and ILC1 [11].

13.3.2 NKG2D

The majority of NK cells as well as ILC1s express NKG2D homodimers (encoded by Klrk1) [11,12,16,19]. Two mouse NKG2D isoforms exist: $NKG2D_L$ with a long cytoplasmic tail signals via DAP10, while $NKG2D_S$ couples to either DAP10 or DAP12 [34,35]. Human NK cells express a long isoform signaling via DAP10 [36]. NKG2D ligands include stress-induced self-proteins share their structural relation to MHC-I molecules. These include MHC class I chain-related gene (MIC)-A and MIC-B, and the UL16-binding proteins 1-4 in humans, and the retinoic acid early transcript 1 (Rae-1) molecules, murine UL-16 binding-like transcript-1 (MULT-1), and the histocompatibility 60 (H60) family of proteins in mouse [37]. Activation via NKG2D induces cytokine production and cytotoxicity by NK cells [38] and IFNγ production by ILC1 [11].

13.3.3 DNAX Accessory Molecule-1 (DNAM-1, CD226)

The Ig superfamily member DNAX accessory molecule-1 (DNAM-1) is expressed by around 50% of mature NK cells and at higher density on all hepatic ILC1s [17]. DNAM-1 ligands include CD155 (poliovirus receptor, PVR) and CD112 (nectin-2) [39] that trigger NK cell cytotoxicity and cytokine production [39,40]. These ligands are upregulated following cellular stress (e.g., after DNA damage) [41,42] similar to NKG2D ligands and may play a role in antitumor and antiviral immunity [43]. The strong DNAM-1 expression by ILC1 could indicate an important role of this receptor in tissue surveillance.

13.3.4 MHC Class I-specific Receptors and NK Cell "Education"

NK cells express two main classes of MHC class I (MHC-I)-specific receptors that can be either activating or inhibitory depending on the intracellular signaling pathways to which they are coupled. The first set recognize "classical" class I molecules (HLA-A, B, C, and H-2D, K, and L). In mice, these receptors are encoded by distinct genes in the "Ly49 complex" (killer cell lectin-like receptors subfamily A gene family or *Klra*). In humans, they are encoded by killer immunoglobulin-like receptors (KIR). In both species, expression of the activating receptors is restricted to NK cells, while inhibitory receptors can be detected on T cells and myeloid cells [44,45]. Inhibitory receptors bind to different MHC-I haplotypes with variable affinities that depend on peptide occupancy [46,47]. A second set of MHC-I receptors include heterodimers comprised of CD94 and members of the NKG2 family. These receptors bind to nonclassical MHC-I molecules, Qa-1 in mice [48] and HLA-E in man [49]. As cell surface expression of these nonclassical MHC-I requires peptides derived from classical MHC-I, the CD94/NKG2 receptors recognize MHC-I molecules in an indirect fashion. Binding to CD94-NKG2A generates an inhibitory signal, while CD94-NKG2C and CD94-NKG2E engagement results in NK cell activation [50].

NK cells require interactions with class I MHC molecules within the stromal microenvironment in order to gain full functional competence [51-53]. This mechanism is generally referred to as NK cell "education" or "licensing" [54,55]. This poorly understood process is not a simple "on-off" switch, but occurs

progressively; the "rheostat model" proposes an integration of inhibitory and activating signals based on interactions with class I MHC by differentiating NK cell that determines their subsequent cellular responsiveness [56]. Non-MHC-I-based self-receptors also appear to affect this process [57]. Since Ly49 and KIR molecules are expressed in a stochastic manner at the single-cell level [58,59], NK cell education generates a heterogeneous pool of NK cells with different functional capacities. Most NK cells express one-three and up to six class I-specific MHC receptors, although a substantial subset NK cells exists (10-15%) that do not express inhibitory receptors for self-MHC-I receptors and are thus "uneducated" [51,52]. "Uneducated" NK are functionally hyporesponsive and phenotypically indistinguishable (except for the lack of self-MHC-I receptors) from "educated" NK cells [52,55]. Education is not linked to a particular stage during NK cell development but appears to be a perpetual process allowing NK cells to incessantly adapt to their environment. It has been shown that "uneducated" NK cells from MHC-I-deficient mice gain functional competence when placed in a MHC-I-sufficient environment [60,61], while "educated" NK cells become hyporesponsive in a MHC-I-deficient environment [61].

Inflammatory conditions associated with viral infections can promote responsiveness in otherwise "uneducated" NK cells [52,54,55,62,63]. In mouse cytomegalovirus (MCMV) infection, "uneducated" NK cells have superior functional capacities compared to "educated" NK cells in the defense against this virus [62].

13.3.5 Are ILC1s "Educated" Similar to Convention NK Cells?

As indicated above, ILC1 express a variety of activating and inhibitory receptors that could play a role in determining functional competence of this innate effector subset. The vast majority of ILC1 express NCRs, NKG2D, DNAM-1, and CD94-NKG2A heterodimers [12,17,64]. In mouse, ILC1 express Ly49C/I, I, F, and G2 at lower frequencies compared to NK cells [10,12,18,64]. Curiously, Ly49E is predominantly expressed by ILC1s starting in embryonic life [64], although its biological relevance is unclear. In man, ILC1 express a restricted set of KIR molecules [15] with hepatic $CD49a^{+}$ NK cells expressing an oligoclonal KIR repertoire that might indicate selective "antigen-driven" expansion [20].

It is not clear whether the mechanism of "education" that has been described in NK cells also operates in ILC1s. As education seems to enable NK cells with the capacity to distinguish self from nonself (i.e., to become activated when encountering a "nonself" or "self-MHC-I-negative" target and eventually eliminate it). As ILC1s have not been yet implicated in these types of immune responses and lack granule-mediated cytotoxicity, it is not immediately clear why ILC1s would need to be educated or rendered self-tolerant to class I MHC.

13.4 Evidence for Distinct Subsets of NK Cells and ILC1

Current models for NK cell maturation make use of differential expression of surface markers (CD27 (TNFRSF7) and CD11b (Mac-1) to define NK cell subsets with distinct functional properties [65]. $CD27^{+}CD11b^{-}$ NK cells prevail in BM

and LN, while $CD27^{-}CD11b^{+}$ NK cells predominate in blood, spleen, and lungs [66]. $CD27^{+}CD11b^{-}$ NK cells are proposed as the least differentiated cells, while $CD27^{+}CD11b^{+}$ NK cells have the highest cytokine secretion and cytotoxic potential. In contrast, $CD27^{-}CD11b^{+}$ NK cells are terminally differentiated cells with reduced effector functions [65].

ILC1s are present in various organs, including liver, small intestinal lamina propria (siLPL), siIEL, uterus, salivary gland (SVG), and - at lower frequencies - in the spleen, bone marrow, and skin [6,10-12,18]. How ILC1 from these different tissues relate to each other is not known. For example, only hepatic and SVG ILC1s have been shown to express TRAIL [14,67], and ILC1s from all sites express high levels of IL-7Rα except those from the liver [10,11]. Hepatic ILC1s express high levels of CXCR3, while siLPL ILC1s express higher levels of CD69 and CCR9 [18]. It is not clear whether these represent true ILC1 subsets or adaptation to specific tissue microenvironments. ILC1s predominate over conventional NK cells in the gut and uterus [10,12], whereas in lung and skin ILC1s represent less than 5 and 20%, respectively, of $CD3^{-}NKp46^{+}NK1.1^{+}$ cells [12]. In liver, NK and ILC1 coexist at roughly equal frequencies, although in spatially distinct regions with ILC1 restricted to the liver sinusoids [6]. Curiously, all ILC1 express CD27 and lack CD11b [6,10-12] and, therefore, resemble undifferentiated NK cells.

13.5 Effector Functions of NK Cells and ILC1

NK cells possess two principal effector functions: cytotoxicity and cytokine/chemokine secretion [68]. Interferon gamma (IFNγ) is abundantly produced by NK cells and exerts pleiotropic activities on target cells and other hematopoietic (myeloid, macrophage) and nonhematopoietic (epithelial, stromal) cells. NK cell cytotoxicity requires cell-to-cell contact between NK and target cells and can be mediated via granule- or TNF superfamily- (FasL, TRAIL) mediated pathways. Recently, activated liver ILC1s were shown to express granzyme B and perforin, to degranulate CD107a and to lyze YAC-1 tumor cells *in vitro* [6,11,12,18]. As such, granule-mediated killing may be inducible in hepatic ILC1, although it is not clear whether this is involved in antitumor responses *in vivo*.

Mature NK cells carry preformed mRNA encoding IFNγ and RANTES [69] allowing them to rapidly secrete cytokines. Such properties necessitate tight control. As with NK cell "education," effector functions in mature NK cells are regulated by balancing activating and inhibitory signals (Figure 13.2). Under steady-state conditions, normal expression of self MHC-I overrides most NK activation signals. However, during infection, MHC-I may be downregulated in infected cells, unleashing inhibitory "missing self" pathways and allowing for NK cell-mediated killing. In addition, cellular stress can induce NKG2D ligands that override MHC-I inhibition [70]. DNAM-1 ligands might be regulated in a similar manner [42,43], although it is not clear whether they are able to override self MHC-I-driven inhibitory signals.

Importantly, NK cell activation not only relies on cell surface receptor signaling but also on stimulation via cytokines, including IL-2, IL-12, IL-18, IL-21, or IFN I.

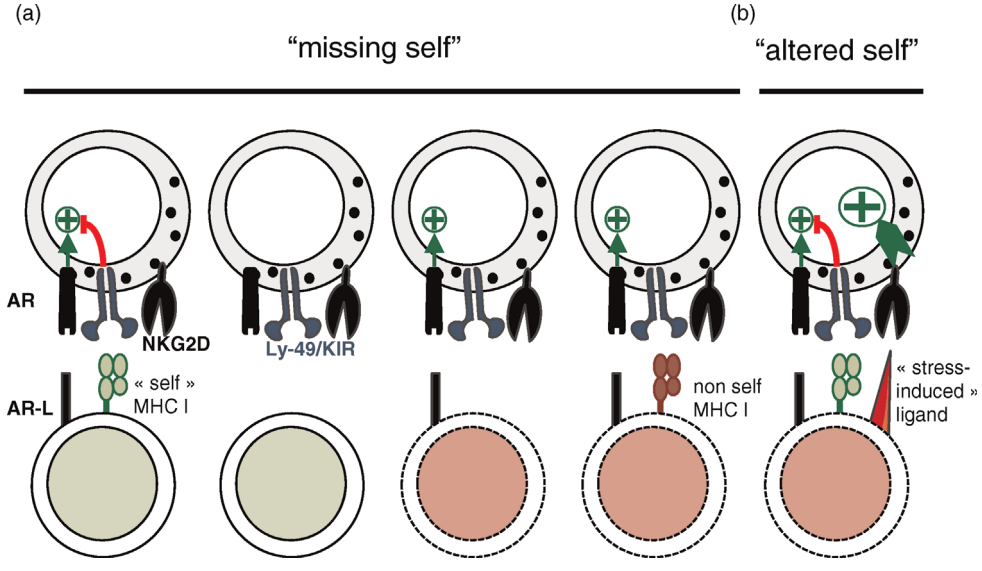

Figure 13.2 Activating and inhibitory signals regulate NK cell activity. "Missing self" (a): NK cells can be stimulated via activating receptors but simultaneously receive inhibitory signals via MHC-I receptors. As a result, NK cells spare target cells (far left). If target cells lack MHC-I expression, NK cell inhibition is released and NK cell target elimination depends on the presence of activating signals that can include target cell nonself MHC I molecules (second from right). "Altered self" (b): cellular stress induces the expression of NKG2D ligands. Activation via NKG2D can override inhibitory signals from MHC I receptors resulting in the elimination of MHC I^+ target cells. AR: activating receptor; AR-L - ligand of an activating receptor.

Combinations of IL-12 with any of the other cytokines are sufficient for NK cell activation in the absence of signals from cell surface receptors.

The full range of activating and inhibitory signals that can regulate effector functions in ILC1 are not known. Much of the published literature has assessed the ability of ILC1 to secrete cytokines (including IFNγ and TNF) in response to soluble factors such as IL-12 and IL-18. Although an exhaustive side-by-side comparison of cytokine production by NK cells and ILC1 from the same tissue has not been performed, it is clear that both are potent producers of IFNγ, while TNF production is enhanced in ILC1 [11,12]. Little is known about the ability of activating receptors (NK1.1, NKG2D, NKp46, and DNAM-1) to stimulate effector functions in ILC1, although cytokine production can be induced in hepatic ILC1 following triggering of NK1.1, NKG2D, or NKp46 [11]. Whether or not ILC1s need to be primed (by inflammatory signals, cytokines, and chemokines) in order to reach full functional competence remains unknown. While some the MHC-I-specific inhibitory receptors are expressed by tissue ILC1, their role in "tuning" cellular responses is unclear. ILC1 express receptors for several soluble factors (IL-10R, TGFβR, and IFNα/βR) that could ultimately modulate their functional properties before, during, or after activation [71].

13.6 NK Cells and Group 1 ILCs in Inflammation and Infection

Inflammation describes the complex process of the body's reaction to tissue damage, often associated with but not restricted to infections with pathogens. NK cells are involved in the immune response to many microbial pathogens; however, in only a few cases have the targets for NK cell recognition been described. In many cases, NK cells are recruited and/or activated via cytokines and chemokines secreted by sentinel cells (epithelial cells, macrophages, and dendritic cells) that initiate immune responses following pathogen detection. NK cell activation and immunity against several different pathogens will be discussed in the next sections.

Sterile inflammation (in the absence of any obvious pathogen) occurs as well, when tissue damage is the consequence of physical, chemical, or metabolic stress [72]. A good example is the case of diet-induced stress that accompanies obesity where systemic inflammation can be observed in visceral adipose tissue (VAT) [73]. An anti-inflammatory state is normally maintained in adipose tissue by a coordinated trio of cells, including alternatively activated (M2) tissue macrophages, ILC2, and eosinophils [74,75]. High-fat diet induces stress in adipocytes leading to the upregulation of NKp46 ligands, resulting in NK cell activation, expansion, and IFNγ production [73]. As a result, adipose tissue macrophages polarize toward a proinflammatory M1 phenotype resulting in the development of a chronic inflammation within the VAT [74,75]. The resultant changes in VAT function lead to insulin resistance and are a risk factor for the development of type 2 diabetes [73].

13.6.1 Mouse Cytomegalovirus

The immune response to infection with cytomegalovirus (CMV) has become a paradigm for studying NK cell functions in mice and man [76]. Cytomegaloviruses are large DNA viruses belonging to the beta-subfamily of Herpesviridae. Several species of cytomegaloviruses have been identified that have a highly restricted host range, including human CMV (also known as human herpesvirus 5 HH5) and MCMV. In immunocompetent individuals, infection with CMV is almost asymptomatic, while it poses a serious threat for immunocompromised individuals [76]. The important role of NK cells in the defense against herpes viruses is evident from patients lacking NK cells or NK cell functions [77]. These patients suffer from severe disease often leading to death [77]. However, even though NK cells are important they are often not sufficient to clear the virus. This requires the coordinated activity of innate and adaptive lymphocytes, especially virus-specific $CD8^+$ T cells (reviewed in [78]).

Strain-dependent genetic differences determine the susceptibility to MCMV. For example, B6 mice are resistant, while BALB/c mice are highly susceptible [78]. The molecular basis for these differences was mapped to the *cmv-1* gene that encodes the activating Ly49H receptor [79]. As indicated above, Ly49 is a member of a family that recognizes MHC class I protein complexes, and it was shown that Ly49H specifically interacts with the MCMV-encoded protein m157 [80,81]. NK cells triggered through Ly49H are amplified (also via cytokines) during the early

phase after infection, with secretion of IFNγ and cytotoxicity that restricts viral spread and allows the adaptive immune response to unfold [82,83].

While mouse and human CMV are rather rapidly cleared from most organs, both can persist for weeks or months in the salivary glands where the virus replicates in the acinar glandular epithelial cells and disseminates via shedding through the saliva. HMCV can be secreted for month following an acute infection in clinically unapparent individuals. Interestingly, NK cells in the SVG are in general hyporesponsive, which translates into much-reduced frequencies of IFNγ-producing NK cells in SVG compared to other organs during acute MCMV infection [84]. This might contribute to MCMV reservoirs within the SVG. Effector $CD4^+$ T cells are important for viral clearance from SVG [85]. However, only lytic virus is cleared from infected individuals, while latent forms persist a lifetime. CMV latency and viral reactivation represents a constant threat for the immune system that can also explain the impact of CMV exposure on global immune signatures [86].

Immune surveillance during MCMV latency is a dynamic situation that requires coordination between innate and adaptive lymphocytes [87]. Effector memory CD8T cells specific for certain viral epitopes gradually increase in CMV latency (a process also termed "memory inflation") [88,89]. This may be driven by limited stochastic viral reactivation [90] or focal transcriptional activities [87] allowing for brief antigen reencounter at barely detectable levels [91]. Depletion of CD8+ T cells or NK cells during viral latency resulted in rapid reactivation of virus within the salivary gland that rapidly reaches the systemic circulation [92]. The same mechanisms leading to CD8T cell memory inflation might also be implicated in the prolonged persistence of "memory" NK (see more below).

The involvement of ILC1s to the anti-MCMV response is not clearly defined. Their lack of Ly49H expression precludes their ability to mount a specific response to m157. ILC1 may possess other receptors that allow for interactions with other CMV viral proteins expressed on productively infected cells. Moreover, given the peculiar ability of hepatic ILC1s to mount recall responses (see more below), they might be able to respond in the context of viral latency. Finally, as tissue-resident cells, ILC1 can rapidly respond to "stress" signals from diverse sentinels enabling them to participate in the early-phase response to MCMV.

13.6.2 Influenza Virus

Influenza A (IFA) is an enveloped RNA virus of the Orthomyxoviridae family. Various serotypes exist based on the type of envelope-encoded hemagglutinins and neuraminidases (NAs), defining HA and NA subtypes (Hynix nomenclature). Direct recognition of IFA-encoded HA by NK cells via NCRs (NKp30 and NKp44 in humans, and NKp46 both in humans and in mice) has been reported [23-25]. HA recognition is essential for the NK cell-mediated viral control in the mouse [93] and mutations in HA allow influenza virus to escape NK cell recognition via NKp46 [94]. Removal of sialic acid residues from viral NA impairs NKp46- [95] and NKp44-mediated [96] recognition.

IFA mainly replicates in the lower airway. In the steady-state, this tissue is rather lymphocyte poor, but interestingly NK cells represent around 10% of

lymphoid cells, which is the highest frequency observed in any tissue [66]. Both beneficial [93] and detrimental [97] roles for NK cells in the anti-IFA response have been reported that are probably due to dosage effects.

13.6.3 NK Cells and Other Viral Infections

NK cells have been shown to become activated during the immune response following infection with Orthopoxviruses (that belong to the Poxviridae family). Two well studied orthopoxviruses are vaccinia virus and ectromelia virus (ECTV, mousepox). B6 mice resist ECTV infection through several mechanisms, including pathways involving CD94 [98]. As such, $CD94^{-/-}$ mice succumb to ECTV infection presumably due to defective CD94-NKG2E function on NK cells [98]. However, this conclusion needs to be revisited in light of studies using $NKG2A^{-/-}$ mice. These mice are highly susceptible to ECTV, which was shown to be independent of NK cell but dependent of $CD8^{+}$ T cell, likely due to a protective role of CD94-NKG2A heterodimers for the function of these adaptive CTL [99].

The implication of NK cells during infections in humans with other viruses including human immune deficiency virus (HIV) (reviewed in [100]), hepatitis C virus (reviewed in [101], hepatitis B virus (reviewed in [102]), dengue virus (reviewed in [103]), and Epstein-Barr virus [104] are well documented. It is out of scope to revisit the literature on human NK cells in these different viral infections, but it is important to underline the fact that defining clear roles for NK cells during the immune response to these infections is quite challenging given the limited access to tissues where the virus is actively replicating and/or achieves latency. In most cases, studies are limited to blood or end-stage diseased tissues. The complex multicellular nature of the early immune responses within draining lymph nodes or acutely inflamed tissues is rarely studied. Another reason for our limited understanding of NK cell responses to these human pathogens is the absence of an accurate small animal model. As these pathogens infect targets with a strict species range (due to species-specific receptors and host restriction mechanisms), normal mouse strains are not permissive. The advent of optimized humanized mouse models holds great promise for future studies of these pathogens [105], especially for studies involving pathogens such HCV and HBV for which compound humanized mice that carry a human immune system and a humanized liver have been recently described [106].

13.6.4 Salmonella

Salmonella spp. are Gram-negative, facultative intracellular, enterobacteria. Infection with *Salmonella* can cause gut-associated, nonsystemic acute inflammation (gastroenteritis), although certain serovars cause more severe typhoid fever [107]. Ingestion of contaminated food represents the dominant cause of infection. Once the bacteria reaches the small intestine, they cross the epithelial barrier and obtain access to the gut-associated lymphoid tissue (GLAT), including Peyer's Patches, from where they disseminate via phagocytes [108]. *Salmonella* spp. are able to survive, divide, and persist inside macrophages that accelerates bacterial spread. Once disseminated via the bloodstream and lymphatics,

endotoxic shock and death rapidly ensue [107]. It has been shown that NK cell-derived IFNγ [109] is critical for the early control of *Salmonella* infection. This cytokine potently polarizes macrophages toward the proinflammatory M1 type and activates their antibacterial activity [110,111]. Accordingly, NK cell depletion results in increased bacteria loads [112]. Another host strategy to restrict pathogen spread involves granuloma formation that assemble a variety of hematopoietic cells (macrophages, neutrophils, NK cells, and T cells). During *Salmonella* infection, granuloma formation and persistence requires TNF [107] that is largely contributed by neutrophils and to a lesser extent by NK cells [113]. The "ex-ILC3" ILC1 are a source of IFNγ in the context of *Salmonella* infection [114] and may also contribute to granuloma formation.

13.6.5 Listeria monocytogenes

Infections with *Listeria monocytogenes* (Gram-positive, facultative intracellular bacteria) result from the ingestion of contaminated food. After crossing the gut epithelial barrier, *L. monocytogenes* reaches the bloodstream and disseminates to the spleen and liver [115]. Innate and adaptive immune cells control *L. monocytogenes* infection [116]. Initial defense involves neutrophils, macrophages, and NK cells [116-118], followed by $CD8^+$ T cells that ensure sterilizing immunity [119]. *L. monocytogenes* are taken up by macrophages but escape destruction via listeriolysin O that destroys the phagosome membrane allowing *L. monocytogenes* to access the cytosol [120]. IFNγ has been shown to be crucial to avoid listeriosis [121] and NK cells secrete this cytokine in an IL-18-dependent manner, thus contributing to the early control of *L. monocytogenes* infections [122]. IFNγ activates the bactericidal activity of macrophages [117] helping to restrict bacterial spread. TNF is crucial for early control of *L. monocytogenes* [123,124], while TRAIL deficiency has been shown to increase the resistance and reduce hepatic pathology [125]. Given that hepatic ILC1s express TRAIL, this might indicate a potential detrimental role for these cells in the defense against *L. monocytogenes.*

13.6.6 Mycobacteria and Other Bacteria

Mycobacterium tuberculosis causes tuberculosis, which frequently involvers the respiratory tract following airborne exposure. Alveolar macrophages phagocytose *M. tuberculosis* leading to the recruitment of neutrophils, NK cells, and T cells. However, the initial immune response is often not successful and *M. tuberculosis* can further disseminate via macrophages and DC to draining lymph nodes and beyond. In most *M. tuberculosis* cases, granulomas are formed that contain the bacteria and generate latent persistent infections. NK cells have been shown to contribute to the anti-*M. tuberculosis* immune response not only by secretion of cytokines (IFNγ and TNF) [126,127] but also through direct bacterial killing via secretion of granulysin [128]. NK cells can lyze *M. tuberculosis*-infected alveolar macrophages and monocytes, a process that appears to involve NK cell recognition of infected cells via NKp46 [31,129] and NKG2D [32]. Taken together, these studies show that NK cells play an active role in restricting *M. tuberculosis*.

Activation of NK cells upon infection with other bacteria, including *Staphyloccocus aureus* [130], *Rickettsia* spp [131]., *Legionella* spp [132]., and *Shigella* spp [133]. has been documented. In these cases, NK cell-derived IFNγ appears to contribute to immune defense against the invading microbe, although some reports suggest that NK cell depletion results in better pathogen clearance (reviewed in [134]).

13.7 NK Cell and ILC1 Memory

While immunological memory is classically associated with adaptive immunity mediated by antigen-specific B and T cells, recent reports have described "adaptive features" of innate immune cells, including those mediated by NK cells (reviewed in [135,136]. As described above, NK cells specifically recognize MCMV in certain mouse strains through the activating Ly49H receptor that specifically interacts with the viral protein m157 [79-81,137,138]. Ly49H activates through an ITAM-based intracellular signaling cascade (similar to antigen receptors), and MCMV was subsequently shown to selectively expand $Ly49H^+$ NK cells [138,139]. Interestingly, virally expanded $Ly49H^+$ NK cells persist for at least 70 days after infection (in contrast with the $Ly49H^-$ subset), suggesting that they represent "memory" NK cells [139]. Moreover, these memory NK cells have enhanced functional capacities compared to "naïve" NK cells ("adaptive features"). Taken together, these results identify a new aspect of innate lymphoid cell "memory" that mirrors the adaptive T-cell response in several important ways. Nevertheless, there are some important differences between MCMV-induced NK-cell and T-cell memory, including the clonal frequency of responding cells (50% for NK cells versus 10^{-5} for T cells), the duration (weeks for NK cells versus months/years for T cells) [140] and the changes in effector functions (about twofold for naïve versus memory NK cells) [139]. Since the molecular signature associated with memory NK cells involves a strong STAT4 response (indicative of IL-12 signaling) and IL-12 blockade abolishes NK cell memory [141], it suggests that inflammatory signals are essential. Whether NK cell memory represents an intrinsic property of NK cells or an environmentally regulated process dependent on inflammatory status remains to be fully explored.

The second type of NK cell memory driven by cytokine stimulation has been described. Exposure of NK cells to IL-12, IL-15, IL-18, and/or IFN results in the generation of long-lived NK cells that produce cytokines more rapidly after restimulation [142,143]. Phenotypically, these NK cells are similar to naïve NK cells and have been termed "cytokine-induced memory-like" (CIML) NK cells. Given their enhanced activities, CIML NK cells might be useful for immunotherapeutic approaches. It remains to be shown if CIML cells are generated *in vivo* and if a similar phenomenon exists for ILC1.

The third type of NK cell "memory" was described in the context of recall responses to haptens in a skin contact hypersensitivity model. Antigens included both classical haptens (DNP) and viral peptides (influenza, VSV) and virus-like particles [6,144,145]. The response could be elicited in $Rag^{-/-}$ mice (excluding a role for adaptive B and T cells), and NK cells were shown to have the capacity to

transfer the contact hypersensitivity phenotype to *Rag2*$^{-/-}$*Il2rg*$^{-/-}$ mice (that are deficient in NK cells and all ILCs). Curiously, only NK cells from the liver were able to perform this type of "memory" responses and this was mapped to subset of hepatic NK cells expressing CXCR6. The specific receptor-mediated hapten-dependent NK cell memory remains undefined. This report suggests that innate lymphocytes can provide "recall" responses in nonlymphoid tissues.

It is interesting to compare and contrast these three situations of NK cell "memory" in light of the dichotomy between NK cells and ILC1. Inflammation is a common theme and suggests that environmental signals, especially elaboration of soluble factors (IL-6, IL-12, IL-18, and IFNs) play an essential role. The necessity for Ly49H in the MCMV model indicates that conventional NK cells and not ILC1 are involved since the latter do not express this receptor [11,12]. Similarly, alloreactivity-mediated through Ly49D would be restricted to NK cells [146]. In contrast, the requirement for CXCR6 in the skin contact hypersensitivity model strongly suggests that ILC1 are involved and not conventional NK cells. Taken together, these observations provide evidence for tissue conditioning of NK and ILC1 phenotypes and functions that may result in "long-term" reactivity for these innate cells. It will be interesting to know if "memory" NK or ILC1 responses play a role in immune responses to other viral, bacterial, or parasitic pathogens or in antitumor immunity.

13.8 Concluding Remarks: NK and ILC1 as Partners in a Type 1 Network

NK cells exert strong effector functions (including cytotoxicity and cytokine secretion) in response to *in vitro* stimulation by tumor cells, viruses, bacteria, and parasites [7,101,147,148] (Figure 13.3). Moreover, some of the signals and pathways that lead to NK cell activation and controlling NK cell effector functions have been identified. Still, NK cells do not act in an isolated manner *in vivo*. Immune reactions are complex and require coordinated activities of multiple diverse cellular actors within tissue-specific microenvironments. Although direct pathogen recognition by NK cells has been described (see above), in many cases of infection and in most cases of inflammation, the specific ligand for NK cell activation is not known. Rather, microbial pathogens are generally detected by macrophages and/or DC, and neutrophil influx occurs subsequent to tissue damage. As such, NK cell-mediated immune responses appear more or less secondary to pathogen-induced alarm signals that involve cytokines such as IL-12, IL-15, and IL-18 that are crucial for the activation of NK cells [149-151] and that also have the capacity to activate ILC1s [6,11,18]. IL-12 is mainly produced by activated DC [152-155], macrophages [156], neutrophils [157], and mast cells subsequent to microbial activation [158]. IL-15 is produced by many cell types, including DC [159-161], macrophages [161], neutrophils [162], and adipocytes [163] and is presented via the IL-15Rα chain "*in trans*" to NK cells [164]. IL-15 is essential for NK cell homeostasis [165-169] and priming [170]. IL-18 is constitutively expressed by barrier cell types [171], including epithelial cells from

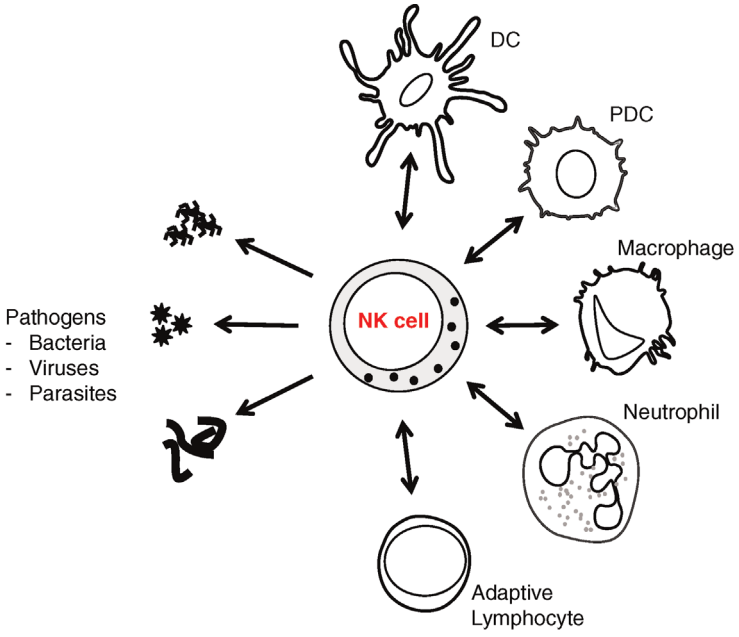

Figure 13.3 NK cells as a "hub" in the type 1 immune network. NK cells interact reciprocally with a diverse set of immune cells. NK cells and ILC1 thereby regulate immune responses to various pathogens, including bacteria, viruses, and parasites.

gut and lung, keratinocytes from skin, and endothelial cells, and also by blood monocytes, macrophages, neutrophils [162,172], and DCs [173]. Its production can be increased upon activation [171] and has also been implicated in the priming of NK cells [174]. As such, NK cells are subject to control by other innate immune cells, including DC, macrophages, and neutrophils, and also by CD4+ T cells that regulate NK cell activity [175].

The interactions of NK cells with innate and adaptive immune cells are far from unidirectional [176-179]. NK cells effector functions impact directly or indirectly on cells within their microenvironment and subsequently influence and regulate them. NK cell-derived IFNγ activates innate and adaptive immune cells [180], induces the maturation, differentiation, and functional capacities of DCs [177,181-183], induces antimicrobial activities of macrophages [110,111] and neutrophils [183], increases the lifespan of neutrophils [184], impacts Ig class switching of B cells [185], and recruits and polarizes T cells toward a Th1-type [187,188]. Activated NK cells have been shown to kill immature DCs [183,189,190], thereby regulating unfolding immune responses and to kill activated $CD4^+$ T cells and consequently indirectly regulating the antiviral $CD8^+$ T cell response and preventing pathology [191]. Similarly, the early restriction of viral load during infection with MCMV prevents pathology as it dampens pDC activation, preserving DC function, and assuring optimal CD8+ T cell control of the virus [82,83,192]. SVG NK cells might help prevent pathology as NK cells reduced $CD4^+$ T cell responses in a TRAIL-dependent manner, while in the

absence of TRAIL MCMV infected mice harbored higher titers of autoantibodies that mimicked Sjogren's syndrome [67].

NK cells and ILC1 have multiple and dynamic connections to the network of innate and adaptive hematopoietic cells that participate in diverse immune reactions. Interactions between these two prominent IFNγ-producing innate lymphocytes with stromal cells, antigen presenting cells, myeloid cells, and adaptive lymphocytes generate a myriad of bidirectional consequences, which focus and intensify immune responses. These intimately intertwined innate lymphoid cells provide the host with an "explosive" mix of defense mechanisms that together provide rapid protection from a large spectrum of potential pathogens. Regulation of innate immune effectors is an important area of future research. Understanding mechanisms of regulation could help improve treatment of autoimmune disease and avoid immune senescence.

Group 2 and 3 Innate Lymphoid Cells: New Actors in Immunity and Inflammation

Nicolas Serafini[1,2] *and James P. Di Santo*[1,2]

14.1 ILCs: A New Family of Innate Effector Cells

Inflammation is associated with many physiological processes, including immune defense, tissue repair, and metabolic regulation [1]. The inflammatory reaction is a complex reaction involving immune cells, soluble factors, and tissue injury in response to infection or trauma; the duration of inflammation can be transient with resolution and restoration of tissue homeostasis or chronic, with tissue dysplasia that can lead to fibrosis or metaplasia. This range of inflammatory outcomes is particularly evident at mucosal sites [2–4]. Recently, a novel family of effector lymphocytes, called innate lymphoid cells (ILCs), has been described that are intimately involved in the inflammatory process [5,6]. ILCs have morphological characteristics of lymphoid cells but lack rearranged antigen receptors, such as the T or B cell receptor, and lack markers associated with myeloid cells and granulocytes. In contrast, ILCs express transcription factors (TF), surface markers, and effector molecules expressed by T helper (T_H) cells or natural killer (NK) cells and can rapidly respond to environment signals with massive production of proinflammatory and immunoregulatory factors [5,6]. As such, ILCs are innate effectors poised to rapidly influence the outcome of immunity following inflammation or infection.

Three major subsets of ILC can be defined by the expression of specific TFs that drive their functional effector programs [6]. Group 1 ILC population (or ILC1) consists of NK cells and others interferon-γ (IFN-γ) producing ILCs require the TFs eomesodermin (EOMES) and/or T-bet (see Chapter 13). Group 2 ILCs (or ILC2) are T_H2-associated cytokines producing ILCs (interleukin (IL) -4, IL-5, and IL-13) that require the TFs GATA-binding protein 3 (GATA-3) and the nuclear hormone receptor retinoic acid (RA) related orphan receptor RORα. Finally, group 3 (or ILC3) includes the cells that express and require the TF RORγt and can produce T_H17-associated cytokines IL-17A and IL-22. Despite these differences, all ILCs share the same lymphoid progenitor and expression of the common γ chain (γ_c; CD132), IL-7 receptor (IL7Rα; CD127), α chain of IL-2 receptor (IL-2Rα: CD25),

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

and Thy-1 (CD90) markers [5,6]. Recent studies in human and mouse models have revealed that ILC have a fundamental role in the inflammatory processes. Here, we discuss the development and heterogeneity of ILC2 and ILC3 and their roles in initiation, regulation, and resolution of the inflammatory reaction.

14.2 ILC2 and ILC3 Heterogeneity and Homeostasis

ILC Lineage Commitment

ILC develop in the fetal liver and adult bone marrow following activation of specific transcriptional programs in hematopoietic progenitors [7]. ILCs are generated by the progressive conversion of common lymphoid progenitors (CLPs) into mature ILC subsets via ILC-restricted intermediates [8–11]. Several TFs are involved in CLP generation and prime the lymphoid program including the TFs Ikaros [12], PU.1 [13], and GFI1 (growth factor-independent 1) [14,15]. As a result, CLP have potential to differentiate into all subsets of lymphoid cells, including B and T cells of the adaptive immune system as well as ILCs. Differentiation of adaptive lymphocytes involves genetic modification associated with the generation of antigen-specific receptors. In contrast, ILC develop independent of the recombinase machinery [7,16] suggesting a branching of ILC versus B/T development from CLP at an early stage. The "E" protein family of TF (including E2A) strongly promotes the B/T cell programs; this activity is offset by inhibitors of DNA binding (Id proteins), thereby providing a molecular mechanism to control ILC versus B/T development [17]. Accordingly, the development of all ILCs requires ID2 [18–21]. Interestingly, ablation of other TFs has been shown to strongly impact the development of multiple ILC subsets, including nuclear factor interleukin-3s (NFIL3)-regulated protein [21–25], GATA-binding protein 3 (GATA-3) [26–29], thymocyte selection-associated high-mobility group box protein (TOX) [30,31], and T cell factor 1 (TCF-1) [32]. Taken together, expression of this combination TF "signature" (ID2, GATA-3, NFIL3, TOX, and TCF-1) appears to define the factors that regulate commitment to the ILC lineage and exclusion to the B- and T-cell pathway.

The specific functions and interactions of these TFs in ILC development are not well characterized. Early ILC progenitors (EILPs) are TCF-1^+ but lack IL-7 receptor expression and are largely $ID2^{lo}$ [32]. EILP are proposed to generate committed ILC precursors (ILCP) that are IL-$7R^+$ and $ID2^+$ [10,11,25,33]. How this occurs is not known, but it has been suggested that NFIL3 and IL-7 signaling [25], supported by TOX [31], is required to initiate ID2 expression. ILCP include α-lymphoid precursors (αLP; Lin^- $Id2^+$ $\alpha4\beta7^+$ $CXCR6^+$ cells) [24] and common helper ILCP (CHILP, common helper innate lymphoid progenitor; Lin^- $Id2^+$ $\alpha4\beta7^+$ $CD117^+$ $CD25^-$ cells) [11] that have potential to generate different ILC subsets, including NK cell [11,24]. Nevertheless, the relationship between these different precursors remains unclear. Recent studies suggest that ILCP may progressively lose the ability to generate particular ILC subsets. In this case, ELIP and αLP can generate all ILC lineages (including $EOMES^+$ ILC1 that are conventional NK cells) [7], while CHILPs can give rise to all ILC subsets but lack NK potential [11]. In addition, a subset of CHILPs express the TF

promyelocytic leukemia zinc fingers (PLZF$^+$ ILCP), which have lost the ability to generate CCR6$^+$ ILC3 (including lymphoid tissue inducer cells, LTi cells) but retain potential for ILC1, ILC2, and other ILC3 subsets [10]. Taken together, these observations suggest the following pathway with successive restriction of ILC potental: EILP → αLP → CHILP → PLZF+ ILCP (Figure 14.1)

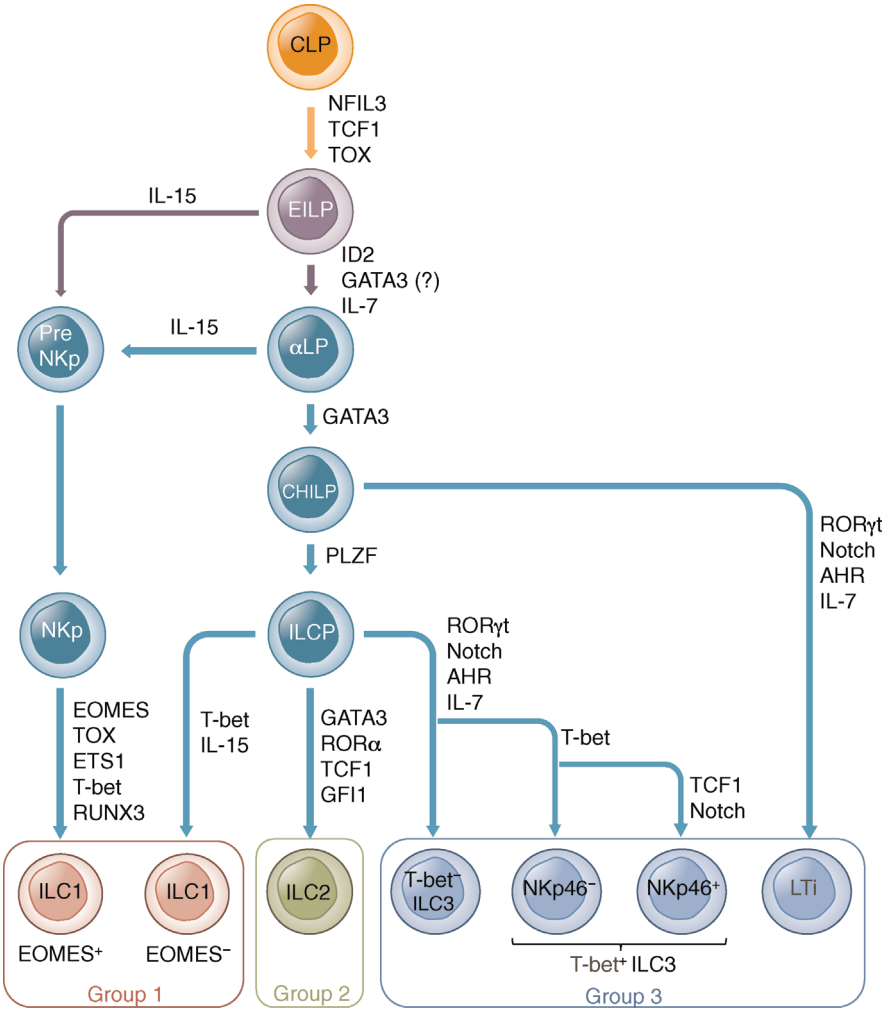

Figure 14.1 A model for ILC development. Innate lymphoid cell differentiate from common lymphoid progenitors and early ILC progenitors in fetal liver or bone marrow via prenatural killer precursors (pre-NKP) and α-lymphoid precursors. These hematopoietic intermediates are regulated by interleukin-7 and the transcription factors Nuclear factor IL-3 induced (NFIL3), inhibitor of DNA binding 2 (ID2), thymocyte selection-associated high-mobility group box protein (TOX), and GATA-binding protein 3 (GATA3). Conventional NK cells (here called EOMES$^+$ ILC1) derive from pre-NKP and NK precursor (NKP) via IL-15 under influence of several TFs including eomosodermin (EOMES), TOX, Runt-related transcription factor 3 (RUNX3), and ETS1. Downstream of the αLP, Id2$^+$ PLZF$^-$ progenitor (or CHILP) and ID2$^+$PLZF$^+$ ILC precursor (or ILCP) direct the differentiation of EOMES$^-$ ILC1, ILC2, or ILC3 subsets based on specific transcriptional programs during fetal and adult life.

Group 2 ILC

ILC2 s were initially denoted "natural helper cells," "nuocytes," or "innate helper 2 cells" [19,34,35] and express IL-7Rα, IL-25R, IL-33R, and TSLP-R and respond by abundant production of type 2 cytokines (including IL-4, IL-5, IL-9, and IL-13) and the EGFR ligand amphiregulin [19,34–36]. Human ILC2 expresses not only IL-7Rα but also the chemoattractant receptor CRTH2 and the natural killer receptor CD161 [37,38]. The TFs GATA-3 [39–42], ROR-α [43,44], GFI-1 [45], and BCL11b [46–48] contribute to ILC2 differentiation and maintenance. In mouse and human, ILC2 are distributed in the blood, spleen, bone marrow, nonlymphoid tissue, and mucosal sites such as liver, adipose tissue, lung, and intestine [19,35,40,41,49–51]. However, ILC2 s seem to be functionally heterogeneous in different tissues and differentially express some receptors including CCR6, CCR9, or KLRG1 likely representing different states of activation or maturation [52,53].

Group 3 ILC

All ILC3 are IL7Rα+ and strongly express the TFs RORγt [9,54–60] and AhR [61–63]. ILC3 s are activated by IL-1β and IL-23, and strongly produce IL-22, IL-17, lymphotoxin-alpha/beta (LTα/β), and/or GM-CSF [55–57,60,64–69]. Several ILC3 subsets have been described, including $CCR6^+$ ILC3 and subsets expressing the natural cytotoxicity receptors NKp46 (in mice and man) and NKp44 (in man) [56–59,70]. Within the $CCR6^+$ subsets are lymphoid tissue inducer cells (LTi cells) that promote formation of secondary lymphoid tissues (lymph nodes, Peyers patches, cryptopatches, and isolated lymphoid follicles) during the fetal life through production of Lt α/β and RANK ligand in response to the microbial signals [71–74] and maternal signals [75]. After birth, LTi cells also contribute to the mucosal defense through production of T_H-17-associated cytokines IL-17A and IL-22 [55,68]. NCR^+ ILC3 s, called "NK22," NCR22," "NK-LTi", or "ILC22" [56–58], and NCR^- ILC3 s [66,76,77] are massive producers of IL-22 or/and IL-17 (for NCR^- ILC3) in response to IL-23 and/or IL-1β stimulation. NCR^+ ILC3 s develop after birth in bone marrow and require the TF T-bet [76,78,79]. T-bet^+ ILC3s are rare in lymphoid tissue but are abundant in mucosal sites such as skin and intestine [56,57,59,66,76,80].

The specific versus redundant roles for $CCR6^+$ and NCR^+ ILC3 in mucosal immunity and intestinal homeostasis are not fully elucidated. Still, all ILC3 s require the presence of commensal bacteria for development notably though the TF AhR [61–63]. Concerning specific signaling pathways, Runx3 [81], Notch [9,78,79], and TGF-β [82,83] are involved in ILC3 differentiation and in the homeostasis of specific ILC3 subsets. In particular, the phenotypic and functional stability of NCR^+ ILC3 is under the control of Notch and TGF-β [82,83].

Maintenance of ILCs in Adult Tissues

Distinct ILC subsets are proposed to contribute to tissue immunosurveillance and homeostasis during the steady state and after aggression (infection, inflammation, etc.). However, the cellular source that maintains ILC pools in the tissue under these conditions remains undefined. Tissue ILCs

homeostasis may involve self-renewal or replenishment from ILC precursors that are stored in "depots" (bone marrow and lymphoid tissue). Recent studies demonstrated a longtime residency of ILC in tissues. Using parabiotic mice to establish a joint bloodstream between congenic mice, it was shown that most ILCs resided in tissues and did not circulate thought the blood. Moreover, ILCs were also locally maintained in tissues during inflammation and after parasite infection. These studies convincingly demonstrate that ILC2 and ILC3 are local tissue resident cells with apparent self-renewal capacity [84].

14.3 ILC2 in Acute and Chronic Inflammation

ILC2 s are critical players in type 2 immune responses having interactions with innate and adaptive immune cells in response to environmental cues relayed through stromal and/or epithelial cells. As such, ILC2 s are an essential part of the network that neutralizes pathogens (including parasites, viruses, etc.). Still, ILC2 responses need to be carefully controlled in order to avoid allergic or atopic inflammatory reactions (Figure 14.2).

ILC2 and Parasitic Infection

Helminth infections are a major cause of chronic human disease in the world causing morbidity or compromising host fitness by anemia and growth retardation [85]. Using mouse models, it has been shown that the cytokine IL-13 is critically involved in parasite expulsion and immune defense against helminths [86]. Recent studies using infection by *Nippostronglus brasiliensis* [19,34,35], *Trichuris muris* [87], or *Strongyloides venezuelensis* [88] have identified ILC2 as one of the most important IL-13 sources. Following infection, epithelial cells release stress mediators (including IL-33, IL-25, and/or TSLP) that activate cytokine production by ILC2 [19,34,35]. Another important ILC2 sentinel involves Tuft cells that constitutively express IL-25 and thereby maintain ILC2 homeostasis and type 2 immune responses [89–91]. ILC2 production of IL13 and amphiregulin can activate several targets, including goblet cells, which produce mucus and limit parasitic infection by production of resistin-like molecule β (RELMβ) [92,93] and the smooth muscle cells to enhance the worm expulsion [19,34,35,94]. Furthermore, the T cell-derived IL-2 [95], epithelial cell activation [19,34,35], IL-9 signaling (by autocrine manner) [96], and TGF-β1 [97] all promote ILC2 expansion, survival, and function. Together, these studies define a complex intercellular "cross-talk" involving ILC2 and nonhematopoietic cells (Figure 14.2).

While ILC2 can directly promote inflammatory reactions, they can also enhance T_H2-associated innate and adaptive immunity. In visceral adipose tissue and in the lung, IL-5-producing ILC2 s promote the accumulation of eosinophils and alternatively activated macrophage (AAM). ILC2 depletion impairs eosinophil accumulation and AAM activation during parasite infection and enhances insulin sensitivity [49]. Interestingly, murine ILC2 express MHC class II molecules [34,43] and can activate T_H cells by antigen presentation [77], similar to

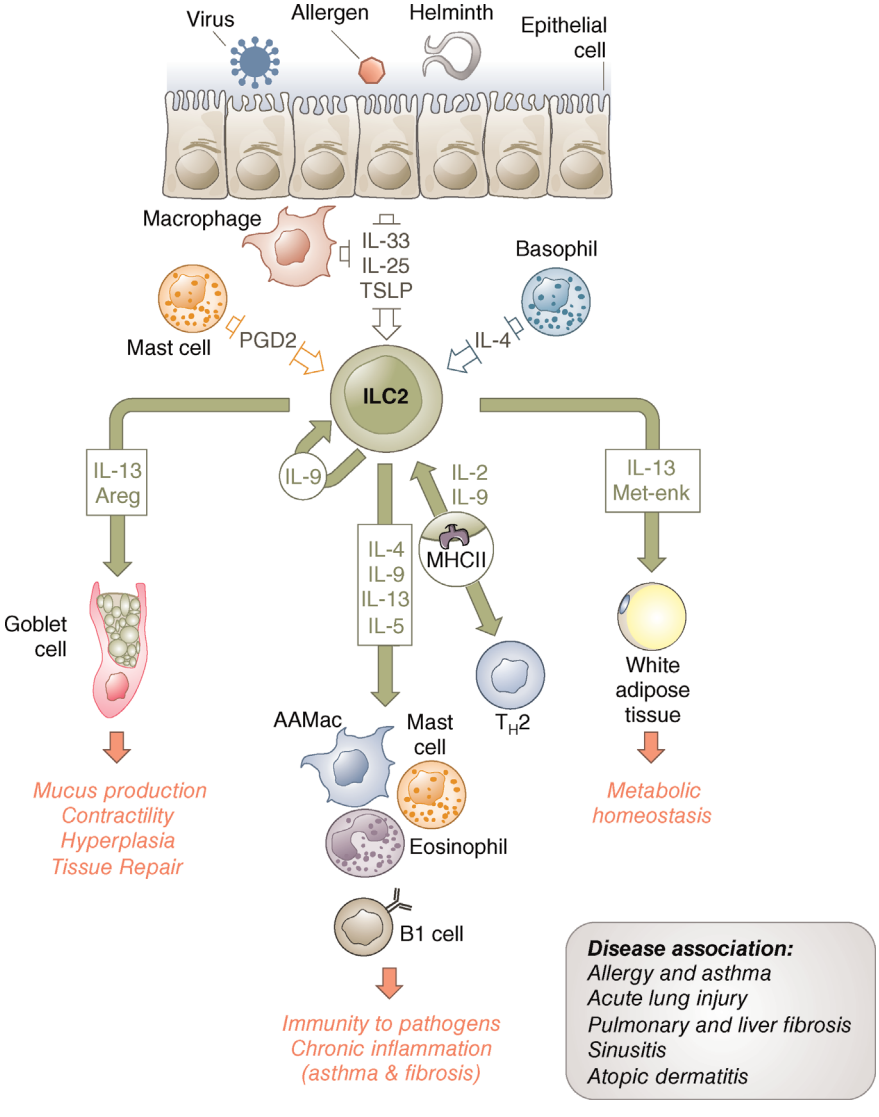

Figure 14.2 ILC2 in infection and chronic inflammation. Epithelial cells, alveolar macrophages, mast cells or/and basophils drive the activation and proliferation of ILC2 via secreted factors including IL-33, IL-25, PGD2, IL-4, and TSLP. Inflammation, allergens, and infection (helminth or viral) activate ILC2 to modulate mucus production and tissue repair through production of type 2 cytokines (IL-4, -5, -9, and -13) and amphiregulin (Areg). ILC2 activation in adipose tissue can promote metabolic homeostasis by stimulation of adipocytes with IL-13 and methionin-enkephalin peptides (Met-enk). Several pathologic conditions associated with ILC2 activation are listed.

mononuclear phagocytes. The absence of ILC2 results in impaired T_H2 responses during worm infection [98,99]. In addition, IL-2 derived from T cells contributes to the ILC2 activation and upregulates MHC expression [98]. Interestingly, ILC2 s seem to respond during dietary stress, notably in vitamin A deficiency, suggesting a link between antiworm immunity and malnutrition [87]. Moreover, recent study shows that the proportion of ILC2 is diminished in young helminth infected children but not older infected patient suggesting a protective preemptive role for ILC2. Interestingly, ILC2 deficiency can be restored after antiparasite treatment. Thus, ILC2 s have essential roles in defense against parasitic infection and blood ILC2 may represent a biomarker for effective resistance to infection [100].

ILC2 and Viral Infection

Viral infection initiates severe inflammation in tissues that can have fatal consequences. In the respiratory tract, influenza viruses replicate locally and induce tissue injury. In addition, the emergence of high pathogenicity influenza strains (such as H5N1) and their potential for pandemic spread represent a significant threat to public health. Taken together, lung-specific immune responses constitute a crucial barrier to contain and eliminate influenza virus [101]. Using a mouse model of influenza infection that acutely induced airway hyperreactivity, ILC2 s were shown to be critical in orchestrating immunity and regulating lung inflammation [36,102]. ILC2 depletion resulted in destruction of epithelial layer and impaired tissue remodeling that strongly impacted on overall lung function. IL-33 production by alveolar macrophages was found to be critical for early immune response and notably for the activation of IL-13 producing ILC2 s [102]. Furthermore, IL-33 enhanced IL-5 production from ILC2 s, which promoted the accumulation of eosinophils during the recovery phase of influenza. ILC2 were shown to be an important source of amphiregulin production that helped restore lung function, barrier integrity, and remodeling of respiratory tissues in the context of acute epithelial injury and asthma [36,94].

ILC2 and Chronic Inflammation

In blood, skin, or lung, deregulation of ILC2 activation has been characterized in multiple chronic inflammatory diseases in human or mice models such as asthma [38,103–106], allergic rhinitis [107,108], chronic rhinosinusitis associated with nasal polyps [37,109], atopic dermatitis [110,111], or pulmonary fibrosis [112]. In this inflammatory context, sentinel cells that initiate ILC2 responses include epithelial cells and various myeloid cell subsets. In a vitamin D analog-induced atopic dermatitis model [113] and in an allergen-induced lung airway inflammation model, IL-4 producing basophils could promote ILC2 proinflammatory responses [114]. In this context, IL5 and IL-13 producing ILC2 s support epithelial cell activation and the recruitment and activation of eosinophils and macrophages to promote chronic inflammation [112,115] and also enhance $CD40^+$-activated dendritic cell (DC) migration into draining lymph to support adaptive T_H2 immunity [116].

ILC2 and Metabolic Disorders

ILC2 s were first characterized in fat-associated lymphoid clusters (or "FALCs") [19]. Since then, ILC2 function within adipose tissue has become a focus of study. Nutrient and metabolic stress impact on systemic homeostasis in the context of obesity or malnutrition [117]. Obesity in human and mice is associated with low frequency of ILC2 s in adipose tissue [51]. In a model of high-fat diet that leads to the build-up of visceral adipose tissue, ILC2 activation by IL-25, IL-33, or vasoactive intestinal peptide (VIP) leads to the production of IL-13 and IL-5 [5,49,118,119]. Thus, ILC2 s appear to control the homeostasis of eosinophils and AAMs that protect the organism in the context of fat-mediated chronic inflammation. ILC2 may also control the accumulation of regulatory T cell (T_{reg}) via direct ICOS–ICOSL interactions [120]. ILC2 regulates adipose function and metabolic homeostasis in white adipose tissue notably through the production of IL-13 and methionine-enkephalin peptides [51,121,122]. This ILC2-dependent activation results in "beiging" of adipocytes that protects against insulin resistance [51,121,122]. Conversely, fat tissue regulates the activation of ILC2 s notably via IFN-γ [120] and through metabolites such as lipoxins or prostaglandins [123] (Figure 14.2).

14.4 ILC3 in Acute and Chronic Inflammation

ILC3 subsets are highly enriched in gut-associated lymphoid tissues (Peyer's patches, mesenteric lymph nodes, cryptopatches, and isolated lymphoid follicles) and are found dispersed throughout the intestinal lamina propria. In this context, ILC3 s are considered as an important contributor to intestinal immune defense to counteract microbial invasion and to maintain equilibrium between the host and the microbial symbionts. As ILC3 s can react rapidly to pathogen or tissue injury signals, they are important actors during bacterial infection or inflammatory bowel disease (IBD) (Figure 14.3).

ILC3 and Commensal or Pathogenic Bacteria

ILC3 populations have been demonstrated to play crucial roles in intestinal homeostasis. ILC3 produce IL-22 that promotes epithelial cell differentiation, glycosylation, and mucus and antimicrobial peptide production [124–126]. In this way, ILC3 s regulate selective containment of commensal bacteria and prevent systemic inflammation [127,128]. In addition, ILC3 s regulate IgA production through specific lymphotoxin α (sLTα3) and β (LTα1β2) control of T cell gut homing and DC functions, respectively [128]. Interestingly, ILC3 s also modulate immune tolerance in the intestine. Expression of MHC class II on specific ILC3 subsets negatively regulates commensal bacteria-specific T_H17 cell responses that limit intestinal inflammation [77] and induce cell death of commensal bacteria-specific $CD4^+$ T cells [129]. Deregulation of ILC3 MHCII expression is correlated with increase in T_H17 cells and commensal bacteria-specific IgG in pediatric Crohn's disease patients [129]. In addition, ILC3 s regulate the homeostasis of mononuclear phagocytes in the gut through production of the granulocyte

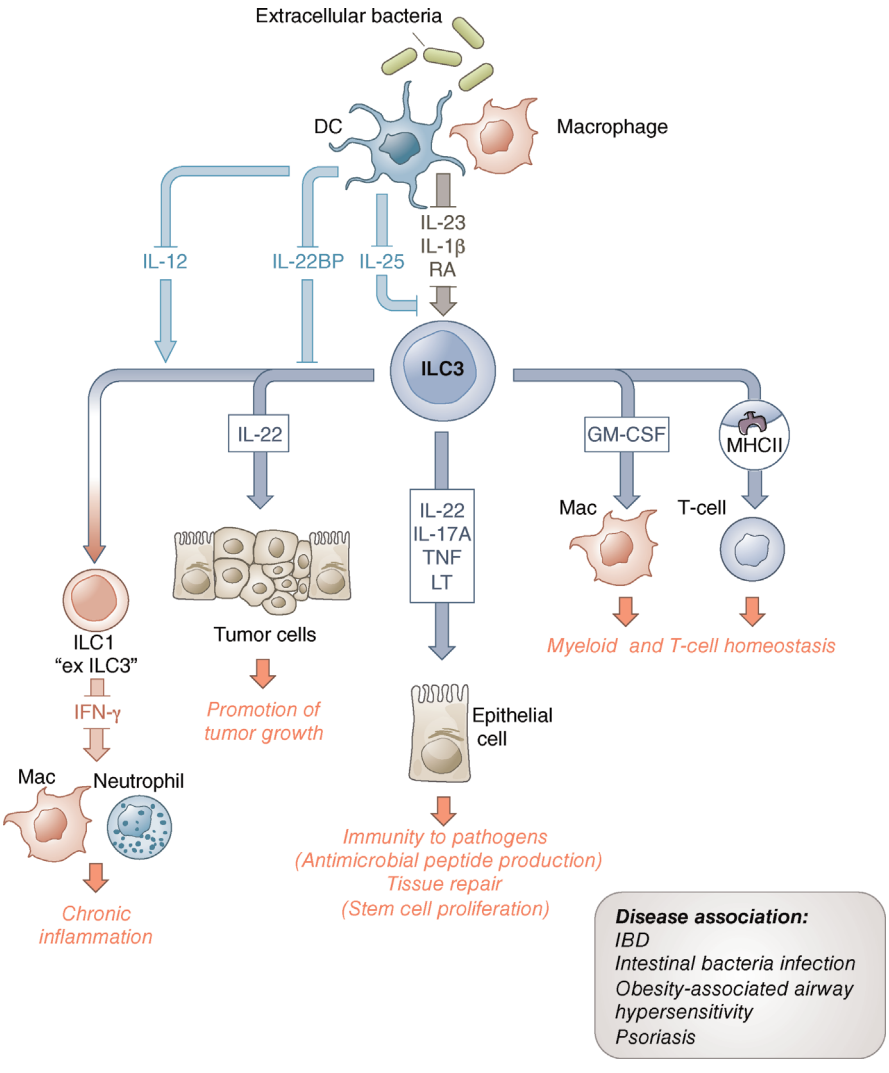

Figure 14.3 ILC3 During gut infection and inflammation. Activation of myeloid cells par microbiota or pathogenic extracellular bacteria mediates ILC3 response via IL-23, IL-1β, or RA. The production of T_H17 cytokines produced by ILC3 increases the antimicrobial activity of epithelial cells mediated by antimicrobial peptides and mucus production. In addition, IL-22 can also contribute to the tumor proliferation and inflammation in mouse colorectal cancer models. IL-25 and IL-22BP secreted by DCs represent negative regulators of this process. ILC3 production of GM-CSF and the surface expression of MHC class II can influence the homeostasis of myeloid cells and pathogenic $CD4^+$ T cells to limit intestinal inflammation.

macrophage colony-stimulating factor (GM-CSF) induced by commensal bacteria [69]. This cross-talk is essential to modulate T_{reg} responses to commensal bacteria and dietary antigens [69]. Altogether, these studies show essential role of ILC3 to maintain intestinal homeostasis that limits the commensal bacteria spread and pathological adaptive immune responses.

ILC3 s promote host protection during *Citrobacter rodentium* (enteric Gram$^-$ pathogen in mouse), *Helicobacter hepaticus* [66], *Salmonella typhimurium* [124], or *Streptococcus pneumoniae* infection [130]. In this context, ILC3 s respond to DC-derived IL-23 and IL-1β [131–133] to produce IL-17 and IL-22 that synergistically promote epithelial cell activation through the STAT3 pathway [126]. Production of chemokines CXCL1 and CXCL9 by ILC3 allows recruitment of neutrophils to the infected tissue [125,134]. Conversely, ILC3 responses can be limited by cell contact with IL-25-activated DCs [135], the presence of IL-22 binding protein (IL-22BP) [136], and through vitamin A metabolites (retinoic acid) [44,75,87,137].

ILC3, Chronic Inflammation, and Cancer

IL-22-producing ILC3 promote tissue repair and are required for protection and recovery from inflammatory colitis [135]. In humans, several inflammatory diseases (including psoriasis, IBD, or autoimmune arthritis) are associated with modulation of IL-17 and IL-22 levels and ILC3 homeostasis appears dysregulated [66,131,138,139]. This may involve changes in phenotype and function of ILC3 subsets ("plasticity") that can occur during inflammation. In mouse models, downregulation of RORγt expression in intestinal ILC3 has been observed, resulting in enhanced T-bet expression and sustained expression of IFN-γ. These RORgt$^-$ T-bet$^+$ ILC3 s have been denoted "ex-ILC3s" [59,76] and appear to represent a ILC3 → ILC1 transition driven by IL-12. Similar findings have been shown in human ILC3 derived from tonsils [140] and have been proposed to occur during inflammatory bowel disease [59,70,140]. ILC3 plasticity suggests the importance of environmental signals in maintaining ILC3 functional diversity in tissues under steady-state and stressed conditions [59,65,76,141]. ILC plasticity is not restricted to ILC3 but has recently been demonstrated in human and mouse ILC2 in the context of chronic inflammation [142–145].

As mentioned previously, ILC3 s promote the epithelial cell proliferation via IL-22 production. Tight regulation of this pathway may be necessary to avoid uncontrolled proliferation that could lead to malignant transformation. Specific roles for ILC3 in tumor development remain unclear. Still, inflammation enhances tumor development and is associated with increased levels of IL-22 [136] and accumulation of ILC3 [146]. IL-22 can directly promote cellular transformation via phosphorylation of STAT3 in colonic epithelial cells. Conversely, this pathway is regulated by DCs that produce a soluble IL-22 binding protein (IL-22BP) capable of downregulating IL-22 activity [136]. Additional cross-regulatory pathways are involved in intestinal homeostasis. IL-23 levels are increased during inflammation [147] resulting in myeloid cell recruitment and blocking of antiapoptotic signals [146] that promote tumor development. In melanoma, CCR7$^+$ LTi and stromal cells have been implicated in tumor progression [148]. CCL21 (CCR7 ligand) expression by tumor cells creates an immunotolerant environment, whereby LTi cells facilitate tumor cell survival and invasion [148]. Together, these observations paint a complex picture of ILC3 regulation of epithelial function that has not been fully explored in the human system. It is likely that ILC plasticity will also play a

key role not only in tumor initiation but also in tumor progression and disease outcome.

14.5 Therapeutically Harnessing ILC2 and ILC3

Because ILCs can rapidly respond to viral or bacterial infection and injury, they represent interesting targets for preventing or enhancing innate immune responses during infection, inflammatory reactions, and in chronic disease settings. Still, ILC-specific targeting approaches that can suppress or enhance their activities have not yet been identified. Still, ILCs share with T cells a plethora of receptors and/or secreted factors, some of which are already targeted in preclinical or clinical trials. It will be important to understand the precise cellular targets for these different therapies (T cell versus ILC) in order to optimize these approaches (Figure 14.4).

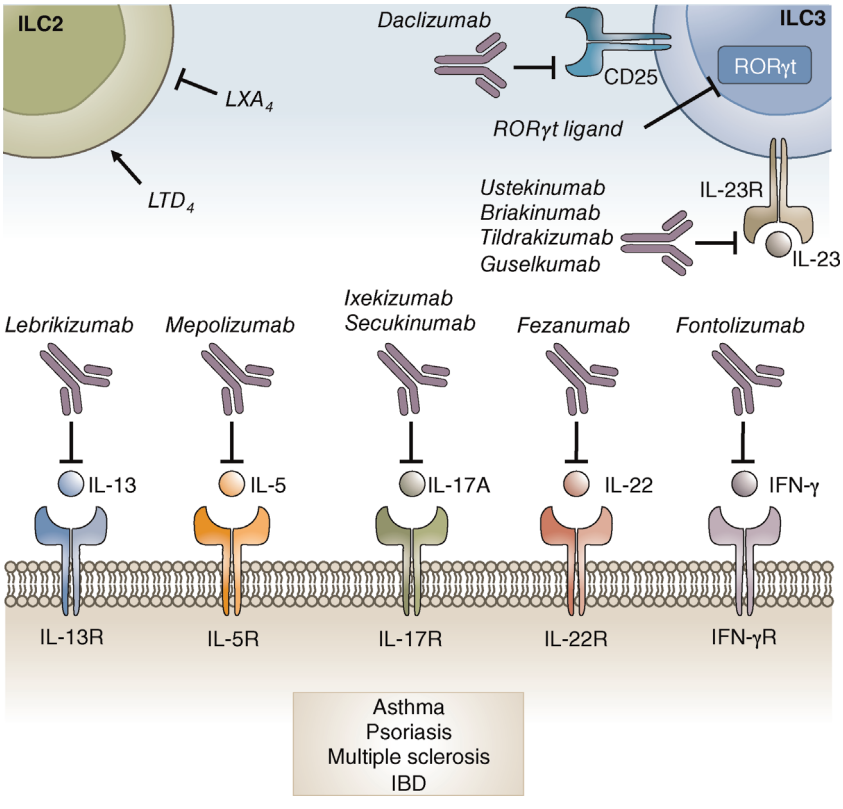

Figure 14.4 Targeting ILC2 and ILC3 in the clinic. ILC2 and ILC3 are associated with inflammatory diseases and ILC activation could be modulated therapeutically using different approaches. Recent preclinical studies and clinical trials show that modulation of ILC2 and ILC3 activity may be developed to control their inflammatory activity using metabolite, ligand, and monoclonal antibodies notably in patients with IBD, asthma, psoriasis, and/or autoimmunity.

ILC2 activity can promote chronic inflammation at barrier sites (e.g., asthma in the respiratory tract). The arachidonic metabolites lipoxin A4 (LXA4) or leukotriene D4 (LTD4) could be used to modulate (negatively or positively) ILC activity in this context [38,123]. Moreover, cytokines IL-5 and IL-13 produced by ILC2 s may be targeted with specific monoclonal antibodies. Along these lines, Mepolizumab (anti-IL-5) and Lebrikizumab (anti-IL-13) are already being used in asthmatic patients [149–151]. In addition, antibodies against IL-25 or IL-33 could be interesting targets in acute allergic diseases [152,153].

During chronic inflammation, activation of potentially pathogenic ILC3 may be involved in local tissue damage. Therapeutic neutralization of IL-23 or IL-1β attenuates ILC-dependent colitis in preclinical mouse models of IBD [66,154,155]. Interestingly, clinical trials with Ustekinumab or Briakinumab (directed against IL-12/23 p40 subunit) or with Tildrakizumab and Guselkumab (against IL-23 p19 subunit) show signs of clinical efficacy in the treatment of psoriasis and Crohn's disease [156–160]. Moreover, the ILC depletion could be an interesting strategy to limit the ILC activity (similar to that used in mouse models with anti-CD90 antibodies) [77,139,154]. Drugs targeting cell ILC subset activation could involve inhibitors of RORγt or cytokine receptors [161–163]. In multiple sclerosis, treatment with anti-IL2Rα (Daclizumab) resulted in a reduced frequency of IL-22 and LTα producing ILC3 s [164]. Finally, selective neutralization of ILC cytokines is other possible strategy. For example, the targeting of IL-17 with Secukinumab, IL-22 with Fezakinumab, or IFN-γ with Fontolizumab presents new opportunities to limit the proinflammatory effects of these cytokines in psoriasis and Crohn's disease [165–167]

14.6 Concluding Remarks

ILCs constitute new actors in innate immunity that have critical roles in maintaining tissue homeostasis, in initiating immune defense against infection, and in regulating inflammatory disorders. The diversity of ILC subsets implies some level of specificity of the innate immune system to protect at individual and distinct mucosal barriers. We have learned much about ILC functions using genetically modified mouse models. In contrast, our understanding of human ILC development, function, and roles in health and disease are less well defined. Recent studies have demonstrated that diverse ILC subsets show functional plasticity, secondary to changes in cytokine and chemokine environments. Because ILCs potently activate and modulate the epithelial cell activity and immune responses, regulation of their activity and plasticity may be important in the context of many inflammatory diseases. Therapeutic modulation of ILCs could be an interesting strategy to bolster immunity against infection, to modulate tissue damage during inflammation, and to prevent cancer. Monoclonal antibodies that can target ILC-derived cytokines might find several applications in the clinic. However, a deeper understanding of ILC biology and responses to environmental and inflammatory signals in humans is necessary before we can fully harness the potential of these novel immune effector cells.

15.1 The History of T Helper Cells

Thirty years ago, reports by Mosmann and Coffman provided the first descriptions of T helper cell subsets [1]. Those first papers demonstrated that T-cell clones, upon antigen stimulation, secreted specific and heritable subsets of cytokines. Some clones secreted IFNγ, IL-2, and lymphotoxin and were termed Th1 cells. Other clones secreted IL-4, IL-5, and/or IL-10 and were termed Th2 cells. The ability of T cells to secrete specific sets of cytokines was a striking finding and suggested a separation in the function of these cells as well. Th1 cells could mediate delayed-type hypersensitivity responses *in vivo* and were thought to be responsible for cellular immune responses [2]. Th2 cells demonstrated a greater ability to provide B cell help *in vitro*, and they were thought to be specialized for the development of antibody responses [2].

The concept that T cells could acquire specialized functions was slow to be accepted. Many researchers initially thought these polarized cytokine-secreting patterns were an artifact of long term *in vitro* culture of the T-cell clones. However, the segregated patterns of cytokine production were observed *in vivo* [3,4], and immune responses to particular pathogens appeared to generate immune responses that were consistent with segregated cytokine secretion [4]. Thus, observations of immune responses *in vivo* were validated the previous work on T-cell clones.

The next major advance was in defining the environment that would promote the development of T cells that produced polarized subsets of cytokines. *In vitro* and *in vivo*, IL-4 promoted the generation of Th2 cells [5]. IL-12 stimulated the generation of Th1 cells [6]. The application or blockade of these cytokines allowed responses to pathogens and in disease models to be manipulated, providing the contextual polarization of T cells that impacted the outcome of the inflammatory response.

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

The Th1–Th2 paradigm lasted almost 20 years before it became clear that it was not sufficient to explain all immune responses. In the interim, Th1 cells were functionally tied to autoimmunity and resistance to pathogens that evaded host responses by growing within cells [7]. The IFNγ produced by Th1 cells activated macrophages to facilitate phagocytosis and efferocytosis, and induced the production of chemokines that recruited additional cells to sites of inflammation [8,9]. Th2 cells mediated allergic inflammation and promoted immunity to helminthic parasites [10,11]. The IL-4 secreted by Th2 cells was required for class switching to IgE and was required for IgE-dependent mast cell responses [12,13]. Furthermore, Th2 cell-produced IL-5 increased circulating eosinophils that further helped mediate immune responses at mucosal surfaces [14,15].

Central to the ability of IL-4 and IL-12 to promote T helper cell differentiation was the activation of the Janus kinase (JAK)-signal transducer and activator of transcription (STAT) pathway [16–20]. Cytokines that bind to receptors that have JAK tyrosine kinases associated with the cytoplasmic portion of the receptor result in the activation of the tyrosine kinase activity. Phosphorylation of tyrosine residues on the cytoplasmic receptor tail results in recruitment of SH2 domain-containing proteins including the STAT proteins. The STAT proteins are subsequently phosphorylated thereby forming dimers, which are able to move to the nucleus and bind DNA to activate transcription. IL-4 specifically activates STAT6 that is required for Th2 differentiation [13,21–23]. IL-12 activates STAT4 and IFNg activates STAT1, both contributing to Th1 development [17,24–27]. The STAT proteins were the gateway to understanding T-cell differentiation in more detail.

Following STAT protein activation, Th1 and Th2 cells expressed specific transcription factors that activated genes encoding cytokines, cytokine receptors, chemokine receptors, and others that were required for the specialized function of each T helper subset. The T-box transcription factor T-bet was induced by STAT1 and STAT4 and cooperated with a number of other factors including STAT4 itself, the homeobox transcription factor Hlx, and the Runt family transcription factor Runx3 to regulate IFNγ and many other Th1-associated genes [24,28–31]. Th2 cells expressed GATA3 that worked other transcription factors including c-maf and interferon regulatory factor 4 (IRF4) [19,32,33]. Together, these transcription factors not only activated gene transcription but also initiated changes in the chromatin structure that allowed target loci, including the cytokine genes, to be primed for subsequent activation by T-cell receptor signaling.

The paradigms developed in Th1 and Th2 cells served as a blueprint for the rapid characterization of additional T-cell subsets described in the twenty-first century (Figure 15.1). Th17 cells secrete IL-17 and are involved in immunity to bacteria and fungi and promote some types of autoimmune responses [34–37]. T regulatory (Treg) cells limit immune responses, inhibiting the development of autoimmune diseases, and preventing pathogen immunity from causing a chronic inflammatory state [38,39]. Each of these subsets is dealt with in detail in separate chapters in this book. T follicular helper cells are a highly specialized of the T cell that develops in the germinal center and promotes B-cell growth, differentiation, class switching, and affinity maturation [40]. These cells are required for development of high-affinity antibody production, but whether or not they contribute to inflammation is not yet entirely clear. It is thought they might

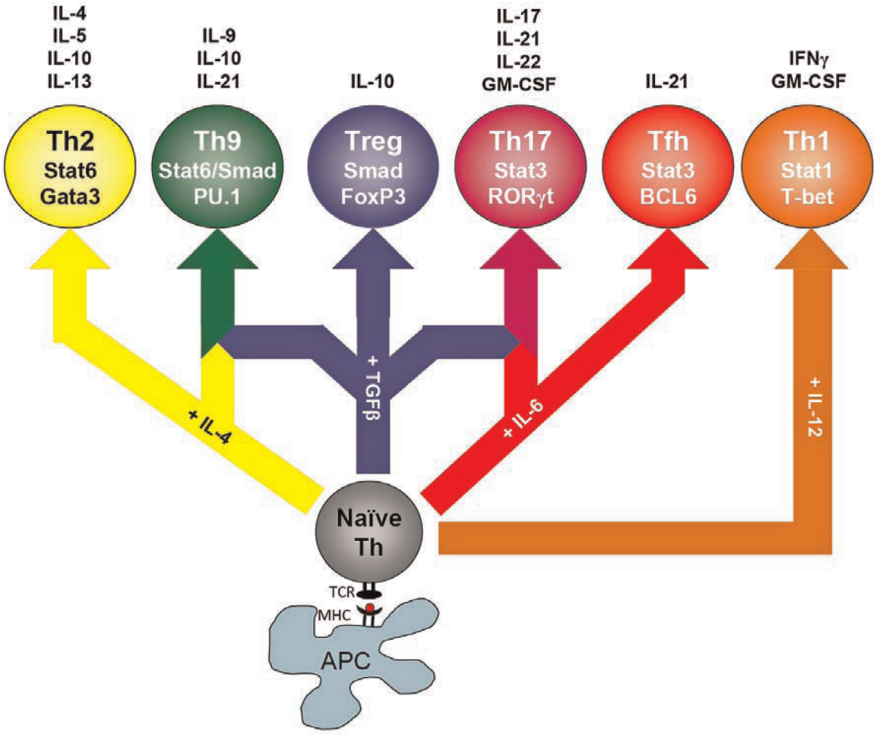

Figure 15.1 Th cell differentiation. Multiple factors are important in determining Th cell fate (e.g., TCR signaling; costimulation); however, research indicates cytokine signaling is the most important factor driving Th cell differentiation. The prototypical cytokines and transcription factors regulating each Th cell pathway are depicted. Predominant cytokines produced by each Th subset are also listed.

be involved in the development of antibody-mediated autoimmune diseases such as systemic lupus erythematosus.

15.2 Introduction to Th9 Cells

15.2.1 Development

The most recently described T helper cell subset is the IL-9-secreting subset of T cells termed Th9 cells. The primary cytokines that promote the differentiation of IL-9-secreting T cells were documented over 20 years and include IL-4, IL-2, and TGFβ [41]. Each of these cytokines activates distinct signaling pathways and increases the expression of transcription factors that are important for IL-9 production and the development of the Th9 phenotype. Because Th9 cells develop from integrated signals activated by IL-4 and TGFβ, Th9 cells share some attributes with Th2 cells (that develop following stimulation with IL-4 alone) and Treg cells (that develop following stimulation with TGFβ alone) [42–44]. Yet,

Th9 cells are a distinct subset that expresses a unique gene signature responsible for the ability of Th9 cells to function in the immune response [43].

Downstream of IL-4, STAT6 activation is critical for the development of Th9 cells and is responsible for the activation of many genes found in the Th9 transcriptional signature [43,45]. Some of these effects may be direct, but STAT6 also activates the expression of a variety of transcription factors important for IL-9 production. Among these are IRF4, basic activating transcription factor-like (BATF), and GATA3 [42,43,46]. These factors activate overlapping sets of genes in the Th9 transcriptional signature, and IRF4 and BATF particularly cooperate in activating Th9 gene expression [43]. STAT6 also represses the expression of transcription factors that impair Th9 development including T-bet, Runx3, and Foxp3, the latter the transcription factor required for Treg development [45].

IL-2 activates STAT5, one of the STAT family members that can contribute to many T helper cell lineages. STAT5 can act directly by binding to the Il9 gene and potentially by interfering with the activity another inhibitory transcription factor, Bcl6 [47,48]. In addition, STAT5 likely promotes Th9 development indirectly. STAT5 induces IRF4 expression, and may activate other Th9 genes as well [47].

TGFβ activates several pathways that are important for Th9 development. One of the common pathways activated by TGFβ and other cytokines in the TGFβ family including activin A (which can replace TGFβ in the induction of Th9 cells [49]) are Smad proteins. The Smad proteins Smad2, Smad3, and Smad4 have each been identified as binding to the Il9 locus and promoting chromatin changes that facilitate Il9 transcription [50,51]. Smad proteins also interact with IRF4, linking the pathways activated by IL-4 and TGFβ [50]. Independent of Smad signaling is the induction of PU.1, an ETS family transcription factor that was one of the first identified with a specific role in Th9 cells [50–53]. PU.1 binds to the Il9 locus and recruits specific histone acetylatransferases that specifically activate IL-9 production [52,54].

15.2.2 Additional Th9-inducing Cytokines

In addition to IL-4, IL-2, and TFGβ, several other cytokines have potent abilities to induce the production of IL-9. Moreover, the function of some of these cytokines is dependent on the ability to induce IL-9. Thymic stromal lymphopoietin (TSLP) has been extensively characterized for its ability to promote allergic inflammation [55]. Much of that function was thought to be dependent upon Th2 cells. However, more recent reports indicate that TSLP function also requires IL-9 and Th9 cells in the generation of allergic airway disease [56]. Mechanistically, TSLP activates STAT5, which as described above, binds directly to the *Il9* locus.

IL-25 is an IL-17 family cytokine member that promotes IL-9 production, and IL-25-induced allergic inflammation requires IL-9 [57]. Interestingly, Th9 cells appear to have the highest IL-25R mRNA expression (*Il17rb*) among the Th subsets [43]. It is not entirely clear how IL-25 promotes IL-9 production, but it could be through activation of NF-κB signaling or by the recently demonstrated ability of IL-25 to activate STAT5 [58].

TL1A is a TNF superfamily cytokine (or costimulatory molecule if surface-bound) that potently activates IL-9 production, parallel to its induction of allergic inflammation [59]. TL1A appears to function by enhancing IL-2 production that feeds back to cells to produce IL-9 in a STAT5-dependent manner.

Finally, IL-1 enhances IL-9 production from Th9 cells through an IRF1-dependent mechanism [60,61]; however, the ability of IL-1 to alter the function of Th9 cells may extend beyond the regulation of IL-9. IL-1-treated Th9 cells have increased both IL-21 production and tumor immunity that is dependent on IL-21, not IL-9 [60]. This altered function will be discussed later in the chapter.

15.2.3 Th9-inducing Cell Surface Ligands

Similar to cytokines that act through cell surface receptors, there are a number of ligands that are cell-associated and also bind to receptors on the developing Th9 cell. A number of these receptors are TNF superfamily members (OX40, 4-1BB, and TL1A) creating a paradigm supporting a general role for TNF superfamily members in the induction of IL-9 [59,62,63]. Although the mechanism of 4-1BB induction has not been investigated, stimulation of OX40 leads to activation of RelB/p52 NF-κB complexes that bind directly to the *Il9* locus [63]. Notch ligands also impact IL-9 production, but the effects can depend on other environmental stimuli [64]. In some contexts, Notch-activated transcription factors can bind directly to the *Il9* gene [64]. However, in other contexts, Notch signaling can induce Th17 or Treg development [65–67], and the precise codependent cues are not clear. PDL2 is unique in being able to inhibit Th9 development following engagement of PD-1 [68]. Most importantly, T-cell activation, through the T-cell receptor and costimulatory molecules such as CD28, induce *Il9* transcription through the activation of NFAT proteins following activation by MHC class II complexes and CD80 or CD86, respectively [69–71].

15.2.4 The Function of Th9 Cells

As predicted by the nomenclature, one of the most important products of Th9 cell activation is IL-9 (see Table 15.1). IL-9 is required for the ability of Th9 cells to mediate allergic inflammation, autoimmune inflammation in colitis models, and tumor immunity, as discussed in more detail in the subsequent section of this chapter. IL-9 has a myriad in the immune system including promoting Th2 cytokine production, enhancing class switching to IgE, and leading to the accumulation of tissue mast cells [72]. IL-9 also impacts structural cells in target organs. It induces chemokine production from airway epithelial cells, airway smooth muscle cells, and tumor stromal cells [72]. IL-9 alters the expression of tight junction proteins in intestinal epithelial cells, decreasing the barrier function of the epithelial layer [73,74]. IL-9 may also have additional functions in particular contexts that have not been explored, and which of these actions are most important *in vivo* is still not entirely clear.

Th9 cells, however, also produce other cytokines (see Table 15.1 and Figure 15.2). IL-3 from Th9 cells impacts the survival of dendritic cells that is important for tumor immunity [75]. In the context of IL-1 stimulation, Th9 cells can also produce

Table 15.1 Soluble mediators and surface markers associated with Th9 cell effector function.

Effector Molecule	Mechanism of Action	References
Soluble mediators:		
BAFF	- promotes B-cell proliferation and differentiation[a)]	[43]
CXCL3	- promotes recruitment of inflammatory cells[a)]	[43]
CCL22	- may promote Th2 cell during Th9-mediated allergic inflammation	[52,53]
IL-1rn	- inhibits IL-1 signaling[a)]	[43]
IL-3	- promotes dendritic cell survival	[75]
IL-9	- antitumor effects - promotes mast cell accumulation and activity - modulates epithelial cell biology (e.g., proliferation) - promotes Th2 cytokine production and ILC2 survival - enhances IgE class switching[a)]	[42,44,72,73,77,78,93]
IL-10	- immune suppression[a)]	[42,44]
IL-21	- antitumor effects - can activate NK and CD8+ T cells - promotes B-cell responses[a)]	[60]
Cell surface mediators:		
CCR3	- ligands include CCL5 and CCL11 - enhances Th9 migration during allergic inflammation	[76]
CCR4	- ligands include CCL17 and CCL22 - associated with homing to skin[a)]	[43]
CCR6	- ligands include CCL20 - enhances Th9 migration during allergic inflammation	[43,76]
CCR8	- ligands include CCL1	[43]
CXCR3	- ligands include CXCL9, CXCL10, and CXCL11 - enhances Th9 migration during autoimmunity	[43,76]
CD103	- localization to mucosal surfaces[a)]	[43]

a) Not investigated with relation to Th9 biology.

IL-21, which is important for tumor immunity as well [60]. Th9 cells were originally identified based on their ability to produce both IL-10 and IL-9 [42,44]. However, the IL-10 producing cells in Th9 cultures largely segregate from the IL-9-producing cells [52], and no specific function has been ascribed to Th9 cell IL-10 production as experiments to assay suppressor activity in colitis studies, Th9 cells activated rather than suppressed disease [42]. Gene profiling studies and subsequent ELISA experiments demonstrated that Th9 cells preferentially secrete IL-1 receptor antagonist (*Il1rn*), BAFF (*Tnfsf13b*), and *Cxcl3* [43]. The Th9-specific functions of these cytokines and chemokines have not yet been defined.

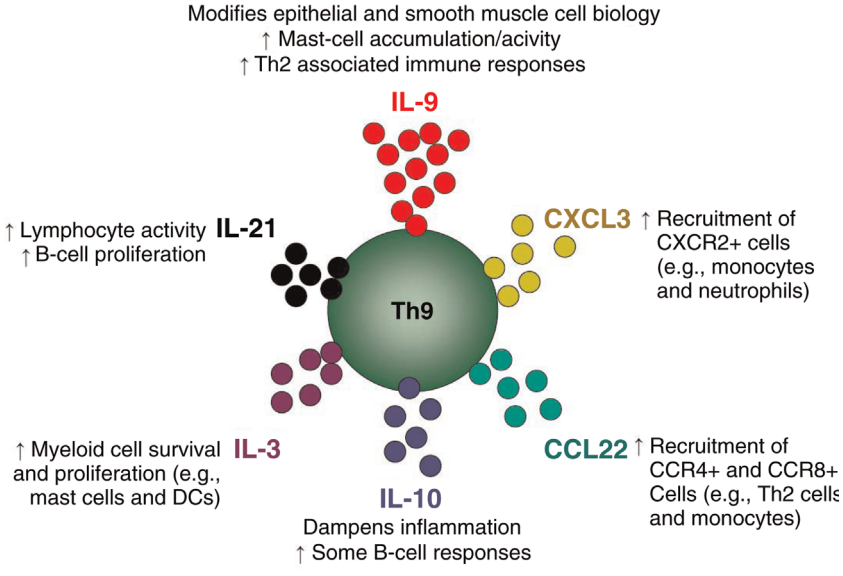

Figure 15.2 Th9-associated cytokines and chemokines. Th9 cells are principally identified by their robust production of the cytokine IL-9; however, cells cultured under Th9 conditions (i.e., IL-4 and TGF-β) are also capable of producing a number of cytokines and chemokines (as depicted above), which may be important in overall Th9-associated pathologies. It is important to note, though, a given cell will not produce all these cytokines. For example, flow cytometry data indicates distinct Th9 cultured cells will produce IL-9 or IL-10 but rarely both.

Th9 cells also preferentially express surface receptors that confer specific functions to these cells (see Table 15.1). Chemokine receptors expressed in Th9 cells include CCR4, CCR8, CCR6, and CXCR3 that are important for recruiting cells to sites of type 2 (allergic) inflammation [43,76]. Th9 cells also express CD103, an integrin that can mediate localization of cells to mucosal interfaces with the environment [43]. Th9 cells also preferentially express cytokine receptors that enhance their function, including IL-25R (*Il17rb*) and TSLPR (*Crlf2*) [56,57]. TSLPR can further be induced by its ligand [56].

15.3 Th9 Cells in Disease: The Helpful and Unhelpful

Here, we explore immune responses and inflammatory disorders that are increasingly recognized as having a Th9 cell component that significantly contributes to the disease process. In the appropriate context, Th9 cells and IL-9 have shown beneficial effects in eradicating both tumor and helminthic infections. In contrast, inappropriate production of IL-9 and Th9 cells has been linked to pathology in colitis and atopic inflammation. In the proceeding segment of this chapter, we will discuss our current understanding of Th9 cells in the clinic supported with background and progress from the bench.

15.3.1 Tumor Immunity

In light of the recent breakthroughs in adoptive immunotherapy for hematological cancers, the role of CD4 effector T cells in the tumor microenvironment of solid tumors is an area of great research interest. Recent studies have demonstrated that Th9-mediated antitumor immunity may prove effective against epithelial tumors such as melanoma and lung adenocarcinoma, two cancers with high rates of incidence and mortality, respectively [77,78]. Adoptive transfer of tumor-specific Th9 cells decreased tumor growth in the mouse model, an effect that was lost with the addition of IL-9 neutralizing antibody. When melanoma cells were coinjected with various T-cell subsets, Th9 cells demonstrated the greatest effect in limiting tumor growth [77,78]. The role of IL-9 in tumor immunity is further supported by a single-nucleotide polymorphism (SNP) in the *IL9* gene that confers an increased risk of malignant melanoma [79].

IL-9 has multiple potential mechanisms of action. Initially, it was found that IL-9 indirectly kills tumors, through the activation of mast cells and granzyme B production [78]. Subsequent studies did not find mast cells in the tumor microenvironment, suggesting that the mast cell-dependent mechanism might be restricted to particular sites or types of tumor progression [77]. In an alternative mechanism, Lu *et al.* found IL-9 acted on epithelial cells in the lung and induced the production of CCL20 in the tumor microenvironment. Increased concentrations of CCL20 act as a chemoattractant for CCR6+CD8α+ DCs to the tumor, thus ensuring greater delivery of tumor-specific antigens to the tumor draining lymph nodes. As a result, greater effector cell activation was found in both the lymph nodes and the tumor microenvironment [77]. More recently, IL-1β was found to enhance Th9 cytokine production of IL-9 and IL-21 resulting in significantly greater Th9-mediated antitumor immunity [60]. Conventional Th9 cells produce large amounts of IL-9 and low amounts of IL-21 with the anticancer effects dependent on the IL-9 production. In the presence of IL-1β, Th9 cells had antitumor activity that was dependent on the IL-21 production. The cytokine IL-21 is known to act in the activation of cytotoxic activity of CD8 T cells and NK cells [60]. Overall, it is unclear at this time if one particular mechanism has a greater contribution to the antitumor activity of Th9 cells or that Th9 cells mediate multiple pathways in the elimination of tumors. Future treatment for melanoma and lung cancer may develop from optimizing strategies to promote Th9 cell production of IL-9 and IL-21 in the tumor microenvironment.

15.3.2 Helminth Immunity

Almost all individuals residing in less developed nations are exposed to intestinal helminth infections. Disease is caused by competition for the host nutrients and inflammation in intestinal mucosa and other organs. Traditionally, helminthic infections have been characterized as a Th2 response, but it has been demonstrated that the Th9 response mediated through IL-9 provides a significant contribution to the host defense as well. For example, patients suffering from filarial lymphedema, a debilitating pathology resulting from parasitic infections, had elevated Th9 and IL-9 production compared to a control population or infected asymptomatic

patients [80]. The degree of filarial lymphedema was directly correlated to the frequency of Ag-induced Th9 cells and IL-9 production in the patient suggesting that Th9 cells are linked to host defense and pathology [80].

There is supportive evidence for Th9 cells and helminthic infections in the widely used experimental murine models of *Trichinella spiralis*, *Trichuris muris*, and *Nippostrongylus brasiliensis. T. spiralis* can be acquired from undercooked meat from infected animals. The larvae hatch in the intestine and if not expelled, they will migrate into skeletal muscle and develop into a nurse cell that is protected from the immune system [81]. In the mouse model, mastocytosis and mouse mast cell protease 1 (mMCP-1) have been identified as important mediators for rapid *T. spiralis* expulsion [82,83]. IL-9 transgenic mice, producing high levels of IL-9 *in vivo*, were resistant to infection with both an increase in mucosal mast cell numbers and mMCP-1 levels. After *T. spiralis* infection, control mice had significant worm burden while IL-9 transgenic mice had no detectable worm burden [84]. When mice were treated with cortisone treatment, thereby inhibiting the adaptive immune response, the effect of IL-9 was reduced [85]. In a second mouse model, *T. muris* is a natural murine parasite that hatches in the small intestine tunneling into the crypts of the mucosal wall [81]. IL-9 blockade, which prevents IL-9 dependent mast cell activation and eosinophil infiltration [86], in resistant mice prevented *T. muris* expulsion [87]. In addition, CD4dnTGFβRII transgenic mice, expressing a dominant negative TGFβ receptor that impairs Th9 differentiation, prevented expulsion of *T. muris* with decreased mast cell numbers in the cecum and low IL-9 levels [44]. Finally, *N. brasiliensis* is a parasite that enters the host through the skin, migrates to the lung, and takes advantage of the host mucus ciliary clearance mechanism to be coughed up and ingested [88]. In *Il9*-deficient mice, there was a decrease in eosinophils, basophils, and mast cells and an increase in worm burden a week postinoculation compared to WT mice [89].

Multiple cell types are known to produce IL-9, including Th9 and type II innate lymphoid cells (ILC2). The major producers of IL-9 in an IL-9 reporter mouse were found to be ILC2 and Th9 cells [89]. In an effort to differentiate the function of ILC2, whose survival is IL-9 dependent [90] in contrast to low IL-9R-expressing Th9 cells [91], an IL-9 receptor mutant (*Il9r*−/−) mouse was utilized in the lung inflammation model. In *Il9r*−/− mice, goblet cell hyperplasia and mast cell accumulation in the lung were not significantly reduced suggesting a role of the Th9 cell in this system. Moreover, Th9 cells when adoptively transferred into IL-9-deficient hosts were sufficient to decrease worm loads [89]. Altogether, it is has been clearly demonstrated that Th9 cells and IL-9 provide a powerful mechanism for protection in the battle between host and parasitic helminthic infection.

15.3.3 Inflammatory Bowel Disease

Inflammatory bowel diseases are chronic relapsing ulcerative disorders that result in life-threatening symptoms of abdominal pain, malnutrition, and diarrhea. The etiology is believed to develop from an inappropriate activation of the mucosal immune system by unknown mediators facilitating defects in barrier function of

the epithelium and the mucosal immune system. Although Th1 and Th2 cells are associated with Crohn's disease (CD) and ulcerative colitis (UC), respectively, Th9 cells may also contribute to inflammation in these diseases.

In human samples, Gerlach *et al.* found that there was an increase in *IL9* mRNA expression in UC patients with active disease compared to both inactive UC and control patients [73]. In mouse models of colitis, IL-9 has been shown to regulate the permeability of the intestinal mucosa through the activation of mast cells and IgE synthesis [92]. Furthermore, it was found that IL-9 downregulated barrier proteins such as claudin 2 in ways that decreased barrier function allowing for the translocation of bacteria across the luminal wall [73]. Interestingly, mice deficient in IL-9 were protected from bacterial translocation and colitis [73]. Finally, IL-9 delays wound healing in intestinal epithelial cell lines [93]. Each of these mechanisms may contribute to the potentially destructive effects of IL-9 in the gut microenvironment.

Although many cells produce IL-9, it is believed that Th9 cells are a major contributor in the intestine in UC. *Spi1* mRNA, encoding the Th9-associated transcription factor PU.1, was upregulated in IL-9 producing cells in patient mucosal biopsies in the inflamed gut [73]. Moreover, specific deletion of PU.1 in T cells diminished autoimmune inflammation in the intestine. In the follow-up study, Nalleweg *et al.* provided convincing evidence that the majority of these cells in patient biopsies producing IL-9 were CD3 T cells. As the disease progressed in severity, the number of cells expressing IL-9 increased in total number and percentage among lamina propria lymphocytes [93]. In addition, human peripheral blood from active UC patients was also found to have a population of CD3+ T cells with IL-9 expression. When these T cells were examined for homing potential, both integrin alpha 4 and beta 7 were present in a proportion of the T cell population leading to the potential for gut homing [93].

15.3.4 Allergic Inflammation

Allergic responses arise from the sensitization of the immune system leading to polarized Th2 and the generation of IgE. These responses are localized to specific organ systems and cause diseases that include asthma, allergic rhinitis, atopic dermatitis, eosinophilic esophagitis, and food allergy. Allergens induce the Th2-associated cytokines IL-5, which acts as a chemoattractant for eosinophils, IL-13, which promotes mucus production and chemokine expression from epithelial cells, and IL-4, which promotes Th2/Th9 differentiation and regulates antibody class switching to IgE. Subsequently, IgE binds to tissue mast cells, and upon reexposure to allergens, IgE mediates activation of mast cells resulting in the release of histamine granules and generation of leukotrienes leading to airway bronchoconstriction, edema, and inflammation. In addition, it has been found that Th9 cells play a necessary and sufficient role in developing allergic inflammation.

Total IgE concentrations are highly correlated in twins concordant for elevated bronchial hyperresponsiveness, a marker of allergic airway inflammation. Further linkage analysis of these siblings found a major gene for atopy on the q arm of chromosome 5 [94]. Investigation in this region identified *IL9* as a candidate gene for asthma risk due to linkage disequilibrium between IgE levels and SNPs within the *IL9* gene [95]. Using contrasting mouse models of airway

hyper- and hyporesponsiveness differences in the *IL9* mRNA were directly correlated with hyperresponsiveness, while there were no differences in the mRNA levels of Th2 cytokines [95]. Additional SNP associations related to the IL-9 pathway in asthma patients were found for *IL9R*, *IL4*, *IL13*, and *STAT6* [96–98].

As a baseline of comparison in healthy human individuals, Th9 cells are found in T-cell subsets tropic to the skin and are regularly absent in the lung and the digestive system [99]. In contrast within atopic children, there is a correlation between IL-9 production from PBMCs and IL-9-positive T cells with serum total IgE [49,52,100]. Furthermore, naïve T cells isolated from the same atopic children and differentiated into Th9 cells expressed a greater level of *IL-9* and *SPI1* mRNA, while no difference was found in Th2 cytokine expression (IL-4, -5, and -13) [100]. In adults, the house dust mite *Dermatophagoides pteronyssinus* was further found to induce IL-9 production, and Th9 cell number providing a marker for asthma and airway hyperresponsiveness correlating to IgE and asthma [49,101]. When IL-9 was increased so were the levels of IL-5 and IL-13 [101].

Adoptive transfer of OVA-specific Th2 and Th9 cells into *Rag1*−/− mice undergoing OVA challenge had enhanced airway inflammatory cell infiltration and mucus production. Blockade of IL-9 greatly decreased airway inflammation and goblet cell metaplasia in mice receiving Th9 cells [46,56]. It is important to note that ILC2 can also produce IL-9 and neutralization of IL-9 might indicate that even the lower concentrations of IL-9 produced by these cells are important for inflammation (46, 56, and 90). Importantly, Th9 cells are required for the ability of TSLP to promote allergic airway inflammation [46,56].

In an IL-9 transgenic airway mouse model, there was increased bronchial hyperresponsiveness when challenged with methacholine. An increased level of IL-9 was found to cause airway inflammation through eosinophil and mast cell infiltration and increased mucus production and muscle cell proliferation [89,102,103]. Interestingly, histamine was not increased [103]. Blockade of IL-9 through autoantibodies prevented IL-9-dependent mast cell activation and eosinophil infiltration [87]. In IL-9-deficient mice, there was a lack of pulmonary goblet cell hyperplasia and mastocytosis, but no difference was found in Th1 or Th2 differentiation or cytokine production [104]. Additional studies where Th9 cell development was prevented also found inhibition of IL-9 production and diminished inflammation [43,105,106]. IL-9 was found to promote airway fibrosis in a mast cell-dependent mechanism [102]. It was suggested that IL-9 effects in lung inflammation and mucus production facilitated the induction of IL-13 production in the lung epithelium, though this is not clear in systems where IL-9 is not overexpressed [107,108].

In allergic disease models, IL-9 clearly promotes mast cell accumulation and inflammation [52,92,104,109]. However, depending on the model, the primary cellular source of IL-9 differs [110]. In a T-cell-independent allergic model, ILC2 s were found to be the significant source of IL-9. In contrast, T-cell-dependent models of allergic inflammation indicate CD4+ T cells are the primary source [110]. Furthermore, mice with a T-cell-specific deletion of PU.1, which impairs Th9 differentiation, restricted allergic inflammation [52]. To further delineate the roles of ILC2 and Th9 cells in the production of IL-9 during allergic

inflammation, mice containing PU.1-deficient T cells were compared with RAG1-deficient mice lacking all T cells that have full functional ILC2. During allergic inflammation, the overall reduction in mast cell numbers was similar between the PU.1-deficient and *Rag1*−/− mice [109], suggesting that Th9 cells are the major T-cell component promoting mast cell accumulation. There was less IL-9 and decreased mast cell numbers and mast cell proteases present in PU.1-deficient mice [52,109]. Altogether, this evidence demonstrates that Th9 T cells are a major producer of IL-9 in models of allergic inflammation.

Further understanding of the role by which Th9 cells promote allergic airway inflammation will be important in preventing associated long-term airway dysfunction. For example, in a chronic allergic mouse model, increased airway resistance and collagen deposition was not resolved 4 weeks after last allergen exposure even though goblet hyperplasia and inflammatory cell infiltrate returned to baseline [102]. Whether these features are dependent on IL-9 production from Th9 cells is not clear. Moreover, whether Th9 cells contribute to other models of inflammation, or more importantly in the pathogenesis of human disease, is still the focus of ongoing research.

15.3.5 Dermatitis

Recent evidence has demonstrated that IL-9 and Th9 cells may have potential roles in various pathologies of the skin. Type I hypersensitivity reactions of the skin in atopic dermatitis have been associated with increased serum levels of IgE compared to normal skin, possibly linked to correlations between IL-9 and serum IgE concentrations [99,100]. Memory helper T cells from healthy donors expressing cutaneous lymphocyte antigen (CLA), a unique skin homing receptor, produced higher IL-9 levels after exposure to *Candida albicans* [99]. In another human study, *Il9* and *Sfpi1* mRNA were found to be significantly elevated in both PBMCs and skin biopsies of atopic dermatitis patients when compared to healthy controls [111]. The percentages of Th9 cells within PBMCs were also elevated in atopic dermatitis patients. In summary, this study indicates that measures of Th9 cell biology correlated with atopic disease severity [111]. However, another report did not identify significant IL-9 CLA+-producing fractions between atopic and normal individuals [112,113] suggesting there may be differences among atopic populations.

Th9 lymphocytes were also found in greater numbers in allergic contact dermatitis skin biopsies compared to normal skin [114]. PBMCs from nickel-allergic patients had increased IL-9 production [114]. In the mouse model of nickel-induced contact dermatitis, there was not a significant difference in disease score between wild-type and IL-9-deficient mice, but the inflammation was skewed to a Th1 phenotype compensating for a decreased Th2 response [114].

What functions IL-9 has in the skin are not yet clear. Certainly, IL-9 might impact recruitment of lymphoid and myeloid cells present in normal or diseased skin. In addition, VEGF, a potent angiogenesis factor, was induced in keratinocytes in cultures with IL-9 [111], suggesting that skin cells themselves might be targets of IL-9. As with other disease models, further work is required to define the relevant IL-9 responding population that results in a pathological response.

15.3.6 Food Allergy

Several reports suggest a link between Th9 cells and food allergy. PBMCs from egg-sensitized infants produce more IL-9 than PBMCs from nonatopic infants when stimulated with anti-CD3 [100]. Microarray analysis of memory Th subsets comparing atopic children with or without peanut allergy found IL-9, IL-5, and IL-13 to be greatly increased in samples from children with peanut allergy [115]. Moreover, IL-9 expression helped discriminate between allergic and clinically tolerant population better than IL-4, IL-5, and IL-13 production [115,116]. In the mouse model, food allergy and antigen sensitization was dependent on IL-9 expression with complete loss of intestinal anaphylaxis in IL-9-deficient mice. In this model, IL-9 increases the permeability of the intestine through mastocytosis and intravascular leakage [92]. The allergy was found to be systemic but limited to oral sensitization through IgE activation [117]. Together, these reports suggest a functional link between IL-9 and food allergy.

15.4 Targeting Th9 Cells Therapeutically

As noted in the preceding section, it is becoming increasingly evident that Th9 cells and IL-9 may promote a variety of human ailments ranging from allergic inflammation to inflammatory bowel disease; however, targeting Th9 cells therapeutically has remained unexplored. In the following sections, we will explore potential approaches to modulate Th9 biology either during differentiation or by neutralizing key effector molecules after differentiation. The key benefits and potential side effects from current and potential therapeutics will be highlighted. Some of the potential therapeutics discussed are in development or have been approved (see Table 15.2).

15.4.1 Th9 Differentiation

15.4.1.1 Cytokines and Costimulators Required for Differentiation

Th9 development is dependent on both IL-4 and TGFβ signaling [41,42,44]; however, the majority of Th9-associated genes are downstream of IL-4 signaling [43,45], indicating inhibition of this pathway would be the most advantageous in impeding Th9 differentiation. Potential therapeutics include Pascolizumab (an IL-4 targeting antibody), Pitrakinra (an IL-4 analog that inhibits IL-4/13 signaling through the IL-4 receptor), and Altrakincept (a decoy IL-4 receptor) [118–120]. IL-4 signaling is also dependent on STAT6 activation by JAK kinases. While no drug specifically targeting STAT6 exists, Teriflunomide, a metabolite of the drug flunomide, can inhibit STAT6 nonspecifically and is currently being used to treat multiple sclerosis [121,122]. Furthermore, specific JAK kinase inhibitors could also inhibit STAT6 signaling. Collectively, these therapeutics would have the additional advantage of impeding Th2 development, which could be beneficial in inhibiting pathologies with a joint Th2 and Th9 immune response such as allergic inflammation.

Table 15.2 Developmental status of therapies potentially beneficial in modulating Th9 responses.

Therapeutic Target	Mechanism of Action	Development Stage	References:
IL-4 signaling: [a]			
Pascolizumab	IL-4 antibody	Phase II	[118]
Pitrakinra	IL-4 analog-binding IL-4 receptor	Phase II	[119]
Altrakincept	Decoy IL-4 receptor	Phase III	[120]
Teriflunomide	Metabolite inhibits STAT6 activity	Approved for treatment of multiple sclerosis	[121,122]
Tofacitinib	Jak1/Jak3 inhibitor	Approved for treatment of rheumatoid arthritis	[172]
TGFβ signaling	Blocking antibodies, peptide inhibitors, and so on.	Numerous in production	[128]
CD28 (Abatacept)	CTLA-4-Ig fusion protein	Approved for treatment of arthritis	[138]
OX40 L		Phase II	
GATA 3 (SB010)	DNA enzyme that inactivates GATA3 mRNA	Phase II	[152]
TSLP (AMG-157)		Phase II	[139]
IL-9 (enokizumab)	IL-9 antibody	Phase II	

a) List is not exhaustive.

A wide range of therapeutics targeting TGFβ signaling are in development or have shown efficacy in animal models including Fresolimumab (a humanized antibody targeting all three TGFβ isoforms), IMC-TR1 (a humanized antibody targeting the TGFb receptor), and Disitertide (a peptide that blocks TGFβ binding to its receptors) [28,123–127]. However, TGFβ signaling is highly complex making this a less than ideal avenue of therapeutic intervention in Th9-mediated pathologies. For one, it was noted that Activin A, a TGFβ superfamily member, could also promote Th9 differentiation [49], potentially necessitating its targeting in any therapeutic regimen. In addition, TGFβ has many functions outside of Th differentiation including effects on cellular proliferation, extracellular matrix deposition, and overall immune suppression [128]. The lethal inflammatory phenotype associated with *Tgfb1*-deficient mice demonstrates the important immune suppressor function of this cytokine [129,130]. It must be noted, however, no complications have been observed in clinical trials targeting TGFβ signaling [128,131]. Furthermore, neutralizing TGFβ signaling in murine studies of autoimmune disease has actually dampened inflammation, likely through inhibiting Th17 development [132,133]. Potentially, TGFβ therapeutics may be beneficial in pathologies involving both Th17 and Th9 responses such as ulcerative colitis and multiple sclerosis and the efficacy might depend on timing of administration and stage of disease.

CD28 and the TNF receptors OX40, 4-1BB (CD137), and T1A have all been linked in stimulating IL-9 production [59,62,63,70,71]. Besides influencing the Th subset fate, these molecules are also associated with promoting survival during activation, enhancing cytokine production, and maintaining T-cell memory independent of TCR stimulation [134–137]. Murine studies have also demonstrated that antagonism of CD28, OX40, 4-1BB, and T1A signaling or genetic deficiencies can impede allergic inflammation among other diseases [59,62,63,70,71,136]. Unfortunately, inhibition of CD28 costimulation with Abatacept, a humanized version of CTLA4Ig, did not alleviate symptoms in people with mild atopic asthma or reduce airway eosinophilia [138]. Furthermore, treatment of patients with OX40 L antagonist also did not alleviate clinical features in atopic patients challenged with allergen extract, although improvement was noted in patient eosinophil numbers and IgE levels [139]. The failure of these trials may be due to overlapping costimulatory function. Thus, greater patient efficacy would be noted with combinational therapy. Furthermore, agonists to these costimulatory molecules may be beneficial in promoting Th9 responses. For example, 4-1BB and OX40 agonists are being explored in promoting antitumor responses [140].

15.4.1.2 Transcription Factors for Differentiation

Each Th subset is defined, in part, by the expression of lineage-determining factors, proteins that not only uniquely drive the fate of a given Th subset but also inhibit the differentiation of most other Th subsets. While the notion of "master" regulators is increasingly becoming anachronistic, there are transcription factors within each Th subset that largely fit this definition: T-BET (Th1), GATA3 (Th2), RORγT (Th17), FOXP3 (Treg), and BCL6 (Tfh) (Figure 15.1). Such proteins would be prominent targets for small molecular inhibitors or other pharmacological interventions for the modulation of a specific Th subset-mediated immune response.

A master transcription regulator of Th9 cells has not been discovered, however. The most specific regulator would be PU.1, as observed in both murine and human studies [45,52–54,141,142]. As mentioned previously, PU.1 is an ETS transcription factor enriched in Th9 cells and regulated by TGFβ signaling [43,45,52], albeit independent of the SMAD pathway [50,51]. In the murine model, PU.1-deficient CD4+ T cells cultured under either Th2 or Th9 conditions have a significantly reduced capacity to produce IL-9 and enhanced production of Th2-associated cytokines [52]. Similar effects were noted in human cells treated with PU.1 siRNA. *In vitro* analysis has revealed that PU.1 interferes with the function of GATA3 and IRF4, resulting in diminished Th2 cytokine production [53,143], and limits Tfh differentiation by inhibiting CD40 L and IL-21 expression [144]. In Th9 cells, PU.1 promotes the expression of IL-9 by recruiting histone acetyltransferases to the *Il9* locus [54]. In summary, PU.1 is the only transcription factor, to date, that induces IL-9 production in other Th cell subsets while also inhibiting an alternative Th fate.

Thus, PU.1 is an attractive target in specifically modifying Th9 development. In murine models of allergic inflammation, PU.1 deficiency did not inhibit Th2 differentiation in the lymphoid tissue [52,109]; however, the impairment of Th9

differentiation did impede the recruitment of Th2 cells to the lung environment potentially due to Th9-mediated production of CCL22 [52] (Figure 15.2), which can promote the recruitment of Th2 cells [145]. It is important to note, though, that PU.1 regulates a small subset of genes outside of IL-9 [43]. Furthermore, several ETS transcription factors are expressed in any given cell type and have overlapping functions [146], which may account for the reduced but still significant numbers of IL-9 producing cells in PU.1-deficient cultures [52]. Thus, targeting PU.1 to inhibit Th9-mediated pathologies may be more efficient in combination with inhibitors of other pertinent ETS factors or Th9-associated transcription factors.

IRF4, downstream of IL-4 signaling [43], is also important in Th9 differentiation [46], as well as Th2 and Th17 cells [33,143,147]. IRF4 promotes *Il9* transcription through binding to the *Il9* promoter and inhibits Th1 cell-associated transcription factors that attenuate Th9 differentiation [43,46]. IRF4 likely cooperates with BATF on the *Il9* promoter to form a transcriptional module [43], a phenomenon also observed in Th17 cells [148,149]. This is highlighted when ectopic expression of both BATF and IRF4 into Th9 cultured cells promotes IL-9 expression greater than expression of either factor alone [43]. Importantly, BATF deficiency in Th9 cultured cells results in a marked defect in the expression of nearly all Th9 cell-associated genes, indicating that BATF is also an important transcription factor outside of the *Il9* gene [43]. Thus, both BATF and IRF4 are attractive therapeutic targets in modulating Th9 activity, although consideration must be given that these factors also regulate other Th subsets.

Although GATA3 is the master transcriptional regulator of Th2 cells, its expression is required for Th9 differentiation as *Gata3*-deficient Th9 cultured cells do not produce IL-9 [42]. Interestingly, ectopic expression of GATA3 in Th9 cells can impede IL-9 production [45]. The differing results in these studies may reflect the amount of GATA3 within the cell, as a gradient of GATA3 expression might be instrumental in driving Th differentiation to one fate or another. Nonetheless, inhibition of GATA3 function could be an attractive candidate in inhibiting both Th2 and Th9 development [42,150,151]. For example, a GATA3-specific DNAzyme has been used to decrease allergen-induced asthmatic responses [152].

15.4.1.3 Factors Required for Promotion of Th9 Biology

Several factors (e.g., cytokines and transcription factors) exist that promote Th9 development and/or effector activity, without being essential for differentiation. Therapeutic interventions in these processes may be of greater importance as by the time of treatment, patients are likely to have established Th9-associated immune responses and ideal therapies would dampen existing immunological disorders.

TSLP, IL-25, and IL-33 are epithelial-derived cytokines that have been linked in the promotion of allergic inflammation and atopic dermatitis [153–159]. Along with their noted activation of ILC2 [155], these factors can also promote Th9 responses. TSLP receptor is expressed on Th9 cells, and TSLP-mediated signaling through STAT5 can substitute for the requirement of IL-2 in promotion of Th9

differentiation [56]. IL-17RB, the receptor for IL-25 signaling, is one of the most highly expressed genes in Th9 cells [43,160]. It has also been demonstrated that IL-25 signaling can promote Th9 responses during allergic inflammation and helminth immunity [57,160]. In the former process, IL-25 promoted the Th9-mediated inflammation independent of Th2 responses and treatment of *T. spiralis*-infected mice with IL-25 neutralizing antibody prevented worm expulsion and decreased IL-9-regulated genes. IL-33 has also been demonstrated to promote IL-9 production in human cultured T cells [161]; however, it is unclear how this cytokine may induce IL-9 expression let alone if there is any impact on Th9-mediated pathology.

AMG-157, a humanized TSLP antibody that prevents receptor interaction, reduced allergen-induced bronchoconstriction in a recent proof-of-concept study [139]. It was also demonstrated that AMG-157 could reduce eosinophil levels in mild asthmatics, and patients trended to have reduced Th2 responses. In addition, an antibody directed against human TSLP receptor has been demonstrated to reduce allergic lung inflammation in a cynomolgus monkey model [162]. While no clinical trials have been reported in therapeutics targeting IL-25 and IL-33, animal models do indicate there is potential in their application. Blockade of IL-25 in a mouse model of rhinovirus-induced allergic exacerbation reduced overall inflammation [163]. Furthermore, administration of an antibody directly against IL-33 or the administration of a decoy receptor to IL-33 reduced allergic inflammation [164]. Careful consideration of patient conditions must be kept in mind with all potential treatments. For example, animal models indicate TSLP, IL-25, and IL-33 may be protective in some diseases including inflammatory bowel disease and arteriosclerosis [165–167].

15.4.2 Th9-associated Effector Molecules

The obvious candidate to neutralize Th9-mediated pathologies would be IL-9 itself; however, clinical trials exploring IL-9 neutralization have been mixed. Initial studies demonstrated that enokizumab (or MEDI-528), a humanized IL-9 neutralizing antibody, had an acceptable safety profile and demonstrated positive effects on patients with mild or exercise-induced asthma [168,169]. These studies, however, had very limited patient numbers, so when studies expanded enokizumab use into a larger patients subset with severe asthma, enokizumab demonstrated no benefit with respect to patients receiving placebo [168]. Thus, IL-9 therapy may be limited only to patients with milder forms of asthma or in conjunction with other therapeutics (e.g., IL-4 and IL-13 antibodies). Furthermore, as increased IL-9 levels are seen early in life in atopic patients and increases are associated with early changes in airway responsiveness [100,170], IL-9 therapy may be more appropriate in high-risk infants to limit atopic disease development. IL-9 therapy may also have greater efficacy in other conditions not tested such as ulcerative colitis.

As noted before, Th9 cells can make a range of effector molecules that could make attractive targets to limit their associated pathologies. Th9 cells can make chemokines including CXCL3 and CCL22 [43,52,53], which can recruit a number of immune cells including Th2 cells and monocytes [145,171]. As noted in the

work investigating Th9 associated tumor immunity, IL-3 and IL-21 are also prominent products [60,75]. In addition, qPCR and ELISA analysis has indicated Th9 cells produce IL-1RN and BAFF [43]. Unlike IL-9, however, no studies have investigated neutralizing these products in an attempt to ameliorate inflammation during Th9-associated pathology. Thus, a number of preliminary studies are required to investigate their potential as therapeutic targets. Furthermore, careful consideration needs to be made on a patient to patient basis to prevent any negative consequences as some effectors (e.g., IL-21) were shown to benefit the host therapeutically [60].

15.5 Summary and Future Directions

Although they are one of the most recently established Th subsets, we learned a tremendous amount about Th9 cells. They participate in immunity responsible for parasite clearance, allergic inflammation, autoimmune diseases, and elimination of tumors. Exactly how and where Th9 cells mediate some of these responses is not entirely clear. Although there are hints that Th9 cells could be involved in bacterial or viral immunity, their contribution is still being defined. Moreover, although we know that IL-9 is a critical mediator of Th9-dependent responses, the extent to which other cytokines produced by Th9 cells contribute to immune responses is only beginning to be explored. The development of Th9 cells requires several transcription factors, although a lineage-defining factor has still not been identified. Similarly, some of the regulatory elements required for *IL9* have been identified, but it is not clear which elements, perhaps yet unidentified, are required for appropriate *IL9* expression in a variety of cell types. As tools for analyzing Th9 cells continue to develop, there should be rapid progress in our understanding of the development and function of IL-9-secreting T cells.

Th17 Cells

Mélissa Noack and Pierre Miossec

University of Lyon, Department of Immunology and Rheumatology, Immunogenomics and inflammation research Unit EA 4130, 69437 Lyon, France

16.1 Introduction

The first line of defense is the immune system with its innate and adaptive components. Its main functions are to recognize and control foreign antigens, to induce an immunologic memory, and to maintain a tolerance to self-antigens. CD4+ T cells play a major role in the initiation and regulation of the immune response, mainly by secreting subset-specific cytokines after being activated and differentiated into distinct effector subsets. The CD4+ population is heterogeneous and different subsets provide effector functions during a large variety of immune reactions. Helper T cells (Th cells) are identified according to their cytokine and transcription factor profiles. The two first described major subsets were Th1 and Th2 cells. Th1 cells provide mainly a response against intracellular bacterial infections, secrete primarily interferon-γ (IFN-γ), and express the transcription factor T-bet. Th2 cells provide mainly a response against parasitic infections and their major cytokine is interleukin-4 (IL-4) and their transcription factor GATA-3 [1]. More recently, a third distinct lineage has been identified, the Th17 subset. Th17 cells produce mainly the proinflammatory cytokine IL-17 and they have a key role in the protection against extracellular pathogens and fungi [1,2]. Furthermore, overactivation of these cells has been associated with autoimmunity and inflammation [1,3]. Despite some common markers with Th1 and Th2 subsets, Th17 cells require specific cytokines and transcription factor for their differentiation [4].

The homeostasis of the immune response is continually controlled by a balance between Th cell activation and suppression of this activation by regulatory T cells (Treg). A disruption of this homeostasis leads to an overactivation of the immune response and chronic inflammation. Th17 cells provide an immediate protective response to foreign pathogens and thus they have an important role in the

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

induction of inflammatory process. In contrast, Th17 cells are proinflammatory and pathogenic underlying the development and chronicity of many autoimmune inflammatory diseases. As such, they are an important target for treatment.

16.2 Differentiation of Th17 Cells

IL-17 was identified in 1995 first in the human system as cytokine involved in inflammation and neutrophil activation [5]. The concept of IL-17 production by some but not all T cells was introduced in 1999 using T-cell clones from the joint of patients with arthritis [6]. The identification of the Th17 subset was made in the mouse in 2005 [2], 10 years after the description of the cytokine [7]. The development of Th17 cells shares major similarities in mice and humans, but with some differences (see Figure 16.1).

16.2.1 Th17 Cell Differentiation in Mice

The differentiation of the distinct lineages of Th cells is driven by the influence of different cytokines and transcription factors. Transforming growth factor-β (TGF-β), an immunosuppressive cytokine [8], and IL-6, a proinflammatory cytokine [9] act in concert to induce the highly proinflammatory subset of Th17 cells. These two opposite cytokines appear to be sufficient for the induction of IL-17 expression in naïve T cells [10–12]. In the absence of IL-6, TGF-β induces FoxP3, the transcription factor of Treg cells [13,14]. In the presence of IL-6, FoxP3 induction is inhibited and replaced by the induction of RORγt, the

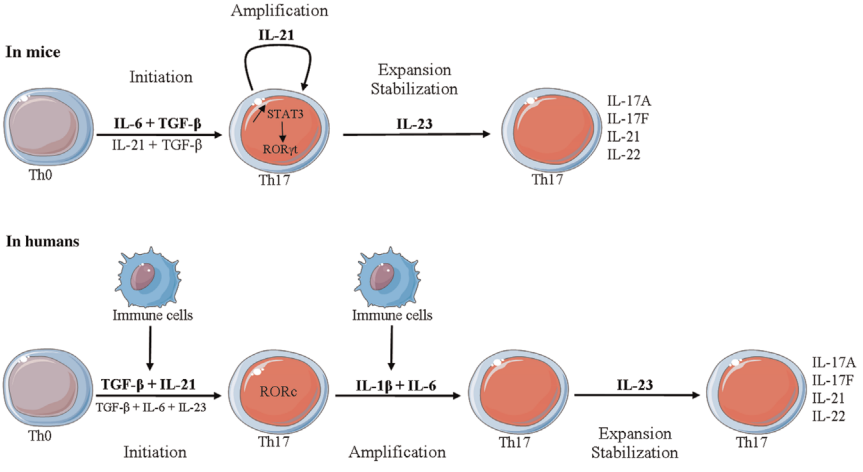

Figure 16.1 Differentiation of Th17 cells in mice and in humans. In mice, TGF-β and IL-6 initiate the differentiation and activate Stat3, which induces RORγt. IL-21 is induced by developing Th17 and in autocrine manner acts on Th17 cell amplification. IL-23 serves to expand and maintain the Th17 cell population. In humans, the differentiation is initiated by TGF-β and IL-21, which induce the transcription factor RORc. IL-1β plus IL-6 are important to enhance the amplification of Th17 cells and IL-23 to maintain the Th17 phenotype. Reproduced with permission from Ref. [111].

transcription factor of Th17 cells. Other proinflammatory cytokines such as tumor necrosis factor-α (TNFα) or IL-1β can enhance TGF-β- and IL-6-mediated Th17 cell differentiation [12].

IL-21, a member of the IL-2 cytokine family, when combined with TGF-β can also induce Th17 differentiation [15–17]. IL-21 is less potent than IL-6 and as it is produced by Th17 cells themselves. It is thus more important in the amplification of Th17 differentiation than in its initiation. IL-21 favors the autocrine loop for Th17 cells. Thus, TGF-β associated with IL-6 initiates Th17 differentiation, while TGF-β associated with IL-21 is a major factor in the autocrine loop of Th17 cells.

After the initiation of differentiation and the expansion of Th17 cells, IL-23, a member of the IL-12 cytokine family, is required for the stabilization of Th17 phenotype [12]. IL-23 alone cannot induce Th17 differentiation as naïve T cells do not express the IL-23 receptor (IL-23R) [18]. IL-23R expression on Th17 cells is induced by IL-6 and IL-21 and also by IL-23 itself [15,19,20] and is thus found only on activated effector or memory T cells. Once activated, T cells become responsive to IL-23 and this leads to the expansion of Th17 cells [21]. IL-23 is not considered as a differentiation factor but as a major player in expansion and stabilization of Th17 phenotype. Accordingly, the differentiation of Th17 cells involves three key steps: the initiation by TGF-β and IL-6, the expansion of Th17 cells by IL-21, and the stabilization of Th17 phenotype by IL-23.

In addition to these specific cytokine patterns, the differentiation of Th17 is driven by a lineage-specific transcription factor, the retinoid-related orphan receptor γt (RORγt) [22]. Cytokines involved in the differentiation of Th17 cells (TGF-β, IL-6, IL-21, and IL-23) induce the expression of RORγt, which depends on Stat3 activation [15,16,23,24]. IL-6-mediated Stat3 activation is crucial for Th17 generation [25,26]. Another transcription factor, RORα, member of the retinoid nuclear receptor family, is also involved in the differentiation of Th17 cells. Its role is similar but not identical to that of RORγt [27]. As RORγt, RORα is strongly induced by IL-6 or IL-21 in association with TGF-β and Stat3 activation increases its expression. This suggests that Th17 cell differentiation could be driven by two lineage-specific transcription factors.

16.2.2 Th17 Cell Differentiation in Humans

The two major cytokines for the differentiation of mouse Th17 cells are TGF-β and IL-6. In humans, the results concerning the role of TGF-β have been confusing. It was demonstrated that TGF-β was dispensable for Th17 differentiation [28,29]. IL-1β in combination with IL-6 [28] or with IL-23 [29] could induce Th17 differentiation. Nevertheless, in these studies, the use of CD45RA+ Th cells purified from peripheral blood as naïve T cells and the presence of serum and platelet contamination, which are important sources of endogenous TGF-β, make the results difficult to interpret.

Other studies, using naïve T cells from cord blood and serum-free medium demonstrated that TGF-β is a key factor, indispensable for the differentiation of Th17 cells. Indeed, the presence of endogenous TGF-β from serum is sufficient to induce Th17 differentiation [30]. Different combinations of TGF-β plus cytokines, TGF-β plus IL-21 and TGF-β plus IL-23 plus IL-6, for instance, can induce

the transcription factor RORc, the human homolog of RORγt, and therefore initiate Th17 differentiation [30–32]. Furthermore, human naïve T cells do not express the IL-1 receptor (IL-1R) and the IL-23 receptor (IL-23R), which are both induced after stimulation by TGF-β and IL-21/IL-6 [33]. Thus in humans, TGF-β has a major role in the initiation of Th17 cell differentiation and it is absolutely required for RORc induction, while IL-6 plus IL-21 is an important combination in the Th17 expansion from central memory cells [30,31]. In conclusion, cytokine requirements and transcriptional program necessary to drive the Th17 cell differentiation in mouse and human do not appear to be so different.

16.2.3 Pathogenic Th17 Cells

The contribution of these various cytokines has an effect on the final pathogenicity of Th17 cells. TGF-β and IL-6 are required for the differentiation of Th17 cells and IL-23 for their expansion and stabilization. Nevertheless, these cytokines also play a role in the regulation of Th17 subtype functions. A continued exposure to TGF-β1 and IL-6 induces not only the production of IL-17 but also the production of IL-10, and these cells produce lower proinflammatory mediators such as IL-22 [34]. Thus, IL-10 production is associated with nonpathogenic Th17 cells. A switch to a pathogenic phenotype can be induced by an IL-23 exposure [34,35]. IL-23 is crucial to confer the Th17 cell ability to induce autoimmunity [35–37]. In the absence of TGF-β signaling, the combination of IL-1β, IL-6, and IL-23 induces pathogenic Th17 cells [38]. Furthermore, IL-23 plays a major role in enhancing the contribution of endogenous TGF-β3 in Th17 development, which has a critical role in inducing pathogenic Th17 cells [39]. Th17 cells induced by TGF-β3 and IL-6 express GM-CSF whose expression is part of the signature of pathogenic Th17 cells [39–41]. Other factors are associated with the Th17 pathogenic signature, including T-bet, IL-23R, and IL-7R [39]. In summary, TGF-β1 and IL-6 induce nonpathogenic Th17 cells, while Th17 cells induced by TGF-β3 and IL-6 are highly pathogenic. IL-23 is also required for Th17 cells to achieve their total pathogenic phenotype, notably by inhibiting the IL-10 production and by promoting TGF-β3 or GM-CSF production.

16.2.4 Circulating versus Tissue Phenotypes

Th17 cells were first identified as a CD4+ T cell population producing IL-17 [42]. Their classic phenotype exhibits also the expression of RORc, IL-23R, and CCR6 [43,44]. Recently, CD161 has been identified as a marker of all circulating IL-17-producing T cells, reinforcing the specificity of the Th17 phenotype [45]. Thus, circulating Th17 cells can be characterized by the phenotype CD4+ RORc+ IL-23R+ CCR6+ CD161+ and IL-17+ (see Figure 16.2). Nevertheless, at this stage, Th17 cells do not produce IL-17, and accumulating evidence indicates that CD4+ T cells are more plastic than previously described. Depending on the environment, Th17 cells can express markers of other Th subsets in addition to IL-17 and can switch their phenotype, notably into Treg cells. However, the double-positive cells are less stable and become single producing cells in inflamed tissue [46–50].

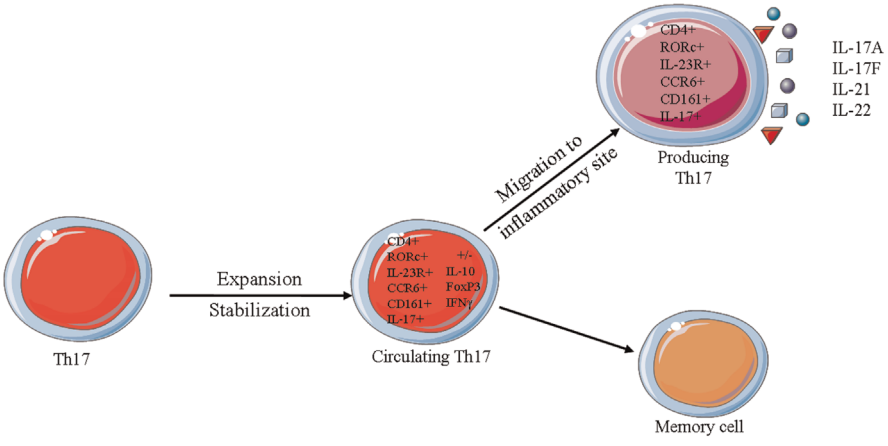

Figure 16.2 Th17 phenotypes. After their expansion and stabilization, circulating Th17 cells are characterized by the phenotype CD4+ RORc+ IL-23R+ CCR6+ CD161+ and IL-17+. At this stage, Th17 cells do not produce IL-17 and can express markers of other Th subsets and can switch their phenotype. The double-positive cells are less stable and become single producing cells in the inflamed tissue, with a plasma cell phenotype.

In most reports, a direct association is made between Th17 cells and IL-17 secretion. The intracellular staining of IL-17, commonly used to identify Th17 cells, is thought to be an equivalent of the actual IL-17 production. Even so the intracellular presence of IL-17 inside Th17 cells does not mean by itself its secretion. *In situ*, Th17 cells interact with local mesenchymal cells in an inflammatory environment and this leads to IL-17 secretion [51]. Furthermore, IL-17+ cells acquire a plasma cell-like morphology under *in vitro* activation and this is correlated with enhanced concentrations of secreted IL-17. In inflamed tissue, IL-17+ cells present the same plasma cell-like morphology [46]. This indicates a major discrepancy between intracellular and secreted IL-17, and it is necessary to distinguish both phenotypes, the plastic circulating Th17 cells and the tissue Th17 cells that secrete IL-17.

16.3 Cytokines and Chemokines Related to Th17 Cells

16.3.1 Major Cytokines and Chemokines Produced by Th17 Cells

Th17 lymphocytes are proinflammatory cells that produce different cytokines and chemokines involved in the pathology of many inflammatory and autoimmune diseases [1,4]. IL-17, IL-21, IL-22, and CCL20 are the most important of these effector molecules [1,4,52].

16.3.1.1 IL-17A (IL-17)/IL-17F

IL-17A and IL-17F have similar biological functions and are genetically linked. IL-17A is the major cytokine produced by Th17 cells and has a stronger effect than IL-17 F. IL-17 signaling goes through a heterodimeric receptor composed of two

chains, IL-17RA and IL-17RC. The distribution of IL-17RA and IL-17RC diverges as IL-17RA is more distributed on immune cells, while IL-17RC is preferentially expressed by nonimmune cells. The binding between IL-17 and IL-17RA induces the recruitment of IL-17RC to form the complex and to transduce the signal. IL-17 plays a central role in the adaptive immune response, mainly against extracellular bacteria and fungi. Excess of IL-17 is involved in a growing list of autoimmune and chronic inflammatory diseases such as rheumatoid arthritis (RA), psoriasis, psoriatic arthritis, multiple sclerosis, or Crohn's disease. The major role of IL-17 is to induce the production of proinflammatory cytokines (TNF-α, IL-6, and IL-1) and chemokines (IL-8 and CCL20), antimicrobial peptides (AMP), and matrix metalloproteinases by many types of cells, such as macrophages, dendritic cells, endothelial cells, or fibroblasts of different origins. This contributes to the recruitment of neutrophils and monocytes at the inflammatory site. IL-17 also plays a role in granulopoiesis by increasing the secretion of G-CSF and GM-CSF. The many proinflammatory functions and the multiple cell targets of IL-17 make it a critical player in autoimmunity and inflammation [1,52–55].

16.3.1.2 IL-21

IL-21 is a cytokine with potent regulatory effects on the immune system and notably on lymphocyte regulation and inflammation [4,52]. IL-21 is also involved in the expansion of activated B cells and in class switching of immunoglobulin isotypes [56]. IL-21 also promotes Th1 responses by enhancing IFN-γ production [57,58] and modulates the functional development of natural killer (NK) cells [59]. Furthermore, it plays a key role in the Th17 pathway, by acting in a positive feedback loop leading to the amplification of Th17 cells and to its own production [15–17]. IL-21 is essential to maintain and amplify the Th17 pool and thus it is an important player in the support of the Th17 response and tissue inflammation [4,52].

16.3.1.3 IL-22

IL-22 is a cytokine produced by terminally differentiated Th17 lymphocytes in response to IL-23. Its receptor IL-22R is widely expressed in different tissue cells such as epithelial and endothelial cells but not in immune cells. Its important local expression is linked to the pleiotropic functions of IL-22 in the biology of epithelia, autoimmunity, and infections [4,52]. For example, by inducing AMP from various cell types such as keratinocytes [60], IL-22 plays a major role in host defense for pathogens and in the immune barrier function of epithelia [60,61]. As a consequence, IL-22 is upregulated in skin and mucosal diseases such as psoriasis, Crohn's disease, and ulcerative colitis [52]. IL-22 is a complex cytokine with both proinflammatory and anti-inflammatory properties, depending on the local conditions, such as during acute liver inflammation [62]. Thus, IL-22 appears as a cytokine used by Th17 cells to interact with tissues but with complex functions that depend on the environment [4,52].

16.3.1.4 CCL20

CCL20 is a chemokine with antimicrobial and chemoattractive activities. It is produced in various tissues by mesenchymal and immune cells [63]. It attracts at

the site of inflammation immature dendritic cells and Th17 cells [64]. Its receptor, CCR6 is expressed by dendritic cells, B lymphocytes, and Th17 cells. Thus, by secreting CCL20, Th17 cells can themselves regulate their recruitment into the inflammatory sites [3].

16.3.2 Major Cytokines Acting on Th17 Cells

Th17 cells contribute to severe tissue inflammation and autoimmunity. Their regulation may be driven in two ways, the persistence of Th17 pool or the inhibition of their differentiation. Two major cytokines IL-23 and IL-27 are involved in this regulation acting in opposite ways.

16.3.2.1 IL-23

IL-23 is a member of IL-12 cytokine family and it has many effects on the immune response. It is mainly produced by innate immune system such as dendritic cells and macrophages and plays a key role in the induction and chronicity of the Th17 response. IL-23 appears as a bridge between the innate immunity and the adaptive immunity [65,66]. After the initiation of Th17 differentiation, T cells start to express the IL-23R and become responsive to IL-23. This leads to the persistence of activated Th17 lymphocytes and to the subsequent production of IL-17. IL-23 is a critical driver for the expansion and the stabilization of Th17 cells and can be the limiting factor to determine if the Th17 response is sustained and pathogenic during immune and inflammatory responses [65–67].

16.3.2.2 IL-27

To counteract the positive effect of IL-23 on Th17 cells, IL-27 acts as a negative regulatory cytokine. IL-27 was first described as an inducer of IFN-γ response [68]. IL-27 and IL-23 belong to the IL-12 cytokine family and are both secreted by antigen-presenting cells, macrophages, and dendritic cells. The anti-inflammatory properties of IL-27 downregulate the immune response during chronic inflammation. One of the mechanisms is the ability to skew T-cell polarization and mainly to inhibit Th17 differentiation. IL-27 can also suppress the production of proinflammatory cytokines, notably IL-17, and thus reduce inflammation [69,70]. In addition to its direct activity on Th17 cells, IL-27 promotes the development of regulatory T cells [71].

16.4 Th17 and Inflammatory Diseases

Th17 cells are highly pathogenic and their deregulation could lead to the development of chronic inflammation and severe autoimmunity. Inflammation is a dynamic process with different stages. At the early stage, neutrophils are recruited first followed by monocytes and finally by lymphocytes. Th17 cells, mainly through the secretion of IL-17, increase the secretion of the proinflammatory cytokines IL-1, TNF, and IL-6 by monocytes and other cell types. Among other secreted molecules, IL-8 is a chemokine for neutrophils and this leads to

their early accumulation at the inflammatory sites. Furthermore, at these sites, Th17 cells interact with local cells and this induces the secretion of metalloproteinases (MMP) involved in matrix destruction [72,73]. Thus Th17 cells contribute largely to inflammation by different mechanisms, which explain their involvement in several inflammatory autoimmune diseases such as psoriasis, arthritic diseases (rheumatoid arthritis, psoriatic arthritis or ankylosing spondylitis), multiple sclerosis, or inflammatory bowel diseases [1,3,4,72,74,75].

16.4.1 Psoriasis

Psoriasis is a chronic immune-mediated inflammatory skin disease characterized by a hyperproliferative epidermis and an immune infiltration, mainly by dendritic cells, macrophages, and T cells in the dermis and neutrophils and T cells in the epidermis. Psoriasis is considered as a Th1/Th17-based disease as both populations are found in psoriatic skin lesions [76]. The infiltrated T cells isolated from the skin lesions present predominantly a Th17 phenotype [77]. Circulating Th17 cells are also increased in psoriatic patients [78]. These increased frequencies of Th17 cells lead to high levels of IL-17, which activates local cells such as keratinocytes to secrete proinflammatory chemokines and cytokines and thus to sustain chronic inflammation. Therefore, Th17 cells contribute largely to the pathogenesis of psoriasis [3,74,75].

16.4.2 Arthritic Diseases

Arthritic diseases combine different pathologies with a common form of chronic immune-mediated inflammatory arthritis. Rheumatoid and psoriatic arthritis are characterized by progressive joint destruction with lack of repair contrasting with the ectopic new bone formation in syndesmophytes of ankylosing spondylitis [79]. Despite this major difference, Th17 cells are involved in rheumatoid and psoriatic arthritis and ankylosing spondylitis pathogenesis. Indeed, Th17 cells are increased in peripheral blood of rheumatoid arthritis [80–82], ankylosing spondylitis, and psoriatic arthritis patients [83–87]. These increased frequencies of Th17 cells exacerbate the inflammatory state of arthritis through the activation of various cell types in the inflamed tissue, such as synoviocytes, dendritic cells, or macrophages. Furthermore, IL-17 produced by Th17 cells in inflammatory site can synergize with other cytokines such as TNF. Interestingly, IL-17 and TNF increase osteoblastogenesis on local isolated cells such as synoviocytes or mesenchymal cells, contrasting with the destructive effect in whole bone [88,89]. The difference between bone loss in rheumatoid arthritis and bone formation in ankylosing spondylitis could be due to the cell composition of the inflammatory environment. In rheumatoid arthritis, osteoclasts are massively activated by IL-17 and TNF and they interact with osteoblasts that leads to bone destruction. Conversely, in ankylosing spondylitis, osteoclasts are not present in tendons and ligaments, and the combination IL-17 and TNF can lead to bone formation as in syndesmophytes. The different effector molecules of Th17 cells synergize to increase the disease activity and this supports the role of Th17 cells in the arthritic pathogenesis by contributing to the chronic inflammatory process [3,74,75].

16.4.3 Multiple Sclerosis

Multiple sclerosis is a chronic inflammatory disease characterized by brain inflammation. Both innate and adaptive immune cells are involved in the inflammation of the central nervous system. As for the previous diseases, the frequencies of Th17 cells and related cytokines are increased in multiple sclerosis patients [90–92]. These cells have the capacity to breach the blood–brain barrier and infiltrate the central nervous system [93]. The role of Th17 cells in multiple sclerosis is reinforced by a lower ratio of Treg/Th17, which correlates with multiple sclerosis severity [91,94]. Furthermore, different treatments used in multiple sclerosis induce a reduction of Th17 cells [74].

16.4.4 Inflammatory Bowel Diseases

The two major forms, Crohn's disease and ulcerative colitis, are characterized by a chronic relapsing inflammatory response to commensal microflora in the gut. Th17-associated cytokines are increased in the inflamed tissues and in the sera and Th17 cells are increased in peripheral blood [95,96]. Furthermore, increased Th17/Treg ratio is associated with disease activity, notably in Crohn's disease patients [97] and activation of the IL-23/Th17 pathway is considered as a biomarker of active disease [98]. As discussed above, IL-17 is also involved in mucosal protection. Although the respective contribution of these opposite mechanisms remains to be elucidated, it is clear that this T-cell subset is important in pathogenesis [3,74].

16.5 Mechanisms in Chronic Inflammation

Inflammation is first a protective response and a reversible mechanism leading to the resolution at inflammatory sites. A dysregulation of the resolution and a sustained inflammatory response lead to irreversible chronic inflammation, which induces various diseases [99,100]. T helper cells, including Th17 cells, are highly present in the inflammatory lesions. As described above, Th17 cells are a pathogenic subset largely involved in the pathogenesis of the chronic inflammatory diseases described above and the number of Th17-associated diseases keeps increasing [75]. Common mechanisms lead to their differentiation and maintenance during chronic inflammation and Th17 cells exhibit similar patterns with increased frequency and elevated Th17 cytokine levels. By activating the innate and adaptive immune cells and local cells in the inflamed site, they contribute to maintain the immune response. Th17 cells act as a bridge between adaptive and innate immunity systems to sustain chronic inflammation.

16.5.1 Differentiation, Recruitment, and Maintenance of Th17 Phenotype during Chronic Inflammation

During the triggering of inflammatory response, immune cells release Th-polarizing cytokines. Among them, TGF-β, IL-6, and IL-1β induce Th17

differentiation. The Th17 transcription factor RORc induces IL-21 production that acts in an autocrine pathway to maintain RORc expression and thus maintain the Th17 phenotype. Once differentiated, Th17 cells express IL-23R and become responsive to this cytokine. IL-23 produced by innate immune cells is a major driver in the maintenance of Th17 phenotype. Furthermore, CCR6 that binds only CCL20 is preferentially expressed by Th17 subset [101] that contributes to the specific recruitment of Th17 cells during inflammation. CCL20, upregulated under inflammatory conditions, is produced by several types of epithelial and immune cells and also by Th17 cells that can themselves regulate their migration [64]. During the inflammatory process, Th17 cells are activated and by secreting proinflammatory cytokines they stimulate local cells that produce, in turn, proinflammatory cytokines and chemokines. These molecules are mainly involved in Th17 differentiation and stabilization. By secreting key cytokines and by interacting with and activating local cells, Th17 cells contribute to their own maintenance. Therefore, the secretion of cytokines and chemokines both by local and immune cells and by Th17 cells contributes largely to the differentiation, the migration, and the maintenance of Th17 cells in the inflammatory site (Figure 16.3). In addition to their own role, another subset of immune cells is crucial to the maintenance of Th17 cells, an inflammatory subset of dendritic cells (inflaDCs) appearing during chronic inflammation. By secreting Th17 cell-polarizing cytokines, inflaDC induce Th17 differentiation from naïve T cells. Furthermore, they can stimulate autologous memory T cells to produce IL-17 [102]. This subset of DC is a major player in the maintenance of Th17 phenotype during chronic inflammation.

16.5.2 Secretion of IL-17 and its Activity

The major effective cytokine of Th17 cells is IL-17 (Chapter 24). During chronic inflammation, the inflammatory environment and the cell interaction lead to activation of cells and release of cytokines that activate intracellular pathway. At molecular level, Stat3 by increasing RORc expression can affect IL-17 secretion. Stat3 can also bind directly the promoter *Il17*. The effective production of IL-17 depends on these two transcription factors, Stat3 and RORc. The secretion of IL-17 is also regulated by other cytokines, such as IL-15, IL-18, and IL-21, which stimulate its production [103,104]. The most efficient cytokine to induce IL-17 secretion is IL-23. Indeed, after IL-23R expression by Th17 cells, IL-23 promotes T cells to produce IL-17 and this requires Stat4 activation for a maximal production [25].

IL-17 exerts various biological functions. Notably, IL-17 stimulates stromal cells to produce proinflammatory cytokines and chemokines, resulting in the maintenance of inflammation [5]. IL-17 can also directly act on the phenotype and survival of cells. Indeed, in combination with TNF, IL-17 increases the survival of rheumatoid arthritis synoviocytes by inducing antiapoptotic molecules, such as synoviolin [105], and contributes to their invasive phenotype [106]. In this way, IL-17 plays a major role in the chronicity of inflammation. Mainly by secreting IL-17, Th17 cells contribute to the irreversible side of diseases induced by inflammation.

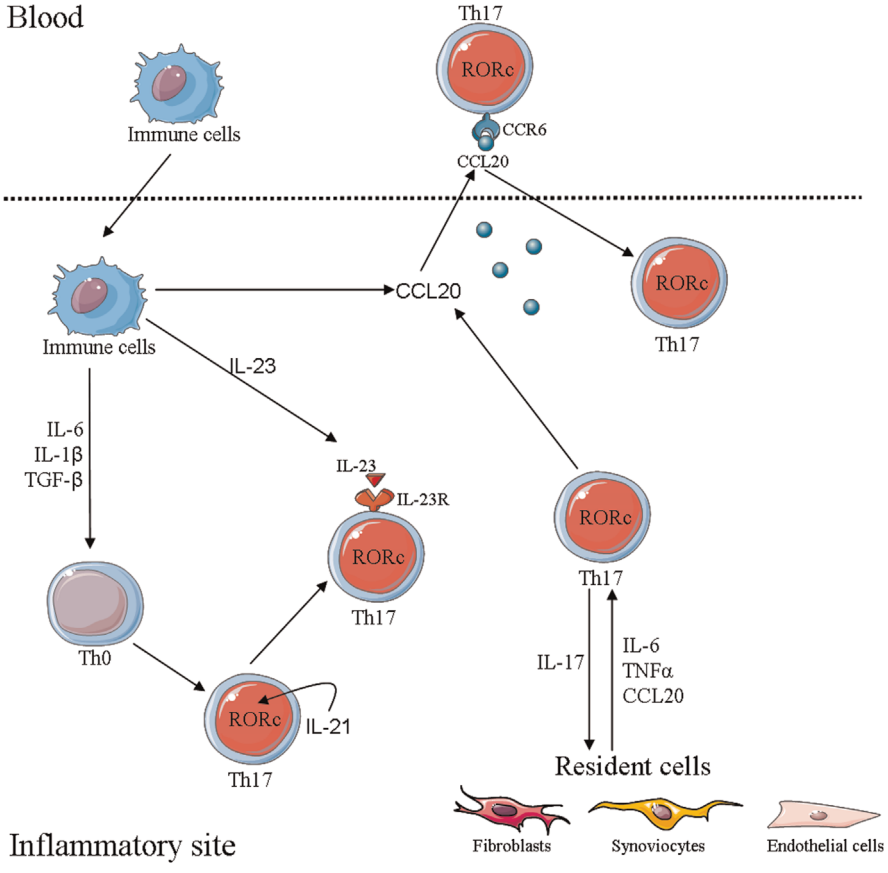

Figure 16.3 Th17 cells during chronic inflammation. During inflammation, immune cells migrate to the inflammatory site and secrete Th-polarizing cytokines. TGF-β, IL-6 and IL-1β induce Th17 differentiation via the induction of the transcription factor RORc. RORc induces IL-21 that acts in autocrine way to maintain the Th17 phenotype. Differentiated Th17 cells express IL-23R and IL-23 drives the maintenance of the Th17 phenotype. Th17 cells express the receptor CCR6, which binds CCL20 and this interaction leads to the recruitment of Th17 cells to the inflammatory site. CCL20 is produced both by mesechymal cells and by Th17 cells themselves. Cytokines produced by Th17 cells, notably IL-17, stimulate local cells such as fibroblasts, synoviocytes, or endothelial cells, to produce proinflammatory cytokines and chemokines involved in Th17 differentiation and stabilization. This way induces the chronicity of the activation of the Th17 cells.

16.6 Plasticity of Th17 Cells

Even if each Th subset requires specific cytokines and transcription factors for their differentiation, Th17 cells keep some degree of plasticity (Figure 16.4) [3,48–50,107]. Thereby, under inflammatory conditions, Th17 cells display plasticity and the produced cytokines can switch from IL-17 to other proinflammatory cytokines, such as IFN-γ. Indeed, in blood, IL-17+ IFN-γ+ double producer cells are easily detected. Different coexpressions during inflammatory

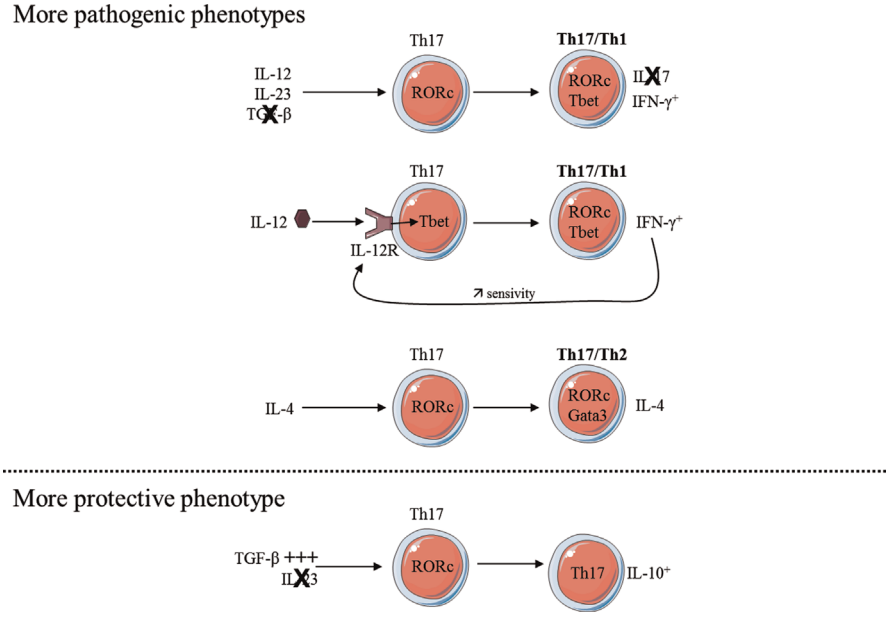

Figure 16.4 Plasticity of Th17 cells. Under inflammatory conditions, the Th17 subset displays plasticity. In the absence of TGF-β, IL-23 and IL-12 suppress IL-17 production and promote T-bet expression that induces IFN-γ expression in Th17 precursors. Exposure of Th17 cells to IL-12, which express IL-12R, induces the switch to Th1 phenotype with the expression of T-bet and the secretion of IFN-γ. In turn, IFN-γ increases the sensitivity of Th17 cells to IL-12. IL-4 can lead to a switch into Th2 phenotype with GATA-3 expression and IL-4 secretion. The Th17/Th1 and Th17/Th2 phenotypes may be more aggressive and pathogenic than unshifted Th17 cells. A high level of TGF-β can induce the secretion of IL-10 by Th17 cells, and this is increased in the absence of IL-23. This phenotype is more protective than the Th17 cells.

responses have been observed, IL-17/IFN-γ, RORc/T-bet, FoxP3/RORc/IL-17, or IL-17/IL-10, and these mixed phenotypes are determined by the inflammatory environment. The prime factors that affect the stability of Th subsets are also those involved in their differentiation. TGF-β plays a major role for maintenance of IL-17 expression. In the absence of TGF-β, IL-23 and IL-12 suppress IL-17 production and promote the emergence of IFN-γ expression in Th17 precursors. This plasticity toward the Th1 profile is dependent on Stat4 and T-bet transcription factors [108]. This coexpression RORc and T-bet leads to a more pathogenic phenotype of Th17 cells. On the contrary, high levels of TGF-β induce the ability to IL-17+ cells to produce also IL-10 and this is reinforced by the absence of IL-23. This phenotype is more protective due to the anti-inflammatory effect of IL-10 [109]. The presence of IL-23 is known to stabilize the Th17 phenotype, but it can also mediate the switch to IFN-γ production during chronic inflammation [110]. Th17 cells express a full IL-12 receptor and thus, in response to exposure to IL-12, they switch to Th1 phenotype by expressing T-bet and secreting IFN-γ. In turn, IFN-γ increases the sensitivity of Th17 cells to IL-12 and contributes to the phenotype Th17/Th1 that coexpressed RORc and T-bet. Furthermore, the interaction with IL-4 can also lead to a switch toward Th2 subset and IL-4 production.

Both phenotypes, Th1/Th17 and Th2/Th17, seem to be more aggressive and more pathogenic than unshifted Th17 cells.

Furthermore, the network between the different transcription factors also affects the stability and the plasticity of Th17 cells, and notably the inhibitory effect of Foxp3 on RORc. The development of Th17 and Treg cells is closely related by TGF-β. Indeed, TGF-β induces both transcription factors, Foxp3 and RORc, but in the absence of inflammation, that is, mainly the absence of IL-6, FoxP3 represses RORc and Treg differentiation is favored. Under inflammatory conditions, RORc is upregulated and induces Th17 differentiation. A transient population made of CD4+ FoxP3+ RORc+ cells can lead to both Th17 and Treg cells according to the local conditions. The plasticity between Th17 and Treg cells is important and plays a major role in the control and outcome of immune responses and inflammation [111]. The plasticity of Th17 cells has important biological implications regarding their ability to switch to a more pathogenic phenotype such as Th17/Th1 or more protective phenotype such as Th17/Treg.

16.7 Clinical Targeting of Th17 Cells

Considering the crucial role of Th17 cells in the pathogenesis of several chronic inflammatory diseases, they have been considered as potential targets for treatment [1,3,72,107]. Various options are available to target the Th17 pathway in inflammatory diseases, cytokine targeting, signaling inhibition, or transcription factor inhibitor.

To act on Th17 differentiation and amplification, inhibitors of IL-6 and IL-1β, largely involved in Th17 differentiation, are currently used in the treatment of inflammatory diseases. Tocilizumab is a humanized anti-IL-6 receptor antibody, anakinra is an IL-1 receptor antagonist, and canakinumab is an inhibitor of IL-1. The first two are currently used in rheumatoid arthritis treatment and the last one for that of autoinflammatory diseases [112]. In contrast, tocilizumab has no clear effect on psoriasis, psoriatic arthritis, and ankylosing spondylitis [113], suggesting different mechanisms by which Th17 cells are involved in these diseases.

Another target is IL-23 as it is critical for the expansion and the stabilization of the Th17 phenotype. IL-23 can be inhibited by two antibodies directed against the p40 chain, a subunit of IL-23, ustekinumab and briakinumab. Ustekinumab is registered for the treatment of psoriasis and psoriatic arthritis. Other indications are in progress [114–118]. All these therapies, by targeting the common p40 chain, affect both the Th17 and the Th1 pathways, and IL-17 and IFNγ, respectively. Targeting the p19 specific chain of IL-23 affects only the Th17 pathways and their cytokines IL-17, IL-21, and IL-22. The anti-IL-23 p19 inhibitors tildrakizumab and guselkumab are now tested in psoriasis and psoriatic arthritis.

Another option is to target the key transcription factor RORc [119], using small molecules. This provides a good opportunity to inhibit Th17 subset but also Th17/Th1 and Th17/Th2 shifted cells, which could be the more pathogenic ones. This will block the entire Th17 program, from Th17 development to

proinflammatory cytokine secretion. Digoxin is an old molecule recently identified as a specific RORγt inhibitor [120]. Other molecules such as ursolic acid and SR1001 bind specifically RORα and RORγt [121]. They inhibit Th17 differentiation and function in murine and human cells and suppress the clinical severity of various models of autoimmune diseases in mice [122]. The use of small molecules to target the transcription factor RORc could provide a simple treatment of chronic inflammatory and autoimmune diseases.

The biologic effects of Th17 cells could also be controlled downstream by targeting directly IL-17. Secukinumab, a fully human anti-IL-17A monoclonal antibody, has been the first inhibitor of IL-17A for the treatment of psoriasis, and registration for psoriatic arthritis and ankylosing spondylitis are in progress [72]. Similar indications have been selected for ixekizumab, a humanized anti-IL-17A [123]. Both antibodies have shown efficacy in rheumatoid arthritis but with a high heterogeneity in the clinical response [124,125]. Another way to inhibit the IL-17 effect is to act downstream on IL-17 receptor complex. Brodalumab is a humanized anti-IL-17RA antibody that has shown efficacy in psoriasis [126,127], in psoriatic arthritis, and ankylosing spondylitis [128] but not in rheumatoid arthritis [129].

16.8 Conclusions

Th17 cells were identified as the third subset of T helper cells, with distinct effector functions from the Th1 and Th2 subsets. Increased knowledge of Th17 cells during the years past has been made in understanding their development and in defining their role in health and diseases. Th17 cells are important effector cells to clear many pathogens. When in excess, this subset becomes highly pathogenic in the induction and the propagation of chronic inflammation. Many diseases are influenced by the activation of the Th17 pathway, such as psoriasis, rheumatoid arthritis, or multiple sclerosis.

Considering their role in inflammatory and autoimmune diseases, the inhibition or the modulation of Th17 cell differentiation and functions could be beneficial under such conditions. Impressive results have already been obtained and more strategies are developed. The final goal is to fine-tune this balance not only to control inflammation but also to induce a cure.

Platelets

Jack Levin

University of California School of Medicine, Departments of Laboratory Medicine, 521 Parnassus Avenue, San Francisco, CA 94143, USA

17.1 Introduction

Mammalian platelets are appropriately considered as functioning primarily to support a range of hemostatic mechanisms, both by maintaining the integrity of blood vessels and by contributing to the process of blood coagulation. However, platelets have many other capabilities, although often rudimentary, which appear to be unrelated to their hemostatic function.

Despite approximately 450 million years of evolution [1], mammalian platelets retain many of the functions of amebocytes, the only type of circulating blood cell in the horseshoe crab, *Limulus polyphemus*, which is justifiably considered to be a "living fossil." This phenomenon may have resulted from the retention of multiple functions previously found in a single "all-purpose" circulating cell type, such as the Limulus amebocyte, whose functions include hemostasis. The potential for platelets to be involved in inflammation was suggested by a comparison of reported but historically ignored platelet functions with the multiple functions of the Limulus amebocyte.

The multiple characteristics shared by mammalian platelets and Limulus amebocytes are summarized in Table 17.1. Platelets have rudimentary bactericidal and some phagocytic or phagocytic-like activity [2–6]. However, an ultrastructural study of interactions between human platelets and various-size particles concluded that platelets were not true phagocytes and that the uptake of bacteria involved the channels of the open canalicular system (OCS) [7]. Nevertheless, an exhaustive review of studies that described the interactions of platelets with particulate materials or bacteria presented considerable data, which appeared to support the conclusion that platelets are capable of phagocytosis [8]. Platelets contain endotoxin-binding substances [9] and have been shown to interact with bacteria, endotoxins, viruses, and fungi [10–14]. Murine [15] and human [16] platelets have been shown to express a functional Toll-like receptor-4 (TLR4), the receptor for bacterial

Characteristic or Function	Limulus Amebocyte	Mammalian Platelet
Hemostasis	Essential	Essential
Blood coagulation	Essential	Ancillary
Clottable protein	Yes	No
Nucleus	Yes	No
Cellular processes	Yes	Yes
Granules	Yes	Yes
Response to endotoxin	Yes	Yes
Phagocytosis	Yes	Yes (?)
Antibacterial activity	Yes	Yes
Motility	Yes	Yes

endotoxin (LPS) [15]. The extensive role of platelets in antimicrobial host defense has been reviewed [14,17]. Staphylococcus can stimulate human platelets to undergo the release reaction [18].

Pneumococcus (*Streptococcus pneumoniae*) and vaccinia virus can induce the release of serotonin from human platelets [19,20]. Other investigations have demonstrated that two endocarditis-producing strains of *S. viridans* can activate human platelets *in vitro* [21], apparently by direct platelet-bacterial interaction. Fibrinogen in conjunction with other unidentified plasma factors was required for platelet aggregation and secretion [21,22]. The aggregation of human platelets by *S. viridans*, *S. pyogenes*, and *S. sanguis* has been demonstrated [23–25]. *S. mitis* has been shown to possess at least two genomic regions that contribute to platelet binding [26].

Human platelets have been reported to be cytotoxic for parasites by a mechanism involving an IgE receptor on the platelet surface [27,28]. Platelets also have been shown to play a role in the excretion of *Schistosoma mansoni* in the stool of mice [29]. Other studies have demonstrated that platelets enhance the adherence of schistosome eggs to endothelial cells and that interleukin (IL)-6, produced by activated monocytes, markedly increases the cytotoxicity of platelets against schistosomula [30]. Under certain circumstances, platelets demonstrate a chemotactic response and migrate [31–34], as do amebocytes [35]. Platelets have demonstrated gradient-driven migration and have been shown to migrate toward formyl peptides [33]. Overall, it is now clear that bacteria, viruses, fungi, and parasites are capable of interacting with platelets. Depending upon the nature of the infectious particles and other poorly understood variables, this interaction can result in platelet aggregation, release of platelet constituents, phagocytosis of the infectious agent, and ultimately a shortened platelet lifespan. Collectively, these and other observations establish the important roles of platelets in a wide range of inflammatory responses (Figure 17.1 and Table 17.2, modified from Ref. [36].

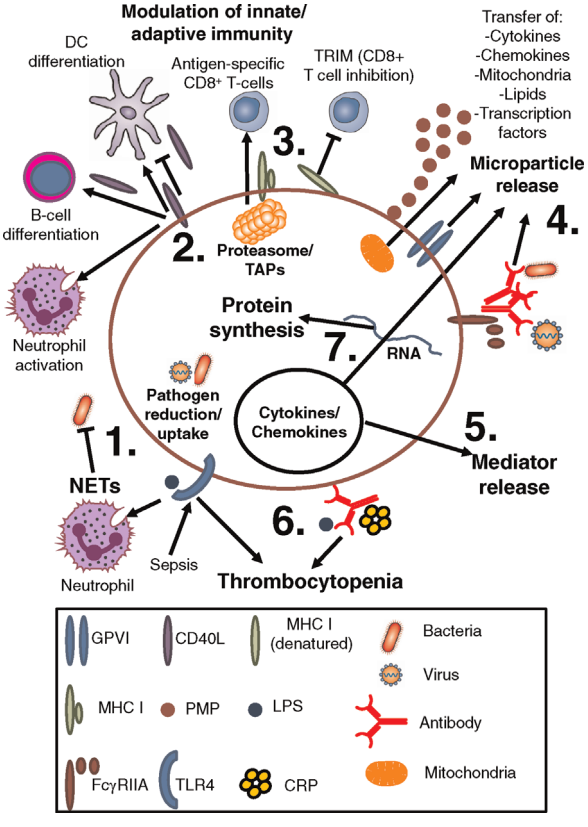

Figure 17.1 The many important roles of platelets in modulating a wide range of inflammatory processes. See also Table 17.2. (Reproduced with the permission from Ref. [36].)

Platelet microparticles (PMPs) are extracellular microvesicles that result from cytoplasmic blebbing. PMPs range in size from 100–1 000 nm, are procoagulant, and have been shown to be present in various inflammatory states [37,38]. PMPs are rich in Il-1 and it has been suggested that they play a role in increasing inflammation [39,40].

17.2 Expression of Toll-like Receptors

TLRs are pattern recognition receptors, present on macrophages, neutrophils, dendritic cells, and platelets, which play a role in activation of the immune response to pathogens [41,42]. Importantly, bacterial endotoxin (lipopolysaccharide, LPS) interacts with TLR4 on platelets, perhaps accounting for, at least in part, the ability of bacterial LPS to produce thrombocytopenia. Figure 17.2 demonstrates the adhesion of a piece of the cell wall of a Gram-negative bacterium (containing bacterial LPS) to a platelet. The resultant activation of platelets probably leads to platelet/neutrophil interactions that may lead to bacterial trapping [43]. LPS enhances responses of platelets to immune complexes and aggregates of IgG, demonstrating integration of diverse inflammatory signaling pathways and providing early evidence for a specific receptor for LPS on these cells [44]. Toll-like receptors on both platelets and monocytes, allowing cross-talk, provide another mechanism for the involvement of platelets in immune responses [45,46].

17.3 Interactions between Platelets and Bacteria

Microbicidal proteins, polymorphic protein-1 (PMP-1) and PMP-2, are small cationic peptides released by rabbit platelets, which disrupt the membrane of *Staphylococcus aureus* and cause cell death [47]. It has been demonstrated that staphylococci have a receptor for the Fc fragment of immunoglobulin G (IgG) that provides a mechanism for aggregation of human platelets by the formation of a complex composed of bacteria, IgG, and platelets [48]. Furthermore, it has been shown that platelet binding by *S. aureus* is mediated,

at least in part, by direct binding of clumping factor A (ClfA) to a novel 118-kDa platelet membrane receptor [49]. Certain surface proteins of *S. gordonii* bind to the extracellular portion of the platelet membrane glycoprotein (GP) Ibα [50]. Some streptococcal adhesins bind to platelet glycoprotein GP1b and enhances virulence in endocarditis [51]. In addition, group B *Streptococcus* possess serine-rich repeat (Srr) surface glycoproteins, important adhesins that contain a fibrinogen-binding region [52]. Similarly, *S. agalatiae* (a group B *Streptococcus*) possesses a serine-rich repeat glycoprotein, Srr1, which appears to play a role in invasion of the central nervous system and in the pathogenesis of endocarditis through its role in fibrinogen-mediated platelet binding [53,54]. *S. sanguinis*, a leading cause of infective endocarditis, expresses a serine-rich adhesion, SrpA, similar to platelet-binding adhesins associated with increased virulence in bacterial endocarditis [55]. Oral Streptococci use a Siglec-like domain of SRR adhesins to preferentially target platelet sialogycans; this provides the viridans group of Streptococci a selective advantage in colonizing damaged cardiac vales and producing infective endocarditis [56].

Platelets have been shown to be bactericidal for *Bacillus subtilis* and *Escherichia coli* (but not *S. aureus*), but only in the presence of thrombin and a heat-labile plasma protein fraction >100 kDa [57,58]. The mechanisms of the multiple interactions between platelets and bacteria have been the subject of an exhaustive review [58]. Importantly, it was pointed out that certain infectious agents may utilize various platelet responses to increase virulence [58].

17.4 Interactions between Platelets and White Blood Cells

Platelets which are adherent to endothelium can result in adhesion of polymorphonuclear leukocytes and monocytes [59–62]. In this circumstance, platelets also contribute to leukocyte function and regulated accumulation, including transmigration of polymorphonuclear leukocytes and monocytes on adherent, activated platelets [63]. Overall, it has been clearly established that platelet–leukocyte interactions are an important response of platelets to inflammation, including the formation of neutrophil extracellular traps (NETs) [64–66].

Platelet/leukocyte aggregates have been detected in the blood of patients with a variety of clinical conditions. (Table 17.3) [67]. Platelet/monocyte aggregates may be more stable than platelet/polymorphonuclear leukocyte aggregates [68,69]. A consequence of platelet/leukocyte aggregate formation is increased accumulation of leukocytes at sites of inflammation and vascular injury. Signals produced by activated, adherent platelets trigger activation of β2 integrins on leukocytes, which is required for tight adhesion to vascular surfaces. The effect on the leukocyte of P-selectin on the activated platelet is a key mechanism, together with other signals also delivered by the platelet [63]. The responses of leukocytes to signals delivered by activated, adherent platelets are clearly relevant to inflammatory diseases (Figure 17.1 and Table 17.2).

b) Systemic lupus erythematosus.
c) Acute respiratory distress syndrome.
This list shows only selected disorders.

17.5 Platelet Integrins

Platelets have multiple surface receptors that transmit outside-in signals to biochemical signal transduction pathways. Many of these signaling pathways trigger inflammatory activities of platelets [63]. Stimulation of human platelets by thrombin induces degranulation and release of inflammatory mediators and antibacterial factors and formation of platelet/monocyte aggregates, which triggers additional expression of chemokines, cytokines, and inflammatory enzymes. These contribute to immune functions of activated platelets [63,70,71]. Platelet integrins not only play critical roles in hemostasis but also directly participate in inflammatory signaling in platelets and in interactions of activated platelets with other inflammatory cells. Integrin GPIIb-IIIa, in addition to playing a major role in hemostasis, is involved not only in interactions of platelets with endothelium in inflamed vessels and with leukocytes but also in interactions with some microbial pathogens [59,63,72]. Outside-in signaling resulting from engagement of integrin GPIIb-IIIa by fibrinogen can also trigger inflammatory responses in platelets. Involvement of integrin αIIbβ3 can also induce a variety of other inflammatory activities of human platelets [63]. Synthesis of interleukin-1β by human platelets [73] is stimulated by the interaction between platelets and collagen and this cytokine plays a role in the response to inflammation [74,75]. GPVI, an immunoreceptor, regulates the activity of αIbβ3 and α 2β1 in platelets and induces alpha granule secretion [71,76]. αIIbβ3 has been shown to play a role in the activation of platelets by multiple types of Streptococci; FcγRIIA is involved [77,78]. GPVI also induces platelet microvesicle release, which can then transmit inflammatory signals by transporting IL-1 [79]. Overall, there are multiple pathways by which platelets signal cells within and without the vascular system that have the potential to alter immune events [63,70,80]. Platelets also express Fc receptors that recognize multiple classes of immunoglobulins [71,81–85]. Platelet Fc receptors appear to participate in some immune and infectious syndromes, including heparin-induced thrombocytopenia, bacterial endocarditis, and diabetes [71,84–86].

17.6 Role of Platelets in Immune Responses

Platelets are involved not only in the response to inflammation but also in a wide range of immune responses [87–89]. P-selectin expression in activated platelets can lead to complement activation [90]. Platelets and neutrophils were reported to be associated at sites of acute inflammation [91]. Platelets can affect the immune system by regulating lymphangiogenesis, which then influences lymphocyte trafficking and related cellular events in adaptive immune responses [92]. Activated platelets interact both with lymphocytes and with dendritic cells and have been reported to regulate the functional state of dendritic cells [93–99].

As stated previously, since they also bind to other leukocytes in the circulation, notably monocytes, activated platelets have the potential to markedly influence a wide range of inflammatory responses. Platelet microparticles may be an important mechanism by which platelets affect other circulating blood cells [89,95,100,101].

17.7 Platelets and Inflammatory Disorders

Thrombocytosis or thrombocytopenia is often associated with inflammatory and infectious states, and platelets are often present at infected sites [87]. In some infectious disorders, platelets are especially prominent and thrombocytopenia may be severe [102]. The role of platelets in innate immunity and host defense has been the subject of an entire issue of a journal [103].

Sepsis (systemic inflammatory response syndrome, SIRS) is a serious condition, associated with a high mortality rate [104]. When associated with Gram-negative infections, bacterial endotoxin (LPS) can often be detected in the blood [105]. Both immune and hemostatic systems are pathologically affected. Increased vascular permeability is commonly present [106]. Abnormal concentrations of thrombin, PAF, and cytokines are present [107]. In Gram-negative sepsis, sequential elevations of TNF, IL3, and IL-6 are observed. Platelets are involved [107–109] and moderate to severe thrombocytopenia is almost always present [108,109]. A correlation between thrombocytopenia and multiorgan failure and death has been reported [109]. Disseminated intravascular coagulopathy (DIC) is common, with consumption of both blood coagulation factors and platelets. There is associated vascular injury and thrombosis [110–112]. During an episode of SIRS, platelets activated by LPS via TLR4 have been suggested to trigger formation of neutrophil extracellular traps (NETS) [107]. Fibrin deposition in small vessels is a feature of sepsis; fibrinogen concentrations in plasma are reduced and fibrin degradation products (FDPs) are elevated. Platelets play multiple roles during SIRS [107,109]. It is noteworthy that platelet–white blood cell aggregates have been observed in the circulation in these disorders [67].

17.8 Malaria

Thrombocytopenia is commonly present in *Plasmodium falciparum* and *P. vivax* infections [113,114]. The pathogenesis of malaria-induced thrombocytopenia involves marrow suppression, immune-mediated platelet destruction, adhesion to injured endothelium, and interactions with sequestered parasitized erythrocytes and leukocytes [114,115]. Platelets may play a role in the pathogenesis of severe malaria [63,115,116] and possibly be protective [117–119], and therefore be critical during immune responses to the blood stages of malaria [120]. In contrast, the aggregation of platelets and leukocytes in cerebral microvesicles probably is a cause of mortality in the cerebral malaria that may develop in children infected with *P. falciparum* [115,121]. Platelets also interact directly with red blood cells, causing clumping of the infected erythrocytes and formation of platelet–erythrocyte aggregates. The detection of platelet factor 4 in plasma samples from infected patients indicates that platelet activation had occurred [122]. Other studies indicate that platelets are important immune effector cells in malaria [115,123]. The pathophysiology of malaria provides a clear example of the important interface between inflammation and blood coagulation [123].

17.9 Systemic Lupus Erythematosus

Thrombocytopenia is a feature of systemic lupus erythematosus (SLE). Platelet activation and increased circulating platelet/monocyte complexes have been described in SLE [124,125]. Altered protein expression appears to correlate with cellular activation and vascular abnormalities in SLE [126]. There is excessive production of autoantibodies by B lymphocytes [127], with dendritic cell activation and release of INFα [128]. It has been reported that activated platelets play a role in some of these key pathological events [129]. There is P-selectin expression and formation of platelet/monocyte and platelet/dendritic cell aggregates [129]. Other reports indicated that alterations in the platelet transcriptome in SLE result in increased expression of factors in the type I IFN system [126]. Platelet signaling as a mechanism of renal injury in SLE is also supported by the observation that platelets from patients with SLE can activate mesangial cells, leading to mesangial proliferation and production of profibrotic TGF-β1 [130].

17.10 Conclusions

It has become increasingly clear that platelets, historically believed to be relatively inert fragments of megakaryocyte cytoplasm, are powerful cellular machines with an enormous range of biological activities. Their roles in a wide range of immunological settings and/or when inflammation is present have been increasingly documented [131–132]. It is of particular biological and clinical significance that these insights have provided clear evidence of the important relationships between inflammation, hemostasis, and the control of pathogens [133–138].

18.1 Introduction

Epithelial cells are the building blocks of epithelial tissues that act as a physical barrier between the body and the external environment. Epithelial cells are tightly arranged into continuous sheets and line the surfaces of organs throughout the body, including the gastrointestinal, urinary, and respiratory tracts, as well as form complex structures such as secretory glands and blood vessels. Under normal conditions, an intact epithelial barrier serves to carefully limit and regulate the bidirectional transport of ions, small molecules, and nutrients, and to prevent unwanted pathogens such as harmful bacteria, viruses, and fungi from entering the host and subsequently the systemic circulation. Beyond providing a physical barrier, epithelial cells also play important roles in coordinating immune responses, secreting signaling molecules to transmit messages between local and distant targets, and initiating mechanisms of self-renewal, regeneration, and repair. These functions are critical to maintain homeostasis locally and throughout the body. However, epithelial cell responses can also contribute to the etiology and pathophysiology of many disease processes, including inflammatory diseases that can induce or result from impaired epithelial cell and/or barrier function. In the intestine, the epithelium is composed of a single continuous layer of simple columnar epithelial cells organized into a series of invaginations and projections into the lumen known as crypts and villi, respectively [1]. These characteristics serve to increase the total surface area and the overall functional capacity of the intestine [2]. In fact, the intestinal epithelium represents the largest surface in the body that is in direct contact with the outside world [3]; therefore, it serves as an archetype for the basis of understanding the structure and function of epithelial cells in health and in the context of inflammatory disease.

18.2 The Intestinal Epithelium: An Archetypal Epithelial Barrier

Along the surface of the gastrointestinal tract, columnar epithelial cells are tightly packed alongside one another into a single layer, adjacent to the lumen. All epithelial cells are uniformly polarized, with an apical surface facing the lumen and a basolateral surface in contact with the underlying basement membrane. This polarity is required for the specialized bidirectional transport and barrier functions of the epithelium [4]. The apical surface of epithelial cells may exhibit ultrastructural specializations such as microvilli, which compose the brush border and serve to further increase the surface and absorptive area of the small intestine [5]. The composition of terminally differentiated epithelial cells varies across epithelia and within different regions of an organ, but in the small intestine, four principal intestinal epithelial cell subtypes have been identified: absorptive enterocytes, goblet cells, Paneth cells, and enteroendocrine cells [6,7]. Each of these cell subtypes arise from four–five pluripotent stem cells located at the base of intestinal crypts. These cells were first observed with electron microscopy and are referred to as crypt base columnar (CBC) cells, for their location and cell shape [8]. More recently, crypt base columnar cells were found to selectively express the evolutionarily conserved G protein-coupled receptor LGR5 [6], a member of the Wnt signaling pathway characterized by a distinct leucine-rich repeat sequence in the extracellular domain [9]. Undifferentiated *Lgr5*-positive daughter cells begin to migrate from their niche at the base of the intestinal crypt along the crypt–villus axis, forming a pool of highly proliferative transit-amplifying cells (TACs) [10]. These cells differentiate through successive cell divisions and underlie the vast regenerative capacity of the intestinal epithelium.

Intestinal epithelial cells represent one of the most rapidly dividing cell types in the entire body, with epithelial cell turnover occurring within three–five days [11,12]. As TACs migrate from the transit-amplifying zone to the villus, they undergo differentiation and commit to an epithelial cell lineage [13]. Once the differentiated cells reach the tip of the villus, they are rapidly shed into the lumen at a rate of approximately 10 000 cells each day [11,14]. Under normal conditions, intestinal epithelial barrier function is maintained despite the presence of gaps resulting from rapid shedding [15] due to the redistribution of tight junction proteins that mediate cell to cell interactions [16]. Continuous epithelial cell renewal and repair along the crypt–villus axis is closely regulated and critical to maintenance of homeostasis and healthy epithelial barrier function.

18.3 Choosing a Cell Fate: The Absorptive Lineage

Epithelial cells throughout the body are named for their cellular morphology (e.g., squamous, cuboidal, or columnar) and their arrangement is classified as simple (single layer) or stratified (multiple layers). The gastrointestinal, respiratory, and urinary tracts are similar as they are all lined with single layer of columnar epithelial cells, but this is not to imply that the epithelial borders of these organs

are homogeneous. Rather, it is imperative that the proper ratio of terminally differentiated epithelial cell subtypes exists to perform the specialized functions of each organ. In the gastrointestinal tract, the composition of resident epithelial cells is organized to facilitate absorption, secretion, and permit the expansion of the epithelium to accommodate luminal contents. The predominant epithelial cell subtype (~90%) in the lining of the small intestine is the enterocyte [8,17], which can have absorptive or nonabsorptive capabilities based on the spatial distribution and gene expression profile [18]. Absorptive enterocytes have a basal nucleus and a densely packed series of microvilli covering their apical surface [19] that contain negatively charged integral membrane glycoproteins and enzymes to facilitate terminal digestion and absorption of nutrients [20,21]. In addition to their role in digestion and absorption, enterocytes also mediate transepithelial electrolyte and fluid transport. Chloride ion secretion from enterocytes is carefully regulated and can be triggered via an increase in intracellular cyclic nucleotides (cAMP or cGMP) or calcium levels within the cell [22,23]. Increased calcium results in transient chloride secretion from the apical cell surface, while intracellular cyclic nucleotides produce a larger, more sustained response [24]. Anionic chloride (Cl^-) ions in the lumen draw cationic sodium (Na^+) ions in through intracellular spaces, leading to an osmotic gradient that pulls water into the lumen via various specialized transporters, exchangers, and ion channels located at the apical and basolateral membranes of the enterocyte [25]. These include Cl^- channels located at the apical membrane and potassium (K^+) channels and the Na^+-K^+-Cl^- cotransporter at the basolateral membrane [26,27]. In addition, inhibitory signaling mechanisms exist to limit chloride and fluid secretion including carbachol- [28] and epidermal growth factor (EGF)-dependent pathways [29]. The mechanisms for regulating chloride and fluid secretion across epithelial barriers are similar in many organs and are central to both normal physiology and pathophysiology of many diseases, including cystic fibrosis and secretory diarrhea [23,25].

18.4 Choosing a Cell Fate: The Secretory Lineage

18.4.1 Goblet Cells

In addition to enterocytes, three other specialized secretory epithelial cell subtypes differentiate from *Lgr*5-positive stem cells located in the base of intestinal crypts: goblet cells, Paneth cells, and enteroendocrine cells. Goblet cells produce a mucus layer that is critical for maintaining the functional integrity of the mucosal epithelium [30–32]. The mucus layer lowers the coefficient of friction to promote movement of luminal contents along the intestine, protects epithelial cells from physical and chemical injury [30], provides binding sites and nutrient sources for intestinal microbes [33], and limits the host's exposure to harmful antigens [34]. Goblet cells synthesize a variety of large glycoproteins known as mucins that have a protein backbone linked to hydrophilic oligosaccharide side chains [35]. Mucin (MUC) proteins are either bound to the membrane itself (MUC1, MUC3, MUC4, MUC12, MUC13, and MUC17) or stored in large vesicles and secreted from the

apical surface of the intestine (MUC2) [36,37]. These proteins are characterized by large "mucin domains" containing heavily O-glycosylated serine and threonine amino acid residues, which contribute to their distinct structure and the assembly of the mucus layer [34]. Under normal conditions, secretory mucin-containing granules are secreted in small volumes and when combined with water, they expand dramatically to form a viscous gel that protects and lubricates the mucosal epithelium [38], while epithelial membrane-bound mucins create the carbohydrate-rich glycocalyx barrier composed of diverse glycoproteins and lipids along the surface of the brush border [39]. Many transmembrane mucins are expressed by both enterocytes and goblet cells, while secretory mucins such as MUC2 are selectively expressed by goblet cells [40].

The mucus layer is a dynamic component of the epithelial barrier with a distinct microenvironment. MUC2 is the predominant gel-forming mucin protein of the mucus layer [32,41] and is released from the apical surface of the epithelial cell via either constitutive (basal) or stimulated (active) secretion. Constitutive secretion refers to the unregulated, passive release of secretory granules, which occurs via existing electrical or chemical gradients, while stimulated secretion is a calcium-dependent mechanism that results from activation of receptors located on the apical surface of goblet cells. Calcium diffusion neutralizes negatively charged mucins and triggers exocytosis of densely packed granules, which can be initiated by hormones and transmitters acting through intracellular signal transduction systems such as the cAMP/PKA pathway [25]. Exocytosis of the mucin granules leads to rapid expansion of the mucus gel [40], which allows for continuous renewal and replacement as it moves along the intestinal surface toward the distal colon and rectum via waves of peristaltic motor activity [42–44].

In contrast to the small intestine, the large intestine has a mucus layer at the luminal surface containing a loose outer layer and a stratified inner adherent layer [45,46]. The proportion of goblet cells in the epithelium increases distally along the gastrointestinal tract, with the largest number found in the distal colon [47]. Interestingly, the number of bacteria in the gastrointestinal tract also increases in this fashion with over 10^{13} bacteria present in the human colon alone [48]. The outer mucus layer serves as a home for the vast commensal bacteria to colonize, while the densely packed inner layer is devoid of bacteria under normal conditions [49]. This inner mucus layer provides additional protection against bacterial interaction with epithelial cells and bacterial translocation into the host. Furthermore, a clear border exists between the mucus layers, suggesting distinct mechanisms governing the transition between the two layers [48]. Interestingly, the absence of the cystic fibrosis transmembrane conductance regulator (CFTR), a Cl^- channel involved in transport of Cl^- across the apical surface of epithelial cells, leads to the development of an adherent mucus layer in the small intestine [50]. The commensal bacteria housed in the outer mucus layer produce a variety of metabolites that further confer protection to the host and the underlying epithelium such as the short chain fatty acids acetic acid, propionic acid, and butyric acid [51]. Conversely, intestinal epithelial cells produce antibacterial proteins [52,53] that serve to shape the adjacent bacterial microbiome in a symbiotic fashion.

18.4.2 Paneth Cells

As stated above, the inner adherent mucus layer that separates the bacteria from underlying epithelial cells is absent in the small intestine under normal conditions. There may be multiple reasons for this, including a smaller bacterial load in the small versus large intestine, as well as the increased absorptive capacity of the small intestinal epithelium that an adherent mucus layer may impair. However, additional mechanisms exist in the small intestine to mediate host–microbe interactions and to prevent bacterial translocation and dysbiosis. These include a subtype of secretory epithelial cells called Paneth cells that produce proteins with antibacterial, antiviral, and antifungal actions [53]. These cells are most frequently found at the base of small intestinal crypts and were named after Josef Paneth, one of the two scientists who first described their unique morphology and large granules [54]. In contrast to other terminally differentiated epithelial cell subtypes of *Lgr*5-positive stem cell origin that have a lifespan of roughly three–five days and migrate up the crypt–villus axis, Paneth cells maintain their position in the base of the crypt for approximately 60 days [55]. Similar to goblet cells, Paneth cells rapidly secrete their granules into the lumen via calcium-dependent exocytosis following exposure to bacteria or bacterial antigens [56–59]. Bacteria or bacterial antigens bind to host membrane-bound pattern recognition receptors (PRRs) such as Toll-like receptors (TLRs) or nucleotide-binding oligomerization (NOD)-like receptors (NLRs) [60]. Receptor coupling leads to activation of downstream signaling cascades and subsequent release of antimicrobial proteins synthesized and stored in granules at the Paneth cell surface. Paneth cells secrete a variety of antimicrobial proteins, including α- and β-defensin, lysozyme C, angiogenin (ANG) 4, secretory group IIA phospholipase A2 (sPLA2), and regenerating islet-derived protein (REG) 3α [61], thereby limiting luminal bacterial translocation of both commensal and pathogenic bacteria to the small intestine [59,62] and extraintestinal tissues such as mesenteric lymph nodes [59,63] and spleen [59]. Antimicrobial peptides such α-defensins also shape the composition of both pathogenic [64,65] and commensal [66] microbiota of the small intestine, without altering the bacterial load. Furthermore, these changes alter the responsiveness of the immune system [66]. In addition to antimicrobial proteins, Paneth cells also secrete inflammatory cytokines including TNF-α [67], IL-17 [68], and IL-23 [69], supporting an important role for Paneth cells in innate immune function [70].

18.4.3 Enteroendocrine Cells

In addition to goblet cells and Paneth cells, enteroendocrine cells comprise the third terminally differentiated cell type of the secretory lineage derived from *Lgr*5-positive progenitor cells. The gastrointestinal tract is the largest endocrine system in the body and produces more than 20 hormones, peptides, and growth factors that detect and integrate signals from the luminal environment and manifest responses via autocrine and paracrine signaling mechanisms [71,72]. These secretory products are synthesized, stored, and secreted into the lumen by approximately 10 enteroendocrine cell subtypes in the intestine, several of which express multiple functionally related secretory products. The peptide hormones

most frequently coexpressed and secreted by enteroendocrine cells of the intestinal epithelium are cholecystokinin, gastric inhibitory polypeptide, glucagon-like peptide-1, neurotensin, peptide YY (PYY), and secretin [73,74]. The epithelial cells that produce these peptide hormones are derived from a common lineage and are specific to the intestine. In contrast, somatostatin-producing delta (D) cells and serotonin-producing enterochromaffin (EC) cells are found throughout the entire gastrointestinal tract. The spatiotemporal differentiation of enteroendocrine cells in the gastrointestinal tract provides an excellent example of cell fate determination governed by specific networks of transcription factors [75]. Enteroendocrine cells are derived from progenitor cells that express the basic helix–loop–helix (bHLH) transcription factor neurogenin 3 (Neurog3) and downstream transcription factors that contribute to subsequent subspecialization [76]. The fate of intestinal-specific enteroendocrine cells depends on coordination of the transcription factors aristaless-related homeobox (Arx) [76,77] and paired box 4 (Pax4) [76]. In contrast, differentiation of D cells and EC cells results from Pax4 expression alone [76]. Peptide hormones secreted from enteroendocrine cells are capable of acting locally or at distant sites in the body and can coordinate immune responses in the presence of commensal and pathogenic bacteria or their metabolites, nutrients, or other secretory products in the lumen via activation of receptors expressed on their apical surface [70].

18.5 The Epithelium: The Sum is Greater than its Parts

The epithelial cells lining the surface of organs must work together to achieve their unique functions. The epithelium is polarized with specific transporters and receptors at both the apical and basolateral surfaces of individual epithelial cells, while the space between cells is sealed with paracellular/intercellular junctional proteins, including tight junctions, adherens junctions, and desmosomes [78,79]. These junctional proteins form complexes between cells that are critical for the protective functions of the epithelium. Adherens junctions are found in all epithelial linings throughout the body and provide adhesive interactions between epithelial cells as well as contribute to the orientation of the apical–basal polarity axis [4,80]. Their structure is based on epithelial (E)-cadherin-dependent intercellular interactions and the actin–myosin cytoskeleton of neighboring epithelial cells [80]. Adherens junctions are located between adhesive plaque-containing desmosomes facing the basolateral domain of the plasma membrane and the tight junction facing the luminal surface of the epithelium, at the interaction of the apical and basolateral surface between adjacent epithelial cells [81]. Based on its structural orientation and function, the tight junction has been referred to as the "gatekeeper of the paracellular pathway" [78]. In contrast to the adherens junctions, tight junctions are not required for the polarized distribution of membrane proteins [82] or establishment of epithelial apical–basal polarity [4] but are necessary for the regulation of paracellular ion, solute, and water transport across the epithelial surface [83]. Tight junctions are comprised of many individual proteins, with three integral membrane proteins most critical to the regulation of epithelial permeability [78]. Occludins and members of the diverse

family of claudin proteins are key structural elements in a series of parallel tight junction strands linking the plasma membranes of adjacent epithelial cells [84]. A logarithmic relationship exists between the number of these tight junction strands and the permeability of the epithelial barrier [85]. At present, more than 20 isoforms of the claudin family have been identified [86], and these can be classified as pore-forming or barrier-forming, thus playing a critical role in the determination of tight junction permeability [87]. The third integral membrane protein component of the tight junctional complex is the immunoglobulin superfamily molecule junctional adhesion molecule (JAM)-1, thought to contribute to the innate immune function of the epithelium for its role in leukocyte trafficking [88,89].

Transepithelial transport of the epithelial barrier represents the sum of the paracellular transport mechanisms described above as well as transcellular transport via transporters and carriers located on the epithelial cell membrane. Transcellular transport allows for import of molecules from the lumen via specialized transporter proteins expressed on the cell apical surface, while export occurs via transporters on the basolateral membrane. Consistent epithelial cell polarity is critical to transcellular transport, as directed in part by paracellular transport mechanisms. Net ion, small molecule, and nutrient transport across the intestinal epithelium can be studied experimentally using chambers to measure short-circuit current (I_{sc}) as an indicator of transepithelial electrical resistance [90].

18.6 Epithelial Homeostasis: Maintaining the Balance

Epithelial cells are presented with a variety of potential threats to homeostasis on a continuous basis, including bacterial invasion, changes in pH and temperature, mechanical stress, and inflammation due to infection or disease processes. Epithelial homeostasis is the physiological equilibrium that exists between epithelial cell proliferation, migration, and differentiation of pluripotent stem cells and subsequent apoptosis of epithelial cells [91]. As discussed above, terminally differentiated epithelial cells in the intestinal epithelium (with the exception of Paneth cells) are constantly renewed within days [11,12]. Recent advances in the understanding of these processes are owed in part to the identification of *Lgr5* as a specific marker of intestinal stem cells [6] and have revealed the involvement of several key signaling mechanisms. Alterations in these highly conserved pathways also often underlie the pathophysiology of inflammatory diseases involving epithelial cells throughout the body.

18.6.1 Wnt Signaling

Intestinal epithelial cells proliferate in the base of the intestinal crypts via the highly conserved canonical Wnt signaling pathway. β-catenin-dependent Wnt signaling is initiated when an extracellular Wnt ligand binds to one of the frizzled family of receptors [92] and a low-density lipoprotein receptor-related protein (LRP)-5 or LRP-6 coreceptor [93–95], creating a Wnt–receptor complex. The

formation of this Wnt–receptor complex stabilizes and prevents phosphorylation of the key cytoplasmic protein β-catenin, thus allowing it to accumulate in the cell nucleus and subsequently activate downstream target genes [96,97]. In addition, several extracellular cysteine-rich glycoproteins function as antagonists of the Wnt pathway, including the family of secreted Frizzled-related protein (sFRP) [98,99] and Wnt inhibitory factor (WIF)-1 [100]. These secreted proteins inhibit Wnt signaling through competitive binding and interaction with other secreted proteins [101]. Both activators and inhibitors of the Wnt pathway are critical for normal rates of cell proliferation; a reduction in Wnt signaling leads to a decrease in the proliferative capacity of the intestinal epithelium, while sustained Wnt signaling results in hyperproliferation of epithelial progenitors [102]. Furthermore, a series of key experiments have illustrated that when Wnt signaling is inhibited, there is a reduction of terminally differentiated epithelial cells of the secretory lineage (goblet cells, Paneth cells, and enteroendocrine cells), thus disrupting the functional capacity of the intestinal epithelium [103–105].

Recently, key advances in understanding the proliferation, cell fate and differentiation of intestinal stem cells have been made in large part to demonstration of a three-dimensional polarized epithelium grown from individual *Lgr5*-positive stem cells *in vitro* [106]. These technical advances have allowed for experimental interventions and manipulations not previously possible. The first such studies from the laboratory of Hans Clevers showed that intestinal epithelial stem cells cultured with EGF, the bone morphogenetic protein antagonist Noggin, and the Wnt agonist R-spondin-1 could give rise to intestinal organoids displaying the crypt-villus structure *in vitro*, representative of the normal intestinal epithelium [106]. Subsequent studies showed that coculture of this organoid system with differentiated Paneth cells improved organoid formation in culture [107], highlighting the importance of this cell type in the stem cell niche and maintenance and renewal of the intestinal epithelium. As discussed previously, Paneth cells are the only terminally differentiated intestinal epithelial cell to remain in the crypt base, where they lie in close approximation to *Lgr5*-positive stem cells. In addition to secreted antimicrobial proteins, Paneth cells also synthesize and secrete EGF, Wnt ligands, and delta-like ligands of the Notch signaling pathway, which are necessary to support proper functioning of the stem cell microenvironment [107].

18.6.2 Notch Signaling

Commitment to an epithelial cell lineage is another critical element of a properly functioning intestinal epithelium. Appropriate representation of each subtype of terminally differentiated epithelial cells is regulated in part by Notch signaling [108]. The highly conserved Notch signaling pathway underlies broad functions throughout the body and is dependent on cell-to-cell interactions that impact intracellular responses, including inhibiting the differentiation of the secretory cell lineage [109]. Notch is a single-pass transmembrane receptor with a large extracellular domain [110]. The Notch receptor is activated when selective ligands such as mammalian Delta-like and Jagged-1 are secreted from a

neighboring cell, leading to a conformational change and subsequent proteolytic cleavage of the Notch receptor. This results in dissociation of the Notch intracellular domain (NCID), which then translocates to the cell nucleus and modulates downstream target genes and cell processes via binding to the DNA-binding transcription factor RBPj [110]. Math1, a bHLH transcription factor that is a critical regulator of cell fate throughout the body, is required for differentiation of goblet cells, Paneth cells, and enteroendocrine cells from progenitor cells in the intestinal epithelium [111–113]. Notch signaling represses Math1 via activation of the Hes1 transcriptional repressor, limiting differentiation of epithelial cell precursors to the secretory lineage and the associated increase in absorptive enterocytes [109,114]. In instances where Notch receptor expression is low or signaling is inhibited, increased expression of the ligand Delta-1 represses Hes1, thus Math1 levels remain high and cells are able to differentiate into secretory goblet cells, Paneth cells, and enteroendocrine cells.

In addition to an active role in regulating the balance between secretory and absorptive cell differentiation in the intestinal epithelium, the Notch signaling pathway has additional important roles in promoting intestinal epithelial homeostasis. For example, mice with a targeted deletion of the Notch transcription factor RBPj in intestinal epithelial cells show compromised intestinal permeability and develop spontaneous inflammation due to bacterial translocation [115]. This study provides direct evidence for a loss of homeostatic regulation and subsequent dysbiosis resulting from altered Notch signaling. This provides a potential mechanism for immune activation and the development of chronic inflammation due to altered intestinal epithelial cell function and compromised epithelial integrity.

18.6.3 Inflammation-induced Alterations in Epithelial Cells

The signaling mechanisms described above are key to the development and maintenance of epithelial cell homeostasis, yet in situations where the epithelial barrier is impaired and constitutive regulatory mechanisms fail, activation of compensatory responses are required to defend against damage to the host. The etiologies of chronic inflammatory conditions involving the intestinal epithelium such as Crohn's disease and ulcerative colitis, collectively known as Inflammatory Bowel Disease (IBD), are not fully understood but thought to involve an overactive immune response to commensal bacteria mediated in part by a defective epithelium [116]. These responses are associated with subsequent activation of the innate and acquired immune systems, resulting in proinflammatory cytokine release and altered barrier function.

A key feature of the innate immune response during inflammation is the early recruitment of neutrophils [117]. During acute inflammation, migration of neutrophils from the systemic circulation into the inflamed tissue and organs is a protective response against host damage [118]. Recruitment of neutrophils and other immune cells to the site of injury occurs through chemotaxis, which is regulated in large part, by the family of C-X-C motif (CXC) ligand 1 chemokines [119]. Beyond their role in initiating the acute immune response, neutrophils also play a predominant role in the pathophysiology of chronic

inflammatory diseases such as IBD. In Crohn's disease patients, the degree of neutrophil infiltration in the lamina propria of the inflamed intestine is correlated with the severity of disease [120]. Once present at the site of inflammation, neutrophils release proinflammatory cytokines and antimicrobial proteins to shape local innate immune responses. Cathelicidins are a family of antimicrobial proteins released by neutrophils and epithelial cells that are similar in function to defensins [53]. Cathelicidins can be released in response to activation of TLRs by bacteria or bacterial metabolites such as short-chain fatty acids [121] and have been associated with increased mucus release and decreased intestinal epithelial cell apoptosis in mouse studies of experimental colitis [52]. Furthermore, cathelicidins promote intestinal epithelial barrier integrity and wound healing [52,122]. Human cathelicidin LL-37 expression is increased in patients with ulcerative colitis, but not Crohn's disease [123], suggesting that cathelicidins and antimicrobial proteins may underlie distinct and disease-specific host defense mechanisms.

Altered Paneth cell expression has also been noted in patients with intestinal inflammation, with increased expression of the Paneth cell secretory products human alpha-defensin (HD) 5 [124,125] and sPLA2 [126,127] in the colonic epithelium of IBD patients. Under normal conditions, Paneth cells are not found in the colonic epithelium; however, studies in IBD patients illustrate that the degree of Paneth cell metaplasia is directly correlated with the extent of colonic inflammation [126]. Similar to cathelicidins, alpha-defensins are synthesized and released from a variety of cell types in addition to Paneth cells, namely, enterocytes and neutrophils [128]. Alpha-defensins can alter cytokine release from epithelial cells, thus linking defense mechanisms of the innate and acquired immune systems [129,130]. Furthermore, patients with Crohn's disease involving the small intestine have decreased HD5 and HD6 expression as compared to control patients [131] and exogenous HD5 can improve experimental colitis *in vivo* [132]. Interestingly, patients with Crohn's disease of the large intestine have reduced expression of the functionally related beta-family of defensins [133]. Constitutive expression of beta-defensins in colonic epithelial cells is maintained by the nuclear receptor peroxisome proliferator-activated receptor gamma (PPARγ) [134]. The release of proinflammatory cytokines is regulated in part by the nuclear factor (NF)-kappa B pathway, and beta-defensins can inhibit cytokine expression by preventing phosphorylation of the NF-kappa B subunit p65 [135], consistent with an anti-inflammatory role for these antimicrobial proteins. In addition, beta-defensins increase tight junction protein and mucin expression and decrease intestinal epithelial cell apoptosis during acute inflammation [135].

Several distinct changes reflecting altered epithelial cell differentiation and function have been associated with intestinal inflammation and IBD, reflecting cross-talk between the immune system and the epithelial cells in addition to roles as the first-line defenders against luminal threats. Changes in goblet cells have been noted in the intestinal epithelium of patients with IBD using scanning electron microscopy, including a decrease in MUC2 expression levels [136]. Furthermore, mice with decreased mucus due to a genetic deletion of the *Muc2* gene have increased disease activity and epithelial damage compared to control

mice during early experimental colitis [137], suggesting that a reduction in goblet cell function may contribute to the onset of intestinal inflammation. In addition, recent data suggest a role for goblet cells as luminal sensors for the interface between the innate and the adaptive immune systems, directly sampling antigens from the intestinal lumen and delivering them to dendritic cells in the adjacent lamina propria [138].

18.7 Concluding Remarks

Epithelial cells, regardless of their location in the body, serve similar functions to maintain the integrity of the barrier and promote homeostasis both locally and throughout the body. This requires complex interplay between several subtypes of epithelial cells and maintenance of the connections between adjacent cells. Under normal conditions, tight regulation of epithelial cell proliferation, differentiation, and migration is maintained by several conserved signaling pathways. In the presence of inflammation or disease, epithelial cells must mount rapid responses to the immune system and between individual epithelial cell subtypes to initiate regeneration and repair mechanisms in an effort to minimize damage to the host. Future efforts in the field of epithelial cell signaling and inflammation must focus on identification of new targets to restore normal functioning and homeostasis to limit the development and the consequences of chronic injury or disease.

Inflammation: The Role of Endothelial Cells

J. Steven Alexander, D. Neil Granger, and Norman R. Harris

Louisiana State University Health Sciences Center-Shreveport, Department of Molecular & Cellular Physiology, 1501 Kings Highway, Shreveport, LA 71130-3932, USA

19.1 Introduction

Inflammation is an underlying component of a variety of human diseases, ranging from arthritis, inflammatory bowel disease (IBD), atherosclerosis, and sickle cell disease, to ischemic stroke. A common and critical feature of the inflammatory response in these conditions is endothelial cell dysfunction, which plays an important role in both the initiation and the perpetuation of inflammation. The endothelial cell dysfunction is evidenced in all three segments of the microcirculation and is manifested as an altered capacity of arterioles to dilate, the adhesion of leukocytes and platelets in venules, enhanced coagulation and thrombogenesis, an increased vascular permeability to water and plasma proteins, and increased rates of blood (angiogenesis) and lymphatic (lymphangiogenesis) vessel proliferation (Figure 19.1). The major consequences and benefits of these responses include (1) an enhanced delivery of inflammatory cells and immunoglobulins to the injured/infected tissue, (2) dilution of the injurious/inciting agents in the affected region, (3) isolation of this region from healthy tissue and the systemic circulation, and (4) setting the stage for the regenerative process. Functional changes in the microvasculature are evident during the acute phase of the inflammatory response, that is, within minutes to hours after initiation of the response. However, structural alterations (e.g., increased numbers of blood and lymph vessels) are manifested during the chronic phase of the inflammatory response, that is, days after the initial inflammatory insult [1,2].

Inflammatory reactions and the associated endothelial cell responses are usually short-lived and result in a protective response. However, under certain pathological conditions, excessive and/or prolonged inflammation can lead to extensive tissue damage, organ dysfunction, and mortality. A notable example of such a pathological condition is the IBDs, which include Crohn's disease and ulcerative colitis. These diseases affect millions of individuals worldwide, with the highest incidence and prevalence reported for westernized nations. Furthermore, epidemiological evidence suggests that the global prevalence of IBD will continue

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

to increase substantially [3]. While it has been proposed that IBD involves a complex interplay among immune, genetic, and environmental factors, the etiology of these inflammatory diseases remains poorly understood. However, there is a large and growing body of evidence from patients with, and animal models of, IBD that implicate a role for the microcirculation and endothelial cell dysfunction in the pathogenesis of these diseases [1,2]. This chapter provides a summary of the endothelium-dependent responses that accompany inflammation, using IBD as a prototype for pathologic conditions that manifest both acute and chronic inflammatory responses.

19.2 Vasomotor Dysfunction

The term vasomotion refers to relaxation or contraction of the smooth muscle cells that surround blood vessels, causing vasodilation or vasoconstriction, respectively. Vasomotion is an important regulator of blood flow to an organ or local tissue, with changes in flow being a necessary response to the requirement for oxygenation, nutrient delivery, and removal of metabolites in tissues. Vasomotor dysfunction refers to an inappropriate regulation of vascular diameter that results from, or contributes to, tissue pathology. In most instances, the

vessels of interest in vasomotor dysfunction are the arterioles, which are called the "resistance vessels" because they are the most influential vessels in controlling the conductance or resistance of tissue perfusion. Flow through a vessel is equal to the pressure gradient (inlet minus outlet) divided by the vascular resistance, with the latter being inversely proportional to the fourth power of diameter. Therefore, even a small change in arteriolar diameter can cause a substantial change in blood flow.

19.2.1 Mechanism of Vascular Smooth Muscle Contraction/relaxation

As with smooth muscle in general, vascular smooth muscle contraction is regulated by the influx of calcium into the cell. Calcium can enter the cytosol through various channels on the outer cell membrane and on the membrane of the intracellular sarcoplasmic reticulum. The entering calcium binds to calmodulin, with the calcium–calmodulin complex activating myosin light chain kinase (MLCK), which can then phosphorylate myosin. The phosphorylation of myosin is critical for binding to actin to cause contraction, which in turn is terminated by dephosphorylation via the enzyme myosin phosphatase. Relaxation of vascular smooth muscle is promoted not only by removal of calcium from the cytosol (by active transport pumps leading back into the sarcoplasmic reticulum or extracellular fluid), but also by inhibition of MLCK. Two inhibitors of MLCK are cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), which is controlled in part by mediators released by the inner layer of the blood vessel, the endothelial cells.

19.2.2 Endothelial Cell-dependent Vasoactivity

The endothelium produces several mediators that contribute to the tone of the adjacent vascular smooth muscle cells. The three main endothelium-dependent vasodilators include nitric oxide (NO), prostacyclin (PGI_2), and endothelium-dependent hyperpolarizing factor (EDHF). Although not a complete list, endothelial cell-derived vasoconstrictors include superoxide, thromboxane A_2 (TxA_2), and endothelin-1 (ET-1).

NO is produced from L-arginine with the aid of NO synthase, which is an enzyme that also can produce the superoxide radical under certain situations (such as substrate or cofactor depletion). Endothelial NO induces vascular dilation by increasing intracellular levels of cGMP in the adjacent smooth muscle. Superoxide can limit NO bioavailability due to the rapid reaction between the two, which results in the formation of peroxynitrite.

Vasomotor tone is often discussed in terms of the balance between NO and superoxide; however, another pair of mediators, TxA_2 and PGI_2, can also create a balance between constriction and dilation. TxA_2 and PGI_2 are both formed during the breakdown of arachidonic acid, which can also yield other prostaglandins. TxA_2 and PGI_2 are often described together in terms of their relative production rates, as their precursor (prostaglandin H_2) can produce either the vasodilator (PGI_2) or the vasoconstrictor (TxA_2), depending in part on the levels of their respective synthases. PGI_2 induces dilation by enhancing smooth muscle

cAMP, whereas TxA_2 causes constriction through an increase in intracellular calcium concentration and enhanced calcium sensitivity.

19.2.3 Endothelium-dependent Vasoactivity in IBD

Vasomotor dysfunction has been documented in patients with IBDs, with the dysfunction involving endothelium-dependent pathways of control. Intestinal blood flow can be altered substantially by chronic gut inflammation. However, the nature and magnitude of the change in intestinal blood flow appear to depend on the phase of progression of the inflammatory response. During the early "exudative" phase of colonic inflammation in patients with either ulcerative colitis (UC) or Crohn's disease (CD), colonic blood flow (especially in the mucosal and submucosal layers) is increased significantly (two–sixfold) [4]. However, in the late "fibrosing" phase of the disease, colonic blood flow is reduced below normal. A reduction in blood flow also has been reported in colonic arterioles of mice in which experimental colitis was induced by either dextran sodium sulfate (DSS) or T-cell transfer into immunodeficient mice [5,6]. However, despite the arteriolar constriction and lower blood flow rates in the individual microvessels, overall blood flow rates to the ileum and colon in both models were only marginally reduced as a result of an approximate twofold increase in vascular density [5–9]. A subset of mice in the T-cell transfer model of colitis does exhibit a significantly reduced overall blood flow, and this is accompanied by mucosal hypoxia and only mild signs of inflammation [10]. In addition, there is evidence that leukocytes recruited into the inflamed bowel may also influence vasoactivity. In a T-cell transfer model of chronic colitis, an association was found between vasodilation of first-order colonic arterioles and venules with the number of circulating leukocytes [11]. However, it should be noted that the dilation was not accompanied by an increase in colonic blood flow, possibly due to the constriction of smaller arterioles mentioned earlier [5].

Studies on colonic arterioles obtained from patients with IBD and from animal models of experimental colitis have revealed an impaired ability of the resistance vessels to respond to endothelium-dependent vasodilators [6,12,13]. The arteriolar dysfunction measured in vessels derived from IBD patients is severe, with acetylcholine-induced dilation reduced to only about 10% of the response measured in normal arterioles. The impaired vasodilatory response appears to result from a reduced ability of arteriolar endothelial cells (ECs) to produce NO, rather than PGI_2. The NO deficiency results from excessive levels of superoxide, which (as mentioned above) rapidly reacts with and inactivates NO, thereby inhibiting smooth muscle relaxation [6,12,13]. The impaired dilation appears to be a consequence of endothelial dysfunction, since vascular smooth muscle function appears to remain unchanged [14]. In addition, recent work has implicated circulating microparticles (which are elevated in plasma of CD patients) in the impaired flow (and NO)-dependent dilation that accompanies IBD [15].

The changes in colonic blood flow in IBD patients also may reflect an altered production of endogenous vasoconstrictors [2,9]. Several reports describe elevated levels of TxA_2 and/or TxA_2 synthase in the colon of IBD patients, with a correlation noted between TxA_2 synthase and disease activity. It remains to be

determined whether TxA_2-induced vasoconstriction contributes to disease progression since TxA_2 synthase inhibitors have shown little benefit in promoting or maintaining remission of IBD. Angiotensin II and ET-1, two other endogenous vasoconstrictors produced by the gut, also are elevated in the colonic mucosa of CD patients [2]. Endothelin-1 has been implicated in the tissue hypoxia that occurs during the ischemic phase of IBD progression [16].

19.2.3.1 Leukocyte– and Platelet–endothelial Cell Adhesion

Leukocyte–endothelial cell adhesion is a long recognized and well-characterized feature of the inflammatory response. This interaction between leukocytes and vascular endothelial cells is observed in postcapillary venules and underlies the recruitment of inflammatory cells to sites of infection and/or tissue injury [17,18]. An important determinant of whether leukocytes adhere to vascular endothelium is the proadhesive force that is generated by adhesion molecules expressed on the surface of both activated endothelial cells and leukocytes. Data derived from both *in vitro* (isolated leukocytes binding to monolayers of cultured endothelial cells) and *in vivo* (intravital microscopic examination of venules) models of leukocyte–endothelial cell adhesion have revealed the relative contributions of different leukocyte and endothelial cell adhesion molecules (CAMs) to the adhesion responses elicited by various inflammatory stimuli [1]. The endothelial cell adhesion glycoproteins that have been implicated in the recruitment of leukocytes in inflamed colonic venules, their ligands (counterreceptors) on leukocytes, and the type of adhesive interaction mediated by the glycoprotein pairs are summarized in Table 19.1. A time-dependent increase in the expression of P- and E-selectin, ICAM-1, VCAM-1, and MAdCAM-1 has been demonstrated in the colonic vasculature of mice with experimental IBD [2,18]. Mucosal biopsy samples derived from patients with active (but not quiescent) ulcerative or Crohn's colitis exhibit similar changes in the expression of endothelial cell adhesion molecules [2,18].

The increased expression of adhesion molecules on colonic endothelial cells is associated with the recruitment of large numbers of rolling, firmly adherent, and

Table 19.1 Endothelial cell adhesion molecules: ligands and functions.

Adhesion Molecule	Leukocyte Receptors	Adhesion Response
P-selectin	L-selectin, PSGL-1	Rolling
E-selectin	L-selectin	Rolling
ICAM-1	CD11/CD18	Adherence, emigration
VCAM-1	VLA_4	Adherence, emigration
MAdCAM-1	Alpha4beta7	Adherence, emigration
PECAM-1	PECAM-1	Emigration

ICAM-1 = intercellular cell adhesion molecule-1; PSGL-1 = P-selectin glycoprotein ligand; VCAM-1 = vascular cell adhesion molecule-1; VLA_4 = very late antigen-4; MAdCAM-1 = mucosal addressin cell adhesion molecule-1; PECAM-1 = platelet endothelial cell adhesion molecule-1.

emigrated (extravasated) leukocytes within (and surrounding) inflamed venules [17,18]. Both leukocyte and endothelial cell adhesion molecules participate in slowing the leukocyte as it exits the capillary and enters the postcapillary venule. The initial low-affinity interaction between leukocytes and venular endothelium is manifested as a rolling behavior. Rolling leukocytes can then become firmly adherent (stationary) to endothelial cells, where the process of transendothelial leukocyte migration can occur when chemotactic signals (e.g., leukotriene B_4) are generated in the perivascular compartment or chemokines presented on the endothelial cell surface. Each of the three stages of leukocyte recruitment, that is, rolling, firm adhesion (adherence), and transendothelial migration, involves the participation of different adhesion molecules, (Table 19.1). The critical importance of adhesion molecules in the genesis of experimental IBD is evidenced by a number of studies demonstrating attenuated inflammatory and tissue injury responses in mice that are genetically deficient in specific leukocyte or endothelial cell adhesion molecules and in animals treated with blocking antibodies directed against these adhesion glycoproteins [1,18].

A number of factors are known to modulate leukocyte–endothelial cell adhesion during inflammation by affecting either the intensity of adhesion molecule expression and/or the ability of these glycoproteins to sustain strong adhesive interactions between the blood cell and the vascular endothelium. Nitric oxide, adenosine, and prostacyclin produced by endothelial cells tend to prevent leukocyte adhesion in the microvasculature, while reactive oxygen species (superoxide, hydrogen peroxide, etc.) produced by activated leukocytes and endothelial cells appear to promote adhesion [17,18]. These endogenous regulators of leukocyte adhesion exert either a direct or an indirect (i.e., altering the production of inflammatory cytokines) effect on the production and expression of endothelial adhesion molecules. Some proadhesive agents, such as histamine, platelet activating factor, and IL-8, rapidly (within 2–3 min) increase the level of activation and/or expression of adhesion molecules on leukocytes (e.g., CD11b/CD18) and/or endothelial cells (e.g., P-selectin), while other agents, such as cytokines, act more slowly to promote leukocyte adhesion by enhancing the transcription-dependent expression of adhesion molecules that prolong the leukocyte rolling (E-selectin) and adherence/emigration (ICAM-1) responses [17,19].

The transcription-dependent expression of endothelial cell adhesion molecules has been linked to specific nuclear transcription factors, most notably nuclear factor kappa-B (NF-κB) and activation protein-1 (AP-1) [17,20]. Both factors represent families of polypeptides with related DNA-binding activity but distinct transactivating potential. NF-κB activation is triggered by the phosphorylation and subsequent conjugation of IκB with ubiquitin, which makes IκB-α (an inhibitory protein that prevents nuclear transport and DNA binding of NF-κB) vulnerable to degradation by the proteasome proteolytic pathway. Point mutations that decrease NF-κB binding to κB response elements result in diminished cytokine-induced E-selectin expression on cultured endothelial cells, suggesting that NF-κB plays an important role in cytokine induction of the E-selectin gene [20]. However, the increased ICAM-1 expression in endothelial cells exposed to hydrogen peroxide [21] appears to be mediated through AP-1 and independent of κB elements [21,22]. Proteasome inhibitors (which prevent the

degradation of IκB and subsequent activation of NF-κB) have been shown to blunt the increased ICAM-1 expression and inflammatory response in animal models of IBD [23].

Nitric oxide, adenosine, and prostacyclin are also potent vasodilators, which raises the possibility these agents also blunt leukocyte–endothelial cell adhesion by altering shear forces generated by the movement of blood through the microvasculature [17]. The number of rolling and adherent leukocytes recruited in inflamed venules is inversely related to wall shear rate, suggesting that it is easier for leukocytes to create strong adhesive bonds with endothelial cells at low shear rates and that high shear rates likely prevent the creation of such bonds. This dependency of leukocyte adhesion on shear rate suggests that the changes in blood flow associated with inflammation may significantly influence the intensity of leukocyte recruitment during IBD [17,24].

Platelets also accumulate in the microvasculature of the inflamed colon [25,26]. The adhesion of platelets to the walls of colonic venules appears to reflect binding to activated endothelial cells rather than adhesion to the collagen-rich subendothelial surface of damaged blood vessels. Intravital microscopic evaluation of platelet binding in inflamed colonic venules has revealed that a relatively small proportion (<10%) of the platelets bind directly to endothelial cells, while most platelets attach to leukocytes that are already bound to the surface of endothelial cells [27]. P-selectin blockade effectively inhibits both the leukocyte-dependent and -independent components of platelet adhesion in colonic venules of colitic mice, suggesting that P-selectin (whether expressed on the platelet or endothelial cell) contributes to both recruitment processes. While platelet binding to endothelial cells is not affected by ICAM-1 or CD18 immunoblockade, the accumulation of leukocyte-bound platelets is dramatically reduced. The findings are consistent with a model wherein leukocytes require P-selectin to roll on venular endothelium and subsequently establish firm adhesion via CD18-ICAM-1 interactions. The adherent leukocytes, which constitutively express PSGL-1, then create a platform onto which platelets can bind using P-selectin [27]. Similar P-selectin (platelet-associated)–PSGL-1 (leukocyte-associated) interactions may also account for the platelet–leukocyte aggregates that are detected in blood of IBD patients. Platelet recruitment into inflamed microvessels may be important because, upon activation, platelets produce/release a variety of proinflammatory mediators (e.g., CD40 L, RANTES, etc.) that can stimulate the production/expression of adhesion molecules on endothelial cells.

19.2.3.2 Enhanced Thrombosis

Another manifestation of the vascular changes and endothelial cell dysfunction that accompanies inflammation is enhanced thrombus development. This response is likely a reflection of the relatively new concept that inflammation and thrombosis/coagulation are interdependent processes that can initiate a vicious cycle wherein each process propagates and intensifies the other [28,29]. Thrombosis and thromboembolism are a significant cause of morbidity and mortality in IBD patients. Clinical studies reveal that the incidence of thrombotic events in IBD patients is ~6.2%, with a 3.6-fold increase in the risk for thrombotic complications compared to the general population [29,30]. A much higher

incidence of systemic thrombotic events (41%) is predicted from postmortem studies. Both the arterial and venous circulations appear to be involved in IBD-associated thrombosis, although venous complications (e.g., mesenteric venous thrombosis) occur more frequently. The thrombotic responses are most commonly manifested as deep vein thrombosis (DVT) or pulmonary embolism (PE), although thromboses have been detected in other regional circulations, including brain, retina, and liver [29].

Endothelial cell dysfunction, platelet abnormalities, and activation of the coagulation cascade have all been implicated in the enhanced thrombosis that accompanies IBD [26]. The altered platelet function that occurs during IBD is manifested as thrombocytosis (resulting from enhanced thrombopoiesis), hyperreactivity to agonist stimulation (e.g., thrombin, ADP, etc.), and hyperaggregability (both homotypic and heterotypic) [26,29]. Intravascular platelet aggregates are detected in mucosal biopsies from patients with ulcerative colitis, and the number of platelet aggregates in mesenteric venous blood is increased in IBD. The enhanced reactivity and aggregability of platelets in IBD are accompanied by evidence of significant systemic activation of the coagulation system. The anticoagulant capacity of endothelial cells is diminished during inflammation, which is manifested as an increased expression of tissue factor and inhibition of the protein C pathway [29–31]. The inactivation of nitric oxide by superoxide has also been implicated in the prothombotic phenotype assumed by endothelial cells during inflammation. Collectively, the functional abnormalities that are manifested by both platelets and endothelial cells during inflammation appear to tip the balance between pro- and anticoagulant mechanisms in favor of thrombus formation.

The hemostatic alterations and endothelial cell dysfunction reported in IBD patients are recapitulated in animal models of these diseases [26,29]. Mice with experimental colitis also exhibit an increased vulnerability to microvascular thrombus formation in vascular beds that are distant from the inflamed bowel. While the enhanced thrombosis in experimental IBD is evidenced in both arterioles and venules, the former exhibit a more consistent and pronounced response [32]. Animal studies have revealed a role for different pro- (e.g., thrombin, tissue factor) and anticoagulants (activated protein C) in the thrombogenic responses to IBD. Tissue factor (TF) immunoblockade experiments in animal models of IBD have revealed an important role for TF in the initiation of thrombus development in DSS colitis, since TF antibody treatment effectively reversed the enhanced onset time (which reflects the initiation phase of thrombogenesis) for thrombus formation in arterioles without altering the time for complete flow cessation (which reflects the propagation/stabilization phases of thrombogenesis). However, transgenic mice that overexpress the endothelial protein C receptor show a significantly attenuated thrombosis response, reflected as a prolonged time to flow cessation, during experimental IBD. Activated protein C (APC) was also shown to protect wild-type colitic mice against thrombosis, while an anti-APC antibody enhanced thrombus formation [33]. Collectively, these findings suggest that TF activation underlies the initiation of thrombus formation and that a blunted production of APC by endothelial cells contributes to the propagation of the thrombogenic response to inflammation.

Cytokines, which are produced and released in high quantities in the inflamed colon, have been implicated as mediators of the distant organ thrombosis response to colonic inflammation. IL-1β, TNF-α, and IL-6 have all been implicated in the accelerated thrombus formation. All three cytokines promote thrombosis, in a dose-dependent manner, when administered at pathophysiologically relevant concentrations. Immunoblockade of either IL-1β or TNF-α, as well as genetic deletion of their receptors, results in a blunted colitis-enhanced thrombosis response. When both cytokines are simultaneously blocked, a more pronounced protective response is achieved, compared to blocking either cytokine alone [26]. Both IL-1β and TNF-α are known to promote the biosynthesis of IL-6, a potent prothrombogenic agent that has been implicated in the coagulopathy of sepsis. Chronic (more than 5 days) administration of IL-6 in otherwise normal mice produces a prothrombotic phenotype that resembles experimental colitis, with an accelerated thrombosis response that is largely evident in arterioles. Furthermore, the colitis-enhanced thrombogenic response is largely prevented in IL-6-deficient mice or following immunoblockade of the IL-6 receptor in wild-type mice in WT mice [34,35].

19.2.3.3 Angiogenesis/vasculogenesis

Angiogenesis, the generation of new blood vessels from existing networks, vasculogenesis, the generation of vascular structures from endothelial progenitor cells, and lymphangiogenesis, the formation of new lymphatic vessels and patterns of vascular remodeling are well-recognized responses of the gut to IBD [36,37]. Although the increased vascular density produced by angiogenesis/vasculogenesis in IBD might be anticipated to improve transport function, angiogenesis in IBD is largely maladaptive and enhances disease severity by activating or intensifying several cellular and molecular inflammatory programs. Consequently, VEGF-depleting antibodies (*bevacizumab* and *ranibizumab*) and reagents that inhibit vascular endothelial growth factor (VEGF) receptor tyrosine kinase signal transduction (*lapatinib*, *sunitinib*, *sorafenib*, *axitinib*, and *pazopanib*) are currently being considered as treatments for human IBD [38,39]. Mesalamine (5-aminosalicylate), a treatment currently used for UC, corrects imbalances in angiogenic and angiostatic regulators in this disease, an effect that at least partly explains its ability to reduce disease activity [40]. Conversely, while angiogenesis in IBD enhances disease activity, lymphatic expansion appears to offer some benefit in some phases of gut inflammation by creating conduits that facilitate the evacuation of accumulated interstitial fluid and immune cells from the inflamed intestine.

Several key cellular events are observed in both angio- and lymphangiogenesis, including proliferation of endothelial cells (in response to the abundance of growth factors and angiogenic stimuli in IBD), extracellular matrix remodeling, cell migration, and vessel maturation. The final events in vessel stabilization appear to be disturbed in IBD such that inflammatory angiogenesis (and lymphangiogenesis) provoke a persistently hyperadhesive, hypermotile, and dedifferentiated endothelial phenotype that is characterized by loss of low-density lipoprotein receptor with mobilization of several endothelial cell adhesion molecules that can bind immune cells and platelets. Vascular remodeling during

angiogenesis also disturbs junctional organization, which contributes to the increased vascular permeability that often accompanies IBD.

At the molecular level, angiogenesis is initiated by binding of VEGF ligands to VEGF receptors (VEGFRs), which are receptor tyrosine kinases expressed on the endothelial surface. Coreceptors for the VEGF/VEGFR complexes include neuropilins-1 and -2 as well as heparin sulfate proteoglycan. In addition, platelet endothelial cell adhesion molecule-1 (PECAM-1/CD31) and VE-cadherin and integrins also represent coreceptor components of a mechanotransduction signaling complex with VEGFR-2 that govern responses to fluid shear and coordinate interactions between flow, proliferation, and permeability [41].

The VEGFs potentially active in IBD include VEGF-A, B, C, D, and placental growth factor (PlGF) that interact with three VEGFRs: VEGFR-1 (also Flt-1), VEGFR-2 (KDR/Flk-1), and VEGFR-3 (Flt-4). Two additional VEGF isoforms also exist VEGF-E and –F, which are expressed by viruses and snake venoms, respectively. Angiogenesis in IBD is largely mediated by increased levels of VEGF-A, which is derived from both local sources (including intermittently ischemic enterocytes and stromal tissues) and infiltrating peripheral blood monocytes. Interactions between immune cells, platelets and intestinal endothelial cells can intensify angiogenic signaling. It has reported that platelets bound to TNF-α stimulated intestinal endothelium via ICAM-1, fractalkine, and αvβ3 integrin stimulate VEGF-A release and enhance the availability of sCD40 ligand, both of which mediate angiogenic signaling [42].

As the central angiogenic stimulus in IBD, VEGF-A not only activates endothelial cell proliferation but also mobilizes endothelial adhesion molecules, enhances leukocyte adhesion, and increases vascular permeability, which collectively increase disease severity [39]. VEGF-A induces the expression of ICAM-1, VCAM-1, and E-selectin on endothelial cells via NF-kB activation, which enhances immune cell binding (similar to TNF-α, β) synthesis [7,43]. VEGF-A-mediated activation of the adhesive endothelial phenotype seen during active IBD also appears to involve cyclooxygenase-2- and mitogen-activated protein kinase activation [44].

Although VEGF-A_{165} appears to represent the major angiogenic and pathological isoform of VEGF-A, several VEGF-A isoforms exist, and alterations in the ratios of active to inactive VEGF-A isoforms (e.g., VEGF-A_{165b}) may modulate angiogenesis, as well as vascular tone, leakage, remodeling, and leukocyte recruitment in IBD [37]. For example, intestinal recruitment of Mac-2^+ macrophages and neutrophils within colon follicular aggregates increases in experimental UC, during both acute and chronic phases of disease and this recruitment appears to depend on the ratio of active to inactive VEGF-A isoforms, since adenoviral induction of an inhibitory VEGF (VEGF-A_{164b}) reduced immune cell infiltration [37]. However, the available evidence suggests that polymorphisms in VEGF-A structure do not influence IBD induction, progression, or remission.

VEGF receptor signaling is highly complex, with VEGF receptors existing mainly as homodimers, although heterodimers of VEGR-1/2 and VEGFR-2/3 exist. VEGF coreceptors include the neuropilins -1 and -2 and heparin sulfate proteoglycan. Proteolytic modification of VEGFs (-C and -D) also controls ligand receptor preference. VEGF receptors -1 and -2 are found on blood vessel

endothelial cells and govern angiogenesis, while lymphangiogenic responses are mainly mediated by VEGFR-3 and VEGFR-2. VEGF receptors are also expressed in several other cells, including monocytes (VEGFR-1), adventitial and stromal cells (VEGFR-2 and VEGFR-3), and enterocytes (VEGFR-1), suggesting that VEGFs also contribute to extravascular forms of cell signaling regulation. While endothelial VEGFR-1 signaling can modulate immune cell recruitment, VEGFR-2 activity appears to represent the major form of VEGF signaling underlying most physiological blood vascular endothelial responses, as well as the pathological effects of VEGFs in IBD.

VEGF-A binding to VEGFR-2 (and the coreceptor neuropilin-1) activates several NF-kB-dependent gene programs, including endothelial cell adhesion molecules, matrix metalloproteinases (MMPs), and cyclooxygenases that contribute to the vascular disturbances in IBD. In addition to VEGF-A, many angiogenic stimuli and regulators including PlGF, VEGFR1, angiopoietin-2, and the Tie-2 receptor are also significantly elevated in CD [7,45,46]. Similarly, circulating levels of VEGF-A and VEGFR-1 are elevated in active UC, with VEGFR-2 receptor expression significantly increased in both clinical and experimental IBD [39].

In addition to the activity of members of the VEGF family in IBD-associated angiogenesis, hepatocyte growth factor (HGF), transforming growth factor-beta (TGF-β), fibroblast growth factor (FGF-2), and platelet-derived growth factor (PDGF) also regulate angiogenesis in IBD. Like VEGF, elevated circulating HGF levels appear to contribute to the microvascular proliferation and microvascular phenotypic alterations observed in IBD. HGF is released by the inflamed intestinal stroma and is post-translationally activated by HGF activator (HGFA) in response to thrombin generation in inflamed tissues. Unlike VEGF-A activity, however, HGF receptor activation may be beneficial in IBD by aiding in restitution of intestinal epithelia and by opposing thrombin-induced permeability changes.

PDGF is another growth factor that is elevated in IBD. PDGF is stored within and released by platelets, and is also synthesized by macrophages, smooth muscle cells, and endothelium. PDGF participates in attracting adventitial cells (pericytes and smooth muscle) to blood vessels and supports smooth muscle and mesenchymal proliferation, but it also contributes to fibrosis in IBD.

Although TGF-β normally functions as an anti-inflammatory growth factor whose levels are increased in IBD, TGF-β signaling can be compromised in IBD by Smad7, leading to unopposed induction and activation of inflammatory cytokines [47]. VEGF-A appears to regulate TGF-β release by enterocytes, which promotes intestinal homeostasis in an autocrine fashion [48]. Angiopoietins represent another class of growth factors that play important roles in angiogenesis during IBD. Endothelial cell signaling through the TEK/Tie-2 receptor modulates the maturation and stabilization of blood vessels via binding interactions with its ligands angiopoietins 1–4 [36]. While angiopoietins -1 and -4 are agonists of Tie-2-mediated phosphorylation, angiopoietins -2 and -3 antagonize the effects of angiopoietin-1. Ang-2 is stored within and released from endothelial Weibel–Palade bodies in response to PKC activation and acts as an autocrine antagonist of Ang-1. In this sense, Ang-2 plays important roles in releasing both blood and lymphatic vasculatures from their "stable" phenotype and allows them to enter

into angiogenic and inflammatory programs. Ang-1/Ang-2 ratios are low in CD, and Ang-2 gene depletion was found to limit both angio- and lymphangiogenesis, inflammation, and neutrophil infiltration into the gut in experimental ulcerative colitis [36].

Bacterial products and antigens are potent stimuli for intestinal angiogenesis. Ligands for NOD-like (NLR) and Toll-like receptors (TLR) that penetrate beyond the mucosal layer can activate angiogenesis via mitogen-activated protein kinase, nuclear factor-κB, vascular endothelial growth factor receptor 2 (VEGFR-2), and focal adhesion kinase (FAK) signaling [49]. Conversely, other products of bacterial metabolism (e.g., butyric acid) can suppress VEGF-A-mediated angiogenic signaling (proliferation, migration, and capillary genesis) via suppression of cyclooxygenase-2 and reduced interleukin-6 secretion [50].

Disturbances in lymphatic transport function in IBD also seem to underlie not only disease initiation but also progression in both UC and CD. Indeed, the initial descriptions of CD by Crohn implicated lymphangitis, lymphostasis, and lymphatic remodeling as features of the disease, which are also seen in UC and contribute to disease severity. Like blood angiogenesis, lymphatic density increases in both forms of IBD but appears to be largely adaptive. While angiogenic processes are pro-inflammatory in the setting of IBD, lymphangiogenesis appears to relieve tissue edema by transporting accumulated interstitial fluid. While angiogenesis is largely mediated by VEGF-A/VEGFR-2 activity, lymphangiogenesis is governed by VEGFR-3 and its ligands VEGF-C and -D. Experimental blockade of VEGFR-3 intensifies experimental IBD, while administration of VEGR-3 agonists, for example, VEGF-C and -D, has demonstrated protection in IBD models. Paradoxically, lymphatic endothelial exposure to VEGF-C increases expression of the lymphatic marker podoplanin, but simultaneously decreases cadherin-5, which dysregulates lymphatic barrier function [51].

Another modulator of lymphatic valve organization and adventitial structure is the FoxC2 transcription factor. FoxC2 is increased in experimental colitis. Importantly, mice with defects in FoxC2 exhibit no differences in lymphatic density (lymphangiogenesis), but they have significantly more intense disease activity in experimental IBD with significantly lower survival, greater histopathological injury, edema, and increased colonic burden of neutrophil, T-cell, and macrophage penetration [52]. Because this model demonstrates more extensive lymphatic dilation, the failure of lymphatic vessels to fully mature (achieve normal valve organization and adventitital coverage) despite normal levels of lymphangiogenesis argues for the necessity of restituting both vessel integrity and vessel abundance in normal intestinal homeostasis.

19.2.3.4 Junctional and Vascular Permeability

Increased microvascular solute permeability is a hallmark feature of inflammation that observed in both acute and chronic forms of CD and UC. Increased microvascular permeability in IBD delivers albumin and opsonizing antibodies, which help to isolate pathogens, but can severely compromise tissue function and exacerbate the tissue injury response. There are at least two pathways for increased microvascular flux seen during inflammation: (1) the "paracellular" pathway that involves opening of interendothelial tight and adherens junctions

and (2) formation of transendothelial pores (transcytosis) that allow bulk transcellular solute flux [53].

At the molecular level, changes in the paracellular restrictive properties of endothelial monolayers in IBD can represent one or more events that include changes in tight and adherens junctional binding with and organization by the cytoskeleton, transient junctional protein internalization, decreased expression of specific junctional elements, and proteolytic degradation of junction components.

Endothelial cells express tight junctions containing occludin, claudins -1, and their zonula occludens (ZO) linker proteins as well as complexus adherens junctions that contain VE-cadherin (cadherin-5) and the immunoglobulin superfamily molecules PECAM-1 and the junctional adhesion molecules (JAM)-A,-B, and -C. Paracellular leukocyte diapedesis is a complex process involving Ig-CAM family members PECAM-1/CD31, JAM-A, and CD99. While JAM-A expressed at endothelial junctions supports leukocyte diapedesis, JAM-B blocks VEGF/VEGFR-2 signaling and JAM-C binding interaction appears to negatively regulate VE-cadherin junctional integrity [54].

Several classes of inflammatory mediators, including cytokines, oxidants, and bacterial products, can acutely provoke microvascular (and epithelial) solute permeability changes that contribute to the tissue edema and injury seen in IBD [55,56]. Cytokines (e.g., TNF-α, IFN-γ, etc.) depress expression of occludin and cadherin-5 that reduce barrier solute restriction across endothelial monolayers, an effect that can be prevented by pretreatment with interleukin-10 suggesting that the abundance and ratios of Th1/Th2 cytokines in IBD may govern junctional makeup and barrier function [56]. Acute vascular permeability changes in response to TNF-α have been shown to involve protein tyrosine kinase-6 signaling that leads to junctional disintegration [57].

Acute vascular permeability changes in erosive models of UC have been shown to be mediated by Src-kinase tyrosine phosphorylation (Src^{416}) within the colon mucosa early on in the course of acute injury. Src inhibition by PP1 prevented Src^{416} phosphorylation and colon vascular permeability linked with VEGFR-2 activation. Mechanistically, VEGF-A can disturb VE-cadherin junctions via VEGFR-2-mediated VE-cadherin phosphorylation, beta-arrestin-2 binding, and internalization of VE-cadherin [58]. Several other inflammatory mediators including hydrogen peroxide and histamine also transiently increase the internalization of VE-cadherin from the endothelial surface [59]. When not present at the cell surface, the normal level of cell–cell apposition maintained by these junctional proteins is low permitting increased exchange. It is unclear if persistent induction of this type of junction internalization would lead to proteolytic degradation.

Matrix metalloproteinases, a family of zinc-dependent proteases secreted by several cell types as zymogen preforms, can contribute to IBD disease activity by degrading tissue matrices to increase microvascular permeability. Several MMPs are released by neutrophils (MMP-8) and monocytes (MMP-1, -2,-3, -9, -10, -14-17,-19, and -25). Activation of matrix metalloproteinases (e.g., MMP-1, -2, and -9) in IBD by inflammatory cytokines as well as homocysteine can lead to destruction of the subendothelial matrix [60].

Several tight junction (occludin, claudin-5, claudins -1 and -12, and zonula occudens-1) and adherens junction components (VE-cadherin) are also susceptible proteolytic cleavage by MMPs, which can reduce microvascular barrier function [59].

Several cytokines and growth factors including VEGF-A can trigger the production and processing of MMP-1, -3, and -9 to their active isoforms in several cell types of the inflamed intestine. Mechanistically, VEGF-A-mediated increase in vascular permeability involves activation of phospholipase C-γ, protein kinase C, extracellular signal-regulated protein kinase, Akt, Src, focal adhesion kinase, and other pathways [61].

TNF-α can also mobilize endothelial MMPs that modulate barrier function [59]. Elastase released by neutrophils recruited in IBD can also degrade VE-cadherin and beta-catenin. The increased production of reactive oxygen species during active IBD also oxidatively inactivates tissue inhibitors of metalloproteases that would normally suppress the proteolytic activity of MMPs. Although levels of junctional proteins are decreased in the intestine during active IBD, it has been suggested that these changes in junctional protein expression are limited to enterocytes and that levels of endothelial junctional components are preserved even during active IBD [62].

The increased endothelial expression of CD146 (melanoma cell adhesion molecule/MCAM and cell surface glycoprotein/MUC18) within intestinal endothelial junctions has been reported as a specific marker of inflammatory activation in IBD and the release of CD146 has been correlated with increased microvascular permeability [63]. Based on these observations, circulating CD146 levels have been suggested as a potential biomarker in IBD.

19.3 Conclusions

The microcirculation plays an important role in the initiation and perpetuation of an inflammatory response. The diverse responses of the microcirculation to inflammation likely reflect the collective contribution of a variety of cells, including blood cells, endothelial cells, vascular smooth muscle (VSM), and perivascular cells (e.g., macrophages, mast cells, etc.). However, endothelial cells appear to have a unique role in modulating the inflammatory response. The importance of endothelial cells in this process is evidenced by the ability of these cells to regulate the migration of inflammatory cells into tissue, modulate the tone of underlying VSM and consequently blood flow, provide an interface for the activation/deposition of coagulation factors and binding of platelets during thrombus formation, as well as their critical role in the formation of new blood vessels. Each of these responses underlie critical pathological features of an inflammatory response and can contribute to the end-organ damage, morbidity, and mortality that are associated with inflammatory diseases, such as IBD. Consequently, the potential for targeting one or more of these endothelium-dependent inflammatory responses raises hope for the development of effective new drugs for the treatment of inflammatory diseases. Indeed, drugs that target a specific microvascular response to inflammation, such as leukocyte–endothelial

cell adhesion or angiogenesis, have shown promise in both the preclinical and the clinical studies of IBD [37,64]. These promising results justify a continued focus on endothelial cells as a therapeutic target in inflammatory diseases.

20.1 Introduction

20.1.1 The IL-1 Family of Cytokines and the Innate Immune System

There are 11 members of the IL-1 family of cytokines and 10 members of the IL-1 family of receptors (Table 20.1). More than any other cytokine family, the interleukin-1 family members are closely linked to damaging inflammation; however, the same members also function to increase nonspecific resistance to infection and the development of an immune response to a foreign antigens (Figure 20.1). These inflammatory and host defense properties are now termed "innate immunity" and augmenting response to antigens is now called "acquired immunity." What characterizes innate immunity is the lack of specificity. Indeed, the numerous biological properties of the IL-1 family are nonspecific. The importance of IL-1 family members to the innate response became evident upon the discovery that the cytoplasmic domain of the IL-1 receptor type I (IL-1R1) is also found in the Toll protein of the fruit fly [1]. The functional domain of the cytosolic component of IL-1R1 [2] is termed the Toll interleukin-1 receptor (TIR) domain. In fact, the TIR domain is highly homologous to the TIR domains of all Toll-like receptors (TLRs). Thus, fundamental inflammatory responses such as the induction of cyclooxygenase type 2, production of multiple cytokines and chemokines, increased expression of adhesion molecules, or synthesis of nitric oxide are indistinguishable responses of both IL-1 and TLR ligands.

Both TLR and IL-1 families nonspecifically augment antigen recognition and activate lymphocyte function. The lymphocyte-activating function of IL-1 was first described in 1979 [3] and is now considered a fundamental property of the acquired immune response. IL-1β is the most studied member of the IL-1 family due to its role in mediating autoinflammatory diseases [4]. Unquestionably, IL-1β evolved to assist host defense against infection [5] and this landmark study established how a low dose of recombinant IL-1β protects mice against lethal bacterial infection in the absence of neutrophils. Although we now accept the concept that cytokines like IL-1β served millions of years of evolution to protect

Table 20.1 IL-1 family of receptors.

Receptor	Function	Ligand
IL-1R1	Ligand binding	IL-1Ra, IL-1α, and IL-1β
IL-1R2	Ligand binding	IL-1β
IL-1R3	Coreceptor	IL-1α, IL-1β, IL-33, and IL-36α, β, and γ
IL-1R4	Ligand binding	IL-33
IL-1R5	Ligand binding	IL-18
IL-1R6	Ligand binding	IL-36α, β, γ, IL-36Ra, and IL-38
IL-1R7	Coreceptor	IL-18
IL-1R8	Coreceptor	IL-37
IL-1R9	Coreceptor	IL-38
IL-1R10	Coreceptor	?

the host, in the antibiotic and antiviral therapies era of today, we view cytokines also as the cause of disease due to acute or chronic inflammation.

The IL-1 family also includes members that suppress inflammation, specifically within the IL-1 family, such as the IL-1 receptor antagonist (IL-1Ra), IL-36 receptor antagonist (IL-36Ra), and IL-37. In addition, the IL-1 family member IL-38, the last member of the IL-1 family of cytokines to be studied, nonspecifically suppresses inflammation and limits innate immunity.

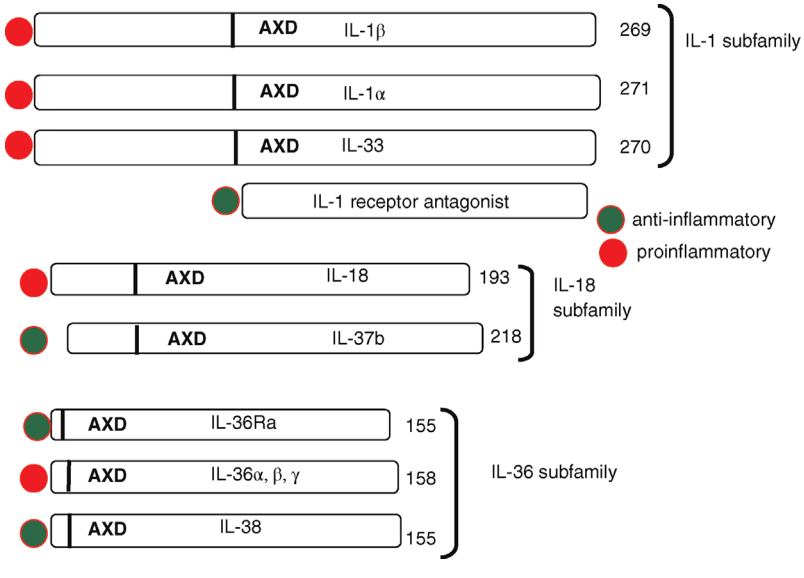

Figure 20.1 Organization of the IL-1 family of ligands into subfamilies. The subfamilies are characterized by similar total number of amino acids of the translated member and the location of the AXD consensus sequence. The vertical bar represents the likely N-terminus based on 9 amino acids forward from the AXD site. The colored circles indicate the primary property of the member, that is, proinflammatory (red) or antiinflammatory (green).

20.1.2 The Family of IL-1 of Receptors

There are 10 members of the IL-1 family of receptors [6]. IL-1R1 binds IL-1α, IL-1β, and IL-1Ra. IL-1R1 binds either IL-1β or IL-1α. IL-1R2 is a decoy receptor for IL-1β. This receptor lacks a cytoplasmic domain and therefore does not signal. IL-1R2 exists not only as an integral membrane protein but also in a soluble form. The term "soluble" is meant to denote the extracellular domain only. The soluble domain of IL-1R2 binds IL-1β in the extracellular space and neutralizes IL-1β. Neutralization of IL-1β by soluble IL-1R2 is greatly enhanced by forming a complex with IL-1R3 (formerly IL-1R1 accessory protein) [7,8]. IL-1R3 is the coreceptor for IL-1α, IL-1β, IL-33, IL-36a, IL-36β, and IL-36γ. IL-1R3 exists as an integral membrane receptor or in a soluble receptor form. In addition, the soluble form of IL-1R3 is produced by the liver and circulates constitutively in health. During inflammation and infection, the liver increases its synthesis and levels of soluble IL-1R3 rise in the circulation.

In that regard, soluble IL-1R2 forms a complex with soluble IL-1R3 or cell bound IL-1R3 and prevents the binding of IL-1β to the IL-1R1. Importantly, the IL-1 family of receptors also contains anti-inflammatory receptors [9]. These are IL-1R8 (formerly SIGIRR, TIR8), IL-1R9 (formerly TIGIRR-2, IL-1RAPL1), and IL-1R10 (formerly TIGIRR-1). In the case of IL-1R8, mice deficient in this receptor develop spontaneous inflammation and when challenged with inflammatory agents, exhibit more severe disease [10]. The IL-18-binding protein (IL-18BP) is not a classic receptor because it is a secreted protein; nevertheless, IL-18BP contains a single IgG domain similar to the extracellular IgG-like domains of the IL-18Rα but no cytoplasmic domain [11]. The IL-18BP functions similarly as do other soluble receptors in the IL-1 receptor family, that is, they bind and neutralize the cognate ligand. In addition to the IL-18BP, there is soluble form of the IL-1R2. As an integral membrane protein, this receptor acts as a decoy receptor [12], but like IL-18BP, soluble IL-1R2 will bind the cognate ligand in the extracellular compartment.

20.1.3 The IL-1 Family Consensus Sequence

With the exception of IL-1Ra, all members of the IL-1 family lack a signal peptide and are not readily secreted. They are found diffusely in the cytoplasm as precursors and each precursor contains a three amino acid conserved consensus sequence A-X-Asp, in which A is any aliphatic amino acid, followed by any amino acid (X) and then aspartic acid [13]. The aspartic acid is not the aspartic acid that indicates a caspase-1 cleavage site. Nine amino acids before the consensus sequence indicate the amino terminal amino acid for optimal folding of the cytokine for receptor binding. For example, truncation of IL-36α, IL-36β and IL-36γ to the ninth amino acid before the A-X-Asp motif results in a 1000-fold increase in bioactivity [13]. In the case of the IL-1β precursor, nine amino acids before the consensus motif (Leu-Arg-Asp) are the caspase-1 cleavage site creating the N-terminus for optimal activity. Other cytokines such as IL-16 and the growth factors, fibroblast growth factor, and vascular endothelial growth factor also lack a signal peptide and are active as precursors. The precursor of IL-1α is also active as a precursor [14]. From cell cultures producing IL-1α, the N-terminus was found at amino acid serine 113 [15]. Serine 113 is not the N-terminus as predicted by the consensus sequence. The processing of human IL-1α from endotoxin-stimulated

macrophages required a calcium-dependent neutral protease [16]. In a mouse macrophage cell line, inhibitors of calpain prevent the processing of the IL-1α precursor [17,18]. Copper is also required for the processing and release of IL-1α via S100A13 in both human macrophages and mouse fibroblasts [19,20].

20.1.4 The IL-1 Family as Therapeutics

Of the 11 members of the IL-1 family, IL-1α, IL-1β, IL-1Ra, and IL-18 have been thoroughly studied *in vitro* in animal models of disease and in humans. In humans, blocking IL-1 activity, particularly IL-1β, is used to treat a broad spectrum of diseases [21]. The IL-1Ra is a specific inhibitor of the activity of both IL-1α and IL-1β and the recombinant form is a pharmaceutically known as anakinra. Anakinra is approved in several countries for treating the signs, symptoms, and joint destruction of rheumatoid arthritis as well as cryopyrin-associated periodic syndrome (CAPS). Over 1000 patients with rheumatoid arthritis have been treated with anakinra, some for over 10 years. Blocking IL-1 activity with anakinra results in an arrest in the progressive joint space narrowing that is one of the hallmarks of rheumatoid arthritis. In a placebo–controlled randomized trial, anakinra appeared to benefit patients with stroke [22]. Anakinra is now the standard therapy for patients with systemic onset juvenile idiopathic arthritis [23], refractory adult Still's disease [24], and other systemic and local inflammatory diseases. These and other diseases are now classified as "autoinflammatory" diseases and are to be distingished from "autoimmune" diseases. The IL-1 Trap, a bivalent construction of the extracellular domains of the IL-1 receptor type I (IL-1R1) and the IL-1R3 [25], has been approved for the treatment of autoinflammatory diseases such as familial cold-induced autoinflammatory syndrome and Muckle–Wells syndrome [26].

For many years, there has been a great interest in the ability of IL-1β to damage the insulin-producing pancreatic beta cell [27]. But recent studies in humans have demonstrated a role for IL-1 in type 2 diabetes. In a placebo–controlled, blinded randomized trial in patients with poorly controlled type 2 diabetes, 13 weeks of anakinra therapy improved glycemic control and the function of the insulin-producing beta cell [28]. In a second study, neutralizing monoclonal antibodies to IL-1β also improved glycemic control and beta-cell function in type 2 diabetic patients [29]. Therefore, destruction of the insulin-producing beta cell appears to be an IL-1β-mediated autoinflammatory disease [30]. Patients with type 2 diabetes at high risk for cardiovascular events such as myocardial infarction and cerebrovascular stroke were treated with statin-type drugs to reduce the atherosclerotic process. Serum C-reactive protein (CRP) levels are used to monitor the risk of a cardiovascular event. When treated with canakinumab (a human antihuman IL-1β) a further decrease in CRP predicts reduced cardiovascular events. To test this hypothesis, a randomized placebo–controlled trial of canakinumab has enrolled over 10 000 patients [31]. This is the largest trial of an anticytokine in treating a specific disease. The trial tests three subcutaneous canakinumab at doses of 5, 15, 50, or 150 mg monthly compared to placebo. In a preliminary study for 4 months, the antibody-treated groups reported statistically significant reductions in circulating CRP, IL-6, and fibrinogen levels compared to the cohort receiving placebo [32].

Another member of the IL-1 family used clinically is the IL-18BP [11], the naturally occurring inhibitor of IL-18 activity. IL-18BP has a high affinity binding to IL-18 and circulates in healthy subjects at 2–3 ng/ml, which is greater than 100-fold molar excess of IL-18 levels [33]. Although IL-18BP is elevated to 5–6 ng/ml in several autoimmune and autoinflammatory diseases, the level of free IL-18 is associated with disease severity [34–38]. IL-18BP has been administered to patients with rheumatoid arthritis and plaque psoriasis [39]. IL-18BP is being tested in patients with macrophage activation syndrome, adult onset Still disease and mutations in NLRC4. In patients with the NLRC4 missence mutation Thr337Ser, there is increased release of IL-1β and IL-18 associated with flares of macrophage activation syndrome [40].

20.2 IL-1α

20.2.1 Historical Background

In 1974, while purifying the endogenous fever-producing protein "leukocytic pyrogen" from the supernatants of human blood monocytes, two molecular weights (36 and 15 kDa) and two distinct isoelectric points (pI 5.1 and 6.8) were observed [41]. The 36 kDA and pI 5.1 leukocytic pyrogen was recognized at IL-1α in 1984; the 15 kDa and pI of 6.8 became IL-1β. Historically, IL-1α was studied for many years in murine immunology as lymphocyte-activating factor (LAF) [42]. LAF activity was defined as an augmentation of mouse thymocyte proliferation to phytohemagglutin (PHA). In general, supernatants from activated macrophages were added to cultures of mouse thymocytes stimulated with PHA and the activity of LAF was an increase in the proliferation of the thymocytes as measured by increased uptake of tritiated thymidine. In other assays, LAF activity was measured by augmented T-cell responses to antigen. In 1984, a mouse macrophage cell line, a cDNA, was isolated and when expressed in *Escherichia coli*, the recombinant LAF increased in the proliferation of the thymocytes [15]. Also in 1984, a cDNA was isolated from human blood monocytes and the recombinant protein increased the proliferation of a mouse T-cell line stimulated with PHA. The two cDNAs were related but not the same. The mouse IL-1 was later named IL-1α and the human IL-1 was named IL-1β. The primary amino acid sequences of IL-1α and IL-1β are only 26% identical.

20.2.2 Systemic Effects of IL-1α in Humans

Following the cDNA cloning of mouse IL-1α in 1984, recombinant IL-1α became available for study in humans with cancer. As a result, clinical studies were performed in cancer patients based on studies in mice that showed an antitumor effect, perhaps related to the immunological properties of cytokine. Humans receiving IL-1α developed fever, generalized systemic inflammation at doses as low as 30 ng/kg; at 100 ng/kg, patients developed hypotension [43,44]. Similar febrile and systemic inflammation developed in cancer patients receiving infusions of IL-1β (reviewed in Ref. [45]. Understandably, IL-1α or IL-1β is not used to treat cancer today; instead, blocking IL-1α or IL-1β has resulted in prolongation and improved quality of life [46,47].

20.2.3 IL-1α is a Dual-function Cytokine

IL-1α is a "dual-function" cytokine. Dual-function cytokines are found in the nucleus where they bind to DNA and function; the same cytokine binds to its cell membrane receptor and initiates signal transduction. In the case of IL-1α, there is a nuclear localization sequence in the precursor region of the cytokine, and one of the functions of IL-1α in the nucleus is as a transcription factor [48]. In that context, nuclear IL-1α functions to increase gene expression, for example, the chemokine IL-8 [48]. Another member of the IL-1 family, IL-33, also is a dual-function cytokine. When the nuclear localization sequence of IL-33 in mice is deleted, cytokine is found only in the cytosol; in these mice, overwhelming unresolved inflammation occurs early after birth, dominated by large numbers of eosinophils [49]. Thus, nuclear localization of IL-33 acts as a sink for its proinflammatory properties. Nuclear translocation of IL-1α can also be a sink for its proinflammatory properties. For example, the IL-1α precursor shuttles between the cytosol and the nucleus within a few nanoseconds [50]. When the cell is exposed to a proapoptotic signal, IL-1α leaves the cytosolic pool and rapidly migrates to the nucleus where it binds tightly to chromatin. Whole lysates of these cells fail to induce inflammation since the chromatin bound IL-1α is not available to bind to IL-1 receptors on adjacent cells. In contrast, when the cell is exposed to a necrotic signal, IL-1α migrates from nucleus to the cytosol and the lysates of these cells are highly inflammatory [50]. There is a clinical correlate of these findings. The epithelial lining cells of the intestine contain large amounts of the IL-1α precursor and these cells routinely undergo apoptosis naturally without producing inflammation. In contrast, when exposed to toxic agents such as dextran sodium sulfate (DSS), cell death occurs by necrosis and the IL-1α precursor is released from the cytosolic pool resulting in lethal inflammation [51].

Following genotoxic stresses such as UV light or hydrogen peroxide, DNA is damaged. Unexpectedly, IL-1α precursor localizes specifically to the damaged foci on the DNA [52]. The localization of IL-1α to the damaged sites is distinct from the nuclear localization of the IL-1α precursor in cells undergoing apoptosis [50]. During genotoxic stress, lysine 82 in the nuclear localization sequence becomes acetylated, which facilitates the binding to the damaged foci. In addition to the nuclear localization of acetylated IL-1α following genotoxic stress, the precursor is released from the cell without loss of membrane integrity [52]. Although the IL-1α precursor is active [14], processing by calpian, granzyme B, mast cell chymase, and neutrophil proteases results in a more active form. However, in the cells undergoing genotoxic stress, the release of the IL-1α precursor takes place without evidence of processing [52].

20.3 Cell Sources, Production, and Secretion

20.3.1 Large Amounts of Constitutive IL-1α in Healthy and Disease Cells

IL-1α is an unusual member of the IL-1 family because IL-1α is found constitutively in epithelial and mesenchymal cell types of healthy subjects, whereas IL-1β is primarily induced under disease conditions. The keratinocytes of the skin contain

large amounts of the IL-1α precursor as are intestinal lining cells, fibroblasts, hepatocytes, brain astrocytes, and renal tubule cells. Endothelial cells contain IL-1α, and cytokine is present in vesicles comprised of the endothelial membrane [53]. These vesicles are termed "apoptotic bodies," but despite the name, they are highly inflammatory [53]. IL-1α is also present in most tumors of mesenchymal origin. As discussed below, tumor-derived IL-1α is released as tumors outgrow their vascular supply, resulting in paraneoplastic syndromes such as fever and loss of appetite. Under conditions of primary cell stimulation *in vitro*, human blood monocytes do not process or readily secrete IL-1α and IL-1α is not commonly found in the circulation during systemic inflammation. However, as cytokine is released from dying cells [50,54], IL-1α is a classic "alarmin" because the IL-1α precursor is active and mediates sterile inflammation [14]. For example, in many ischemic diseases such as myocardial infarction, cell death is by necrosis and IL-1α is released into the extracellular space where it stimulates the production of chemokines resulting in the infiltration of neutrophils first followed by monocytes. This transition from neutrophils to monocytes in ischemic tissues has been demonstrated in cells exposed to hypoxic conditions where the IL-1α precursor is released [55]. Since nearly all tumors contain the IL-1α precursor, upon death by necrosis, the IL-1α precursor triggers the infiltration of monocytes and chemokines.

20.3.2 IL-1α as a Growth Factor

Most cell lines including tumor cell lines contain constitutive levels of IL-1α [48,56,57]. The concept that IL-1α acts as an autocrine growth factor assumes that the intracellular IL-1α precursor regulates normal cellular differentiation. In support of this concept, an antisense oligonucleotide to IL-1α reduces senescence in endothelial cells [58]. Although the concept that IL-1α acts as an autocrine growth factor in fibroblasts or endothelial cells *in vitro*, the data must be interpreted carefully since mice deficient in IL-1α show no demonstrable defects in growth and development, including skin, fur, epithelium, and gastrointestinal function [59]. However, mice deficient in IL-1α still retain the propiece that functions as nuclear factor. The term precursor is used for the entire IL-1α molecule. The term mature is used for the carboxyl end and the term propiece for the N-terminus. In the case of IL-1α, the N-terminal 115 amino acids translocates to the nucleus and these amino acids are often termed the propiece.

Is there a role for intracellular precursor IL-1α in normal cell function? The IL-1α precursor is constitutive in all epithelial cells and large amounts of the intracellular form of IL-1Ra (icIL-1Ra) are also present in these cells [60,61]. This form of IL-1Ra also binds to IL-1RI and prevents signal transduction. In fact, icIL-1Ra is produced in the same cells expressing the IL-1α precursor and thought to compete with the intracellular pool of precursor IL-1α for nuclear-binding sites.

20.3.3 Membrane IL-1α

Precursor IL-1α can be found on the surface of several cells, particularly on monocytes and B lymphocytes, where it is termed membrane IL-1α [62]. Membrane IL-1α is biologically active [63]; its biological activities are neutralized by

antibodies to IL-1α but not against IL-1β. Thus, membrane IL-1α is an integral membrane protein. Membrane IL-1α plays an important role in inflammation as mice deficient in IL-1α exhibit reduced inflammation in models in which cell death and the release of intracellular IL-1α does not take place [64]. In models of immune-mediated killing of tumor cells, membrane IL-1α has a role to augment recognition of neoantigens on cancer cells [65]. Constitutively expressed IL-1α is critical for several IFNγ activities. Using the WISH epithelial cell line, what was considered to be intrinsic IFNγ activities depended largely on constitutively expressed IL-1α. IFNγ activities inhibited antibodies to IL-1α, but not to IL-1β [57].

20.3.4 Studies in IL-1α-deficient Mice

Mice deficient in IL-1α are born healthy and develop normally. Following subcutaneous injection of turpentine, which induces a local inflammatory response, wild-type and IL-1α-deficient mice develop fever and acute-phase proteins, whereas IL-1β-deficient mice do not [59]. In addition, although the induction of glucocorticoids after turpentine injection was suppressed in IL-1β-deficient mice, this suppression was not observed in IL-1α-deficient mice. Expression of IL-1β mRNA in the brain decreased 1.5-fold in IL-1α-deficient mice, whereas expression of IL-1α mRNA decreased more than 30-fold in IL-1β-deficient mice. These data suggest that IL-1β exerts greater control over production of IL-1α than does IL-1α over the production of IL-1β. In caspase-1-deficient mice, IL-1α production is also reduced [66], suggesting that production of IL-1α is under the control of IL-1β.

The effects of IL-1 on atherogenesis by a high-cholesterol diet were evaluated in mice deficient in either IL-1α or IL-1β [64]. Serum amyloid A protein, a marker of inflammation in atherogenesis, was markedly lower in IL-1α-deficient mice compared to wild type or IL-1β-deficient mice. IL-1α-deficient mice had significantly higher levels of nonhigh-density lipoprotein cholesterol. Reduced atherosclerosis and inflammatory cytokines were observed in apolipoprotein-E-deficient mice lacking bone marrow-derived IL-1α [67]. Transplantation of bone marrow cells from IL-1α-deficient mice resulted in a reduction in aortic lesion size twice that observed in mice transplanted with bone marrow from IL-1β-deficient mice. Using deficient mice, there is a signifcant role for IL-1α in the transformation of steatosis to steatohepatitis and liver fibrosis in hypercholesterolemic mice [68]. However, the role of IL-1α in steatohepatitis stems from the hepatocyte, rather than the myeloid compartment.

20.4 IL-1β

20.4.1 Historical Background

In 1977, IL-1β derived from the supernatants of freshly obtained human blood monocytes stimulated with heat-killed *Staphylococcus epidermidis* was purified to homogeneity [69]. At the time, IL-1β was termed leukocytic pyrogen because the

activity was that of the endogenous fever-producing molecule. Purified human leukocytic pyrogen characteristically produced a monophasic fever in rabbits at 10 ng/kg [69]. The specific activity was unexpectedly low compared to other bioactive proteins, but recombinant human IL-1β [70] causes fever in humans at 10 ng/ml, as reviewed in Ref. [71]. After the cDNA cloning of human IL-1β in 1984 [70], recombinant IL-1β was available to study and during the following years, the biological properties of IL-1β expanded greatly. Although the properties of recombinant IL-1β indicate the likely role in inflammation, a causative role for IL-1β in disease was shown in clinical trials using specific neutralization of IL-1β by monoclonal antibodies as reviewed in Ref. [72].

20.5 Systemic Effects of IL-1β in Humans

20.5.1 Transcription, Translation, and Synthesis of IL-1β

Although nearly all microbial products induce IL-1β via TLR ligands, IL-1 induces itself both *in vivo* and in monocytes *in vitro* [73]. Other studies supporting this concept have been reported [74,75]. Following LPS stimulation in human blood monocytes, IL-1β mRNA levels rise rapidly within 15 min, reach peak levels in 4 h but begin to decline 4 h thereafter due to the half-life of the mRNA or the action of micro-RNA. However, using IL-1 itself as a stimulant, IL-1β mRNA levels are sustained for over 24 h compared to microbial stimulants [76]. Raising intracellular cAMP levels with histamine enhances IL-1-induced IL-1 gene expression and protein synthesis [77]. The IL-1β precursor accumulates in the cytosol and processing by caspase-1 is triggered by ATP activating the P2X7 receptor. In freshly cultured human blood monocytes, endogenous levels of ATP rise and are sufficient for triggering the assembly of the inflammasome [78].

Non-TLR ligands such as the complement component C5a, hypoxia, adherence to surfaces or clotting of blood induce the synthesis of large amounts of IL-1β mRNA in monocytic cells without significant translation into the IL-1β protein. In these cells, the IL-1β mRNA assembles into large polyribosomes, but there is no significant elongation of the peptide [79]. This failure to complete the translation into IL-1β protein may be due to the instability element present in the coding region. This instability region is also found in IL-18 and IL-37 and appears to limit the production of these cytokines [80]. However, completion of translation of the mRNA into the respective cytokines can be accomplished by adding low concentrations of TLR ligands or IL-1 itself to the "primed" monocytes [81].

20.5.2 Regulation of IL-1β Production

Unlike most cytokine promoters, IL-1β regulatory regions are distributed over several thousand base pairs upstream from the transcriptional start site. In addition to a cAMP response element, there are NFκB-like and activating protein-1 sites. IL-1β gene regulation has been reviewed in detail [82]. The primary sources of IL-1β are the blood monocyte, tissue macrophages, and

dendritic cells. B lymphocytes and NK cells also produce IL-1β. Fibroblasts and epithelial cells, however, generally do not produce the cytokine. In healthy humans, the circulating blood monocyte or bone marrow cells do not constitutively express mRNA for IL-1β. Several malignant tumors express IL-1β as part of their neoplastic nature, particularly acute myelogenous leukemia, melanoma, multiple myeloma, and juvenile myelogenous leukemia, each of which exhibits constitutive expression of IL-1β.

20.5.3 The NLRP3 Inflammasome-dependent Processing and Secretion of IL-1β

Regardless of the stimulus, in monocytes and macrophages, specific inhibitors of caspase-1 reduce the secretion of mature IL-1β, while precursor IL-1β accumulates inside the cell. The rate-limiting step in the processing and secretion of IL-1β takes place with activation of the inflammasome. Several intracellular proteins form a complex with NLRPe, also termed cryopyrin. NLRP3 was initially discovered in patients with "familial cold autoinflammatory syndrome," a genetic disease characterized by constitutional symptoms, fevers, and elevated acute-phase proteins following exposure to cold [83]. Assembly of the inflammasome components with inactive procaspase-1 takes place following a fall in intracellular potassium. ATP activation of the P2X7 receptor opens the potassium channel, and simultaneously as potassium levels fall, caspase-1 is activated by the inflammasome [84–87].

The cleavage of the IL-1β precursor by active caspase-1 can take place in the specialized secretory lysosomes or in the cytoplasm. However, more than one pathway seems available for processed IL-1β to exit the cell. These include exocytosis of the secretory lysosomes [84,85], shedding of plasma membrane microvesicles, direct release via transporters or multivesicular bodies containing exosomes [88], or a process termed pyroptosis [89]. In general, the release of processed IL-1β takes place before there is significant release of lactate dehydrogenase [90], although *in vitro* cell death eventually takes place. Pyroptosis is a caspase-1-dependent form of cell death and employed by certain bacteria using Ipaf, a member of the NLR family of intracellular receptors [91]. An increase in intracellular calcium is also required for the mature IL-1β to exit the cell and is phopholipase C dependent [85].

The function of caspase-1 inflammasome is primarily to convert inactive procaspase-1 into the active enzyme and this step requires activation of the P2X7 receptor by ATP. However, in freshly obtained human blood mononuclear cells from healthy subjects, the p10 subunit of active caspase-1 is present even in the absence of stimulation [78] and during the subsequent incubation, extracellular levels of ATP increase [78]. Upon differentiation into macrophages, activation of the inflammasome requires exogenous ATP [78]. But in monocytes from patients with single amino acid mutation in cryopyrin, activation of caspase-1 occurs without a requirement for a rapid fall in the level of intracellular potassium [92]. Therefore, mutated cryopyrin allows for the assembly of the complex of interacting proteins in the presence of normal intracellular levels of potassium. Although often studied using LPS-induced synthesis of the IL-1β

precursor [93], it is unlikely that LPS plays a role in autoinflammatory diseases. On the other hand, spontaneous secretion of IL-1β from monocytes of patients is due to endogenous IL-1β stimulation. In patients with NOMID, there is a decrease in steady-state levels of procaspase-1 mRNA with IL-1Ra treatment [74], suggesting that IL-1β stimulates its own production and processing. Thus, any disease process that includes an increase in the steady-state levels of procaspase-1 mRNA, components of the inflammasome, or the IL-1β precursor explains the "autoinflammatory" nature of the disease. Type 2 diabetes appears to be an example of an autoinflammatory disease where glucose induces IL-1β production from the insulin-producing beta cell and IL-1β induces the beta cell to produce its own IL-1β [30].

20.5.4 P2X7 and the Activation of the Inflammasome

Patients with classic autoinflammatory diseases such as FMF or NOMID have nearly identical clinical parameters, secrete more IL-1β, and respond dramatically to IL-1 receptor blockade yet have no mutation in NALP3. It is, therefore, possible that mutations in P2X7 itself or regulation of the other genes controlling potassium channels [23] may account for dysfunction secretion of IL-1β. For example, monocytes from patients with rheumatoid arthritis are more sensitive to release of IL-1β following ATP activation of the P2X7 receptor compared to monocytes from healthy controls [94]. However, monocytes from subjects with a P2X7 Glu496Ala loss-of-function polymorphism secrete significantly less IL-1β [95]. Monocytes from subjects homozygous for this polymorphism also released significantly less IL-18 [96]. Another P2X7 receptor polymorphism is associated with increased mortality in patients undergoing allogenic stem cell transplantation [97]. Bacteremia was documented in 68% of patients with this polymorphism compared to 18% in wild-type control patients [97].

In mice deficient in P2X7 receptors, inflammation, pain, and IL-1β-mediated IL-6 production are markedly reduced [98]. In addition to a fall in intracellular potassium, ATP triggers formation of peroxynitrite, which is required for caspase-1 activation since peroxynitrite scavengers prevent IL-1β secretion [99]. Pannex-1, a mammalian protein that functions as a hemichannel for the uptake of dyes, is required for caspase-1 processing and release of IL-1β via the P2X7 receptor [100]. Pannexin-1 can also function for LPS-induced IL-1β synthesis in the absence of TLR4 [101]. P2X7 receptor activity is also regulated by "regeneration and tolerance factor" [102].

20.5.5 Noncaspase-1 Processing of IL-1β

A caspase-1 site exists for the IL-1β, IL-18, IL-33, and IL-37 precursors. However, for each of these cytokines, noncaspase-1 mechanisms also exist and generate active forms. For example, sterile inflammation induces fever, elevated IL-6, and increased production of hepatic acute-phase proteins. These responses are absent in mice deficient in IL-1β but present in mice deficient in caspase-1 [103]. Sterile inflammation is often associated with neutrophilic infiltration, and neutrophils produce IL-1β. Because neutrophils are short-lived cells dying within hours upon

emigration, release of the IL-1β precursor from intracellular stores is not unexpected. Therefore, processing of the IL-1β precursor extracellularly into an active cytokine has been reported for the common neutrophil protease, proteinase-3 [104]. Proteinase-3 also contributes to the processing of IL-18 [105]. Other proteases such as elastase, matrix metalloprotease 9, and granzyme A process the IL-1β precursor extracellularly. In addition, a mast cell chymase generates active IL-1β.

Mice with a targeted IKKβ deletion in myeloid cells are more susceptible to LPS-induced shock than control mice [75] and markedly elevated levels of IL-1β are found in the circulation associated with a prominent neutrophilia [75]. The elevated levels of IL-1β are lethal since blockade with IL-1Ra protects these mice from death. The source of the IL-1β in these mice is the neutrophil. When incubated with proteinase-3, cleavage of the IL-1β precursor is observed with molecular weights of 25 000 and 15 000 Da [75]. In fact, the products of proteinase-3 cleavage of the IL-1β precursor are biologically active. In other studies, the molecular weight of active IL-1β at 23–25 000 Da has been observed [86]. Therefore, under inflammatory conditions such as urate crystal arthritis, which is characterized by a prominent neutrophilic infiltration, proteinase-3 cleavage of extracellular IL-1β precursor likely takes place. Mice deficient in caspase-1 are not protected against urate-induced inflammation. Although IL-1Ra is effective in treating gout, IL-1Ra would be equally effective in any disease with extracellular processing of the precursor [106]. The importance of extracellular processing of the IL-1β precursor by serine proteases may explain, in part, the anti-inflammatory properties of alpha-1-antitrypsin [107].

20.5.6 Effects in Mice Deficient in IL-1β

After 10 years of continuous breeding, mice deficient in IL-1β exhibit no spontaneous disease. However, upon challenge, IL-1β-deficient mice exhibit specific differences from their wild-type controls. The most dramatic is the response to local inflammation induced by a subcutaneous injection of turpentine. Within the first 24 h, IL-1β-deficient mice injected with turpentine do not manifest an acute-phase response, do not develop anorexia, have no circulating IL-6, and have no fever [108,109]. These findings are consistent with those reported in the same model using anti-IL-1R type I antibodies in wild-type mice [108]. IL-1β-deficient mice also have reduced inflammation due to zymosan-induced peritonitis [110]. In contrast, IL-1β-deficient mice have elevated febrile responses to LPS, IL-1β, or IL-1α compared to wild-type mice [111]. IL-1β-deficient mice injected with LPS have little or no expression of leptin mRNA or protein [112].

20.6 IL-18 and IL-18-binding Protein

IL-18 was first described in 1989 as "IFNγ-inducing factor" isolated in the serum of mice following an intraperitoneal injection of endotoxin. Days before, the mice

had been pretreated with *Proprionibacterium acnes*, which stimulates the reticuloendothelial system, particularly the Kupffer cells of the liver. With purification from mouse livers and molecular cloning of "IFNγ-inducing factor" in 1995 [113], the name was changed to IL-18. Unexpectedly, the new cytokine was related to IL-1β. Similar to IL-1β, IL-18 is first synthesized as an inactive precursor and without a signal peptide remains an intracellular cytokine. The tertiary structure of the IL-18 precursor is closely related to the IL-37 precursor and the intron–exon borders of the IL-18 and IL-37 genes suggest a close association. Since 1995, many studies have used neutralization of endogenous IL-18- or IL-18-deficient mice to demonstrate the role of this cytokine in promoting inflammation and immune responses (reviewed in Refs [114–116]). However, the biology of IL-18 is hardly the recapitulation of IL-1β. There are several unique and specific differences between IL-18 and IL-1β. For example, both in healthy human subjects and in healthy mice, gene expression for IL-1β in blood mononuclear cells and hematopoietic cells is absent and there is no evidence that the IL-1β precursor is constitutively present in epithelial cells [117]. In contrast, the IL-18 precursor is present in blood monocytes from healthy subjects and in the epithelial cells of the entire gastrointestinal tract.

20.6.1 Processing of the IL-18 Precursor by Caspase-1

The IL-18 precursor has a molecular weight of 24 000 Da and is processed by caspase 1, which cleaves the precursor into an active mature molecule of 17 200 Da. As with the processing of IL-1β, inactive procaspase-1 is first converted into active caspase-1 by the nucleotide-binding domain and leucine-rich repeat pyrin containing protein-3 (NLRP3) inflammasome. Following cleavage of the IL-18 precursor by active caspase-1, mature IL-18 is secreted from the monocyte/macrophage, although over 80% of the IL-18 precursor remains unprocessed inside the cell. Importantly, any phenotypic characteristic of capsase-1-deficient mice should be studied to know if the deficiency is due to reduced IL-1β or IL-18 activity. For example, the caspase-1-deficient mouse is resistant to dextran sodium sulfate-induced colitis [118], but the IL-1β-deficient mouse is susceptible in the same disease model [51]. Since neutralizing antibodies to IL-18 are protective in the DSS colitis model, caspase-1 deficiency appears to prevent the processing of IL-18 [118,119] rather than IL-1β.

Similar to IL-1α and IL-33, the IL-18 precursor is constitutively expressed in endothelial cells, keratinocytes, and intestinal epithelial cells throughout the gastrointestinal tract. Macrophages and dendritic cells are the primary sources for the release of active IL-18, whereas the inactive precursor remains in the intracellular compartment of mesenchymal cells. Also, similar to IL-1α and IL-33, the IL-18 precursor is released from dying cells and processed extracellularly, most likely by neutrophil proteases such as proteinase-3 [105].

20.6.2 Signal Transduction by IL-18

IL-18 forms a signaling complex by binding to the IL-18 alpha chain (IL-18Rα, now called IL-1R5), which is the ligand-binding chain for mature IL-18; however,

this binding is of low affinity. In cells that express the coreceptor, termed IL-18 receptor beta chain (IL-18Rβ, now IL-1R7), a high-affinity complex is formed, which then signals. The complex of IL-18 with the IL-1R5 and IL-1R7 chains is similar to that formed by other members of the IL-1 family with the coreceptor IL-1R3. Following the formation of the heterodimer, TIR domains approximate and a cascade of sequential recruitment of MyD88, the four IRAKs, and TRAF-6 takes place. These steps are followed by the degradation of IκB and release of NFκB. Thus, IL-18 signaling is nearly identical to IL-1 signal transduction [120]. However, there are differences between IL-1 and IL-18 signaling. With few exceptions, IL-1α or IL-1β is active in cells in the low nanogram/milliliter range and often in the picogram/milliliter range. In contrast, IL-18 activation of cells expressing the two IL-18 receptor chains requires 10 to 20 ng/ml and sometime higher levels [121,122].

20.6.3 Role of IL-18 in the Production of IFNγ

Together with IL-12, IL-18 participates in the Th1 paradigm. This property of IL-18 is due to its ability to induce IFNγ either with IL-12 or with IL-15. Without IL-12 or IL-15, IL-18 does not induce IFNγ. IL-12 or IL-15 increases the expression of IL-18Rβ, which is essential for IL-18 signal transduction. Importantly, without IL-12 or IL-15, IL-18 plays a role in Th2 diseases [123]. The importance of IL-18 as an immunoregulatory cytokine is derived from its prominent biological property of inducing IFNγ from NK cells. Membrane IL-18 is expressed in 30–40% of M-CSF-primed macrophages, but LPS treatment is necessary for the release of membrane IL-18 [124]. A major immunoregulating role for IL-18 is in the NK cell. Several human autoimmune diseases are associated with elevated production of IFNγ and IL-18. Diseases such as systemic lupus erythematosus, rheumatoid arthritis, type 1 diabetes, Crohn's disease, psoriasis, and graft versus host disease are thought to be mediated, in part, by IL-18.

20.6.4 IL-18, IL-17, and Gamma/delta T-Cell Activation

The role for IL-17 in the pathogenesis of autoimmune diseases has not only been studied in animal models but also validated in humans treated with either neutralizing antibodies to IL-17 or the IL-17 receptor. Is there a role for IL-18 in the production of IL-17? Attention has focused on a role for IL-18 in Th17 responses primarily because both IL-1β and IL-18 are processed into active cytokines via caspase-1. Using a model for multiple sclerosis termed experimental autoimmune encephalomyelitis (EAE) [125], a role for IL-18 was studied. As expected, using the adjuvant of *Mycobacterium tuberculosis* plus the myelin-derived immunogen for EAE, bone marrow-derived mouse dendritic cells released IL-1β and IL-18, which was dependent on caspase-1 [126]. The primed dendritic cells induced IL-17 from T cells, which when transferred to nonimmunized mice resulted in encephalomyelitis. However, the disease did not develop when the dendritic cells were exposed to a caspase-1 inhibitor [126]. Treating mice with either IL-1β or IL-18 restored the ability of the T-cell transfer to induce the disease. Moreover, treating the recipient mice with the caspase-1 inhibitor

both reduced the disease and reduced the production of IL-17 from CD4-positive T cells and from gamma-delta T cells. Gamma-delta T cells produce IL-17 when stimulated with IL-18 plus IL-23, as these T cells express high levels of the IL-18 receptor alpha chain. Thus, similar to caspase-1-dependent IL-1β, IL-18 induces T cells to produce IL-17 and promote autoimmune responses to specific antigens.

20.7 IL-18 and Inflammation

20.7.1 Proinflammatory Properties of IL-18

In the absence of IL-12 or IL-15, IL-18 exhibits characteristics of other proinflammatory cytokines of the IL-1 family, such as increase in cell adhesion molecules, nitric oxide synthesis, and chemokine production. In general, inhibition of IL-18 activity results in a reduction in disease severity. Blocking IL-18 activity reduces metastasis in a mouse model of melanoma; this is due to a reduction in IL-18-induced expression of vascular call adhesion molecule-1 [127]. The induction of fever, a well-studied property of IL-1α and IL-1β as well as acute-phase proteins, TNFα, and IL-6, is not a significant property of IL-18. Injection of IL-18 into mice or rabbits does not produce fever [128,129]. In a clinical study of intravenous IL-18 dosing in patients with cancer, chills and fevers were not common and were grade 1 (low fevers). Unlike IL-1 and TNFα, fever in humans was observed in all patients at doses of 10 ng/kg, whereas IL-18 fevers were observed in 3 of the 21 patients and only at doses of 100 and 200 μg/kg [130].

Unlike IL-1 and TNFα, IL-18 does not induce cyclooxygenase-2 and hence there is no production of prostaglandin E2 [122,131]. IL-18 has been administered to humans for the treatment of cancer in order to increase the activity and expansion of cytotoxic T cells. Not unexpectedly and similar to several cytokines, the therapeutic focus on IL-18 has shifted from its use as an immune stimulant to inhibition of its activity [39,115].

Because IL-18 can increase IFNγ production, blocking IL-18 activity in autoimmune diseases is an attractive therapeutic target since anti-IL-12/23 reduces the severity of Crohn's disease as well as psoriasis. As discussed below, there appears to be a role for blocking IL-18 in Crohn's disease. However, there are several activities of IL-18 that are independent of IFNγ. For example, IL-18 inhibits proteoglycan synthesis in chondrocytes [132] and proteoglycan synthesis is essential for maintaining healthy cartilage. IL-18 also increases VCAM-1 expression in endothelial cells independent of IFNγ. VCAM-1 plays a major role in multiple sclerosis, in other autoimmune diseases, and in the metastatic process [133].

A commonly used mouse model for colitis is dextran sodium sulfate, which is added to the drinking water and which damages the intestinal wall. Thus in DSS-induced colitis, the epithelial barrier defenses against luminal bacterial products are breached. In this model, reducing IL-18 with a neutralizing antibody is protective and linked to a reduction in IFNγ [119]. Blocking IL-18 with the IL-18-binding protein (IL-18B) also reduces colitis induced by antigen sensitization [134]. Since the generation of active IL-18 requires caspase-1, studies have also been performed in mice deficient in caspase-1 and subjected to DSS colitis.

Nevertheless, despite many studies, the role of caspase-1 in DSS colitis remains unclear. The first study showed that mice deficient in caspase-1 were protected [118,135]. In addition, treatment of mice with a specific caspase-1 inhibitor was also effective in protecting against the colitis [136–138]. In both studies, the effect of caspase-1 deficiency was linked to reduced IL-18 activity, whereas reducing IL-1 activity with the IL-1Ra was ineffective [118]. In support of the role of IL-18 in DSS colitis, inhibition of endogenous merprin β to reduce the generation of active IL-18 was protective in DSS colitis [139].

However, a conundrum has developed whether caspase-1-deficiency is protective or detrimental in DSS colitis. DSS colitis is not the optimal model for Crohn's disease as the model is one of the rapid loss of the protective barrier of the intestinal epithelium exposing the lamina propria mononuclear cells to a large amount and variety of bacterial products. Using the same DSS model, mice deficient in the adapter protein inflammasome component ASC experienced increased disease, morbidity, and precancerous lesions compared to wild-type mice exposed to DSS [140]. Similarly, mice deficient in caspase-1 died rapidly from DSS compared to wild-type mice [141], whereas mice deficient in caspase-12, in which caspase-1 is enhanced, were protected [141]. Administration of exogenous IL-18 restored mucosal healing in caspase-1-deficient mice [141]. Also, mice deficient in NLRP3 were more susceptible to either DSS or TNBS-induced colitis and exhibited both decreased IL-1β and decreased beta-defensins [142]. Macrophages from NLRP3-deficient mice failed to respond to MDP [142]. Mice deficient in NLRP6 are also more vulnerable to DSS [54,143] and the susceptibility appears to be due to lack of sufficient IL-18.

20.7.2 IL-18 in Heart Disease

Heart disease includes coronary vessel disease with associated myocardial infarction, postviral myocardopathies, autoimmune heart disease, and chronic heart failure. Increasing numbers of animal and clinical studies indicate a role for IL-18 in heart disease. The myocardium of patients with ischemic heart failure express the alpha chain of the IL-18 receptor and have elevated levels of circulating IL-18 and are associated with death [144]. Daily administration of IL-18 results in ventricular hypertrophy, increased collagen [145], and elevated left ventricular diastolic pressure in mice [146]. In a model of myocardial suppression associated with septic shock, mice injected with LPS and a neutralizing antibody to murine IL-18 were protected [147]. In another study, human atrial muscle strips were obtained from patients undergoing by-pass surgery and the atrial tissue exposed to ischemia. The addition of IL-18BP to the perifusate improved contractile function from 35% of control to 76% with IL-18BP [148]. Serum from patients with heart failure intravenously administered to mice results in myocardial suppression. However, using mice deficient in IL-18 or IL-18R5 did not develop the suppression [149]. Mice pretreated with IL-18BP or caspase-1 inhibition also were protected. Although myocardial suppression in mice is induced by IL-1β, it was not expected that IL-18 was required. Thus, IL-1β induces heart failure in mice by an IL-18-dependent pathway. Since the IL-18 precursor is present in myocardiocytes and the endothelium, caspase-1 is induced by IL-1β, which

then processes the IL-18 precursor into an active cytokine. Another role for IL-18 in heart is a model of isoproterenol-induced cardiomyocyte hypertrophy. Mice transgenic for IL-18BP are protected [150].

20.8 IL-18 as a Protective Cytokine

There are a growing number of studies supporting a protective role of IL-18. Mice deficient in caspase-1 experience increased disease severity when subjected to DSS colitis and administration of exogenous IL-18 restored mucosal healing in these mice [141]. Mice deficient in NLRP3 are more susceptible to DSS colitis, which is thought to be due to decreased IL-18 [142]. Mice deficient in NLRP6 are also more vulnerable to DSS [54,143] and the susceptibility appears to be due to lack of sufficient IL-18. A protective role for IL-18 is not limited to the gastrointestinal track. In the eye, a condition resembling "wet macula degeneration" worsens with antibodies to IL-18 [151]. In a mouse model of "wet" age-related macular degeneration, the disease was worse in mice deficient in NLRP3 but not in IL-1RI-deficient mice [151]. Therefore, IL-18 rather than IL-1α or IL-1β was protective and upon administration of IL-18, the disease severity improved.

Starting at 16 weeks of age, IL-18-deficient mice begin to overeat, become obese, and exhibit lipid abnormalities; there is increased atherosclerosis, insulin resistance, and diabetes mellitus reminiscent of the metabolic syndrome [152]. IL-1R7-deficient mice also develop a similar phenotype. The higher body weight is attributed to enhanced food intake, in which the IL-18-deficient mice begin to diverge from wild-type animals at a relatively early age and to reach values 30–40% higher than that of wild-type mice. Others have observed similar findings [153]. A striking finding was an increase of more than 100% in adipose tissue in the IL-18-deficient animals that was accompanied by fat deposition in the arterial walls. The insulin resistance in these mice is corrected by exogenous recombinant IL-18. The unexpected and unique mechanism responsible for the higher food intake in the IL-18-deficient animals appears to be due a central nervous system loss of appetite control. IL-18-deficient mice eat throughout the day, whereas wild-type mice eat once, nocturnally.

20.9 IL-18-binding Protein

20.9.1 Background on IL-18BP

The discovery of the IL-18BP took place during the search for the soluble receptors for IL-18 [11]. With a clear signal peptide, IL-18BP is a constitutively secreted protein. IL-18BP with an exceptionally high affinity for IL-18 of 400 pM, although recent studies indicate an affinity of 5 pM. IL-18BP is present in the serum of healthy humans at a 20-fold molar excess compared to IL-18 [33]; thus, IL-18BP may contribute to a default mechanism by which a Th1 response to foreign organisms is blunted. Although IL-18BP is readily secreted, it falls into the functional category of being a shed soluble receptor. IL-18BP contains only one

IgG domain, whereas the IL-1 receptor-2 (IL-1R2) contains three domains. In this regard, the single IgG domain of IL-18BP is similar to IL-1R8 (SIGIRR), which also has a single IgG domain and also functions as a decoy receptor. The salient property of IL-18BP in immune responses is in downregulating Th1 responses by binding to IL-18 and thus reducing the induction of IFNγ [123]. Since IL-18 also affects Th2 responses, IL-18BP also has properties controlling a Th2 cytokine response [123].

20.9.2 The Concept of Free IL-18

Because a single IL-18BP molecule binds a single IL-18 molecule, one can calculate bound versus free IL-18 in a mixture of both molecules [33]. If one examines immunologically mediated diseases where IFNγ plays a pathological role such as Wegener's granulomatosis and systemic lupus erythematosus, one must consider the level of free IL-18 compared to IL-18 bound to IL-18BP. In fact, in these diseases both IL-18BP and IL-18 are high [34,35], but the level of IL-18BP is not high enough to neutralize IL-18 and, therefore, the level of free IL-18 is higher than in healthy subjects. In macrophage activation syndrome, where IFNγ plays a pathological role, both IL-18BP and IL-18 are also high, but the clinical and hematological abnormalities correlate with elevated free IL-18 [36].

A unique property of IL-18BP is that the molecule also binds IL-37 [154] and in doing so, enhances the ability of IL-18BP to inhibit the induction of IFNγ by IL-18. IL-37 binds to the IL-18Rα with a very low affinity, but in mice expressing human IL-37, a profound anti-inflammatory effect is observed [155], particularly of LPS-induced cytokines and dendritic cell maturation [155]. Human IL-37-expressing mice are also resistant to colitis [156]. Thus, the anti-inflammatory property of IL-37 can be affected by the concentration of IL-18BP. As the concentration of IL-18BP increases and binds IL-37, there is the possibility that IL-37 becomes less available as an anti-inflammatory cytokine. Indeed, this has been observed in mice injected with IL-18BP. At low dosing of IL-18BP, there is reduced inflammation in a model of rheumatoid arthritis, but as the dosing of IL-18BP increases, the anti-inflammatory properties of IL-18BP are lost [157].

20.9.3 Regulation of IL-18BP

IL-18BP is highly regulated at the level of gene expression and unexpectedly, IFNγ increases gene expression and synthesis of IL-18BP [158,159]. Therefore, IFNγ driving an increase in the natural and potent inhibitor of IL-18 falls into the category of a negative feedback loop. The concept is supported by clinical data showing that patients being treated with IFNα for hepatitis have elevated levels of IL-18BP [37,160]. IL-27, like IFNγ, functions as both a pro- and an anti-inflammatory cytokine and both may accomplish their roles as anti-inflammatory cytokines at the level of increased production of IL-18BP. In the skin, IL-27 also acts through a negative feedback loop for inflammation. IL-27 acts, as does IFNγ, by induction of IL-18BP gene expression and synthesis [161].

20.9.4 Viral IL-18BP

Natural neutralization of human IL-18 by IL-18BP takes place during a common viral infection. In *Molluscum contagiosum* infection, characterized by raised but bland eruptions, there are large numbers of viral particles in the epithelial cells of the skin, but histologically there are few inflammatory or immunologically active cells in or near the lesions. Clearly, the virus fails to elicit an inflammatory or immunological response. Amino acid similarity exists between human IL-18BP and a gene found in various members of the poxviruses; the greatest degree of homology is found to be expressed by *M. contagiosum* gene [162]. The ability of viral IL-18BP to reduce the activity of mammalian IL-18 likely explains the lack of inflammatory and immune cells in the virally infected tissues and provides further evidence for the natural ability of IL-18BP to interfere with IL-18 activity.

20.9.5 Hemophagocytic Lymphohistiocytosis and Macrophage Activation Syndrome

These are life-threatening conditions characterized by a severe hyperinflammatory state. There is a rare genetic form of hemophagocytic lymphohistiocytosis. However, macrophage activation syndrome (MAS) is not a hereditary disease and can be secondary to infections and lymphoma. Development of MAS is associated with several infectious diseases, notably due to Epstein–Barr virus, cytomegalovirus, herpes virus, or intracellular bacteria and parasites and also various lymphomas, especially of T-cell lineage. In addition, patients with rheumatological conditions, particularly systemic onset juvenile arthritis (sJIA), and also systemic lupus erythematosus, Kawasaki disease, or systemic vasculitis can develop MAS [163–166]. One of the most prominent hematologic and metabolic characteristics of MAS is thrombocytopenia and hepatic injury, respectively. Indeed, IFNγ may be responsible for the thrombocytopenia as well as several of the immunological abnormalities of the disorder. Although treatment with anti-IL-1β or anakinra is the treatment of choice for MAS, the mechanism of resolution of the hyperinflammatory state may be the reduction in IL-18. For example, some patients enrolled in anakinra trials for the treatment of septic shock have MAS. In those patients treated with anakinra, all-cause 28-day survival was 65% compared to patients treated with placebo ($p = 0.007$) [167].

20.9.6 IL-18 in the Hemophagocytic Syndromes

In the case of familial hemophagocytic lymphohistiocytosis or MAS, gene expression for IL-18 is upregulated in peripheral mononuclear cells [168,169] and serum IL-18 is unusually elevated [36,170–173]. Although levels of IL-18 in the circulation are below 1 ng/ml in inflammatory diseases such as severe sepsis, in active phase of MAS, serum IL-18 is usually in the range of 5–7 ng/ml, and both in familial hemophagocytic lymphohistiocytosis complicating XIAP gene mutations and in MAS complicating sJIA, levels of circulating IL-18 can be in 20–30 ng/ml range [24,36,174,175]. However, it is necessary to calculate the

level of free IL-18 since IL-18BP is present in the circulation in health and disease [33]. In patients with MAS, free IL-18 but not IL-12 concentrations significantly correlated with clinical status and the biologic markers of MAS such as anemia ($p < 0.001$), hypertriglyceridemia, and hyperferritinemia ($p < 0.01$) and also with markers of Th1 lymphocyte or macrophage activation, such as elevated concentrations of IFNγ and soluble IL-2 and TNFα receptor concentrations [36]. Patients with a mutation in NLRC4 experience a life-threatening hyperinflammation state, mostly manifested by intractable colitis. Free IL-18 is markedly elevated and treatment with IL-18BP provides resolution of the inflammatory state [176].

20.10 IL-33

20.10.1 The Discovery of IL-33

For many years, the IL-1 receptor family member ST2 (proper nomenclature IL-1R4) was studied without knowing its specific ligand. Because IL-1R4 contains the TIR domain, the biology of the orphan ligand (IL-33) was linked to innate immune responses, inflammation, and acquired immunity [177]. For many years, the role of this receptor was established for promoting the Th2 response in diseases such as asthma and parasitic infections. For example, IL-1R4 was required for the production of IL-4, IL-5, and IL-13. Mice deficient in IL-1R4 exhibited reduced allergic responses. Blocking antibodies targeting, this receptor generated similar data, as did the use of the extracellular domain (soluble IL-1R4) and mice deficient in IL-1R4. IL-1R4 was also reported to function in the suppression of inflammation [178]. However, in 2005, using *in silico* research methods, the IL-1 family member IL-33 was identified as the ligand binding to IL-1R4 [179]. Considerable uncertainly surrounded this discovery since other members of the IL-1 family discovered with *in silico* research methods were reported in 2000. Similar to IL-1α and IL-18, IL-33 is present in its precursor form in healthy tissues, particularly in endothelial and epithelial cells and also the brain. In fact, in the brain, the IL-33 precursor is found in microglia, astrocytes, and oligodendroglia.

20.10.2 Processing of IL-33

The IL-33 precursor contains a caspase-1 cleavage site at amino acid aspartic acid 111 and this site was thought to provide a mechanism similar to that of IL-1β and IL-18, that is, processing intracellularly by caspase-1 and secretion of the active cytokine. Indeed, the caspase-1 site was used to produce the first recombinant IL-33 with amino acids 112–270 [179]. However, subsequent studies revealed that caspase-1 and caspase-3 inactivate cytokine [180]. The full-length IL-33 precursor (amino acids 1–270) is active and processing takes place extracellularly by enzymes such as neutrophil elastase and cathepsins [181]. Processing by these and mast cell enzymes results in significantly greater activity of IL-33 [181]. The release of the IL-33 precursor from endothelial cells takes place with damage or

frank necrosis, similar to that of IL-1α [53]. Thus, IL-33 is considered an alarmin; that is, it is released upon cell damage and is active as a precursor. Depending on the neutrophilic infiltration, more active forms of IL-33 are generated. Although the crystal structure of IL-33 with IL-1R4 has been reported, the various N-termini generated extracellularly suggest that signal transduction is triggered differentially depending on the various affinities. The processing of the IL-33 precursor extracellularly generates mature forms, which are more active than the parent precursor [181]. In fact, processing takes place by the same neutrophil and mast cells proteases that process IL-1β [181,182]. There are at least three mature forms of IL-33 resulting from mast cell proteases that are significantly more potent than the precursor and each activates group 2 innate lymphoid cells [182]. It is unclear which N-terminus of IL-33 is present in inflammatory tissues, given the multiple neutrophilic enzymes that cleave the IL-33 precursor.

20.10.3 IL-33 Shares with IL-1 the Coreceptor IL-1R3

IL-33 binds to IL-1R4, which then undergoes a conoirmational change, similar to IL-1β or IL-1α binding to IL-1R1. The affinity of IL-33 for IL-1R4 has a K_d of 74 nM [183]. In the case of IL-33 binding to IL-1R4, there is no signal transduction. However, the conformational changes in IL-1R4 allows for binding to IL-1R3 and the formation of the heterotrimer complex [184], which signals via MyD88, IRAKs, and NFκB. IL-1R3 binds to the side of IL-1R4 [183], again similar to that of IL-1R1 [185]. In this model, there is no contact of IL-1R3 with IL-33.

IL-33 as an anti-inflammatory cytokine. Due to its structure, IL-33 belongs to the IL-1 subfamily with IL-1α and IL-1β. Sharing common coreceptor IL-1R3, IL-33 biological properties are similar to those of IL-1α and IL-1β, that is, proinflammatory. The ST2 tissue and cell distribution determines the Th2 paradigm for IL-33, but IL-1β also falls into the class of Th2, particularly because IL-1 increases antibody production due to its properties as an adjuvant. Although IL-33 is primarily a proinflammatory cytokine in several murine models of human disease, IL-33 has anti-inflammatory properties. For example, IL-33 exerts anti-inflammatory properties in a model of heart disease, obesity, and uveitis. It is unclear if these anti-inflammatory properties of IL-33 are due to a shift to the Th2 paradigm or an independent mechanism. One mechanism for the anti-inflammatory properties of IL-33 appears to be due to the requirement for IL-1R8 [186]. According to a press release, a human trial of anti-IL-33 has shown some efficacy in patients with asthma.

20.10.4 Nuclear Function of IL-33

The nuclear translocation of the N-terminal domain of IL-33 is similar to that of IL-1α. While many researchers focused on recombinant IL-33 and the allergic models, the French scientist Girad and coworkers reported that IL-33 translocated to the nucleus where it bound to chromatin, an observation that had been published earlier in endothelial cells [187]. As described above, the N-terminal domain of IL-1α binds to chromatin via its nuclear localization sequence and acts as a transcription factor [48]; during apoptosis, nuclear IL-1α is sequestered in the

nucleus and not available for binding to its extracellular receptor [50]. A similar mechanism seems to take place with IL-33 as there is suppression of transcription [187]. Further studies on the nuclear function of IL-33 revealed that the full-length IL-33 precursor binds to NFκB specifically via amino acids 66–109 and suppresses activation by IL-1β [188]. Thus, both IL-1α and IL-33 binding to chromatin acts to sequester cytokine and reduce inflammation. A dramatic proof of this mechanism was revealed when the nuclear localization of IL-33 was deleted and the mutated IL-33 expressed in mice. In heterozygous mice expressing IL-33 with the nuclear localization sequence and IL-33 without nuclear localization, overwhelming lethal inflammation was reported [49]. The inflammation consisted of elevated IL-33 plasma levels and massive infiltration of eosinophils in the organs. The inflammation was absent in mice deficient in IL-1R4 [49]. Thus, similar to nuclear IL-1α, chromatin binding of IL-33 acts as a sink to prevent inflammation.

20.10.5 Role of IL-33 in Human Disease

Unlike IL-1α, IL-1β, and IL-18, humans have not received IL-33. Furthermore, unlike IL-1α, IL-1β or IL-18, there are no reports of blocking therapies at the time of this writing that target IL-33, such as neutralizing IL-33 antibodies, blocking antibodies to IL-1R4, blocking antibodies to IL-1R3, or soluble forms of IL-1R4. However, animal studies are numerous and suggest that IL-33 is indeed a target to combat allergic diseases such as asthma. The objective of IL-33 blocking therapies is to reduce Th2 cytokines such IL-4, IL-5, or IL-13. Since IL-33 is upstream of these Th2 cytokines, IL-33 blocking therapies have a rationale basis. In addition to a role for IL-33 in the Th2 paradigm, there are also studies revealing a role for IL-33 in classic Th1 diseases such as inflammatory bowel disease [189] and rheumatoid arthritis [190,191]. IL-33 also increases the production of IFNγ [192].

20.11 IL-36

20.11.1 IL-36 Background

There are four ligands that bind to the IL-36 receptor, IL-36α, IL-36β, IL-36γ, and the IL-36 receptor antagonist, each was reported in 2000–2001 by *in silico* research [193–195]. The IL-36 receptor was previously known as IL-1 receptor-related protein 2 [195]. IL-36 is part of the IL-1 gene cluster located on chromosome 2q13 in a stretch of 360 kb with IL-1 and IL-37 [196].

20.11.2 Role of IL-36 in Disease

A great deal of attention focused on IL-36 when it was reported that a mutation in IL-36Ra resulted in pustular psoriasis [197–199]. Indeed, IL-36 is expressed primarily in the skin.

20.12 IL-37

20.12.1 Background of IL-37

IL-37 was discovered in 2000 using *in silico* research [193]. The earlier name for IL-37 was IL-1 family member 7 (IL-1F7); there are four isoforms due to exon deletions and il37b is the most complete form. IL-37 is unique in the IL-1 family in that unlike other members of the family, IL-37 broadly suppresses not only innate but also acquired immunity. Another distinguishing characterization of IL-37 is that there is no homologue for IL-37 both in mouse and in chimpanzee. IL-37 is often elevated in humans with inflammatory and autoimmune diseases where it likely functions to limit inflammation. But in some diseases, for example, psoriasis, asthma, and calcific aortic valve disease [200], the levels of IL-37 are lower or it is absent, suggesting a relative deficient state. Transgenic mice expressing human IL-37 (*IL37*-tg) exhibit less severe inflammation in models of endotoxin shock, colitis, myocardial infarction, and lung and spinal cord injury, as reviewed in Ref. [201]. *IL37*-tg mice have reduced antigen-specific responses and dendritic cells from these mice exhibit characteristics of tolerogenic dendritic cells [202].

20.12.2 The IL-37 Signaling Complex: Requirement for IL-1R5 and IL-1R8

IL-18 binds to IL-1R5 and recruits IL-1R7. The crystallization of IL-18 allows for binding to IL-1R5 and the conformational changes that allow for the binding of IL-1R7 [203]. The TIR domains of each chain approximate, the adapter molecule myeloid differentiation factor 88 (MyD88) binds to the TIR domains, and a strong proinflammatory signal is initiated. IL-37 also binds to IL-1R5 [154,204,205]; specifically, IL-37 binds to the third domain of IL-1R5 [154,203]. However, IL-1R8 does not recruit IL-1R7, but rather IL-1R8. The TIR domain of IL-1R8 is mutated (termed TIRb) and MyD88 binding to TIRb results in a reduced signal to the nucleus [10,206]. IL-1R8 overexpression decreases the expression of MyD88, IL-1 receptor-associated kinase 4 (IRAK4) and tumor necrosis factor receptor-associated factor 6 (TRAF6) [207]. IL-1R8 functions as a sink for MyD88, depriving MyD88 from binding to native TIR domain, resulting in a weak or no signal. There is a similar sequestration of MyD88 by IL-1R8 for TLR signaling [208]. Regulation of IL-1R8 is relevant for the effects of IL-37. Evidence reveals that expression of IL-1R8 decreases with age in rats, but when rats were subjected to a calorie-restricted diet, expression of IL-1R8 increased [207]. In that study, caloric restriction resulted in decreased NFκB expression.

Although IL-1R5 is expressed on most cells, not all cells are responsive to IL-18. IL-1R5 responsiveness requires IL-1R7, as reviewed in Ref. [209]. IL-1R8 is also expressed by all cells and functions to inhibit innate and acquired immunity [9,210]. Increased expression of IL-1R8 in intestinal epithelial cells is protective in models of colitis [211]. Until recently, no ligand had been identified that binds to surface IL-1R8; nevertheless, the single immunoglobulin

extracellular domain of IL-1R8 is required for its function [208] suggesting an interaction with a ligand. In mice deficient for IL-1R8, there is heightened inflammation in several diverse models, as reviewed in Ref. [10,210,212]. For example, colitis is worse in mice deficient in IL-1R8 [213].

20.12.3 Binding Studies

Early studies indicated that IL-37 binds to IL-1R5 [204,205]. In fact, cells from IL-1R5-deficient mice or WT cells treated with a blocking antibody to IL-1R5 reveal a hyperresponsive state [214]. The anti-inflammatory properties of IL-37 is not observed in cells with a knockdown of IL-1R5 [215] supporting the concept that IL-37 binds to IL-1R5. Specific binding of IL-37 to IL-1R5 has been demonstrated using immunofluorescence, immunoprecipitation, foerster resonance energy transfer (FRET), and proximity ligation assay (PLA) in primary cells expressing constitutive levels of the receptor [215]. In addition to these methods, bioluminescence resonance energy transfer (BRET) and ground-state depletion superresolution microscopy were used to show the formation of the tripartite complex of IL-37–IL-1R5–IL-1R8 [215].

20.12.4 The IL-37, IL-18Rα, and IL-1R8 Complex

Primary macrophages and DCs from IL-1R8-deficient mice do not exhibit anti-inflammatory properties [215,216]. Most impressive are the *in vivo* responses in *IL37*-tg mice deficient in IL-1R8. As summarized above, *IL37*-tg mice are protected from systemic endotoxemia, but in *IL37*-tg mice deficient in IL-1R8, there is a near total loss of this protection [215]. Moreover, cells from *IL37*-tg mice deficient in IL-1R8 lack the suppression of cytokines, transcription factors, and signaling kinases, including suppression of mTOR and the increase in AMPK [215], lending more evidence of the requirement for a complex of IL-37, IL-1R5, and IL-1R8 for anti-inflammatory activity. However, not all changes in IL-37-mediated signaling kinases are IL-1R8 dependent [215]. One explanation for separation of IL-1R8-dependent from -independent functions may be due to the nature of the TIRb domain, which can transmit a "weak" signal, as was shown for another IL-1 receptor chain containing TIRb (IL-1R3b) [217].

In addition to the failure of *IL37*-tg deficient in IL-1R8 to protect against endotoxemia [215], the protection afforded by recombinant IL-37 in inflammatory aspergillosis was also not observed in mice deficient in IL-1R8 [218]. Other studies reveal that the beneficial effects of recombinant IL-37 in WT mice are not observed in mice deficient in IL-1R8. *In vitro*, the reduction in LPS-induced TNFα and IL-6 by recombinant IL-37 in DCs from WT mice was not observed in DCs from IL-1R8-deficient mice [219]. In IL-37-transfected macrophages, an 83% reduction in IL-1β production was observed compared to WT macrophages, but only a 34% reduction was observed when endogenous IL-1R8 was silenced [215]. A similar attenuation of the IL-37 effect was observed in PBMCs by the silencing of IL-18Rα [215]. In summary, IL-1R8 functions as a coreceptor for IL-18Rα and IL-37 is transiently associated with IL-1R8 and IL-18Rα on the cell surface upon stimulation with IL-1β or LPS [215]. This interaction is needed for intracellular

pathways to block inflammation, including not only the anticipated inhibition of MAPKs and NFκB but also the unexpected pseudostarvational effects on the mTOR pathway, inhibition of TAK1 and Fyn, and activation of the anti-inflammatory STAT3, Mer, and PTEN.

20.12.5 Production of IL-37

Using immunohistochemistry, the IL-37 protein is expressed by human blood monocytes, tissue macrophages, synovial cells, tonsillar B cells, plasma cells, T cells, neoplastic cells, and epithelial cells of the skin, kidney, and intestine. IL-37 is not constitutively expressed by blood monocytes from healthy subjects but rather requires stimulation by IL-1β, TLR agonists, or TGF-β [220]; in human keratinocytes, beta-defensin-3 induces IL-37 [221]. In the human lung type II epithelial cell, lipoarabinomannan from *Mycobacterium tuberculosis* induces IL-37 production via upregulating ERK1/2 and p38 [222]. The abundance of IL-37 transcripts is low in human blood monocytes and dendritic cells due to an instability sequence in *IL37*. This instability sequence limits mRNA half-life of IL-37 [80]. Indeed, despite having a CMV promoter, resting mRNA level for IL-37 in *IL37*-tg mice is either absent or low but rapidly increases with inflammation [156,220,223,224]. Even in stimulated human blood monocytes, the level of IL-37 protein is low at 10–20 pg/million cells.

Despite low production, recombinant IL-37 is highly active. Studies have employed picomolar concentrations of recombinant IL-37 to reduce LPS-induced IL-1β, IL-6, and TNF production *in vitro* [219]. IL-37 forms dimers [204], which are biologically inactive. Recombinant forms of IL-37 contain as much as 80% dimer and therefore to trigger a signal, the preparation is diluted in order to reduce the concentration of the dimer, which results in monomeric IL-37. With crystallization of IL-37 [225], two amino acids have been identified that participate in dimer formation: a tyrosine at position 85 and a lysine at position 73.

20.12.6 Processing and Release

Similar to other members of the IL-1 family, the IL-37 precursor contains no classical signal peptide. The precursor can be observed by western blotting of endotoxin-stimulated human blood monocytes [223]. IL-37 in the extracellular space likely reflects an unorthodox mechanism to exit the cell, which is unrelated to cell death. Nevertheless, there is a caspase-1 cleavage site at aspartic acid (D20) in exon 1 and therefore is present in isoforms IL-37b, c, d, and e. In LPS-stimulated human blood monocytes, the addition of exogenous ATP results in a modest release of processed IL-37 [223], but most of the secreted IL-37 is in the precursor form. Also, similar to IL-1α and IL-33, both precursor and processed forms of IL-37 are active [204,219,224].

A form of recombinant IL-37b with the N-terminus at valine 46 [205] was apparently processed naturally during the expression in mammalian cell. A recombinant form of IL-37 from *E. coli* has been generated (V46–218) and is 20–30-fold more active than the precursor form [219]. It remains unclear what enzyme(s) cleaved the N-terminal 45 amino acids, but extracellular proteases

from neutrophils likely generate more than one N-terminus. The high activity of IL-37b (V46–218) is likely due to its proximity to the IL-1 family AXD consensus sequence [13]. In the consensus sequence, A is any aliphatic amino acid, X is any amino acid, and D is aspartic acid. For optimal folding of the beta-fold barrel structure for receptor binding of IL-1 family cytokines, the N-terminus is nine amino acids forward from AXD towards the N-terminus.

20.12.7 Effects of Recombinant IL-37

The administration of 1 μg or less of recombinant IL-37 to WT mice reduces circulating levels of IL-1β, TNF-α, and IL-6 [219], neutrophil infiltration into the lungs [218], myocardial monocyte infiltration following infarction [226], and airway hyperresponsiveness following antigen challenge [227].

Recombinant forms of IL-37 have been shown to be active *in vivo* in WT mice in various models of inflammation. In addition, IL-37-expressing plasmids have been administered to WT mice. Because the N-terminus for endogenous IL-37 may vary, different forms of recombinant IL-37 have been tested in WT mice; the full-length IL-37b precursor (1–218) [218,219] is active *in vivo* and *in vitro*. *In vitro*, recombinant full-length IL-37b (1–218) reduced LPS-induced IL-1β, IL-6, and TNFα in human blood M1 differentiated macrophages associated with a decrease in ERK and p38 MAP kinase [219]. A dose of 1 μg or less of the IL-37 precursor protected mice against acute lung injury following intracellular-tracheal instillation of *Apergillus fumigatus* [218]. The numbers of infiltrating neutrophils were reduced as were gene expression for IL-1β, NLRP3, caspase-1, and several chemokines, whereas IL-10 increased [218]. However, recombinant IL-37b with the N-terminus at valine 46 (46–218) [205] is more active than the IL-37b precursor [219,228]. WT mice subjected to systemic endotoxemia or acute myocardial infarction are similarly protected against inflammation-induced damage [219,226]. In an asthma model of ovalbumin-sensitized mice, a low dose of recombinant IL-37 protected against antigen-challenge airway hyper-responsiveness [227]. Recombinant IL-37a with the N-terminus at lysine 27 is also active [229]. The N-terminus of this form is nine amino acids forward from the IHD consensus sequence.

20.13 Disease Models in *IL37*-tg Mice

20.13.1 IL37-tg Mice

IL37-tg mice were generated using the full-length precursor cDNA of *IL37b* isoform driven by the CMV promoter for constitutive expression [220], as this promoter is commonly used to drive expression in most cells. *IL37*-tg mice breed normally and have no obvious phenotype. However, compared to WT mice, *IL37*-tg mice are protected against LPS challenge, exhibiting significantly less hypothermia, acidosis, hyperkalemia, hepatitis, and dehydration in addition to lower levels of cytokines [220]. *IL37*-tg mice are also protected against spinal cord injury [224] as well as in other models.

20.13.2 Experimental Colitis

In *IL37*-tg mice subjected to dextran sodium sulfate-induced colitis, clinical disease scores and histological indices of colitis were significantly reduced [156]. These reductions were associated with decreased leukocyte recruitment into the colonic lamina propria. Release of IL-1β and TNFα from colonic tissue explants incubated *ex vivo* was decreased 5- and 13-fold, respectively, whereas IL-10 was increased sixfold. Since an IL-10 receptor blocking antibody did not reverse the anti-inflammatory effects on the *IL37*-tg mice, the response in these mice is independent of IL-10. Bone marrow transferred from *IL37*-tg mice into WT mice significantly reduced the severity of the colitis, suggesting that myeloid cells expressing IL-37 provided the protection [156]. Another study showed that mesenchymal stromal cell (MSC) transfected with *IL37* afforded the same level of protection as observed in *IL37*-tg mice subjected to DSS colitis [230]. MSCs without gene expression of IL-37 were not protected [230]. Also, increased myeloid-derived suppressor and T-regulatory cells were observed in mice treated with *IL37* MSC [230], whereas decreased CD4 positive cells expressing IFNγ were present [230].

20.13.3 Ischemic and Damage Models

IL37-tg mice subjected to coronary artery ligation have markedly reduced infarct size and improved left ventricular function compared to similarly challenged WT mice [231]. Reduced accumulation of myocardial mononuclear cells was observed in the *IL-37*-tg mice [231]. Cardiac vascular endothelial cells isolated from *IL37*-tg mice had reduced NFκB activation when stimulated with TLR2 and TLR4 agonists compared to endothelial cells from WT mice [231]. Hydrodynamic injection of *IL-37* in WT mice was used in a mouse model of acute renal ischemia; kidney function was preserved, mononuclear cell infiltration was reduced, and inflammatory cytokine levels were lower compared to mice injected with the control plasmid [232].

20.13.4 Spinal Cord Injury

Traumatic injuries to the spinal cord of humans following accidents leave the subjects with various degrees of lower limb paralysis. In mouse, a localized spinal cord contusion results in reduced motor function and spinal cord tissue damage. *IL-37*-tg mice were protected against the injury and exhibited greater mobility compared to WT subjected to the same injury [224]. The clinical improvement was associated with decreased infiltration of neutrophils and monocytes, fewer numbers of microglia exhibiting activation markers and reduced levels of proinflammatory cytokines [224].

20.13.5 Metabolic Syndrome

Complications of obesity, such as metabolic syndrome and type 2 diabetes, have been studied in the context of IL-18 and IL-1β and, particularly, the role of

caspase-1 [233,234]. *IL37*-tg mice fed a high-fat diet for 16 weeks had reduced numbers of adipose tissue macrophages, less lipid accumulation in the liver, improved response to insulin, and increased glucose tolerance compared to WT mice on the same diet [235]; moreover, the transgenic mice gained less weight than WT animals despite equal food and caloric intake [235]. The adipokine adiponectin is an anti-inflammatory cytokine produced by fat cells. Serum levels of adiponectin in *IL37*-tg mice were markedly higher during the high-fat diet. The anti-inflammatory properties of adiponectin include improved insulin sensitivity, although the mechanism for this property remains unknown.

In 80 human subjects, steady-state IL-37 mRNA levels in subcutaneous adipose tissue were positively associated with appropriate insulin responses, lower adipose tissue leptin, and lower inflammatory status of the adipose tissue [235]. Thus, increased levels of IL-37 in humans seem to buffer the inflammation associated with obesity and raise the possibility of recombinant IL-37 to treat metabolic syndrome in humans. Relevant to a therapeutic use of IL-37, WT mice were subjected to 20 weeks of high-fat diet and then were treated with recombinant IL-37 during the last 2 weeks of the diet. Compared to WT treated with vehicle, insulin sensitivity and glucose disposal increased significantly, secretion of IL-1β from adipose tissue decreased, and plasma levels of IL-1Ra increased by 75% in mice treated with recombinant IL-37 [228].

20.13.6 Aging in IL37-tg Mice

Increased inflammation is a characteristic of aging. The incidence of B-cell cancers such as lymphoma is higher in the elderly. Bone marrow B-cell progenitors in 20-month-old mice exhibited multiple defects in signaling, gene expression, and metabolism compared to 20-month old WT mice. Old *IL37*-tg mice preserved the function of B-cell progenitors and did not develop virus-induced leukemia [236]. The study concluded that chronic inflammatory microenvironments in old age leads to a lower resistance of B-cell bone marrow progenitor populations to oncogenesis [236]. IL-37 seems to provide an anti-inflammatory microenvironment in the aging bone marrow.

20.13.7 Translocation of IL-37 to the Nucleus

In addition to forming cell surface receptor complexes, three members of the IL-1 family, IL-1α, IL-33, and IL-37, translocate to the nucleus where they bind to nuclear DNA and participate in transcription. IL-37 translocates to the nucleus [223,237] and, in this regard, is termed a "dual-function" cytokine, similar to IL-1α [50] and IL-33 [187]. After LPS stimulation of mouse macrophage cell lines, there is a lag phase of 15 h before IL-37 is detected in nuclei [238] and after 18 h, levels of TNFα, IL-1α, IL-6, and chemokines are substantially reduced (72–98%) compared to cells transfected with an empty plasmid [220,237]. The nuclear translocation of IL-37 requires active caspase-1; inhibition of caspase-1 in LPS-stimulated mouse macrophages not only prevents nuclear translocation but also prevents IL-37 from suppressing LPS-induced IL-6 [237]. The caspase-1 cleavage site at aspartic acid 20 (D20) in exon 1 of IL-37b was mutated to alanine

and thereby prevents the cleavage of IL-37 by caspase-1 but without inhibition of caspase-1 itself in the cell. Cells expressing the mutant IL-37D20A not only failed to translocate in the nucleus [223] but also failed to suppress LPS-induced IL-6 [223]. Together, these data reveal an unexpected role of caspase-1 in enabling the nuclear translocation of IL-37 and subsequently suppression of inflammation. As of this writing, it remains unknown how much of the suppression of inflammation or acquired immunity in *IL37*-tg mice is due to nuclear IL-37 or extracellular IL-37.

20.13.8 Requirement for Smad3

Smad3 is a kinase downstream of the TGF-β receptor; Smad3 is associated with the immunosuppressive and anti-inflammatory properties of TGF-β. A proteomics-based search for intracellular proteins that interact with Smad3 identified IL-37 [239]. IL-37 immunoprecipitates with phosphorylated Smad3 and the IL-37–Smad3 complex has been observed in the perinuclear space [220]. Also, a specific inhibitor of Smad3 reversed IL-37-mediated inhibition of IL-6 induced by IL-1β [220]. Depletion of Smad3 by lentiviral shRNA or siRNA also prevented the ability of IL-37 to suppress inflammation both *in vitro* and *in vivo* [220]. As intracellular levels of the IL-37 precursor increase, LPS activation of caspase-1 cleaves IL-37 at D20. One working hypothesis is that the carboxyl domain of IL-37 binds to Smad3 and becomes phosphorylated. It is proposed that this complex then migrates to the nucleus and suppresses gene expression. Unlike IL-1α and IL-33, IL-37 does not contain a classic nuclear localization sequence and, therefore, it is likely that Smad3 transports IL-37 to the nucleus.

The IL-37 precursor exits in the cell by the loss of membrane integrity, by frank cell death, or by an unknown mechanism. Although the precursor is active *in vivo* and *in vitro*, whether there is subsequent processing by extracellular enzymes to a "mature" form is unknown. Nevertheless, from studies with recombinant IL-37, we know that the most active form of IL-37b *in vivo* and *in vitro* is a processed form (46–218) [205,219,224]. Binding to the IL-18Rα has been reported [215,219]. The complex of IL-18Rα and IL-1R8 then signals the cell to initiate a program to reduce inflammation.

20.13.9 A Role for IL-37 in Human Disease

Increased levels of IL-37 have been reported in several human disease conditions by measuring mRNA levels in cells derived from subjects affected with a specific disease as well as the concentrations of IL-37 in the circulation. In addition, immunohistochemistry of tissues and production from cells *in vitro* are also reported. For example, IL-37 is present in colonic tissues from patients with inflammatory bowel disease, but it is absent in biopsies from healthy subjects [240,241]. IL-37 is elevated in patients with rheumatoid arthritis [242–245], but patients with a coding region mutation in IL-37 had lower joint disease scores and less pain compared to patients without the mutation, suggesting a gain of function mutation for the anti-inflammatory properties of IL-37 [246]. In PBMC from HIV-1-infected subjects, steady-state mRNA levels are fourfold higher

compared to noninfected subjects and correlate with the levels of soluble CD14 [247]. These and similar studies support the concept that infection or inflammation increases IL-37 expression, which is an appropriate response to limit disease severity. Anti-inflammatory mediators such as IL-1 receptor antagonist, soluble TNFα receptors, and the IL-18-binding protein are also elevated in several of the diseases.

In contrast, in some diseases, the opposite is observed, that is, there is a lower level of IL-37 compared to the level in healthy subjects. A low level of IL-37 likely contributes to increased disease severity. Patients with a wide range of inflammatory diseases and low levels of IL-37 may reflect a failure to have sufficient levels to combat inflammation. In obesity, increased levels of IL-37 in human adipose tissue are associated with less insulin resistance [235] and therefore are consistent with a functional role of IL-37 in limiting inflammation. In HIV-1, the elevated levels of IL-37 can be interpreted in two ways: the elevation is an appropriate response to limit the inflammation of a chronic infection or the elevation contributes to the immunosuppression of HIV-1 [247].

Missense coding mutations in cytokines such as IL-1β, TNFα, and IL-6 are rare compared to coding mutations in receptors, intracellular proteins, and kinases. IL-37 may be an exception since there are missense sssociated with disease. For example, SNP rs3811047 (A–G in exon 2) results in threonine to alanine change. This SNP is associated with less severe disease in patients with rheumatoid arthritis [246,248]. In the case of humans with IL-37 haplotyope2, decreased levels of IL-37 protein may contribute to more pronounced inflammation [249]. Africans have the highest incidence of haplotype2 (17%), whereas, globally, the incidence is 8% [249].

20.14 IL-38

20.14.1 The Functional Role of IL-1 Family Member 10, Recently Renamed IL-38

IL-38 also was discovered by *in silico* research from the large data bases of the human genome. IL-38 was an orphan cytokine in the IL-1 family until the discovery that recombinant human IL-38 bound to the IL-36 receptor [250]. Interest in IL-38 is derived from the finding that in a large genome-wide association analysis study in over 66 000 subjects with elevated C-reactive protein looking for a missense mutations reported IL-38 was one of the top risk factors [251]. IL-38 belongs to the IL-36 subfamily. Using killed *Candida albicans* yeast cells, recombinant human IL-38-stimulated PBMC released IL-17 and IL-22. The reduction in IL-22 and IL-17 caused by IL-38 was similar to that caused by the naturally occurringIL-36Ra in the same peripheral blood mononuclear cells cultures [250]. When human blood monocyte-derived dendritic cells were used, both IL-38 and IL-36Ra increased LPS-induced IL-6 by twofold. IL-38 bound only to the IL-36 receptor, as did IL-36Ra. The dose-response suppression of IL-38 and that of IL-36Ra of Candida-induced IL-22 and IL-17 was not that of the classic IL-1 receptor antagonist (anakinra), because low concentrations were optimal for

inhibiting IL-22 production, whereas higher concentrations modestly increased IL-22. These data provide evidence that IL-38 binds to the IL-36R, as does IL-36Ra, and that IL-38 and IL-36Ra have similar biological effects on immune

TNF Superfamily

Salvatore Cuzzocrea

University of Messina, Biological & Environmental Sciences, Viale Stagno d'Alcontres 31, 98166 Messina, Italy

21.1 Introduction

Tumor necrosis factor superfamily (TNFSF) is a group of cytokines composed of 19 ligands and 29 receptors [1]. This family plays a pivotal role in immunity, in inflammation, and in controlling cell cycle (proliferation, differentiation, and apoptosis). TNFSF receptors can be divided into two different groups depending on the presence or absence of the intracellular death domain (DD). Signaling via the death domain demands the involvement of adapter proteins FADD (Fas-associated death domain) and TRADD (TNF receptor-associated death domain) and leads to activation of caspases that results in apoptotic death of a cell [2]. The second group of TNFSF receptor signals act only via adapter proteins termed TRAFs (tumor necrosis factor receptor-associated proteins), although DD containing receptors can also use this pathway. TRAFs bind either to TRADD or directly to the cytoplasmic part of the receptor and initiate signal transduction pathways that also lead to the activation of several transcription factors, such as AP-1 and NF-*k*B that are responsible for the activation of prosurvival genes, even though they are implicated in proapoptotic signaling [2]. In this context, functional activity of TNFSF receptors depends on the cellular context and the balance between pro- and antiapoptotic factors inside the cell and in the environment. Mostly, the TNFSF members are revealed on cells of the immune system and play a notable function in maintaining the equilibrium of T-cell-mediated immune responses by arranging direct signals required for the full activation of effector and regulatory T cells, regulation of their expansion, contraction of the T-cell effector pool, and survival of memory T cells [3]; for this reason, the TNFSF members are necessary in the development of pathogenesis of many T-cell-mediated autoimmune diseases, in particular asthma, diabetes, and arthritis [4].

21.2 TNFα

Tumor necrosis factor alpha, also called TNFα or TNFSF2, is classified as homotrimeric transmembrane protein with a preminent role in systemic inflammation. TNFα is expressed as a membrane-bound precursor (tmTNFα), which is later cleaved between Ala^{76} –Val^{77} by a metalloproteinase known as TNFα-converting enzyme (TACE), and called soluble TNFα (sTNFα). Several cell types are able to produce TNFα, including activated macrophages, dendritic cells, monocytes, NK cells, $CD4^+$ T cells, $CD8^+$ T cells, microglia, and astrocytes.

Macrophages/monocytes are able to produce TNFα in the acute phase of inflammation and this cytokine drives a wide range of signaling events within cells, leading to necrosis or apoptosis. TNFα drills its effects by binding, as a trimer, to either a 55 kDa cell membrane receptor defined as TNFR-1 or a 75 kDa cell membrane receptor known as TNFR-2. The TNF superfamily incorporates RANK, CD40, CD27, and FAS. The defining trait of these receptors is represented by an extracellular domain made of two–six repeats of cysteine-rich motifs. Moreover, a number of structurally related "decoy receptors" subsist that act to sequester TNF molecules, thereby rescuing cells from apoptosis. For the first time in 1975, this protein was discoverd in the circulation of animals subsequent to stimulation of their reticuloendothelial system and lipopolysaccharide challenge [5]. This protein has been found to provoke a rapid necrotic regression of certain forms of tumors. This discriminatory TNFα-mediated cytotoxicity may be correlated to the tumor cell's ability to undergo nitrotyrosinylated tubulin-mediated microtubule dysfunction [6]. TNFα and TNFβ structures were defined and these proteins were found as a "pear"/"cone" shaped trimers, TNF receptors, TNFR-1, and TNFR-2; moreover, they were cloned and expressed as 55 and 75 kDa proteins.

21.3 TNFα: Biological Roles

Several biological functons are ascribed to the TNFα and for this reason the mechanism of action is somewhat complex (Figure 21.1). Because this proteine confers resistance to certain types of infections and in parallel cause pathological complications, it carries out contradictory roles. This may be connected to the varied signaling pathways that are activated [7].

TNFα modulates several therapeutic roles within the body, such as immunostimulation, resistance to infection agents, resistance to tumors, sleep regulation, and embryonic development [8]. On the other hand, parasitic, bacterial, and viral infections become more pathogenic or fatal due to TNF circulation [7]. The major role of TNF is explicated as mediator in resistance against infections; moreover, it was postulated that TNF plays a pathological role in a number of autoimmune diseases such as graft versus host rejection or rheumatoid arthritis [9]. In addition, TNF exibits antimalignant cell cytotoxicity in particular in association with interferon [7]. Nevertheless, high concentrations of TNFα are toxic to the host (in fact, the maximum tolerated dose in humans is 200 mg/m^2), and it is necessary to increase the therapeutic index either by decreasing toxicity (e.g., pretreatment with IL-1) or by increasing effectiveness. This may be possible

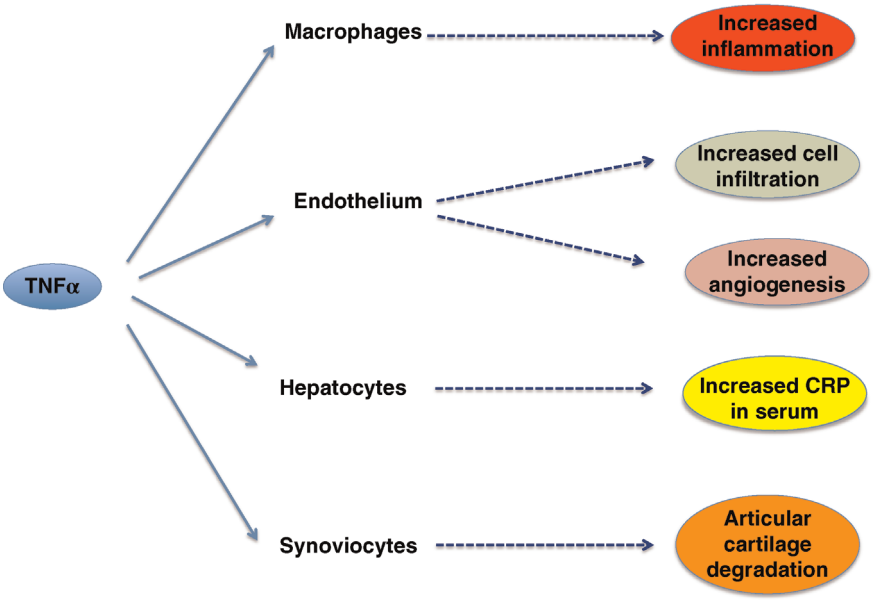

Figure 21.1 Actions of TNF superfamily.

through mutations that reduce systematic cytotoxicity and increase TNF's effectiveness in selectively eliminating tumor cells. TNFα is also implicated in physiologic sleep regulation. Administration of exogenous TNFα is able to induce increased sleep, however, contrary to its inhibition reduces spontaneous sleep. TNFα mRNA is generated during diurnal rhythm in brain with the highest levels occurring during peak sleep periods. The absence of the TNFR-1 receptors resulted in reduced sleep in animal models. Similar effects were observed with the cytokine IL-1. TNF-mediated apoptosis also seems a part of normal embryonic development [8]. TNF can also induce necrotic or apoptotic cell death. Several actions are correlated with the TNFα pathway; for example, TNF related proteins such as RANKL are required for osteoclast differentiation, necessary for bone resorption [10].

21.4 Mechanisms of Action

The TNFα effects are exerted by binding and clustering high-affinity receptors present in great numbers in most cell membranes [11]. The ligand/receptor complex is easily internalized via clathrin-coated pits and ends up in secondary lysosymes where it is degraded. Interestingly, the binding of TNFα to the 75 kDa TNFR-2 is not sufficient to reach cytotoxicity, but rather binding to the 55 kDa TNFR-1 is sufficient to reach TNFα-mediated cell killing. TNFα exerts its effects by activating several secondary proteins that provoke a variety of responses within the cell such as activation of gene transcription and/or production of reactive oxygen or nitrogen radicals (e.g., NO).

Activated proteins include GProtein, transcription factors such as NF-κB and AP-1, protein kinases such as CK II, erk-1, erk-2, and MAP2, phospholipases such as PLA2, PLC, and PLD, and sphingomyelinase mitochondrial proteins such as manganese superoxide dismutase, and serine and cysteine proteases, known as caspases. Many members of the TNF receptor superfamily have intracellular "death domains," which represent protein interaction domains each consisting of 65–80 amino acids; these proteins participate in TNFα-mediated apoptosis process.

21.5 Characterization of the TNFα Gene and Molecule

The gene of TNFα is a single-copy gene, preceded by the TNFβ on the short arm of human chromosome 6 and murine chromosome 17 [12]. TNFα is always 39 to the TNFβ gene and is around 3 Kb long. This gene is composed of four exons, arranged approximately 3 kb of DNA, interrupted by three introns. More than 80% of the mature TNF sequence is encoded in the fourth exon, while exons I and II contain almost entirely leader peptide sequence. The TNFα mRNA seems to be transcribed in a wide variety of cells. The 59 flanking region of the TNFα gene contains several kB homologous sequence enhancer elements and a MHC class II like "Y box." Probably, these sequences seem to be involved in transcriptional activation. The gene also seems to be regulated at the translational level through the UA-rich sequence in the 39 untranslated region of the human TNFα mRNA. The mRNA translates into a 157 amino acid protein in human and 156 in murine cells [12]. Two different forms of TNFα are available: a membrane-bound and a soluble form; each form possibly carries out a distinct physiological role [13]. Human TNFα is expressed as a precursor molecule of a 157 amino acid sequence, preceded by a 76 amino acid presequence (79 in murine). This presequence is highly conserved and seems to serve to anchor the precursor polypeptide in the membrane. Hence, unlike TNFβ, which is secreted, TNFα is produced as a type II membrane protein. TNFα exists in a more diverse range of cells than TNFβ. TNFα is produced in a wide variety of hematopoietic and nonhematopoietic cells, both normal and malignant. Among these macrophages, for instance, there are CD41 and CD81 T-lymphocytes, B-lymphocytes, neutrophils, NK cells, LAK cells, astrocytes, smooth muscle cells, endothelial cells, and a nonhematopoietic tumor cell lines. Actually, the classical cell line for testing TNF cytotoxicity is represented by murine fibrosarcoma cell line L929, although others, for example, WEHI164 clone, display heightened sensitivity. Some cells can be stimulated to produce the two different forms of TNF.

21.6 TNF Receptors and the TNF Receptor Superfamily

TNFα links to two cognate receptors of molecular weight 55 and 75 kDa [14]. A total 434 amino acids form human TNFR-1 and 439 amino acids TNFR-2. Both receptors share very restricted homology in the extracellular region. The superfamily of TNF receptor is determined by the presence of repeating units of

cysteine clusters. No homology is observed in the intracellular regions of the proteins. All known cell types showed a TNF receptors, such as unstimulated T lymphocytes and erythrocytes. Its density ranges is from 200–10 000 per cell. No correlation is reported between the number of receptors present on a cell and the magnitude or direction of the TNF-induced response [15]. In the serum of cancer patients and in human urine, soluble forms of TNFR-1 and TNFR-2 were detected. It was postulated that both forms regulate TNFs activity by decoying the ligand, thereby downregulating the generated signals. Members of the TNF receptor family belong to the type I transmembrane glycoproteins. They share a common cysteine-rich motif repeated two–six times in the extracellular N-terminal domain [9]. The average homology in these repeats is around 25% between the various members. The receptors differ in the possession of a cytoplasmic "death domain," which is missing in a several components of the TNFR family. Both TNFR-1 and TNFR-2 are N-glycosylated, only TNFR-2 is O-glycosylated. All other membrane receptors are glycosylated. The primary sequence of TNFR-1 suggests the presence of a number of potential phosphorylation consensus sites for PKC or CK II. TNFR-1 showed ubiquitous distribution on cells such as epithelial cells and fibroblasts, while TNFR-2 is more restricted, primarily to the cells of hematopoietic origin. CD40 is revealed as a 50 kDa glycoprotein on a variety of cells such as B cells, monocytes, thymic epithelium, dendritic cells, and at a low level of T cells. Fas receptor is expressed in activated T cells, monocytes, B cells, and neutrophils. Fas mRNA is detected in several organs in rodents. CD30 receptor was identified in Hodgkin's cells, but it is expressed in a number of non-Hodgkin's lymphoma cells as well as virally mutated B- and T-cell lines [16]. CD27 is showed on the majority of medullary thymocytes and peripheral blood T cells. It is also present on some B and NK cells. The receptor 4-1BB is manifested on activated CD81 and CD41 T cells and human lung epithelial cells and intestinal intraepithelial T lymphocytes [16].

21.6.1 TL1A

TL1A, also called TNF-like molecule 1A or TNFSF15, was discovered in 2002 and is classified as a member of the TNF superfamily [17]. The human species is caractherized by three isoforms of the protein produced from TNFSF15 gene as a result of alternative splicing, in particular VEGI-174, VEGI-192, and TL1A (VEGI-252), although VEGI-174 is most probably a cloning artifact [17]. VEGI-192 inhibits angiogenesis, whereas TL1A represents a proinflammatory factor embroiled in the pathogenesis of autoimmune diseases such as allergic lung inflammation, arthritis, autoimmune encephalomyelitis, and inflammatory bowel disease (IBD) [18]. Dendritic cells, macrophages, and CD4(+) and CD8(+) T cells express TL1A, whereas very little TL1A was discovered in nonactivated immune cells [18]. TNF, IL-1, Fc fragments of IgG1 antibodies, and certain parasite- or bacteria-related Toll-like receptor ligands, such as synthetic bacterial lipoprotein Pam3CSK4, LPS, polyinosinicpolycytidylic acid, lipopeptide FSL, single-stranded RNA, tachyzoite antigen, and unmethylated DNA sequences, are considered inducers of TL1A expression. DR3 is the main receptor for TL1A with a similar structure of TNFR1. This receptor is upregulated in activated monocytes, NKT

cells, NK cells, B cells, and CD8(+) T cytotoxic cells and CD4(+) T helper. TL1A is considered a proinflammatory molecule able to boost proliferation and effector functions of CD8(+) cytotoxic T cells, as well as Th1, Th2, and Th17 cells, in the presence of TCR stimulation; under physiological conditions, TL1A is not required for the differentiation of these lymphocytes [19]. TL1A stimulates maturation of dendritic cells and production of IL-8, TNF, and monocyte chemotactic protein-1 by macrophages [20]. Moreover, TL1A/DR3 interaction triggers proliferation of regulatory T cells (Tregs) [21]. *In vitro* studies suggested that TL1A inhibited differentiation of Tregs from their precursor cells [22]. TL1A seems to be a promising therapeutic target for patients with T cell-mediated autoimmune diseases, such as IBD, although to this day none of TL1A blocking agents has yet been studied in clinical trials.

21.6.2 FasL

Fas ligands, namely, FasL, CD95 L, or TNFSF6 and its receptors Fas, CD95, and TNFRSF6 are members of the TNF superfamily involved in the pathogenesis of IBD. Fas ligands, namely, FasL, CD95L, or TNFSF6 and its receptors Fas, CD95, and TNFRSF6 are members of the TNF superfamily embroiled in the pathogenesis of IBD. Structurally, FasL is known a transmembrane molecule, although it can be enzymatically derived from cells [23].

Cytotoxic T cells and natural killer cells take FasL to kill tumor cells and virus-infected cells expressing Fas. FasL is also implicated in keeping immune homeostasis and preventing autoimmunity via activation-induced cell death that depends on killing activated T cells following their expansion and differentiation in a FasL/Fas-dependent manner, thus preventing hyperactivation of T-cell mediated immunity [24].

FasL expression is finely regulated and restricted to activated CD4(+) and CD8(+) T cells, NK cells, and monocytes [25]. Phisiologically, Paneth cells represent the only cells of the intestinal epithelium that express FasL [26]. Their expression was also discovered in tissues and organs lacking resident or infiltrating lymphocytes and in neurons and astrocytes as well as in tumors where it may cause the suppression of immune responses via induction of T cell apoptosis [25]. Fas and FasL, while playing an important role in the regulation of apoptosis, have also nonapoptotic functions. Fas holds the death domain and, contrary to TNFR1, has been thought to be implicated only in proapoptotic but not prosurvival signaling [27].

Strong Fas stimulation blocked activation of human CD4(+) helper T cells, while weak Fas stimulation together with TCR signaling augmented their proliferation via activation of MAP kinases, transcription factors, and cell cycle activators [28].

21.6.3 LIGHT

LIGHT, also called lymphotoxin-like inducible protein that compete with glycoprotein D for binding herpes virus entry mediator on T cell, TNFSF14, ligand for the lymphotoxin beta receptor (or LTβR or TNFRSF3), and the herpes virus entry mediator (HVEM or TNFRSF14) is primarily expressed in activated T cells, although it is also found in monocytes, granulocytes, and immature dendritic

cells [29]. Both LTβR and HVEM receptors do not encompass the death domain; therefore, they are considered to be involved in prosurvival signaling [21]. As a matter of fact, interaction between LIGHT and HVEM was found to enhance proliferation and effector functions of CD8(+) cytotoxic T cells [30], boost expansion of CD4(+) helper T cells, and facilitate their differentiation intoTh1 cells [31]. It was reported that LIGHT contributes to the development of intestinal inflammation; for example, transgenic mice with elevated expression of LIGHT naturally develop colitis [32].

21.6.4 DcR3

DcR3 represents a soluble receptor for TL1A, LIGHT, and FasL and is a member of the TNF receptor superfamily that does not possess the transmembrane domain [33]. It is able to inhibit the interaction between its ligands and their membrane-bound receptors, thus repressing their biological activity. A high-level expression of DcR3 was shown in inflamed mucosa and serum of CD and UC patients [34].

21.6.5 TRAIL

TRAIL,TNF-related apoptosis-inducing ligand or TNFSF10, is another member of TNF superfamily expressed in a large variety of tissues including intestines may be implicated in the pathogenesis of IBD [35]. Similar to TNF, TRAIL induces apoptosis and can also stimulate the prosurvival transcription factor NF-κB. Five receptors of TRAIL have been identified: TRAILR1 (TNFRSF10A or DR4) and TRAIL-R2 (TNFRSF-10B or DR5) that possess the death domain in their cytoplasmic fragments and are entailed in functional TRAIL signaling; TRAIL-R3 (TNFRSF10C or DcR1) without death domain and TRAIL-R4 (TNFRSF10D or DcR2) with defective death domain and soluble osteoprotegerin (OPG or TNFRSF11B) are regarded to be decoy receptors [36]. Expression of TRAIL was found to be downregulated in intestinal epithelial cells of IBD patients [180]; however, it was significantly elevated in mononuclear cells of the resected inflamed mucosa in both CD and UC patients with highly active, steroid-refractory disease [37].

21.6.6 TWEAK

TWEAK, also named TNF-like weak inducer of apoptosis or TNFSF12, operates through its receptor Fn14 (TNFRSF12 or TWEAK-R) and has several biological activities, incorporating induction of proinflammatory cytokines and stimulation of cell growth, and, in certain experimental settings, induction of apoptosis. TWEAK protein is expressed in particular in immune cells such as T cells, macrophages, or dendritic cells, although it was discovered in nonhematopoietic cell types such as astrocytes or endothelial cells [38]. Expression of TWEAK receptor, Fn14, was discovered in many types of cells including intestinal mucosa cells. Fn14 does not contain the death domain and its stimulation with TWEAK results in activation of the transcription factor NF-κB [39]. Deficiency or

reduction of TWEAK and its biological activity by anti-TWEAK monoclonal antibodies diminished expression of proinflammatory cytokine, neutrophil, and macrophage infiltration decreasing severity of trinitrobenzenesulfonic (TNBS) acid-induced colitis in rodents [40]. Thanks to *in vitro* studies on rhabdomyosarcoma cell line Kym-1, it was demonstrated that TWEAK upregulated expression of transmembrane TNF that in turn provoked cell apoptosis via TNFR1 [41]. Moreover, TWEAK stimulation enhanced TNFR1-mediated apoptotic cell death of Kym-1 cells [41] that can be clarified by the fact that TWEAK promotes translocation of antiapoptotic adapter protein TRAF2 from the TNFR1 signaling complex, increasing proapoptotic signaling of this receptor [42].

21.6.7 BAFF-R–BAFF

The B-cell-activating factor of the tumor necrosis factor family (BAFF, also called TNFSF13B or CD257 or B lymphocyte stimulator "BLys") was for the first time described as a molecule secreted by T cells and dendritic cells that ensure maturation and survival of peripheral B cells. Its expression was also reported in macrophages, dendritic cells, and neutrophils [43]. BAFF transgenic mice have wired numbers of B and effector T cells and display symptoms similar to that observed in B-cell-mediated autoimmune diseases [44]. For example, immature B cells in the bone marrow manifest BAFF receptor (also BAFF-R) and this expression is upregulated in the development from transitional B-cell stage to mature B cell in the secondary lymphoid organs [45]. BAFF is able to interact with transmembrane activator calcium modulator and cyclophilin ligand interactor (also TACI) and B-cell maturation factor (BCMA) [46]. TACI is expressed in marginal-zone B cells; moreover, BCMA is expressed in germinal center B cells, plasma cells, and memory B cells. BAFF, TACI, and BCMA interact with APRIL, another TNFSF member.

21.6.8 OX40–OX40L

The OX40 or ACT35 or CD134 or TNFRSF4 represents a type I glycoprotein of ~50 kD, expressed in activated T cells, such as Th1, Th2, Th17, Foxp3+ regulatory CD4+ T cell (Treg), and CD8+ T cells [47]. Its ligand, namely, OX40 ligand or OX40 L or gp34, CD252, and TNFSF4, is a glycoprotein expressed in APCs, such as dendritic cells, B cells, macrophages, and endothelial cells. The interaction of OX40–OX40 L gives a costimulatory signal to T cells, which leads to their activation and also cytokine secretion [48]. Blocking OX40–OX40 L interactions protects from several inflammatory autoimmune diseases such as EAE. OX40–OX40 L signaling in CD4+ T cells stimulates IL-12Rβ2 [49] expression and inhibits CTLA-4, Foxp3, and IL-10 expression. Upregulation of IL-12Rβ2 drives Th1 differentiation, whereas loss of Foxp3, CTLA-4, and IL-10 inhibits the Tregs suppressive function. Loss of balance between pathogenic and regulatory cells could relieve autoimmune pathology. OX40–OX40 L interactions regulate CD4+ T-cell subsets' differentiation, and deficiency of OX40 weakens Treg development [50]. Moreover, OX40L–OX40 signaling inhibits Foxp3 expression and plays as a differentiating factor for Th9 in airway inflammation [51].

21.6.9 GITR–GITRL

Glucocorticoid-induced TNFR family-related gene known as CD357 or TNFRSF18 is revealed at the low levels in resting mouse and human T cells, and is upregulated in activated $CD4^+$ and $CD8^+$ T cells. It is constitutively expressed in Tregs [52]. Interaction with GITRL is able to prevent the suppressive function of $CD4^+$ $CD25^+$ Tregs, and blocking these links breaks the peripheral immune tolerance. B and endotelian cells, bone marrow-derived dendritic cells, and macrophages express GITRL [53]. Moreover, signaling through GITR promotes cytokines production such as IFN-γ, IL-4, IL-2, and IL-10 in $CD4^+$ T cells [54].

21.7 TNF Family: Role on Inflammatory Bowel Diseases

IBD patients showed elevated expression of TNF. TNF mRNA was overexpressed in involved colonic tissue of patients affected from CD (Crohn's disease) as well as in both involved and uninvolved colonic tissue of UC (ulcerative colitis) patients compared to healthy subjects [55]. High-level expression of TNF protein was detected in blood serum of CD patients, while other groups had elevated levels of TNF protein in serum and in the intestinal lamina propria of both CD and UC patients as well as the intestinal submucosa of CD patients [56]. The production of TNF in the colon mucosa of UC patients was localized to lamina propria macrophages. Pathogenesis of IBD is correlated with modified expression of TNF receptors since both CD and UC patients revealed elevated expression of TNFR2 on colonic epithelial cells [57]. A positive correlation was ascetained between UC and CD activity and serum concentration of both soluble forms of TNFR1 and TNFR2 [55]. Moreover, upregulated expression of TNFR2 was established in intestinal lamina propria CD4+ cells and in peripheral blood T cells of CD-affected patients [58]. Many reports showed that TNF leads to the disruption of intestinal epithelial barrier that allows for intestinal penetration of luminal antigens and facilitates intestinal inflammation [59]. The integrity of intestinal epithelium is arranged by the presence of TJ (tight junctions) situated in the apical region of intestinal epithelial cells. *In vitro* studies by Ma *et al.* [59] revealed that stimulation of colonic epithelial Caco-2 cells with TNF is able to downregulate expression of TJ-associated zonula occludens-1 proteins and modified their junctional localization in an NF-κB-dependent manner [59]. Moreover, IBD patients showed elevated mucosal expression of another TNF sheddase, namely, metalloprotease ADAM19 that is localized mainly in epithelial cells [60], whereas a mouse study demonstrated that shedding of TNF can also be modulated by matrix metalloproteinase 13 [61]. *In vitro* studies demonstrated that TNF upregulated expression of MLCK in Caco-2 cells pretreated with IFN-γ that increased expression of TNF receptors in the cell surface [62]. A recent study on TNFR1 or TNFR2-deficient mice showed that upregulation of MLCK and the loss of intestinal epithelial barrier in CD4(+) CD45RB (high) T cell transfer model of intestinal inflammation were dependent on TNFR2 expressed in intestinal epithelium but not TNFR1 [63]. TNF signaling upregulated expression of inducible nitric oxide synthase led to increased expression of a proapoptotic

protein p53 [64]. Moreover, TNF takes part in transactivation of epidermal growth factor receptor that upregulates the expression of cyclooxygenase-2 (COX-2) [65]. High-level expression of COX-2 has been linked to enhanced cell resistance to inflammation, apoptosis, and promotion of tumor progression; it is relevant that this aspect of TNF activity might have importance to development of IBD-associated cancers of the GI tract [66]. All components of the TNF superfamily lead to the pathogenesis of IBD and in particular (1) TNF acts to destroy the integrity of intestinal epithelium by mutating the arrangement of adhesion proteins in enterocytes; TNF, FasL, TRAIL, and TWEAK act to elicit apoptotic death of enterocytes and (2) TNF, TL1A, LIGHT, TWEAK, and perhaps FasL encourage the proinflammatory activity of mucosa infiltrating mononuclear cells and influence the activity of regulatory T cells and regulatory macrophages. Recently, TNF superfamily members have drawn a lot of attention as potential therapeutic targets in IBD management. At present, the only TNFSF component employed in clinical treatment of IBD is represented by TNF. Another hopeful target, while still not assessed in clinical trials, is TL1A that looks to be one of the key factors adjusting the inflammatory pathways in IBD. FasL, TRAIL, LIGHT, and TWEAK still require more in-depth studies to better define their function in intestinal inflammation.

21.8 Role in Neuronal Inflammation

The CNS represents as an immune-privileged site and it is caractherized by a network of CNS microvessels. These are constituted by a highly specialized endothelial lining sustained by astrocytes, pericytes, microglial cells, and neurons, which form the blood–brain barrier (BBB). The BBB confines entry of immune cells into the CNS, thereby maintaining a homeostasis. Nevertheless, in inflammatory states, the BBB gets disaggregated and immune cells move into the CNS parenchyma. A lesioned BBB is one of the hallmarks of autoimmune demyelinating diseases such as EAE and MS [67]. A good body of evidence demonstrated that TNF–TNFR interactions are implicated in the pathogenesis of CNS disorders such as EAE and MS. These interactions are able to monitor the disease outcome by fine-tuning peripheral immune response as well as interactions between CNS-resident cells and effector immune cells in the CNS. TNFRSF21 and TNFRSF19 are tuned in the acquisition and development of barrier property in BBB [68,69]. Both these TNFRSF members are downstream objective of the Wnt/beta-catenin signaling pathway in the BBB endothelial cells. Dysregulation of TNFRSF21/TNFRSF19 signaling guides to the rupture of endothelial BBB. Since Wnt/beta-catenin signaling is necessary for CNS angiogenesis but not for peripheral vasculature, an understanding of the molecular mechanism of this signaling would aid in designing novel therapeutics or biologics that target TNFSF–TNFRSF interactions, to control CNS autoimmunity [69].

TNFα operates as a proinflammatory cytokine in the early phase of EAE and indicates immunosuppressive properties during the later phase. The administration of a TNFR-1–IgG fusion protein or neutralization of anti-TNF antibody has been demonstrated to manage the development of EAE [70]. This regimen also

modulated the activation of $CD4^+$ T cell and microglia cells and avoided demyelination in CNS [71]. It was demonstrated that a deficiency of TNFα defers the disease progression and also resulted in disease of comparable severity; moreover, other authors have reported that TNFα-deficient mice expanded a more severe myelin oligodendrocyte glycoprotein (MOG) peptide-induced EAE compared to wild-type littermate controls [72]. TNFα expression, in particular in neurons in transgenic mice, leads to the progression of spontaneous inflammatory demyelination [73]. Deficiency of TNFα, LT-α and TNFR-1 or neutralization of TNF-α and LTα with monoclonal antibodies diminished the severity of EAE [74]. TNFR-2-deficient mice evolved more severe inflammation and demyelination in MOG35–55 -induced EAE [75]. In patients suffering from MS, TNFα was detected to be expressed at high levels in the CNS lesions and cerebrospinal fluids and not in serum [71], suggesting that TNFα was locally made in the inflamed CNS. This indicates that TNFα might be a target for therapy against MS. TNFα inhibitors indicated protection in the mouse model of EAE, but adverse effects were reported in clinical trials in MS patients [76]. Likewise, a clinical trial with TNFR-1 fusion protein in MS patients revealed disease aggravation and the trial was stopped [77]. This incremented demyelination with TNFα antagonist might be due to the some possible reasons such as (a) downregulation of anti-inflammatory cytokine IL-10 and overexpression of inflammatory cytokine IL-12 and IFN-γ; (b) downregulation of TNFR-2, known to modulate proliferation of oligodendrocytes and damage repair; (c) possibility of reduced or nonpermeability of the BBBs to TNFα blockers that would avoid their action through these molecules could still enhance the disease by increasing autoreactive T cells in the peripheral tissues, which can migrate into the CNS and damage the tissues; (d) unmasking of latent infection, which is crucial for inducing the autoimmune demyelination reaction.

The interaction of Fas with FasL on infiltrating cells in the CNS or activated CNS-resident cells such as microglia, astrocytes, and neurons also leads to the induction of apoptosis. This interaction plays an important role in immune cell homeostasis; moreover, its dysregulation leads to various autoimmune diseases. Mice with autosomal recessive mutations in Fas and FasL genes generate a spontaneous autoimmune syndrome accompained by production of autoantibodies and accumulation of CD4–CD8 T cells in the secondary lymphoid tissues, resulting in the progressive development of lymphadenopathy and splenomegaly [78]. Moreover, Fas- and FasL-deficient mice are also resistant to MOG-induced EAE compared to wild-type mice, and intrathecal injection of recombinant FasL protein or neutralizing with anti-FasL antibody suppresses acute EAE [79]. Mice that have genetic deficiency of BAFF-R showed hypersusceptibility to MOG35–55 peptide-induced EAE [80], indicating that this receptor is involved in a regulatory function in EAE. Moreover, BAFF can stimulate the autoreactive Th17 response, leading to increased progression of EAE [81]. Interaction of OX40–OX40 L in CD28-deficient mice brings the identification of OX40–OX40 L signaling as being costimulatory in EAE, and it also blocks interaction-protected mice from EAE [82]. In the rat EAE model, pathogenic OX40+ CD4+ T cells were identified in CNS lesions and neutralization of OX40 by anti-OX40 antibody improved the EAE [83]. Brain endothelial cells are the important component of the BBB and are known to express OX40 L,

which recruit OX40+ autoreactive T cells in the CNS. OX40 treatment of human umbilical cord endothelial cells leads to the upregulation of CCL5, prompting that this signaling modulates endothelial cells to engage a selective population of immune cells at the BBB [84]. Blocking OX40 L by anti-OX40 L antibody diminished the infiltration of OX40+ myelin-specific T cells in the spinal cord without modulating the priming of the myelin-specific CD4+ T cells in the draining lymphnodes in EAE [85]. Therefore, OX40–OX40 L not only controls the activation and differentiation of CD4+ T cells but also potentiates their migration into the CNS. These results indicate that OX40–OX40 L sustains the development of neuroinflammation and CNS autoimmunity.

It was demonstrated that transgenic mice that constitutively express GITRL in B cells (GITRL+ B cells) displayed a higher number of peripheral Tregs, indicating that GITRL+ B cells might play a crucial role in the homeostasis of Tregs [86,87]. Animals receiving B cells pretreated with antimouse GITRL antibody showed a significantly decreased Tregs induction and severe EAE, suggesting that GITRL+ B cells sustain both proliferation and homeostasis of Tregs [87]. Administration of a monoclonal antibody that depletes B cells, including Bregs, takes to severe exacerbation of human ulcerative colitis, suggesting that Bregs play a crucial role in controlling CNS autoimmunity [88].

Several TNF superfamily members have the capacity to modulate neuroinflammatory processess in different ways. Comprehension of their profile, kinetics of expression, and interactions between TNF ligands and their TNFRs on different CNS-resident and infiltrating immune cells at diverse stages of the disease would aid to better design strategies to control neuroinflammation and CNS autoimmunity.

21.9 Conclusions

Since their discovery in 1984 until today, studies conducted during the past two decades have demonstrated the existence of a superfamily of TNF proteins consisting of 19 members that signal through 29 receptors. These ligands are able to regulate

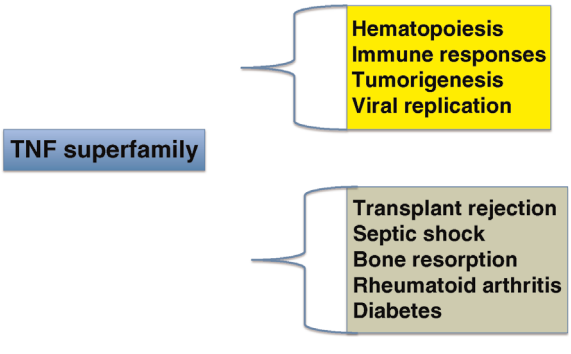

Figure 21.2 TNF superfamily members are fundamental for hematopoiesis, viral replication, immune responses, and tumorigenesis (indicated in yellow); moreover, its dysregulation drives to several diseases (indicated in green).

physiological functions, such as hematopoiesis, morphogenesis, and immune responses, and have also been involved in transplant rejection, septic shock, tumorigenesis, bone resorption, viral replication, rheumatoid arthritis, and diabetes, so pointing to their role as "double-edged swords" (Figure 21.2). Moreover, these cytokines stimulate cellular proliferation, survival, differentiation, and apoptosis. Blockers of TNF have been acknowledged for human use in treating TNF-linked autoimmune and inflammatory diseases. Pathways downstream of receptor ligation supply critical points for interjection for planning new therapeutic strategies.

Interleukin-17 A-E

Giovanni Monteleone, Irene Marafini, and Edoardo Troncone

University of Rome, Tor Vergata, Department of Systems Medicine, Via Montpellier 1, 00133 Rome, Italy

22.1 Introduction

The interleukin (IL)-17 cytokine family is composed of IL-17A and five other members (IL-17B, IL-17C, IL-17D, IL-17E, also referred to as IL-25, and IL-17 F), which share a similar protein structure characterized by four highly conserved cysteine residues [1]. IL-17-related cytokines play key roles in defense against extracellular pathogens (e.g., bacteria, fungi, etc.) and autoimmunity, and accumulating evidence indicates that some of these molecules are involved in the amplification and perpetuation of pathological processes in many inflammatory diseases, such as inflammatory bowel diseases (IBDs), psoriasis, rheumatoid arthritis, multiple sclerosis, and allergy [1]. However, the same cytokines can exert anti-inflammatory effects in specific settings and play key role in the control of immune homeostasis [1]. These progresses have paved the way for the development of various compounds targeting IL-17 family members, which have been tested in patients with immune-mediated diseases [2]. In this chapter, we will summarize the biology of IL-17 cytokines and the more recent novelties about the therapeutic armamentarium directed against this group of cytokines.

22.2 Cell Sources of IL-17 Cytokines

IL-17A, a glycoprotein of 155 amino acids originally identified as a product of activated CD4+ T cells, is the signature cytokine of a subset of CD4+ T helper (Th) cells, termed Th17 cells [3,4]. Th17 cells arise from naïve CD4+ T cells under the influence of the polarizing and stabilizing cytokines, transforming growth factor (TGF)-β1, IL-6, IL-21, and IL-1β, and the activity of the master regulator retinoid acid-related orphan receptor (ROR)-γt. Additional transcriptional factors that

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

contribute to the optimal induction of cytokines in Th17 cells include Stat3, IRF4, BATF, Runx1, and c-Maf [4–8]. IL-23 receptor (IL-23R) is not expressed in naïve murine T cells and, therefore, this cytokine cannot induce Th17 cell differentiation. However, IL-23 targets IL-23R-expressing Th17 cells, thereby facilitating their maintenance/expansion through a Stat3-dependent mechanism [9]. Human CD4+ T cells and mouse T cells bearing the γδ TCRs, which are prominent in mucosal tissues, express IL-23R and respond functionally to IL-23 with enhanced production of IL-17 [10]. In addition to IL-17A, Th17 cells produce IL-17 F and variable amounts of IL-21, IL-22, and IL-26 [6]. IL-17 cytokines can also be produced by cytotoxic CD8+ T cells, γδ T cells, natural killer (NK) T cells, type 3 innate lymphoid cells, neutrophils, and eosinophils [6]. B cells are a major source of rapid formation of IL-17A *in vivo* in response to infection with *Trypanosoma cruzi* [11]. IL-17A and IL-17 F production is not restricted to immune cells, since these cytokines can be synthesized by intestinal Paneth cells and IL-17A is made by mesenchymal stem cells [12,13]. Both IL-17A and IL-17 F are secreted as disulfide-linked homodimers, even though human and mouse T cells can produce IL-17A/F heterodimers [3,14].

IL-25 is synthesized by Th2 cells, bone marrow-derived mast cells upon IgE cross-linking, activated macrophages, eosinophils and basophils, and nonimmune cells, including lung cells, intestinal epithelial cells, and brain capillary endothelial cells [15]. For a more detailed analysis of factors/mechanisms involved in the control of IL-17 cytokine production, the reader is directed toward other chapters of this book.

22.3 IL-17 Receptor: Structure and Biology

The activity of IL-17 cytokines is mediated by a group of five receptors belonging to the IL-17 receptor (IL-17R) family. IL-17RA, the leading component of this family, can heterodimerize with all the other members to form receptors for all the IL-17-related cytokines except IL-17B [16]. IL-17RA interacts with IL-17RC to form heterodimers and binds both IL-17A and IL-17 F [17,18]. IL-17RA can also associate with IL-17RB to form the functional receptor for IL-25 [19]. Much less is known about IL-17RD and IL-17RE biology and ligands. IL-17 receptors are all single transmembrane-containing domain receptors with an extracellular fibronectin III-like domain and a cytoplasmic SEF-IL-17R (SEFIR) motif, adjacent to a SEFIR extension (SEFEX) domain [20]. After the ligand–receptor interaction, the adapter protein ACT1 is recruited to the SEFIR domain and mediates most of the intracellular events downstream to IL-17 receptors [21]. In particular, ACT1 recruits TNFR-associated factor (TRAF) 6, mediates K63-linked ubiquitination, and leads to activation of mitogen-activated protein kinase (MAPK) and nuclear factor (NF) kB, thus controlling various survival pathways and transcription of innate proinflammatory cytokines [22–24]. Another important group of transcription factors activated by IL-17R-transduced signal is the CCAAT/enhancer-binding protein (C/EBP), which together with NF-kB contributes to the transcription of proinflammatory target genes (e.g., IL-6) in an ACT1-independent manner [25].

22.4 Production and Role of IL-17 Cytokines in Normal and Inflamed Intestine

IL-17-type cytokines are constitutively produced in the gut of normal mice and humans, where they contribute to combat pathogenic bacteria and fungi [1]. Indeed, these cytokines have the ability to promote neutrophilia, tissue remodeling/repair, and production of antimicrobial peptides, such as defensins [26]. Production of IL-17 cytokines, particularly by Th17 cells and epithelial cells, is dependent on luminal bacteria. Indeed, IL-17-producing cells are absent in Germ-free mice but accumulate rapidly in the gut of mice colonized with the gut commensal, segmented filamentous bacterium (SFB) [27]. Moreover, mice overexpressing a human α-defensin in intestinal epithelial Paneth cells are resistant to the colonization of SFB and exhibit decreased number of IL-17-producing cells in the intestinal lamina propria [28]. Luminal bacteria-derived ATP is a major driver for the differentiation and/or accumulation of IL-17-producing cells, even though SFB-mediated Th17 cell intestinal accumulation is independent of ATP [29]. There is also evidence that bacteria can expand Th17 cell responses trough DNA-driven Toll like receptor-mediated mechanisms [30]. Studies in mice indicate that intestinal lamina propria Th17 cells are in part generated in mesenteric lymph nodes and Peyer's patches [31].

IL-17A-producing cells are abundant in inflamed intestine of patients with Crohn's disease (CD) and patients with ulcerative colitis (UC), the major forms of IBD in human beings. In inflamed mucosal areas of IBD patients, there is also marked synthesis of IL-17 F, IL-22, and IL-26 [32–34]. Some of the IL-17A-producing cells coexpress IFN-γ and/or Foxp3, the marker of regulatory T cells [35,36]. The latter cell type shows phenotypic characteristic of both conventional Th17 cells (e.g., expression of ROR-γt, CCR6, and CD161) and regulatory T cells (e.g., high CD101 and low CD127 expression) and has suppressor activity *in vitro* [35]. Analysis of the TCR repertoire revealed a similar TCR-β chain variable region usage by Foxp3-expressing IL-17A-producing T cells and Foxp3-expressing IL-17A-negative T cells, raising the possibility that Foxp3-expressing IL-17A-producing T cells can originate from classical regulatory T cells exposed to specific inflammatory stimuli present in IBD tissue [35]. On the other hand, there is evidence that cells coexpressing IL-17A and IFN-γ are not stable and, under various influences, can undergo transformation into typical Th1 cells. This occurs, for example, if these cells are stimulated with IL-12 [37]. Since TGF-β1 signaling is needed to maintain IL-17A expression by *in vitro* generated Th17 cells, in a milieu lacking TGF-β1, cells initially producing IL-17A can become cells producing other cytokines [38,39]. CD-related inflammation is marked by defective TGF-β1 activity due to high levels of Smad7, an intracellular inhibitor of TGF-β1 signaling [40]. Therefore, it is plausible that, in CD, deviation from IFN-γ-producing Th17 cells to typical Th1 cells can be facilitated by high Smad7. Support to this hypothesis comes from recent work by Weaver's group showing that Th1 cells are generated from IL-17F-expressing Th17 cells in the late stages of colitis development in the absence of TGF-β1 and in the presence of IL-23 [38]. The functional role of Th17-related cytokines in human IBD is not

fully understood, but it is conceivable that these molecules can contribute to amplify some inflammatory pathways that sustain the pathological process. Indeed, IL-17A and IL-17 F can increase the synthesis of inflammatory cytokines, chemokines, and adhesion molecules [41,42]. IL-17A also stimulates the synthesis of extracellular matrix-degrading proteases by stromal cells [43]. In this context, it is, however, noteworthy that evidence generated in mouse models of colitis suggests that IL-17 cytokines are not essential in the development of intestinal inflammation and, in some circumstances, could exert protective rather than proinflammatory effects. Oral administration of dextran sulfate sodium (DSS) in mice causes disruption of the epithelial layer and an acute inflammatory response mediated by luminal bacteria [44]. Excessive production of IL-17 occurs in the colon of DSS-treated mice and administration of a blocking IL-17A monoclonal antibody to wild-type mice exacerbates colitis [45]. Consistently, IL-17A-deficient mice are more susceptible to DSS-colitis compared to wild-type mice [46], thus supporting the counterregulatory role of IL-17A in this acute model of intestinal inflammation. These findings are not surprising as IL-17A stimulates intestinal epithelial cells to produce mucous and defensins, thereby limiting translocation of luminal bacteria to lamina propria [47].

Mice lacking the chemokine receptor CX3CR1 display increased translocation of commensal bacteria to mesenteric lymph nodes, produce high levels of IL-17A, and are more susceptible to DSS colitis as compared to wild-type mice. CX3CR1-deficient mice given a neutralizing IL-17A antibody develop a less severe DSS colitis, indicating that, at least in this specific setting, IL-17A is pathogenic [48]. In line with this latter finding is the demonstration that IL-17RA-null mice or wild-type mice given a neutralizing IL-17RA IgG fusion protein develop less severe colitis following intrarectal administration of trinitrobenzene sulfonic acid (TNBS) [49]. As pointed out above, IL-17RA mediates the effects of both IL-17A and IL-17 F [50]; therefore, it remains unclear whether the pathogenic effect of IL-17RA signaling in TNBS colitis is mediated by either IL-17A or IL-17 F. The possibility that IL-17 F is more inflammatory than IL-17A in the gut is supported by the demonstration that IL-17F-deficient mice are protected against DSS-induced colitis [46].

Even more complex appears the role of IL-17 cytokines in murine models of chronic intestinal inflammation. Administration of an anti-IL-17A antibody ameliorates the spontaneous colitis developed in mice bearing a conditional deletion of Stat3 in Foxp3-positive regulatory T cells [51]. Th17 cells are also pathogenic in the colitis models induced by either transfer of the cecal bacterial antigen-specific C3 H/HeJBir (C3Bir) CD4 (+) T-cell line to C3 H/HeSnJ SCID mice or colonization of mice with enterotoxigenic *Bacteroides fragilis*, a human colonic bacterium [52]. To evaluate the role that Th17 cytokines play in the initiation and progression of colitis, Leppkes *et al.* transferred IL-17A-, IL-17F-, or IL-22-deficient T lymphocytes into RAG1-null mice and showed that the lack of single cytokines did not prevent the development of colitis [53]. Similarly, Noguchi *et al.* showed that colitis induced in RAG mice by transfer of IL-17A-deficient CD4+ T cells does not differ in terms of severity from that induced by transfer of wild-type cells [54]. Leppkes also reported that colitis induced by transfer of IL-17F-deficient T cells was suppressed by a neutralizing anti-IL-17A

antibody, indicating redundant biological effects of IL-17A and IL-17 F. Consistently, RORγ-deficient T cells, which do not produce all Th17 cytokines, cannot transfer colitis to RAG-deficient mice [53]. A different scenario emerges from studies published by the Flavell' group showing that adoptive transfer of IL-17A-deficient naïve CD4+ T cells into recipient immunodeficient mice resulted in severe colitis and wasting disease, with significantly increased colon IFN-γ production [55]. Transfer of IL-17R-deficient T cells induced the same aggressive disease indicating that IL-17 exerts its effects directly on T cells. Furthermore, it was shown that IL-17A blocks differentiation of IL-17RA-expressing CD4+T cells in Th1 cells, raising the possibility that the IL-17A-mediated negative regulation of colitis relies on suppression of pathogenic Th1 cell responses [55].

22.5 IL-17 Blockers are Not Therapeutic in CD

Although IL-17A is overproduced in inflamed intestine of CD patients and this cytokine can trigger inflammatory signals in mucosal cells, a recent clinical trial has shown that neutralization of IL-17A with the blocking antibody Secukinumab was not effective in patients with CD [56]. In another clinical trial, brodalumab, a fully human anti-IL-17RA monoclonal antibody, determined significant CD activity worsening compared to placebo [57]. The reason why IL-17 blockers failed in CD remains unknown even though there are some explanations. A possibility relies on the fact that IL-17A is anti-inflammatory, rather than proinflammatory, in the gut due to its ability to enhance the intestinal barrier integrity [47]. The tissue-damaging immune response in CD is characterized by simultaneous activation of multiple and disconnected inflammatory pathways and some of them (e.g., Th1-mediated signals) are negatively regulated by Th17 cytokines [55]. Therefore, treatment of CD with IL-17 blockers could suppress IL-17A-driven inflammatory pathways but at the same time promote amplification of Th1-driven inflammation.

22.6 IL-17 Cytokines in Psoriasis

Psoriasis is a common, chronic, and immune-mediated skin disorder characterized by distinctive histopathological features (i.e., epidermal acanthosis, hyperkeratosis, and parakeratosis) combined with a rich inflammatory infiltrate of innate and adaptive immune cells [58]. Genome-wide association studies have identified genes encoding proteins involved in the IL-17 pathway associated with psoriasis and psoriatic arthritis. For instance, a single nucleotide substitution in exon 9 of the IL-23R gene is protective against psoriasis [59]. A polymorphism at TRAF3IP2 (the gene encoding Act1) confers increased risk of both psoriasis and psoriatic arthritis, presumably secondary to dysregulation of downstream signaling from the IL-17 receptor [60]. Many descriptive and experimental data have focused on the role of Th17 cytokines, and in particular IL-17 and IL-22, in the complex cross-talk between immune cells and resident epithelial cells. Numbers

of IL-17A-positive cells are increased in lesional skin, of which the vast majority are T cells, both CD4+ and CD8+, mast cells, and neutrophils [61–63]. IL-17A, IL-17C, and IL-17 F RNA transcripts are highly produced in lesional versus nonlesional skin, whereas IL-17B and IL-17D RNA levels are decreased [64], and there is correlation between cutaneous IL-17A RNA expression and disease activity [65]. The relevance of IL-17A in the pathogenesis of psoriasis is supported by the demonstration that clinical response to various therapies is associated with a marked downregulation of IL-17 production in psoriatic skin and functional studies showing the ability of this cytokine to induce or amplify inflammatory signals leading to epidermal pathology [66]. In this context, it is known that IL-17A enhances expression of antimicrobial peptides (i.e., β-defensins and S100A family members) and stimulates keratinocytes to produce chemokines, such as CCL20 (which mediates recruitment of Th17 and dendritic cells to skin) and CXCL1, 3, 5, 6, and 8 (which drive neutrophil recruitment) [67–69]. IL-17A decreases expression of cell adhesion factors, leading to disruption of the skin barrier [70]. IL-17A-driven pathogenic effects can be amplified by other cytokines overproduced in psoriatic lesions, such as TNF [67]. In primary keratinocytes IL-17A and TNF upregulate a multitude of genes, which correlate with the psoriasis gene signature (e.g., β-defensin-2, S100A7, CCL20, CXCL1, CXCL8, and IL-23 p19 subunit) [67]. Studies in murine models of psoriasis-like pathology confirmed the pathogenic role of IL-17A, as no epidermal hyperplasia was seen following IL-23 injection in mice devoid of IL-17 [71] and induction of skin damage in response to IL-21 injection or cutaneous application of TLR7 agonist was paralleled by upregulation of IL-17 cytokines [72,73].

22.7 Anti-IL-17 Therapy in Psoriasis

Various IL-17 inhibitors have been used with success in patients with moderate to severe psoriasis. Initial studies with secukinumab showed that at 3 mg/kg intravenously (i.v.), the drug reduced mean psoriasis area and severity index (PASI) scores compared to placebo at week 4. Secukinumab reduced cutaneous expression of multiple chemokines, cytokines, and proteins involved in the tissue-damaging immune response, including IL-17A, IL-17 F, IL-21, IL-22, IL-12p40, CCL20, β-defensin-4, and keratin 16, a marker of activated keratinocytes [74].

Randomized, placebo–controlled phase 2 trials showed that subcutaneous administration of 75 or 150 mg secukinumab at baseline and weeks 4 and 8 was superior to placebo in increasing PASI 75 response at week 12 primary end point [75]. Better results were seen following subcutaneous administration of secukinumab 150 mg at weeks 0, 1, 2, and 4 (early regimen). The anti-inflammatory effect of the drug was supported by the demonstration that readministration of secukinumab at weeks 12 and 24 maintained clinical response [76]. In two phase 3, double-blind, 52-week trials, ERASURE (Efficacy of Response and Safety of Two Fixed Secukinumab Regimens in Psoriasis) and FIXTURE (Full Year Investigative Examination of Secukinumab vs. Etanercept Using Two Dosing Regimens to Determine Efficacy in Psoriasis), subcutaneous secukinumab at a dose of 300 mg or 150 mg (administered once weekly for 5 weeks, then every 4

weeks) reduced PASI 75 scores in patients with moderate to severe plaque psoriasis [77].

The therapeutic efficacy of IL-17 neutralization was confirmed by studies with ixekizumab, a humanized monoclonal antibody against IL-17A, and brodalumab. In randomized, placebo–controlled phase 2 trials, ixekizumab at doses of 25, 75, or 150 mg subcutaneously at baseline and weeks 2, 4, 8, 12, and 16 was clinically superior to placebo; the therapeutic effect of ixekizumab was evident by week 1 and maintained through week 20 [78]. Treatment with ixekizumab caused a broad downregulation of markers of epidermal pathology and of psoriasis-associated inflammatory molecules [79]. More recently, two phase 3 studies (UNCOVER-2 and UNCOVER-3) evaluated the clinical efficacy of ixekizumab compared with placebo or etanercept in patients with widespread moderate to severe psoriasis. Patients were randomized to receive subcutaneous placebo, etanercept, or one injection of ixekizumab every 2 weeks or 4 weeks. Both ixekizumab dose regimens had greater efficacy than placebo and etanercept over 12 weeks [80].

Brodalumab was administered subcutaneously at 70, 140, or 210 mg at baseline and weeks 1, 2, 4, 6, 8, and 10, or at 280 mg at baseline and weeks 4 and 8. Brodalumab was more effective than placebo in reducing mean PASI scores [81], significantly improved dermatology life quality index and reduced markers of disease pathology [82]. Two phase 3 studies (AMAGINE-2 and AMAGINE-3) compared the efficacy and safety of brodalumab with those of ustekinumab, an antibody against the p40 subunit shared by IL-12 and IL-23 approved for the treatment of psoriasis. Patients were assigned to receive subcutaneously brodalumab (210 mg or 140 mg every 2 weeks), ustekinumab (45–90 mg), or placebo for 12 weeks, and then continued with a maintenance dose through week 52. At week 12, both brodalumab regimens were superior to placebo and ustekinumab in controlling clinical activity of moderate to severe psoriasis [83].

22.8 IL-17A in Psoriatic Arthritis

Psoriatic arthritis (PsA) affects nearly one fourth of psoriasis patients and its onset occurs after cutaneous disease [84]. Th17 cells are increased in the circulation of PsA patients, and a high number of IL-17A-producing cells, including Th17 cells and c-Kit-positive mast cells, is seen in the synovial fluid of these patients [85–87]. Moreover, synovial fibroblasts isolated from PsA patients express high level of IL-17RA and produce enormous amount of IL-6, CXCL-8, and matrix metalloproteinase 3 in response to IL-17A [86].

The efficacy of secukinumab (10 mg/kg i.v. at baseline and week 3) in patients with active moderate to severe PsA was initially evaluated in a double-blind, placebo–controlled, proof-of-concept phase 2 study. The primary end point, American College of Rheumatology (ACR) 20 response at week 6, was not met. However, good European League Against Rheumatism responses and remission (Disease Activity Score using 28 joint count (DAS28) scores $\leq$2·6) at week 6 occurred more frequently in the secukinumab group (both 22% versus 9%), and significant decreases compared to placebo were seen for health assessment questionnaire–disability index (HAQ-DI) and the SF-36 physical component

score. Treatment with secukinumab also caused a significant reduction in serum concentration of β-defensin-2, a potential surrogate marker of psoriatic disease activity [88]. Data of phase 3 clinical trials in PsA with ixekizumab have not yet been published. Prespecified subanalyses of the phase 3 FIXTURE and ERASURE studies showed that secukinumab improves physical function in patients with psoriasis and concomitant PsA [77]. These preliminary results were confirmed by a phase 3 double-blind placebo–controlled trial, in which secukinumab was given intravenously (10 mg/kg) at week 0, 2, and 4, followed by subcutaneous doses of either 150 mg or 75 mg every 4 weeks or placebo. Response rates at week 24 were significantly higher in the group receiving secukinumab and improvements were maintained at week 52. However, infections and serious adverse events, such as strokes or myocardial infarction, were more frequent in secukinumab groups than placebo [89]. Interestingly, a double-blind, placebo–controlled trial of patients with another immune-mediated disease related to PsA, ankylosing spondylitis, showed that two intravenous infusions of 10 mg/kg secukinumab yielded favorable results [90].

22.9 IL-17A in Rheumatoid Arthritis

Rheumatoid arthritis (RA) is an autoimmune disease leading to synovial inflammation and destruction of cartilage and bone. Like many autoimmune diseases, RA is supposed to occur in genetically at risk individuals, in response to a trigger or triggers [91]. IL-17A-positive cells are abundant in synovial fluid of patients with RA and elevated levels of IL-17A in the synovia correlate with greater disease activity [92]. IL-17A exerts multiple biological functions that could be relevant for RA-associated joint inflammation, cartilage degradation, and bone erosion. For instance, IL-17A enhances the production of chemokines (e.g., CCL2, CCL20, and CXCL-8) and cytokines (e.g., TNF, IL-1β, and IL-6) from synovial fibroblasts, increases production of cartilage-degrading matrix metalloproteinases, blocks new matrix synthesis by chondrocytes, and stimulates bone reabsorption [93]. The pathogenic role of IL-17A in RA is supported by studies in animal models of arthritis. Neutralization of endogenous IL-17A with a soluble murine IL-17 receptor protein or anti-IL-17A suppresses synovial inflammation and joint damage in collagen-induced arthritis (CIA) in mice [94]. In contrast, IL-17A overexpression by gene transfer or intra-articular injection aggravates the disease course [95]. Consistently, the pathologic process characteristic of CIA is markedly reduced in IL-17A-null mice [96].

22.10 Clinical Findings

Secukinumab was the first IL-17 blocker used in RA. In a proof-of-concept study in patients with active RA despite stable methotrexate therapy, 10 mg/kg intravenous secukinumab at baseline and week 3 significantly improved the clinical and laboratory parameters of joint inflammation. The activity of secukinumab

was evident by week 1 and maintained until the final assessment at week 16 [74]. A subsequent randomized, placebo–controlled phase 2 trial showed a partial clinical benefit of subcutaneous secukinumab at doses of 75, 150, or 300 mg monthly. The clinical efficacy of secukinumab among responders was maintained through week 52, while patients who did not respond to secukinumab by week 16 derived little benefit from subsequent dose increase [97].

Ixekizumab was also evaluated initially in a proof-of-concept trial, which showed that the combined ixekizumab group (0.2, 0.6, or 2 mg/kg intravenous at baseline and weeks 2, 4, 6, and 8) was superior to placebo in reducing inflammatory scores in patients with active RA despite at least one conventional disease-modifying antirheumatic drug (DMARD) [98]. A subsequent phase 2 study confirmed the efficacy of ixekizumab in patients on background DMARD therapy either biologically naive or resistant to TNF blockers [99]. In contrast, a randomized, double-blind, placebo–controlled phase 2 trial showed the clinical inefficacy of subcutaneous brodalumab in biologically naïve RA patients [100]. Therefore, brodalumab is not being explored further in RA.

22.11 IL-17B, IL-17C, and IL-17D

The biological activities and role of IL-17B, IL-17C, and IL-17D in immune-inflammatory diseases remain largely unknown. These cytokines bind to IL-17RB and IL-17RE and share with IL-17A-F some proinflammatory effects [101]. IL-17B and IL-17C promote neutrophil recruitment and induce TNFα and IL-1β *in vivo* and *in vitro* [102,103]. IL-17C also stimulates epithelial cells to produce proinflammatory mediators and antimicrobial peptides and enhances tight junctions [104]. IL-17C is pathogenic in a murine model of skin inflammation but exerts a protective function in DSS colitis. This later finding is in accordance with the demonstration that IL-17C-deficient mice develop a more severe DSS colitis compared to wild-type mice [105]. IL-17C is synthesized by intestinal epithelial cells stimulated by intestinal microbiota (e.g., flagellin), but it is not yet known if such a production is dysregulated during IBD [106]. IL-17C is abundant in psoriatic skin lesion and overexpression of this cytokine in keratinocyte leads to psoriasis-like lesions [107]. Despite its ability to induce proinflammatory molecules and to mediate articular damage, IL-17B plays a protective role in DSS-induced colitis and *Ci*trobacter *rodentium*-driven intestinal inflammation [108]. IL-17D stimulates IL-6, IL-8, and GM-CSF *in vitro*, but its contribution in immune-mediated pathologies has yet to be clarified [109].

22.12 IL-25 (IL-17E)

Although originally identified as a member of the IL-17 cytokine family, IL-25 has just 20% homology with IL-17A and reveals unique biologic activities. IL-25 is highly produced by polarized Th2 cells and positively regulates Th2 cell responses. When injected into mice, IL-25 induces IL-4, IL-5, and IL-13 gene

expression, increases IgE production and determines pathological changes in different tissues such as liver, lungs, heart, and the digestive tract [110]. These lesions are characterized by inflammatory infiltration, hyperplasia, and eosinophilia [111]. IL-25 also enhances IL-9 synthesis [112]. The positive effect of IL-25 on Th2 cell responses is mediated by the ability of this cytokine to act directly on human Th2 cells, which bear a specific IL-25R, as well as on basophils, eosinophils, and mast cells, which indirectly promote Th2 cell differentiation [113,114]. In gut-associated lymphoid tissues, IL-25 promotes the accumulation of a lineage-negative cell population, which is involved in Th2 cell responses against parasites [115] and enhances responsiveness of innate lymphoid cells (ILC) type 2 to IL-33, thus contributing to helminth expulsion [116]. Consistently, IL-25-knockout mice infected with *Trichuris muris* fail to eradicate the infection, due to an impairment in type 2 immunity [117]. In *Nippostrongylus brasiliensis*-infected mice, intestinal epithelial cell-derived IL-25 stimulates ILCs to produce IL-13, thus leading to a rapid worm clearance [118].

IL-25 production by commensal bacteria-stimulated epithelial cells is, however, a physiologic phenomenon in the gut, which contributes to restrain detrimental immune responses. For example, intestinal epithelial cell-derived IL-25 targets IL-25R-expressing lamina propria dendritic cells and macrophages with the downstream effect of reducing Th1 and Th17 cell response and attenuating experimental colitis [119,120]. In colitic mice, the anti-inflammatory effect of IL-25 is associated with the enhanced expression of alternatively activated macrophages [121], a subset of macrophages with regulatory properties. This phenomenon is not organ-specific as in mouse models of renal ischemic/reperfusion injury, IL-25 significantly ameliorates renal function and such a protective effect is associated with increased levels of Th2 cytokines and induction of alternatively activated macrophages [122].

In the human gut, IL-25 is also produced by subepithelial macrophages and its synthesis is positively regulated by TGF-β1 [120,123]. Production of IL-25 is markedly reduced in the inflamed intestine of patients with CD and patients with UC. This decrease is not an epiphenomenon of the ongoing inflammation because IL-25 overproduction occurs in the duodenum of patients with celiac disease, another intestinal immune-mediated disorder [120]. The specificity of this decrease suggests that in IBD there might be factors that selectively downregulate IL-25. One of such factors is TNF-α, a proinflammatory produced in excess in IBD but not in celiac disease. Indeed, stimulation of normal colonic biopsies with TNF-α inhibits IL-25 expression, while anti-TNF-α restores IL-25 expression in IBD patients [123]. Defects in TGF-β1 activity, due to the increased expression of its intracellular inhibitor Smad7 [40], could also be responsible for IL-25 downregulation in IBD as knockdown of Smad7 with a specific antisense oligonucleotide in IBD mucosal explants increases IL-25 synthesis.

IL-25 production is constitutive in human and mouse liver and is reduced during fulminant hepatitis. In mouse models of fulminant hepatitis, IL-25 administration prevents and cures liver damage due to its capacity to enhance the accumulation of myeloid-suppressor cells that inhibit T-cell activation [124].

The IL-25-mediated promoting effects on Th2 cell responses well fit with the prominent role of this cytokine in allergic diseases. Genetic deletion of IL-25

decreases lung inflammation in a mouse model of Th2/Th9-driven allergic-induced asthma [112]. In the same model, overexpression of IL-25 in lung epithelial cells leads to mucus production and airway inflammation [113]. Both IL-25 and IL-25R are upregulated on epithelial cells of human asthmatic lung [114,125], and this cytokine may be involved in virus-induced exacerbations of the disease [126]. In experimental acute OVA-induced allergic asthma, blocking IL-25 prevents airway hyperresponsiveness during both the sensitization and the challenge phases leading to reduced levels of IL-5 and IL-13 production, eosinophil infiltration, goblet cell hyperplasia, and serum IgE secretion [127]. Chronic exposure of murine airways to IL-25 promotes angiogenesis and may contribute to bronchial vascular remodeling [128]. Moreover, IL-25 levels are increased in nasal lavages of patients with allergic rhinitis, compared to normal controls [129]. IL-25, together with IL-33, is also the pivotal cytokine inducing innate lymphoid cells type 2 in a mouse model of atopic dermatitis and plays a role in skin inflammation [130].

22.13 Conclusions

In recent years, a considerable amount of work has been done to clarify the expression and role of IL-17 cytokines in many immune-inflammatory pathologies, thus paving the way for the development of novel biologics to treat patients with such disorders. Some of these compounds have already reached the clinic and promising results have been documented in patients with psoriasis, PsA, and RA but not in patients with IBD. The cellular context in which IL-17 cytokines are produced, the stage or duration of disease, previous therapy, and the genetic architecture of the disease in individual patients could be factors influencing the therapeutic efficacy of IL-17 blockers in the various immune-mediated disorders. There may also be differences in proportions of subjects in these conditions who have IL-17-dependent pathways. The demonstration that such cytokines are constitutively produced in various organs highlights, however, their role both in physiologic processes (e.g., maintenance of epithelial barriers) and in the host defense against pathogens and neoplasia. So far, safety findings from clinical trials have indicated that IL-17A pathway inhibition results in higher infection rates compared to placebo. Therefore, further work is needed to better understand the physiologic role of IL-17 cytokines and provide insight into potential risks of IL-17 blockade.

23.1 Introduction

Cytokine is a soluble protein that functions as a messenger to transmit intercellular signals to distant organs, to adjacent cells in local sites in a paracrine manner, or to identical cytokine-producing cells in an autocrine manner. Simply stated, many cytokines use multicomponent receptor systems, including cytokine-binding and signal transducing receptors on target cells to induce intracellular signals. Expression of cytokine-binding receptors on target cells dictates which organs and which cells respond to the cytokine. Binding of a cytokine to its receptor leads to the formation of homo- or heterodimerization of signaling receptors, and triggers activation of intracellular signaling pathways. Interleukin-6 (IL-6) is a prototypical cytokine featuring functional pleiotropy and redundancy, the latter often leading to overlaps with other members of the IL-6 family of cytokines. This chapter focuses on the signaling system of the IL-6 family of cytokines and recent progress in their clinical application.

23.2 IL-6 and its Family of Cytokines

23.2.1 Biological Activity and Signaling System of IL-6

IL-6 exerts pleiotropic effects on inflammation, immune response, and hematopoiesis [1–3]. It is produced at the inflammation site by infection or tissue damage. IL-6 induces production of acute phase proteins such as C-reactive protein (CRP), serum amyloid A, fibrinogen, and hepcidin in liver [4]. It also

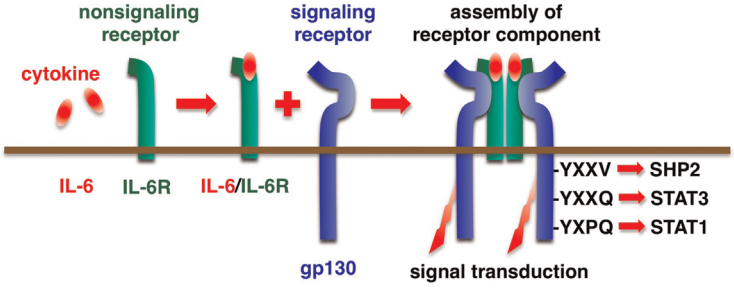

Figure 23.1 Nonsignaling and signaling receptor components. Visualization of the IL-6 receptor system representing the IL-6 family of cytokines. IL-6 binds to IL-6R to form the IL-6/IL-6R complex, which induces the gp130 homodimer to transduce intracellular signaling. Cytoplasmic tyrosine-based motifs of gp130, YXXV, or YXXQ (Y: tyrosine; Q: glutamine; V: valine; and X: any amino acid), select the SH2-containing molecule, SHP2, or STAT3 to lead the downstream signal.

plays an important role in acquired immune response to induce differentiation of activated B cells into antibody (Ab)-producing cells and to prolong survival of plasmablasts [5], while it promotes the development of Th17 cells and follicular helper T cells by naïve T cells and inhibits the differentiation into regulatory T cells (Treg) [6]. Moreover, IL-6 can promote differentiation or proliferation of several nonimmune cells, such as cardiac myocytes, neuronal cells, hematopoietic cells, vascular endothelial cells, and others. When IL-6 binds to its specific IL-6 receptor (IL-6R) with low affinity, the resultant IL-6/IL-6R complex associated with gp130, leading to homodimerization of gp130 to form a high-affinity IL-6-binding receptor complex, which in turn results in the formation of a hexamer structure consisting of two molecules each of IL-6, IL-6R, and gp130 (Figure 23.1) [7,8]. The cytoplasmic membrane-proximal domain of gp130 lacks enzymatic activity but is associated with JAK tyrosine kinases. Dimerization of gp130 allows JAKs to come close to each other, which then leads to phosphorylation in cytoplasmic tyrosine residues of gp130. The SH2 domain-containing molecules, the signal transducer and activator of transcription 3 (STAT3), and STAT1 and SH2 domain-containing protein-tyrosine phosphatase 2 (SHP2) are recruited to the tyrosine-phosphorylated motifs of gp130, YXXQ for STAT3, YXPQ for STAT1, and YXXV for SHP2 (Y: tyrosine, Q: glutamine, P: proline, V: valine, and X: any amino acid). STAT3 and STAT1 are then phosphorylated by JAK kinases and form STAT3-STAT3, STAT3-STAT1, or STAT1-STAT1 dimer via phosphorylated tyrosine and SH2 domain of each STAT molecule. They translocate to the nucleus, which produces the transcriptional output. SHP2 initiates activation of the Ras-MAP kinase pathway. Thus, the tyrosine-based motif in the cytoplasmic region of gp130 is a module for downstream signaling molecules [8–10]. The presence of a two-chain receptor system raises the possibility that the signaling chain is shared with some other cytokines. The above leads to the definition of the IL-6 family of cytokines as cytokines that are characterized by the use of gp130 as a common signal transducing receptor component, so that it is also known as the gp130 receptor cytokine family [11].

23.2.2 Original Members of IL-6 Family of Cytokines

The members of the IL-6 family of cytokines first identified comprised IL-6, leukemia inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), cardiotrophin 1 (CT-1), and IL-11. All of them feature a four-helix bundle structure and have similar effects on immune, hematopoietic, and nervous systems. The characteristic features of cytokines are the pleiotropic effect and functional redundancy. The pleiotropic property is explained by the wide distribution of signaling receptors on various types of cells. Functional redundancy resulting from different cytokines acting on the same cell to induce similar responses was observed among the first members of the IL-6 family of cytokines. These responses consisted of acute-phase protein induction in hepatocytes, differentiation of myeloid leukemia M1 cells, neurite growth in neuronal cells, and stimulation of cardiac myocytes. Later, cardiotrophin-like cytokine factor 1 (CLCF1) and viral IL-6 (vIL-6) were also included in the IL-6 family. CLCF1, referred to as neurotrophin-1 or B-cell-stimulating factor 3, features neurotrophic and B-cell-stimulating functions [12], while vIL-6 is a viral protein produced by human herpesvirus 8 (also referred to as Kaposi sarcoma-associated herpesvirus) with functions that overlap with those of many of IL-6 cytokines [13].

23.2.3 New Members of IL-6 Family of Cytokines

The two new members, IL-27 and IL-35, are structurally different from the original members of the IL-6 family. They are heterodimeric cytokines since IL-27 consists of p28 and EB virus-induced molecule 3 (EBI3) and IL-35 of p35 and EBI3. Originally, the IL-27p28 subunit was identified as the IL-6-related protein IL-30 [14] and the IL-35p35 subunit was cloned as a subunit of IL-12 and is homologous with IL-6. Both p28 and p35 have a four-helix bundle structure. Later, it was found that the complex of p28 or p35 with EBI3 produced the heterodimer cytokine IL-27 or IL-35, respectively. IL-27 and IL-35 belong to the IL-12 family of cytokines with a feature of heterodimeric structure. However, their subcomponent EBI3 is structurally related to the soluble IL-6R (sIL-6R), so that IL-27 and IL-35 are analogous with the IL-6/sIL-6R complex, and it is thought that they have evolved from the IL-6 family of cytokines and a soluble form of their original receptor. IL-27 and IL-35 are, therefore, included in the IL-6 family of cytokines, so that the current members of the IL-6 family consist of IL-6, LIF, OSM, CNTF, CT-1, IL-11, CLCF1, vIL-6, IL-27, and IL-35.

23.2.4 Receptor Components of IL-6 Family of Cytokines

Receptor components of the IL-6 family of cytokines are summarized in Table 23.1. IL-6, CNTF, IL-11, and CLCF1 first bind to nonsignaling receptors with short cytoplasmic domain and next to the ligand–receptor complex; IL-6/IL-6R, CNTF/CNTFR, IL-11/IL-11R, or CLCF1/CNTFR associates with and activates signaling receptors. While CNTF primarily binds to CNTFR, CNTF can also bind to IL-6R lower but with an affinity of 60 times lower than that of IL-6 binding to IL-6R [15]. For CT-1, a GPI-linked receptor has been postulated [16].

Table 23.1 IL-6 family of cytokines and their receptor components.

IL-6 Family of Cytokines	Nonsignaling Receptor	Signaling Receptor
IL-6	IL-6R	gp130 + gp130
LIF	—	gp130 + LIFR
OSM	—	gp130 + LIFR gp130 + OSMR
CNTF	CNTFR	gp130 + LIFR
CT-1	?	gp130 + LIFR
IL-11	IL-11R	gp130 + gp130
CLCF1 CLCF1+CLF	CNTFR	gp130 + LIFR
vIL-6	—	gp130 + gp130
IL-27 (p28+EBI3)	—	gp130 + IL-27R
IL-35 (p35+EBI3)	—	gp130 + IL-12Rβ2 gp130 + gp130 IL-12Rβ2 + IL-12Rβ2

IL-6 cytokine family members transduce their signals via the gp130 homodimer (gp130 + gp130) or gp130 heterodimer (gp130 + LIFR, OSMR, IL-27R, or IL-12Rβ2). IL-6, CNTF, IL-11, CLCF1, and CLCF1/CLF first bind to their respective nonsignaling receptor. IL-27 and IL-35 are heterodimeric cytokines and activate gp130-IL-27R and gp130-IL-12Rβ2 heterodimer and gp130-gp130 or IL-12Rβ2-IL-12Rβ2 heterodimer, respectively.
Abbreviations: LIF, leukemia inhibitory factor; OSM, oncostatin M; CNTF, ciliary neurotrophic factor; CT-1, cardiotrophin 1; CLCF1, cardiotrophin-like cytokine factor 1; CLF, cytokine-like factor; EBI3, EB-virus-induced molecule 3.

The cytokine/nonsignaling receptor complex assembles the gp130-gp130 homodimer or gp130-LIFR heterodimer to transduce signals. CLCF1 can form a heteromeric complex with cytokine-like factor-1 (CLF) that belongs to the cytokine receptor family. Both CLCF1 itself and the CLCF1/CLF complex bind to CNTFR and induce the gp130-LIFR heterodimer. In contrast, LIF, OSM, or vIL-6 can directly bind to and assemble the gp130-LIFR, the gp130-OSMR heterodimer, or the gp130-gp130 homodimer, respectively, without binding to a nonsignaling receptor [17]. The functional redundancy of these cytokines is clearly evidenced by the model in which signal transducing receptors gp130 and LIFR are shared among family members; moreover, the cytoplasmic regions of both gp130 and LIFR contain YXXQ, YXPQ, and YXXV motifs that recruit and activate the same set of signaling molecules, that is, STAT3, STAT1, and SHP2 [9].

IL-27 uses IL-27R (also referred to as WSX-1) and gp130 for its signal. Although IL-27 shares gp130 with IL-6, transgenic overexpression of IL-27p28 *in vivo* was found to reduce antigen-specific antibody production. It was shown that IL-27p28 by itself is able to inhibit IL-6-gp130 signaling independent of EBI3 [18]. The effect of IL-27 on T cells is also different from that of IL-6, since IL-27 inhibits differentiation of Th17 and induces IL-10-producing Treg-like populations. The opposite effects of IL-6 and IL-27 on T cells derive from the functional difference in signaling receptors of the gp130-gp130 homodimer and the gp130-IL-27R heterodimer. Although both IL-6 and IL-27

can induce activation of STAT3 and STAT1, analysis of transcriptional output by IL-6 and IL-27 revealed that transcriptional output of STAT3 is induced mainly by IL-6, whereas STAT1 is preferentially activated by IL-27 [19]. The difference in balance between STAT3 and STAT1 may thus determine the cellular response by cytokine stimulation [20]. IL-35, the most recently identified member of the IL-6 family of cytokines, is thought to be an inhibitory cytokine produced by Treg [21]. A receptor reconstitution study reported that IL-35 could induce the gp130-IL-12Rβ2 heterodimer, the gp130-gp130 homodimer, or the IL-12Rβ2-IL-12Rβ2 homodimer [22]. Although IL-35 uses gp130 as a receptor component, the effect of IL-35 on T cells is different from that of IL-6, since IL-35 inhibits the development of Th1 and Th17 cells.

23.2.5 Soluble Forms of Receptors of IL-6 Family of Cytokines

Soluble forms of cytokine receptor components in human serum regulate functions of their ligands under certain physiological and pathological conditions. Soluble forms of the nonsignaling receptors of the IL-6 family of cytokines, that is, sIL-6R, sIL-11R, and sCNTFR, can bind to their respective ligands and activate signaling receptors on target cells [23,24]. Proteolysis of the membrane-bound receptors and alternative splicing of receptor mRNA are the mechanisms by which soluble receptors are created. For example, sIL-6R occurs in serum at around 79 ng/ml, binds to IL-6, and transduces the IL-6 signal to cells that express gp130 but not cell surface IL-6R and are unresponsive to IL-6 alone (Figure 23.2). The IL-6/sIL-6R-mediated signal is known as the IL-6 trans-signaling, while the IL-6 signal mediated through cell surface IL-6R is differently classified as the classical signaling [25]. On the other hand, soluble forms of signaling receptors such as sgp130, sLIFR, and sIL-27R are natural inhibitors by functioning as antagonists to inhibit signal transduction. sgp130 occurs in human serum at around 390 ng/ml, can bind to IL-6/sIL-6R, and inhibit IL-6 function. sgp130 is also an antagonist to CNTF/sCNTFR, LIF, and OSM [23]. Similarly, sLIFR is present in human serum at around 4.3 ng/ml, binds to LIF, and inhibits functioning of LIF [26], while its quantity increases 12 times during pregnancy [27].

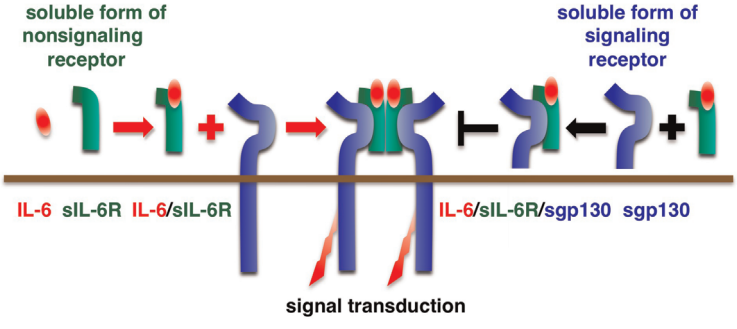

Figure 23.2 Different functions of soluble forms of nonsignaling and signaling receptors. The figure shows that IL-6 binds to sIL-6R and that the IL-6/sIL-6R complex associates with and activates cell surface gp130 in the form of IL-6 trans-signaling, whereas sgp130 blocks IL-6/sIL-6R to associate with gp130.

sIL-27R is found in human serum at around 10.3 ng/ml and inhibits IL-27 binding to its cell surface receptor and IL-27 function [28].

23.2.6 Redundant and Nonredundant Functions of IL-6 Family of Cytokines

Cytokine-deficient mouse or neutralizing antibody (Ab) against IL-6 family members was used for *in vitro* studies addressing which function of which member is compensated or unique for the respective cytokine. An IL-6 inhibitor has been successfully used for the treatment of inflammatory diseases in clinics. This inhibitor is tocilizumab, a humanized anti-IL-6R monoclonal antibody that binds to transmembrane IL-6R and sIL-6R and inhibits both IL-6 classical signaling and trans-signaling. Various clinical trials of tocilizumab for patients with chronic inflammatory diseases, such as Castleman disease, rheumatoid arthritis (RA), and idiopathic juvenile arthritis, have verified its outstanding effectiveness and tocilizumab is now clinically used for the treatment of these diseases [1–3]. Although *in vitro* studies using the hepatocyte cell line previously showed that members of the IL-6 family of cytokines overlap with IL-6 to induce acute-phase proteins, IL-6-deficient mouse or inhibition of IL-6 by administration of tocilizumab to patients demonstrated almost complete suppression of acute-phase protein production, indicating that IL-6 plays an essential role in acute-phase protein production and that other members of the IL-6 family do not offset this function. In fact, it was reported that circulating levels of IL-11 and LIF were not elevated in spite of the inflammation with high level of acute-phase protein [29].

In the case of Ab production, IL-6 induces differentiation of activated B cells into Ab-producing cells. Tocilizumab treatment corrects hypergammaglobulinemia in patients with Castleman disease, but the treatment dose not reduce immunoglobulin (Ig) concentration to abnormally low levels and appears not to impair Ab production in response to influenza and pneumococcal polysaccharide vaccination [30,31], suggesting that in humoral immune response the pathological elevation of Ig depends on IL-6, but other cytokines including those of the IL-6 family may interfere with physiological Ab production.

23.3 Clinical Application of Members of IL-6 Family of Cytokines and Their Inhibitors

23.3.1 Clinical Application of Members of IL-6 Family of Cytokines

Molecular characterization of the signaling system of the IL-6 family of cytokines and clarification of their biological activity and pathological roles raised expectations that a cytokine itself or its specific inhibitor might be a novel drug for a variety of diseases. So far, IL-11 is the only cytokine approved for the clinical treatment. Recombinant human IL-11, oprelvekin, stimulates megakaryocytes to increase platelet and prevents severe thrombocytopenia after myelosuppressive chemotherapy [32]. Clinical trials of LIF to evaluate its efficacy for chemotherapy-induced peripheral neuropathy, platelet recovery following chemotherapy, and

infertility in women were also performed, but the results were not promising [33]. The result of a clinical trial of CNTF for retinal degenerative diseases was reported [34]. CNTF was successfully delivered intraocularly for long term via intraocular encapsulated cell implant, but therapeutic benefit was not obvious.

23.3.2 Clinical Application of Inhibitors of Members of IL-6 Family of Cytokines

Gp130, a common signal transducer of the IL-6 family of cytokines, is an attractive target molecule for inflammatory diseases and cancers, and this led to the development of several gp130 inhibitors [35]. Targeted therapies against STATs are also being developed, while the JAK1/2 inhibitor ruxolitinib has been already approved for the treatment of psoriasis, myelofibrosis, and RA, the JAK3 inhibitor to facitinib has been approved for the treatment of psoriasis and RA [36,37]. Although a phase II clinical trial of a humanized anti-OSM Ab (GSK315234) in patients with RA showed potential therapeutic effect [38], so far IL-6 blockade strategy is the only successful clinical application of members of the IL-6 family of cytokines.

23.3.3 Present Status and Prospects of IL-6 Blockade Therapy

As explained before, IL-6 exerts various biological effects by acting on different target cells. When infections or tissue injuries occur, IL-6 is immediately produced from macrophages and monocytes by stimulation of pattern recognition receptors with pathogen- or danger-associated molecular patterns and then triggers immune, acute phase, and hematological responses [3]. IL-6 thus contributes to host defense against such emergent stresses. When the source of stress is removed from the host, the production of IL-6 is terminated and results in normalization of serum levels of IL-6 (less than 4 pg/ml) and CRP. However, dysregulated IL-6 production is involved in disease development in two ways [39,40]. First, during immune response against infectious agents or tissue injuries, excessive production of IL-6 causes fatal multiple organ failure that can be diagnosed as septic shock or systemic inflammatory response syndrome. In this case, serum IL-6 concentration can increase by a factor from one thousand to one million and the level is associated with disease severity and mortality rate. Second, chronic dysregulated and persistent IL-6 production by a particular cell population leads to the development of various chronic immune-mediated diseases.

The first demonstration that IL-6 was pathologically involved in disease development was observed in a patient with cardiac myxoma [41]. The culture fluid obtained from the myxoma tissue of this patient with unclassified connective tissue disease contained a large quantity of IL-6 and the myxoma tissues stained positively with anti-IL-6 Ab. The patient had presented with fever, polyarthritis, Raynaud phenomenon, increased serum CRP level, anemia, and hypergammaglobulinemia with positivity for antinuclear factor, rheumatoid factor, and anti-DNA Ab. Subsequent studies have also found excessive expression of IL-6 in synovial fluids of RA [42], germinal center B cells in swollen lymph nodes of Castleman disease [43], myeloma cells [44], and peripheral blood cells or

infiltrating cells in tissues involved in various other diseases, as well as in many tumor cells [1–3,39,40,45]. However, the mechanisms causing dysregulated IL-6 production remain unknown. The regulation of IL-6 gene expression is mediated by transcriptional factors, micro-RNAs and RNA-binding proteins [39,40]. Recently, several micro-RNAs and regulatory RNA-binding proteins such as Arid5a, regnase-1, and roquin have been identified [46–49], so that elucidation of these molecules is important for clarification of the pathogenesis of IL-6-related diseases.

The concept of IL-6 blockade treatment strategy for diseases has been supported by numerous experimental findings obtained with the use of IL-6 gene knockout mice or administration of neutralizing anti-IL-6 or anti-IL-6R Ab. For instance, IL-6 blockade resulted in a striking reduction in susceptibility to Castleman disease-like symptoms in IL-6 transgenic mice, and suppressed disease development in models of RA, systemic lupus erythematosus, systemic sclerosis, polymyositis, multiple sclerosis, uveitis, endotoxin shock, and various other diseases [2,3].

These findings led to the development of the humanized anti-IL-6R monoclonal Ab tocilizumab [50]. Starting with the first-in-man trial for a patient with refractory multiple myeloma at Osaka University Hospital, various clinical trials of tocilizumab have been performed worldwide. The results of these trials verified that tocilizumab is strikingly effective for the treatment of several chronic inflammatory diseases. Tocilizumab is now approved for the treatment of RA in more than 130 countries, as well as for systemic or polyarticular juvenile idiopathic arthritis in Japan, USA, EU and India, and for Castleman disease in Japan and India. Moreover, numerous clinical trials of tocilizumab for other refractory diseases and off-label use of tocilizumab for orphan diseases strongly suggest that it can be widely used for the treatment of various diseases. These include systemic and organ-specific autoimmune diseases, acute severe systemic inflammatory diseases with cytokine storm such as cytokine release syndrome and hemophagocytic histiocytosis, chronic inflammatory diseases including autoinflammatory syndromes, and other diseases such as myocardial infarction, atherosclerosis, diabetes mellitus, atopic dermatitis, sciatica, amyotrophic lateral sclerosis, schizophrenia, and various cancers and cancer-associated cachexia (Table 23.2) [2,39,40]. In particular, accumulated evidence provides strong indications that tocilizumab appears to be highly promising for the treatment

Table 23.2 IL-6 blockade therapy for a wide variety of diseases.

Autoimmune Disease
Rheumatoid arthritis (approval in more than 130 countries)
Systemic sclerosis[c]
Systemic lupus erythematosus
Vasculitis syndrome (Giant cell arteritis[b,c], Takayasu disease[c])
Polymyositis and dermatomyositis[b]
Sjogren's syndrome[b,c]
Relapsing polychondritis

- Autoimmune hemolytic anemia
- Acquired hemophilia
- Neuromyelitis optica and multiple sclerosis
- Cogan's syndrome

Inflammatory Disease

- Castleman disease (approval in Japan and India)
- Juvenile idiopathic arthritis (approval in Japan, USA, EU, and India)
- Cytokine storm (cytokine release syndrome, septic shock, systemic inflammatory response syndrome, hemophagocytic histiocytosis[b], and macrophage activation syndrome)
- Adult onset Still's disease
- Amyloid A amyloidosis
- Polymyalgia rheumatica[b] and remitting seronegative symmetrical synovitis with pitting edema
- Crohn's disease
- Behcet's disease and uveitis[a,b]
- Autoinflammatory diseases
- Graft versus host disease[a,b]
- IgG4-related diseases
- Pulmonary arterial hypertension
- Eosinophilic fascilitis

Endocrinal and Metabolic Disease

- Type I and II diabetic mellitus[b]
- Atherosclerosis
- Thyroid-associated ophthalmopathy[b]

Bone and Cartilage Disease

- Osteoarthritis[c]
- Fibrous dysplasia of bone[b]

Neuropsychiatric Disease

- Amyotrophic lateral sclerosis[b]
- Schizophrenia[b,c]
- Sciatica

Neoplastic Disease and Paraneoplastic Syndrome

- Multiple myeloma, solid carcinoma, B-cell chronic lymphocytic leukemia[a], Erdheim–Chester disease[b], and cachexia

Others

- Myocardial infarction[b], atopic dermatitis, kidney transplantation[a,b], and HIV infection[a,b]

Tocilizumab, a humanized anti-IL-6R monoclonal Ab, is currently approved for the treatment of rheumatoid arthritis, Castleman disease, and juvenile idiopathic arthritis. Off-label use of tocilizumab indicates that it will be widely applicable for the treatment of various diseases. [a], [b], or [c] denote, respectively, ongoing phase I, II, or III clinical trial of tocilizumab registered in ClinicalTrials.gov. For neuromyelitis optica, a phase III clinical trial of SA237, a new fully human IL-6R Ab generated from tocilizumab by techniques for structural antibody optimization, is in progress.

of systemic sclerosis, large-vessel vasculitis, neuromyelitis optica, adult-onset Still's disease, amyloid A amyloidosis, and cytokine release syndrome, for all of which clinical trials are in progress.

23.4 Concluding Remarks

IL-6, a prototypical cytokine with pleiotropic and redundant activity, belongs to the IL-6 family of cytokines, which also includes IL-11, LIF, OSM, CT-1, CNTF, CLCF1, IL-27, IL-35, and viral IL-6. This cytokine family uses a common signal transducing molecule, gp130, and shows some redundant but not uniformly identical biological activity. Molecular clarification of the signaling system of the IL-6 family of cytokines and recent progress in elucidation of their biological functions and pathological roles have facilitated the clinical application of the cytokines themselves or their inhibitors to a variety of diseases. The physiological and pathological role of IL-6 is the most characterized among the members of his family. IL-6 contributes to host defense against infections and tissue damages, but dysregulated excessive or persistent production of IL-6 plays a pathological role in various kinds of diseases. IL-6 blockade therapy is currently in clinical use for the treatment of several diseases including RA, juvenile idiopathic arthritis, and Castleman disease, while this procedure is expected to have a wide range of applications for a large variety of diseases.

Type I and II Cytokine Superfamilies in Inflammatory Responses

William F. Carson IV and Steven L. Kunkel

University of Michigan Medical School, Department of Pathology, Ann Arbor, MI, USA

24.1 Introduction

Protective immunity relies on the decision-making capabilities of the cellular immune response. Is the microbe in question pathogenic, opportunistic, or commensal? Is the site of exposure conducive to repair, such as the skin, or will inflammatory responses damage nonregenerating tissues, such as neurons? Is the pathogen in question extracellular or intracellular, and which effector mechanisms need to be mobilized in response? When should the immune response switch from inflammatory to reparative processes? If these decisions are made in the correct fashion, the immune system can provide immunity to any number of pathogenic microorganisms. However, when these decision-making processes are aberrantly regulated, the host becomes susceptible to infections.

Central to these decision-making processes is the ability of leukocytes to communicate to each other via the expression of soluble signaling factors such as cytokines. Signal transduction events mediated by cytokine binding to membrane receptors help to guide these cells in lineage commitment decisions, activation, and/or resolution of inflammatory processes (Figure 24.1). Cytokines can function in autocrine, paracrine, and endocrine fashions to drive systemic immune responses to localized infections. Cytokines are expressed by multiple leukocyte lineages in generalized functional "families," with key cytokines synergizing to shape the quality of an inflammatory response to an infectious agent. Regulated cytokine expression is central to protective immunity and the development of immunological memory, while unchecked expression of proinflammatory mediators leads to devastating immunopathologies and autoimmune disease.

In this chapter, an overview of cytokine networks will be discussed with a focus on the inflammatory outcomes of cytokine expression. Following an overview of cytokine superfamilies organized by structure similarity, specific cytokine subfamilies will be organized based on shared receptor usage and listed based on nomenclature. The purpose of this chapter is to give a big-picture context to the

complex, interdependent role of heterogeneous cytokine production in guiding specific immune responses to infectious agents.

24.2 Cytokine–Receptor Interactions

Cytokines are secreted proteins that serve to instruct both hematopoietic and nonhematopoietic cells during inflammatory responses. Cytokines can be delineated as a distinct class of signaling molecules from hormones based on two key factors. First, the kinetics of cytokine secretion (rapid, dramatic induction following specific extracellular stimuli) are quite different from that of hormone production, which is often prolonged at less dramatic concentrations to effect physiological changes. Second, cytokines can signal in autocrine, paracrine and endocrine fashions, whereas hormones function primarily through endocrine signaling. The rapid kinetics of cytokine production coupled with the ability to localize signaling to distinct sites of infection allows cytokines to tailor immune responses for specific pathogens at specific tissue sites.

Type I and type II cytokines exhibit a monomeric structure based on the grouping of four alpha-helix motifs. Certain members of the type I superfamily consist of combinations of shared protein subunits that associate following mRNA transcription, including the IL-12 subfamily. For example, association of IL-12α (p35) and IL-12β (p40) results in mature IL-12, whereas association of IL-12β with IL-23α (p19) results in mature IL-23 [1]. Type I and II superfamilies are translated as fully functional proteins (unlike the propeptides of the IL-1 family [2]) and are not normally anchored to the plasma membrane (as with the TNF family [3]). Subgroupings of type I and II cytokines are organized based on shared receptor usage and/or similarities in gene organization.

Cytokine receptors are remarkably heterogeneous, including simple single-pass transmembrane receptors of the immunoglobulin superfamily to complex multimeric receptors sharing common signaling chains (such as with the type I common β- and γ-chain cytokines). Cytokine receptors signal via protein kinase-dependent signal transduction cascades, often initialized by autophosphorylation of the cognate receptor followed by phosphorylation of downstream signal transduction proteins. Many of the type I and II cytokines utilize the Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathway for signal transduction [4]. Distinct cytokines will activate specific JAK/STAT pathways based on their receptor specificity, and in many cases cytokines with similar physiological functions will signal via common JAK/STAT pathways. For example, both type I and type II interferons (IFNs) participate in T-helper type 1 (T_H1) immune responses to intracellular pathogens by regulating expression of gene families regulated by STAT1 [5]. In this fashion, cytokines can have a regulatory effect on the function of multiple immune cell subtypes by regulating common gene expression pathways across cell lineages.

The cytokines to be discussed in this chapter will be grouped by similarities in either structure or receptor usage and will then be discussed in terms of their contribution to immunity. As the IL-17 superfamily of cytokines was discussed in previous chapters, the T-helper type 17 response to extracellular pathogens will be discussed only in terms of the contribution of other type I and II cytokines to the development of IL-17 producing cells.

24.3 Cytokine Superfamilies

24.3.1 Type I Superfamily

The type 1 cytokine superfamily includes the common γ-chain, common β-chain, and IL-12 subfamilies, as well as similar cytokine products with unique receptor characteristics (including IL-14, -16, -32, and -34). Included in the type 1 superfamily are the IL-6 and IL-6-like cytokines such as IL-11, -27, and -30; these cytokines will not be discussed in this chapter. In addition, type I superfamily members that belong in the IL-1, IL-17, and TNF subfamilies will not be discussed, as they have been reviewed in depth in previous chapters.

24.3.2 Common Gamma Chain

Cytokines that share the common γ chain for signal transduction include IL-2, -4, -7, -9, -13, -15, and -21 [6] (Figure 24.2). These cytokines all utilize the common γ chain (also known as IL2Rγ or CD132) for activation of JAK1/JAK3 and downstream STATs. The common γ chain does not exhibit any specificity for distinct type I cytokines; instead, it is responsible for the initiation of signal transduction following binding of cytokine to the cytokine receptor complex. Receptor specificity is conferred by the α and β subunits that complex with the common γ chain to make a functional type I cytokine receptor. For example, interaction of the common γ chain with IL-2Rα/CD25 and IL-2Rβ/CD122 results in a fully

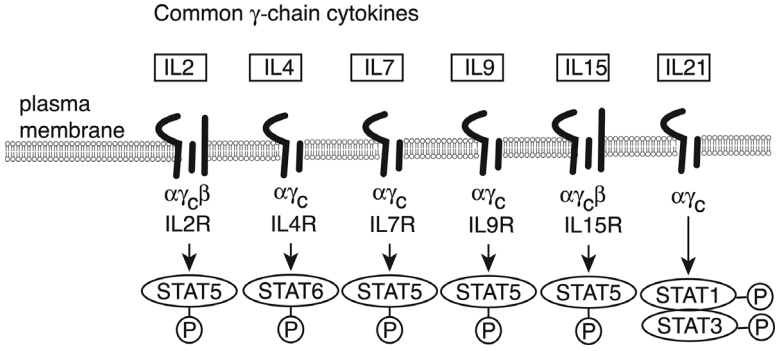

Figure 24.2 Common γ-chain cytokines.

functional IL-2 receptor [7]; however, replacement of the IL-2Rα subunit with IL-15Rα/CD215 results in functional IL-15 receptor [8], and interaction of the same γ subunit with only IL-7Rα/CD127 and no β subunit results in a functional IL-7 receptor [9]. As all three receptors share the same γ subunit with JAK3 signal transduction capability, these cytokines are all capable of activating STAT5a/b gene transcription in target cells [10]. In addition to STAT5 activation, cytokines within the common γ-chain family can also activate distinct STATs based on signal transduction capabilities provided by distinct cytokine receptor complexes, such as STAT1, STAT3, and STAT6 [10].

24.3.2.1 IL-2

IL-2, also known as T-cell growth factor, is responsible for guiding the development and proliferation of T cells. IL-2 is produced by activated T cells [11], certain myeloid lineage cells (e.g., dendritic cells [12]), and cells in the thymus [13] to support the proliferation of thymocytes and activated T cells. Upon activation with antigens bound to major histocompatibility complex (MHC), along with costimulatory ligand binding such as CD80 to T-cell-expressed CD28, activated T cells will produce IL-2 [14]. This IL-2 can signal through IL-2 receptors expressed in the IL-2-producing T cell (autocrine), as well as other T cells within the inflammatory microenvironment (paracrine) and T cells in distant sites (endocrine). IL-2 is critical for the development of immunological memory, and IL-2-dependent proliferative responses are central for the development of T-helper (T_H)-1, -2, and regulatory T-cell lineages [15]. Reports also suggest that IL-2 is essential for the development of T_H-9 through its ability to activate STAT5-dependent gene transcription [16]. However, IL-2 can suppress the development of T_H17 differentiation [17]. Animal models of IL-2 deficiency exhibit significantly decreased T-cell numbers in peripheral lymphoid organs [18]. As these animals age, they develop spontaneous autoimmune inflammation, indicating a loss of regulatory T-cell function and breakdown of peripheral tolerance [19].

24.3.2.2 IL-4

IL-4, also known as B-cell growth factor, links T- and B-cell activation during inflammatory responses. IL-4 promotes the proliferation of B cells and supports

class switching by activated B cells toward the production of immunoglobulin (Ig)-E [20]. IL-4 also drives MHC II expression by B cells, supporting antigen presentation [21]. IL-4 stimulation of activated CD4+ T cells results in differentiation toward the T_H2 lineage [22]; as T_H2 T cells can produce IL-4, this positive feedback loop promotes the development of T_H2 memory [23]. IL-4 also has potent effects on innate immunity; for example, macrophages stimulated with IL-4 exhibit alternative activation, characterized by a reduction in pathogen clearance phenotypes and an increase in reparative functions [24]. IL-4-deficient mice exhibit significantly decreased IgE production [25] and T_H2 T-cell function [26], resulting in resistance to the development of experimental allergy models [27].

24.3.2.3 IL-7

IL-7-dependent signals are critical for the differentiation of lymphoid progenitor cells from multipotent hematopoietic progenitors. IL-7 is produced in sites of lymphoid differentiation, particularly in the bone marrow and thymus [28]. Stromal cells in these tissues produce IL-7 to support lymphopoiesis and the development of T and B cells [29]. Stromal cells in other tissues can also produce IL-7, including hepatocytes [30]. IL-7 is also produced by structural cells in barrier tissues (e.g., keratinocytes [31] and epithelial cells [32]) for maintenance of lymphocytes in mucosal surfaces. The IL-7 receptor (IL-7R) is expressed by leukocytes and consists of the IL-7 receptor α chain (CD127) complexed with the common γ chain [33]. STAT5 activation by IL-7 binding to the IL-7R is a critical step in T-cell development; as such, IL-7 knockout animals exhibit an atrophied thymus with reductions in total thymocytes and peripheral T cells [34]. IL-7 is also important for the maintenance of memory T cells in the periphery; IL-7R expression can delineate effector from central memory T cells [35] and T-helper lineage memory cells from long-lived regulatory T cells [36].

24.3.2.4 IL-9

IL-9 is the primary cytokine produced by the T-helper lineage known as T_H9 T cells [37]. IL-9 is also produced by members of the innate lymphoid cell (ILC) lineage, most notably ILC2 cells [38]. The initial characterization of IL-9 indicated a role for this cytokine in promoting T_H2 responses, as IL-9 could synergize with other type 2 cytokines to promote class switching to I_gE and immunity to parasitic infections [39]. However, T_H9 T cells and ILC2 cells appear to have a much broader function in immune responses, both helping to shape inflammation through concomitant production of cytokines such as IL-10 and helping to skew type 1 responses toward type 2 [40]. The IL-9 receptor is a heterodimer consisting of the IL-9 receptor α chain (CD129) with the common γ receptor, and is expressed in lymphoid cells such as T cells, myeloid lineage cells such as eosinophils and mast cells, and certain epithelial cells [41]. IL-9 functions to promote the differentiation and effector function of target cells. For example, the type 2 promoting functions of IL-9 manifest through its ability to stimulate mast cell and eosinophil differentiation and accumulation in inflamed tissues [42]. IL-9's ability to promote generalized type 2 responses and mast cell function makes IL-9 an important mediator of immunopathology during food allergy responses [43].

24.3.2.5 IL-15

IL-15 shares structural and functional similarity with IL-2 and as such is an important cytokine for the proliferation and survival of T cells. IL-15 is often found expressed as either a membrane-bound protein or in a complex with the IL-15 receptor α (CD215) [44]. The trans-presentation of IL-15 through cell–cell interactions (membrane-bound IL-15 or IL-15/IL-15Rα complex) or through interactions with soluble IL-15/IL-15Rα complexes proceeds via the IL-15 receptor complex, consisting of the high-affinity IL-15Rα complexed with the β and (common) γ chains of the IL-2 receptor [45]. Downstream activation of JAK3 and STAT5a/b proceeds in a similar fashion as with IL-2, driving similar antiapoptotic and proliferative signals [46]. IL-15 supports memory CD8+ T cell and NK cell homeostasis in the periphery [47]. IL-15 production by epithelial cells can activate the cytotoxic activity of intraepithelial lymphocytes (IELs) that serve as a first line of defense against pathogens [48]. Due to its ability to support cytotoxic T and NK cell functions, IL-15 is a potent inducer of immune responses against intracellular pathogens.

24.3.2.6 IL-21

IL-21 is a potent proinflammatory cytokine produced by CD4+ T cells, including T_H2, T_H17, and T follicular helper (T_{FH}) cells [49]. Expression of the IL-21 receptor, consisting of the high-affinity IL-21 receptor (CD360) in a heterodimeric complex with the common γ chain, is largely restricted to lymphocytes, including T cells, B cells, and NK cells [50]. IL-21 stimulation proceeds through JAK1/JAK3, leading to STAT1 and STAT3 activation [51]. IL-21 drives B-cell class switching and plasma cell differentiation [52,53]. Animal models of IL-21 deficiency provide evidence for the importance of IL-21 in the maintenance of T_H1 versus T_H2 lineage differentiation [54], as well as negatively regulating eosinophil recruitment to inflamed tissues [55]. Paradoxically, IL-21 receptor-deficient animals exhibit increases in I_GE production, which is a hallmark of type 2 immune responses [56]. These results suggest that the physiology of IL-21 is more complex than simply a T-helper subtype cytokine. For example, IL-21 can potentiate the activation of macrophages, leading to increased phagocytosis [57] and production of macrophage elastase [58]. IL-21 can suppress the activation and survival of T_{reg} cells while stabilizing T_H17 T cells, suggesting an important role for IL-21 in driving inflammatory responses [59]. IL-21 can suppress antigen presentation by dendritic cells, which blunts antigen-specific responses by effector/memory T cells [60]. Ultimately, IL-21 has complex nonredundant effects on cellular immunity and has the potential to both support and suppress multiple types of inflammatory responses.

24.3.3 Common Beta Chain

Cytokines that share the common β chain for signal transduction include IL-3, IL-5, and granulocyte–monocyte colony-stimulating factor (GM-CSF) (Figure 24.3). All these cytokines utilize the common β chain (CSF2RB/CD131) for activation of the JAK/STAT pathway through interactions with JAK2 [61]. Common β-chain cytokine receptors often signal through STAT5a/b, with additional signals

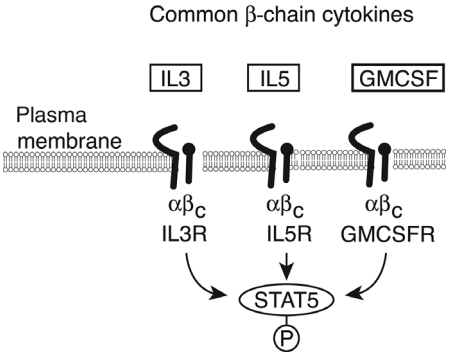

Figure 24.3 Common β-chain cytokines.

transmitted through PI3 K/AKT and RAS/MAPK pathways [62]. Cytokines in the common β-chain subfamily are involved in the growth and differentiation of leukocytes from hematopoietic precursors. However, all three of the cytokines in the common β-chain subfamily also play important roles in the initiation and maintenance of inflammatory responses.

24.3.3.1 IL-3

IL-3 plays a central role in hematopoiesis, helping to guide multipotent hematopoietic precursor cells to commit to either the myeloid or lymphoid lineage [63]. IL-3 is produced by stromal cells in hematopoietic tissues (e.g., bone marrow stromal cells [64] and thymic epithelial cells [65]). Activated T cells can also produce IL-3 to stimulate T-cell proliferation and differentiation in an auto- and paracrine manner, similar to the effects of IL-2 [66]. The IL-3 receptor consists of the high-affinity IL-3 receptor α chain (CD123) complexed with the common β chain, and signal transduction through the IL-3 receptor proceeds through PI3K/AKT and RAS/MAPK pathways in addition to STAT5 [67]. The effects of IL-3 stimulation are highly dependent on the local cytokine milieu. For example, stimulation of multipotent hematopoietic stem cells (HSCs) with IL-3 alone leads to differentiation to the myeloid lineage [68]. Conversely, stimulation of HSCs with IL-3 along with IL-7 results in differentiation to the lymphoid lineage [69]. Despite the important role for IL-3 in immune cell development, mice deficient in IL-3 production exhibit few changes to peripheral immune cell numbers compared to wild-type mice [70]. While eosinophil and mast cell development is negatively affected, the distribution of other leukocyte subsets is largely unaffected. These results suggest that IL-3 signals may be more important for guiding cell fate decisions, rather than being absolutely necessary for the initiation of hematopoiesis.

24.3.3.2 IL-5

IL-5, also known as eosinophil differentiation factor, is a key cytokine for the development of type 2 inflammation through its ability to stimulate eosinophil differentiation and chemotaxis. Activated T_H2 T cells and mast cells produce IL-5 [71]. The IL-5 receptor consists of the high-affinity IL-5 receptor α chain (CD125) complexed with the common β chain, and signal transduction through the IL-5 receptor is similar to the IL-3 receptor [72]. The IL-5 receptor is

primarily expressed by eosinophils, and IL-5 is a potent inducer of eosinophilia [73]. B cells can also express the IL-5 receptor, and IL-5 stimulation can synergize with IL-4 to drive class switching in these cells toward I_gE [74]. The IL-5 receptor is expressed by a subset of B cells known as B-1 cells, and IL-5 signaling helps to drive B-1 cell proliferation and survival [75]. IL-5 knockout mice exhibit decreased production of eosinophils [76] and resistance to experimental models of allergic airway disease [77]. Because of its central role in driving eosinophilia and B-cell activation, as well as its primary source in T_H2 T cells, IL-5 is considered to be a central mediator of type 2 responses.

24.3.3.3 GM-CSF

Functionally, granulocyte–monocyte colony-stimulating factor is often grouped with the colony-stimulating factors, including macrophage colony-stimulating factor (M-CSF) and granulocyte colony-stimulating factor (G-CSF). However, unlike the M- and G-CSF receptors, which are single-pass trans-membrane receptors, the GM-CSF receptor is a heterodimeric complex consisting of the GM-CSF receptor α chain (CD116) complexed with the common β chain [78]. GM-CSF signals through JAK2/STAT5a/b in addition to PI3 K, RAS/MAPK, and NF-κB [79]. GM-CSF receptor is expressed in a wide array of myeloid precursors and mature monocytes/granulocytes [80]. GM-CSF drives the differentiation of granulocytes and monocytes from precursor cells in the bone marrow [81]. GM-CSF can also drive the differentiation of monocytes into either macrophages with classical activation phenotypes [82] or myeloid-derived dendritic cells with potent antigen-presenting capabilities [83]. GM-CSF is also produced during inflammatory responses by activated T cells, especially T_H1 and T_H17 cells [84]. GM-CSF has important roles as both a hematopoietic factor and an inducible proinflammatory cytokine.

24.3.4 IL-12 Subfamily

The IL-12 subfamily cytokines (IL-12, -23, -27, and -35) consist of heterodimeric interactions between two of the five subunit proteins (including p19, p28, p35, p40, and Ebi3) and heterodimeric receptor complexes containing two of the five receptor chains (including IL-12Rβ1, IL-12Rβ2, IL-23R, IL-27R, and gp130). IL-12 subfamily cytokines can signal through multiple STATs, including STAT1, STAT3, and STAT4, and can have a wide range of effects on inflammatory responses, from highly stimulatory (IL-23) to inhibitory (IL-35) (Figure 24.4).

24.3.4.1 IL-12

IL-12 is a heterodimeric cytokine consisting of the IL-12α (p35) and IL-12β (p40) subunits. A homodimer of β subunits can also be formed (known as IL-12p40 homodimer or $p40_2$); certain studies have indicated a role for IL-12p40 in driving immune suppression [85]. Cells of the myeloid lineage produce IL-12, including monocytes, macrophages, and dendritic cells [86,87]. Activated neutrophils can also produce IL-12 in response to inflammatory stimuli, such as Toll-like receptor (TLR) ligands [88]. IL-12 promotes the differentiation of activated T cells into T_H1 T cells [89]. Stimulation of the IL-12 receptor, consisting of IL-12 receptor β1 (CD212) and β2 subunits, results in activation of STAT4, leading to the

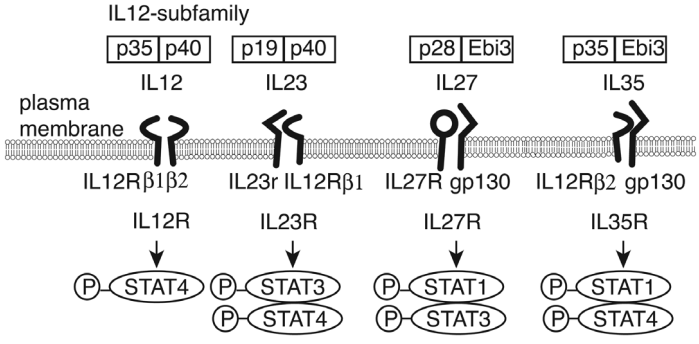

Figure 24.4 IL-12 subfamily cytokines.

production of IFNγ and TNFα in activated T cells and NK cells, as well as the production of the T_H1 lineage transcription factor T-bet [90]. IL-12 stimulation also drives the cytotoxic activity of activated CD8+ T cells [91]. IL-12 is a central cytokine for the development and maintenance of type 1 immune responses against intracellular pathogens.

24.3.4.2 IL-23

IL-23 is comprised of the IL-12p40 subunit complexed with the IL-23 α subunit (p19). IL-23 signals through the IL-23 receptor, a heterodimeric complex of the IL-12Rβ1 with IL-23R. The IL-23 receptor signals through STAT4 in a similar fashion as the IL-12 receptor, with IL-23 receptor subunit adding STAT3 signal transduction to the IL-23 receptor complex [92]. As IL-12 promotes T_H1 cells, IL-23 promotes the activation and differentiation of T_H17 T cells [93]. IL-23 is produced by activated macrophages and dendritic cells, and it can signal naïve T cells to differentiate to T_H17 in the context of antigen stimulation [94]. IL-23 can also mediate the activation of γδ and NK-T cells [95]. IL-23 has been implicated in numerous autoimmune diseases, including inflammatory bowel disorders [96], rheumatoid arthritis [97], and multiple sclerosis [98]. Studies highlighting the importance of IL-23 in autoimmune disease have helped to shift the accepted paradigm of T-helper subtype participation in autoimmunity toward a greater appreciation of the pathogenic role of T_H17 T cells.

24.3.4.3 IL-27

IL-27 is comprised of two distinct subunits in the IL-12 subfamily, IL-27p28 (also known as IL-27B or IL-30) and Epstein–Barr Virus induced gene 3 (Ebi3). IL-27 binds to the IL-27 receptor, a heterodimeric complex consisting of the IL-27 receptor α subunit (WSX-1) and gp130 (also known as IL6-β or CD130). Activation of the IL-27 receptor results in signal transduction through STAT1, STAT3, and MAPK [99]. IL-27 shares little similarity with the other IL-12 cytokine/receptor subfamily members, save for Ebi3 that is shared with IL-35; however, IL-27 functions in a synergistic fashion with other IL-12 subfamily cytokines to guide immune responses in both innate and adaptive immune cells [100]. IL-27 is produced by numerous immune cells, with dendritic cells being the primary source [101]. IL-27 stimulation of myeloid cells (e.g., monocytes) results not only in expression of

inflammatory cytokines such as TNFα and IL-6 but also in the upregulation of suppressive cytokines such as IL-10 [102]. For adaptive immune cells, IL-27 can help potentiate T_H1 responses through the promotion of IL12Rβ2 expression, which sensitizes T cells to respond to IL-12 [103]. However, IL-27 can also suppress IL-2 production, which in turn not only suppresses T_{reg} responses (indirectly promoting T_H1) but also enhances T_H17 responses (indirectly suppressing T_H1) [104]. STAT1 activation by IL-27 can drive T-bet expression in T cells, further supporting T_H1 differentiation [105]. IL-27 has pleiotropic effects on many facets of cellular immunity, with a preference toward the promotion of type 1 cytokine responses at the expense of type 2 responses and general immune cell proliferation.

24.3.4.4 IL-35

Of the IL-12 subfamily, IL-35 is the most immunosuppressive and has been linked with T_{reg} function and the induction of tolerance. IL-35 is a heterodimer consisting of the IL-12α subunit and Ebi3 from IL-27, and the IL-35 receptor consists of the IL12Rβ2 subunit complexed with gp130 from the IL-27 receptor [106]. Signal transduction through the IL-35 receptor proceeds though both STAT1 and STAT4, leading to the expression of immunosuppressive cytokines in target cells (i.e., IL-10 and TGFβ) [107]. IL-35 is produced by T_{reg} cells [108] and regulatory B cells [109] and expression of IL-35 receptor is found on T and B cells, suggesting that IL-35 can serve in an auto- and paracrine fashion to drive regulatory responses in peripheral tissues [110]. In addition, IL-35 produced by tolerogenic dendritic cells can also support the development of induced (i-) T_{regs} [111]. IL-35 can, therefore, drive the differentiation of iT- and B_{regs} that then produce IL-10 and TGFβ. As the subunits of both IL-35 and the IL-35 receptor are shared by other members of the IL-12 subfamily, it is challenging to selectively inhibit IL-35 in animal models; however, studies suggest that IL-35 blockade inhibits the conversion of inducible suppressive lymphocytes, especially B_{reg} induction [112].

24.3.5 Orphan Type I Cytokines

The remaining type I cytokines share basic structural similarities with other type I cytokines. However, these cytokines do not classify easily with other subfamilies, as they do not share common receptor or cytokine subunits with other members of the type I cytokines (Figure 24.5).

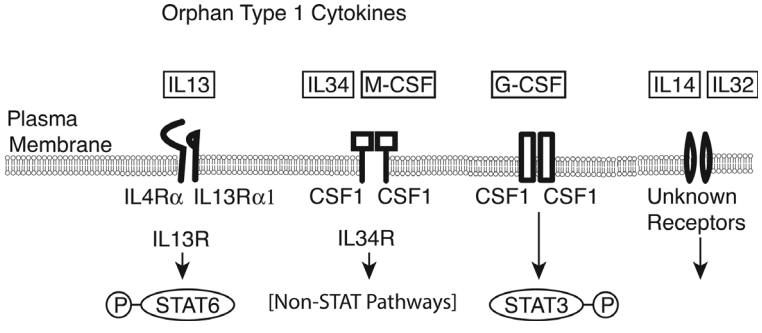

Figure 24.5 Orphan type I cytokines.

24.3.5.1 IL-13

IL-13 functions in concert with IL-4 and IL-5 to help drive type 2 inflammatory responses and T_H2 functions. IL-13 promotes mucus secretion by cells of the mucosal epithelium [113] and can enhance airway hyperreactivity through effects on bronchial/intestinal smooth muscle [114]. Interestingly, IL-13 knockout mice are still capable of generating T_H2 responses and I_gE antibodies, albeit at reduced levels, as long as IL-4 production remains unaffected [115]. The IL-13 receptor consists of the IL-4 receptor α subunit complexed with the IL-13 receptor α1 (CD213A), and binding of IL-13 to the mature IL-13 receptor results in signal transduction via STAT6 [116]. A second receptor for IL-13 also exists, known as the IL-13 receptor α2 (CD213A2); this receptor lacks an intracellular signal transduction domain and functions as a sequestering receptor [116]. IL-13 is grouped with IL-4 and IL-5 as the core cytokines driving type 2 inflammatory responses, which include the differentiation of both T_H2 T cells and alternatively activated/M2 macrophages.

24.3.5.2 IL-14

IL-14, also known as α-taxilin or high molecular weight B cell growth factor (HMW-BCGF), helps to drive proliferation of many different lineages of B cells. Activated T cells can produce IL-14 following activation [117]. Little is known about IL-14, save that the receptor is induced in B cells following activation, and IL-14 stimulation results in increases in cyclic AMP in activated B cells [118]. Studies of human patients suggest that IL-14 may be important in supporting B cell memory [119], and overexpression of IL-14 in animal models results in expanded B-cell populations, correlating with increased serum antibody levels and susceptibility to autoimmune disease [120].

24.3.5.3 IL-32

Little is understood about the biological functions of IL-32, also known as natural killer transcript 4 (NK4), as there are no rodent homologues of this cytokine, making experimental design challenging. Studies of human leukocyte responses have identified six isoforms of IL-32, all of which appear to have similar functions [121]. IL-32 can be expressed by numerous cells, including hematopoietic (e.g., NK, T cells, monocytes, and mast cells) and nonhematopoietic (e.g., epithelial cells and keratinocytes) cell types, and its production can be induced by IL-18 [122,123]. IL-32 helps to drive expression of proinflammatory cytokines in target cells, including IL-1β and IL-6 [124]. IL-32 stimulation can also drive expression of IL-17 in CD4+ T cells [125]. Studies have implicated IL-32 as an important proinflammatory cytokine in numerous immunopathologies, including autoimmune diseases such as rheumatoid arthritis [126].

24.3.5.4 IL-34

IL-34 is a homodimer expressed by a wide range of cell types. IL-34 signals through the CSF-1 receptor (CD115) that also binds macrophage colony-stimulating factor [127]. IL-34 stimulation through CSF-1 results in signal transduction primarily through non-STAT pathways, such as PI3 K and Ras/Erk [127]. IL-34 affects the differentiation and activation of cells responsive to M-CSF, specifically

microglia and Langerhans cells [128], and can induce the differentiation of blood monocytes [129]. These results suggest that IL-34 signals are critical for the survival of terminally differentiated myeloid-lineage innate immune cells in peripheral tissues.

24.3.5.5 G-CSF

Granulocyte colony-stimulating factor, also known as colony-stimulating factor 3 (CSF3), is the primary cytokine for the differentiation of neutrophils. G-CSF signals through the monomeric G-CSF receptor (CD114) that contains both extracellular ligand-binding domains and intracellular signal transduction domains [130]. Binding of G-CSF to its receptor induces signal transduction through STAT3, PI3K, and ERK [131]. G-CSF receptor is found on hematopoietic precursor cells, and stimulation with G-CSF results in their differentiation to neutrophils [132]. Animal models of G-CSF deficiency exhibit neutropenia, supporting the central role for G-CSF in neutrophil development [133]. G-CSF can be produced by hematopoietic (e.g., macrophages [134]) and non-hematopoietic (e.g., endothelial [135]) cells during inflammatory responses, and G-CSF production during the initial stages of microbial infection is critical for neutrophil-mediated immunity [136].

24.3.5.6 M-CSF

Macrophage colony-stimulating factor (also known as CSF1) signals through a monomeric receptor (CSF1R/CD115) to support myeloid cell development [137]. M-CSF is produced by bone marrow stromal cells [138] and activated T cells [139] to support the survival and effector function of monocytes/macrophages in peripheral tissues. CSF1R is expressed on myeloid cells, and binding of M-CSF to CSF1R results in activation of RAS/MAPK, ERK, and PKC pathways [140]. M-CSF signals also regulate the balance of osteoclast and osteoblast functions, with paracrine signaling by activated osteoblasts having a stimulating effect on the opposing functions of osteoblasts [141]. M-CSF ligand [142] and receptor [143] deficient animals exhibit osteopetrosis (excessive bone formation) due to the loss of osteoclast regulation.

24.3.6 Type II Superfamily

The type II superfamily, which contains the interferons and the IL-10 subfamily, has many similarities to type I cytokines, including the use of multimeric receptors with shared subunits. The major difference between type I and II superfamily cytokines is based on the sequence of the extracellular portion of the receptor, with type I cytokine receptors exhibiting a common WSXWS amino acid motif that type II cytokines do not exhibit. Within the type II superfamily, there are two major subfamilies, the IFNs (in three classes) and the IL-10 subfamily (including IL-10, -19, -20, -22, -24, and -26). The IFNs are responsible for inducing antiviral responses in both hematopoietic cells and structural cells, serving as an essential mediator of cross-talk between the immune system and host physiology during viral infections. The IL-10 subfamily contains both pro- and anti-inflammatory cytokines; this subfamily grouping is primarily due to

commonalities with receptor composition. Type III IFNs are often classified as members of the IL-10 subfamily and assigned interleukin identities – IFNλ1 as IL-29 and IFNλ2/3 as IL-28A/B – and these classification schemes differ based on the specifics of the subgroup's chromosomal location and gene organization (i.e., the use of multiple exons for mRNA transcription). In this chapter, these cytokines will be organized under the type III IFNs.

24.3.7 Interferons

24.3.7.1 Type I: IFN-α, -β, and Variants

Type I IFNs are produced by numerous cells, with IFNα primarily produced by leukocytes and IFNβ produced by fibroblasts [144] (Figure 24.6). A subset of dendritic cells known as plasmacytoid dendritic cells (pDCs) are particularly robust producers of type I IFN [145]. The type I IFN receptor consists of a heterodimeric complex containing IFNAR1 and IFNAR2, and signaling through this receptor results in activation of multiple STATs, NF-κB, P38/JNK, and ERK1/2 [146]. This extensive signal transduction cascade helps to drive the potent proinflammatory effects of type I IFNs. The two major subtypes of type I IFN are IFNα and IFNβ. "IFNα" is a class of at least 12 different proteins, expressed as single exons arising from a common IFNA gene cluster [147]. In contrast, the function of IFNβ is primarily mediated by IFNβ1 [148]. Other variants include IFNε, -κ, -δ, -ζ, -ω, and possibly -ν; these are expressed at various levels (if at all) in different mammals, and are not as well described as IFNα and β [149]. Type I IFN can stimulate antiviral responses by immune cells and can synergize with type II interferon (i.e., IFNγ) to potentiate T_H1 lineage commitment by T-helper cells [150] and cytotoxic activity by CD8+ "killer" T cells [151]. Type I IFNs signal nonhematopoietic cells in the body to initiate an antiviral program meant to limit viral replication. Type I IFN signaling drives expression of antiviral genes such as 2′-5′ oligoadenylate synthase, protein kinase R, and the Mx proteins (Mx1 and Mx2); these genes have broad downregulatory effects on protein synthesis, meant to limit viral replication in infected cells [152]. Type I IFNs can also drive the febrile response [153]. This global suppressive effect on protein synthesis can have a suppressive effect on immune responses, and type I IFN production during

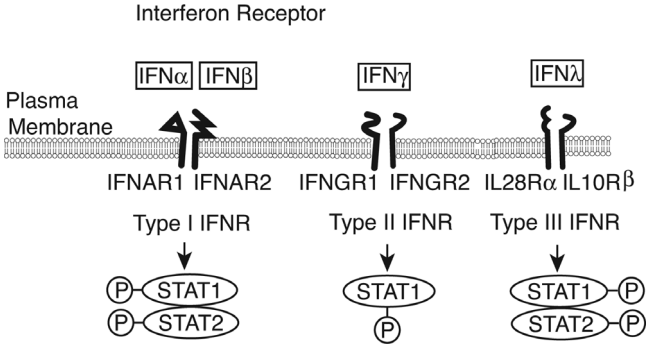

Figure 24.6 Interferon receptors.

chronic infection has the potential to be detrimental to immunity [154]. Animal models of type I IFN deficiency, such as the IFNAR1 targeted deletion in mice, results in significant impairments in antiviral [155] and antitumor [156] immune responses.

24.3.7.2 Type II: IFNγ

The only cytokine in the type II interferon subfamily is IFNγ, which mediates adaptive–innate immune cell cross-talk. IFNγ is produced by activated lymphocytes, especially CD4+ and CD8+ T cells and NK and NK-T cells [157]. The IFNγ receptor is similar to the type I IFN receptor in that it is a heterodimer consisting of IFNGR1 and IFNGR2; however, the IFNγ receptor primarily signals through STAT1, unlike the multiple STATs activated by the type 1 IFN receptor [158]. The IFNγ receptor is expressed by lymphocytes (both B and T cells) and macrophages, and IFNγ stimulation of these cells drives type 1 immune responses [159]. IFNγ promotes class switching of B cells toward the production of IgG2a, an important antibody isotype for Fc-mediated phagocytosis and complement activation [160]. IFNγ also promotes cytotoxic T-cell activity and T_H1 cell differentiation by promoting the expression of the transcription factor T-bet [161]. IFNγ promotes the upregulation of both class I and class II MHC molecules on antigen-presenting cells, helping to stimulate adaptive immune responses to antigens [162]. IFNγ promotes classical activation of macrophages, resulting in enhanced antimicrobial functions such as increased phagocytosis and killing of microorganisms [163]. Animals that are deficient in IFNγ signaling (IFNGR1 knockout) are extremely susceptible to intracellular infections [164].

24.3.7.3 Type III: IFNλ-1, -2, and -3

The Type III interferons walk a fine line between subfamilies in the type II cytokine superfamily. For example, IFNλ2 and IFNλ3, also known as IL-28A and IL-28B, respectively, regulate the expression of many type I IFN responsive antiviral genes, such as 2′-5′ oligoadenylate synthase and Mx1/2, highlighting their functional similarity to other interferons [165]. However, these two cytokines are expressed from gene loci containing multiple exons, unlike the type 1 IFNs that are typically encoded by a single exon [166]. In addition, the IL-28 receptor complex contains both an IL-28 receptor α chain and a β chain shared with the IL-10 receptor (IL10Rβ/CDW210B), which links these cytokines with the IL-10 subfamily [167]. IFNλ1 shares a high degree of sequence similarity with the other type III IFNs, and also signals through the IL-28 receptor [168]. Regardless of the classification, the type III IFNs function in a similar fashion to the type I IFNs. Signal transduction through the IL-28 receptor leads to STAT1 and STAT2 activation, and serves to induce antiviral responses in numerous cell types, albeit not to the same widespread effect as the type I IFNs [168].

24.3.8 IL-10 Subfamily

The IL-10 subfamily shares the same common receptor subunit as the type III IFNs, IL10Rβ (Figure 24.7). The subfamily is named after its founding member, a potent anti-inflammatory cytokine that can suppress the downstream expression

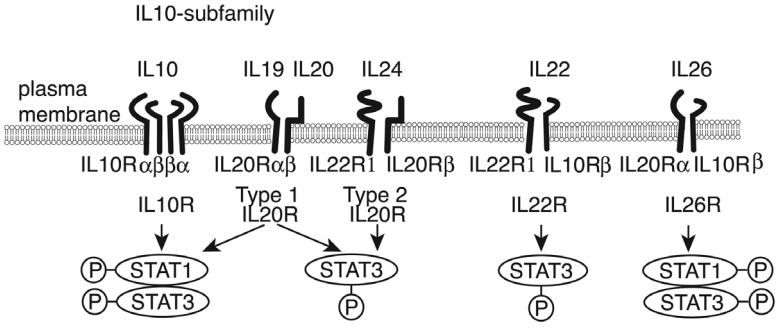

Figure 24.7 IL-10 subfamily receptors.

of many proinflammatory genes in immune cells. Despite the shared receptor subunit, the other members of the IL-10 subfamily do not all function as anti-inflammatory cytokines. In fact, many of the other IL-10 subfamily cytokines both promote or suppress lineage-specific inflammatory cytokine responses and mediate cross-talk between the immune system and structural cells during wound healing and scar tissue formation.

24.3.8.1 IL-10

IL-10 is a potent anti-inflammatory cytokine, as evidenced by its alias as cytokine synthesis inhibitory factor (CSIF). IL-10 is a homodimer that binds to a multimeric receptor made up of pairs of IL-10Rα and IL-10Rβ molecules, for a total of four subunits per receptor [169]. IL-10 signals through STAT1, STAT3, PI3K, and p38 MAPK pathways [170,171]. IL-10 is produced by monocytes and macrophages, along with T_H2 and T_{reg} cells [172]. IL-10 has strong immunosuppressive functions and directly antagonizes T_H1 cytokine production, classically activated/M1 macrophage inflammatory gene expression, and costimulatory ligand expression in antigen-presenting cells [173]. Despite its anti-inflammatory properties, IL-10 expression is primarily induced by microbial stimuli, including TLR signaling [174] and cross-linking of Fc receptors [175]. This implicates IL-10 as an important regulatory cytokine to help restrain inflammatory responses and limit collateral damage to healthy cells and tissues. IL-10 is also critical for gut homeostasis, and IL-10 production in the intestine plays a role in tolerance induction against commensal bacteria. As evidence of this, animals lacking the IL-10 gene develop spontaneous colitis due to unchecked inflammatory responses to gut bacteria [176].

24.3.8.2 IL-19

IL-19 is produced by activated monocytes and macrophages, B cells, and structural cells such as epithelial cells and keratinocytes [177]. IL-19 signals through the IL-20 receptor, consisting of the IL-20Rα chain complexed with the IL-10Rβ chain, and results in signaling through STAT1 and STAT3 [178]. IL-19 shares functionalities with IL-10, such as suppression of macrophage inflammatory responses and production of TNFα and IL-1β [179]. IL-19 deficiency results in increased disease severity in animal models of colitis [178]. IL-19 also drives

expression of T_H2 cytokines such as IL-4, IL-5, and IL-13 [180]. However, IL-19 has also been shown to drive inflammatory responses in psoriasis, which is considered to be a T_H1-driven inflammatory response [181]. IL-19 drives the differentiation and proliferation of keratinocytes, and these cells can also produce IL-19; this positive autocrine feedback loop may drive psoriasis pathology through aberrant keratinocyte proliferation [182]. IL-19 is difficult to slot as strictly a T_H1, T_H2, or suppressive cytokine. It is clear that IL-19 plays an important role in immune cell–structural cell cross-talk at mucosal or barrier surfaces.

24.3.8.3 IL-20

IL-20 shares similar functions with IL-19 and IL-24 as a proliferative signal for keratinocytes. IL-20 can signal through two distinct receptor complexes that each use the IL-20 receptor β chain, the type 1 IL-20 receptor (complex with IL-20 receptor α chain), and the type 2 IL-20 receptor (complex with IL-22 receptor α1) [183]. IL-20 signals result in activation of STAT3 in target cells, including keratinocytes, adipocytes, and endothelial cells [183]. IL-20 is produced in response to microbial stimuli (e.g., TLR ligands) and inflammatory cytokines such as IL-1β and TNFα [184]. IL-20 can be produced by activated macrophages and T_H1 T cells, yet appears to counteract type 1 cytokine responses through the promotion of T_H2 cytokines [185]. IL-20 plays a central role in psoriasis, using a similar keratinocyte-activating mechanism to IL-19 and IL-22 [186]. IL-20 production has been implicated both in the pathophysiology of chronic inflammatory responses and in wound healing following tissue damage [187].

24.3.8.4 IL-22

IL-22 is produced by inflammatory lymphocytes, such as T_H17 T cells and activated NK cells [188]. The IL-22 receptor is composed of the common IL-10 receptor β chain complexed with the IL-22 receptor α1; this receptor is specific for IL-22 and signals through STAT3 [189]. IL-22 signals support the proliferation of epithelial cells and keratinocytes [190], along with supporting systemic inflammatory responses. IL-22 drives the production of acute-phase proteins from hepatocytes [191] and antimicrobial defensins from epithelial cells [192]. IL-22 production supports protective inflammatory responses in mucosal surfaces and barrier tissues during microbial infection [193].

24.3.8.5 IL-24

IL-24, or melanoma differentiation-associated 7 (mda-7), shares similar functions and receptor complexes to IL-19 and IL-20 (type I and type II IL-20 receptors). Unlike other IL-10 family cytokines that are produced by "classic" inflammatory cells such as M1 macrophages or T_H1T cells, IL-24 is primarily produced following stimulation with T_H2-associated cytokines such as IL-4 [194]. Keratinocytes, T_H2 T cells, and activated monocytes stimulated with IL-4 can produce IL-24 [195]. IL-24 functions in an opposite fashion to other IL-10 subfamily cytokines, as it restricts rather than promote proliferative responses during wound healing [196]. In this way, IL-24 may play a role in the resolution of wound healing through its ability to restrict keratinocyte proliferation after

successful repair of localized tissue damage. IL-24 can also stimulate the apoptosis of cancer cells, possibly by utilizing the same antiproliferative molecular mechanisms that are activated in IL-24 responsive structural cells [197].

24.3.8.6 IL-26

IL-26 signals through a receptor consisting of the IL-20 receptor α chain complexed with the common IL-10 β chain, expressed in structural cells such as epithelial cells [198]. Stimulation with IL-26 results in signal transduction through STAT1 and STAT3 [198]. IL-26 is produced by T cells, and T_H17 T cells in particular [199], although it can also be produced by NK cells following activation [200]. IL-26 serves as a proinflammatory cytokine at mucosal surfaces through its ability to induce CXCL8 secretion and subsequent accumulation of T_H17 T cells [201]. This makes IL-26 arguably the most proinflammatory member of the IL-10 superfamily, as its expression can have direct effects on neutrophil influx into barrier surfaces [202].

24.4 Summary: Cytokine Networks in Cellular Immunity

It is important to note that this discussion of the alpha-helix cytokines omitted cytokine families discussed in previous chapters (i.e., IL-1, IL-6, and IL-17 cytokines). Many other soluble factors can also have drastic effects on immune cell function and inflammatory responses, including chemokines, growth factors, and hormones. There is little doubt that in the future, the physiological effects ascribed to specific cytokines will be changed to other previously described or novel cytokines. As our understanding of the molecular biology of cytokines grows, so will our understanding of the functions of specific cytokines in specific inflammatory contexts.

It is also important to remember that the functions of these signaling molecules are dependent upon the tissue microenvironement and the inflammatory milieu. Cytokines that function as proinflammatory mediators in one environment may function to suppress inflammation in others. This is especially important when discussing lineage-specific cytokine expression, such as classical versus Alternatively activated macrophages, or T_H1 versus T_H2 T cells. A cytokine that might drive one type of inflammatory response (e.g., IFNγ for M1/T_H1) could be viewed as suppressive or anti-inflammatory in the contrasting context (M2/T_H2). "Inflammation" is a catch-all term that encompasses distinct immunological mechanisms geared toward protection against disparate pathogens (e.g., intracellular viruses versus multicellular parasites). It is, therefore, important when studying cytokine functions in disease pathology to consider the effects of the specific cytokine of interest especially as it relates to the overall immune response.

Cytokines provide the necessary signals for tailoring the inflammatory response for optimal protection against specific pathogens, through their signals meant to promote the differentiation and proliferation of specific leukocyte subsets, their ability to tailor the effector functions of activated leukocytes as needed to promote protective immunity, and their capacity to suppress inflammation following clearance of the pathogen, promoting tissue repair and a return to homeostasis.

Productive immune responses rely on the coordinated expression of specific cytokines from both innate and adaptive immunities; conversely, aberrant production of cytokines can lead to autoimmune disease, immunopathology, and hypersensitivity reactions. Understanding the molecular mechanisms underlying cytokine expression and cytokine receptor-mediated signal transduction and gene expression is central to the study of immunology and the continued search for better treatments and therapies for inflammatory disorders.

25.1 Introduction

While the term "chemokine" is coined from chemotactic cytokine, the chemokine superfamily is a group of mostly basic, heparin binding, 8–14 kDa secretory proteins, whose main functions are to induce directed migration (chemotaxis) in cells expressing their receptors [1–7]. Chemokines have four well-conserved cysteine residues and, based on the arrangement of the N-terminal two cysteine residues, they are further divided into CXC, CC, (X)C, and CX_3C subfamilies (X indicates other amino acids). The XC or C subfamily has only the second and fourth cysteines. Humans are now known to have at least 44 ligands (Table 25.1) and 24 receptors including 5 scavenger receptors (Table 25.2) [6–8]. All chemokine receptors belong to the family of seven-transmembrane G protein-coupled receptors (GPCRs), which represent the largest gene family in the human genome (~800) and react to a wide variety of external stimuli including light, taste, smell, peptide hormones, bioactive amines, lipid mediators, autacoids, and various chemoattractants including chemokines. The so-called "classical chemotactic factors," which were known before the discovery of chemokines such as formyl peptides (bacteria derived), C5a, and C3a (the complement cleavage products), prostaglandins and leukotrienes (the arachidonic metabolites), and platelet-activating factor (a phospholipid), also use this type of receptors [9,10]. Indeed, GPCRs are the universal receptor system employed by the cell for quick and transient responses to external stimuli. The unique characteristics of the chemokine system that are quite different from the conventional cytokines are likely to be closely related to the nature of the GPCR system.

Chemokines can be produced by a wide variety of tissue cells such as epithelial cells, endothelial cells, and stromal cells. Furthermore, leukocytes often produce chemokines that act on themselves, thus generating a feedforward loop for recruitment of the same types of leukocytes in inflammation [1–7]. Production of many chemokines is strongly induced by inflammatory stimuli. Such

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

Abbreviations: APC, antibody-producing cells; B, B cells; Bas, basophils; CLA, cutaneous lymphocyte antigen; DC, dendritic cells; En, endothelial cells; Eo, eosinophils; Ep, epithelial cells; iDC, immature dendritic cells; IEL, intraepithelial lymphocytes; HEV, high endothelial venule; Mac, macrophages; Mo, monocytes; Neu, neutrophils; mNeu, mouse neutrophils; NK, natural killer cells; NKT, natural killer T cells; Plt, platelets; RBC, red blood cells; SI, small intestine; SLO, secondary lymphoid organ; T_{CM}, central memory T cells; Th1, type 1 helper T cells; Treg, regulatory T cells.

chemokines usually attract neutrophils, monocytes, eosinophils, and effector lymphocytes and play important roles in acute or chronic inflammation. In addition, some chemokines are constitutively expressed by specific tissue cells and are involved in homeostatic migration of lymphocytes and dendritic cells. Yet some chemokines play important roles in organogenesis during the development [1–7]. Chemokines also contribute to cancer stroma formation and metastasis [11]. Moreover, certain chemokine receptors are known to directly contribute to the infection of human immunodeficiency virus (HIV) by acting as entry coreceptors [12]. Thus, the chemokine superfamily is involved in a wide range of biological phenomenon. In this chapter, we provide an overview of the chemokine superfamily with a particular focus on their role in the immune system.

25.2 Chemokine and Chemokine Receptor Nomenclature Systems

Concerning the chemokine receptor nomenclature, it was impractical to give a name based on its ligand because of the existence of multiple ligands for a single receptor. It was, however, noted that ligand chemokines of a receptor belong to the same subfamily. Therefore, in 1995, a method was adapted in which "R" was affixed to the ligand subfamily such as CXC and CC to indicate a receptor followed by a sequential number in the order of identification [2]. Similarly, the names of ligands were quite confusing particularly in the case of recently identified chemokines because of multiple names given to a single chemokine. Thus, in 1999, a similar nomenclature system was adopted in which "L" was affixed to the subfamily name to indicate a ligand and a sequential number [3]. However, the sequential numbers were not in the order of discovery but were the same numbers used by the gene symbols, which consist of SCY indicating small cytokine; A, B, C, or D indicating the subfamily; and a sequential number in the order of chromosomal gene mapping. As for the chemokines to be reported in the future, however, the sequential numbers will be in the order of discovery and those of gene symbols will be matched [3].

25.3 Extravasation of Leukocytes: The Multistep Model

Inflammation is a tissue reaction to accumulate fluid and leukocytes upon microbial infection or injury. Therefore, infiltration of leukocytes along with increased vascular permeability is a common sign of inflammation. Neutrophils are the main infiltrating cells in acute inflammation, while monocytes and lymphocytes represent the majority in chronic inflammation. In allergic inflammation, eosinophils and lymphocytes are the predominant cells. A combination of specific cell adhesion molecules and chemokines/chemokine receptors cooperatively promote tissue infiltration of select leukocytes [13,14]. The extravasation of leukocytes takes place in the postcapillary venules through several steps (Figure 25.1): (i) circulating leukocytes in the blood transiently stick to and

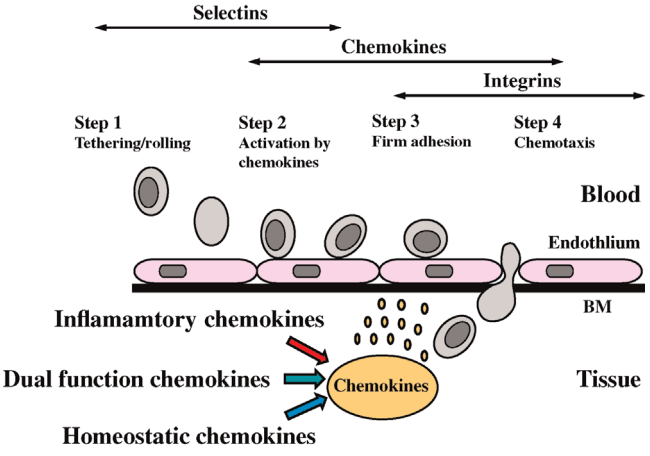

Figure 25.1 The multstep model of leukocyte extravasation.

slowly roll on the surface of endothelium through weak interactions involving selectins and selectin ligands or integrin VLA4 and its ligand VCAM-1 (tethering and rolling), (ii) if chemokines or other chemoattractants are produced and presented on the surface of endothelial cells, leukocytes expressing their receptors are activated and firmly bind to the endothelium by interactions between integrins (LFA-1 and Mac-1) and their ligands (inside-out signaling and firm adhesion), (iii) attached leukocytes further polarize their morphology and start crawling on the endothelial surface by ameboid movement (outside-in signaling, polarization, and diapedesis), and (iv) leukocytes extravasate mainly via paracellular route and sometimes via transcellular route penetrate the basement membrane and migrate within tissue by sensing gradients of chemotactic factors/chemokines. As the combinations of cell adhesion molecules and chemokines/chemokine receptors specify the kind of leukocytes to extravasate, the model is also referred to as the "address code model."

25.4 Inflammatory Chemokines and Homeostatic Chemokines

The field of chemokines started in 1987 when interleukin-8/CXCL8 was first discovered as a chemotactic factor for neutrophils. This was followed by reports in 1989, wherein monocyte chemotactic protein-1/CCL2 was described as a chemotactic factor for monocytes [15]. The comparison of these molecules quickly revealed that they form a family with some other secretory proteins of unknown function. Specifically, the four well-conserved cysteine residues served as a useful molecular signiture to identify the members of this family and new chemokines were rapidly identified among genes whose expression was strongly induced by inflammatory and other stimuli [1,4]. Subsequently, the chemokine paradigm was formed: (i) chemokines were divided into two subfamilies based on the motif

formed by the N-terminal two conserved cysteine residues: CXC (one other amino acid exists between the two cysteine residues) and CC (the two cysteine residues are adjacent), (ii) CXC chemokines mainly attract neutrophils and their genes are clusterd in chromosome 4 in humans, (iii) CC chemokines mainly attract monocytes and their genes are clustered in chromosome 17 in humans, and (iv) chemokines have highly promiscous ligand–receptor relationships: one ligand acts on multiple receptors and one receptor interacts with multiple ligands [1,4].

However, these chemokines could not sufficiently explain the immune cell migrations such as homeostatic recirculation of mature lymphocytes, migration of dendritic cells to regional lymph nodes upon antigen loading, and tissue infiltration of effector lymphocytes upon various immune responses. Therefore, the existence of chemokines that attract immune cells was postulated [16]. Meanwhile, the EST (expressed sequence tag) databases consisting of partial sequences of randomly assorted cDNAs were rapidly expanding and became publicly available. It thus became relatively easy to search for new members of a gene family using bioinformatics. Specifically, chemokines had advantages for this kind of search because of their small sizes and the molecular signiture of four conserved cysteine residues [3,4]. Thus, a new wave of chemokine discovery started around the mid-1990s with surprising revelations: (i) most of the newly discovered chemokines are expressed in some normal tissues (constitutive expression), (ii) most of them attract lymphocytes and dendritic cells (new target cells), (iii) their genes are mostly mapped to chromosomal sites different from the classical major chemokine clusters (evolutionarily distant), and (iv) they have relatively specific ligand–receptor relationships (low redundancy). Thus, an entirely new group of chemokines that are evolutionarily and functionally distinct from the previous chemokines emerged [3,4].

In this way, in addition to the classical CXC chemokine group that mainly acts on neutrophils and the CC chemokine group that mainly acts on monocytes, the new CXC and CC chemokine groups that mainly act on lymphocytes and dendritic cells, along with new molecular species of (X)C and CX_3C chemokines, have been identified (Table 25.1) [3,4,6]. Furthermore, since the entire sequence of the human genome has been determined, we now know almost all the members of the chemokine superfamily [6]. The classical chemokine groups are now referred to as "inflammatory chemokines," because (i) they are strongly induced by inflammatory stimuli, (ii) mainly attract neutrophils and monocytes, and (iii) play crucial roles in acute and chronic inflammatory reactions. On the other hand, the new groups of chemokines are often referred to as "homeostatic chemokines" since (i) they are constitutively expressed in some normal tissues, (ii) mainly attract lymphocytes and dendritic cells, and (iii) play essential role both in homeostasis of lymphoid tissues and in immune responses. However, in reality, many of the new chemokines are also strongly induced by various inflammatory and other stimuli and could have a role in acute and chronic inflammatory reactions. Thus, such chemokines are often referred to as "dual function chemokines" [6]. However, it should be noted that these classifications are not mutually exclusive and at most tentative.

Now, the question is why the inflammatory chemokines have such ligand redundancy and receptor promiscuity? This can be explained as follows. The ancestral chemokine genes in chromosomes 4 and 17 rapidly increased in number

by repeated gene duplications that occurred relatively recently in the evolutionary term. As a result, multiple ligands binding to a single receptor had been generated. However, the ancestral receptor genes also increased in number by repeated gene duplications. Thus, complex relationships involving multiple ligands and multiple receptors had been created and evolved [4,5]. However, even when multiple ligands act on a single receptor, the binding affinities and signaling functions may be different among the ligands. In addition, due to differences in expressing cells and tissues along with other molecular characteristics, each ligand can have a unique role in the body. Nevertheless, why did such large-scale gene duplication events involving the CXC and CC chemokines in chromosomes 4 and 17 occur in the evolution? This is probably related to the fact that these CXC and CC chemokines attract cells such as neutrophils, monocytes, and eosinophils in inflammatory reactions where it is necessary to rapidly recruit a large number of select leukocytes to a local inflammatory site in response to microbial infection or tissue injury. Therefore, concerted activities involving multiple chemokines and their receptors may be advantageous for such large scale reactions [4,5]. On the other hand, the chemokines that act on lymphocytes and dendritic cells are evolutionary older and their ligand–receptor relationships are more restricted [4,5]. This can be understood by the facts that the migration and homing of specific subsets of lymphocytes and dendritic cells in homeostasis and immune responses need to be tightly regulated. For example, migration of T cells to different target sites such as the secondary lymphoid organs, the gastrointestinal tract, and the skin are mostly determined by the combinatorial expression of specific adhesion molecules and specific chemokine receptors [3,4,6]. In other words, the expression of chemokine receptors specifies the migratory property of each T-cell subset and as such, chemokine receptors often serve as useful surface markers of various functional T-cell subsets (Table 25.3) [3,4,6].

Table 25.3 Chemokine receptor expression by T-cell subsets.

Subset	Major Chemokine Receptors
Naïve T cells	CCR7
Central memory T cells (T_{CM})	CCR7
Type 1 helper T cells (T_H1)	CXCR3, CCR5, and CXCR6
Type 2 helper T cells (T_H2)	CCR4 and CCR3
IL-17-producing T cells (T_H17)	CCR6 and CCR4
IL-22-producing T cells (T_H22)	CCR6
Regulatory T cells (T_{REG})	CCR4
Follicular helper T cells (T_{FH})	CXCR5
Gut-homing T cells ($\alpha4\beta7^+T$)	CCR6
Skin-homing T cells (CLA^+T)	CCR4 and CCR10
Small intestine T cells	CCR9
Skin resident T cells	CCR8
Cytotoxic effector T cells (T_{CT})	CX_3CR1

25.5 The Structure of Chemokines

The structures of many chemokines have been solved both by NMR and X-ray crystallography, revealing that all chemokines have a similar tertial structure that are stabilized by two disulfide binds formed between the first and third and the second and forth cysteine residues (Figure 25.2) [17,18]. The C chemokines have only one disulfide bond and is in equilibrium between a monomer chemokine structure and a dimer nonchemokine glycosaminoglycan (GAG)-binding structure [19]. Some chemokines such as CCL1, CCL15, CCL23, and CCL28 have two extra cysteine residues, one between the second and the third residues and another in the C-terminus, forming the third disulfide bond [17]. The N-terminal sequence prior to the two conserved cysteine residues exhibits a disorganized structure and is important for receptor activation [17,18]. The central part stabilized by the two disulfide bonds consists of a long N-terminal loop and three antiparallel β sheets connected by two short loops. A short loop connects the third β strand and the C-terminal sequence that forms an overlaying α-helix (Figure 25.2) [17,18]. Some chemokines such as CXCL9, CCL24, CCL16, CCL21, CCL25, and CCL28 have extra long C-terminal sequences, often highly basic, suggesting some biological functions [17]. The CXC chemokines with the Glu-Leu-Ag (ELR) motif prior to the first cysteine residue (CXCL1, CXCL2, CXCL3,

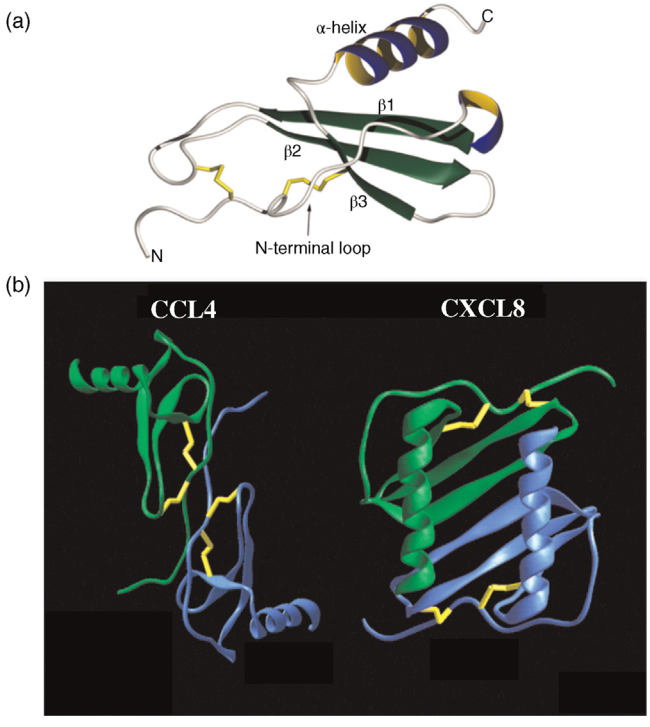

Figure 25.2 Ribbon diagrams of a typical chemokine monomer (a) and dimers (CCL4 and CXCL8) (b). The disulfide bonds are indicated by yellow. The monomer subunits in dimer are indicated by green and blue.

CXCL5, CXCL6, and CXCL7) that commonly signal via CXCR2 are also known to be antiogenic, while non-ELR CXC chemokines such as CXCL4, CXCL9, CXCL10, and CXCL11are angiostatic [20]. Many CXC and CC chemokines have a proline residue at the second position of their N-termini and can be cleaved between the second and the third resides by a membrane-associated serine protease CD26 (dipeptidyl peptidase IV), mostly resulting in impaired activity [17,21]. However, some chemokines are also capped with N-terminal pyroglutamate and thus resistant to the cleavage by CD26 [17].

In solution, chemokines are in equilibrium between monomers and dimers or even higher oligomers [18]. Monomers are the primary forms of receptor activation, while dimers are the form for GAG binding. The binding to GAG is also considered to promote the dimer formation of chemokines [18]. A BBXB (B, basic) motif, a common heparin-binding motif for several proteins, is also found in many CC chemokines close to the fourth cysteine residue [17] and has been shown to be the principal heparin-binding site of CCL5 [22]. The basic residues involved in GAG-binding has also been shown to be aligned in proximity on the dimer interface of CCL3 and CCL4 [23,24]. Similarly, positively charged residues are aligned at the dimer interface of CXCL12 and involved in the binding of heparan sulfate [25]. The binding to GAGs is considered to be important for locally sequestering chemokines on cell surfaces and tissues to establish immobilized chemokine gradients for haptotactic cell migration [26]. Importantly, however, dimers of CXC and CC chemokine subfamilies have distinct quaternary conformations (Figure 25.2) [17,18]. CXC chemokines tend to dimerize into a more globular structure with the interface made up of residues largely from the first β-strand. On the other hand, CC chemokines associate into a relatively elongated structure with the subunit interface composed of residues from part of the extended N-terminus [17,18]. Thus, CXC chemokines have many residues involved in receptor binding still on the surface of the protein, while CC chemokines bury such residues within the dimer interface. Consistently, a covalent CXCL8 dimer is still able to bind CXCR1 and CXCR2, albeit with lower affinity than the wild-type protein [27]. Similarly, CXCL12 monomer and dimer both induce intracellular Ca^{2+} mobilization but only monomeric CXCL12 efficiently induces chemotactic cell migration [28]. In contrast, CCL4 dimer is unable to bind or activate its receptor [29].

In the case of two transmembrane-type chemokines CX3CL1 and CXCL16, an N-terminal chemokine domain is connected to a muchin-like stalk with a transmembrane α-helix and a short cytoplasmic tail [17,30]. Thus, these chemokines are primarily membrane associated and function as a soluble chemokine upon cleavage at membrane proximal sites by disintegrin and metalloproteinases ADAM10 and ADAM17 [21]. By the membrane-bound form, CX3CL1 acts as an efficient signal-independent cell adhesion molecule under flow conditions [31,32], while CXCL16 may also act both as a cell adhesion molecule and as a scavenger receptor for oxidized LDL [30]. Of note, monocytes are divided into two major subtypes: $CX3CR1^{low}$ classical monocytes ($CD14^{+}CD16^{-}$ in humans and $Ly6C^{+}CD43^{-}$ in mouse) and $CX3CR1^{high}$ nonclassical monocytes ($CD14^{dim}CD16^{+}$ in humans and $Ly6C^{-}CD43^{+}$ in mouse) [33]. The $CX3CR1^{high}$ nonclassical monocytes are characterized by their unique ability to patrol the

vascular endothelium independent of the direction of blood flow (~12 μm/min) under homeostatic and inflammatory conditions [33]. The adhesive property of the CX3CL1-CX3CR1 axis appears to play a role in this patrolling behavior of nonclassical monocytes [33].

25.6 Chemokine Receptors

All chemokine receptors are seven-transmembrane-type receptors and form a subgroup within the class A rhodopsin-like family of GPCRs [1–7]. Their structures consist of a relatively long N-terminal extracellular domain enriched with acidic amino acids and tyrosine-sulfated, the relatively well-conserved seven-transmembrane α-helices that are connected by three intracellular loops (ICL1-3) and three extracellular loops (ECL1-3), and a C-terminal cytoplasmic region forming α-helix and enriched with serine and threonine residues (Figure 25.3). The receptors are also divided into CC, CXC, (X)C, and CX3C subfamilies based on the subfamily of their ligands (Table 25.2). At present, 19 receptors are known that mediate chemotactic and calcium flux responses in responding cells [6–8]. They are commonly coupled with pertussis toxin-sensitive $G\alpha_i$-type trimeric G proteins. Moreover, five atypical chemokine receptors (ACKRs) that do not signal via trimeric G proteins have been identified [6,7]. Their primary functions

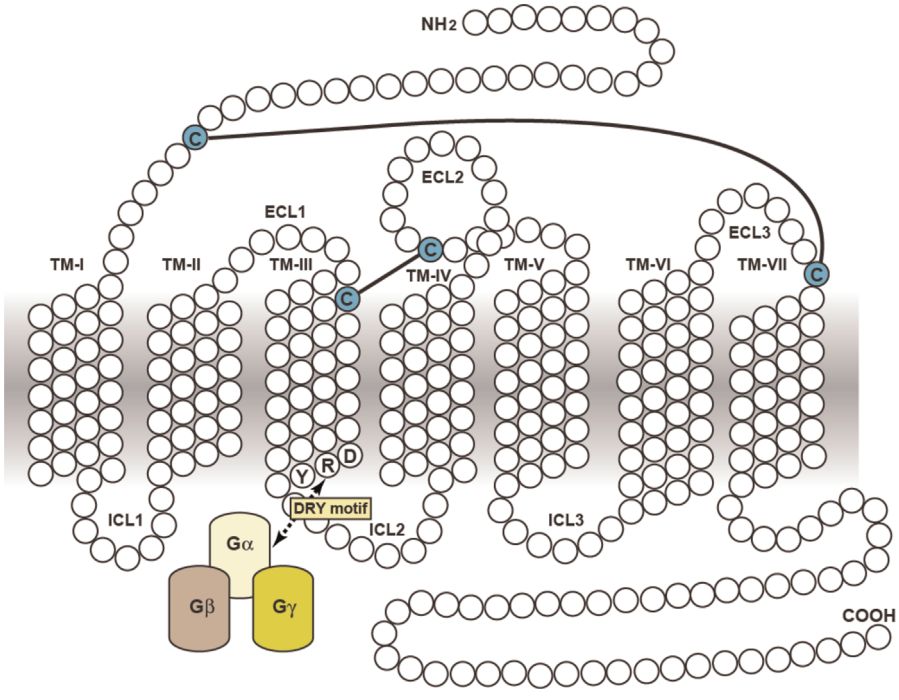

Figure 25.3 A schematic depiction of a typical chemokine receptor. Abbreviations: DRY, aspartic acid–arginine–tyrosine; ECL, extracellular loop; ICL, intracellular loop; TM, transmembrane.

are to scavenge chemokines. Similar to the case of ligands, there exists a large gene cluster consisting of mainly CC chemokine receptors on chromosome 3 in humans [5].

Most GPCRs are known to form homodimers or heterodimers, and the chemokine receptors are no exceptions [34]. The formation of homodimers or even heterodimers with other chemokine receptors or even with different GPCRs adds a new dimension to the complex regulatory mechanisms of the chemokine receptor system through mechanisms such as changes in ligand-binding affinity due to allosteric effects, changes in signal transduction efficiency due to competition for G proteins, and passive internalization by ligand binding to the partner receptor [34]. Furthermore, chemokine receptors may associate with membrane molecules other than GPCRs. The best studied examples are the association of CCR5 and CXCR4 with CD4, which explains why CCR5 and CXCR4 are preferentially used as the major coreceptors of HIV along with the primary receptor CD4 for target cell infection [35,36]. In particular, CCR5 is strongly expressed by activated T cells, intestinal T cells, and monocytes/macrophages, the major target cells of HIVs, and constitutively associated with CD4 with a stoichiometry of 5 to 1 [36]. In addition, the affinity of CCR5 to HIV-1 gp120 is much higher than that of CXCR4 (Kd: <10 nM versus 200–500 nM) [35]. These facts explain why R5-type strains using CCR5 are initially dominant in HIV-infected patients, while the X4-type strains using CXCR4 appear only at the terminal stages of the disease when $CD4^+$ T cells are almost depleted [12].

25.7 The Two-step Model of Chemokine Receptor Activation

Chemokines activate their receptors through a two-step binding process [18,34,37]. First, the structurally rigid central part of a chemokine docks on a chemokine recognition site 1 (CRS1) of its receptor mainly formed by the free N-terminus and ECL2, the longest extracellular loop forming a β-hairpin structure. Since chemokines are generally rich with basic amino acids and thus highly cationic, the electrostatic interactions are considered to play the major role in high-affinity binding. In particular, the N-terminal-free structures of chemokine receptors, which are rich with acidic amino acids and are also tyrosine sulfated, are likely to be involved in initial trapping of positively charged chemokine molecules. Subsequently, if the flexible N-terminal short sequence of a chemokine fits into the binding pocket buried in the cavity formed by the outer parts of the seven-transmembrane helices (CRS2), the interactions cause a drastic conformational change in the receptor, thereby resulting in its activation [18,34,37]. Thus, the N-terminal short amino acid sequence of a chemokine is crucial for receptor activation and can be regarded as a functional mimic of a conventional GPCR ligand, which is usually a small molecule. Accordingly, proteolytic processing of the N-terminal sequence of a chemokine can drastically alter its activity, often from an agonist to an antagonist, without changing its binding affinity to the receptor [21]. Conversly, N-terminal peptides of a chemokine may act as agonists

or antagonists, albeit with low potency [38]. It also explains why some chemokines act as natural antagonists (Tables 25.1 and 25.2); a chemokine may bind to CRS1 of a receptor with high affinity without fitting to its CRS2. For example, CXCL9, CXCL10, and CXCL11 (the CXCR3 ligands) function as antagonists to CCR3, while CCL11 (the CCR3 ligand) behaves as an antagonist to CXCR3 [39]. Given that CXCR3 is mainly expressed by Th1 cells while CCR3 is expressed by eosinophils, basophils, and some Th2 cells, the mutual antagonism may further polarize immune responses. Furthermore, some chemokines such as CCL14, CCL15, CCL16, and CCL23, often present at high concentrations in the blood, have a relatively long N-terminus compared to those of other chemokines and become a potent antagonist only after the N-terminal sequences are processed by proteases such as neutrophil-derived catepsins at inflammatory sites [6]. Thus, these "plasma chemokines" can be regarded as the precursor-type chemokines [6].

25.8 Signal Transduction

The mechanism of signal transduction by chemokine receptors follows the general rule of GPCR activation (Figure 25.4) [9,40]. When a chemokine binds to its receptor, GDP bound to the α-subunit of trimeric G proteins (consisting of the three subunits of α, β, and γ) coupled to the receptor is exchanged for GTP (the GDP–GTP exchange reaction). Thus, the ligand-activated receptor functions as a GDP–GTP exchange factor (GEF). This results in release of the trimeric G proteins from the receptor and dissociation of the α-subunit and the βγ-subunit.

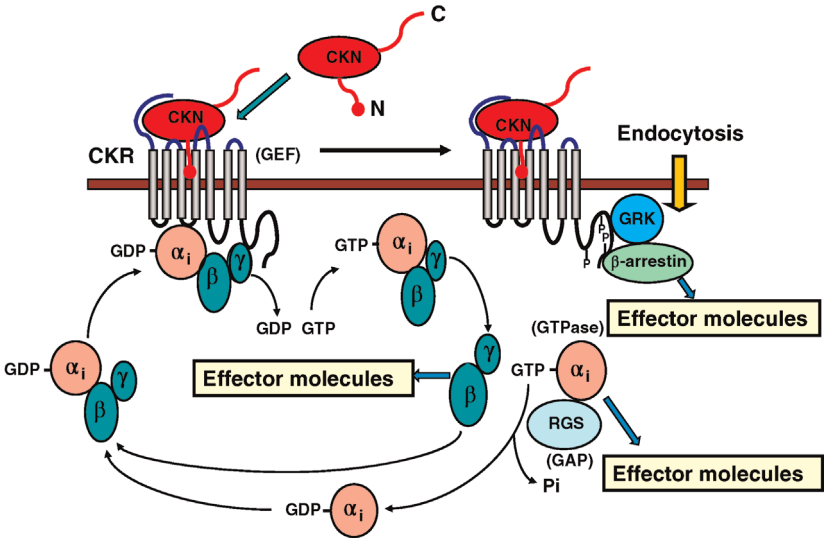

Figure 25.4 The activation cycle of GPCR. Abbreviations: CKN, chemokine; CKR, chemokine receptor; GAP, GTPase activation protein; GEF, GDP-GTP exchange factor; GRK, G protein-coupled receptor kinase; RGS, regulator of G protein signaling.

The dissociated subunits have been shown to activate various downstream effector molecules. However, because the α-subunit has its own GTPase activity, the bound GTP is quickly converted to GDP, thereby the α-subunit and βγ subunits reassociate and signal transduction stops. The GTPase activity of α-subunits is also regulated by a group of proteins referred to as regulators of G protein signaling (RGS), which can be regarded as GTPase-activating proteins (GAPs). Thus, a GPCR can function as a quick molecular on–off switch in response to its ligand. Moreover, ligand-bound chemokine receptors are quickly phosphorylated at the serine/threonine residues in the C-terminus by G protein-coupled receptor kinases (GRKs). This results in association of β-arrestins with the C-terminus and internalization of chemokine receptors into the cells by endocytosis. Internalized receptors may be degraded in the lysosomes or recycled back to the cell surface after releasing bound ligands under endosomal low pH conditions. As for the downstream signaling pathways, activation of molecules such as phosphoinositide 3-kinase γ (PI3 kinase γ), phospholipase C, protein kinase C, Mitogen-activated kinase (MAP) pathways, and small G proteins Rac-1 and Rap-1 have been reported [9,40,41].

25.9 Atypical Chemokine Receptors

There are five atypical chemokine receptors (ACKRs) [6,7,42]. While they have the seven-transmembrane structures similar to the standard chemokine receptors, they do not transduce signals via the trimeric G proteins. This is because the Asp-Arg-Tyr (DRY) motif (typically DRYLAIV) that is present in ICL2 of the standard chemokine receptors and is necessary for efficient coupling with the Gαi class G proteins is missing or substantially altered. However, the signaling via β-arrestins may still occur. It is now known that ACKRs play essential roles in the chemokine biology primarily by acting as chemokine scavengers [6,7,42].

ACKR1/DARC is expressed by erythrocytes and binds many inflammatory CXC and CC chemokines. It is thus considered that ACKR1 regulates chemokine concentrations in the blood by functioning as a chemokine sink. Moreover, ACKR1 is expressed by venular endothelial cells and transports chemokines from tissues to the vascular surface by transcytosis [7,43]. ACKR2/D6 also binds many inflammatory CC chemokines and continuously recycles between the cell surface and the cytoplasm, while internalized chemokines are dislodged from the receptor by low pH in endosomes and destroyed in lysosomes. ACKR2 is strongly expressed by lymphatic endothelial cells and functions as a chemokine scavenger receptor for lymphatic fluids, thereby suppressing unnecessary inflammatory reactions within the lymphatic vessels [7,42]. ACKR3/CXCR7 is a chemokine scavenger receptor of great interest in both development and disease [44]. Along with CXCL12 and CXCR4, ACKR3 is one of the oldest and highly conserved members of the chemokine superfamily in vertebrates [5]. ACKR3 binds CXCL11 and CXCL12 [6,7]. In particular, ACKR3 is closely involved in some developmental processes that are controlled by the CXCL12-CXCR4 axis (see below). Moreover, ACKR3 is often expressed by tumor cells and tumor vessels and promotes tumor cell growth and angiogenesis by activating MAPK cascades and

other signaling pathways [44,45]. ACKR4/CCRL1 binds CCL19 (a CCR7 ligand) and is likely to modulate the function of the CCR7 axis, which plays an essential role in homeostatic migration of lymphocytes and dendritic cells. Similarly, ACKR5/CCRL2 binds CCL19 and CCL21 (the CCR7 ligands) as well as CCL25 (the CCR9 ligand). Thus, it may modulate the functions of not only the axis of CCR7 but also that of CCR9, which is involved in mucosal immunity [7,42].

25.10 Organ Development and Chemokines

CXCL12, CXCR4, and ACKR3 are the oldest members of the chemokine superfamily, being present even in the jawless fish sea lamprey [5]. From the analyses of the respective KO mice, it has been revealed that CXCL12 and CXCR4 are critically involved in various developmental processes during the fetus such as B lymphopoiesis in the liver, colonization of hematopoietic stem cells in the bone marrow, vascularization of the gastrointestinal tract, formation of the cardiac ventricular septal, and migration of granule cells in the cerebellum and interneurons in the neocortex [46]. Ventricular septal defects are also observed in ACKR3 KO mice [47]. This is probably due to the necessity of ACKR3 for modulating the CXCL12-CXCR4 axis both by scavenging excess CXCL12 and by promoting internalization of CXCR4 through heterodimer formation. Among others, ACKR3 also plays an important role in the migration of embryonic primordial germ cells to the future gonads [48,49]. In this case, ACKR3 expressed by somatic cells along the migratory pathway scavenges CXCL12 in the rear side to maintain the CXCL12 gradient, thereby enabling the primordial germ cells to proceed [48,49]. ACKR3 is also involved in the formation of lateral lines in fish, which comprise the mechanosensory system to perceive the water flow [50]. In this case, the precursor cells migrate as a single mass along the lateral lines during the process of neuromast formation. Migrating cells at the front express CXCR4 and proceed toward CXCL12, while cells in the rear stop migration by upregulating ACKR3 and form neuromasts [50].

25.11 The Primary Lymphoid Organs and Chemokines

The CXCL12-CXCR4 axis that plays crucial roles in the fetal hematopoiesis remains to be involved in bone marrow functions thereafter. For example, the CXCL12-abundant reticular (CAR) cells form the niche in which hematopoietic stem cells and other hematological cells adhere, grow, and differentiate [51]. In addition, the CXCL12–CXCR4 interactions are necessary for retention of immature hematological cells in the bone marrow. Evidence is also provided by a “nature’s experiment” WHIM (warts, hypogammaglobulinemia, infections, and myelokathexis) syndrome, an autosomal dominant immunodeficiency disease caused by mutations in the CXCR4 gene resulting in C-terminal truncations, which is characterized by enhanced bone marrow retention of mature hematological cells and peripheral pancytopenia [52]. The mutations cause truncations of

the C-terminal region of CXCR4, leading to enhanced CXCR4 activity due to impaired ligand-induced internalization and desensitization. In the same vein, AMD3100 (plerixafor), a low molecular weight antagonist of CXCR4, has been clinically approved for mobilization of hematopoietic stem cells from the bone marrow in order to perform autotransplantation in patients with non-Hodgkin lymphomas and multiple myeloma [7]. Conversely, aged neutrophils in the peripheral blood return to the bone marrow for destruction via upregulating CXCR4 [53].

In the case of T cell development, thymic precursor cells released from the bone marrow home to the thymus primarily via CCR7 and CCR9, while medullary epithelial cells produce CCL19/CCL21 (the CCR7 ligands) and CCL25 (the CCR9 ligand) [54,55]. CCR7 is also involved in medullary entry of positively selected single-positive thymocytes from cortex [55,56], while CCR4 facilitates negative selection in the medulla where medullary dendritic cells produce CCL17 and CCL22 (the CCR4 ligands) [57]. After positive and negative selections, mature thymocytes increase the surface expression of sphingosine-1-phosphate receptor type 1 ($S1P_1$) and leave the thymus by sphingosine-1-phosphate (S1P), which is present at high concentrations in the peripheral blood [58].

25.12 The Secondary Lymphoid Organs and Chemokines

The secondary lymphoid organs (SLOs) such as regional lymph nodes, spleen, and Peyer's patches in the small intestine have common histological characteristics: (i)high endothelial venules (HEVs) functioning as the gateway for lymphocytes to enter from the bloodstream (note that HEVs do not exist in the spleen; instead, sinusoids, which exist in the marginal zone between the red pulp and the white pulp, function as the gates), (ii) the specialized T-cell area (paracortex) and B-cell areas (follicles), (iii) the backbone network structures formed by fibroblastic reticular cells in the T-cell area where dendritic cells and macrophages are positioned as well as the distinct network structures formed by follicular dendritic cells in the B-cell areas, (iv) afferent lymphatics by which antigen-loaded dendritic cells flow in from peripheral tissues (note that these do not exist in the spleen or Peyer's patches), and (v) efferent lymphatics by which lymphocytes flow out of the SLOs [59,60]. Mature T and B cells continuously recirculate between the blood and the SLOs [16,59]. On the other hand, dendritic cells distributed in the peripheral tissues initiate maturation upon antigen loading and home to the T-cell areas of regional lymph nodes via afferent lymphatics, where they function as professional antigen-presenting cells that efficiently activate naïve T cells [4,61]. Thus, SLOs serve as the crossroads for circulating lymphocytes and antigen-presenting dendritic cells.

Naïve T cells express CD28 and CD40L, while mature dendritic cells express their respective ligands CD80/CD86 and CD40. In addition to the T-cell receptor (TCR) signals, naïve T cells require the costimulatory signals via CD28 and CD40L for full activation, making their activation dependent on mature dendritic cells functioning as professional antigen-presenting cells in the SLOs [62]. On the other hand, the activation of effector/memory T cells is less dependent on the

costimulatory signals, which enables their activation in tissues other than SLOs. Therefore, their migratory routes include peripheral tissues such as the skin and mucosa, where they are more likely to encounter their cognate antigens [62]. In the case of B cells, immature B cells are released from the bone marrow and migrate into the white pulp of the spleen where most B cells are short-lived and only a portion of B cells form primary follicles to become a pool of circulating long-lived mature naïve B cells [63]. Circulating naïve B cells also enter the SLOs via HEVs. Upon antigenic stimulation within SLOs, B cells grow and differentiate within extrafollicular areas to become short-lived plasma cells, which localize in the medullary areas of the SLOs and produce low-affinity IgM antibodies, or migrate to the B-cell areas where they form germinal centers, undergo somatic hypermutation and affinity maturation, and differentiate into long-lived plasma cells that produce high-affinity IgG or IgA antibodies [64]. These plasma cells home to the bone marrow or submucosal tissues via the blood flow. To form germinal centers, costimulatory signals through the interaction between CD40 expressed by B cells and CD40 L expressed by activated T cells are necessary [64]. Moreover, follicular dendritic cells in the germinal centers retain and present immune complexes by Fc receptors and complement receptors, thereby enhancing the selection of B cells producing high-affinity antibodies [64]. On the other hand, B cells that undergo apoptosis in the germinal centers produce CX3CL1 as an "eat me" signal and are removed by macrophages expressing its receptor CX3CR1 [65].

After homing to the SLOs, T cells migrate on the network structure formed by fibroblastic reticular cells with a fast ameboid movement and repeatedly make brief contacts with dendritic cells on the network [66,67]. If the TCRs recognize cognate antigen peptides presented by dendritic cells in association with the MHC molecules, T cells stop migration and firmly adhere to the dendritic cells. This lasts from several minutes to hours and results in the activation of T cells [66,67]. On the other hand, T cells that fail to encounter antigenic peptides upregulate their surface expression of $S1P_1$ and leave the SLOs via efferent lymphatics where the concentration of its ligand S1P in the lymphatic fluid is high [58]. The time from entering to leaving the SLOs is approximately 6–24 h [66,67].

The combined expression of L-selectin and CCR7 endows circulating T cells and B cells to home into SLOs via HEVs [4]. On the other hand, immature dendritic cells express various receptors for inflammatory chemokines, which supports their migration from the bone marrow to various peripheral tissues via the blood [4]. In particular, immature dendritic cells express CCR6, while epidermal keratinocytes and mucosal epithelial cells produce its ligand CCL20 [4]. Upon antigen loading, dendritic cells start maturation and increases the expression of CCR7, while decreasing other chemokine receptors including CCR6, thus enabling their emigration via afferent lymphatics where endothelial cells constitutively express its ligand CCL21 [4,68]. In the T-cell areas of SLOs, mature dendritic cells produce CCL19 (another CCR7 ligand) to facilitate their interactions with CCR7-expressing naïve T cells and central memory T cells [4,68]. Interestingly, CCL19 and CCL21 that similarly act on CCR7 in terms of chemotaxis induction *in vitro* play different roles *in vivo* [68]. Only CCL21 is

abundantly produced by the afferent lymphatic endothelium. The endothelial cells of HEVs also constitutively produce CCL21, while CCL19 produced by dendritic cells and stroma cells in the SLOs can be presented by HEVs through transcytosis. CCL21 also possesses a positively charged 40 amino acid long C-terminus that enables its strong binding to GAGs. On the other hand, only CCL19 efficiently induces internalization and desensitization of CCR7. Therefore, T cells and B cells home to the SLOs primarily via CCL21. Within the SLOs, CCL19 produced by dendritic cells can override CCL21-mediated migration and eventually downregulates the expression of CCR7, allowing T cells to be localized in the T-cell areas [68]. Dowregulation of CCR7 is also necessary for B cells to redirect their migration to the B-cell areas where follicular dendritic cells produce CXCL13, while B cells express its receptor CXCR5 [4,69]. Follicular B helper T (T_{FH}) cells that both provide costimulatory signals via CD40L and ICOS for B-cell activation and produce IL-21 to promote B-cell differentiation into antibody-producing cells also express CXCR5 to be localized in the B-cell areas and produce CXCL13 to attract B cells [4,69].

25.13 Memory/effector T Cells and Chemokine Receptors

Memory/effector T cells are divided into two major subpopulations according to the surface phenotypes of L-selectin$^+$CCR7$^+$ and L-selectin$^-$CCR7$^-$. The former represents central memory T cells (T_{CM}), which, like naïve T cells, home to the SLOs and efficiently activate dendritic cells but are slow to exert effector functions. The latter represents effector memory T cells (T_{EM}), which migrate to peripheral tissues and quickly exert effector functions [4,70]. Furthermore, memory/effector T cells are subdivided into several functional subsets based on their cytokine signature [4,71]. This is because activated naïve T cells differentiate into each functional subset in accordance with the cytokine milieu during their differentiation (cytokine imprinting). Th1 cells that produce IL-2 and IFN-γ are involved in cell-mediated immunity and granuloma formation. IL-12 promotes Th1 differentiation by inducing T-bet, the Th1 master regulator transcription factor [72]. Th1 cells thus induced express CXCR3 as one of the downstream target genes of T-bet, while IFN-γ is a potent inducer of CXCL9, CXCL10, and CXCL11 (the CXCR3 ligands) [4], thereby amplifying Th1 responses by further recruiting Th1 cells expressing CXCR3. Th1 cells may also express other chemokine receptors such as CCR5 and CXCR6 [4]. Th2 cells produce IL-4, IL-5, IL-13, and so on and are involved in humoral immunity and allergic reactions. IL-4 promotes Th2 differentiation by inducing the Th2 master regulator transcription factor GATA-3 [72]. Th2 cells predominantly express CCR4, while Th2 cytokines such as IL-4 and IL-13 are potent inducers of CCL17 and CCL22 (the CCR4 ligands) in various cells [4], thereby amplifying the Th2 responses by further recruiting Th2 cells expressing CCR4. Th2 cells may also express receptors such as CCR3 and CRTH2, a G protein-coupled receptor for prostaglandin D_2 [4,71]. Th17 cells produce IL-17 and IL-22 and are involved both in immune responses toward extracellular pathogens and in various autoimmune diseases. The combination of IL-6 and TGF-β promotes Th17

differentiation by inducing the expression of RORγt, the Th17 master regulator transcription factor [71]. While Th17 cells express CCR6 as one of the downstream target genes of RORγt, IL-17 induces the production of CCL20 (the CCR6 ligand) in various cells [73], thereby amplifying Th17 responses by further recruiting Th17 cells expressing CCR6. Th17 cells may also express chemokine receptors such as CCR4. T_{FH} cells are localized in the B-cell areas of SLOs and produce CXCL13 (the CXCR5 ligand) along with IL-21, thereby both attracting B cells expressing CXCR5 and promoting their differentiation into antibody-producing cells by IL-21 [74]. Treg cells are important for immunosuppression and express FOXP3, the master regulator transcription factor of Treg [75]. While natural Treg cells are generated in the thymus, the combination of TGF-β and IL-2 promotes differentiation of Treg cells in the periphery by inducing FOXP3 [75]. Treg cells predominantly express CCR4 and are recruited by CCL17/CCL22 produced by cells such as dendritic cells and tumor cells [76]. Treg cells may also express other chemokine receptors such as CCR5 and CXCR3 to regulate a wide range of immune responses by colocalizing with diverse effector T cells. Similarly, effector $CD8^+$ T cells and natural killer cells express a wide range of chemokine receptors such as CCR2, CCR5, CXCR3, CXCR1, and CX3CR1 in accordance with their differentiation and activation states [77,78].

25.14 Mucosal Immunity and Chemokines

Mucosal tissues form the boundary between the inside and the outside of the body. For instance, the small intestine is covered with a monolayer of columnar epithelial cells, with a surface area of 200–300 m^2 in adults. Thus, the mucosal immunity is vital for the host defense. The intestinal immune system is composed of organized lymphoid tissues and free lymphoid cells. The former includes Peyer's patches and isolated lymphoid follicles, while the latter consists of IgA-producing plasma cells, effector T cells, and intraepithelial T cells. The organized lymphoid tissues are the inductive sites of the immune response. On the other hand, free lymphoid cells constitute effector cell populations in intestinal immunity [4]. In particular, Peyer's patches are covered by follicle-associated epithelium (FAE) where specialized cells referred to as microfold cells (M cells) exist. While FAE epithelial cells produce CCL20 and recruit dendritic cells expressing its receptor CCR6 underneath the FAE, M cells actively take up intestinal antigens and pathogens (antigen sampling) and transport them to underneath dendritic cells and macrophages [4]. In addition, intestinal epithelial cells express CX3CL1, while subepithelial dendritic cells extend their cellular processes through the epithelial cells by expressing its receptor CX3CR1, thereby directly sampling antigens in the lumen [79].

T cells that home to Peyer's patches express α4β7 integrin and L-selectin, while the HEVs of Peyer's patches express their common ligand MAdCAM-1 [80]. Once T cells are activated by antigenic stimuli in Peyer's patches, they start differentiation and migrate to the mesenteric lymph nodes via efferent lymphatics. After returning to the blood, most of these cells redistribute to the lamina propria of the intestinal mucosa to become effector cells [80]. Moreover,

intraepithelial lymphocytes (IELs) exist within the intestinal mucosa with a frequency of one to every three to five epithelial cells. IELs are locally generated from the precursor cells present in the intestinal mucosa and express αEβ7 integrin, while epithelial cells express its ligand E-cadherin [4,81]. Intestinal epithelial cells also express CX3CL1, while IELs express its receptor CX3CR1 [4].

The epithelial cells of the small intestine produce CCL25 at high levels, while $\alpha4\beta7^{+}$gut-homing T cells in the blood express its receptor CCR9 [4,80]. Moreover, effector T cells, IgA-producing B cells, and IELs present in the small intestine express CCR9 [4,80]. Thus, the CCL25–CCR9 axis plays a pivotal role in localization of immune cells in the small intestine. In this context, dendritic cells present in the mesenteric lymph nodes produce retinoic acid, the metabolite of vitamin A, which is a potent inducer of α4β7 integrin and CCR9 expression in activated T cells [82]. Thus, gut-associated dendritic cells are able to imprint gut tropism to activated T cells.

In contrast to CCL25 production by the small intestine, other mucosal tissues in the body such as the large intestine, airway mucosa, salivary glands, and lactating mammary glands produce CCL28 at high levels, while its receptor CCR10 is widely expressed by mucosal IgA-producing B cells [83,84]. Therefore, the CCL28–CCR10 axis is considered to play an important role in the pan-mucosal immune system by redistributing locally generated IgA-producing B cells throughout the body. Moreover, CCL28 is secreted in the mucosal fluids and exerts a strong antimicrobial activity [85]. In fact, a number of chemokines have been shown to possess a significant antimicrobial activity [86]. The mechanism of how chemokines carry out antimicrobial action is not clear at present but may be related to the molecular features similar to classical antimicrobial peptides, the natural antibiotics in multicellular organisms, such as disulfide bridges, high canionic amino acid contents, and amphipathic stretches [86].

25.15 Skin Immunity and Chemokines

Like the mucosal tissues, the skin functions as an interface between the inside and the outside of the body. In the case of skin, however, the keratinized stratified squamous epithelium provides a strong physical barrier. While no organized lymphoid tissues are present in the skin, there exist large numbers of epidermal and dermal dendritic cells, which upon activation by antigen-loading upregulate the expression of CCR7 and home to regional lymph nodes via afferent lymphatics to become professional antigen-presenting cells in the T cell area [4,68]. Epidermal dendritic cells are specifically referred to as Langerhans cells, which express CCR6 and are considered to be recruited to the epidermis by CCL20 produced by epidermal keratinocytes [4]. The CCL1–CCR8 axis may also regulate the localization of dendritic cells in the skin [87]. On the other hand, cutaneous lymphocyte antigen (CLA)-positive skin-homing memory/effector T cells present in human peripheral blood express CCR4, while the CCR4 ligands CCL17 and CCL22 are produced in inflamed skin by microvascular endothelial cells and epidermal dendritic cells, respectively [4,88]. Thus, skin-homing memory/effector T cells extravasate into inflamed skin by the guidance of CCL17 and further

migrate within the dermis by the guidance of CCL22. This is possible because, although both CCL17 and CCL22 similarly induce chemotaxis via CCR4 *in vitro*, only CCL22 efficiently induces internalization and desensitization of CCR4 [88]. Thus, CCR4-expressing T cells can migrate into and within the skin by responding to CCL17 and CCL22 sequentially. Furthermore, CLA-positive skin-homing memory/effector T cells express CCR10, while epidermal keratinocytes produce CCL27 (a CCR10 ligand) [4,89]. Therefore, after CCR4, CCR10 may take over the migration of T cells toward the epidermis by the guidance of CCL27. In parallel to retinoic acid in the gut, vitamin D_3 is produced in the skin epidermis from 7-dehydrocholesterol by the action of ultraviolet B radiation and converted into the active form 1, 25-$(OH)_2$-vitamin D_3 by dermal dendritic cells. 1, 25-$(OH)_2$-vitamin D_3 induces the expression of CCR10 and suppresses the expression of α4β7 integrin and CCR9 in activated T cells [90]. This suppression of α4β7 integrin expression by 1, 25-$(OH)_2$-vitamin D_3 explains why CCR10-expressing T cells are unable to home to the mucosal tissues where CCL28, another CCR10 ligand, is highly expressed. In addition, the vast majority of T cells present in the normal human skin express CCR8, while subcutaneous microvascular endothelium and epidermal dendritic cells produce its ligand CCL1 [91]. CXCL14 is also produced in the skin by keratinocytes, macrophages, and mast cells and exhibits a potent antimicrobial activity against various microbes [92]. Like CXCL12, CXCL14 is a chemokine highly conserved among the vertebrate species. No major abnormalities are, however, observed in CXCL14-deficient mice and its receptor has not yet been identified [93]. Of note, the N-terminal sequence of CXCL14 prior to the first cysteine residue consists of only two amino acids (Ser-Lys), which may be too short to activate a GPCR receptor [17].

25.16 Clinical Applications

The chemokine superfamily plays important roles in both innate and acquired immunity by inducing tissue infiltration of select leukocytes [1–7]. However, tissue accumulation of leukocytes is a "double-edged sword" and could be a cause of disease. Therefore, drugs targeting the chemokine superfamily are expected to be therapeutically useful for diseases involving excess inflammatory reactions. Furthermore, given that many successful drugs in use are known to target GPCRs, the chemokine receptors are considered to be highly promising molecular targets for drug development. Moreover, since hematological tumors are derived from leukocytes at particular stages of differentiation, the expression patterns of chemokine receptors often reflect both their cellular origins and their preferred sites of invasion. Thus, the chemokine receptors are also expected to provide excellent target molecules for diagnosis and treatment of hematological tumors. In addition, chemokines are involved in various clinically important problems such as cancer growth and metastasis, angiogenesis, and HIV infection [11,12].

Despite such promising features, however, the list of successful drugs targeting chemokine receptors still remains small [7,94]. At present, only three drugs are clinically approved: an orally available CCR5 inhibitor maraviroc as an entry

inhibitor of R5 type HIV-1, a low molecule CXCR4 inhibitor AMD3100 (plerixafor) as a mobilizer of hematopoietic stem cells from the bone marrow for stem cell autotransplantation, and a defucosylated humanized anti-CCR4 antibody (mogamulizumab) developed in Japan for the treatment of CCR4-expressing adult T-cell leukemia/lymphoma and peripheral T-cell lymphoma [7,88]. The unexpected difficulties in the development of drugs targeting chemokine receptors may be explained by reasons such as the intrinsic redundancy of the chemokine system and mainly charge-driven and less conformation-driven interactions of chemokines and chemokine receptors in the first step of the two-step receptor activation. Other reasons may include the considerable species differences in the chemokine system even between humans and mice, making it often difficult to use the same compounds in animal studies or to directly translate results from animal studies to human diseases. However, the recent progress in the elucidation of crystal structures of GPCRs including chemokine receptors will now open new possibilities for rational design of drugs having improved inhibitory profiles and mechanisms of action [95–97].

Meanwhile, the chemokines are also expected to be useful biomarkers of various disease conditions due to their excessive production by some tissue cells in the event of inflammation and immune responses. For instance, the blood concentrations of CCL17 and CCL22 are highly elevated and serve as sensitive markers of disease activity in patients with atopic dermatitis [88]. This has led to the approval of a CCL17 measurement kit (Alaport TARC) in Japan to monitor the disease activity and therapeutic efficacy of atopic dermatitis [88]. There are many studies demonstrating significant elevations of some chemokines in association with particular diseases [87,98–100].

26.1 Introduction: Biosynthesis, Degradation, and Receptors of Lipid Mediators

Lipid mediators reviewed in this chapter include prostaglandins (PGs), leukotrienes (LTs), endocannabinoids, platelet-activating factor (PAF), lysophosphatidic acid (LPA), sphingosine-1-phosphate (S1P), and others. Biosynthesis, degradation, and receptors of these lipid mediators are depicted in Figure 26.1. PGs and LTs are produced from carbon 20 unsaturated fatty acids, mainly arachidonic acid (AA) in mammals fed on normal diet. AA is esterified to *sn*-2 position of phosphoglycerides in resting cells and is cleaved out from them on cell activation [1]. The classic pathway catalyzing the AA release is phospholipase A_2 (PLA_2), either cytosolic PLA_2 ($cPLA_2$) or secretory PLA_2 ($sPLA_2$), which acts on glycerophospholipids and release AA. More recently, it was found that monoacylglycerol lipase acts on 2-arachidonyl glycerol, one of the endocannabinoids, to liberate AA and that this pathway operates in the brain, liver, and lung [2]. AA liberated is then converted to PGs and LTs by the action of cyclooxygenase (COX) and 5-lipoxygenase (5-LOX), respectively. COX converts AA to PGH_2, which is then converted to PGD_2, PGE_2, $PGF_{2\alpha}$, PGI_2, thromboxane (TX) A_2, and 12-hydroxyheptadecatrienoic acid (12-HHT) by respective synthases. These PGs are released out of the cells and exert autocrine and/or paracrine functions by acting on the cognate receptor on the surface of target cells [3]. The PG receptors include PGD receptor (DP or DP1), four subtypes of PGE receptor (EP1–EP4), PGF receptor (FP), PGI receptor (IP), and TXA receptor (TP). These receptors are G protein-coupled receptors (GPCRs), with seven transmembrane domains, and constitute a subfamily in the GPCR superfamily. There is another GPCR responding to PGD_2 outside this subfamily, which is called CRTH2 or DP2 and belongs to the chemokine receptor family. PGs are inactivated by being taken up by the cell via PG

Inflammation: From Molecular and Cellular Mechanisms to the Clinic, First Edition.

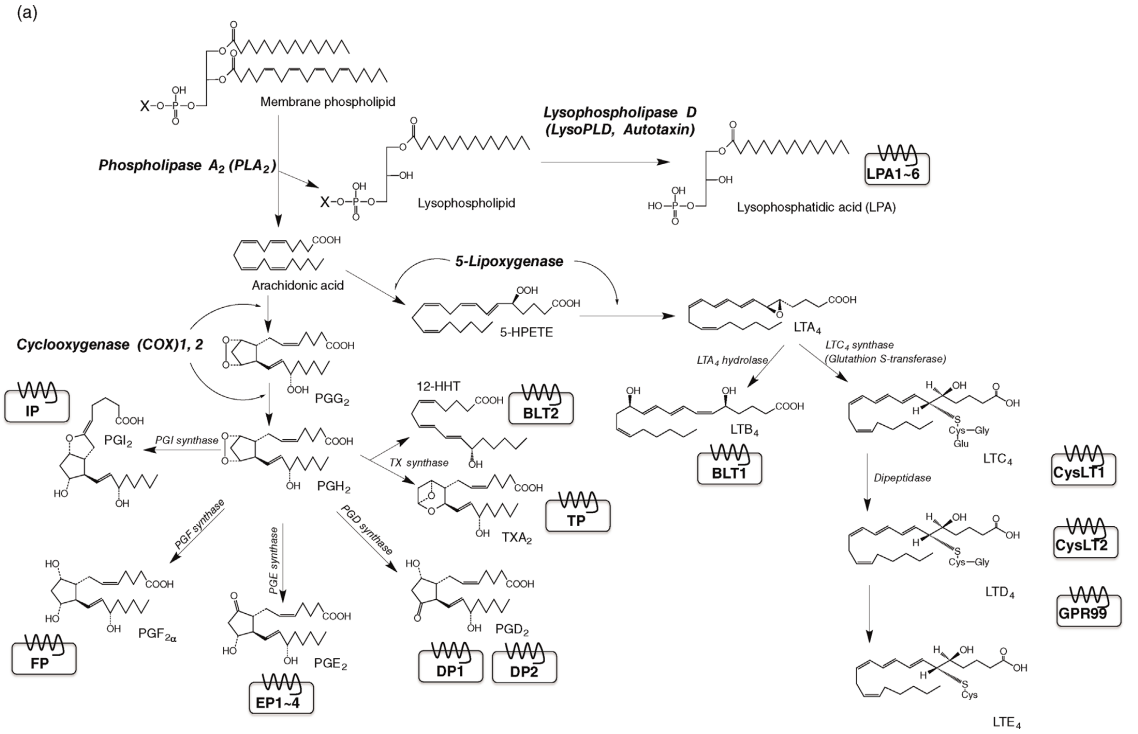

Figure 26.1 Biosynthesis, degradation, and receptors of lipid mediators. (a) Biosynthesis of prostaglandins (PGs), leukotrienes (LTs), and lysophosphatidic acid from membrane phospholipids. Italics indicate enzymes and bold characters in boxes show the nomenclature of receptors. (b) General scheme of inactivation of prostaglanidns. Hydroxyl group at C15 is dehydrogenated by a dehydrogenase (PGDH), and the double bond at C13, 14 is reduced by a reductase (PGR). In addition to this pathway, omega and beta oxidation of PGs is reported.

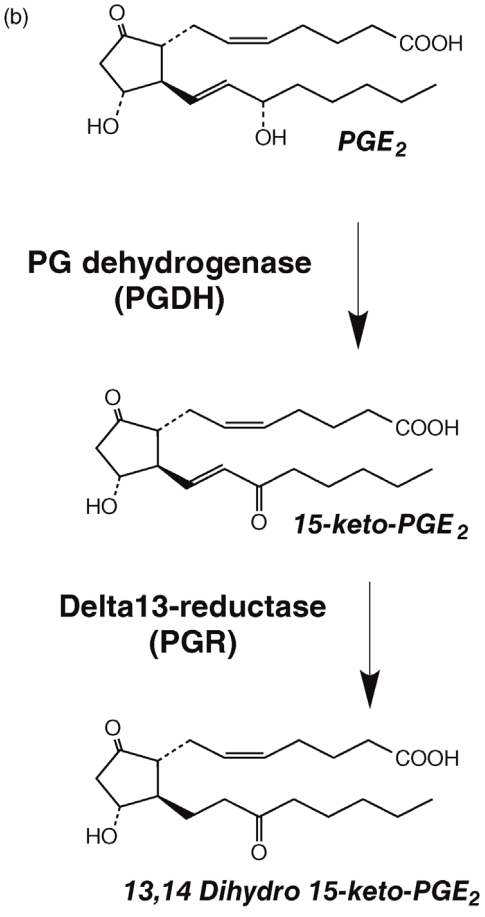

Figure 26.1 (*Continued*)

transporter and conversion to 13, 14-dihydro-15-ketoPGs by 15-hydroxyPG dehydrogenase (PGDH) and PG Δ^{13}-reductase (Figure 26.1b) [4].

In some cells, such as granulocytes, eosinophils, and macrophages that express 5-LOX, released AA is converted by dual enzymic activities of 5-LOX into an unstable intermediate, leukotriene A_4 (LTA_4) without any known biological activities. LTA_4 is hydrolyzed into a dihydroxyLT, leukotriene B_4 (LTB_4) by LTA_4 hydrolase [5]. In addition to LTB_4-producing activity, LTA_4 hydrolase has an aminopeptidase activity, which was recently reported to cleave and inactivate an inflammatory peptide Pro-Gly-Pro (PGP) derived from collagen [6]. Thus, LTA_4 hydrolase exhibits both pro inflammatory and anti-inflammatory functions. In mast cells, LTA_4 is conjugated with a glutathione into a peptideLT, leukoctiene C_4 (LTC_4) by LTC_4 synthase. LTC_4 is transported to extracellular space by multidrug-resistant protein 1 (MRP1) [7], because MRP1 recognizes glutathione-modified molecules. Extracellular peptidases cleave amino acids from LTC_4 and generate LTD_4, the most important bronchoconstrictor in bronchial asthma, and LTE_4. In contrast to the limited expression of 5-LOX and LTC_4 synthase in phagocytes, LTA_4 hydrolase is ubiquitously expressed in various tissues and cells.

Now, the concept "transcellular biosynthesis of LTB_4" in which LTA_4, produced in inflammatory cells, is transferred to the others cells to be converted to LTB_4 is widely accepted [8].

26.2 PGs in Inflammation

26.2.1 PGs in Acute Inflammation

Rubor (redness), calor (heat), tumor (swelling), and dolor (hyperalgesia) are cardinal signs of acute inflammation. Acute inflammation also causes systemic symptoms such as fever, activation of the hypothalamo–pituitary–adrenal (HPA) axis, anorexia, lethargy, and hypersomnia, which are collectively termed sickness behavior. Since aspirin-like, nonsteroidal anti-inflammatory drugs (NSAIDs) that inhibit COX and suppress PG production lessen these signs of acute inflammation, it has been thought that PGs are involved in elicitation of these signs and symptoms [9]. Further, since pathogen-associated molecular patterns (PAMPs) such as lipopolysaccharide (LPS) and proinflammatory cytokines such as interleukin (IL)-1β induce two pivotal enzymes for PGE_2 synthesis, a COX isoform, COX2, and membrane-type PGE synthase (mPGES) [10], PGs are thought to function downstream of these molecules in innate immunity as terminal mediators of acute inflammation.

Local redness and heat are caused by increased blood flow in microcirculation and local swelling is induced by increased permeability of postcapillary venules and resultant plasma exudation. It is generally believed that PGs induce vasodilation and other inflammatory mediators such as histamine, bradykinin, and leukotriene C_4 act on dilated venules and induce increased vascular permeability. Identities of PGs and receptors involved in these processes have been examined by subjecting mice deficient in each PG receptor and applying receptor type/subtype-specific antagonists to various models of acute inflammation. Murata *et al.* [11] injected carageenan into the mouse foot and found that edema formation in IP-deficient mice was suppressed to the level found in indomethacin-treated wild-type mice, suggesting that PGI_2-IP pathway plays a major role in edema formation in this model. On the other hand, effusion induced by carageenan injection to the pleural cavity was significantly decreased in not only $IP^{-/-}$ mice but also $EP2^{-/-}$ and $EP3^{-/-}$ mice [12]. Furthermore, EP2 deficiency and an EP4-selective antagonist suppressed edema formation in UV-irradiated skin in an additive manner by inhibiting irradiation-induced vasodilation and increase in blood flow [13]. In addition, Morimoto *et al.* [14] recently studied AA or PGE_2-induced edema formation in the skin and found that PGE_2 activates mast cells there through EP3 and induces histamine release for edema formation. These results suggest that either PGE_2 or PGI_2 or both are involved in inflammatory microcirculation responses in a context-dependent manner through receptors, EP2, EP3, EP4, and IP, and can be involved indirectly in vascular permeability change.

PGs also cause inflammatory hyperalgesia by sensitization of the nociceptive neurons mostly in the periphery. The primary sensory afferents have their cell

bodies in the dorsal root ganglion, and IP, EP1, EP3, and EP4 mRNAs were found in these neurons [15,16]. Studies subjecting mice deficient in these receptors to various pain models revealed that all of these receptors are involved in mediating pain sensation in a context-dependent manner. For example, $IP^{-/-}$ mice showed markedly decreased pain responses in acetic acid writhing test to a level observed in indomethacin-treated wild-type mice. While this study indicates that the hyperalgesic response in this model is evoked by endogenous PGI_2 acting on the IP receptor, LPS priming induced EP3-dependent hyperalgesia in the same test [17], indicating that hyperlagesic response can be induced either by PGI_2 or by PGE_2 or both, depending on what species of PGs are produced in the context. The TRPV1 cation channel detects heat and pH for pain sensation. Moriyama *et al.* [18] found that both PGE_2 and PGI_2 can augment thermal hyperalgesia mediated by TRPV1 through EP1 and IP, respectively, by lowering the threshold of the TRPV1 channel to temperature and pH in a manner dependent on protein kinase C (PKC)-mediated phosphorylation (Figure 26.2a). The channel can be activated also through the protein kinase A (PKA)-dependent manner by the EP4 signaling, which may be consistent with the finding that the selective EP4 antagonist can attenuate thermal hyperalgesia after complete Freund' adjuvant-induced peripheral inflammation [19]. In addition to these hyperalgesic actions in the periphery, PGE_2 added into the rat spinal cord dorsal horn reduces inhibitory glycinergic synaptic transmission in pain transmission through EP2 to induce central hyperalgesia, thus facilitating the transmission of nociceptive input through there to higher brain areas [20]. Interestingly, EP2-deficient mice exhibit only short lasting hyperalgesia after a peripheral inflammatory stimulus and lack a second sustained hyperlagesic phase of spinal origin [20].

Systemic symptoms of acute inflammation including fever and HPA axis activation are driven by the central nervous system and induced by blood-borne factors such as LPS and proinflammatory cytokines including IL-1β, IL-6, and TNF-α. These factors induce COX-2 and mPGES-1 in brain microvessels, and resultant PGE_2 is believed to enter the brain regions poor in blood–brain barrier and mobilize relevant neural circuits [21]. Ushikubi *et al.* [22] found that both LPS and IL-1β failed to induce febrile response in $EP3^{-/-}$ mice, suggesting EP3 in the brain for fever generation. A later work by Nakamura *et al.* [23] revealed that EP3 is expressed in GABAergic neurons in the preoptic area (POA) and that EP3 activation inhibits activity of these neurons. Combined with other studies, it is now proposed that PGE_2 suppresses EP3-expressing POA neurons, thus disinhibiting two downstream neural pathways, one directly projecting to Raphe pallidum neurons to control skin vasoconstriction and the other projecting indirectly to Raphe pallidum via dorsomedial hypothalamus to control heat generation in brown adipose tissue, which in combination induce the elevation of body temperature [24] (Figure 26.2b).

Like fever, the HPA axis activation is also evoked by LPS and IL-1β, which release corticotropin releasing factor (CRF) from neurons in the paraventricular hypothalamus (PVH). CRF then evokes ACTH release from the pituitary, which in turn stimulates glucocorticoid production and secretion from the adrenal cortex. This response measured as ACTH release in mouse consists of two components, one being of long duration and insensitive to NSAIDs and the other

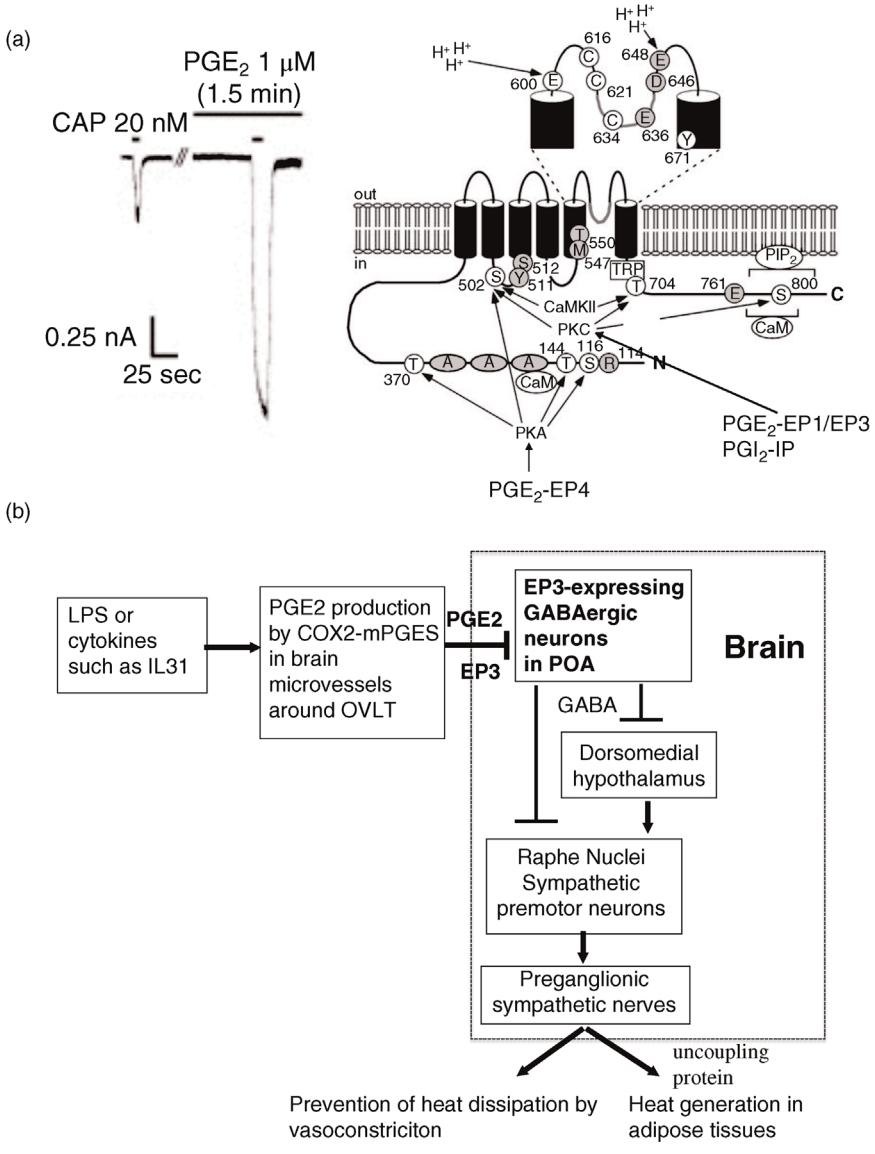

Figure 26.2 Roles of PGs in nervous system. (a) PG-mediated sensitization of TRPV1. (*Left*) Incubation with 1 μM PGE_2 augmented the TRPV1 current caused by 20 nM capsaicin (CAP) (reproduced with permission from Ref. [14]). (*Right*) PG-mediated modification of TRPV1 channel. Stimulation of PG receptor, EP1, EP3, IP, or EP4, induces phosphorylation of the cytoplasmic structure of TRPV1 channel through activation of PKC, CaMKII, or PKA (modified from Figure 2 of Ref. [81]). (b) Fever generation pathway. PGE_2 formed in brain microvessels acts on EP3 of GABAergic POA neurons and disinhibits downstream neural pathways for fever generation.

being transient and sensitive to NSAIDs. The latter response is absent in mice deficient in either EP1 or EP3 [25], suggesting that PGE_2 acts on EP1 and EP3 in an interdependent manner for HPA activation. c-fos mapping suggested that EP1- and EP3-mediated neural pathways converge to activate PVH neurons [25]. Since EP1 is localized at presynaptic structures on PVH neurons and PGE_2 injection to the PVH evokes ACTH release [26], it is proposed that EP1 facilitates neurotransmitter release from the terminals to CRF-containing neurons in PVH and facilitates CRF release.

Sickness-induced lethargy and anorexia can also be attenuated by NSAIDs, indicating the involvement of PGs in these processes. EP1 may be involved in the former process, because EP1 regulates impulsivity through modulation of dopaminergic system and $EP1^{-/-}$ mice exhibit extensive aggression behavior even after LPS administration [27]. On the other hand, PGE_2-EP4 system is implicated in anorexigenic responses to complement C3a agonist peptides and angiotensins [28]. Furthermore, although PGD_2 can induce slow-wave sleep and is suggested to be involved in regulation of physiological sleep [29], PGD_2-DP signaling appears not to be involved in inflammatory hypersomnia [30].

26.2.2 PGs in Chronic Inflammation

Chronic inflammation is inflammation of prolonged duration (weeks to months to years) in which active inflammation, tissue injury, and healing proceed simultaneously, and is histologically characterized by infiltration of mononuclear cells including macrophages, lymphocytes, and plasma cells, tissue destruction by products of the inflammatory cells, and repair involving angiogenesis and fibrosis [31]. Chronic inflammation underlies various chronic diseases including autoimmune diseases, cancer, neurodegenerative diseases, vascular diseases, and metabolic syndrome. Recent studies using animal models of these diseases indicate that PGs are involved in various phases of chronic inflammation.

26.2.2.1 PGs Act as Cytokine Amplifiers and Form Positive Feedback Loops of Inflammation Through Induction of COX-2

Recent studies revealed that, in addition to their short-lived actions in acute inflammation, PGs exert long-term inflammatory actions by acting on messenchymal, epithelial and immune cells and regulating gene expression at the transcription level. In these actions, PGs often cooperate with various cytokines and enhance their actions in gene expression. Honda *et al.* [32] used collagen-induced arthritis of mice as a model and found that PGI_2-IP signaling facilitates arthritis through augmentation of IL-6 content in arthritic paws. By analyzing the mechanism of this action *in vitro* in IL-1β-stimulated synovial fibroblasts, they found that IL-1β induces production of PGI_2 in synoviocytes, which acts on IP and amplifies the IL-1β-induced gene expression; affected genes include those related to inflammation such as IL-6 and IL-11, those related to cell proliferation such as fibroblast growth factor (FGF) and vascular and endothelial growth factor (VEGF), and those related to tissue remodeling such as HIF-1α and RANKL. Since PGI_2 alone did not induce expression of these genes, these results suggest that PGI_2 can function as an amplifier of IL-1β signaling. Intriguingly, PGI_2-IP

signaling augmented expression of IL-1 receptor (IL1R1) itself, suggesting that induction of the receptor for relevant cytokine is one of the mechanisms of PGI_2-mediated amplification. As described below, induction of relevant cytokine receptor is seen also in PG-mediated facilitation of differentiation and expansion of helper T-cell (Th) subsets in acquired immunity. Amplification by PGs is also seen in actions of innate immunity molecules such as PAMPs and DAMPs. For example, LPS-induced expression of COX-2, IL-1β, and IL-6 in cultured macrophages was ameliorated by the addition of a COX-2 inhibitor or an EP4 antagonist [33]. PGE_2-EP2 signaling was reported to amplify TNF-α-induced gene expression in macrophages and neutrophils (see below). In these actions, PG signaling and signaling from PAMPs and cytokines converge at the level of transcription factors such as NFκB for synergy. These amplifying mechanisms by PGs combined with cytokine-induced COX-2 expression make a self-amplification loop for inflammation.

Several studies have demonstrated the formation and contribution of such PG-mediated positive feedback loops in various animal models of chronic inflammation. Intracranial aneurysm (IA), a major cause of subarachnoid hemorrhage, is a regional bulging at bifurcation sites of intracranial arteries and is chronic inflammation histologically characterized by degenerative changes and inflammatory cell infiltration mainly of macrophages in the arterial wall. Aoki *et al.* [34] demonstrated induction of COX-2 and EP2 in endothelial cells at prospective site of IA formation in an animal model of IA. Importantly, COX-2 inhibition by celecoxib significantly suppressed EP2 expression and EP2 deficiency suppressed COX-2 induction, and both suppressed inflammation in IA walls and prevented IA formation *in vivo*. PGE_2-EP2 signaling activates NFκB and stimulates NFκB-mediated expression of various proinflammatory genes including COX-2 itself and MCP-1, a macrophage chemokine, in endothelial cells and macrophages *in vitro* [34]. These findings led the authors to suggest that the positive feedback loop composed of COX-2-PGE_2-EP2-NFκB-COX-2 is formed in endothelial cells and recruited macrophages to amplify inflammatory responses (Figure 26.3). Macrophage infiltration recruited by MCP-1 plays a crucial role in the pathogenesis of IA, because administration of chlodronate liposome to deplete macrophages and gene deletion of MCP-1 prevented IA formation [35,36]. Recruited macrophages themselves also form the above amplification loop, and produce MCP-1 in addition to various cytokines and tissue-destructive proteinases, thus

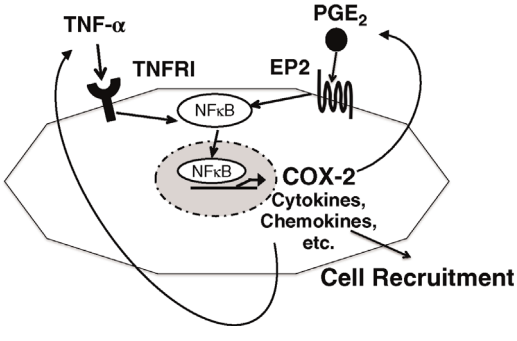

Figure 26.3 EP2-mediated positive feedback pathway of inflammation.

making an autocrine loop for sustained macrophage accumulation and further exacerbation of inflammation in the lesion [35,37].

Chronic inflammation also underlies cancer development and is typically characterized by COX-2 expression in tumor lesion [38]. Pharmacological inhibition of COX by NSAIDs is long known to reduce incidence of colorectal cancer (CRC) in humans [39], and genetic deletion of COX-2 in mice reduced intestinal adenoma formation in animal model of human familial adenomatous polyposis coli [40]. Ma *et al.* [41] used azoxymethane-dextran sodium sulfate treatment as a model of colitis-associated colon cancer and examined the identity of PG receptor and its role in inflammation of CRC. They found that EP2 deficiency remarkably reduced inflammatory infiltrates and suppressed tumorigenesis in this model. Notably, EP2 was expressed in both neutrophils, the major infiltrating cells in lesions, and tumor-associated fibroblasts surrounding tumor cells and worked synergistically with TNF-α to produce various cytokines and chemokines through the self-amplification loop of COX-2-PGE_2-EP2 to promote tumorigenesis. One of the genes whose expression is amplified by this loop is CXCL1, a neutrophil chemokine. Intriguingly, infiltrating neutrophils expressed both EP2 and CXCL1, and EP2 deficiency suppressed neutrophil infiltration and CXCL1 expression. Further, EP2 stimulation of primary culture of neutrophils augmented CXCL1 expression synergistically with TNF-α. These results suggest that neutrophils self-amplify their recruitment through the PGE_2-EP2-CXCL1 pathway, which critically contributes to tumorigenesis in their model [41]. Similarly, Oshima *et al.* [40] used *Helicobacter pylori*-infected gastric tumor as a model and found that bacterial colonization and PGE_2-EP4 signaling cooperatively induced MCP-1 expression to recruit macrophages to promote gastric tumors. These findings clearly show that PG signaling sustains infiltration of inflammatory cells under different inflammatory settings through induction of various chemoattractants in a positive feedback manner and makes inflammation long-lasting.

26.2.2.2 PGs in Autoimmune and Allergic Inflammation

In response to invasion of foreign pathogens, the adaptive immune system is activated by engagement of T-cell receptor (TCR) on T cells with antigenic substances presented by MHC-II on antigen-presenting cells (APCs). Activated APCs also produce various cytokines to prime activated T cells to differentiate into different helper T-cell (Th) subsets, IL-12, IL-4, and TGF-β plus IL-6 for Th1, Th2, and Th17 cell differentiation, respectively. Resultant Th1, Th2, and Th17 cells produce subset-specific cytokines, interferon (IFN)-γ, IL-4 and IL-5, and IL-17 (also called IL-17A), and IL-17 F and IL-22. While these Th subsets fight against external pathogens through producing these cytokines, uncontrolled differentiation and activation of these cells also trigger immune diseases [42]. Th1 cell and Th17 cells mediate development and progression of autoimmune inflammatory diseases such as multiple sclerosis (MS), inflammatory bowel disease (IBD), rheumatoid arthritis (RA), and psoriasis, while Th2 cells mediate development of allergic inflammation such as atopic dermatitis and asthma. PGs appear to function in opposite ways in Th1/Th17-mediated autoimmune inflammation and Th2-mediated allergic inflammation.

26.2.2.3 PGs in Th1/Th17-mediated Autoimmune Inflammation

It was long known that PGE_2 added to naïve T cells in culture inhibits T cell responses, including antigen-driven TCR activation, T-cell proliferation and cytokine (e.g., IL-2, IFN-γ, etc.) production, through cAMP signaling [43]. Based on these findings, it was thought that PGE_2 suppresses Th1 cell development and function. However, there is now accumulating evidence that stronger physiological stimulation of T cells conquers this suppressive effect and PGE_2 can facilitate both IL-12-induced Th1 differentiation under the Th1 skewing conditions and Th17 expansion under stimulation with IL-23. Yao *et al.* [44] showed these PGE_2 actions in mouse T cells and revealed that they are mediated through EP2/EP4-cAMP-PKA signaling. They further showed that the former Th1-facilitative action of PGE_2 is elicited through induction of receptors involved in Th1 differentiation, namely, IL-12Rβ2 and IFN-γ-R1, by the cAMP-PKA-CREB/CRTC2 pathway [45]. PGE_2-mediated facilitation of Th17 cell expansion was also seen in human Th17 cells stimulated with IL-23 and/or IL-1β [46]. Interestingly, PGE_2 acts on EP2 in human cells and upregulates expression of IL-23R and IL-1R, suggesting that PGE_2 also amplifies the cytokine action here by inducing the relevant cytokine receptors. Intriguingly, IL-23 production by activated APCs was also enhanced by PGE_2. This PGE_2 action was observed in DCs stimulated with various TLR ligands, that is, LPS, Poly-I-C, CpG, and proteoglycan [47] and those stimulated with anti-CD40 antibody. Interestingly, treatment with indomethacin or an EP4 antagonist almost completely suppressed the IL-23 production in the latter [44], suggesting the presence of the PGE_2-mediated self-amplification cycle for IL-23 production in activated DCs. EP2 and EP4 mediate the former PGE_2 action through interaction of NFκB activated by TLR pathway and CREB and C/EBP-β activated by cAMP signaling [48]. Interestingly, whereas this PGE_2 action in TLR-stimulated cells is transient, peaking at 1 h, the one by CD40 stimulation lasts over 36 h, in which the early phase is mediated canonical and the late phase is mediated by noncanonical NFκB signaling, both being similarly enhanced by the PGE_2-EP4 signaling [49]. Thus, PGE_2-EP2/4 signaling facilitates IL-23 production, Th1 differentiation, and Th17 expansion for immune inflammation (Figure 26.4).

Several animal models for autoimmune inflammatory diseases supported these *in vitro* findings and revealed the importance of PGE_2-EP2/4 signaling in immune inflammation mediated by Th1 and Th17 cells. In experimental autoimmune encephalomyelitis (EAE), an animal model for human MS, EP4 deficiency, or administration of an EP4-selective antagonist during T cell priming stage after immunization markedly suppressed EAE development, which is accompanied by reduction of IFN-γ and IL-17 production in lymph node cells. EP2 deficiency also showed inhibition of EAE development and production of Th1 and Th17 cytokines, which was additive to that of EP4 antagonism, while mice deficient in other PG receptors developed EAE similar to WT mice [44,50]. Blockade of EP4 signaling also reduced skin swelling and downregulated Th1/Th17 cell function in contact hypersensitivity [44]. Further, selective deletion of EP4 in T cells substantially suppressed IFN-γ-producing Th1 cell development and colonic inflammation in a T-cell transfer colitis model [45]. EP4 antagonism also ameliorated CIA progression with concomitant suppression

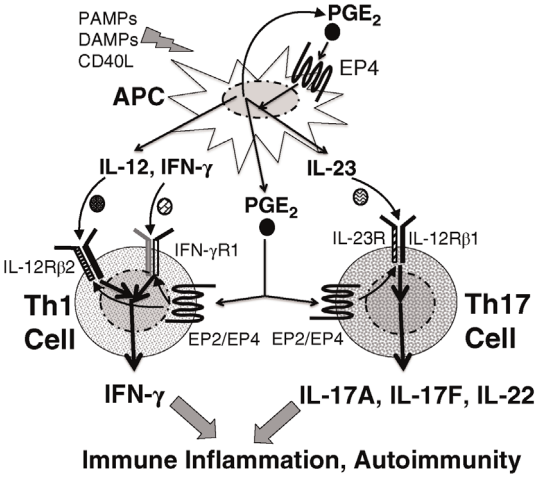

Figure 26.4 PGE_2-EP2/EP4-mediated facilitation of Th1 differentiation and Th17 expansion for immune inflammation.

of IFN-γ and IL-17 production by lymph node cells [51]. Conversely, intraperitoneal administration of PGE_2 or an EP3/EP4 agonist, misoprostol, exacerbated CIA and 2,4,6-trinitrobenzene sulfonic acid-induced colitis accompanied by the increase of IL-23 p19 and IL-17 in the lesions [52]. Such Th1 activating function of PGs is not limited to PGE_2 and is also seen in PGI_2-IP signaling, which couples to cAMP elevation like EP2/EP4. Nakajima *et al.* demonstrated that PGI_2-IP signaling facilitates Th1 differentiation *in vitro* and that IP deficiency impairs CHS [53].

Clinical relevance of these findings to human autoimmune diseases was indicated by recent genome-wide association studies (GWAS), which have identified *Ptger4* (EP4) as a susceptible locus in a number of autoimmune diseases including Crohn's disease [54], multiple sclerosis [55], and allergy [56]. Further, causal single-nucleotide polymorphisms (SNPs) related to these autoimmune diseases are enriched in enhancer region of *Ptger4* locus and these SNPs well correlate with EP4 expression [57]. Further, Kofler *et al.* [58] found overexpression of EP2 in T cells of patients of multiple sclerosis. EP2 simulation of these T cells induces highly pathogenic T-cell phenotype expressing both IL-17 and IFN-γ. Taken together, these findings strongly suggest that PGE_2 promotes autoimmune inflammation through facilitating proinflammatory Th1 and Th17 cells.

26.2.2.4 PGs in Th2-mediated Allergic Inflammation

On the contrary to Th1 differentiation and Th17 expansion that PGs can facilitate, PGs appear to inhibit Th2 differentiation. For example, Nakajima *et al.* [53], who found the IP-mediated facilitation of Th1 differentiation, reported that the same IP stimulation concentration-dependently suppresses Th2 differentiation of native $CD4^+$ T cells from BALB/c mice under the Th2-skewing condition. If this operates *in vivo*, the inhibition of this pathway may lead to enhancement of Th2 response. Indeed, a study subjecting mice deficient in either

COX-1 or COX-2 to ovalbumin (OVA)-induced allergic asthma model found that allergic inflammation of the lung was significantly enhanced by the deficiency of either COX isoform with significantly higher serum IgE levels compared to wild-type mice [59]. Consistent with these findings, $IP^{-/-}$ mice subjected to OVA-induced allergic asthma model developed higher IgE levels and exhibited exacerbation of lung inflammation [60]. Furthermore, Kunikata *et al.* [61] examined lung inflammation of mice deficient in each EP subtype and found that $EP3^{-/-}$ mice developed enhanced inflammation compared to wild-type mice with the serum IgE level similar to that in wild-type mice. They further examined expression and action mechanism of this EP receptor and reported that EP3 is expressed in airway epithelial cells and activation of this receptor with an EP3-selective agonist suppressed expression of a variety of genes induced by OVA challenge to the lung. These results suggest that PGE_2-EP3 signaling negatively regulates allergic inflammation by downregulating inflammation-related genes in the epithelium. Similar action of the PGE_2-EP3 signaling was reported in allergic conjunctivitis and delayed-type hypersensitivity in the skin [62,63]. On the other hand, Birrell *et al.* [64] reported that lung inflammation induced by various stimuli including OVA, LPS, and cigarette smoke was suppressed in $EP4^{-/-}$ mice. Since $EP4^{-/-}$ mice were in mixed genetic background of C57BL/6 and 129/ola, their results are difficult to interpret. However, they also found that EP4 stimulation inhibits expression of various inflammation-related genes including TNF-α and IL-6 in human monocyte cell line, THP-1, and suggested that this might be a responsible inhibitory mechanism. It is enigmatic that the same EP4 signaling and the similar signaling of EP2 often amplify inflammatory gene expression in macrophages in different contexts and exacerbate inflammation. Whether this difference is due to macrophage subclasses remains to be examined.

Mast cell activation by IgE binding initiates allergic inflammation in most cases. Mast cells are, therefore, obviously the therapeutic target for antiallergy treatment including asthma. Mast cells express four EP subtypes differentially in individual subsets, but EP2 and EP3 generally predominate [65]. Contrary to the findings by Kunikata *et al.* in C57BL/6 mice [61], the de Mora's group reported that an EP3-selective agonist was without effect in house dust mite-sensitive asthma in Balb/c mouse strain and found that EP2 agonist was effective in this model [65]. They attributed this effect to EP2-mediated inhibition of mast cell activation observed in different mast cell preparations. Since mast cells release PGD_2 upon activation, the pathophysiological role of this PG has been studied. One role is to induce bronchoconstriction by acting TP in bronchial smooth muscle [66]. In relation to allergic inflammation, Matsuoka *et al.* [67] reported suppression of OVA-induced allergic inflammation in $DP^{-/-}$ mice. Since DP is induced in the bronchial epithelial cells, they ascribed the effect of DP deficiency to its role in the epithelium. Although this phenotype may be in part due to impaired mast cell differentiation found recently in $DP^{-/-}$ mice [68], allergic inflammation in allergic rhinitis, conjunctivitis, and asthma models was attenuated by administration of a selective DP1 antagonist, S-5751, to wild-type mice, validating the role of DP1 in elicitation of allergic inflammation [69]. Furthermore, genetic association of two SNPs of DP1 with higher risk of asthma was noted in Caucasians and African-

Americans but not in Japanese, Han Chinese, and Hispanics [70]. PGD_2 acts also on DP2/CRTH2. Because this receptor is expressed in Th2 cells and eosinophils, and exerts chemotactic function, CRTH2 is thought to play an important role in allergic inflammation. Although the CRTH2 deficiency did not suppress allergic inflammation in acute asthma model, it dampens the infiltration of inflammatory cells including eosionophils in BALF of mice subjected to chronic asthma model [71].

26.2.2.5 PGs in Tissue Remodeling (Fibrosis, Angiogenesis, Lymphangiogenesis, etc.)

Tissue remodeling including tissue metaplasia, fibrosis, angiogenesis, and granulation follow destruction of affected tissues in chronic inflammation. PGs either facilitate or suppress these processes in a context-dependent manner. For example, in the OVA-induced allergic asthma model, OVA challenge induced expression of genes involved in tissue remodeling such as Gob-5, Munc5ac, MMP-12, and ADAM-8, and stimulation of PGE_2-EP3 potently suppresses this induction as mentioned [61]. On the other hand, Amano *et al.* [72] implanted a Matrigel sponge or tumor cells in mice and found the same PGE_2-EP3 signaling facilitates angiogenesis associated with chronic inflammation in the sponge and tumors. Their bone marrow transfer experiment indicates that EP3-bearing bone marrow-derived cells mediate VEGF expression in the stroma around the implants and recruitment of VEGFR-1^+/VEGFR-2^+ cells [73]. Katoh *et al.* [74] used implants of tumor cells and micropore chamber and found that PGE_2-EP3/4 signaling at the site of implant induces expression of CXCL12 around the implants, which recruits $CXCR4^+S100A4^+$ fibroblasts from bone marrow to the site for granulation. The PGE_2-EP3/4 signaling was also suggested to mediate lymphangiogenesis by inducing VEGF-3 and VEGF-4, growth factors for lymph endothelial cells [75].

Lastly, tissue fibrosis occurs in various organs including lung, heart, liver, and kidney and is characterized by proliferation of fibroblasts and excessive deposition of extracellular matrix proteins. Oga *et al.* [76] used bleomycin-induced pulmonary fibrosis as a model of idiopathic pulmonary fibrosis in humans and found that $PGF_{2\alpha}$-FP signaling mediates collagen synthesis independent of TGF-β without affecting inflammation. On the other hand, Lovgren *et al.* demonstrated that the loss of IP augmented lung fibrosis in the same pulmonary fibrosis model [77]. PGI_2-IP signaling appears to exert similar antifibrotic action in the heart of mice subjected to pressure overload [78], which was antagonized by TXA_2-TP signaling [79]. Protective action of PGs was also reported for the PGE_2-EP4 signaling, which protects mice from tubulointerstitial fibrosis in the kidney in unilateral ureteral obstruction [80].

26.2.3 Anti-inflammatory Actions of PGs

Although PGs usually exert proinflammatory actions, they also elicit anti-inflammatory actions as discussed above in "their actions in Th2-mediated allergic inflammation." In addition, Kabashima *et al.* [81] showed that PGE_2-EP4 signaling protects mouse from dextran sodium sulfate (DSS)-induced colitis and that

this action of EP4 may be due to increasing barrier function of epithelial cells in the gut. This protective function of PGE_2-EP4 signaling in intestinal epithelium has been confirmed recently by the study inhibiting PG-degrading enzyme, 15-PGDH, in mice [82]. This study found that this procedure elevates the levels of endogenous PGs and potentiates PG-mediated tissue regeneration including intestine, bone marrow, and liver. Furthermore, Soontrapa *et al.* [83] examined the mechanism of UV irradiation-induced systemic immunosuppression, which is known to be sensitive to NSAIDs. They found that this immunosuppression is due to induction of regulatory T cells, which is mediated by PGE_2 produced in response to UV irradiation in the skin. PGE_2 acts on EP4 in keratinocytes, induces RANKL, which activates $DEC205^+$ dendritic cells for regulatory T cell induction. Thus, PGs can exert protective actions in some contexts. Therefore, when clinical application of manipulation of PG signaling is considered, it is utmost important to identify whether PG signaling is pro- or anti-inflammatory in that context.

26.3 LTs in Inflammation

26.3.1 LT Receptors
