This influence, obviously acquired in childhood, can be generally described as a body of rules and practices that defines what is appropriate and desirable food and how it is to be eaten. The most systematic description of the food itself comes from Elisabeth Rozin's (1982, 1992) analysis of cuisine. She posits three components that give a characteristic ethnic quality to any dish: The staple ingredients, the flavor principles (for example, the recurrent soy sauce, ginger root, rice wine combination in Chinese food), and the method of processing (for example, stir-frying for many Chinese foods).

Furthermore, cuisines specify the appropriate ordering of dishes within a meal (Douglas and Nicod 1974) and the appropriate combinations and occasions on which particular foods are consumed (Schutz 1988). All of these factors, along with rules about the manner and social arrangement of eating and the importance and function of food in life, are major parts of the human food experience and are basically part of the transmission of culture. That these cultural forces are strong is indicated by the persistence of native food habits, sometimes called the conservatism of cuisine in immigrant groups. Generations after almost all traces of original-culture practices are gone, the basic food of the family often remains the native cuisine (see, for example, Goode, Curtis, and Theophano 1984).

Psychological Determinants of Food Selection

Within the minimal constraints of biology and the substantial constraints and predispositions imposed by culture, any individual develops a set of culture-appropriate, but also somewhat unique, food preferences. I shall now address what little we know about how this happens.

Early Childhood: Milk and Weaning

Humans and other mammals begin life with one food: milk. It is both nutritive and associated with maternal nurturance. A first trauma in life is weaning away from this "superfood," which is accomplished in culturally variable ways. There is no evidence for special attachments that humans develop to this earliest food, although such a permanent attachment (liking) has been documented with respect to species recognition in a number of species: Exposure to a member of the species (usually a parent) at a critical period in development leads to a permanent attachment to and preferential recognition of that object. But this process of imprinting would be highly maladaptive for early food for mammals because they would then spend their lives seeking an unattainable food. Milk, for example, only became available as a food for some humans after infancy with the development of dairying, which occurred relatively recently in human history (see Rozin and Pelchat 1988, for further discussion).

Neophilia and Neophobia

As omnivores, humans show both a tendency to be interested in new foods and a fear of new foods. Both tendencies have benefits and risks. The neophilic (attraction to new food) tendency manifests itself not only in an interest in genuinely new foods but also in a desire for variety in the diet. Thus, humans (and other animals) tend to come to like a food less if they eat it almost exclusively (boredom effect) and tend to eat more when confronted with a variety of foods. This general phenomenon has been called sensory specific satiety and has been subjected to systematic analysis by B. J. Rolls and her colleagues (Rolls et al. 1985).

Below the age of about 2 years, children seem to have little neophobia and, quite willingly, put almost anything into their mouths (reviewed in Rozin, 1990c). Presumably, parental monitoring of their food access controls this otherwise dangerous tendency. After 2 years of age, at least in American culture, children sometimes enter a neophobic phase, in which they refuse all but a few types of food. We do not know the origin or adaptive value (if any) of this pattern. In American culture, some adults also find an extremely limited range of foods acceptable, though most children with this extreme neophobia recover from it. Neophobia varies greatly across individuals in North America, and a scale has been developed to measure this tendency in both children and adults (Pliner and Hobden 1992).

Food Preferences and the Adult Taxonomy

We know very little about how, within any culture and individual, specific foods become categorized in accordance with the taxonomy presented in Table VI.11.1. I review here what is known.

Acquired dislikes. Best understood is the origin of the distinction between the danger and distaste categories. Generally, if a relatively new food is consumed, and this is followed within hours by unpleasant symptoms that include nausea, the food comes to be a distaste. However, if nausea is not a part of the symptoms, the result is usually that the food enters the danger category; that is, it is avoided because of anticipated harm, but is not distasteful (Pelchat and Rozin 1982). The taste-aversion learning originally described in rats by J. Garcia and his colleagues (1974) seems to be an example of acquired distaste mediated by nausea. Hence, nausea appears to be a magic bullet, producing distastes. This is not, however, to say that this is the only way in which distastes can be produced. There is evidence, for example, that when a food is accompanied by a bad taste (for example, when a bitter taste is added to a food), the food itself becomes distasteful, even when the originally unpleasant taste is removed (Baeyens et al. 1990).

Acquired likes. So far as we know, there is no magic bullet like nausea on the negative side that makes a potential food into a good taste (a liked food). However, this happens very frequently. There is evidence for three processes that contribute to acquired likes.

One of these is mere exposure. That is, simple exposure to a food (meaning its ingestion) is usually accompanied by an increased liking for the food (Pliner 1982). The mechanism for this may be nothing other than mere exposure. The effects of mere exposure on liking have been shown in many domains other than food (Zajonc 1968).

A second process that accounts for acquired likes is classical (Pavlovian) conditioning. That is, if an already liked entity (called an unconditioned stimulus) is paired with (that is, is contingent with) a relatively neutral potential food, the potential food tends to become more liked. This process of change in liking for a stimulus as a result of contingent pairing in humans has been called evaluative conditioning (Martin and Levey 1978; Baeyens et al. 1990). One example involves pairing of a flavor (conditioned stimulus) with the pleasant experience of satisfaction of hunger (unconditioned stimulus). In a laboratory setting, humans have been shown to increase liking for a food the ingestion of which is followed by satiety (Booth, Mather, and Fuller 1982).

Another example involves presentation (contingent pairing) of one flavor of herbal tea (conditioned stimulus) with sugar (unconditioned stimulus) and another flavor of tea without sugar. After a number of presentations, subjects tend to prefer the flavor of the tea that was paired with sweetness, even when that flavor is presented without sugar (Zellner et al. 1983).

Within the context of evaluative conditioning, it is likely that the major class of potent (unconditioned) stimuli that influence food likes is social. In particular, the perception (often, perhaps, by facial expression) of positive affect in another (respected) person in conjunction with consumption of a particular food probably makes that food more liked by the "observer." Recently, a first study has shown such an effect in the laboratory. Subjects who observe a person indicating pleasure in drinking a beverage from a glass of a particular shape (as opposed to other shapes) come to prefer that particular glass shape (Baeyens et al. 1994).

A third process that influences liking is also social, but it does not operate through conditioning. Rather, the perception of liking or value in a respected other operates more directly to influence one's own attitudes. For example, when a respected other uses a food as a reward (indicating that he/she values the food), a child tends to come to prefer (like) that food more (Birch, Zimmerman, and Hind 1980). Furthermore, there is evidence, both from the general literature in social psychology (Lepper 1983) and the development of food preferences (Birch et al. 1982), that the perception that the self or others consume a food for clear personal gain (nutrition, social advantage) is destructive to the development of liking. That is, when children perceive that a food preference (in themselves or others) is "instrumentally" motivated, that is, connected to a specific reward, they tend not to shift their liking for the food in question.

Reversal of Innate Aversions

Humans are almost unique among mammalian (if not all) generalists in developing strong likes for foods that are innately unpalatable. These include such common favorites as the oral or nasal irritants in chilli peppers, black pepper, ginger, horseradish, and alcoholic beverages or tobacco, and the bitter tastes in certain fruits, tobacco, most alcoholic beverages, coffee, chocolate, burnt foods, and so forth. Reversals of innate aversions seem to occur in all cultures (cuisines). They might well be accounted for in terms of the operation of the factors (mere exposure, evaluative conditioning, social influence) that have already been identified. But there are also some special mechanisms of acquired liking that require an initially negative response. Two have been identified, with particular reference to the acquisition of a liking for the innately negative oral burn of chilli pepper (Rozin 1990a).

In the service of maintaining the body at an optimum level of function, humans and other species seem to have compensatory mechanisms, which neutralize disturbances by producing, internally, events that oppose the original event. These internally generated events are called opponent processes (Solomon 1980). For example, it is widely believed that endorphins, natural opiatelike substances, are released in the brain to reduce a chronic pain experience. R. L. Solomon (1980) and others have suggested that opponent processes become more potent as they are repeatedly stimulated and have used this feature to account for the basic process of addiction. Normally, when one experiences something painful, one withdraws and avoids the situation in the future. However, in the case of the chilli pepper and other culturally supported innately negative entities, there is a strong cultural force that reintroduces the aversive experience. Thus, children end up repeatedly sampling the unpleasant burn of chilli pepper, permitting the development of a strong opponent process, which may grow to the extent that it overcompensates for the pain and produces net pleasure (perhaps by oversecretion of endogenous opiates) (Rozin 1990a). Hence, the negativity of an innately aversive substance may provide the conditions for an acquired liking.

A more cognitive account of the reversal of innate aversions engages a uniquely human interest in mastering nature. The signals sent to the brain from innately unpalatable substances impel the organism to reject them; they are adaptively linked to a system that rids the organism of harmful entities. But many innately unpalatable substances are not harmful, at least in modest doses (chilli pepper, ginger, coffee). Though chilli pepper makes the novice feel as if his palate will peel away, it is, in fact, harmless. It is possible that the realization that a substance-experience elicits bodily defensive mechanisms, but is actually safe, is a source of pleasure. We call this pleasure that comes from mastery over nature benign masochism (Rozin 1990a). A more striking instance is the unique human activity of enjoying bodily manifestations of fright (as opposed to pain): People presumably enjoy roller coasters because their body is frightened, but they know that they are actually safe.

Disgust: The Food-Related Emotion

The strongest reaction to a potential food is surely the revulsion associated with disgusting entities (Table VI.11.1). The emotion of disgust elicited in these situations is characterized by withdrawal, a sense of nausea, and a characteristic facial expression. According to our analyses (Rozin and Fallon 1987; Rozin, Haidt, and McCauley 1993), following on the seminal contributions of Charles Darwin (1872) and A. Angyal (1941), disgust is originally a food-related emotion, expressing "revulsion at the prospect of oral incorporation of offensive substances. The offensive substances are contaminants, that is, if they contact an otherwise acceptable food, they tend to render that food unacceptable" (Rozin and Fallon 1987: 23). Our analysis holds that disgust originates from distaste (and shares, to some extent, a facial expression with distaste), but is in fact quite distinct from distaste in adults. For example, the idea of a distasteful entity in one's stomach is not upsetting, but the idea of a disgusting entity in one's stomach is very upsetting.

The intensity of the disgust experience derives, in part, from the "you are what you eat" principle, since, by this principle, one who ingests something offensive becomes offensive. Virtually all food-related disgust entities are of animal origin. We have proposed that the core disgust category is all animals and their products (Rozin and Fallon 1987). In line with Angyal's suggestion (1941), we agree that feces is the universal disgust substance, and almost certainly the first disgust, developmentally. The potency of disgust elicitors is evidenced by the contamination property, a feature that seems to characterize disgust cross-culturally.

Disgust provides an excellent example of how a food system becomes a template or model for more elaborated systems. The emotion of disgust seems, through cultural evolution, to have become a general expression of anything offensive, including nonfoods. Our analysis suggests that principal elicitors of disgust cross-culturally include reminders of our animal origin (such as gore, death), a wide range of interpersonal contacts (such as wearing the clothing of undesirable persons), and certain moral offenses often involving purity violations or animality (Rozin et al. 1993).

Transmission of Food Preferences and Attitudes

Most available models for the acquisition of food preferences would predict a rather high correlation between the food preferences of parents and those of their children. For the first years of life, parents are the primary teachers and exemplars of eating and food choice for children. In addition, to the extent that there are individual differences in preferences that have genetic contributions, one would expect parent-child resemblances. Yet, the literature (reviewed in Rozin, 1991) indicates very low correlations between the food preferences of parents and their children (in the range of 0 to 0.3), whether the younger generation in the studies is one of preschoolers or of college age. There is no reasonable account for these low correlations; they do not result from the fact that the parents have different preferences for the foods under study, so that the child gets "mixed messages." Parent-child correlations remain low even when the parents are very similar in their preferences for the foods under study (Rozin 1991). Alternative sources of influence on children include peers and siblings (for whom there is evidence of some substantial resemblance [Pliner and Pelchat 1986]), and the media. The effectiveness and mode of operation of these and other influences has yet to be evaluated.

The low parent-child correlation for food preferences is part of what has been called the family paradox (Rozin 1991). The paradox is extended by the fact that there is no consistent evidence that mothers (as principal feeders and food purveyors) show higher child resemblance than do fathers, nor that same-sex parents have greater influence than opposite-sex parents – as views about identification might suggest (Pliner 1983; Rozin 1991).

The puzzling lack of parent-child resemblance for food (and other) preferences contrasts with much higher parent-child resemblance for values (Cavalli-Sforza et al. 1982; Rozin 1991). Apparently, values (such as religious or political attitudes) are more subject to parental influence. In this regard, it is of interest that food preferences may, under some circumstances, become values. Food is intimately related to moral issues in Hindu India, such that a leading scholar of this area has described food in Hindu India as a "biomoral substance" (Appadurai 1981). But even in Western cultures, specific foods may enter the moral domain. For example, vegetarianism for some has moral significance. It would be interesting to see if parental influence is greater on children for whom a preference has been moralized than for those for whom the preference is not moralized.

Attitudes and Choice: An Alternative Approach

The framework I have provided for examination of human food selection emphasizes the psychological categorization of foods and the combined influences of biological, psychological, and cultural factors on food selection. The emphasis has also been on the developmental history of food preferences. There are alternative formulations from within both psychology and marketing. A particularly prominent approach, based on the study of attitudes and their relation to behavior, examines the factors currently influencing selection of a particular food, independent of the ultimate origin of these causes. In other words, this approach models what would be going on in the head of a person in a supermarket faced with a choice between two products. For convenience, the forces acting on a person at a time of choice can be categorized as those attributable to the food and its properties, the person, and socioeconomic factors (Shepherd 1988).

The theory of reasoned action (Ajzen and Fishbein 1980) has probably been the most successful framework for analysis of choices in terms of the action of contemporary forces. According to this approach, the principal cause of a behavior (for instance, selecting a particular food) is the intention to behave in such a manner, and the principal predictors of the intention are personal attitudes to the behavior (for instance, whether it is seen as good or bad) and subjective norms (the perceived opinions of significant others about whether the behavior should be performed). Personal attitudes are themselves a function of a set of beliefs about the outcome of the behavior (food choice) in question (will it promote overweight, will it produce a pleasant taste?) and the evaluation of that outcome (is it good or bad?). A set of salient beliefs is determined, and the sum of the product of each belief and its evaluation composes the attitude score. The subjective norm is predicted in the same manner by the sum of normative beliefs about whether specific relevant people or groups think that the target person should perform the behavior, each norm multiplied by the motivation to comply with it.

A number of studies (see Tuorila and Pangborn 1988; Towler and Shepherd 1992) have applied the Ajzen-Fishbein model to food choices, with some success, in terms of prediction of consumption from (usually) questionnaire data on beliefs, evaluations of beliefs, subjective norms, and motivation to comply with those norms. Target foods have included a variety of dairy products, meats, and other high-fat foods. The results, on subjects from the Western-developed world, show a tendency for personal attitudes to be better predictors of choice than subjective norms. They also suggest that taste of food is the most important predictor of attitudes, with health effects often the second-best predictor (see Shepherd 1989b for a general discussion).

Food Selection Pathology in America

Throughout history, food has been viewed as not only the principal source of sustenance but also a major source of pleasure. In the United States, a surfeit of food, a developing concern about long-term harmful effects of certain foods, and a standard of beauty for women (at least among the white middle class in the United States) that is much thinner than the average woman have all contributed to an ambivalent, sometimes negative attitude to food (Polivy and Herman 1983; Rodin et al. 1985; Becker 1986; Rozin 1989; Rodin 1992).

Consumption of foods, especially those that are highly tasty and fattening, becomes for many a source of fear and guilt, rather than pleasure. The focal group for this (what I will call) pathology of food is white middle-class American women, among whom there is considerable concern about obesity and, consequently, considerable efforts aimed at dieting (Rodin 1992). One consequence of this is that eating disorders, such as anorexia nervosa and various forms of bulimia, are increasing in American women, whereas such disorders are at much lower levels in American males and virtually absent in developing countries (McCarthy 1990).

One cause of this hyperconcern about food, as mentioned, is the standard of thinness accepted by American women; unlike American men, American women see themselves as substantially overweight (Rozin and Fallon, 1988). Furthermore, white middle-class American women are more worried about being above ideal weight than are men; that is, even when men recognize that they are overweight, food is less likely to become a source of fear and guilt for them.

Although food is obviously a necessity for survival, potentially harmful effects on health of certain foods have come to be a matter of concern for many Americans. This recent concern results from a number of factors:

1. The reduction in death from infectious diseases has produced a corresponding increased incidence of death from degenerative diseases. This changes the focus of food risk from acute to chronic effects.
2. Epidemiological evidence on harmful effects of food, which is accumulating at a rapid rate, is conveyed to a public fascinated with such information in a salient – even sensational – way by the media.
3. Americans have become obsessed with longevity, or perhaps, immortality.
4. Americans (and others) are unprepared to deal with and evaluate the constant wave of food (and other) risk information to which they are exposed. They have never been taught cost–benefit analysis or interpretations of very low probabilities and have beliefs about food that are often incorrect. For example, many believe that if something is thought to be harmful at high levels, then it is also

harmful at trace levels. Such dose insensitivity causes some to shun even traces of salt, fats, or sugars (Rozin, Ashmore, and Markwith 1996). In addition, many Americans falsely believe that "natural" foods are invariably healthy, and processed foods are likely to be harmful. In fact, over the short term, the opposite is clearly true (that is, acute illness is more likely to be caused by natural foods), and there is reason to believe that in many cases, the long-term risks posed by the consumption of natural foods are higher than those posed by processed versions of the same foods (Ames et al. 1987). The centrality of food in life and the great concern about putting things in the mouth and body probably causes people to overestimate long-term food risks in contrast to other risks, such as driving.

The result is that eating, which is one of the greatest sources of pleasure and health that humans can experience, has become a nightmare for some and, in fact, threatens to become an American cultural nightmare. We can only hope that this obsessive concern does not, like so many other attitudes and beliefs of Americans, spread around the world.

Paul Rozin

Notes

1. See Rozin (1976) and Rozin and Schulkin (1990) for more detailed discussions of the biological and psychological frameworks for human food selection.
2. More extended reviews of the area covered in this chapter can be found in the volumes of collected papers by Barker (1982), Dobbing (1988), Shepherd (1989a and 1989b), and Thomson (1988); in books by Fischler (1990) and Logue (1991); and in specific review articles by Birch (1986), Blundell (1983), Booth (1982), Krondl and Lau (1982), Meiselman (1988), Pangborn (1980), P. Rozin (1982), Rozin and Schulkin (1990), Rozin and Vollmecke (1986), and Schutz and Judge (1984). Major historical summaries of basic points of view on food selection include those by Mead (1943), Richter (1943), and Young (1948).

VI.12 Food Fads

The term "food fad" often refers to socially deviant, cultlike eating behavior. Examples include diets that contain massive amounts of supposedly healthy foods, such as garlic; those that prohibit the consumption of allegedly hazardous products, such as sugar or white bread; and those that emphasize natural foods and question the purity of goods available in supermarkets (Fieldhouse 1986). Charlatans claiming to have discovered nutritional fountains of youth and cures for cancer become best-selling authors overnight, only to disappear shortly afterward. But they are not the only promoters of culinary fads. The *Webster's Third New International Dictionary* defines *fad* as "a pursuit or interest followed usu. widely but briefly with exaggerated zeal. . . ." Sophisticated diners who flock to Ethiopian restaurants one month and to Thai restaurants the next thus qualify as faddists but not necessarily as deviants.

That a food or group of foods is especially health promoting serves as the most characteristic claim of food faddists, both wild-eyed cult leaders and bottom-line business executives. Nevertheless, profit and power often provide unspoken motivations behind the crusades of both groups. Moreover, the nutritional science used to back assertions of healthfulness has developed in a halting, incomplete, and often contradictory manner. This chapter evaluates the validity of many of these nutritional claims while it examines a wide range of food fads that have appeared throughout the world, particularly in the last two centuries, in the contexts of the spread of industrial capitalism, the concern for moral standards, and the creation of social identity.

Food and Industry

Prior to the age of industrial capitalism, fads of any sort were limited to a small elite. Peasants living at the edge of subsistence simply could not afford to experiment with fashions that were soon discarded. With the rise of mass production, however, disposable goods became not only a possibility but almost a necessity: Planned obsolescence, for example, allowed auto makers to continue producing cars although virtually everyone already owned one. The imperatives of food marketing led to product differentiation as manufacturers sought to market ever greater quantities of food, and culinary fashions changed with startling speed in the restaurant industry's fiercely competitive environment. Food fads have also spread throughout the world in recent decades as multinational corporations have cultivated markets in developing countries.

Cuisine and Capitalism

The rise of European industrial capitalism depended on a surplus of workers, which required a corresponding surplus of food. Quantitative increases in the food supply resulted from an eighteenth-century agricultural revolution, but at the same time, European diets underwent qualitative changes as well. Anthropologist Sidney Mintz (1985) has shown that refined sugar from Caribbean colonies became an essential part of British working-class diets. Whether drunk with tea or eaten in jam, sugar provided the cheapest possible source of energy for workers and thus helped hold down industrial wages. The role of sugar continued to grow as food manufacturers expanded their control over world markets. In ongoing efforts to increase sales, advertisers have launched countless new food fads in the hope that they would become cultural icons.

Sociologist Jack Goody (1982) has identified four basic components in the industrial transformation of food: improvements in preservation, mechanization, transportation, and retailing. Salt, sugar, and vinegar had long been used to preserve food, but modern canning dates only to 1795, when French chef Nicolas Appert combined pressure cookers with glass bottles to help supply Napoleon's armies. Nineteenth-century technological improvements allowed the substitution of cheaper tin cans for bottles and permitted the mass marketing of canned fish, meat, vegetables, condensed milk, and prepared foods. At the same time, artificial freezing of meats became widespread, although frozen vegetables remained impractical until the early–twentieth-century development of moisture-proof cellophane wrapping.

Mechanization, in turn, allowed the mass production of canned and frozen foods, which the steadily improving transportation methods, such as steamships and railroads, carried to distant markets. Finally, these foods were distributed to consumers through a nineteenth-century revolution in retailing. Grocers, who formerly had specialized in small-scale, nonperishable luxury goods, such as spices, tea, and sugar, took over the trade in canned goods. As this market grew, such grocers as Thomas Lipton built chains of stores and, ultimately, incorporated butchers, bakers, and other traditional food suppliers into new supermarkets.

The food-processing industry made its most dramatic advances in the 1950s, a decade when food scientists seemed to have discovered the legendary philosopher's stone. These modern alchemists could grant virtual immortality to foods, and if they failed to create gold, Twinkies came pretty close. With chemical preservatives, breads lasted longer, vegetables maintained their color, and fats did not go rancid. At the same time, vitamins, hormones, and antibiotics increased livestock productivity. Artificial flavors and colors even made it seem possible to do away with plants and animals entirely: A General Foods researcher claimed that there were not enough strawberries grown in the world to meet the demand for Jell-O (Levenstein 1993).

Demand for industrial food products, such as strawberry Jell-O, derived largely from modern marketing techniques, including branding, packaging, and advertising. An early pioneer in this field was the National Biscuit Company, which came to dominate the soda-cracker industry at the turn of the twentieth century. Nabisco packaged its crackers in waxed-paper wrapping to convey a sanitary image quite different from that of the crushed and moldy crackers available in general stores' cracker barrels. In 1899, the company adopted a distinctive, if rather corny, brand name, the "Uneeda" cracker, and with heavy advertising, it captured 70 percent of the American cracker market. Imitators came up with similar names, such as "I wanta cracker" and "Hava cracker," but lacking Nabisco's enormous advertising budget, they proved commercial failures (Levenstein 1988).

Marketing techniques have become more sophisticated with the growth of mass media. Children in particular are the targets of television advertisements for junk foods, such as Chocolate Frosted Sugar Bombs. A recent study found that the odds of a child's being overweight go up by 2 percent for every hour per day spent watching television (O'Neil 1994). Although obesity is not solely a function of watching television, modern marketing techniques can be enormously successful in creating a demand for new foods. For example, Pringles "newfangled" potato chips, made by Procter and Gamble in a Tennessee factory from dehydrated potato mash and shipped across the country in tennis ball cans, seemed a particularly unlikely commercial venture. Nevertheless, with the assistance of a $15 million advertising campaign, the product captured 10 percent of the national market despite the fact that it tasted, as a company executive admitted, "more like a tennis ball than a potato chip" (Levenstein 1993: 197).

Retailers, likewise, contributed to the proliferation of new products. Supermarket chains, in their ongoing effort to maximize sales, stocked ever greater numbers of manufactured foods. Trendy new items were displayed in conspicuous places – at eye level on shelves and at the ends of aisles – where they were more likely to be purchased. Marketing research also found that simply having a superabundance of foods on hand encouraged people to buy more. This "virtuous circle" has seemed to fulfill the capitalist dream of production feeding consumption in never-ending succession. Perhaps the greatest threat to supermarket sales has come not from declining consumption of processed foods but, rather, from the ever-greater convenience offered by fast-food restaurants (MacClancy 1992).

The Rise of Restaurants

Culinary legend credits the French Revolution with having launched the modern restaurant industry. With noblemen fleeing the country or facing the guillotine, great chefs supposedly offered their services to the newly ascendant bourgeoisie by opening restaurants. But in fact, restaurants had already existed for centuries in England and had even begun to spread to the Continent before 1789 (Mennell 1985). Given the French stereotype of being a nation of cooks, it is not surprising that they have claimed the restaurant as their own invention. With more recent trends in fast-food chains, however, it seems only just that history returns the birthplace of the restaurant to its native "nation of shopkeepers."

There may be some truth in the French claim, however, for French haute cuisine reached its highest peaks in nineteenth-century Paris. Chef Antonin Carême (1784–1833) developed an architectural approach to cuisine, not only in the sculpting of elaborate centerpieces but also in the harmonious blending of multiple flavors. He constructed his dishes meticulously from the *fonds* up, adding, extracting, reducing, and garnishing, yet arriving in the end at a simple and unified whole. His successor, Auguste

Escoffier (1846–1935), codified these techniques in the 1902 *Guide Culinaire,* which provided a standard reference work for future chefs.

The consumers of this haute cuisine consisted exclusively of the rich, for no one else could afford its costly ingredients and rarefied preparations. Carême spent his final years working for the Baron James de Rothschild, whereas Escoffier and his partner, César Ritz, founded some of Europe's finest hotels. Their wealthy clients demanded more than refined cuisine; they also wanted constant novelty, preferably in the form of new dishes named in their honor, such as Escoffier's melba toast, named for Austrian opera singer Nellie Melba. Constantly searching for new recipes, chefs often turned for inspiration to traditional peasant dishes, which they transformed by substituting expensive truffles and caviar for more rustic ingredients. The results of this faddish search for novelty are cataloged in Escoffier's *Guide Culinaire,* with its almost 3,000 recipes (Mennell 1985).

It is no oxymoron to speak of a haute cuisine fad, for although few could afford to eat at the great hotels, their cooking styles were followed widely by lesser restaurants in late-nineteenth-century Paris. Jean-Paul Aron (1979) has shown that expensive cuisine became affordable to the masses through the creative use of leftovers. Paris supported thriving networks for distributing secondhand foods, and as the meats and vegetables got older, the sauces covering them got thicker. Fraudulent restaurants displayed counters full of fresh fruits, meats, and vegetables, but these foods were only rented, and clients actually received nothing but leftovers. Even the wine was bad, pressed as it was from the bloated grapes of overfertilized vines, blended with grain alcohol for added bite, then adulterated with plaster to deepen the color (Loubère 1978).

Concern about impure food in the United States led to perhaps the most important development in the modern restaurant industry, the franchise system. Chains, such as the Fred Harvey System, had long catered to traveling Americans, but although they offered reliable service, the corporate owners often had difficulty finding managers who could turn a profit. Howard Johnson, a Massachusetts businessman, solved this problem in the 1930s by creating a franchise system in which individual owner-operators managed the restaurants and paid royalties to the parent company. Gleaming orange porcelain tile not only advertised the restaurants' cleanliness but was also visible to motorists miles away. Franchising truly came of age in the 1950s, when "Ronald McDonald" became surrogate uncle to the baby-boom generation. McDonald's appealed to suburban families by offering immediate service, made possible by assembly-line grills and drive-through windows. But competing chains soon appeared, and just as the great chefs of Europe struggled to create new dishes, McDonald's, Burger King, and Kentucky Fried Chicken marketed countless food fads, from the now-extinct Hulaburger to the seemingly immortal Egg McMuffin (Love 1986; Levenstein 1993).

While fast-food chains sprouted across the landscape, and even gourmet restaurants began using frozen vegetables, a new trend appeared at the highest levels of the restaurant universe. The *nouvelle cuisine* of the 1970s insisted on the use of only the freshest ingredients in the kitchen. Inspired by the great Fernand Point (1897–1955), who shunned Paris to operate a small restaurant in Vienne, the *nouvelle cuisiniers* became chef proprietors in provincial towns. What made their style unique was not the artful decoration of plates borrowed from the Japanese, or the minuscule portions, which led to confusion with the haute dieting of Michel Guérard's *cuisine minceur.* Instead, as Raymond Sokolov (1991) notes, the new recipes parodied rules laid down at the turn of the century by Escoffier. The salmon scaloppine with sorel sauce of Jean and Pierre Troisgros followed the procedure for pounding veal into thin scallops but resulted in a different, more delicate taste. Such chefs as Paul Bocuse eventually rose to become globetrotting show-business stars, although from that status it was a quick tumble to obscurity.

The nouvelle cuisine attracted perhaps its most devoted following in California, which has always been a natural location for restaurant fads. Trendy chefs wore the spokes off their exotic-ingredient wheels of fortune in the 1980s, and enterprising restaurateurs were willing to invest in any theme, no matter how bizarre. Such places as the Bombay Bicycle Club, Orville Bean's Flying Machine, and Thank God It's Friday each had appropriate wall decor, if not menus. Meanwhile, Ed Debevic's, an upscale version of greasy-spoon diners, demonstrated the powerful appeal of restaurant nostalgia. Owned by Chicago's Lettuce-Entertain-You Restaurant Corporation, Debevic's attempted to recreate the "Happy Days" of the 1950s, but at least one skeptical patron had to ask her gum-smacking waitress: "Is this place fun, or is it just pretending to be?" (Belasco 1993: 241; Gutman 1993; Levenstein 1993).

Coca-Colonization

Critics might question the ambience of restaurants like Debevic's, but no one could doubt the profitability. With annual revenues of more than $4 million per restaurant, the only question for executives was how to grow further, and the answer seemed to lie in global expansion. Food manufacturers had been building international networks for more than a century. Kellogg's shipped breakfast cereals to Europe, Hormel marketed Spam in Latin America, Nestlé sold baby formula in Africa, and Coca-Cola distributed its bottles just about everywhere. But it was not until the 1970s that McDonald's led fast-food franchises into a search for global markets. Once the process had begun, golden arches sprang up in large cities everywhere, and the Big Mac seemed destined to become the culinary standard for middle-class consumers across the planet.

The success of international food marketing derived largely from the prestige value of its Western origins. In peasant societies around the world, the high cost of canned spaghetti and Spam gave these products status appeal far beyond their intrinsic culinary value (Kalčik 1984). Fast-food chains purposely resisted adapting to foreign tastes, calculating that their American origins would maximize sales. Kentucky Fried Chicken, for example, boosted sales in Japan with clever advertisements showing Americans eating the Colonel's chicken for Thanksgiving dinner. One Japanese executive even claimed that "if we eat McDonald's hamburgers and potatoes for a thousand years, we will become taller, our skin will become white, and our hair blonde" (Love 1986: 426).

Not all Japanese wanted white skin and blond hair, however. Many people rejected the foreign products and assumed ultranationalistic attachments to domestic foods, such as rice. More commonly, non-Western nations created industrialized versions of their own native cuisines. Japanese children ate tuna-fish crackers, while their Mexican counterparts munched pork-rind–flavored chips. Coke and Pepsi competed in Asia against local brands of ginseng cola. Unlike McDonald's, they increased sales by reformulating their syrup to suit indigenous tastes, typically by making them even sweeter than the American versions. So even as international capitalism worked to create a homogeneous world cuisine, it also contributed to ethnic diversity.

Food and Morality

Connections between diet and morality are common throughout world history. Jewish and Moslem dietary laws, for example, defined pork as unclean and prohibited its consumption. Many followers of Buddha went further and, out of a belief in reincarnation, abstained from all animal products. Confucius laid down social rather than religious rules for the correct preparation and consumption of foods. Because of their ancient heritage, none of these beliefs qualify as fads. Yet modern advocates of dietary restrictions – branded charlatans, and often with good reason – make similar claims that certain foods must be avoided as either polluted or sacred.

Victorian Movements

Sylvester Graham (1794–1851) originated modern food fads in the United States. About 1830, this Presbyterian minister from Connecticut developed a theory of health and morality he called "the Science of Human Life." He claimed that "natural" living was the secret to happiness and was the only way to avoid the menace of "dyspepsia" or indigestion, at the time a widely feared affliction. The two greatest dangers to a natural life were an improper diet and sexuality. Graham warned his followers to avoid highly seasoned food, rich pastries, and, especially, meat. These foods stimulated the body, provoked sexual activity, and led to irritation, inflammation, and debility. Physical excitement, in turn, impaired spiritual health; vegetarianism, thus, became vital to personal salvation. Graham lectured up and down the Atlantic coast, building a loyal following and providing a model for future food faddists.

Historian Stephen Nissenbaum (1980) has found the key to Graham's crusade in his namesake bread. Graham decried the widespread consumption of commercially baked white bread and called for a return to coarse, homemade, whole wheat "Graham" bread (very different, despite its name, from the modern "Graham cracker"). The problem lay not in the loss of nutrients from removing the bran; instead, he concluded, white bread was too nutritious for the human body to digest. The additional bulk of whole wheat helped to balance the diet and prevent the alarming excesses caused by the consumption of white bread. According to Nissenbaum, the true concern was not the type of flour but, instead, the rising commercialization of production and the imminent breakdown of family life in Jacksonian America. Graham bread represented a return to a simpler subsistence lifestyle, sheltered by family values from the vagaries of the market economy.

The future of Graham's bread lay, ironically, in the breakfast cereal industry. Dr. James C. Jackson (1811–95), a recovered dyspepsia patient, created the first of these breakfast foods in 1863. "Granula," as he called it, consisted of Graham flour and water, formed into thin sheets and baked, then ground and baked again. The product proved a commercial failure, however, because it had to be reconstituted overnight in milk to provide an edible consistency. This drawback was later overcome by Dr. John Harvey Kellogg (1852–1943), a member of the Seventh-Day Adventist Church, who had adopted Sylvester Graham's dietary doctrines. Kellogg served "Granola" at the Adventist's sanitarium in Battle Creek, Michigan, to patients who included John D. Rockefeller, Theodore Roosevelt, and Amelia Earhart. However, a copyright infringement suit by Jackson prevented him from marketing the product. In 1895, Kellogg and his younger brother Will Keith (1860–1951), who actually founded the eponymous corporation, perfected a ready-to-eat breakfast cereal of wheat flakes, then proceeded to develop corn and rice flakes. But what ultimately made Battle Creek's breakfast cereal industry successful was not the convenience of Kellogg's corn flakes but rather the advertising genius of rival Charles W. Post (1854–1914), who made millions selling his own brand of wheat flakes with outlandish patent medicine claims (Carson 1957).

The Reverend Graham and Dr. Kellogg shared their vegetarian doctrines with European counterparts, such as the German clergyman Eduard Baltzer (1814–87). Influenced by Christoph Wilhelm Hufeland's 1796 work, *Makrobiotik,* which described magical forces for prolonging life, Baltzer published his four-volume *Die natürliche Lebensweise* (The natural way of life), a treatise on vegetarianism, from 1868 to 1872, and also founded Germany's first vegetarian club (Kühnau 1970).

The Victorian preoccupation with dyspepsia gave health advocates an enormous concern for regular bowel movements. Kellogg and others considered three trips to the lavatory a daily minimum. To assure this routine, young boys, in particular, received enemas and mineral oil, for cleansing the body was believed to be the only way of preventing less healthy outlets, such as masturbation. British Prime Minister William E. Gladstone himself stated that to assure proper digestion (and, presumably, regularity), he chewed each bite of food 32 times, once for each tooth. American businessman Horace Fletcher (1852–1919) took this advice to the extreme and chewed food until it dissolved in his mouth. He considered 32 chews sufficient for a piece of bread but claimed that a shallot had once required 720 chews. Although mistaken in his belief that digestion took place in the back of the throat, Fletcher produced remarkably odor-free stools, which he distributed freely by mail. Despite such promotional efforts, the chewing fad quickly passed, but the dream of healthy bowels lives on with the popularity of high-fiber bran cereals (Levenstein 1988; MacClancy 1992).

Nineteenth-century food faddists, although they seem absurd to modern science, nevertheless made a number of sound points. Vegetarian diets with large quantities of whole grains contrasted favorably with the carnivorous appetites of wealthy Victorians. Frequent complaints of indigestion and constipation seem quite understandable among people who consumed beefsteak, mutton chops, corned beef hash, scrambled eggs, fried potatoes, and hot cakes for breakfast (Levenstein 1988).

Science, Reform, and Fads

Elite banquet tables attracted the criticism of scientists as well as faddists. Harvey Levenstein, in a pathbreaking, two-volume social history of food in the United States (1988, 1993), examined how nutritional science affected American diets. Beginning in the late nineteenth century, home economists, the extension agents of this new science, attempted to transform the nation's eating habits. They particularly deplored the diets of newly arrived immigrants, such as Italians, Slavs, and Jews, but immigrant cooks clung tenaciously to their Old World recipes. And contrary to the reformers' expectations, popular awareness of nutrition opened fertile ground for a new generation of food faddists.

Chemists Wilbur Atwater and Ellen Richards initiated the study of domestic science in the United States in the 1880s. Using nutritional methods developed several decades earlier by German researcher Justus von Liebig, they attempted to determine the most efficient way to feed people the required proteins, carbohydrates, and minerals. The ideal diet, they concluded predictably, consisted of New England dishes, such as pressed meat, creamed codfish, boiled hominy, baked beans, and Indian pudding. The only acceptable seasoning was a bland white sauce. Home economists, seeking to gain scientific respectability, distanced themselves from mere cooking teachers, a field in which they perhaps recognized their own incompetence. As a result, they emphasized accuracy over taste, giving students scientifically precise recipes and warning them never to improvise in the kitchen (Shapiro 1986; Levenstein 1988).

Although middle-class housewives dutifully followed their textbook recipes for white sauce, no amount of coaching sufficed to persuade immigrants to give up their ethnic foods. Social workers tried in vain to convince Italian women of the inefficiency of paying high prices for imported pasta and cheeses. They had greater luck in changing the eating habits of children eager to fit in with their peers, even though the milk in school lunches often caused problems for lactose-intolerant ethnic groups. But these children counted as triumphs for the dietary reformers, who were more concerned about assimilating foreigners than improving their diets. Not until World War I, when Italy allied with the United States, did home economists concede that pastas offered an economical source of nutrition at a time of meat shortages (Levenstein 1988).

Dietary reform also became an important program for Mexican leaders around the turn of the twentieth century. They accepted the Victorian idea that spicy foods provoked immorality, and they blamed the disorderly behavior of the working classes on the consumption of chilli peppers. Mexican reformers, like their North American counterparts, established schools of domestic science to inculcate bourgeois family values among poor women. Educational kitchens took as their model diet the bland food of Britain, a drastic change indeed, and one that never caught on among Mexican cooks (Pilcher 1993).

The language of science appealed not only to elite reformers attempting to transform popular behavior but also to food faddists seeking to justify their outlandish claims. Dr. William Howard Hay, for example, used the difference between carbohydrates and proteins to explain eating disorders. This City University of New York medical school graduate developed a theory for the proper combination of foods. He believed that carbohydrates and proteins should never be eaten at the same meal because the body uses alkaline enzymes to digest carbohydrates whereas acids work on proteins. Thus, if a person ate both types of foods together, the alkalines and acids would neutralize one another, the stomach would be unable to digest anything, and the food would simply rot in the intestines. This posed a dilemma, for most foods contain both proteins and carbohydrates. Fortunately, although Hay's combining rules gained great popularity in the 1920s and 1930s, his theory was exposed as flawed because the alkaline enzymes operate in one part of the intestine and the acids in another (Pyke 1970; Deutsch 1977).

Hay's ideas about acids and alkalines, however, were carried to even greater extremes by Alfred W. McCann (1879–1931). A journalist in the muckraking tradition, McCann crusaded against food-processing firms with dramatic headlines that attracted both a wide popular following and numerous libel suits. He also predicted the imminent depletion of world food supplies and advocated the slaughter of all cattle to make grain cheaper. But his most outlandish claim was that Americans suffered from an epidemic of "acidosis." The causes of this supposed acid overdose ranged from improperly combined carbohydrates and proteins to eating meat and processed foods. The deadly effects, as McCann preached tirelessly in the press and on the radio, included "kidneycide" and heart attacks. In 1931, following a radio broadcast warning the public of the dangers of acidosis, McCann himself died of a heart attack (Deutsch 1977).

As with Graham, the food industry ultimately had the last laugh by turning McCann's crusades into advertising copy. The California Fruit Growers, for example, asserted that Sunkist brand citrus fruits actually had a beneficial alkaline effect despite their apparent acidity (Levenstein 1993). By the 1950s, food manufacturers had seemingly conquered American supermarkets with their myriad frozen, condensed, dehydrated, preserved, and otherwise processed products. But a backlash soon developed that revived many of the food fads of the nineteenth century.

The Counterculture Strikes Back

Like Upton Sinclair, who intended his 1906 book *The Jungle* as a radical call for socialism and instead contributed to a middle-class crusade for pure food, the late-1960s counterculture's attempt to overthrow industrial capitalism left one of its deepest imprints on the American diet. Food made an appealing medium of protest, both for its basic role in human life and because of the enormous changes effected by the food-processing industry. The radicals denounced such technological marvels as Wonder Bread, Minute Rice, and instant mashed potatoes, and echoing Sylvester Graham, they called for a return to natural foods, including whole wheat bread, brown rice, and wildflower honey. And although the majority of hippies ultimately abandoned their communes and reincorporated themselves into the society they had condemned, they did bring health foods and herb teas back with them into the mainstream (Belasco 1993).

The counterculture's pure-food protests grew out of news stories concerning the health hazards of pesticides and additives. In her 1962 book *The Silent Spring,* Rachel Carson warned that the pesticide DDT accumulated in the fatty tissue of both humans and animals with potentially fatal results. The U.S. Department of Agriculture insisted that the pesticide posed no danger; nevertheless, within a decade additional studies had confirmed Carson's claim, and the government banned DDT. And this was only the first wave in a flood of media revelations proclaiming the hazards of mercury in tuna, hormones in beef, arsenic in chickens, and carcinogens in bacon (Belasco 1993; Levenstein 1993).

Food-industry spokesmen, with the support of the U.S. Food and Drug Administration (FDA), responded by denying all charges against additives. Working on the theory that anything carbon was natural, they defended the use of petrochemicals as preservatives. They also observed that all foods contained carcinogens, which was true but begged the question of whether additives were in fact harmful in the quantities found in processed foods. Food lobbies' credibility suffered when the public learned of ties between scientific experts and the food industry. Frederick Stare, for example, founder of Harvard's Department of Nutrition and a leading crusader against food fads, testified in support of Kellogg's, Carnation, and other food corporations that donated large sums to his school (Levenstein 1993).

To avoid potential hazards in foods, the counterculture turned for guidance to organic gardening and to health-food experts, such as Jerome Irving (J. I.) Rodale (1899–1971). Rodale had founded the magazine *Organic Gardening and Farming,* in 1940, but had made little money because of the limited interest in compost fertilizers and natural insecticides. Another of his magazines, *Prevention,* was constantly accused of quackery by the medical establishment. By about 1969, however, such abuse by the medical establishment actually benefited Rodale; although by this time his son Robert had taken over editorial duties, hippies who rejected conventional authorities began to follow the Rodale gospel. Wilderness survivalist Euell Gibbons (1911–75) and vitamin supplement advocate Adelle Davis (1904–74) also enjoyed revivals. Perhaps the most persuasive arguments for the vegetarian cause came from Frances Lappé's best-selling *Diet for a Small Planet* in 1971. She relied on science, not mysticism, and based her diet on protein complementarity, those combinations of grains and legumes that supply the full range of amino acids needed for protein utilization. At the same time, her observations about beef cattle displacing peasants resonated with the moral outrage then being expressed by Vietnam War protesters (Deutsch 1977; Belasco 1993; Levenstein 1993).

Counterculture members, in search of social revitalization and alternate methods of health maintenance, often joined groups that were following natural and even mystical lifestyles. The most dedicated withdrew to agrarian communes, but the goal of independence proved elusive, and many survived poor harvests with the help of food stamps. Health-food stores and co-ops boomed during the early 1970s by offering more convenient sources of organically grown products. At the same time, large numbers of people formed communal kitchens, many of which grew into health-food restaurants. Mystical religious groups, such as the Hare Krishna and Divine Light, also contributed to the spread of health foods (Kandel and Pelto 1980; Belasco 1993).

Zen macrobiotics became one of the most controversial of the mystical health-food movements. Created by Japanese philosopher George Ohsawa (early in the twentieth century), macrobiotics applied the principles of yin and yang to food. Animal foods, such as meats and eggs, stood at the yang end of the spectrum while sugar and chemicals tended toward yin. The center included vegetables, fruits, and whole-grain cereals, and a diet of these foods represented the path to harmony with nature. Brown rice formed the exact midpoint, and this alone constituted the ideal macrobiotic diet. Unfortunately, nutritional-deficiency diseases began appearing in the Berkeley area, and in 1965, a young woman starved to death while seeking enlightenment. Nevertheless, macrobiotic restaurants attracted large audiences even among nonbelievers (Fieldhouse 1986; Levenstein 1993).

Other fads, such as the vitamin craze, penetrated deep into mainstream society. Megavitamin advocates claimed that when taken in sufficient quantities, vitamin C cured colds and other infections, whereas vitamin E improved sexual performance. Faddists even invented new vitamins, such as B_{15}, supposedly found in apricot kernels and capable of curing cancer. Scientific support for vitamins came from Nobel Prize–winning scientists Albert Schweitzer and Linus Pauling, and by 1969, half of all Americans regularly took vitamin supplements. Nevertheless, megavitamins provided questionable benefits. Excessive quantities – and some people advocated consuming hundreds of times the recommended daily allowances – of vitamins were simply eliminated by the body (Deutsch 1977; Levenstein 1993).

The health-food movement, considered a fad in the late 1960s and early 1970s, had become an important part of nutritional orthodoxy by the 1990s. Breakfast cereal manufacturers, some of the worst abusers of consumers' nutritional health, reformulated such products as Fruit Loops, Sugar Pops, and Cocoa Krispies to give them nutritional respectability. Meanwhile, artisanal bakers of crusty whole grain breads, although still no threat to the makers of Wonder Bread, have appeared throughout the country. And Alice Waters parlayed a communal kitchen for Berkeley radicals into Chez Panisse – one of the country's most innovative and respected restaurants (Thorne 1992; Belasco 1993; Levenstein 1993).

Food and Identity

Jean-Anthelme Brillat-Savarin (1755–1826), one of the pontiffs of French cuisine, affirmed the connection between cuisine and identity in his often abbreviated phrase, "Tell me what you eat, and I'll tell you who you are." One wonders how the venerable French gourmet would respond to modern food faddists recounting their gastronomic experiences. Certainly, he would find kindred souls among the new generation of globe-trotting gourmets, constantly seeking out variety among diverse ethnic cuisines. The legions of dieters starving themselves to attain fashion-model figures might be more difficult for him to comprehend. But most baffling of all would be the culinary changes wrought by modern technology and mass advertising.

The Obsession with Weight

Historian Hillel Schwartz (1986) dates the origins of the modern obsession with weight to the turn of the twentieth century. Although Victorian dyspepsia cures often resembled contemporary reducing diets, adherents hoped to gain a *feeling* of lightness, rather than to transform their outward appearance. But with the *fin de siècle,* fat went out of fashion. The husky men of Gilded Age banquets were condemned for their conspicuous consumption, while the voluptuous women portrayed in impressionist paintings turned to diets and exercise. Once the general trend toward slimness had begun, it proved difficult to stop. Feminine ideals fluctuated – the boyish flappers of the 1920s gave way to more rounded figures in the 1930s – but the overall trend headed ever downward, and by the 1960s, many considered film stars Marilyn Monroe and Jayne Mansfield to be overweight. The increasingly impossible standards of physical beauty encouraged countless fad diets.

Patent-medicine hucksters quickly saw the potential profits from dieting. Some were relatively benign, such as Jean Down's "Get Slim," which was simply pink lemonade, and Dr. W. W. Baxter's "phytolacca," a purgative found in the pokeberry, and supposedly eaten by overweight migratory birds. Other formulations proved more hazardous, such as "Helen's Liquid Reducer Compound," which promised in the 1930s that you could "Gargle your fat away!" with a compound of peppermint, bleach, and hydrogen peroxide. One of the most dangerous patent medicines of all was an obesity tablet marketed about 1910 that contained strychnine and arsenic (Deutsch 1977; Schwartz 1986).

As scientific knowledge advanced and the FDA's enforcement powers increased, patent medicines were replaced by liquid diets and prescription drugs. The former consisted of food powders mixed with water and taken in place of breakfast and lunch. Beginning in the 1930s with Dr. Stoll's Diet Aid, these milkshake-like concoctions have returned regularly to later generations under the names "Metrecal," "Naturslim," "Herbalife," and "Slimfast." The 1930s also marked the discovery of amphetamines as appetite suppressants. Although widely prescribed since the 1950s, often with barbiturates to offset the jitters, amphetamines lose their effectiveness after six to ten weeks. Pharmaceutical companies have nevertheless continued to search for dieting drugs, one of the latest being a fat-blocking pill that attempts to prevent the body from absorbing dietary fats (Schwartz 1986).

The diet industry has offered seemingly endless opportunities for market growth and product differentiation. In the 1950s and 1960s, dieters could turn for help to group therapy in TOPS (Take Off Pounds Sensibly), Overeaters Anonymous, and Weight Watchers. The latter company, founded in 1964 by Brooklyn housewife Jean Nidetch, had built revenues of $39 million in little more than a decade. By the 1980s, food manufacturers had focused much of their chemical wizardry on producing an amazing array of "lite" foods, including diet colas, low-calorie "spreads," low-fat cheese foods, light beers and wines, and diet frozen dinners (Schwartz 1986; Belasco 1993).

Self-proclaimed diet experts also kept a constant eye out for new gimmicks, in the process reviving many food fads from the past. Harvey and Marilyn Diamond, for example, in the 1985 best-seller *Fit for Life,* advocated a "natural" life of vegetarianism and Fletcher-style chewing and warned against the mixing of proteins and carbohydrates. Dr. Robert Atkins, meanwhile, had rediscovered the high-protein, low-carbohydrate diet first made famous by Englishman William Banting (1798–1878). *Dr. Atkin's Diet Revolution,* published in 1972, not only sold millions of copies but also served as advertising for his extremely lucrative weight-loss clinic. Susan Powter, author of the 1992 *Stop the Insanity,* reversed this plan and called for a high-carbohydrate, low-fat diet. Best known for her white, crew-cut hair, Powter also marketed highly successful aerobic exercise videos.

The dieting mania dramatizes the continued importance of food in the social construction of identity. Diet and exercise fanatics considered a fashionable body image, rather than health, the ultimate goal. And as the anorexia nervosa epidemic of the 1970s demonstrated, the pursuit of such a fashionable body can ultimately prove hazardous to the health. Actress Jane Fonda admitted that she had suffered from bulimia, making her both advocate and victim of the culture of slimness. It seems appropriate that such a culture first appeared in advanced capitalist countries because the contradictions inherent in this search for perfection have alienated large numbers of people from their own sources of nourishment.

The Ethnic Revival

Food helps define the identity not only of individuals but also of groups. Just as progressive dietary reformers used cooking classes as a means of assimilating immigrants in turn-of-the-century America, people in the postcolonial world have sought to counter Western capitalist hegemony by forging national cuisines. This culinary ethnic revival eventually began to colonize the United States through the combined efforts of talented immigrant cooks and adventuresome American eaters. The resulting mixtures have enriched the diets and tastes of both groups.

Cookbooks defining national cuisines have recently emerged throughout the postcolonial, postindustrial world, and in some places, middle-class women, searching for a national identity to replace colonial ideologies, have often turned to indigenous folk traditions. In Mexico, such traditions have revived the popularity of peasant foods (for example, maize tortillas and tamales), which had formerly been snubbed as Indian foods by both Spanish and Creole elites. Following the revolution of 1910 and the resulting search for Mexico's indigenous roots, an emerging middle class embraced tamales as national symbols. In much the same way, Egyptians proclaimed their patriotism by eating *ful medames,* a peasant bean dish, while Brazilians honored *feijoada,* a combination of meats, beans, and rice similar to African-American "soul food" (Roden 1972; Oliven 1984; Pilcher 1993). In India, the national revival did not seek out lower-class traditions because of strict caste laws about purity. Instead, as Arjun Appadurai (1988) notes, cookbooks allowed middle-class women to experiment with regional recipes and thus eliminate ethnic barriers to Indian nationalism.

As national cuisines appeared in many countries, gastronomic pluralism gained new acceptance in the United States. Historian Donna Gabaccia (1998) shows how ethnic businesses packaged Chinese, Mexican, Italian, and other foreign foods for mainstream American consumers. These enterprises often began as neighborhood restaurants and grocery stores, and although catering at first to immigrant communities, they had to adapt to produce available in the United States. Chow mein, for example, was invented in San Francisco by an immigrant Chinese cook. Recipes often needed further alterations to attract wider audiences, as Italians found when they sold more tomato sauce by limiting the garlic, which most Americans found distasteful. Such modified ethnic foods often gained great popularity; salsa sales recently surpassed those of catsup in the United States. Ethnic identities themselves became blurred by constant mixing as the culinary melting pot produced such hybrids as taco pizza.

Many consumers rejected this trend and sought out more authentic versions of foreign cuisines. Sophisticated diners in the 1960s and 1970s, led by Craig Claiborne of the *New York Times* and Gael Greene of *New York Magazine,* discovered new dialects of French, Italian, and Chinese in the regional cuisines of Provence, Lombardy, and Sichuan. From there it was a small step to the foods of Thailand, Turkey, Ethiopia, and Argentina. In the 1980s, residents of New York City, Washington, D.C., and San Francisco had to work full time just to keep up with the latest fads in Afghan, Moroccan, and Peruvian restaurants. And those bold enough to seek out ethnic grocers could reproduce exotic dishes at home with the help of cookbooks by Diana Kennedy, Claudia Roden, Ken Hom, and Paula Wolfert or the excellent series by Time-Life Books. Alternately, cooks could follow Jane and Michael Stern across the interstate highway system to sample the regional foods of the United States (Barr and Levy 1984; Levenstein 1993).

The search for ethnic and regional variety eventually percolated down to that culinary lowest common denominator, the fast-food franchise. Taco Bell, the most successful example, mass-marketed a bowdlerized version of border cuisine, while the Golden Wok and Teriyaki Express served up Asian-style fast foods, and Wienerschnitzel claimed German ancestry for its hot dogs. Meanwhile, the drive-through menus of major chains featured regional American dishes, such as McDonald's southern-barbecue–inspired McRib sandwich, and Arby's Philadelphia steak and cheese sandwich. Perhaps the greatest variety in ethnic fast food can be found, appropriately, in the food court of any neighborhood shopping mall. Adolescents searching out new styles in clothes or the latest in music can now take a break for the most recent food fad.

The Meal Is the Message

The pursuit of fashion, whether in food, dress, music, or automobiles, preoccupies many in modern society. People spend enormous sums keeping up with the latest trends, investing not only their money but also their personal identity in constantly changing commodities. For fashionable elites, being seen in the newest restaurant is more important than the meal itself, while the success of a dinner party depends on serving food that the guests have never before tasted. Fashion's arbitrary whims, likewise, facilitate contradictions, such as "lite" foods that are low in fat but high in sodium. As fads come and go, social norms seem increasingly arbitrary, and moral behavior, ultimately, loses all meaning (Finkelstein 1989).

Roland Barthes (1979) notes further that mass-marketed food has expanded far beyond the dining room, invading all aspects of modern life. Snack foods and TV dinners have made eating a part of the media experience; drive-through windows have transformed dashboards into lunch counters (Levenstein 1993). At the same time, the social implications of eating have changed as fast-food combo meals and individually packaged frozen dinners have replaced the traditional family dinner pot. Each person seemingly has greater freedom of choice, yet choices are actually often determined by marketing executives in corporate offices (Mintz 1985).

Important changes have occurred in the production as well as the consumption of food. The alienation of cook from food had already become apparent by the 1950s when cake-mix manufacturers changed the recipe on the boxes to include eggs and oil – at first they required only water – so that people would feel they were actually doing something (Levenstein 1993). But more fundamentally, as John Thorne (1992) has pointed out, the oral culture of the kitchen is being replaced by the written word, and with it an artisanal approach to cooking is giving way to science. Microwave ovens and food processors have taken over the demanding skills needed at the cutting board and over the stove, while cookbooks with fixed recipes, exact measures, and precise times have obviated tasting, smelling, or even watching what is going on in the kitchen. Ironically, a rapid growth in cookbook sales has coincided with a sharp decline in the number of meals eaten at home (Shapiro 1994). Cookbooks have gone from utilitarian kitchen manuals to glossy coffee-table books, travel guides, and parodies, such as the 1989 *Manifold Destiny: The Only Guide to Cooking on Your Car Engine* and *The Bubba Gump Shrimp Co. Cookbook,* which appeared in 1994.

These changes do not necessarily herald the culture of annihilation predicted by Umberto Eco (1968). Mass culture, according to Eco, relies on simple, repetitive formulas, such as commercial jingles, that deny consumers any form of participation in producing and interpreting the message. Yet even, or perhaps especially, small children are far from the defenseless consumers assumed by Eco. Recall the oft-repeated tale of Pop Rocks, a candy that fizzes in the stomach like carbonated water. Some nameless youth of urban legend supposedly ate a bag of Pop Rocks, washed them down with a cola, and then exploded. This story, in its very childishness, reveals a world far different from that of television's Pepsi Generation.

Food has long provided rich material for anthropologists seeking to interpret societies, and in the modern world this symbolic wealth is particularly great in the recent fad of food movies. The darkest fears of Barthes and Eco are played out in the film *Age of Innocence* (1993), where lavish depictions of Delmonico's haute cuisine have more appeal than do the repressed members of Gilded Age high society. Nevertheless, food can also serve as a means to personal fulfillment, both spiritual, in *Babette's Feast* (1987), and sexual, in *Like Water for Chocolate* (1992); both in the workplace, as in *Tampopo* (1987), and at home, as in *Eat, Drink, Man, Woman* (1994). The meaning of food fads, whether they annihilate individual judgment or facilitate culinary expression, must ultimately be decided anew as each philosopher gazes into his or her Cuisinart.

VI.13 Food Prejudices and Taboos

Over the past 2,000 years, scholars have produced a vast literature on food prejudices and taboos. This literature, however, is complicated by confusing etymology and indiscriminate or inconsistent application of several terms, such as food aversions, avoidances, dislikes, prejudices, prohibitions, rejections, and taboos/tabus.

The term *aversion* is used by food-habit researchers primarily in the context of disliked or inappropriate foods, whereby individuals elect not to consume items because of specific, defined, biological or cultural criteria. Some human food aversions, for example, are immediate as when foods are tasted and disliked because of sensory properties of odor, taste, and texture. Other foods are avoided because of biological-physiological conditions posed by nausea and vomiting, "heartburn" or "acid stomach," intestinal distress associated with flatulence, or acute diarrhea. Still other food aversions are cultural or psychological in origin, as evidenced when individuals report that they dislike specific foods even though the items have never been consumed by them. In such instances, anticipation triggers avoidance or aversive behavior, and merely the color, shape, or images of the food source itself are enough to elicit aversion and the individual decision not to eat.

The word *taboo* or *tabu,* in contrast, implies a moral or religious context of foods or food-related behavior. Taboo, the Polynesian concept to "set apart," includes the suggestion that some human activities, and eating behavior specifically, may be either protective or deleterious to the environment, to the consumer, or to society at large. Food-related taboos in this context are identical to dietary prohibitions, whereby foods and food-related behaviors are forbidden for specific positive or negative reasons.

Attached to food prohibitions and taboos are a broad range of ecological, economic, religious, and social attributes that define intake restriction. Thus, consumption of prohibited foods may produce serious consequences for individuals, groups, and societies at large, and as a result, violators may face personal and social condemnation. Some taboos may be imposed to protect food crops at specific periods of the growth cycle, whereas other food-related practices may be instituted to distribute economic gain more effectively among individuals or groups in society. Most food-related taboos, however, are religious in nature and are imposed to provide structure and to regulate individual and social behavior.

Although individual food dislikes may lead to food rejection and, ultimately, to food prejudice, food dislikes are not dietary prohibitions or taboos. Nor are food aversions. Taboos, in essence, have their basis in behavioral, ecological, and religious strictures. Accordingly, all food-related taboos result in avoidance behavior – but food-related avoidance patterns may not result in taboos.

Approaches, Paradigms, and Themes

Scholars interested in the origins, development, and evolution of food prejudices and taboos range from professionals in the humanities to researchers in the biological and medical sciences (Frazer 1935; Gaster 1955; Simoons 1961, 1978; Douglass 1977; Grivetti 1978a, 1981a). The literature presented within this broad spectrum poses a basic conflict. Anchored at one end are representative descriptive studies where explanations for food-avoidance behavior and dietary taboos are set within concepts of folklore and mythology and where magic and superstition play important interpretive roles.

In opposition to this approach are studies by researchers who reject such empiricism and seek scientific understanding of and validation for human food-related behavior. Some scholars argue that there is logic in the so-called protective magic of food taboos, whereas others seek the rationale for dietary prohibitions in causal relationships between ingestion and manifestation of disease.

A review of food-habit literature from antiquity to the twentieth century reveals that scholars have advanced at least 11 hypotheses to explain the origins of dietary codes (Grivetti and Pangborn 1974; Grivetti 1980):

1. Aesthetics: Prohibitions are instituted because the appearance, behavior, source, or origin of certain foods is aesthetically revolting, contaminating, or polluting to humans (Douglas 1966).
2. Compassion: Prohibitions are intended to demonstrate human compassion toward specific animals that might otherwise serve as food resources (Scott 1866; Chadwick, 1890).
3. Divine commandment: Prohibitions have their origins in instructions directly to humans by a god, priestly intermediaries, or other cultural authorities. Adherents reject twentieth-century attempts at scientific enquiry and explanation (Singer 1907).
4. Ecology: Prohibitions evolve because of logical interrelations between human economic systems and the environment that ultimately determine which foods will be favored or rejected (Harris 1972, 1973).
5. Ethnic identity: Prohibitions are instituted to strengthen ethnic bonds that reinforce cultural identification by setting practitioners apart from food-related practices of other societies (Mays 1963).
6. Health and sanitation: Prohibitions reflect religious or medical insights on causal associations between ingestion and disease or illness (Arrington 1959).
7. Literary allegory: Prohibitions are not directed toward food, per se, but serve instead as oblique references to other behavioral, cultural, or political nonfood practices (Novatian 1957; Ginzberg 1961).
8. Natural law: Food-related behaviors and prohibitions are instituted to reinforce concepts of compassion and to identify abominations and define "unnatural" appetite gratification (Mackintosh 1959; Cook 1969).
9. Self-restraint/denial: Prohibited foods, once highly desired, are forbidden by priests or other cultural authorities to reduce gastronomic pleasure and to teach and reinforce moral discipline (Kellogg 1899).
10. Staple conservation: Prohibitions and taboos are established to conserve and extend the food supply, thereby improving human survival potential during periods of environmental crisis or conflict (Thompson 1949).
11. Sympathetic magic: Food prohibitions are related to specific behavioral or physical characteristics of animals and qualities that humans wish to avoid (Frazer 1935; Gaster 1955).

Although there have been thousands of descriptions of food and food-related taboos from antiquity into the twentieth century, contemporary analysis of how and why dietary prohibitions have evolved and how taboos and practices stabilize social and ethnic groups stems from the classic studies of food patterns and human food-related behavior in southern African societies (Richards 1932, 1939; Willoughby 1932).

Regarding thematic approaches taken by researchers on food prejudices and taboos, the most attractive and recognized theme has been religion, given the extensive literature on the dietary taboos of the major world faiths as exemplified by (1) Judaism (Kaufman 1957; Korff 1966; Cohn 1973; Dresser 1979; Regenstein and Regenstein 1979, 1988, 1991); by (2) Christianity (Hehn, 1885; Simoons 1961; Knutsson and Selinus 1970; Bosley and Hardinge 1992; Pike 1992); by (3) Islam (Roberts 1925; Sakr 1971, 1975; Grivetti 1975; Rahman 1987; Twaigery and Spillman 1989; Chaudry, 1992); and by (4) Hinduism (Harding 1931; Prakash 1961; Grivetti 1991a; Kilara and Iya 1992).

Gender and age are perhaps the second most common theme, and especially the question of how dietary prohibitions or taboos reinforce sex roles in society and characterize rites of passage, such as birth, coming of age, marriage, and death (Frazer 1935; Gaster 1955; Douglas 1966, 1977; Garine 1972).

A third common theme involves protection and takes two directions. One of these focuses on the question of whether dietary prohibitions are protective medically or nutritionally to humans (Bolton 1972; Jelliffe and Jelliffe 1978). The second has to do with whether dietary taboos protect the cultural-ecological setting of different societies and provide a balance to human use of environmental resources (Heun 1962; McDonald 1977).

Religion

Many religious practices that developed in antiquity and still regulate human behavior and social activities are known from accounts written in ancient Egypt and also stem from the religious practices and dietary codes of Judaism, Christianity, Islam, and Hinduism.

Ancient Egypt

The Nile Valley civilizations present a rich archaeological record and literature that reveal food-related practices, cooking, dining, and food patterns, and dietary prohibitions (Loret, 1892; Keimer 1924; Emery 1962; Darby, Ghalioungui, and Grivetti 1977). Although numerous dietary taboos are known from ancient Egypt, only two are reviewed here.

Cattle and beef. Herodotus (*The Histories* 11:41), writing in the fifth century B.C., stated that local Egyptian priests abstained from beef, especially the flesh of cows, and that this dietary pattern extended beyond the geographical limits of Egypt westward into Libya. Such a taboo attached to beef was also described in the fourth century B.C. by Philochorus of Athens, who attempted to explain the practice when he wrote that

> at one time, also when there was a dearth of cows, a law was passed, on account of the scarcity, that they [the Egyptians] should abstain from these animals since they wished to amass them and fill up their numbers not be slaughtering them (Philochorus, cited in Athenaeus 1927–41, 9:375:C).

Porphyry (1965, 2:11), writing in the third century A.D., provided a relatively late glimpse of what might be taken as the impact of the beef prohibition in ancient Egypt when he stated that: "[w]ith the Egyptians . . . any one would sooner taste human flesh than the flesh of a cow."

Greek and Roman texts notwithstanding, the archaeological evidence emphatically disputes the presence of a sweeping beef taboo throughout ancient Egypt. Tomb and temple art throughout the dynastic period, 3200–341 B.C., provides abundant pictorial evidence of bovine slaughter and butchering. Indeed, thousands of carvings and paintings depict the capture and killing of cattle, butchers at work cutting up the carcasses, the display of beef haunches and organ meats in shops, and boiling and roasting beef (Darby et al. 1977).

It is true that specific types of bulls were worshiped at the urban sites of Heliopolis, Hermonthis, and Memphis, and that cows were worshiped throughout the Nile Valley as the incarnation of the goddesses Hathor and Isis. But such deification did not inhibit beef consumption throughout the Nile Valley of ancient Egypt at all geographical localities (Monet 1958).

Other writers, however, have readily accepted the Greek texts, ignored the archaeological data, and attempted explanations for Egyptian beef avoidance. J. G. Wilkinson, for example, wrote that "by a prudent foresight, in a country possessing neither extensive pasture lands, nor great abundance of cattle, the cow was held sacred and consequently was forbidden to be eaten" (Wilkinson 1854).

Yet deification of bulls and cows in ancient Egypt was not related to available pasture land or threatened extinction but to specific physical characteristics of individual bulls and cows (Darby et al. 1977). Furthermore, given the wide range of texts that clearly identify offerings of meat from bulls, bullocks, calves, and cows, it is erroneous to conclude that there was a sweeping beef prohibition associated with Egyptians of all periods. It may be that a more limited beef prohibition was intact during late- and postdynastic times, but it is not possible to state, categorically, whether the prohibition applied to all varieties of beef, or specifically to cows, or perhaps to female calves, or to other bovine categories (Darby et al. 1977).

Another aspect of the late dynastic beef prohibition deserves attention since it relates not to meat, per se, but to the Egyptian manner of butchering. Herodotus (*The Histories* 4:1) commented that "[n]o native of Egypt, whether man or woman . . . will use the knife of a Greek . . . or taste the flesh of an ox, known to be pure, if it has been cut with a Greek knife." Because the ancient Egyptian standard method of butchering was to cut the throat, then drain and collect the blood for food, it may be that this passage indicates some significant differences in butchering techniques between Egyptians and Greeks. It could also, of course, be taken as evidence of (or it possibly reflected) an Egyptian aloofness and sense of superiority over the Greeks (Darby et al. 1977).

Fish. Fish held a dual position throughout the dynastic period of ancient Egyptian history. Texts and tomb art document geographical locations where (and historical periods when) fishing was an accepted occupation and eating fish was acceptable. Indeed, Egyptian kings regularly supplied beef, fish, and vegetables to soldiers as military rations and sometimes presented fresh and dried fish as temple offerings. But other passages and depictions indicate that priests abstained from fish, that fishing as a profession was abhorrent, and that fish eaters were ceremonially impure (Darby et al. 1977).

Five specific varieties of Nile fish figured prominently in Egyptian religion and were widely rejected as food: the latus *(Lates niloticus;* perhaps *Tilapia nilotica),* the lepidotus *(Barbus bynni),* the maeotes (possibly a siluride), the oxyrhynchus (*Mormyrus* spp.), and the phagrus (identification uncertain; possibly *Hydrocyon forskalii*). The latus was worshiped at the site of Esna where thousands of mummified examples have been discovered, but reverence and dietary avoidance of this species at Esna did not preclude its widespread consumption elsewhere along the Nile.

The lepidotus was revered throughout the Nile Valley and thus widely rejected as food. The maeotes was worshiped near Aswan where it was rejected as food because it was considered a harbinger of the Nile flood. The oxyrhynchus was universally avoided as food for two distinctive reasons: The fish was associated with the god Seth, whose followers rejected it out of respect, whereas the followers of Osiris avoided oxyrhynchus because this species reportedly fed upon the phallus of their deity and, therefore, was an abomination. The phagrus was rejected for two reasons: (1) because its appearance also signaled the Nile flood, and (2) because it, too, had fed upon the phallus of Osiris (Darby et al. 1977).

Judaism

Two central texts present the Jewish dietary traditions and laws. The Torah stems from ancient oral traditions and was codified in its present literary form by, perhaps, the sixth century B.C. The Talmud, produced in Babylon and Jerusalem in the sixth century A.D., provides guidelines for Jewish moral conduct and incorporates numerous discussions and critical assessments of food and food-related issues.

Study of the Torah and Talmud suggests the development and evolution of Jewish dietary codes through seven stages:

Stage One: In Genesis 1:29–31, all products on earth are clean.

Stage Two: In Genesis 1:29–31, plant food constituted the initial diet of humans.

Stage Three: At the time of the flood, in Genesis 7:1–2, clean and unclean animals are differentiated, but not identified or specified.

Stage Four: In Genesis 7:1–2, both clean and unclean animals are saved and brought into the ark.

Stage Five: In Genesis 9:3–4, Noah and his descendants are permitted all food except blood after the biblical flood. An appropriate human diet is defined as a combination of plant and flesh foods.

Stage Six: Clean and unclean flesh foods are identified and specified, other forbidden foods and food-related behaviors are codified:

A. Clean meats were specified in Leviticus 11:2–3, 9, 21–2; and Deuteronomy 14:4–6, 9, 11, 20.
B. Unclean meats are discussed in Leviticus 11:4–8, 10–20, 23–31, 41–4; and Deuteronomy 14:7–8, 10, 12–19.
C. Blood was prohibited in Genesis 9:3–4; Deuteronomy 12:16, 23–4, and 15:23; 1 Samuel 14:32–4; and Ezekiel 44:7, 15.
D. Carrion was prohibited in Exodus 22:31; Leviticus 11:39–40, 17:15–16, 22:8; Deuteronomy 14:21; and Ezekiel 4:14.
E. Fat was prohibited in Exodus 29:13, 22; Leviticus 3:3–4, 9–10, 17, 23–5, and 9:19–20; 1 Samuel 2:15–16; and 2 Chronicles 7:7.
F. Meat offerings to idols were prohibited in Exodus 34:15.
G. Sinew was prohibited in Genesis 32:32.
H. Food contaminated by dead animals was prohibited in Leviticus 11:37–8.
I. Seed contaminated by dead animals was prohibited in Leviticus 11:37–8.
J. Food from the inside of a house where a person has died was prohibited in Numbers 19:14–15.

Stage Seven: Regulations forbidding mixing meat and milk products (Epstein 1948) are believed to stem from the commandment not to seeth a kid in its mother's milk in Exodus 23:19, 34:26; and Deuteronomy 14:21.

Clean-unclean food lists. The form, structure, and content of the clean and unclean food lists of Leviticus and Deuteronomy have remained the subject of considerable interest and debate since the early years of the Christian era (Barnabas 1961). If the clean and unclean food lists are examined in light of twentieth-century archaeological data and linguistic advances, two basic questions emerge. These concern translation accuracy and assignment rationale.

Taking up the question of translation accuracy first, an examination of Table VI.13.1 reveals linguistic consistency throughout the centuries for a number of specific forbidden foods, among them *arnevet* (hare), *gamal* (camel), and *hazir* (pig). The translations of other terms for forbidden foods, however, have not been consistent, and through the years some have been quite variable. The term *a’nakah,* for example, has been translated variously as ferret or gecko; *’aiyah* as crow, falcon, hawk, kite, and vulture; *homet* as lacerta, lizard, sand lizard, snail, and winding lizard; and *tinshemet* has been rendered variously as barn owl, chameleon, maldewerp, and mole.

Most identification and translation problems concern amphibians, birds, and reptiles. The difficulty lies with honest attempts at zoological identification based upon incomplete linguistic evidence, set within a wide range of possible eastern Mediterranean faunal representatives. Such linguistic difficulties were compounded in recent centuries when Christian missionaries translated the Old Testament into languages far removed from the origins of Judaism, where Mediterranean animals did not exist.

In the area of assignment rationale, the question of why foods became listed as clean or unclean has also been the subject of considerable debate. Seven of the eleven hypotheses discussed in the section “Approaches, Paradigms, and Themes” have been employed by various authors to support the origins of the Jewish dietary codes. Only three, however, can be critically examined: health or sanitation, ethnic identity, and ecological arguments (Grivetti and Pangborn 1974).

In the matter of *health and sanitation,* however, it is not logical to presume that the ancients were more observant and astute medically than nineteenth- and twentieth-century scientific physicians. Furthermore, few foods on the forbidden or unclean list pose direct health threats to consumers, whereas some foods on the clean list are vectors for anthrax, brucellosis, and various parasitic diseases.

Explanations based on *ethnic identity* presume that foods on the unclean list were once the dietary prerogatives of the ancient Egyptians, Canaanites, or other societies among whom the ancient Israelites lived or whom they had as geographical neighbors. Such explanations also hold that foods on the Jewish clean list once were prohibited or forbidden to non-Jews in the Mediterranean region. Analysis reveals that the ancient Egyptians in certain geographical areas and during certain historical periods ate pork, and they also consumed bustard, hare, locust, and ostrich. Moreover, several other animals on the Jewish unclean food list were worshiped by the ancient Egyptians, among them egret, hawk, heron, and vulture. But some meats on the clean list, such as beef, goat, and lamb, were also consumed, and cattle, goats, and sheep were worshiped by the ancient Egyptians (Darby et al. 1977).

The *ecological* hypothesis applied to pork avoidance suggests that pigs in the Mediterranean region could not compete economically with sheep and goats because they offered no hair products or milk, posed herding difficulties, and were ill suited to Middle Eastern heat. Supporters also state that as swine were in direct competition for scarce water and food resources, forbidding pork as food would not have been likely to cause sociocultural difficulties (Harris 1972, 1973). Archaeological evidence, however, can be used to counter these arguments because pigs were raised in Egypt for more than 5,000 years and, thus, were hardly ill suited to the region (Darby et al. 1977).

Ritual slaughter. The Judaic preparation of meat is characterized by a highly structured ritual that regulates slaughter, butchering, meat preparation, and cooking. Common explanations for the religious laws governing these practices suggest that compliance assures that meat products will be religiously suitable, that ritual requirements for human consumption will be met, and that meats prepared in such a manner will be safe for consumption (Levin and Boyden 1940; Maimonides 1956, 1967).

Within Judaism, meats are divided into two categories: *kosher,* or fit and suitable for human consumption, and *terephah,* or forbidden and unsuitable. Both kinds of meats are found in the food lists of Leviticus and Deuteronomy. In essence, terephah animals and meat products always are forbidden and never suitable as human food, whereas kosher meats and products may become terephah if ritual law is not followed.

The butcher must be an Orthodox Jew and in normal practice is a rabbi or a trained rabbinical designate. The butcher is responsible for inspecting animals prior to slaughter and declaring whether or not all accepted religious criteria are met. Thus, animals selected must be certified alive just before slaughter; a knife and no other instrument must be used. The cut must be made without hesitation or pause, in a straight line directly across the throat, with a motion that severs both gullet and windpipe.

Once the throat has been cut, the animal is suspended and bled. The cut is inspected carefully by the butcher, and if any minor lacerations are detected along the cut line, the meat is declared terephah. Similarly, after the carcass is skinned and muscle tissues inspected, there must be no ruptured blood vessels. Next, the lungs are inflated, placed under water, and inspected for any bubbles that might appear; if detected, the meat is declared terephah. Internal organs, including gall bladder, heart, kidney, liver, intestines, spleen, and stomach, are also examined for a wide range of critical signs that determine whether or not meat from the carcass will be classified as fit or unfit (Levin and Boyden 1940).

After inspection and certification, only the forequarters of the animal can be used as food; hindquarters are terephah. Rejection of the hindquarters is symbolic and linked with the account in Genesis 32:32 of Jacob's wrestling with an angel who touched Jacob on the ischiatic nerve.

In modern times, if the carcass meat must be held in a cooler for more than 72 hours, or if transportation of the carcass will exceed 72 hours, the meat must be ritually washed, otherwise kosher status is lost and the meat is reclassified terephah (Lipschutz 1988).

Because the eating of blood is prohibited, several food preparation and cooking techniques have been devised through the centuries that separate Orthodox Jews from others. Kosher meats are soaked in tap water, salted on all surfaces, then placed on a slanted drain board. They are rinsed twice to remove the salt. Rare meat is terephah and so all meats must be cooked thoroughly. As a consequence, cooking techniques, such as broiling and boiling, became institutionalized in order to meet the religious law and maintain kosher designation (Grunfeld 1972; Lipschutz 1988).

Meat and milk. Within the Jewish food tradition, kosher foods are assigned one of three categories: *fleishig* (meat and meat products), *milchig* (milk and dairy products), and *parveh* (neutral foods, defined as all other permitted foods). A wide range of laws govern the cooking and blending of these three categories: Fleishig and milchig foods can never be blended or combined, whereas parveh items, because of their neutral status, may be mixed with either meat or milk and dairy items. This strict observance of not mixing meat with milk is called *basar be halab.*

Yet the Jewish injunction against mixing meat and milk is not specifically defined in the Torah. Scholars searching for the basis of the *basar be halab* law consider three oblique Torah references with the common admonition found in Exodus 23:19, 34:26; and Deuteronomy 14:21: "Thou shall not seeth a kid in its mother's milk." But examination of the Torah also reveals that Jews once readily consumed meat and milk together at the same meal. And in Genesis (18:7–8) it is written that "Abraham ran unto the herd, and fetcht a calf tender and good, and gave it unto a young man; and he hastened to dress it. And he took butter, and milk, and the calf which he had dressed, and set it before them; and he stood by them under the tree, and they did eat."

Nonetheless, the laws and regulations that govern the dietary separation of meat and milk products are outlined in a wide range of Talmud texts, as noted by Akiba ben Joseph (A.D. 50–132), who stated that every kind of flesh is forbidden to be cooked in milk (Epstein 1948, 8:104a).

Talmud discussions define that which constitutes meat and milk, along with the concept of mixing (Grivetti 1980). The ancient rabbis agreed that beef certainly was meat but differed as to the definitions of poultry and fish. Most Orthodox Jews, both historically and in modern times, have considered poultry to be fleishig, but a minority view, championed by Rabbi Jose of Galilee (first to second century A.D.), held that poultry should be designated parveh and, thus, permitted to be mixed with either milchig or fleishig foods. Jose's semantical and biological argument was based on the premise that it was impossible to seeth poultry in "mother's milk"; although fowl could be mothers, they were incapable of producing milk (Mishayoth 8:4 in Blackman 1964).

What constitutes milk was easily answered in the ancient Mediterranean world: Permitted milks could come only from mammals on the clean-food lists. The definition of milk, however, has become less clear during the twentieth century with the use of nondairy cream substitutes prepared from soy-based products. Some nondairy creamers, for example, contain the milk protein sodium caseinate, which would make the product milchig; soy-based milks, however, would be parveh and permitted to be mixed with fleishig products (Freedman 1970).

Definitions for mixing involve less obvious considerations. It seems clear that foods blended during the preparation or cooking process would be classified as mixed, but Orthodox Jewish tradition presents expanded, broader definitions that allude to concepts of proximity and touching.

Consider, for example, that two people, not related to each other, sit at the same table but dine separately: One wishes to consume roast beef, the other cheese. If both persons sitting at the table are Orthodox Jews, the law governing mixing of meat and milk is broken. But if one is Orthodox and the other gentile, the law is maintained and differentiation is based upon proximity and the probability of social exchange: If the two were Orthodox they would experience the temptation to share food because of ethnic affiliation or because of friendship (Epstein 1948, 8:107b).

Mixing presents other difficulties as well. Suppose that an Orthodox Jew wishes to purchase meat and cheese from different sections of the same store. When purchased, the products are wrapped separately, then placed inside a shopping bag. In this case, the law is not broken because fleishig and milchig products cannot touch physically (Epstein 1948, 8:107b). But when both categories of wrapped food are carried into the consumer's house, and then unwrapped, the law is precise: Fleishig and milchig products must be placed inside separate pantries. Furthermore, in the modern era of electricity, both categories of food must be kept inside separate refrigerators, and specific parveh foods must not be interchanged with the other refrigerator; otherwise all such items become terephah. Food preparation and cooking of meat or milk products must be done independently, using separate sets of utensils and appliances for fleishig and milchig products. Similarly, meat and milk dishes must be baked, broiled, or otherwise cooked inside separate ovens (Korff 1966; Grunfeld 1972).

Mixing meat and milk also includes the question of time. How long, for example, should consumers wait before dining on the other food class so that the two food categories do not mix inside the human body? Rabbi Hisda (third century A.D.) stated that the order of consumption determined the law: Meat could be eaten immediately after cheese, but one day had to pass if the order was reversed. In contrast, Rabbi Ukba (third to fourth century A.D.) argued that the order of consumption was unimportant and that one day must pass before consuming any food from the other category (Epstein 1948, 8:105a). By the twelfth century A.D., however, a compromise had been reached: a wait of six hours between meals of either food class (Kaufman 1957; Maimonides 1967).

Cultural-religious manifestation of the dietary separation of meat and milk are readily observable in Orthodox Jewish homes, less so in Conservative Jewish homes, and not usually apparent in Reform Jewish homes. Among the Orthodox, the following conditions are required when keeping the law: separate sets of table linen, separate pantries for food storage, separate electrical appliances and food preparation utensils, separate ovens (and microwave ovens) for cooking fleishig and milchig meals, separate condiment containers for meat and dairy dishes, and separate dishwashers (Frazer 1919; Gaster 1955; Natow, Iteslin, and Raven 1975).

Basar be halab. A wide range of arguments have been advanced to explain the law of *basar be halab.* Several have argued that the Torah passages are mistranslated, or that the law originally did not forbid boiling or preparing meat and milk together, but was intended to apply to cooking or mixing meat with blood (Cheyne 1907; Smith 1969). Others feel that the basis was one of "Natural Law and Divine Order," that cooking a kid in the milk of its mother would be an abomination and contrary to nature (Scott 1866; Mackintosh 1959; Cook 1969). Still others have explained the law using the argument that the ancient Jews were a compassionate people, not prone to acts that would lead to a baby goat's being boiled in the fluid intended for its own nourishment (Chadwick 1890).

Early writers such as Philo (1954, 4:16:97, 4:17:111, 4:24:124) offered still another explanation when he wrote that the meat-milk codes were instituted because the two foods in combination were stimulating and pleasure giving to the consumer and, therefore, should be denied to demonstrate self-restraint.

Other commentators have suggested that the reason might have to do with sympathetic magic, specifically the belief that animals could control their milk after humans had obtained it. In this case, the boiling or heating of milk would have been tantamount to applying fire to cattle udders. These writers suggest that the code was a part of widespread cultural practices adopted to protect herds, lest the cattle be damaged (Frazer 1907a, 1907b, 1919; Schmidt 1926).

Still other writers conclude that the basis for the dietary separation of meat and milk was based upon considerations of food spoilage and bacterial contamination. They have argued that given the hot, desert conditions found throughout the Middle East, although both meat and dairy products spoil, they spoil more quickly if blended. This view, however, may be easily rejected since blended foods, in fact, do not spoil more rapidly than meat or milk products served alone (van den Heever 1967).

Within Judaism, meat and milk are forbidden in combination – yet meat and milk dishes are highly esteemed within Islam. Middle Eastern Muslims, in turn, reject dietary combinations of fish and milk – yet fish and milk dishes are desirable within Judaism. These acceptable and forbidden patterns of mixing foods clearly have separated Jews and Muslims in the Middle East since at least the seventh century A.D. when Muslim forces invaded and occupied the lands of ancient Palestine. Since that time, the meat-milk and fish-milk prohibitions have served as ethnic markers and as a clear means of religious and cultural separation (Grivetti 1975, 1980).

Other food-related issues. A wide range of Jewish dietetic rules codified in the Torah and Talmud have been reviewed and summarized by modern scholars (Preuss 1978). One important Talmud directive encourages eating in moderation with the saying, "More people have died at the cooking pot, than have been victims of starvation" (Shabbach 33a). Salt and yeast are identified as harmful to consumers if eaten in large quantities (Berachoth 34a).

Numerous rabbis cited in the Talmud present arguments well beyond those governing the clean and unclean food lists of Leviticus and Deuteronomy. Rabbi Abaye (A.D. 280–339) argued that Jews should abstain from fish, fowl, and salted meat, and argued further that consumption of fish was detrimental to human eyesight (Nedarim 54b). Rabbi Mar bar Rav Ashi (fifth century A.D.) suggested that fish and meat, in combination, should not be salted and that the consumption of this mixture resulted in leprosy (Pesachim 112a). Rabbi Rab (second century A.D.) considered fish that had been chewed upon by other sea creatures; he concluded that in such cases where the fish already were dead, the dietary law could be kept by merely cutting away the chewed-upon portions (Jerushalmi Terumoth 8:46a).

Other Talmud passages discuss foods thought to be life threatening. Among them were peeled garlic, peeled onions, peeled eggs, and any diluted liquid kept overnight and exposed to the air (Niddah 17a). The Talmud also ponders the problem of honey and the law: Since the bee is an insect not on the clean list, how could honey be allowed as a food fit for human consumption? Various rabbis argued that bee honey should be permitted since the insect "expels unchanged that which it sucketh out of blossoms." By contrast, the rabbis viewed honey obtained from hornets or wasps as a type of saliva (ri'r), and thus a product expressly forbidden as food (Bechoroth 7b; Tosefta Bechoroth 1:8).

Further evolution of Jewish dietary codes is seen in the sixteenth-to-eighteenth-century health and dietary compendium called *The Book of God's Deeds* or *Sefer Mif'alot Elokim.* This text is important because it bridges the period between ancient and modern health-related issues and diet and contains several specific food and food-related prohibitions. It forbids almonds, hazelnuts, and walnuts (unless eaten after meals), enjoins the faithful from reading or studying while eating, and provides the strict instruction never to eat bread unless the loaf has been well baked (Ba'al Shem and Katz 1936).

Christianity

Early food taboos. Dietary prohibitions and taboos associated with Christianity developed in response to a classic philosophical schism: Should all foods be allowed, or should portions of the dietary codes of Judaism be incorporated by Christians? The early position regarding dietary taboos was Christian repudiation of earlier Jewish food laws and the concept that all foods were acceptable (Mark 7:18–21; Acts 10:8–16, 11:5–10; 1 Corinthians 6:12–13, 10:23, 25–7; 1 Timothy 4:3–5; Titus 1:14–15).

Subsequent debate, however, resulted in Christian reevaluation that permitted converts to maintain their earlier dietary restrictions. This, ultimately, led to the development of three Christian dietary taboos that have not been enforced throughout the centuries: blood (Acts 15:20, 29; 21:25), carrion and "things strangled" (Acts 15:20, 29 and 21:25), and foods previously offered or dedicated to idols (Acts 15:20, 29; 21:25; 1 Corinthians 8:1, 10, 28). Subsequent New Testament texts, however, advise only: "Whether, therefore ye eat, or drink, or whatsoever ye do, do all to the glory of God" (1 Corinthians 10:31).

Subsequent food taboos and concerns. Such a laissez-faire attitude regarding dietary matters within the church continued toward the present. One notable flurry of debate erupted in the second century concerning marine species of fish. Although fish were widely consumed by Mediterranean Christians at this time, concern was expressed that marine species might feed upon the bodies of mariners and soldiers buried at sea. In this case, was the human consumption of such fish tantamount to cannibalism? A second concern had to do with the "essence" of the human body incorporated into fish tissue, which was viewed as an impediment to the reconstitution of the deceased for resurrection, and from this concern flowed another. If the soul of a sailor became part of fish tissue, it would pass directly into the consumer's body. Yet two souls could not occupy the same human body. Clearly, argued the opponents of marine fish consumption, such a food should be avoided.

Fortunately for fish lovers, however, Athenagoras, an Athenian Christian apologist, ably presented a number of positive counterarguments that succeeded in ensuring that the Christian faithful could continue dining on Mediterranean fish.

If there was little proscribing of foods in the history of early Christianity, there was much concern over foodstuffs that centered on physical, in contrast to spiritual, health. For example, John Chrysostom (later Saint John, 345?–407), an important fourth-century Christian leader and author of numerous religious tracts, also wrote extensively on diet. One of his major themes was that reduced food intake and regular fasting were important for Christians. In his words (Homily 22):

> frugality and a simple table are the mother of health. . . . Now if abstinence is the mother of health, it is plain that eating to repletion is the mother of sickness and ill health, and brings forth diseases . . . caused by gluttony and satiety. . . . Abstinence [from food], in truth, as it is the mother of health, is also the mother of pleasure.

In like fashion, the fifth-century Greek physician Anthimus, in his work on *The Dietetics,* advised Christians to be moderate in their eating and drinking habits. In addition, he cautioned that foods consumed should be readily digestible, and he warned against eight items: bacon rind, aged cheese, hard-boiled eggs, fish that were not fresh, mushrooms, oysters, pickled meats, and pigeons (Gordon 1959).

Such warnings may also be found in the thirteenth-century text *Regimen Santitatas Salernitatum,* which is a blend of Christian and Muslim dietary traditions. Foods specifically identified to be avoided were those supposed to engender the formation of black bile. Other foods, described as "enemies of the sick," were also to be avoided by Christians. These offenders were: apples, cheese, goats, hares, salted meats, milk, peaches, pears, veal, and venison (Temkin 1953; Harrington 1957; Arano 1976).

Absolute food prohibitions within Christianity, however, are a relatively recent phenomenon, initiated by newly formed denominations. The Seventh-Day Adventists, for example, maintain the dietary prohibitions of the Jews against foods on the unclean lists found in Leviticus and Deuteronomy. They also abstain from alcohol consumption and frown upon "hot" spices and condiments, specifically, chilli pepper and black pepper. Aged cheeses (Limburger and Roquefort) are also discouraged. Moreover, the faithful are cautioned:

> Those who indulge in meat eating, tea drinking, and gluttony are sowing seeds for a harvest of pain and death. . . . A diet of flesh meat tends to develop animalism. . . . Flesh meats will depreciate the blood. Cook meat with spices, and eat it with rich cakes and pies, and you have a bad quality of blood. . . . Tea is poisonous to the system. Christians should let it alone. The influence of coffee is in a degree the same as tea, but the effect on the system is still worse. . . . Never take tea, coffee, beer, wine, or any spirituous liquors (Counsels on Diet and Foods 1938).

Members of the Church of Jesus Christ of Latter-day Saints, the Mormons, also reject alcohol and so-called hot drinks, defined as coffee and tea (Word of Wisdom in Smith 1833). In fact, many Mormons have extended this "hot drink" prohibition to any food or beverage that contains caffeine (Pike 1992).

Islam

Muslim dietary prohibitions are documented in two sources, the Koran and the Hadith. The Koran, the divine word of God revealed to the Prophet Mohammed, divides food into two basic categories: halal, or permitted, and haram, or forbidden. The Koran specifically forbids six foods or food categories: blood, carrion, pork, intoxicating beverages prepared from grapes *(khmr),* intoxicating drugs, and foods previously dedicated or offered to idols (Roberts 1925; Sakr 1971). The Hadith, or the collected traditions and sayings attributed to the Prophet Mohammed, contains a broad range of food-related passages.

A wide assortment of human behaviors relating to food and the food quest are carefully coded in both the Koran and the Hadith. Muslims, for example, may not hunt when on religious pilgrimage to Mecca (Koran 99). At the time of slaughter of permitted animals, the name of God must be mentioned, specifically the phrase: "In the Name of God, the Compassionate, and the Merciful," or *Bisimallah er Rahman er Rahim.* The throat of the animal must be cut in front with a knife, with the exception of two allowed foods: fish, because their throat already is cut (that is, gills), and locusts, because they spring upward and aspire to heaven. If the butcher is distracted and the name of another person or deity is mentioned during slaughter or while butchering the carcass, the flesh of that animal is designated haram, forbidden. If meat is slaughtered correctly, but not permitted to bleed out, the flesh also is designated haram. Meat slaughtered by Christians and Jews may or may not be permitted; meat from animals slaughtered by atheists is always forbidden (Sakr 1971).

Because conservative Muslims living beyond the boundaries of the Middle East frequently do not know the religious orientation of butchers who prepare meat for sale in markets, some turn to vegetarianism during their time abroad or butcher their own animals on specific feast dates (Grivetti, unpublished data).

Local traditions also dictate food prohibitions. In Egypt, for example, some birds consumed elsewhere in the Middle East and Mediterranean region by Muslims are not killed because the bird call resembles pious, religious phrases. The dove (*Streptopelia* spp.) may be avoided as food in Egypt because its call is said to imitate the words: "Oh, all merciful; Oh, all merciful," or *Ya Rahman; Ya Rahman.* Other prohibited birds include the hoopoe *(Upupa epops),* who produces the sound: "Oh, all pitiful; Oh, all pitiful," or *Ya Raouf; Ya Raouf,* and the stone curlew *(Burhinus oedicnemus),* whose cry is said to mimic: "The Universe is Yours, Yours, Yours, Oh, master of the Universe," or *Al-Moluk lak lak lak Ya Sahib al- Moluk* (Darby et al. 1977).

The Hadith also delineates specific kinds of animals to be avoided as food. Among them are all quadrupeds that seize their prey with their teeth. Expressly identified are hyenas, foxes, and elephants. All birds with talons are prohibited. Specifically forbidden (without talons) is the pelican (Guillaume 1924).

The prominent medieval Persian physician Ibn Sina wrote, regarding prohibited foods, that fish should not be taken after laborious work or exercise because it undergoes decomposition and then decomposes the humors (*The Canon* No. 767). Elsewhere, he wrote on prohibited combinations of food:

> Certain rules must be noted in regard to combinations of food: milk must not be taken with sour foods; fish must not be taken with milk for in that case chronic ailments such as leprosy *(juzam)* may develop; pulses must not be taken with cheese or radishes or with the flesh of flying birds; barley-meal should not follow a dish of rice and sour milk (Ibn Sina 1930).

Other texts by Ibn Sina document still more inappropriate food combinations: milk with acid food, Indian peas with cheese, and fine flour with rice and milk ("Advice on Foods," cited in Kamal 1975).

Hinduism

The most ancient known Hindu document that considers food and dietary prohibitions is the Caraka-Samhita, written about 1500 B.C. and attributed to the physician Caraka. Specific passages in this important text (Caraka 1981) identify dietary principles, permitted and prohibited foods, and regimens for various diseases. Ancient Hindu diet was perceived as consisting of two types: immobile (plants) and mobile (animals). Diet patterns were classified according to four manners of intake: beverages, eatables, chewables, and lickables. Each of these intake categories was further based upon six types of taste: astringent, bitter, pungent, salty, sour, and sweet. Innumerable variations of diet resulted that were based upon 12 categories of food and factors of abundance, combination, and preparation (Grivetti 1991a).

The Caraka-Samhita (Caraka 1981) identifies food items designated as unwholesome and to be avoided by the majority of people. Among them are black gram bean (pulse category); rainy season river water (water category); beef (animal meats category); young dove (bird and fowl category); frog (animals living in holes category); sheep milk (animal milks category); and elephant fat (fats of plant-eating animals category).

Included elsewhere in the Caraka-Samhita (Caraka 1981) are other foods to be avoided:

> Meat from animals who die natural deaths, are emaciated, too fatty, too old, too young, any animal killed by poison, not maintained on pasture [land], and meat from all animals bitten by snakes or tigers. . . . Vegetables affected by insects, wind, or sun; vegetables that are dried, old, unseasonable or not cooked with fat. . . . Fruits that are old, unripe, damaged by insects, animals, by snow, or sun, [all vegetables that] grow in unnatural places or [at] unnatural times, or are rotted.

A further development and expansion of Hindu food-related codes is embodied later in texts collectively called the Dharma-Sutra. These law codes, derived from oral tradition that date perhaps to 1500 B.C., had been collected, edited, and presented in written form by the sixth century B.C. The texts are divided into separate tracts: Apastamba (Müller 1896a), Baudhayana (Müller 1882a), Gautama (Müller 1896b), and Vasishtha (Müller 1882b). The document called Manu (1896c), or Laws of Manu, is a subsequent summary and synthesis that probably dates from the third century A.D.

The Hindu dietary prejudices and taboos presented in the Dharma-Sutra are subsumed under five broad rubrics that reflect aspects of human occupation, food location, human and animal behavior, and animal morphology. The fifth category identifies specific proscribed items (Apastamba 1896, 1:5.16:1–1:6:19:15; Baudhayana 1896, 1:5:9:1–2:7:12:12; Gautama 1896, 17:1–38; Manu 1896, 4:205–25; 5:5–56; Vasishtha 1896, 14:2–48; Grivetti 1991a):

Prohibitions associated with human professional and physiological status: All foods offered by an actor, artisan, basket maker, blacksmith, carpenter, cobbler, dyer, eunuch, goldsmith, harlot, hermaphrodite, hunter, hypocrite, informer, jailer, leaser of land, manager of a lodging, menstruating woman, miser, musician, paramour of a married woman, person who is ill, physician, police officer, prisoner, ruler of a town, seller of intoxicating beverages, spy, tailor, thief, trainer of hunting dogs, usurer, weapons dealer, or woman with no male relative.

Prohibitions associated with food location: All foods stored inside the house where a relative has died, all foods served from a wooden platform or table, items eaten while standing, and all foods prepared out of sight and sold by street vendors.

Prohibitions associated with human behavior and contact: All foods received directly from the hand of another person, any food sneezed upon or touched accidentally by a human garment or human foot, any item that contains a hair or insect, all foods specifically prepared for another person, and any consumables that have remained overnight in contact with air that subsequently have soured.

Prohibitions associated with animal behavior and contact: All foods sniffed at by a cat or smelled by a cow, meat from any animal that died after being worried by dogs, meat from any animal that behaved in a solitary manner, and all birds that scratch with their feet or thrust forward with their beak.

Prohibitions associated with animal morphology: All meats or milk products from animals with a single hoof, five toes, double rows of teeth, excessive hair, or no hair; any mammal with young that has recently died, milk or meat from any cow that has suckled a strange calf, and any permitted animal that has delivered twins.

Prohibitions associated with specific foods: Specifically identified prohibited foods fit three broad categories:

1. Plants and plant products: garlic, leek, mushroom, onion, turnip, young sprouts, tree resin, and red juice or sap extracted from any plant.
2. Animals: alligator, crab, crocodile, fish with misshapen heads; cormorant, crow, dove, duck, egret, falcon, flamingo, heron, ibis, osprey, parrot, black partridge, pigeon, raven, sparrow, starling, swan, vulture, and woodpecker; village pig and other tame village animals; black antelope, flying fox, and porpoise.
3. Beverages: milk from any buffalo, cow, or goat within 10 days after calving; any milk from camels, sheep, or wild deer; and water that accumulates at the bottom of a boat.

Prohibitions by Gender and Age

Numerous dietary prohibitions within a society are universal, applying to males and females of all ages. In other instances, however, taboos may be instituted at specific ages or associated with one gender. Dietary taboos practiced in the Republic of Botswana by the baTlokwa ba Moshaweng, a Tswana agro-pastoral cattle-keeping society of the eastern Kalahari Desert, offer examples of both.

General Prohibitions

Female and male baTlokwa of all ages reject antbear or aardvark *(Orvcheropus afer afer)* as food because they consider it inappropriate to kill and eat their tribal totem animal (see Table VI.13.2 for a list of

Table VI.13.2. *BaTlokwa ba Moshaweng: Foods restricted by gender and age*

	Females		Males	
	Characteristic or permitted	Prohibited or restricted	Characteristic or permitted	Prohibited or restricted
Death				
–	Eggs	Antbear	Eggs	Antbear
–	Meat: chin	Insects	Honey	Insects
Elderly	Meat: nose	–	Francolin	Small birds
Adults	Meat: placenta	–	Kidney	Small mammals
			Meat: stillborn calf	
			Tortoise	
Menopause or activity decline				
–	Liver	Antbear	Eggs, heat	Antbear
Active	–	–	Lung, rumen	Insects
Adults	–	–	Meat: forelegs & hindlegs	Small birds
				Small mammals
				Stillborn calf
Puberty				
–	Fish	Antbear	Eggs	Antbear
–	Insects	Eggs	Fish	Francolin
Childhood	–	Francolin	Insects	Honey
		Honey	Small birds	Tortoise
		Tortoise	Small mammals	
Weaning/off breast				
–	Breast milk	Beans	Breast milk	Beans
–	Donkey milk	Eggs	Donkey milk	Meat
Infancy	–	Solid food	–	Solid food
Birth				

foods restricted by age and gender). Pork is also not consumed by males and females of all ages for other reasons. Many state that pork is a disgusting food and offer explanations, such as that pigs are dirty, smelly, and disgusting in appearance and that they consume feces and even their own young. Still others reject pork because they say that the meat is too fatty for human consumption. BaTlokwa who break their universal taboo and eat pork, however, still may reject specific portions of the carcass: In contrast with the bones of acceptable animals, those of pigs are never cracked and chewed to extract marrow, lest the consumer become deaf (Grivetti 1976).

Several agro-pastoral Tswana societies living in the eastern Kalahari Desert do not eat locally grown oranges in the belief that the first maturing fruit is poisonous. Respondents state that it is impossible to determine precisely which orange ripens first. Therefore, locally grown oranges are all rejected, and oranges that are consumed are imported from South Africa.

Some baTlokwa, however, believe that planting orange trees is unnatural and possibly dangerous because this tree is not native to the eastern Kalahari. Other baTlokwa explain their prohibition using an analogy with another local Kalahari tree, *Melia azsedarach:* Although baTlokwa men and women readily dig up wild plants from surrounding bushlands and transplant them into their household gardens, they never experiment with *Melia azsedarach* in the belief that transplanting it will cause the death of all family members except the gardener, who then must suffer a life of loneliness (Grivetti 1976).

The baKwena, linguistic and cultural relatives of the baTlokwa who occupy territory southwest of the baTlokwa homelands, also reject oranges as food for still another reason. Documentation exists that the nineteenth-century missionary David Livingstone was the first to import orange trees into the Kalahari Desert in baKwena territory, and he is suspected of initiating the orange taboo to curtail theft from his orchard (Grivetti 1978b).

Age-Gender Matrix

The baTlokwa ba Moshaweng exhibit a well-structured pattern of food prohibitions reflecting dual themes of age and gender. But those dietary taboos and prohibitions that reinforce gender identification at specific periods of the human physiological cycle are balanced by other foods that are characteristically associated with the consumer's age and gender.

Infancy. Certain baTlokwa food-related behaviors regulate infant feeding practices. Parents must eat before feeding their infants, as it is forbidden to hold or allow the infant to sit on the parent's lap while the adult is eating. They believe that to do so makes the infant greedy. Furthermore, widows and widowers are discouraged from feeding infants. But if they do, the infant must be held facing away from the adult to avoid eye contact (Grivetti 1978b).

Childhood. Seven foods expressly taboo to baTlokwa children are dietary prerogatives of elderly men. These foods include two types of honey, tortoise, and five birds: dikkop *(Burhinus capensis),* francolin (*Francolinus* spp.), guinea fowl *(Numida meleagris),* horn-bill (*Tockus* spp.), and red-crested korhaan *(Lophotis ruficrista).* The baTlokwa associate these seven items with memory and believe that their consumption exacerbates forgetfulness: Because elderly men are perceived as forgetful anyway, and memory should be developed in children, these seven foods are critical markers for age (Grivetti 1978b).

Other food taboos of childhood are associated with food remnants, especially sorghum porridge that sticks to wooden serving spoons. Boys are told that if they lick porridge from such utensils, they will develop breasts and resemble women (cultural reference to gynecomastia). Girls, on the other hand, are cautioned that such behavior will delay breast development (Grivetti 1976).

The actions of children at mealtime are also regulated. BaTlokwa children are forbidden to touch the floor with the left hand while eating as this is interpreted as a sign of laziness. Furthermore, children are not allowed to speak during mealtime because of a widely held conviction that "a talking child becomes lean" (Grivetti 1976).

When baTlokwa children are ill, mothers prepare a special sorghum beer called *bojalwa jwa tlhogwana,* to be drunk by all family members in the belief that this practice hastens recovery. While the tlhogwana is being prepared, no one in the family is allowed to sample it at any stage of the brewing process or to taste the sediment at the bottom of the clay or iron beer pot. To do so, reportedly, will make the child's illness acute (Grivetti 1976).

Adolescence. After baTlokwa children mature sexually and enter their reproductive years, other food-related prohibitions and taboos become operative. Teenage girls are prohibited from consuming eggs, a restriction that differentiates them sharply from male counterparts, who may eat eggs with impunity. The adolescent female egg prohibition is explained at several levels. Some respondents state that the prohibition is linked to the undesirable condition of adolescent pregnancy. It is thought that girls who eat eggs will become sexually overactive, possibly promiscuous, and, consequently, might conceive at an age when they would be unable to care properly for their babies. Others think that adolescent girls who eat eggs will experience difficult labor, and should the mother and child survive, the neonate will likely die soon after delivery because of impaired breathing. Adolescent women should also avoid eggs because even if they deliver healthy children, the latter will cry regularly and wake the family in the early morning in silly attempts to mimic roosters (Grivetti 1976).

Adult/mature years. Three cuts of beef are prohibited to baTlokwa pregnant women in the belief that they cause difficult labor and delivery. These are the fourth stomach *(ngati);* the large intestine *(mongopo);* and both meat and marrow extracted from lower leg bones *(ditlhako tsa kgomo).* Also forbidden during pregnancy are the meat, fat, and skin located under the belly of an ox *(mofufu wa kgomo),* thought to make the child greedy, or to promote the development of a large stomach (Grivetti 1976).

Commercial candy, available to the baTlokwa since the late nineteenth century, is proscribed during pregnancy. Its consumption is thought to cause the ensuing newborn to drool and spit up saliva. Similarly, sour milk *(madila)* is forbidden to the mother during pregnancy in the belief that it will later cause the newborn to vomit copiously (Grivetti 1978b).

After delivery, baTlokwa mothers enter a period of confinement for 3 to 6 months. During this period the mother is not permitted to eat with her bare hands. All foods must be cut, then transferred to the mouth with a utensil; otherwise it is believed that the mother's supply of breast milk will be adversely affected (Grivetti 1978b).

Elderly pattern. Elderly baTlokwa men and women are released from all previous culturally imposed dietary prohibitions and may eat any available food.

Gender, Pregnancy, and Allopathy

Throughout the Old and New Worlds, millions of people follow allopathic practices that specifically encourage or prohibit various foods during illness and during changes in physiological status, such as pregnancy and lactation. Allopathic systems emerged initially in India and subsequently spread to China and westward into the Mediterranean basin to influence Greek, Roman, Byzantine, and Jewish, Christian, and Muslim medical practices. Such practices became global during the fifteenth- and sixteenth-century era of exploration, and influenced the development of medicine in North, Central, and South America, as well as those portions of Africa and Asia colonized by Europeans (Grivetti 1991a).

At the core of allopathic medicine is the concept that illness and disease may be classified as hot or cold, and wet or dry, and that foods available to consumers are, likewise, hot (heating) or cold (cooling). Health in this system is perceived as a state of balance, whereby healthy individuals are neither too hot nor too cold; illness, accordingly, is perceived as a state of imbalance, and cures aim at restoring balance by treating with opposites. Thus, hot diseases are treated with cold foods, dry diseases with wet foods, and so forth (Grivetti 1991a, 1991b, 1991c, 1992).

Chinese Yang–Yin

Of specific interest to the study and evaluation of food prohibitions and taboos is the question of how concepts of hot or cold remain constant or shift, depending upon the consumer's gender and, in the case of women, whether or not they are pregnant or lactating. Traditional Chinese allopathic practitioners explain that pregnancy produces a physiological state of extreme heat (yang), which requires a cooling (yin) diet in order to restore balance. Dietary management during pregnancy has been considered in a wide range of works by ancient and medieval Chinese physicians.

Among them are texts on diet and food prohibitions by Chang Chi (A.D. 142–220), Hsü Chih-Ts'asi (A.D. 510–90), Sun Ssu-Mo (A.D. 581–682), Chen Tzu Ming (perhaps A.D. 960–1027), and Chu Chen-Heng (A.D. 1281–1358). In addition to these classical Chinese texts, numerous social scientists and physicians of the past 50 years also have written on hot–cold foods, and especially foods that are encouraged or prohibited during pregnancy and lactation (Platt and Gin 1938; Read 1976, 1977a-e; Pillsbury 1978; Anderson 1980, 1984; Tan and Wheeler 1983; Wheeler and Tan 1983; Hsu et al. 1986).

A review of both ancient and modern sources reveals that Chinese dietary prohibitions during pregnancy generally fit eight food categories (Grivetti 1991c).

1. The first and largest category is that of *meats and eggs.* Here prohibited items include: beef, bullfrog, carp, carp roe, chicken, crab, deer fat, dog, donkey, duck (wild and domesticated types), eel, eggs, elk, frog, gecko, goat (both meat and liver), horse, mule, pheasant, rabbit, sheep (mutton and liver), shellfish, sparrow brain, toad, and turtle.
2. Under the category of *cereals,* only barley is prohibited.
3. In the *legumes and seeds* group, almonds, amaranth, beans, and soybeans are prohibited.
4. Prohibitions on *vegetables* include bean leaf and mushrooms.
5. Among the *fruits,* banana, litchi, pear, pineapple, and watermelon are taboo.
6. In the category of *spices and flavorings,* garlic and ginger are forbidden.
7. Proscribed *beverages* include beer, soda pop, tea, and wine.
8. Among the *miscellaneous foods,* all frozen items are prohibited, along with malt, seaweed, and sloughed snake skin (used medicinally).

Set within the hot–cold paradigm, which encourages cooling foods, there seem to be three primary categories of explanation for these food prohibitions (Grivetti 1991c): Some of the foods are viewed as likely to cause *potential miscarriage or spontaneous abortion.* Among these are almonds, amaranth, banana, barley, beans, beer, eggs and salt, frozen foods, horse meat, pineapple, seaweed, and soybeans. Another group of foods is implicated in *transverse presentation, difficult delivery,* and *postpartum bleeding.* These are alcoholic beverages, crabs, donkey meat, duck, horse meat, mule meat, pheasant, sheep liver, shellfish, and tiger bones.

A final group of foods is believed to have a *negative impact on the neonate.* Birthmarks, for example, can be the work of beef, sparrows, or soybean paste, whereas deer fat, elk meat, or sparrow brain can cause blindness or other eye diseases. Boils, sores, and other skin lesions are associated with carp, carp roe, and shellfish, a deformed neck with turtles, and an early death (or during childhood) with frogs. Epilepsy in the child can be caused by either mushrooms or sheep (mutton). The latter is also held responsible for fever. A hoarse voice is linked to toads, jaundice to bananas, muteness or a hare lip to bullfrogs, chickens, dogs, ducks, eels, goats, rabbits, and turtles, whereas fresh ginger can trigger polydactyly (an extra digit).

Still other dietary prohibitions during pregnancy are related to the notion that the foods in question will produce specific undesirable behaviors once the child has grown to maturity. Chinese traditionalists believe, for example, that should women consume sparrow cooked in alcohol or wine during pregnancy, the child will exhibit lewd, licentious behavior as an adult (Grivetti 1991c).

The focus is upon cooling foods (yin) during pregnancy, and yin foods are commonly low in protein and energy. Consequently, dietary reliance upon these items during pregnancy often results in a low-birth-weight baby – but an easier delivery for the mother.

After delivery, the Chinese allopathic system classifies lactating women as strongest yin. Consequently, diet at this time is based upon hot (yang) foods that are high in protein and energy, thus providing a sound nutritional basis for postpartum recovery and breast milk production (Pillsbury 1978).

Taboos as Protective for Society and the Individual

Dietary taboos and prohibitions have also been considered from the viewpoint of protection. In some instances, such practices protect local and regional ecology or agricultural crops during various phases of their growth cycle; in other cases, they have to do with human health and disease.

Crop Protection

As residents of the arid Kalahari Desert of eastern Botswana, the baTlokwa face uncertainties of unseasonable weather, specifically uneven rainfall and drought, hail, and desiccating winds. The baTlokwa attempt to minimize these uncertainties by instituting a range of taboos and prohibitions in a cultural attempt to regulate weather.

The appearance and timing of rainfall in the Kalahari is critical to growing crops, and three specific taboos are instituted in the conviction that enforcement will assure rain. If the following taboos are broken, however, traditionalists believe that the rain clouds will be driven away:

1. Salt must never be thrown into a cooking fire or accidentally spilled onto flames or embers.
2. During their one-year mourning period, widows and widowers cannot wash their body during daylight and are forbidden to walk about the village during the heat of midday.
3. Pregnant or menstruating women are not allowed to walk across agricultural fields, or to touch agricultural equipment, such as plow blades, harnesses, and yokes, lest the heat of their bodies burn the earth or render the ground sterile (Grivetti 1981b).

Health Protection

There is also much in the way of literature that suggests that the origin and development of many dietary taboos may lie in attempts to maintain human health and reduce disease.

Pigs and pork. In ancient Egypt, swine played a role in both religious and dietary practices. In some historical eras, at specific geographical localities, pork was a highly favored food, but during other periods and at other locations pork was forbidden.

Before 3200 B.C., Egypt consisted of two distinctive geographical-cultural entities: a pork-consuming north or Lower Egypt, and a pork-avoiding south or Upper Egypt (Menghin and Amer 1932). Shortly after 3200 B.C., however, both regions were united politically when the South conquered the North. One result of this conquest was a broadly based pork avoidance throughout the Egyptian Nile Valley and Delta that predates the Jewish pork prohibition by more than 2,000 years.

Pigs in the ancient Egyptian pantheon were associated with Seth, the evil brother of Osiris. During political periods when Osiris worship dominated, pork was avoided, but when Seth gained ascendancy, pork was widely consumed. Certainly pork was an important food during the reign of Amenhotep III (about 1405–1370 B.C.), who offered pigs to the temple of Ptah at Memphis. Seti I, father of Ramses II (about 1318–1298 B.C.), allowed pigs to be raised inside the temple of Osiris at Abydos (Newberry 1928: 211). That swine were eaten by Egyptians during the Ramessid Period is confirmed by the large numbers of pig bones found in refuse-trash heaps associated with the workman's village of Deir-el-Medina at Thebes (Kees 1961).

By late dynastic times and during the subsequent Greek and Roman periods, however, literary and pictorial evidence for pork consumption or avoidance in

Egypt reveals the same kind of curious dichotomy that was noted previously for beef. On the one hand, a wide range of sources document pork consumption. One description, dating from the third century B.C., indicates that Egyptian priests at the city of Naucratis in the Egyptian delta were served pork (Hermeias, cited by Athenaeus *Deipnosophists* 4, 149:F). Moreover, numerous Greek and Roman writers commented on the widespread presence of pigs throughout Egypt. Pliny (*Natural History,* 13:50) reported that swineherds fed their animals dates and lotus stems, and Polynaeus (*Stratagems of War* 4:19) noted that herds of swine were raised near Memphis. Heliodorus's Ethiopian history (1587: 130) described herds of pigs at Aswan.

There are also, however, Greek and Roman writers who indicate that there was a strong dietary avoidance of pork in Egypt. Indeed, both Plutarch (*Isis and Osiris* 353: 5) and Aelian (*Characteristics of Animals* 10: 16) stated that pork was forbidden as food throughout Egyptian territory, and Sextus Empiricus (*Outlines of Pyrrhonism* 3: 233) wrote that Egyptian priests would sooner die than eat swine's flesh.

This ancient Egyptian pork avoidance, which dates from about 3200 B.C., predates the Mosaic codes against pork by more than 200 years. Yet, as we have seen in Egypt, pork avoidance was not associated with any relationship between ingestion and disease, but rather was instituted by the followers of Osiris because the pig was the cult animal of Seth (Darby et al. 1977).

It is true that one frequently mentioned reason for pork avoidance links pork consumption with trichinosis (Sakr 1991; Chaudry 1992). But although pork taboos have been instituted in Africa and the Middle East for at least 5,200 years, the relationship between eating pork and contracting trichinosis was not established until the nineteenth century (Hilton 1833; Owen 1835; Zenker 1860; Paget 1866).

Moreover, although associations between parasitism and disease would have been readily apparent in cattle, goats, sheep, and a wide range of fish and fowl, dietary taboos in Judaism, Christianity, and Islam do not exist for these animals. Further, there are no formalized, coded taboos in these three faiths for toxic mushrooms, or such plants as aconite or datura, which are lethal and clearly more deadly than eating pork infected with *Trichina (Trichinella) spiralis.*

Carrion. Meat from an animal that "dies of itself" is proscribed by each of the monotheistic faiths that developed in the Mediterranean region. For Jews, the injunction is repeated six times (Exodus 22:31; Leviticus 11:39–40, 17:15–16, and 22:8; Deuteronomy 14:21; and Ezekiel 4:14); for Christians, three times (Acts 15:20, 29, 21:25); and for Muslims, four times (Koran: The Cow, 168; Koran: The Table, 4; Koran: Cattle, 145; Koran: The Bee, 115).

The rejection of carrion as human food is hardly universal, however. Many societies readily consume carrion and "rancid meat" as dietary staples. Indeed, dietary use of carrion by circumpolar Arctic societies has been reviewed extensively (Borgoras 1909; Eidlitz 1969), and consumption of carrion by European Gypsies has been well documented, especially the use of animals burned to death by brush and forest fires (Petrovic 1939).

All of this brings up the question of whether religious prohibitions against carrion are in fact protective. Clearly, the potential for disease transmission exists if humans consume infected carrion, but to reject carrion as human food merely upon the *potential* for disease transmission is illogical, given that humans consume fish, fowl, meats, and plant foods that can and do create serious health problems after consumption.

In fact, it could be argued that eating carrion is protective in that it has helped millions of people survive periods of food shortages, wartime famines, and climatic stress. Indeed, droughts of recent decades in the southern African Kalahari Desert region severely challenged regional agro-pastoralists, who suffered loss of their herds but maintained their dietary and nutritional status by consuming carrion. When cattle and other livestock died of thirst or environmental stress, the baTlokwa butchered the carcasses and the carrion was steamed, with leaves of *Croton gratissimus* used to remove "off" odors. Such meat then was sun-dried and jerked and could be readily stored as a suitable famine food (Grivetti 1976, 1978b).

It is interesting to note that most baTlokwa agro-pastoralists are animists or moderate Christians; in contrast, most agro-pastoralists of the drought-stricken Sahel are Muslim. Both Christianity and Islam prohibit carrion consumption, but there are distinctive regional and cultural differences in keeping "the law."

Harmful foods not prohibited. Returning to a question posed earlier, if health considerations lie at the root of the carrion (and other food) prohibitions, then it might be asked why there are no codified prohibitions in Buddhism, Christianity, Hinduism, Islam, or Judaism for moldy grain (manifest as the human disease ergotism), or for fava beans (favism), or for field vetch (lathyrism).

To employ another example, human poisoning from eating European migratory quail *(Coturnix coturnix)* is manifest as the human illness coturnism. This food-related problem, documented since biblical times (Numbers 11:31–4), was known to Greek and Roman naturalists, among them Aristotle (*On Plants* 820: 6–7), Lucretius (*On the Nature of Things* 4: 639–40) and Pliny (*Natural History* 10: 33). However, no dietary codes were instituted to protect consumers. Furthermore, subsequent medieval Jewish and Muslim physicians described human poisoning from quail, among them Maimonides (*Commentary*

Epidemiarum 6: 5), Ibn Sina (*The Canon* 2:2:2:5), Qazwiny (*Kitab Aga'il* 2: 250), and al-Demiri (*Hayat al-Hayawan al Kubra* 1: 505). Nonetheless, not only were potentially toxic quail not proscribed but they have also remained a favorite food of Middle Eastern Jews, Christians, and Muslims throughout the centuries (Kennedy and Grivetti 1980).

Concluding Comments

The literature on food prohibitions and taboos is ancient and voluminous, and most certainly reflects human interest in understanding how and why specific foods have been proscribed throughout the ages. More than 10 hypotheses have been advanced to explain the origins and development of food-related taboos, and evidence in support of them and against them can be marshaled for each.

Some who study food-related taboos have worked for decades to identify unifying concepts that would explain ancient as well as contemporary human behavior toward food. Some have attempted scientific explanations; others have sought meaning in nonscientific descriptions. Most accounts have stressed the cultural-religious aspects of food prejudices in Christianity, Hinduism, Islam, or Judaism. Beyond religion, however, lie still other categories of food prohibitions associated with the consumer's age and gender, ecological protection, and medical-nutritional themes. But within this enormous body of literature, there remains a single concept that has been expressed in two ways: *Food for one is not food for all,* and *One man's meat is another's poison.*

VI.14 The Social and Cultural Uses of Food

Food is what Marcel Mauss (1967) called a "total social fact." It is a part of culture that is central, connected to many kinds of behavior, and infinitely meaningful. Food is a prism that absorbs a host of assorted cultural phenomena and unites them into one coherent domain while simultaneously speaking through that domain about everything that is important. For example, for Sardinians, bread is world (Counihan 1984). In the production, distribution, and consumption of bread are manifest Sardinian economic realities, social relations, and cultural ideals. An examination of foodways in all cultures reveals much about power relations, the shaping of community and personality, the construction of the family, systems of meaning and communication, and conceptions of sex, sexuality, and gender. The study of foodways has contributed to the understanding of personhood across cultures and historical periods (see Messer 1984).

Every coherent social group has its own unique alimentary system. Even cultures in the process of disintegration reveal their plight in the ways they deal with and think about eating.[1] Cultures articulate and recognize their distinctiveness through the medium of food. The English call the French "Frogs" because of their habit (wildly barbarian to the English) of eating the legs of that creature (Leach 1964: 31). In the Amazon region, Indian tribes that appear alike in the eyes of an outsider nonetheless distinguish themselves from one another in part through their different habits, manners, and conceptions of eating. Maligned other groups are defined as those who eat people and animals thought disgusting, as for example, "frogs and snakes and mice" (Gregor

1985: 14). Food systems are, of course, intimately related to the local environment, but in most cultures "only a small part of this edible environment will actually be classified as potential food. Such classification is a matter of language and culture, not of nature" (Leach 1964: 31). The study of foodways enables a holistic and coherent look at how humans mediate their relationships with nature and with one another across cultures and throughout history.

Food and Power

David Arnold (1988: 3) suggests that "food was, and continues to be, power in a most basic, tangible and inescapable form." Frances Moore Lappé and Joseph Collins (1986) make a strong argument that there is no more absolute sign of powerlessness than hunger, since hunger means that one lacks the control to satisfy the most basic subsistence need. Food is a central concern in the politics of nation states. Whereas Piero Camporesi (1989: 137) argues that chronic hunger and malnutrition were part of a calculated strategy of early modern political elites to maintain their power by keeping the poor debilitated and dazed, Arnold (1988) and others[2] point out that extreme hunger can bring about popular protest that may seriously weaken a government's stability. According to Arnold (1988: 96), "The fortunes of the state, whether in Europe or in Africa or Asia, have long been closely bound up with the containment or prevention of famine and, more generally, with provisioning the populace."

In stratified societies, hunger – like poverty – is far more likely to strike people in disadvantaged and devalued social categories: small children, the mentally ill, the handicapped, women, people of color, and the elderly (Physicians Task Force on Hunger in America 1985; Brown 1987; Brown and Pizer 1987; Arnold 1988; Glasser 1988). Food scarcity mirrors and exacerbates social distinctions; famine relief goes first to groups with power, and in times of economic crisis, the rich get richer by buying the land and other resources of the poor as the latter give them up in the struggle to eat.

A person's place in the social system can be revealed by what, how much, and with whom one eats. As Jack Goody (1982: 113) says, "the hierarchy between ranks and classes takes a culinary form." In India, caste is marked quite conspicuously by different food habits and rules prohibiting eating with those of lower caste (Goody 1982: 116 ff.; Khare and Rao 1986). Different consumption patterns are one of the ways the rich distinguish themselves from the poor (Bennett 1943; Fitchen 1988; Weismantel 1988). For example, according to Carol J. Adams (1990: 30), the consumption of meat protein reveals "the white Western world's enactment of racism. . . . The hierarchy of meat protein reinforces a hierarchy of race, class, and sex." Sugar was at first only a food of the rich, who used it to (among other things) create fabulous, ostentatious sculptures that proclaimed their wealth and power through extravagance with the precious and desirable commodity (Mintz 1985).

As sugar became more plentiful, however, the poor were increasingly able to eat it, which they did, in part, in an effect to emulate the rich and achieve a like status. Sugar consumption conveyed "the complex idea that one could *become* different by *consuming* differently" (Mintz 1985: 185). But to eat sugar, the poor sacrificed other foods, and their diet suffered, whereas the rich who could eat sugar *and* other foods simply chose new ways of proclaiming their difference. According to Stephen Mennell:

> Likes and dislikes are never socially neutral, but always entangled with people's affiliations to class and other social groups. Higher social circles have repeatedly used food as one of many means of distinguishing themselves from lower rising classes. This has been manifested in a succession of styles and attitudes towards food and eating (Mennell 1985: 331–2).

Class distinctions are also manifest through rules about eating and through the ability to impose rules on others (Counihan 1992). For example, we live in a culture that values thinness.[3] The dominant culture – manifest in advertising, fashion, and the media – projects a belief that thinness connotes control, power, wealth, competence, and success (Dyrenforth, Wooley, and Wooley 1980). Research has revealed that obesity for women varies directly with class status and ethnicity. Greater wealth and whiteness go along with thinness; poor Puerto Rican, black, and Native American women have lower status and greater obesity rates than well-off Euro-American women (Garb, Garb, and Stunkard 1975; Beller 1977; Stunkard 1977; Massara and Stunkard 1979; Massara 1989; Sobal and Stunkard 1989). The standard of thinness upholds a class structure where men, whites, and the rich are superior to women, people of color, and the poor.

Food and Community

Manners and habits of eating not only display the complex intricacies of the social hierarchy but also are crucial to the very definition of community, the relationships between people, interactions between humans and their gods, and communication between the living and the dead. In many societies, communal feasts involve a periodic reaffirmation of community "based upon primal conceptions of the meaning of eating and drinking in common. To eat and drink with someone was at the same time a symbol and a confirmation of social community and of the assumption of mutual obligations" (Freud 1918: 174).

Sharing food ensures the survival of the group both socially and materially. A companion is literally a person one eats bread with (Farb and Armelagos 1980: 4). Refusal to share food is a sign of enmity and hostility; as Marcel Mauss (1967: 58) reports of Brahmans, "A man does not eat with his enemy." For eating together is a sign of kinship, trust, friendship, and in some cultures, sexual intimacy, as we shall discuss further.

On a day-to-day basis, food exchanges are crucial in maintaining good relations between individuals. The message of the following Sardinian proverb (Gallini 1973: 60) is relevant in many cultures:

Si cheres chi s'amore si
  mantenzat
prattu chi andet, prattu
chi benzat.

If you want love to be
  maintained
for a plate that goes,
let a plate come back.

Mauss (1967) has shown the pervasive cultural power of the gift that keeps individuals constantly indebted to each other and continuously engaged in positive interaction through giving. In his interpretation of Mauss, Marshall Sahlins has said, "The gift is alliance, solidarity, communion, in brief, peace" (1972: 169). Food is an extremely important component of reciprocal exchanges, more so than any other object or substance (Mauss 1967). As Sahlins says: "By comparison with other stuff, food is more readily, or more necessarily shared" (1972: 215).

Bronislaw Malinowski (1961: 168–72), Miriam Kahn (1986, 1988), and Michael Young (1971) have explicitly demonstrated how in Melanesia, feasting both joins people in community and establishes power relations. Kahn (1986, 1988) describes two different kinds of feasts held by the Wamirans of Papua New Guinea, the T-mode (transaction) feast that serves to reinforce power ranks and the I-mode (incorporation) feast that strengthens community solidarity; "both types of exchanges are equally necessary" (Kahn 1986: 125). Similarly, in the Sardinian community of Tresnuraghes (Counihan 1984), the annual St. Mark celebration involves a collective feasting on mutton, donated by wealthy shepherds, and bread, donated by villagers seeking or repaying divine assistance. This redistributive feast serves simultaneously to bring the community together, to make abundant food available to the poor, and to display the wealth and prestige of those able to sponsor the feast. Similar redistributive celebrations occur in a wide range of peasant and tribal societies and are central to the maintenance of community and political organization.[4]

In many cultures, food is instrumental in maintaining good relations between humans and their gods. In Christianity, a central symbol is the consumption of bread, both by Christ and his disciples at the Last Supper, and regularly by the faithful in the Communion ritual (Feeley-Harnik 1981; Bynum 1987). The bread, or host, is the body of Christ; it stands for redemption, holiness, and salvation. The faithful literally eat their God, and, in so doing, incorporate the values and messages of their religion. Ancient Greeks, and many other peoples, use food sacrifices as a means of propitiating their gods (Mauss 1967; Detienne and Vernant 1989). Tibetan Buddhist Sherpas consciously cajole their gods with food offerings and say, "I am offering you the things which you eat, now you must do whatever I demand" (Ortner 1975: 147). By consciously employing the mechanisms of hospitality with the gods that facilitate human interaction, Sherpas hope that "aroused, pleased, and gratified, the gods, like one's neighbors, will feel 'happy' and kindly disposed toward the worshippers/hosts and any requests they might make" (Ortner 1975: 146–7).

Offerings of food to the deceased are a common cultural means of ensuring good relations with them (Frazer 1951; Goody 1962; Huntington and Metcalf 1979; Nutini 1988). On All Souls' Day or Eve, throughout the Christian world, people make food offerings and sometimes prepare entire meals for the dead. Some Sicilians eat fava beans; others consume cooked cereals (De Simone and Rossi 1977: 53–4). In Bosa, on All Souls' Day, Sardinians prepare *sa mesa,* literally, "the table," which is a meal for the deceased that they lay out as they are going to bed (Counihan 1981: 276–9). They always include spaghetti and *pabassini,* a special cookie made for All Souls' Day, as well as many other foods, including bread, nuts, fruit, and sometimes wine, beer, Coca-Cola, juice, coffee, snuffing tobacco, or cigarettes. The meal is destined specifically for one's own dead relatives, and often the optional food items reflect a specific deceased person's preferences in life. The meal serves to communicate and maintain good relations with the dead, just as food exchanges regularly do with the living.

In some cultures, the living actually eat the dead to honor them and gain some of their powers (Arens 1979; Walens 1981; Sanday 1986). Sigmund Freud argued that consumption of the deceased is based on the belief that "by absorbing parts of the body of a person through the act of eating we also come to possess the properties which belonged to that person" (1918: 107). The Yanomamo Indians of the Venezuelan Amazon eat the ashes of their deceased loved ones to ensure a successful afterlife. When ethnographer Kenneth Good was deathly sick with malaria, his informants expressed their affection by assuring him, "Don't worry, older brother. Don't worry at all. We will drink your ashes" (Good and Chanoff 1991: 133). Consumption establishes connection between the living and the dead, between humans and their gods, among neighbors and kin, and, in particular, among family members.

Food and Family

Feeding is one of the most important channels of infant and child socialization and personality formation.[5] In fact, the Pacific Atimelangers studied by Cora Du Bois believe that the original creation of human beings was from food; they were "created from molded rice and corn meal" (1941: 278–9). Food and the manner of giving it make the child. As Margaret Mead said, "It seems probable that as he is fed every child learns something about the willingness of the world to give or withhold food, to give lavishly or deal out parsimoniously" (1967: 70).

According to Freud, the child's earliest experiences of eating are the stage for important developmental processes and shape his or her lifelong personality: "The first and most important activity in the child's life, the sucking from the mother's breast," introduces the child to sexual pleasure and prefigures later adult sexuality (Freud 1962: 43; see also Malinowski 1927). Furthermore, breast feeding becomes part of the process of individuation for the child. As it recognizes gradually that the mother is other, and that its source of food is outside of itself, the child begins to establish an autonomous and bounded identity.

In some cultures, the family may be most effectively conceptualized as those people who share a common hearth (Weismantel 1988: 169). As Janet Siskind says of the Sharanahua Indians of the Peruvian Amazon, "Eating with people is an affirmation of kinship" (1973: 9). So important is feeding to the establishment of parent–child relations in Kalauna, Goodenough Island, that "fosterage . . . is wholly conceived in terms of feeding" (Young 1971: 41). Young goes on to note that this same "identification is buried in our own language: Old English 'foster' means 'food' " (1971: 41). In Kalauna, the father establishes his paternity by providing food for his pregnant wife. Young says:

> While the role of the mother in producing the child is self-evident, the father must reinforce his own role by feeding his wife during pregnancy. This is explicitly seen as nurturing the foetus, and it is a principal element in the ideology of agnatic descent (1971: 40).

Problematic feeding can lead to personality disturbances in children, and dysfunctional families may have members who suffer from eating problems (Palazzoli 1971; Bruch 1973). Anna Freud suggests that disturbed eating patterns may be "symbolic of a struggle between mother and child, in which the child can find an outlet for its passive or active, sadistic or masochistic tendencies towards the mother" (1946: 121).

Dorothy N. Shack (1969) and William A. Shack (1971) attribute a host of personality characteristics of the Gurage of Ethiopia to their inconsistent early-childhood feeding habits and later patterns of want and glut that reveal severe "dependency-frustration" (W. Shack 1971: 34). Gurage children are often neglected when hungry and then finally fed to excess after crying for hours (D. Shack 1969). Adults eat sparingly and quickly on normal occasions, but occasionally find themselves forced to eat when not hungry at feasts or as guests (W. Shack 1971). D. Shack argues that such eating patterns contribute to the development of personality traits that include "selfishness," "emotional detachment," "unrelatedness," "passivity," "dependency," and feelings of worthlessness (1969: 298).

W. Shack suggests that because the food supply is particularly unreliable for low-status men, they are susceptible to *awre* (spirit possession), marked by "loss of appetite, nausea and intermittent attacks of severe stomach pains" (1971: 35). The affliction is cured through a collective ritual in which the victim is covered by a white shawl, seated in a smoky room, and given special food called *bra-brat.* With this, he "begins greedily and ravenously stuffing his mouth" and continues to do so until the spirit, "speaking through the possessed person, utters with a sigh, several times – *'tafwahum'* – 'I am satisfied' " (W. Shack 1971: 36). The rite of *awre*-spirit exorcism allows a low-status man deprived of both food and prestige to gain both. It is a temporary overcoming of the dependency frustration embedded in the cultural foodways that produces a chronic anxiety in those most often hungry. The Gurage exemplify how feeding patterns can influence personality formation and show how different cultures have distinct ways of ensuring that people get fed.

Food as Meaning, Symbol, and Language

In every culture, foodways constitute an organized system, a language, which – through its structure and components – conveys meaning and contributes to the organization of the natural and social world. According to Roland Barthes (1975: 49–50), "Food . . . is not only a collection of products that can be used for statistical or nutritional studies. It is also a system of communication, a body of images, a protocol of usages, situations and behavior." Foodways are a prime domain for conveying meaning because eating is an essential and continuously repeated activity; foods are many; there are different characteristics of texture, taste, color, and modes of preparation of food that are easy labels for meaning; food constitutes a language accessible to all; and eating is extremely pleasurable.

In examining the meaning of food, social scientists have studied *cuisine,* the food elements used and rules for their combination and preparation; *etiquette and food rules,* the customs governing what, with whom, when, and where one eats; *taboos,* the prohibitions of and restrictions on the consumption of certain foods by certain people under certain conditions; and *symbolism,* the specific meanings attributed to foods in specific contexts.[6] There is of course much overlap between these four domains. For example, the study of Jewish dietary law[7] involves examination of foods eaten and not eaten and the legitimate bases of their combination (cuisine). But it also concerns the study of meals, the arrangement and sequence of foods, peoples' roles in the preparation and serving of food, and their placement at the table (etiquette). In addition, it includes the study of foods not eaten and why (taboo). And finally, to make sense out of all this, it involves the study of the complex and multivocal meanings of the foods and the behaviors centered around them (symbolism).

Food functions effectively as a system of communication because human beings organize their foodways into an ordered system parallel to other cultural systems and infuse them with meaning: "The cuisine of a people and their understanding of the world are linked" (Soler 1973: 943, my translation). It is to this cultural association between food and meaning that Claude Lévi-Strauss (1963a: 89) was referring in his oft-quoted statement that certain animal species are chosen as totems "not because they are 'good to eat' but because they are 'good to think.'" Foods have and convey meanings because they are part of complex systems; "food categories . . . encode social events" (Douglas 1974: 61). Jean Soler suggests that a food taboo "cannot be understood in isolation. It must be placed in the center of the signs of its level, with which it forms a system, and this system must itself be connected to systems of other levels, with which it articulates to form the socio-cultural system of a people" (1973: 946, my translation).

Structuralists (for example, Lévi-Strauss 1966; Verdier 1969) emphasize the dual nature of food and cuisine, which both stand between and mediate nature and culture. The process of naming a wild product as food and transforming it into something edible involves the "culturizing" of nature. And cuisine, because it is a "means of transformation, must facilitate at least metaphorically all transformation" (Verdier 1969: 54). Hence, foods are very often used in rites of passage (see Goody 1982: 79–81).

Among the Mehinaku, initiation ceremonies for girls involve the ritual of first menses, for boys the ear-piercing ceremony. These rituals and the related blood flow are seen as parallel and involve the same restrictions on eating:

> Both boys and girls must follow certain food taboos to ensure the rapid cessation of the flow of blood and a favorable dream. Initially, the children are subject to a fast; they are allowed to drink water after twenty-four hours. . . . Following the fast, they may eat all foods but fish, which would prolong the blood flow. "Fish," it is said, "eat other fish and therefore are filled with blood." Monkeys and birds eat only fruit and have a "different kind of blood" and are therefore acceptable to "menstruating" boys and girls. . . . With the total cessation of the flow of blood, a ceremony reintroduces fish to the diet. The boys are led outside, taste a small amount of fish, and spit it onto a fiber mat. The girls follow the same ritual inside the house. . . . Fish are now permissible . . . (Gregor 1985: 189).

Here food is used to signify the transformation of boys to men and girls to women while it simultaneously marks the similarity of the maturation of boys and girls (see also S. Hugh-Jones 1979 and C. Hugh-Jones 1979, especially chapter 5).

Food can be used metaphorically to convey just about any imaginable condition, thought, or emotion. American college students, for example, express feelings of love, anger, anxiety, depression, sorrow, and joy through their eating habits (Counihan 1992). After a satisfying meal, Sardinians say, "*consolada(o) soe*" – "I am consoled" – and imply the metaphorical and physical overlap between good food and good feelings (Counihan 1981). Because of the strong visceral pleasure of eating and pain of hunger, food readily adopts powerful connotations and is a rich symbol in written and oral literature.

Food in Folklore and Literature

Food meanings are paramount in Lévi-Strauss's (1963b, 1966, and 1969) monumental study of mythology. He is concerned with understanding, through mythology, the structure of the human mind. According to Lévi-Strauss, binary oppositions are embodied in our brains and appear in many levels of our thinking. The oppositions in the human relationship to nature mediated through food (for example, "the raw and the cooked," nature and culture, or animal and human) reveal universals in human thinking.

In stories told to children, proper eating represents humanness and effective socialization, whereas out-of-control eating and cannibalism stand for wildness and incomplete socialization. The widely known European folktale "Hansel and Gretel" is a good example of these themes; it "is about conflicting family loyalties expressed in terms of sharing and hoarding food" (Taggart 1986: 435). Bruno Bettelheim interprets the food themes of the story as being about children's struggle to outgrow oral dependency and symbiosis with the mother (1975: 159–66). Hansel and Gretel are forced from home due to food scarcity and they, subsequently, gobble up the candy house without thought or restraint.

This regression to "primitive incorporative and hence destructive desires" only leads to trouble, as they are trapped by the wicked witch, "a personification of the destructive aspects of orality" (Bettelheim 1975: 160, 162). Eventually, the children use reason to dominate their oral urges and refuse food so as to be able to kill the witch. Then they inherit her jewels and become reunited with their family in a new status: "As the children transcend their oral anxiety, and free themselves of relying on oral satisfaction for security, they can also free themselves of the image of the threatening mother – the witch – and rediscover the good parents, whose greater wisdom – the shared jewels – then benefit all" (Bettelheim 1975: 162). Their struggle with food, in essence, represents stages in their maturation.

The same theme about the power of food in family relations is beautifully depicted in Maurice Sendak's Caldecott Medal–winning children's story *Where the Wild Things Are* (1963). The tale, which many have placed in the category of superb children's literature, goes something like this: Once upon a time there was an energetic little boy, Max, who put on his wolf costume and pretended to be a ferocious animal. He annoyed his mother so much with his rambunctious behavior that she called him a "wild thing." When in response he threatened to eat her up, she made him go to bed without his supper.

While Max was lying in the dark, his room turned into a dense forest, and a boat arrived. He boarded it and it took him to the land where the wild things lived. He "tamed" them, and they liked him so much that they crowned him their king, which began a boisterous and rowdy time for all.

After a while Max became annoyed by all the commotion and wanted it to stop. As their king he called an end to the rumpus and sent everyone to bed without supper. By now he missed his family and their love for him, and he detected a wonderful aroma that could only be the good food at his house. Very homesick now, he decided to give up his crown and leave the kingdom. He told the wild things that he wanted to go home.

His unruly subjects, however, were not willing to let him leave. They first claimed to love him too much to let him go; in fact, they said that they loved him so much they would rather eat him up than see him leave. But when he insisted, they acted ferociously toward him, making horrible sounds and showing their fangs, and their eyes were evil and menacing. The boy relinquished his kingdom nonetheless and boarded the boat from which he waved good-bye. The way home was a very long journey. It seemed to the little boy to take over a year – but when he finally arrived back in his room, a meal was laid out to greet him. It was still warm.

Sendak's story shows how food is a source of love, power, socialization, and connection between parents and children. In the story, Max is a "wild thing," an incompletely socialized child. His wildness is shown by the wolf suit and his desire to eat his mother up, a desire that simultaneously expresses the incomplete separation of the child from the mother. This theme of eating as incorporation is recreated later in the story when the wild things want to eat Max up, to keep him from leaving them. But Max does not stay with the wild things; he feels the pull of love in the smells of "good things to eat" that come from the place "where someone loved him best of all." He follows a long journey home where love awaits him in the form of the supper that was previously denied him because of his bad behavior. The fact that "it was still hot" symbolizes the mother's love that persists and is there to facilitate his socialization.

Food, Gender, Sex, and Sexuality

One of the most significant domains of meaning embodied in food centers on the relation between the sexes, their gender definitions, and their sexuality:

> Wives are like mothers. When we were small our mothers fed us. When we are grown our wives cook for us. If there is something good, they keep it in the pot until we come home. When we were small we slept with our mothers; when we are grown we sleep with our wives. Sometimes when we are grown we wake in the night and call our wives 'mothers' (Du Bois 1944: 96).

Eating is a sexual and gendered activity throughout life. Food may stand for sex; as Thomas Gregor says of the Mehinaku Indians, "A literal rendering of the verb to have sex might thus be 'to eat to the fullest extent.' . . . The essential idea is that the genitals of one sex are the 'food' of the other's" (1985: 70). Food and sex are metaphorically overlapping: Eating may represent copulation; foods may stand for sexual acts. The poet George Herbert captured this relation in the early seventeenth century: " 'You must sit down,' says Love, 'and taste my Meat.' / So I did sit and Eat" (quoted in Starn 1990: 78). In many cultures, particularly those with food scarcity, food gifts may be an important path to sexual liaisons (Holmberg 1969: 126; Siskind 1973).

In all cultures there are associations between eating, intercourse, and reproduction.[8] These activities share certain biopsychological attributes – particularly their contributions to life and growth, their passing in and out of the body, and their mingling of discrete individuals – that endow them with metaphorical and symbolic identity. Food and sex are analogous instinctive needs (Freud 1962: 1), and there is a lifelong connection between oral pleasure and sexual pleasure (Freud 1962: 43). Eating together connotes intimacy, often sexual intimacy or kinship (Freud 1918: 175; Siskind 1973: 9). Hence, both eating and copulation could be seen as effecting social merging.

Precisely because eating and intercourse both involve intimacy, they can be dangerous when carried out with the wrong person or under the wrong conditions. Hence, food consumption and sexual activity are surrounded with rules and taboos that regulate them and also reinforce beliefs about gender basic to the social order (see especially Meigs 1984). Food and sex both have associated etiquette about their appropriate times, places, and persons; often people with whom one can eat are those with whom one can have sex and vice versa (see, for example, Tambiah 1969). Among the Trobriand Islanders, a man and woman announce their marriage by eating yams together in public; before this they must never share a meal (Weiner 1988: 77).

Maleness and femaleness in all cultures are associated with specific foods, and rules exist to control their consumption (see Frese 1991 and Brumberg 1988: 176–8). For example, the Hua of New Guinea have elaborate conceptions about *koroko* and *hakeri'a* foods. The former are cold, wet, soft, fertile, fast-growing foods associated with females; the latter are hot, dry, hard, infertile, and slow-growing foods associated with males. Women can become more like men by consuming *hakeri'a* foods, which, it is believed, help minimize menstrual flow. Men, on the other hand, proclaim publicly that female foods and substances are "not only disgusting but also dangerous to the development and maintenance of masculinity." Secretly, however, they eat foods associated with females to gain vitality and power (Meigs 1984).

In general, the association between food and sex is deeper, more extensive, and more intimate for women than it is for men (see, for example, Bynum 1987: xiv). In all cultures, women's primary responsibilities involve food provisioning and the bearing and rearing of children (D'Andrade 1974; Moore 1988). Although these activities are undertaken with widely ranging amounts of autonomy, prestige, and control, they are nonetheless universally linked to womanhood. Women *are* food to the fetus and infant: The breasts can be sources of both sexual pleasure and food. As Mead noted, for women but not for men, both food and sex involve a posture of inception: "[T]he girl finds that the reinterpretation of impregnation and conception and birth fits easily into her early experience with the intake of food" (1967: 143). Where women are valued, their parallel experiences of eating, intercourse, and birth are likely to be positive, but where women are devalued, these activities can be a source of shame and subordination.

In the United States, for example, female college students report that they feel ashamed to eat in front of men with whom they have a romantic involvement (Counihan 1992). They fear fat with obsession and terror (Orbach 1978; Millman 1980; Chernin 1981), and report that men denigrate and gain power over them by saying they eat too much or are too fat (Millman 1980; Counihan 1992). In gender-stratified cultures as diverse as England (Charles and Kerr 1988), Italy (Counihan 1988), and Andean Ecuador (Weismantel 1988), men control women by claiming the authority to judge the meal the latter have cooked for them.

The power relations around food mirror the power of the sexes in general.[9] Whereas men gain power in some cultures by controlling money, and hence food purchasing power (Charles and Kerr 1988), women exert considerable power in all cultures by their control of food preparation and consumption. Adams (1990) argues that patriarchal power in Western society is embodied in the practice of eating meat, which involves the linking of women and animals and their objectification and subordination. Women can rebel through vegetarianism, which from this perspective is a political statement: a rejection of patriarchal power and values, an expression of feminism, and a claiming of female power over self and nature.

Among the Zumbaguan Indians of Andean Ecuador, the senior female is in charge of preparing and serving meals (Weismantel 1988: 28–9). This gives her the ability to determine hierarchies by the order in which she serves people and the contents of the plate she gives them (Weismantel 1988: 182). A woman can even punish an errant husband who finally returns from a drinking spree by serving him massive quantities of rich food that the husband, by force of etiquette, eats, with extremely unpleasant physical results.

In Western societies, for at least eight centuries, some women have used food in symbolic ways as a path to power.[10] Today, modern anorexics starve themselves, sometimes to death, to achieve physical and spiritual perfection. Their behavior is strikingly similar to that of medieval holy women in the fourteenth, fifteenth, and sixteenth centuries, although the cultural contexts of their behaviors are rather different (Bell 1985; Bynum 1987; Brumberg 1988; Counihan 1989). Medieval holy women fasted for religious and spiritual perfection (that is, holiness): They used eating or fasting as a path to reach God and to circumvent patriarchal, familial, religious, and civil authority. Some women achieved sainthood by virtue of the spirituality they revealed, primarily through fasting and other food-centered behaviors, such as multiplying food in miracles, exuding holy oils or milk from their own bodies, and giving food to the poor (Bynum 1987). Contemporary anorexics attempt to achieve perfection through self-control and thinness. They receive pitying recognition from family, friends, and medical professionals, and may die unless they find a path to the self-esteem, sense of control, and autonomy they so desperately seek through fasting (Bruch 1973, 1978; Lawrence 1984; Brumberg 1988).

Between men and women, food is a means of differentiation, as well as a channel of connection. By claiming different roles in regard to food and distinct attributes through identification with specific foods, men and women define their masculinity and femininity, their similarities and differences. They use food and food metaphors to achieve the most intimate union, as witnessed through language that equates eating with sexual relations and through practices that equate the exchange of food – whether with candlelight dinners in four-star restaurants or with baked taro on Trobriand verandas (Weiner 1988) – with sexual intimacy.

Conclusion

Food, although essential to biological survival, takes on myriad meanings and roles in contributing to "the social construction of reality" (Berger and Luckmann 1966). As humans construct their relationship to nature through their foodways, they simultaneously define themselves and their social world (Berger and Luckmann 1966: 180–3). Through the production, distribution, and consumption of food, they act out their most important relationships: with their family, with their own and the opposite sex, with the community, with the dead, with the gods, and with the cosmos. Food orders the world and expresses multiplex meanings about the nature of reality. The social and cultural uses of food are many and they provide much insight into the human condition.

Carole M. Counihan

Notes

1. The following sources treat social responses to food shortages and famine: Richards 1932, 1939; Firth 1959; Holmberg 1969; Turnbull 1972, 1978; Laughlin and Brady 1978; Colson 1979; Prindle 1979; Dirks 1980; Young 1986; Vaughan 1987; Messer 1989; Newman 1990.
2. See, for example, Tilly 1971; Hilton 1973; Kaplan 1976, 1984, 1990; Barry 1987; Mackintosh 1989.
3. Some works that explore the U.S. value on thinness are the following: Powdermaker 1960; Bruch 1973, 1978; Boskind-Lodahl 1976; Stunkard 1977; Orbach 1978; J. R. Kaplan 1980; Millman 1980; Styles 1980; Boskind-White and White 1983; Counihan 1985, 1989; Schwartz 1986; Sobal and Stunkard 1989.
4. Perhaps the most well-known redistributive ritual is the potlatch of the Northwest coast Indians, a feast that involves enormous conspicuous consumption in a competition between tribes to establish prestige and power relations, debts, social congress, and communion with the gods. See Benedict 1934; Codere 1950; Mauss 1967: 31–7; Piddocke 1969; and Harris 1974.
5. Some sources on feeding as a form of socialization and personality formation are the following: Du Bois 1941, 1944; Bossard 1943; A. Freud 1946; S. Freud 1962; Mead 1963, 1967; Holmberg 1969; D. Shack 1969; W. Shack 1971; Bruch 1973; Farb and Armelagos 1980.
6. The following sources have material on the meaning of food through the study of symbolism, taboo, etiquette, and/or cuisine: Lévi-Strauss 1966; Holmberg 1969: 78–81, 173–5; Lehrer 1969, 1972; Verdier 1969; Firth 1973; Murphy and Murphy 1974: 162–3; Ortner 1975; C. Hugh-Jones 1979, especially chapters 5 and 6; S. Hugh-Jones 1979; Farb and Armelagos 1980; Goody 1982; Laderman 1983; Mennell 1985; Manderson 1986.
7. On Jewish dietary law see Douglas 1966; Soler 1973; Alter 1979; Feeley-Harnik 1981; Fredman 1981; Harris 1985.
8. Works that have abundant material on the overlap between food, sex, and sexuality are Tambiah 1969; Verdier 1969; Murphy and Murphy 1974; Farb and Armelagos 1980; Meigs 1984; Gregor 1985; Pollock 1985; Kahn 1986; Herdt 1987; Frese 1991.
9. Some sources that focus explicitly on food and the power relations between men and women are the following: Charles and Kerr 1988; Counihan 1988; Weismantel 1988; Babb 1989; McIntosh and Zey 1989.
10. There is an enormous literature on what Jane R. Kaplan (1980) has called "the special relationship between women and food." In Western culture, women have variously used compulsive eating, obesity, fasting, or the symbolic value of food as a means of expressing themselves and coping with the problems of achieving a meaningful place in a world where they are defined as subordinate. Some sources dealing with women's complicated relationship to food are the following, in alphabetical order: Bell 1985; Beller 1977; Boskind-Lodahl 1976; Boskind-White and White 1983; Bruch 1973, 1978; Brumberg 1988; Bynum 1987; Charles and Kerr 1988; Chernin 1981, 1985; Counihan 1985, 1988, 1989, 1992; Gordon 1988, 1990; J. Kaplan 1980; Lawrence 1984; Massara 1989; Millman 1980; Orbach 1978; Palazzoli 1971; Schwartz 1986; Styles 1980; Thoma 1977; Waller, Kaufman and Deutsch 1940.

VI.15 Food as Aphrodisiacs and Anaphrodisiacs?

According to the first edition of the *Encyclopaedia Britannica* (1771), aphrodisiacs are "medicines which increase the quantity of seed, and create an inclination for venery." Since the twentieth-century advent of sexual endocrinology, the definition of an aphrodisiac has become restricted to "a substance which excites sexual desire" (*Steadman's Medical Dictionary,* 25th edition, 1990). The search for aphrodisiacs is rooted in universal anxieties about sexual performance and fertility. In many instances since ancient times, a distinction has been made between substances that were alleged to improve fertility (quantity of seed) and those that only stimulate the sex drive (inclination to venery). Some authorities held that the latter could only be achieved by achieving the former.

The scope of this essay is limited geographically to Europe and the Near East and, so far as possible, to foods and their preparation. Adequate nourishment has always been recognized as a requirement for health and a normal level of sexual activity, although the norm for the latter undoubtedly varies somewhat among cultures.

In ancient medical practices, when and by what indications nutritive and medicinal qualities of foods were differentiated is uncertain. A rather clear distinction, however, was made by Heracleides of Tarentum, a Greek physician in the first century B.C. In writing about aphrodisiacs, he said that "bulbs, snails, eggs and the like are supposed to produce semen, *not because they are filling,* but because their very nature in the first instance has powers related in kind to semen" (Athenaeus 1951: 275).

Another nagging question had to do with whether plant and animal products that ordinarily are not foods should be considered medicines or just special foods. Andrew Boorde (died 1549), a London physician, exemplified the vagueness of dietary–medicinal distinctions: "[A] good cook is half a physician. For the chief physic (the counsel of a physician excepted) does come from the kitchen: wherefore the physician and the cook for sick men must consult together for the preparation of meate [foods] for sick men" (1870: 227).

According to ancient literature, aphrodisiacs and their opposite, anaphrodisiacs, were generally simple rather than multi-ingredient prescriptions. This pattern gradually changed, and the most elaborate prescriptions were written in sixteenth- and seventeenth-century Europe (and much earlier in the Near East). Table VI.15.1

**Lower gladiolus root.

Sources: Pliny (1963); Gunther (1959); Adams (1847).

lists the substances that were cited as aphrodisiacs and anaphrodisiacs by three ancient authorities, Pliny and Dioscorides from the first century A.D. and Paul of Aegina from the seventh century. The former two listed more substances than did Paul because they, and especially Pliny, sought to record every one they encountered and did not necessarily vouch for each. All three concurred about only three aphrodisiacs: varieties of orchid bulbs, leaves and seeds of rocket *(Eruca sativa),* and the flesh of the skink (a North African lizard). They agreed on only two anaphrodisiacs: the seed and, presumably, leaf decoction (tea) of *Vitex agnus castus* (also called the chaste tree), and parts of rue *(Ruta graveolens),* an evergreen shrub (Adams 1847, 3; Gunther 1959; Pliny 1963: Vols. 7 and 8).

A Western philosophical association between dietary gratification and sexual stimulation was enunciated most clearly by St. Thomas Aquinas (died 1274) in his *Summa Theologica.* The biological aspects of the explanation were those of Galen, and they remained unchallenged for almost three more centuries. According to Thomas, the most urgent of the carnal vices was lust, with gluttony the second. Both were viewed as vices because they distracted from intellectual pursuits that brought men close to God. Moreover, certain foods both provided sensual gratification and created great incentive to lust. Such potentially lust-inducing foods and the qualities by which they could be identified should be learned so as to avoid them.

Procreation, according to Thomas, who did not distinguish this from "lust," required the participation of three components: heat, vital spirit, and humor. Whatever enhanced the production of any of the three might be sexually stimulating. Substances that heated the body, such as wine, would stimulate the production of more heat. Flatulent foods, in turn, were part of the production of the vital spirit. Meat, the most nutritious food, was needed to produce humor. Lust, however, was kindled more by drinking wine than by eating meat. The more an animal resembled humans, the greater pleasure and nutrition it offered as food: "Animals which rest on the earth and breathe air and also their products, such as milk. Because of these resemblances to mankind, when they are eaten they produce a greater surplus of the seminal matter which is the immediate inciter of lust" (Aquinas 1932, 9: 189; 13: 71–2).

This definition, however, fails to explain the selection of one particular lizard and is inconsistent with the aphrodisiacal properties that, by the Middle Ages, were attributed to birds' eggs, roe, and fowl. A final peculiarity shown in Table VI.15.1 is that different parts or combinations of the same sources were accorded opposite effects. A bifid root might have stimulant properties assigned to one segment and inhibitory effects to another. The small quantity of flesh adjacent to the skink's kidneys was deemed especially stimulating because of its proximity to an excretory organ. However, if this was mixed with lentils or lettuce seed, the opposite effect was achieved (Gunther 1959: 108).

The reputation of several ancient remedies can be attributed to their alleged physical resemblance to genitalia. Illustrative is the association of double orchid bulbs with testes, with the very names of these bulbs revealing their perceived application: *Orchis* means testicle, and a single bulb variety was called *satyrion* (the mythological sexually aggressive satyr) (Brondegaard 1971). But orchid bulbs, along with carrots, turnips, and the like (which possibly bear some genital resemblances), were not ordinarily considered aphrodisiacal. Rather, the quality nearest to a common denominator that ancient aphrodisiacs supposedly possessed was that they presumably stimulated urine flow.

Some ancient aphrodisiacal attributions were based on mythology. Aphrodite, the goddess of love, for example, was said to consider sparrows sacred because of their "amorous nature" and, thus, they were included in some love potions. Although both bird and fish eggs were prescribed, among birds a predilection for the eggs and (especially) the brains of sparrows persisted at least through the Middle Ages. Geoffrey Chaucer in 1390 in *The Canterbury Tales* described the Summoner to be "as hot and lecherous as a sparrow" (1952: 42). Sparrows also were distinguished from other small birds by allegedly being "hard of digestion" (Chaucer 1952: 270). Yet this quality would, for most authors, have disqualified sparrows as aphrodisiacs.

Because the anatomic and physiological ideas expounded by Galen (A.D. 129–210) reigned unchallenged from the third to at least the sixteenth century, their relationship to the identification of supposed aphrodisiacs requires some scrutiny. According to Galenic humoral principles, the effects of nutrients on sexual function, most clearly that of the male, were governed both by their inherent humoral qualities and by the responses they elicited when consumed. To be effective as an aphrodisiac, a nutrient had to be "warm and moist." Substances that were "cold and dry" had the opposite effect. The production of semen and erectile potency were differentiated. Although both required warm and moist nutrients for nonspecific stimulation, semen production needed particularly nourishing foods. Improvement of erectile potency demanded foods that generate "windiness" because "the penis is tensed . . . when the hollow nerve [corpus cavernosus] is filled with pneuma" (Galen 1968: 656–60). Thus, the English anatomist Thomas Vicary (died 1562) could write: "This member has three holes. Through one passeth insensible pollution and wind that causes the penis to rise. The other two holes . . . are for the sperm and . . . for urine" (1888: 81–2). "Insensible pollution" was the pneuma, which in this location was viewed as an inflator. "Wind" provided the expulsive force for semen and other excreta. Consequently, foods reputed to be flatulent were also thought to stimulate the emission of semen, provided the diet was sufficiently nutritious for an adequate amount to have been produced.

Earlier, the influential medical translator and commentator Constantinus Africanus (Constantine of Carthage, 1015–87) had concurred that the ideal aphrodisiac is nutritious, warm, and moist and that it generates windiness. And it was because few substances were reputed to contain all of the required humoral qualities that later prescriptions tended to become much more complex than they had been in the more ancient, particularly pre-Galenic, writings. Constantine, for example, prescribed "a tested electuary which increases lust" containing 19 ingredients. One of these, which remained popular for several centuries, was *linguae avis* (Delany 1970: 55–65), which in this case did not mean birds' tongues, but rather was the name for ash seeds. It is interesting to note that in *The Merchant's Tale,* Constantine was cursed because his "book" *De Coitu* apparently revealed aphrodisiacal recipes (Chaucer 1952: 36–7).

The Spice Trade

Spices were vital ingredients in the formulation of aphrodisiacs, rendering many such recipes dependent on imported materials. While the Roman Empire was in existence, spices doubtless reached Europe from Asia Minor via Roman legions, and probably supply was never interrupted entirely after its collapse. By the ninth century or so, Arab traders were supplying parts of Europe with spices from as far away as India and China. However, a great increase in the quantity and variety of spices for Europe was initiated in 1499 when the Portuguese navigator, Vasco da Gama (died 1524), rounded the Cape of Good Hope to reach India and returned to Lisbon with a cargo of pepper. A round-trip between Lisbon and the west coast of India in the late sixteenth century took about 18 months but could produce great profits. One hundred pounds of pepper, purchased in Calicut for 3 ducats, wholesaled in Lisbon for 25 ducats, and then retailed for 80 ducats in Venice.

Spices were the predominant Asiatic import, and pepper, used also as a food preservative, was the most important. Illustrative is the inventory of four ships that returned to Lisbon from India in 1580. It revealed a total cargo weighing 2,695,100 pounds, of which 97.6 percent was spices (Guerra 1965). Spain, the other Iberian nation, also got into the spice business following its conquest of Mexico in 1521. The Americas not only had indigenous spices to offer but also provided locations to cultivate spices previously grown only in Asia. Thus, ginger (the first transplanted spice crop) was introduced into Mexico in 1530; by 1587 Spain was importing 2¼ million pounds of ginger, ten times that carried by the Portuguese from India.

All of this activity in spices made a big business out of spice retailing, the practitioners of which since the Middle Ages had not only filled prescriptions but also supplied cooks with spices. Indeed, guilds of "pepperers" and "spicers" had been formed from the twelfth to the fourteenth centuries, and in England in 1617, a separate guild of apothecaries that distinguished them from grocers was created by royal edict (Kremers and Urdang 1951: 83–4, 136–40).

Semitic Influences

One of the tales from *The Book of the Thousand Nights and One Night* [The Arabian Nights], which probably is at least a thousand years old, contains an early example of the complexity that aphrodisiacal prescriptions achieved quite early in the Near East. The story of "Beautyspot" pertains to a merchant whose marriage has been childless for 40 years. This was cured by a prescription that consisted of spices and foods. Different translations vary in some of the ingredients, but two versions agree on six of the spices. Richard Burton's version also includes opium, skink meat, frankincense, and coriander (1885: 30–2). These were to be mixed in honey and consumed after a meal of hotly spiced mutton and pigeon. In another text, musk and roe are added as final ingredients. But before consuming this prescription, a special aphrodisiacal diet had to be adhered to for three days; it was limited to hotly spiced roasted pigeons, male fish with intact genitalia, and fried rams' testicles.

Another ancient ingredient that found its way into some European prescriptions was mandragora, or mandrake. Dioscorides said obscurely that "the root seems to be a maker of love medicines" (Gunther 1959: 473–4). Pliny, on the other hand, made no claim for a sexual effect (Pliny 1963, 7: 241–3). Both referred to a white male and a black female variety, but neither suggested that the plant might resemble human form as did later writers. They agreed that ingesting it induced sleep, that it could be used for surgical anesthesia, and that an overdose was fatal.

It is interesting that mandrake differs from most plants alleged to affect sexual function in that it actually has demonstrable physiological effects. It is related to deadly nightshade, or belladonna, and its content of hyoscyamine makes it potentially lethal. Yet it had a long-standing reputation in the Near East for encouraging female fertility. In Genesis 30:14–21, for example, Leah, who had become infertile, was given mandrake (manner unspecified), after which she conceived three more children.

Although most claims that mandrake corrects female infertility derived from this biblical reference, in the seventeenth century decoctions of the "white male" variety were alleged to overcome impotence as well (Thorndyke 1958: 10–13). Yet in 1771, the medicinal demise of mandrake was announced in an entry of the first edition of the *Encyclopaedia Britannica:*

"Authors have spoken very largely and idly of the virtues of this plant. The most common quality attributed to it, is that of rendering barren women fruitful: but we have no tolerable foundation for this: what we certainly know of it is, that is has a soporific virtue like that of opium."

A leading medieval writer who expounded the aphrodisiacal qualities of various foods was Rabbi Moses ben Maimon, or Maimonides (1135–1204). A Talmudic scholar who became physician to Sultan Saladin of Egypt, Maimonides was medically a follower of Galen and of Avicenna. He differed from others of the period in regard to aphrodisiacs mainly in placing greater emphasis on meats and organs, although not ignoring vegetables and spices. Maimonides was blunt about the relative aphrodisiacal merits of foods and medicines, insisting that nutriments were of much greater value than medications. However, one needed to be selective. Foods (and medications) that moistened and warmed the body (that is, had the Galenic qualities of heat and humidity) were deemed to some degree aphrodisiacal, whereas those that were cooling and drying were to be avoided because of their anaphrodisiacal effects.

In addition to the guidance provided by Galenic qualities, symbolism also played a role in identifying other substances (Rosner 1974: 18–29). For example, one of Maimonides's "very special" prescriptions required one to: "[t]ake the penis of an ox, dry it and grind it. Sprinkle some of this on a soft-boiled egg, and drink in sips" (Rosner 1974: 29).

The desired stimulation was sometimes transmitted through an intermediate. According to an Indian recipe some two centuries after the foregoing: "Boil the penis of an ass together with onions and a large quantity of corn. With this dish feed fowl, which you then eat" (Burton 1964: 242).

During the late sixteenth century in Europe, the compounding of ingestible phallic symbols varied only slightly from some of the prescriptions of Maimonides. For example:

> A man whose conjugal ardor has cooled should take the penis of a stag that has been killed while in rut, dry it and grind it into a powder. He should take 5 gm. of this and a dram of black pepper, mix these together in a drink of malmsey, and take it in the morning. Taken several days in a row it will make him right again (Mattioli 1590: 447b).

The Doctrine of Signatures

It is clear that symbolism has been used in the assignment of aphrodisiacal properties to plants and animal parts since pre-Christian times. But the delineation of a philosophy based on analogizing the appearance of natural objects with their perceived utility was delayed until the sixteenth century. It sprang from the ideas of the anti-Galenic itinerant Swiss physician Paracelsus (1493–1541) and was popularized by some of his followers. One of the best known of the latter was German physician Oswald Croll (about 1560–1609). In the introduction to his *Basilica Chymica* (original 1609, English 1670) he stated the belief most clearly:

> If he so desireth to be an expert physician, and to have knowledge of those things which point to Medicine, by that Art, which Nature externally proposeth by Signes, he may understand that those internally signify: for every thing that is intrinsical, bares the external figure of its occult property, as well in insensible as sensible Creatures. Nature as it were by certain silent notes speakes to us, and reveals the ingenuity and manners of every Individual. . . . As our intimate manners from external figures of the Body may be found out, so from the exteriour Signatures of Plants, Man may be admonished of their interiour Vertues. For Plants do as it were in occult words, manifest their excellency, and open the Treasures of hidden things to sickly Mortalls; that Man, of all Creatures the most miserable, may learn in grievous Diseases, where to find relief (Croll 1670: 3).

Herbals in the Sixteenth and Seventeenth Centuries

The complexity of European aphrodisiacal prescriptions in the sixteenth century is particularly well illustrated by concoctions called *diasatyrion* (so named because although they were based on an orchid bulb, they had additional ingredients as well). The following directions for the preparation of a diasatyrion were published in 1536:

> Take male orchid bulb, satyrion bulb, parsnip, sea holly, nutmeg, pistacio nuts, and pine nuts, 12 drams each, carnation, ginger, anise, ash seed, and rocket seed, each 5 drams, and musk 7 grains. Compound with a sufficient amount of honey.
>
> Grate orchid bulbs and parsnip and cook for a short time while stirring with a spatula. Then add the pine nuts and pistacios, also grated. After brief cooking, remove from the fire and add the other ingredients, except for the musk. The latter is added the very last, [diluted] in rosewater (Schumacher 1936: 98–9).

Judging by the contents of herbals, which were the principal textbooks of materia medica of the time, the number of botanicals to which aphrodisiacal properties were attributed reached their peak between the late sixteenth and the late seventeenth centuries. The 1554 herbal of Pietro Mattioli (1500–77), in its expanded German edition of 1590, contained 39 such entries, about two-thirds of which would ordinarily be considered vegetables, spices, or edible nuts

Table VI.15.2. *Most commonly cited aphrodisiacs, 1546–1710*

Orchis, cynosorchis, dog-stones	8
Carrot	8
Mustard	7
Anise	6
Asparagus	6
Nettles	6
Claire, scarlet sage (Salvia)	5
Ladies bedstraw (Galium verum)	5
Ash seed (Lingua avis)	4
Rampion	4
Rocket	4
Sweet pea	4
Terebinth seed (Pistacia terebinthus)	4

(1590: 28). Yet most of the time the various herbalists failed to agree on the foods that had aphrodisiacal qualities, and even in comparing the 1597 and 1636 editions of the herbal of John Gerarde (1545–1612), one discovers numerous changes. For example, 35 substances in the earlier edition but only 30 in the later are said to be sexual stimulants. Moreover, only 24 were endowed with such a virtue according to both texts (Gerarde 1597; 1636).

A survey of eight herbals published between 1546 and 1710 found 13 substances (see Table VI.15.2) with alleged aphrodisiacal properties that are identified in at least four of them (Bock 1546; Dodoens 1578; Mattioli 1590; Gerarde 1597, 1636; Parkinson 1640; Theodorus 1664; Salmon 1710). The list was led by the double orchid bulb (8) and the carrot (8) (now gaining in aphrodisiacal reputation), followed by mustard seed (7), and anise, asparagus, and nettles (6 each).

It is difficult to explain the aphrodisiacal reputation of some foods in terms other than those having to do with their remote origin or their initial scarcity. The reception of the American potato in Europe serves as a good example.

The English word "potato" is derived from the generic term for the sweet potato, *Ipomoea batatas.* The sweet potato was a staple food in the West Indies and was among the plants that Columbus brought back from his first voyage. It was planted in Spain, but because it requires a warm climate, it did not do well in northern Europe, where it became a scarce, imported item. The white potato probably reached Spain no later than 1570 and it may have been introduced in England by Francis Drake in 1586. During the first half of the seventeenth century, the "common potato" and the "Virginia potato" were the names of the sweet and the white potato, respectively (Salaman 1949: 130–2, 142–8, 424–33).

The sweet potato, at least in sixteenth- and seventeenth-century England, was eaten mainly as a candied delicacy. But in a late sixteenth-century description of English dietary customs, it was referred to as a "venereous root" (Harrison 1577: 129), and it repeatedly appears on the seventeenth-century stage as an aphrodisiac, by itself and in complex recipes. In *The Merry Wives of Windsor* (Shakespeare 1971) Shakespeare has Sir John Falstaff tell a lady before embracing her: "Let the sky rain potatoes; let it thunder to the tune of Green Sleeves; hail kissing comfits, and snow eringoes; let there come a tempest of provocation, I will shelter me here" (Act 5, Scene 4).

In modern terms, Falstaff fantasized being inundated with sweet potatoes and candied fruit or vegetables (which could be a reference to the preferred preparation of the sweet potato), and candied sea holly, which was also recognized as an aphrodisiac. According to Gerarde's herbal:

> The roots [of eringoes, which is the same as sea holly] preserved with sugar . . . are exceeding good to be given unto old and aged people that are consumed and withered with age. . . . It is also good for other sorts of people that have no delight or appetite to venery, nourishing and restoring the aged, and amending the defects of nature in the younger (1597: 1000).

In the mid-seventeenth century, as potatoes became more available (although still expensive), it is probably this tuber that was now being referred to in various recipes and theatrical comments. The entry on the potato in the 1710 herbal by the English physician William Salmon (1644–1712) combines its nutritive quality with its alleged effect on libido and fertility:

> They stop fluxes of the bowels [diarrhea], nourish much, and restore a pining Consumption [tuberculosis]. Being boiled, baked, or rosted [sic], they are eaten with good Butter, Salt, Juice of *Oranges* or *Limons,* and double refined Sugar, as common Food: they encrease Seed and provoke Lust, causing Fruitfulness in both sexes, and stop all sorts of Fluxes of the Belly. (1710:)

In 1805, however, Sir Joseph Banks (1743–1820), then president of the Royal Society of London, called quasi-official attention to the fallacious use of these vegetables:

> [T]he sweet potatoe was used in England as a delicacy long before the introduction of our potatoes; it was imported in considerable quantities from Spain and the Canaries, and was supposed to possess the power of restoring decayed vigor. The kissing comfits of *Falstaff,* and other confections of similar imaginary qualities, with which our ancestors were duped, were principally made of these, and of eringo roots.
>
> The potatoes themselves were sold by itinerant dealers, chiefly in the neighborhood of the Royal Exchange, and purchased when scarce at

> no inconsiderable cost, by those who had faith in their alleged properties (Banks 1805, 1: 8–12).

Although potatoes and sweet potatoes are examples of foods that lost their aphrodisiacal reputation quite early, that of the oyster has persisted from ancient times into the twentieth century. The Roman author Juvenal (second century A.D.), in a satire on the unrestrained behavior of contemporary women, associated loss of sexual decorum with alcoholic intoxication and the eating of "giant oysters at midnight" (Ramsay 1940: 107). Oysters, however, appeared infrequently among the aphrodisiacs in medical texts, and their folkloric popularity has been better reflected in literature. For example, in a comedy staged in 1611 by the London playwright George Chapman (died 1634), a "lover" in preparation for seduction is to be strengthened with "a banquet of Oyster-pies, Potatoes, Skirret rootes, Eringoes, and divers other whetstones of venery" (Act 2: 31). And it is interesting that in the nineteenth century, Jonathan Pereira (1804–53), professor of materia medica in London, in his authoritative textbook on medications merely commented: "An aphrodisiac property is usually ascribed to oysters" (1846: 47).

A hypothesis for the stimulatory reputation of oysters harkens back to the doctrine of signatures with their influence due to a resemblance to the female pudenda. But even if correct, it does not explain why, as therapeutics gradually became more rational, oysters maintained their aphrodisiacal reputation.

In the twentieth century, Havelock Ellis (1859–1939), the pioneer English sexologist, returned to the ancient principle that an aphrodisiac must foremost be nutritious. He speculated that "oysters and other shellfish . . . in so far as they have an action whatsoever on the sexual appetite, only possess it by virtue of their generally nutritious and stimulating qualities." He therefore concluded that because it is nutritious and easily digestible, "[a] beefsteak is probably as powerful a sexual stimulant as any food." Since it required relatively little energy to digest, more energy was available for other activities, including those that were sexual (Ellis 1906: 174). This is reminiscent of Galen's concept that to effect spermatogenesis, foods must be particularly nutritious.

Beverages and Anaphrodisiacs

A glimpse of the ancient ambivalence about the role of wine in sexual matters can be found in the Old Testament story of Lot's daughters, who each intoxicated their aged father with wine in order to be impregnated by him (Genesis 19:32–6). Perhaps the role of wine in this case was not that of an aphrodisiac but rather a sedative to overcome the taboo against incest. In the ancient world wine was consumed extensively, in part as medicine, but seemingly not as a sexual stimulant.

By the time of the Middle Ages this had changed. Maimonides, for one, strongly advocated wine as a sexual stimulant:

> Drinking honey water promotes erections, but even more effective in this regard than all medicines and foods is wine. . . . [I]t arouses the erections all the more when one enjoys the wine with desire, and after the meal and after the bath, because then its effect is far greater than that of anything else (Rosner 1974: 20–1).

About two centuries later, the Catalan physician Arnaldus de Villanova (1236–1311) wrote a manuscript on wine that, in 1478, became the first book on the subject to be printed. He believed that many specific varieties of wine exerted a restorative effect in the face of certain ailments. Thus "[w]ine made from fennel seeds stimulates sexual urge, consumes dropsy and leprosy. . . . It increases milk and the natural sperm" (1943: 39).

Later in the fourteenth century, Chaucer had one of his female characters voice the understanding that wine may affect both sexes similarly:

> Whenever I take wine I have to
> think of Venus, for as cold engenders hail
> A lecherous mouth begets a lecherous tail.
> A woman in her cups has no defense,
> As lechers know from long experience (1952: 295).

Yet if inebriation could leave a woman defenseless, it could also render a male incapable of taking advantage of her. This was expressed especially well by the French physician-novelist, François Rabelais (died 1553):

> When I say that wine abateth lust, my meaning is wine immoderately taken; for by intemperance, proceeding from the excessive drinking of strong liquor, there is brought upon the body . . . a chillness in the blood, a slackening in the sinews, a dissipation with a pervasive wryness and convulsion of the muscles, all which are great lets and impediments to the act of generation. . . . Wine nevertheless, taken moderately, worketh quite contrary effects, as is implied in the old proverb which saith: Venus taketh cold when not accompanied by Ceres and Bacchus. [Love is suppressed when it is not accompanied by food and drink] (1931, Book 3: 540).

The best-known literary comment on such contradictory effects of alcohol emanates from Shakespeare (*Macbeth,* Shakespeare 1971): "Lechery, sir, it provokes, and unprovokes; it provokes the desire, but it takes away the performance. Therefore much drink may be said to be an equivocator of lechery" (Act 2, Scene 3).

Most discussions of the sexual effects of alcohol have pertained to wines and, more recently, to liqueurs.

An exception is found in the herbal of Jacobus Theodorus (died 1590), a southern German physician who was enthusiastic about another beverage:

> Beer brewed from wheat, above all as a beverage, but also when used in food: on soups, sauces, and porridge, increases the natural seed, straightens the drooping phallus up again, and helps feeble men who are incapable of conjugal acts back into the saddle (1664: 641).

Nothing substantial has been added to an understanding of the behavioral effects of alcohol in the twentieth century. Clinicians who wrote extensively on sexual matters, such as the Swiss psychiatrist August H. Forel (1848–1931) and the German venereologist Iwan Bloch (1872–1922), both expounded on the pseudoaphrodisiacal effects that may occur when inhibitions are suppressed by small amounts of alcohol and the increasing anesthetic effect of gross intoxication.

Bloch speculated that moderate quantities of alcohol exert a dual effect, as "general psychic stimulant" and as a specifically sexual stimulant. But with a more protracted consumption of alcohol, the "psychic stimulation" deteriorates into "psychic paralysis" (loss of inhibition or judgment) before sexual excitement also wanes, leaving a gap of unrestrained sexual excitation. He concluded: "For the normal individual alcohol is not a means for the increase of sexual potency, but the reverse" (1919: 293, 444).

Other writers, biased by the temperance movement, were more outspoken. Thus, according to Forel:

> The drink habit corrupts the whole of sexual life. . . . Most narcotics, especially alcohol (either fermented or distilled) have the peculiarity of exciting the sexual appetite in a bestial manner, thereby leading to the most absurd and disgusting excesses, although at the same time they weaken the sexual power (1926: 332, 503).

Moving to nonalcoholic beverages, cacao (or cocoa), imported to Spain from the Caribbean islands, became a popular drink by 1580, after it had been modified into chocolate by the addition of sugar and milk. Although it was designated as "cold and dry," chocolate gained some reputation as an aphrodisiac. The reasons for this are uncertain. One mid-eighteenth-century French author implied that chocolate "promotes Venery" due to its nutritive quality. Because it is also a stimulant, its consumption is desirable as a restorative for old and phlegmatic people, while it should be avoided by "young people of a hot and bilious Constitution" (Lemery 1745: 364, 366).

Another reference work of the period states that cacao is cooling and yet "stimulates to Venery causing Procreation and Conception, facilitates Delivery, preserves Health, helps Digestion, makes people inclinable to seed" (Pomet 1748: 131–2). Yet in the seventeenth century, it had also become customary to mix various traditionally aphrodisiacal spices, such as pepper and cinnamon, with cacao. Proportions were adjusted to taste or according to the medicinal purpose. Hence, cacao may have been used by some to modify the potency of more traditional aphrodisiacs, and not actually accorded much potency of its own.

Although introduced to Europe toward the end of the sixteenth century, coffee did not become a popular beverage until about the middle of the seventeenth century – somewhat later than chocolate. As the popularity of coffee spread, so too did a rumor from its source in the Near East that, at least when consumed in excess, it suppressed sexual desires. Yet coffee was (correctly) recognized as having the ability to stimulate urine production, and since there had been an association between diuretics and aphrodisiacal properties since ancient times, any easy acceptance of the rumor seems inconsistent. Indeed, an English author felt the need to point out (published posthumously, 1746) that it is "an egregious Mistake, not only among the Persians, but also among most other Nations, to think that the Seed which when toasted is called Coffee . . . is of so cooling a Quality as to produce Impotence, even in those who use it frequently; for it dries them (Paulli 1746: 138–9).

In the nineteenth century, some settled for the same explanation that had been offered for the dual effects of alcohol. For example, M. Lallemand, a member of the Montpellier medical faculty, declared that coffee "augments the venereal desires, favors erections, and accelerates ejaculations; taken in excess, however . . . they are diminished and even completely extinguished." His explanation was that "what passed in the urinary organs is a good index of what is going on in the spermatic; the secretion of semen was increased as well as that of urine" (1866: 199–200). The implication was that although coffee is primarily an aphrodisiac, impotence eventually results from gonadal exhaustion caused by the protracted spermatorrhea-inducing stimulus.

Half a century later, Bloch continued to insist that coffee in sufficient volume induced impotence, which persisted as long as excessive coffee consumption continued (1919: 444). And an author in 1928, who still accepted that coffee ordinarily was an anaphrodisiac, recommended that in cases of impotence due to depression, it could act as a sexual stimulant by counteracting the symptom of fatigue (Loewe 1928: 184–6).

Anaphrodisiacs

As indicated in the discussion of coffee, save for alcohol consumed in excess, the list of dietary anaphrodisiacs is rather short and ambiguous. Among generally accepted foodstuffs, however, lettuce has had the most durable reputation – one probably originating in Greek mythology. The beautiful youth Adonis, killed by a wild boar, was laid out on a bed of lettuce by his lover, Venus (*Larousse Encyclopedia of Mythology* 1959: 81–2). Alternatively, he was killed in a field of wild lettuce (Athenaeus 1951: 301–3), or Venus threw herself on a bed of lettuce to lull her grief and repress her desires (Paris 1828: 9). In any event, the transient survival of a mortal, even when loved by a deity, became equated with the rapid withering of lettuce, which, in turn, became associated with impotence. Thus, according to Dioscorides, lettuce "is somewhat in virtue like unto Poppy.... [I]t is in generall soporiferous and easing of Paine" (Gunther 1959: 177). Such a notion is readily associated with the obviously anaphrodisiacal effect of sedation. According to Boorde, who wrote in the sixteenth century, lettuce "doth extynct veneryous actes, yet it doth increase mylke in a womans breste" (1870: 281).

One of the simpler seventeenth-century anaphrodisiacal recipes was a salad of lettuce, purslane, and mint with vinegar (Plater, Cole, and Culpeper 1662: 172). A contemporaneous prescription combined the alleged chemical and mineral anaphrodisiacal magic of many plants. Its ingredients were conserves of water lilies and of mint, candied lettuce and coolwort, seeds of Agnus castus (chaste tree), rue, coral, crystal, and camphor, made into an electuary with syrup of purslane.

Complex prescriptions were in demand, in part, at least, because of the paradoxical response of some persons to any one ingredient. In this regard, Nicolas Venette (1633–98), a French physician, informed his readers:

> Lettice and Succory, for Example, prevents the Generation of seed in most Men. But I know that in some it produces such a Plenty, especially if they eat it at Nights, as to subject them to Nocturnal Pollutions. This same experience teaches us, that Pepper and Ginger [usually aphrodisiacal] diminish the Seed, and dissipate Winds that are necessary to the action of Love (1906: 174–5).

Although most sexually inhibiting advice pertained to men, in the seventeenth century anaphrodisiacs were also prescribed to control "womb-furie." This was a manifestation of an "immoderate desire for carnal copulation [which] is able to master the Rational faculty [resulting in] Love-melancholy." The ailment was attributed mainly to virgins, young widows, and wives of impotent husbands. Thus a diagnosis of "immoderate desire" was doubtless based, at times, on some quite overt symptoms (Riverius 1655: 417–18).

Relevant prescriptions resemble those for the control of male lust, which were "cooling and sedating." Foodstuffs made up a minority of the ingredients, but among them, the leaves, stalks, and seeds of lettuce were the most common. Their alleged sedative effect was fortified by the inclusion of poppy seeds among the dozen or so ingredients (Riverius 1655: 417–8).

Disbelievers

Over the centuries, doubts about the effectiveness, mechanism of action, and the very existence of aphrodisiacs were occasionally raised, although most were limited or ambiguous. The Roman poet Ovid (43 B.C.–A.D. 18), who may have been the first recorded doubter, wrote in his *Ars Amatoria* (The Art of Love):

> There are, that strong provoking potions praise
> and nature with pernicious med'cines raise:
> Nor drugs nor herbs will what you fancy prove,
> And I pronounce them pois'nous all in love.
> Some pepper bruis'd, with seeds of nettles join,
> And clary steep in bowls of mellow wine:
> *Venus* is most adverse to forc'd delights
> Extorted flames pollute her genial rites.
> With fishes spawn thy feeble nerves recruit,
> And with eringo's hot salacious root.
> The goddess worship'd by th' *Erycian* swains,
> *Megara's* white shallot, so faint, disdains.
> New eggs they take, and honey's liquid juice,
> And leaves and apples of the pine infuse.
> Prescribe no more my muse, nor med'cines
> give,
> Beauty and youth need no provocative
> (1776, Book 2: 55–6).

Clearly, Ovid has provided a fine list of aphrodisiacal ingredients. But he warns that youth and beauty are sufficiently strong attractants that artificial stimulants are not only superfluous but counterproductive because artificially induced passion ("extorted flames") destroys true love.

Disagreement had always existed about the substances that affect sexual function and in which ways, but because the concept of objective therapeutic evaluation had yet to be devised, authors tended to ignore, rather than attack, claims with which they disagreed. But this situation gradually began to change at the end of the sixteenth century, with mandrake the first target. Gerarde, who acknowledged numerous botanical aphrodisiacs, disparaged anyone who would prescribe this root:

> Mandrake is called of the Graecians *Circea* of Circe the Witch, who by Art could procure love: for it hath beene thought that the roote heere of serveth to winne love. . . . There have been many ridiculous tales brought up of this plant, whether of olde wives or some runnegate surgeons or phisickmongers, I know not . . . , but sure some one or moe *[sic]* that sought to make themselves famous in skillful above others were first brochers of that errour I spake of (1597: 280–2).

Mandrake also came under attack in a larger effort aimed at the demolition of the doctrine of signatures by Sir Thomas Browne (1605–82). Although he did not mention aphrodisiacs as such in his *Pseudodoxia* *epidemica* (1646), his argument is relevant because "signatures of nature" were so important in the identification of these substances. Browne denounced as a "false conception" the notion that bifurcated root resembled human thighs. He pointed out that mandrake did not necessarily have a bifid root, and when it did, the two were often interwoven, destroying any human resemblance. Furthermore, bifid roots were not unique to this plant, and thus it made no sense to ascribe powers to mandrake because of a natural signature and not ascribe the same to a bifid carrot or a parsnip. In addition, such a notion gave rise to fraud because roots of other plants were carved to imitate bifid mandrake "to deceive unfruitful women" (1927: 285–99).

The waning of the conviction that the physical appearance of a natural object offered clues to its medicinal value did not, however, foster skepticism about substances believed to have a genital effect. But it did shift the focus to their intrinsic qualities. According to *A Golden Practice of Physick,* a well-known English medical text of 1662:

> [I]t is our opinion that such medicines [aphrodisiacs] work by a manifest quality, rather than by stretching the Yard [penis] with Wind as some say (which cannot be) besides their secret hidden quality which was observed by the first teachers of such things, from the whiteness of the flesh, fruits, and roots, resembling seed: Or because Taken from Leacherous Creatures; or from their shape resembling Stones [testicles] as the Satyrions or plants called Dog-stones; or like a rough wrinkled Cod [scrotum], as Toad-stools or Mushrooms (Plater, Cole, and Culpeper 1662: 172).

Having disposed of both the pneuma mechanism of erection and a doctrine of signatures, the authors proceeded to provide a lengthy list of animals, animal products, vegetables, and seeds that would serve as sexual stimulants. Meats were best because they nourish well and produce much blood. Species to be selected should have white tissue, such as brain, testicles, and much marrow, particularly when these were obtained from "the most lecherous Beasts." The latter were cocks, quail, and the ever-present sparrow, along with beaver flesh and, in the case of the fox, just his testicles.

The sea creatures on the list were exclusively invertebrate, and were followed by nuts, grains, and vegetables. But at this point, without explanation, the authors veer away to conclude that the preparation of sexual stimulants was more important than the ingredients. All of these foods had the same effect, but "especially if they be peppered and salted: for Pepper stimulateth and provoketh Venery, and we suppose that when such things are so eaten it comes rather from the sauce than the meat" (Plater, Cole, and Culpeper 1662: 172).

Hermann Boerhaave (1668–1738), a famous professor of medicine at Leiden, wrote somewhat hesitantly regarding "generators of seed." These were the various botanicals, mammalian and rooster testicles and brains that "are commended by the Ancients; but these are doubtful, and perhaps vain" (1740: 152).

Later in the eighteenth century, however, the very existence of aphrodisiacs was clearly denied for the first time, with the credit going to William Cullen (1710–90), a leading physician of Edinburgh. Among the terms he defined in his *Treatise on the Materia Medica* (1789) we find:

> *Aphrodisiaca.* Medicines supposed to be suited to excite the venereal appetite, or to increase the venereal powers. I do not know that there are any medicines of specific power for these purposes; and therefore the term seems to have been for the most part improperly employed (1808: 107).

Nevertheless, despite Cullen's influential reputation, and the increasing skepticism of science, the popularity of aphrodisiacal prescriptions and recipes did not lose their popularity.

Lay Literature

Until recently, physicians saw only a minority of medical problems and were not consulted at all by large segments of the population. Medical advice, however, still reached many through a genre of "domestic medicine" books that began to appear in the vernacular in the seventeenth century. They became particularly popular toward the end of the eighteenth century and continue to be published today. And until the middle third of the twentieth century, far more people were likely to have been influenced by the recommendations in these popular books than by any personal contact with physicians.

Because these publications focused on actions that could be taken without the intervention of a physician, dietary advice was prominent, and as late as the nineteenth century, the problems that diets were intended to correct were "acidity" and "wind" (gas formation). Acids were deemed to irritate the urinary passages, thereby stimulating sexual sensations, and gaseousness stimulated the urge to expulsion, that is, ejaculation. Substances that induced either were generally considered aphrodisiacal, and those that counteracted them were anaphrodisiacal.

Thus, a domestic-advice book from 1800 recommended that to increase seminal fluid, the diet should emphasize milk, eggs, and tender and nutritious meats, as well as herbs and roots that were mild, spicy, and diuretic. Conversely, to inhibit passion, one was advised to resort to a diet that was less nutritious, to avoid spices, and to abstain from alcoholic beverages. "Cooling" nourishment, such as lettuce and cucumbers, was seen to be beneficial (Willich 1800: 557–61).

A similar volume in the latter part of the nineteenth century relied more on medicines than on diet to counteract impotence. In regard to nutrition, the reader was told only to rely on "plain, simple, easily digested, and nourishing food." Much greater attention, however, was paid to "spermatorrhea" (involuntary seminal emissions), as well as, implicitly, those voluntary emissions resulting from the sin of masturbation. The dietetic component of this therapy for spermatorrhea consisted of the avoidance of carbohydrates because they were thought to readily ferment, producing gas in the stomach and acid in the intestines. Such acids were then absorbed, and they acidified the urine, "causing great irritation of the lining surface of the bladder and urinary passages, greatly increasing and perpetuating the disease." More specifically, fruits and vegetables were to be eaten sparingly and milk was to be avoided. Distilled spirits were preferable to beer, wine, and other fermented liquors, although water and black tea were viewed as the safest beverages. Coarse, well-baked wheat bread, fresh eggs, and various meats, stewed or boiled to tenderness, formed the most curative diet. The author conceded that it did not afford much variety, but "it offers the most abundant nutrition, and aids materially in the cure of this ailment" (Gleason 1873: 454–60).

In a book written in 1894, Dr. J. Harvey Kellogg (1852–1943), the inventor of corn flakes, taught that the sole cause of almost all impotence was sexual excess of some kind. Consequently, controlling spermatorrhea prevented impotence. Such control required avoidance of all stimulation, dietetically including "tea and coffee, spices and other condiments, and animal food [because they] have a special tendency in this direction" (1894: 267–77, 319, 613). Other (and earlier) widely used books, such as those by S. A. Tissot (1769) and H. Buchan (1778), had avoided sexual matters other than pregnancy.

The Early Twentieth Century

The observation of Havelock Ellis (1906) that high nutritive value and ease of digestion are the only criteria for a dietary aphrodisiac coincided with a shift, at least in the medical literature, away from the notion that some foods could exert a specifically sexual effect. In texts of materia medica published between 1891 and 1911, the only real food item to which aphrodisiacal powers were attributed was in a work by the American physiologist Roberts Bartholow (1831–1904). He wrote: "Carrot seems . . . to produce diuresis, augment menstrual flux, and cause aphrodisiac effects in the male" (1903: 791). Some newer herbs, such as *damiana,* were recommended, as were metals reminiscent of Paracelsian teachings, among them gold chloride, iron arsenite, and zinc phosphide (Bartholow 1903: 297, 175, 135).

With the disappearance of aphrodisiacal foods from (at least) *scientific* discussion in the twentieth century, however, there remains only the question of vitamins to be dealt with, and of these the only ones shown to be specifically relevant to any aspect of sexual function are vitamins A and E. The American biochemist Herbert M. Evans (1882–1971), who discovered vitamin E in 1922 (Evans and Bishop 1922), subsequently found with collaborators that a lack of this substance from the diet of male rats resulted in sterility due to deterioration of the seminiferous tubules, but not to a loss of the sex drive. Females did not become sterile, but they did abort their fetuses. Vitamin A deficiency also resulted in male sterility (Evans 1932a, 1932b).

Rodent experiments such as these were misunderstood or distorted by the lay press and by charlatans touting the "anti-sterility vitamin" as a cure for all sorts of sexual dysfunctions of men and women. Some published case reports suggested that vitamin E might assist those women who have had spontaneous abortions to carry a pregnancy to term (American Medical Association Council on Pharmacy and Chemistry 1940: 2214–18). However, habitual abortion is not the result of vitamin E deficiency, and the reliability of vitamin E administration for such a problem has not been proven. Vitamin deficiencies, unless they are a part of starvation, seem to have no effect on human sexual activity.

Conclusion

According to modern science, the only substances in the realm of food and drink that can be considered to have a potentially aphrodisiacal effect are alcoholic beverages in quantities sufficiently small to reduce inhibitions without overtly sedating. There are no positive sexual stimulants and no inhibitors other than sedating amounts of alcoholic beverages. Circumstances surrounding the consumption of food or drink may, of course, exert a positive or negative psychological influence on sexual desire, which is another way of saying that the alleged sexual effects of foods are culturally determined, psychological factors. And the desire of the public for aphrodisiacal foods to exist continues to support the publication of books with titles such as *Aphrodisiac Culinary Manual* (Heartman 1942), *Venus in the Kitchen* (Douglas 1952), *The Virility Diet* (Belham 1965), and *Lewd Food* (Hendrickson 1974).

VI.16 Food as Medicine

Definitions

The eminent medical historian Henry E. Sigerist once noted that "[t]here is no sharp borderline between food and drug," and that both dietetic and pharmacological therapies were "born of instinct" (Sigerist 1951: 114–15). Today we tend to focus our studies of food on its nutritive values in promoting growth and health and in preventing disease, but for many centuries past, food had an additional, specifically medical role – as a remedy for illness.

The United States Food, Drug, and Cosmetic Act, signed into law June 27, 1938, provides no clearer differentiation between "food" and "drug" than Sigerist could. According to the current wording of that legislation, which updated the Pure Food and Drug Act of 1906, "the term 'food' means (1) articles used for food or drink for man or other animals, (2) chewing gum, and (3) articles used for components for any other such article," whereas "the term 'drug' means (A) articles recognized in the official United States Pharmacopoeias [and several other compendia]; and (B) articles intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man or other animals; and (C) articles (other than food) intended to affect the structure or any function of the body of man or other animals; and (D) articles intended for use as a component of any articles specified in clause (A), (B), or (C)." Under clause (B) above, many items that have traditionally been considered foods might also be regarded as drugs under federal law, although they seldom are. The Food and Drug Administration (FDA) can intervene in cases involving food only when it judges an item to be misleadingly labeled as a "food"; it specifically excludes vitamins from the category "drugs."

The Foundation for Innovation in Medicine recently coined the word "nutraceutical" to signify "any substance that can be considered a food and provides medical and health benefits, including the prevention and treatment of disease. Such products include traditional foods, isolated nutrients, dietary supplements, genetically engineered 'designer' foods, herbal products and processed foods" (*Tufts Journal* 1992: 10). However, the very concept of nutraceuticals seems to sidestep even the vague definitions with which the FDA is tethered. Indeed, it is probably not possible to differentiate foods from drugs with mutually exclusive definitions. The ambiguity, troublesome as it may be in some contexts, has deep historical roots. Until the early twentieth century, physicians routinely prescribed specific foods and diets for their medical – that is, curative or preventive – value. The reader should also keep in mind that nonprofessional healers, such as wives and mothers, have employed the same food remedies for similar purposes.

Rarely is it possible to pinpoint the putative healing roles of specific components of traditional foods, such as the oils that confer distinctive tastes on several botanical flavors and spices, or extracts with known pharmacological properties, such as the active principles of coffee, tea, and cocoa. Similarly, we are not concerned with toxins or biological contaminants of foods, such as the ergot alkaloids produced by a fungus that sometimes infects bread made with rye (Hofmann 1972) or the anticoagulant found in spoiled sweet-clover fodder for domestic cattle. Nor does this chapter deal with foodstuffs that only incidentally provide raw starting materials for synthesizing what are unmistakably drugs – for example, the yams from which are extracted the diosgenins that are used as starting material in the manufacture of steroids.

Medical Dietetics

Its Roots in the Ancient World

Beginning with the premise that "[m]an knew only too well that he could not live without food, that food sustained life," Sigerist postulated: "Physiology began when man . . . tried to . . . correlate the actions of food, air, and blood" (Sigerist 1951: 348–9). Ancient Egyptians, for instance, developed an ingenious theory to account for the transformation of food and air into the substance of the human body and to explain disease. Not only did they recognize the hazards of an inadequate food supply but they also knew when to prescribe a normal diet for the sick or injured, and their physicians used many items in the ordinary diet as remedies that would become common in later European cultures (Estes 1989; Manniche 1989).

The Egyptians' major sweetening agent, honey, was perhaps the most effective of all their medicines. Its efficacy as a wound dressing, attributable chiefly to the desiccating effect on bacteria of its 80 percent sugar content, probably led to its further use in many oral remedies because of its ability to prevent infection; Egyptian medical theory associated even superficial infections with internal disturbances. Modern laboratory studies have shown that honey could, indeed, have inhibited the growth of the bacteria that often contaminate wounds until normal immunological and tissue repair processes had been completed (Estes

1989: 68–71). Because it has the same effect on bacteria as honey, a thick paste of ordinary granulated sugar is sometimes applied to infected wounds today (Seal and Middleton 1991), but honey is unlikely to have been selectively effective as an antimicrobial agent when taken internally.

Although some of the Egyptians' speculative pathophysiological concepts can be recognized among the Greeks' explanations of health and disease, it was the latter that directly shaped many aspects of the relationship between food and health that survived for the next 2,500 years. As early as the sixth century B.C., the philosopher-physician Alcmaeon of Croton recognized that the body's growth depends on its food intake. A century later, the Hippocratic school of physicians described food as one source of the body's energy and its heat (Winslow and Bellinger 1945). Other sixth-century Greek thinkers tried to explain the conversion of food to parts of the body. Thales of Miletus, for example, in Asia Minor, thought that its primary substance was water, whereas Anaximenes, also of Miletus, argued that it was air. In the fifth century, the Sicilian philosopher Empedocles said that the four irreducible elements – fire, water, earth, and air – were the basic components of both food and body. He and his contemporary Anaxagoras, the first major philosopher to live in Athens, agreed with Alcmaeon that each foodstuff contains particles that are assimilated to specific parts of the body; Empedocles said that each assimilated particle fits exactly into the body part that takes it up (King 1963: 56–68; Leicester 1974: 9).

In the fourth century B.C., Aristotle followed Empedocles and Anaxagoras when he postulated that the four elements are blended from four "qualities" – hot, cold, moist, and dry – that are reciprocally paired in each element. He also held that the primary "chemical" reaction of the body is *pepsis,* a word that has historically been translated into English as "coction," from the Latin *coquere,* to cook. In both Latin and English forms, coction implies heating and ripening (of both fruit and morbific matter), and it was associated in English medical texts with perfecting something via natural processes. Aristotle used pepsis in the same way, describing it as the changes a foodstuff undergoes as it is prepared in the gastrointestinal tract for assimilation into the body. In short, both the Greek "pepsis" and the English "coction" were taken to mean "digestion." Hence, the diagnosis of dyspepsia was a synonym for indigestion. According to Aristotle, normal coction of foods, fueled by the body's innate heat, thickens the body's fluids. By contrast, coction is incomplete in the sick, resulting in abnormally thin, or watery, fluids (Leicester 1974: 15–18, 33–5).

In the second century A.D., the physician whose teachings came to dominate Western medical thought for seventeen centuries, Galen of Pergamum, in Asia Minor, reemphasized the teachings of Hippocrates, and postulated that all physiological activity depends on balances described by Aristotle (Winslow and Bellinger 1945; King 1963: 56–68; Leicester 1974: 9). According to Galen's medical configuration of Aristotle's physiological model, blood is associated with heat and moisture, phlegm is associated with moisture and cold, black bile is associated with cold and dryness, and yellow bile with dryness and heat.

Moreover, each humor was associated with one of the seasons, just as Posidonius of Rhodes, in about 100 B.C., had associated each with a corresponding temperament (Leicester 1974: 30–2). Blood was now associated with spring and the sanguine temperament, water with winter and the phlegmatic temperament, black bile with autumn and melancholy, and yellow bile with summer and the choleric or bilious temperament. (These terms for the temperaments, however, were not introduced until the twelfth century A.D., by Honorius of Autun.) The humoral theory satisfactorily explained the physiological clues to the balances that had to be rectified in order to restore health and stability to the sick body. At the same time, it permitted the construction of a pragmatic approach to the principles of medical therapy, including dietetics.

These principles were based on the premise that imbalances among the humors could be corrected by administering drugs – or foods – with appropriately opposite properties. Thus, because bilious fevers were associated with dryness and increased body heat, they should be treated with moist, cool remedies in order to rebalance the blood and yellow bile – the humors most disturbed in such patients. Similarly, dropsy, the accumulation of water in the tissues, should be treated with remedies that dried them, such as diuretics. Obviously, many foods could correct imbalances as well as doctors' drugs could. Cool, moist vegetables, for example, like cucumbers, were well suited to the needs of bilious fever patients.

The Hippocratic texts show that physicians of the fifth century B.C. recognized the influence of nourishment on human health. This was almost certainly not a new idea even then, but these are the earliest such writings to have survived. The *Regimen for Health* focuses on the therapeutic value of food, whereas the first section of the *Aphorisms* describes diet with special reference to illness. It teaches that proper nourishment, because of its influence on digestion, is more important to the sick patient than drugs (Lloyd 1978: 206–10, 272–6). Other authorities added that a carefully chosen diet can rectify disturbances in the balances of heat, cold, dryness, and moisture caused by exhaustion of the energy normally derived from the diet, or by changes in one's external circumstances, such as sudden wealth or poverty. Remedies were classified medically by the proportions of the same four qualities in each, and foods were further categorized as to whether they were wild or domesticated (Edelstein 1987, orig. 1931). In short, foods, like drugs, were prescribed in order to correct imbalances among the humors or to modify digestive processes that would themselves influence the humors, as far as ancient physicians could tell.

Dietetic instructions were designed to ensure optimum digestion, in order to minimize the amount of undigestible residues that could accumulate in the alimentary tract. Hence, in a physiological echo from the banks of the Nile, Diocles of Carystus, an Athenian physician of the fourth century B.C., cautioned: "The chief meal is to be taken when the body is empty and does not contain any badly digested residues of food" (Sigerist 1987: 238–40, orig. 1961), which, in the Egyptian tradition, were major causes of illness (Estes 1989: 80–91).

Hellenistic medical writers went beyond the Hippocratics when they asserted that a healthy diet is more important than post hoc healing of the sick. But emphasis on merely maintaining a healthy lifestyle receded when it became less feasible in the rapidly changing world of the Roman Empire. And by then, physicians were giving increased attention to diet as a coequal branch of their practice along with drugs and manual operations, such as bleeding – a differentiation that dominated the structure of professional medicine well past the Middle Ages (Siraisi 1981: 252; Edelstein 1987).

Early in the first century A.D., the Roman encyclopedist Celsus again echoed the Egyptian preoccupation with the intestines when he wrote that "digestion has to do with all sorts of troubles." His dietary guide, in the time-honored Aristotelian tradition, included lists of drugs that heat or cool; those that are least and most readily digested; those that move the bowels or constrict them; those that increase urine output, induce sleep, and draw out noxious materials that cause disease; and those that suppress illness with or without simultaneously cooling the patient. Celsus, however, concluded his pages on dietetics on a note of skepticism: "But as regards all these medicaments, . . . it is clear that each man follows his own ideas rather than what he has found to be true by actual fact" (Celsus 1935, 1: 77, 207–15).

A century later, Galen taught that most illnesses are caused by "errors of regimen [including diet], and hence avoidable." He went on to explain how appropriate attention to food, drink, and air can preserve and restore health (Temkin 1973: 40, 154–6). Indeed, his *Therapeutic Method* required that the physician understand precisely how the four basic physiological qualities of life were mixed in every foodstuff, as well as in every drug (Smith 1979: 103).

The complexities involved are evident in the *Materia Medica* by Celsus's near contemporary Dioscorides, a peripatetic Greek physician from Asia Minor (Dioscorides 1934). His book remained the fountainhead of European therapeutics – and dietetics – for 15 centuries, and traces of its influence can be detected even today. Over the years, but especially in the Middle Ages, Dioscorides's descriptions were altered and expanded by commentators who, as Celsus had feared, relied as much on what they thought was true as on what was evident to the senses. An anonymous sixth-century author cited Hippocrates and Dioscorides in his book on the nutritional medical uses of plant foods, but he, too, found it difficult to differentiate clearly between "foods" and "drugs" (Riddle 1992, orig. 1984).

Dietetics in Medieval Europe

Diet retained its position as one of the three major modes of therapy, along with medicine and surgery, throughout the Middle Ages (Siraisi 1990: 121, 137). Although emphasis on the healthful properties of diet was first systematized by Greek writers, much of it was transmitted back to Europe in Arabic texts of the ninth to eleventh centuries that preserved Hippocratic and Galenic principles (Levey 1973: 33–5).

For instance, the *Canon of Medicine,* written about A.D. 1000 by the Persian physician Avicenna, made its initial impact on Europe when it was translated into Latin in the twelfth century at Toledo, by Gerard of Cremona. It had become a medical text at Montpellier by at least 1340, which helped to ensure the diffusion of Avicenna's ideas throughout Europe.

Avicenna perpetuated the Egyptian notion that excess food tends to putrefy, and its Greek corollary that it promotes indigestion and alimentary obstruction. He expanded the teachings of Greek, Roman, and Indian writers with his assertion that foods have medicinal properties that are unrelated to their hot, cold, moist, or dry qualities, while recognizing that some foods have therapeutic properties even when they have no nutritional value. His *Canon* classifies foods as of rich or poor quality, light or heavy, and wholesome or unwholesome, and includes dietary rules applicable to both health and disease, as well as a diet for the aged (Shah 1966: ix–x, 182–7, 309–20, 338–40, 359–61).

Avicenna simplified Galen's description when he explained how food is subjected to its first coction in the stomach, resulting in chyle, which passes, via the portal veins, to the liver. There a second coction turns it into yellow bile, black bile, and blood, while its aqueous residue is carried to the kidneys for eventual release from the body. At the same time, the residue of the first, gastric, coction is discharged, partly as phlegm, into the lower intestinal tract. The blood alone is subjected to a third coction, when the heart converts it to what Aristotle had called the vital spirit, and a fourth, in the brain, where it is further transformed into a psychic spirit (Leicester 1974: 59). This satisfying explanation facilitated the physician's choice of appropriately therapeutic drugs – or foods.

Constantinus Africanus, who died 50 years after Avicenna, translated many Arabic texts at Salerno (site of the first major medical school in Europe) and

Monte Cassino. His *Book of Degrees* complicated therapeutic procedures when he described gradations in the heat, cold, dryness, and moisture of foods and medicines: A food is hot in the first degree if its heating power is less than that of the human body; it is hot in the second degree if its heating power equals that of the body; in the third degree if its heat exceeds that of the body; and in the fourth degree if it is simply unbearably hot. In his translation of a commentary on a book by Galen, Constantinus summarized current thinking about the dietary approach to therapy: "Good food is that which brings about a good humor and bad food is that which brings about an evil humor. And that which produces a good humor is that which generates good blood" (Thorndike 1923, 1: 751; Leicester 1974: 62–5).

By the thirteenth century, Latin translations of Galen's specifically dietary works, such as *De Alimentorum Facultatibus* and *De Subtiliante Dieta,* along with translations of pseudo-Galenic works on the same subjects, such as *De Nutrimento* and *De Virtutibus Cibariorum,* had joined the works of Avicenna and other Arabic writers, and the dietary works of a ninth-century Egyptian writer, Isaac Judaeus, in many medical curricula. One of the most widely consulted late medieval medical manuals was by Peter the Spaniard, or Petrus Hispanus, of Paris (later Pope John XXI, for a year until his accidental death in 1277). His scholastic commentaries on Isaac's *Universal Diets* and *Particular Diets* led him to pose such questions as: "Why does nature sustain a multitude of medicines, but not of foods? . . . Is fruit wholesome? . . . Are eggs or meat better for convalescents? . . . Should paralytics eat fried fish? Are apples good in fevers? . . . Why do we employ foods hot in the fourth degree and not those cold in the same degree?"

Peter answered such queries with syllogisms premised on gradations in the four basic qualities of foods. At the same time, he disputed the ancient idea that foods could be fully assimilated into the structure of the body (Thorndike 1923, 2: 488–507). However, Peter was not alone in rationalizing medical dietetics. As late as the 1570s, medical faculty and students at Montpellier debated such theses as "[w]hether barley bread should be eaten with fruit," "whether it was safe for persons with kidney trouble or fever to eat eggs," and "whether dinner or supper should be the more frugal meal" (Thorndike 1941, 6: 222–3).

The prominent attention given to diet in the fourteenth century is exemplified by the physician among the tale spinners who accompanied Chaucer's pilgrimage to Canterbury:

> He was well-versed in the ancient authorities;
> In his own diet he observed some measure;
> There were no superfluities for pleasure,
> Only digestives, nutritives and such (Chaucer
> 1960: 31).

It was not only physicians who were concerned with the relationship of diet to health in the Middle Ages, however. Medical authorities from Hippocrates to Avicenna were cited in many manuscripts designed for lay use (Thorndike 1940; Bullough 1957), such as several late medieval *Tacuina Sanitatis* (Handbooks of Health) based on the works of the eleventh-century Arabic physician Ibn Botlân. These manuscripts aimed, among their medical goals, to teach "the right use of food and drink," the "correct use of elimination and retention of humors," and how to moderate the emotions associated with each humor (Arano 1976: 6–10).

By the late Middle Ages, the therapeutic benefits of food had entered into the everyday planning of at least the grand households, the only ones for which evidence has survived. Spices, for example, were regarded as both aids to digestion and evidence of a host's wealth. Medieval herbals and dietaries listed the health-giving properties of foods in the classical humoral tradition. They classified foods and medicines by their degrees of heat, cold, moisture, and dryness. Thus, melons, obviously cold and moist, were suitable for treating patients with fevers. But it may be that this new order resulted from a misreading of the original texts, inasmuch as later writers did not retain it.

Largely under the influence of the *Regimen of Health,* which codified the prescripts for healthy living taught at Salerno in the eleventh century, physicians devised diets appropriate to both Aristotelian physiology and specific illnesses. Thus, Taddeo Alderotti, professor of medicine at Bologna in the late thirteenth century, recommended to many patients (probably chiefly those with fevers) that they avoid hot bread, cheese, fruits, beef, and pork, in favor of less-stimulating foods. However, in many instances, it is difficult to differentiate between his culinary and medical directions (Siraisi 1981: 293).

The patient's age was another determinant of therapeutic diets. In 1539, for example, a moderately moist and warm diet was still being recommended for young children, who were viewed as phlegmatic (that is, as very moist and cold). As they grew older, they were thought to become more sanguine or choleric, which meant that they would now benefit from much moister and colder foods. And as their strength declined in old age, they needed foods that were only as moderately moist and warm as those that had benefited them in childhood. Indeed, many foods were more closely associated, in medieval thinking, with illness than with their gustatory effects, although taste was a major clue to the presumed Galenic properties of any drug or food (Drummond and Wilbraham 1958: 65–77; Teigen 1987). In short, the medical correlates of food permeated many aspects of medieval life, from the preparation of patients for surgery to the choice of menus for banquets and bathing establishments (Cosman 1978).

Dietetics during the Scientific Revolution

The rudiments of modern chemistry were beginning to influence medical ideas in the late Middle Ages through the writings of alchemical physicians. In the late fifteenth century, for example, Conrad Heingartner of Zurich cautioned his readers to chew food thoroughly, in order to maximize its digestibility, and not to eat too many courses at one meal, because some foods are more readily digested than others. He also urged that the principal meal be taken at night, because the cold night air aids digestion by forcing the body heat necessary for its completion to stay deep inside the body (Thorndike 1934, 4: 377–8).

It is clear that Heingartner's concept of the physiology of digestion owed much to Hippocratic–Galenic medical concepts, but the latter were about to disappear in favor of more explicitly chemical explanations. The experimental science that began emerging in the late sixteenth century began, however slowly, to replace the classical Greek and Islamic traditions that had heretofore dominated European thought.

By the late seventeenth century, a major new hypothesis was beginning to hold sway over medical thinking. It postulated that illness represents imbalances not only in the classical four humors but also in the tone – the innate strength and elasticity – of the solid fibrous components of blood vessels and nerves. Both organs were considered to be hollow tubes that propelled their respective contents through the body with forces proportional to the tone of their constituent fibers. That is, the body was healthy when blood or "nerve fluids" could circulate freely, or when sweat, urine, and feces could be expelled freely, and so forth.

Thus, a fast pulse was the distinguishing hallmark of fever, which was interpreted as the result of excessive arterial tone, requiring depletive therapy to bring it under control. Conversely, a slow pulse was interpreted as evidence of a weakness that required stimulant therapy (Estes 1991a). Historians have labeled the new hypothesis as the "solidist theory," to distinguish it from the older humoral theory. The two concepts were by no means mutually exclusive, however, and most therapeutic effects were interpreted within the frameworks of both. Nevertheless, the older Hippocratic–Galenic focus became progressively less prominent in medical texts.

Dietetics fitted into the new theory as well as into humoralism. By the time solidism had taken hold in medical thinking, the specifically therapeutic role of diet had been clarified by categorizing daily menus as full, moderate (or middle), or low (or thin). As Thomas Muffett wrote in 1655: "The first increaseth flesh, spirits, and humors, the second repaireth onely them that were lost, and the third lessenth them all for a time to preserve life" (Drummond and Wilbraham 1958: 121–2). That is, full diets are appropriate, if not necessary, for maintaining growth and strength in vigorous younger people, whereas moderate diets are more suitable for middle age, and low diets for old age or during illness at any age. Muffett's description would surely have been recognizable to Aristotle, but within the solidist framework, the low diet was said to be depletive, "sedative," or antiphlogistic (that is, antifebrile), suitable for reducing excessive tone of the arteries and nerves, whereas the stronger diets were said to be stimulating.

Although the discovery of the Americas put new foods on European tables, medical properties were initially ascribed only to sassafras, sarsaparilla, and the pleasurable stimulating beverages – coffee and chocolate. When John Josselyn returned to London from New England, he reported that American watermelons were suitable for people with fevers, and cranberries for those with scurvy and "to allay the fervour of hot Diseases" (Josselyn 1672: 57, 65–6). Yet such foods could not survive the transatlantic crossing to European markets. Immigrants to colonial New England harvested both "meate and medicine" in their gardens, sometimes from the same plant, in the tradition they had learned before leaving home. Many relied on herbals for descriptions of each plant's medical properties, which closely followed those of Dioscorides (Leighton 1970: 134–7).

Early in the eighteenth century, Ippolito Francesco Albertini, professor of medicine at Bologna, echoed Avicenna when he wrote that his mother should not eat a food, such as meat, "that is easily converted into blood." At about the same time, Albertini's brother-in-law, Vincenzo Antonio Pigozzi, also a physician, directed a correspondent to strengthen his patient's stomach with food and medicine because, as Celsus had said, it was "apt to be weak in students and other diligent and well-behaved persons," so that "their daily food, on account of its coldness, is poorly purified and digested" (Jarcho 1989: 99, 177).

Eighteenth-century British hospitals developed standard diets based on humoral and solidist precepts. A 1782 London hospital dietary mandated the same breakfast for patients on both low and full diets: water-gruel or milk porridge (made of 1.25 ounces of oatmeal, and raisins, in a pint of water or milk). The supper menu was the same, supplemented by the addition of a pint of broth (made by boiling a leg of lamb or other meat for 1.5 hours) four times a week, or a quarter pound of cheese or butter during the week. The full and low diets differed chiefly in their midday dinner menus.

Febrile patients on the low diet received rice milk twice a week. Also twice a week they were served bread pudding (made by soaking a half pound of bread crumbs in one pint of milk overnight and then adding two or three eggs before the mixture was boiled in a bag for a hour or so). Lamb or other meat broth was also on the menu twice a week, or plumb broth (made by boiling six ounces of meat or bone with a half pint of peas and a half ounce of oats in water). A quarter pound of boiled beef or mutton, or roast veal, was added to the menu twice a week, and a 14-ounce loaf of bread was served every day.

By contrast, patients on a full diet received rice milk once a week. A half pound of boiled pudding appeared weekly (made by boiling a mixture of one pound of flour, a quarter pound of suet or meat or eels, and fruits, in 13 ounces of water, for one to two hours). A half pound of beef or mutton was served with greens four times weekly, and a loaf of bread daily. In addition, patients on the low diet received one pint of small beer daily, while those on the full diet were allowed four times as much. The presumed medical qualities of the two diets differed chiefly with respect to the stimulating property of red meat; their total mass was nearly the same (Estes 1990: 66–7). Such diets perpetuated the ancient admonition to "feed a cold and starve a fever," whose origins are in the Hippocratic texts, and it has remained a guiding therapeutic principle down to our own time.

In 1772, Dr. William Cullen of Edinburgh lamented that although dietetic prescriptions were among the most valuable of all therapies, they had fallen out of regular medical use in recent years (Risse 1986: 220). He might have been surprised when, a few years afterward, his colleague, Dr. Andrew Duncan, Jr., increased the proportions of stimulating foods served to his febrile or otherwise debilitated patients, chiefly by increasing their meat allowances (Estes 1990: 65–8). In fact, by the end of the century, Dr. William Heberden of London was complaining that "[m]any physicians appear to be too strict and particular in the roles of diet and regimen," and he urged that the sick be allowed to choose their own diets, according to their own tastes (Heberden 1802: 1–5).

In the meantime, experimental chemistry had begun to shed new light on the physiology of digestion and on the respiratory processes involved in the conversion of food into energy, carbon dioxide, and the tissues of the body. Early in the seventeenth century, Jan Baptista Van Helmont, who lived near Brussels, showed that gastric juice is acid, and that it is necessary for the digestion of food. He may even have identified hydrochloric acid as its chief component, but it was not until 1752 that this was proved by René Antoine Ferchault, Sieur de Réamur, in France. Although Van Helmont's concept of digestion contained some Aristotelian elements, he did show that the acid in gastric juice is neutralized in the duodenum by bile from the liver. However, it was in 1736 that Albrecht von Haller, at Göttingen, established that bile emulsifies fats. Haller's teacher, Hermann Boerhaave of Leiden, had already laid the groundwork for differentiating what were later named proteins (in 1838) and carbohydrates (in 1844). Haller added the last major food class, fats. But Boerhaave and Georg Ernst Stahl, professor of medicine at Halle, both leading proponents of solidism, denied that gastric juice was acid. Instead, they favored the ancient concept that digestion was a putrefactive or fermentative process, which eventually was abandoned in the face of Réamur's proof that digestion represents the dissolution of foodstuffs in gastric acid (Drummond and Wilbraham 1958: 232–55; Leicester 1974: 96–7, 118–27; Estes 1991a).

Between 1700 and 1850, when modern experimental pharmacology began to be applied to the study of drug effects on living organisms, physicians trained in the European medical tradition used as drugs about 500 botanical remedies, and 170 chemical compounds and other materials. Any given eighteenth-century physician employed some 125 different botanical remedies in his standard repertoire, depending on his training and experience. Save for the few botanical remedies that had been introduced from the New World by then, the majority of plants prescribed in the eighteenth century had also been used by healers in the ancient Mediterranean world, including most of the medically important foodstuffs shown in the seven tables that follow (Estes 1990). They illustrate the specifically therapeutic roles of familiar culinary ingredients, while reemphasizing the difficulty of discriminating between foods and drugs. These tabulations may not be all-inclusive, and several items could have been included in more than one list. Most of these foods are more fully described elsewhere in this work.

Comments on Table VI.16.1

Many of these foodstuffs, familiar in both the kitchens and apothecary shops of the eighteenth and nineteenth centuries, had been used as medicines for at least 2,000 years. As in the Middle Ages, their tastes were the most valuable clues as to how they could benefit the sick. Although some had clear-cut effects, especially the stronger cathartics, others were more speculative, as dictated by humoral and solidist theory, than verifiable.

One need not wonder that physicians prescribed these or any other time-tested remedies for as long as they did. Because 90 to 95 percent of adult patients recovered following treatment, whatever it was, their physicians had no reason not to conclude that their prescriptions benefited their patients. The double-blind controlled clinical trials on which we rely today to *prove* the therapeutic efficacy of putative remedies were not developed until the mid-twentieth century (Estes 1991a). Thus, although a few items listed above might have moved the bowels to a modest extent, most of their other effects, such as those on body tone, digestion, or uterine function, were only presumed to occur, in accord with prevalent pathophysiologic theories.

Table VI.16.1 *Past and present medicinal uses of flavorings and spices*

Angelica: Weak cathartic, tonic, carminative.
Anise: Tonic, pectoral, carminative; lactagogue.
Assafoetida: Antispasmodic, expectorant, emmenagogue, diuretic, diaphoretic, mild cathartic, anthelmintic.
Canella: Stomachic, gentle tonic.
Capers: Weak cathartic, diuretic, deobstruent.
Caraway: Stomachic, carminative, diuretic.
Cardamom: Carminative, diaphoretic.
Chocolate: Stomachic, antidysenteric.
Cinnamon: Tonic, stomachic, carminative, astringent.
Cloves: Tonic, mild styptic.
Coriander: Carminative.
Cumin: For plasters.
Dill: Carminative.
Fenugreek: Aphrodisiac; for emollient plasters.
Garlic: Tonic, diaphoretic, expectorant, diuretic, carminative, emmenagogue, rubefacient.
Ginger: Tonic; rubefacient.
Horse radish: Tonic, diuretic, diaphoretic.
Hyssop: Expectorant, antitussive, pectoral, carminative.
Juniper: Carminative, stomachic, diuretic, diaphoretic, emmenagogue.
Licorice: Cathartic, expectorant.
Marjoram: Tonic, cephalic, expectorant, errhine.
Mustard: Stomachic, digestive, diuretic, diaphoretic, emetic, mild cathartic, antiscorbutic; blistering agent.
Nutmeg–mace: Tonic, narcotic, stomachic, antiemetic, astringent.
Parsley: Carminative, aperient, diuretic, emmenagogue.
Peppermint: Tonic, carminative, antispasmodic.
Peppers: Stimulant, digestive, antispasmodic.
Pimento: Tonic, carminative.
Rosemary: Antispasmodic, sedative, cephalic, emmenagogue.
Saffron: Cordial, narcotic, antispasmodic, emmenagogue.
Sage: Astringent, carminative, stomachic, nerve tonic.
Sarsaparilla: Antirheumatic, antivenereal, demulcent, diaphoretic.
Sassafras: Weak cathartic, tonic, blood purifier, diuretic, diaphoretic, antirheumatic, antisyphilitic.
Sesame: Mild cathartic.
Spearmint: Carminative, stomachic, antispasmodic, antiemetic, anti-icteric.
Thyme: Analgesic for toothache.
Tumeric: Tonic, weak cathartic, emmenagogue, anti-icteric.
Wintergreen: Astringent, antidiarrheal, emmenagogue, lactagogue.

Interesting and odoriferous compounds, some of which have biological effects in animals or man, have been extracted from several of these flavorings and spices, but most cannot be related to the clinical effects listed. The few extracts that might have modest pharmacological activity include the gingerols isolated from ginger (they can stimulate cardiac action); the terpinem-4-ol in juniper (which can increase renal glomerular filtration and irritate the uterus); the mildly cathartic glycerrhizin in licorice; the apiol in parsley (which may promote diuresis and stimulate the uterus); the weak smooth-muscle relaxant menthol in the mints; and the extremely potent irritant capsicin in peppers. Safrole, which is responsible for the taste of sassafras, has been banned in the United States because it is carcinogenic to animals when administered in high doses; like nutmeg, it has mild stimulating effects in man (*Lawrence Review* 1987–91). Still, many of these items can be found in modern grocery stores and among over-the-counter remedies.

Comments on Table VI.16.2

It is difficult to discover how these fruits and nuts entered common medical usage, although it seems likely that their adoption followed the discovery of their gustatory merits. A few have a mild cathartic effect, oranges and strawberries might well appear cool to the taste, and the slightly bitter taste of others might make them seem astringent, but no consistent pattern seems to associate these foods medically.

Comments on Table VI.16.3

Lettuce and endive produce a cooling sensation, but the other alleged properties of lettuce probably owe more to its confusion with another lettuce species that was rarely prescribed by physicians. Several compounds have been extracted from chicory, including its aromatic principle, acetophenone, but none has any ascertainable role in the effects listed for it in this table. The oxalic acid in the sorrels might have contributed to their reputations as refrigerants and antiscorbutics at a time when acids were deemed appropriate for the treatment of scurvy (Estes 1979), but the irritating (and potentially dangerous) acid is unlikely to have had any true therapeutic effect (*Lawrence Review* 1987–91).

Table VI.16.2. *Past and present medicinal uses of fruits and nuts*

Almond milk: Diluent; mild cathartic; counteracts blisters.
Blackberries: Slightly astringent.
Cherries: Tonic, slightly narcotic, anthelmintic, antiseptic.
Currants: For sore throat.
Damsons: Tonic, astringent, cathartic, emetic.
Dates: Emollient, slightly astringent.
Elderberries: Cathartic, deobstruent, diuretic, diaphoretic.
Figs: Mild cathartic.
Lemons: Stomachic, antiseptic; antiscorbutic (after the 1790s).
Olive [oil]: Demulcent cathartic; antidote to rattlesnake venom.
Oranges: Tonic, refrigerant, antispasmodic, stomachic, carminative, antiseptic, antiscorbutic (after the 1790s).
Peaches: Cathartic, sedative, anthelmintic.
Pokeberries: Emetic, cathartic, mild narcotic.
Pomegranate: Cathartic, astringent, antidiarrheal, anthelmintic.
Raspberries: Refrigerant, stomachic, diuretic, diaphoretic.
Strawberries: Refrigerant, tonic, diuretic, cathartic.
Tamarinds: Cathartic, refrigerant.
White walnut: Anti-inflammatory, cathartic.

Table VI.16.3. *Past and present medicinal uses of vegetables*

Asparagus: Diuretic, weak cathartic, deobstruent.
Cabbage: Cathartic, emollient (Sauerkraut: antiscorbutic).
Celery: Weak cathartic, carminative.
Chicory: Cathartic, gastrointestinal tonic, stomachic, refrigerant.
Endive: Cooling weak cathartic.
Lettuce: Cooling sedative narcotic, antidiarrheal, antitussive.
Onion: Stomachic, diuretic, diaphoretic, expectorant.
Sorrel: Refrigerant, diuretic, weak cathartic, antidiarrheal, antiscorbutic.
Watercress: Weak cathartic, antiscorbutic.

Table VI.16.4. *Past and present medicinal uses of beverages*

Alcohol: Tonic, carminative, digestive; rubefacient.
Chocolate: See under flavorings and spices in Table VI.16.1
Coffee: Astringent, antiseptic, strong tonic, digestive; to stay awake.
Milk: To stimulate natural secretions; antiscorbutic.
Tea: Diluent, diuretic, diaphoretic.
Wine: Stomachic, diaphoretic, tonic, digestive, astringent.

Comments on Table VI.16.4

Alcohol and wine were among the first remedies subjected to quantitative experimental studies which, in the end, merely validated their age-old use as tonics. The major active ingredients in chocolate, coffee, and tea are, respectively, theobromine, caffeine, and theophylline, which share several pharmacological properties, such as diuresis and central nervous system stimulation, although to varying degrees. Theophylline is a mainstay of bronchodilator therapy for patients with asthma and related diseases, whereas caffeine still has a minor role as a stimulant, chiefly in a few over-the-counter painkillers (Estes 1991a).

Comments on Table VI.16.5

Barley water had been a common drink for the sick since antiquity, especially in low diets for fever patients. Barley, bread crumbs, and wheat or wheat flour contributed their soothing and gluten-based binding and stiffening qualities to plasters and wound dressings. The bran in oatmeal does increase stool bulk, but before the twentieth century, no medical use could have been made of oat bran's ability to bind cholesterol in the intestinal tract, which can help lower cholesterol concentrations in the blood. Ergot first entered medical usage as a result of its contamination of bread made from its agricultural host, rye. It was recommended for obstetrical use in Germany in 1582, and reintroduced for that purpose in 1787. In 1807, Dr. John Stearns of New York promoted its use for hastening birth, and in 1824 Dr. David Hosack of the same city recommended it for the control of postpartum bleeding (Estes 1990: 175), but such use remained controversial (Berman 1992). It is now well established that the alkaloids extracted from ergot are potent constrictors of blood vessels; they have been used to control postpartum bleeding in the twentieth century.

Table VI.16.5. *Past and present medicinal uses of grains*

Barley: Refrigerant, demulcent.
Bread crumbs: For gastrointestinal symptoms; in plasters, to stimulate suppuration.
Ergot, on rye: For postpartum care.
Oats: Cathartic.
Wheat: Visceral tonic; paste for plasters.

Table VI.16.6. *Past and present medicinal uses of gums and roots*

Jujubes: Deobstruent, decongestant.
Manna: Cathartic, expectorant, carminative.
Marshmallow: Emollient, demulcent.
Slippery elm: Emollient, expectorant, antidiarrheal; demulcent dressing.

Comments on Table VI.16.6

None of these gummy plant extracts is known to contain pharmacologically active principles. They probably owe their roles in medicine to their soothing qualities. The slippery, or red, elm entered medical usage largely through the works of Samuel Thomson, the botanical physician who stimulated the practice of do-it-yourself medicine in the United States early in the nineteenth century (Estes 1992). Later in the century, New England Shakers, who had adopted Thomson's medical system, made and promoted a flour derived from the tree's bark (Estes 1991b).

Comments on Table VI.16.7

Although burned eggshells might well be presumed to neutralize acids, it is doubtful that they would have provided an efficient remedy for the hyperacidity that was frequently diagnosed after Réamur's discovery of hydrochloric acid in the stomach. It was probably a remedy that evolved out of the discovery that the calcium oxide produced by burning eggshells was chemically equivalent to the alkaline quicklime made by similar techniques. Egg whites, on the other hand, can help neutralize toxic metal ions in the stomach. The cathartic effect of yolks is arguable, but their reputation as a cure for jaundice most likely stems simply from the fact that they are yellow. The properties associated with honey in the eighteenth century were

Table VI.16.7. *Past and present medicinal uses of miscellaneous foodstuffs*

Eggs: Burned shells, as antacid; whites, as an antidote for copper and mercury poisoning; yolks, as cathartic or anti-icteric.
Honey: Weak cathartic, detergent, expectorant.
Rapeseed: Attenuating, detergent, antiseptic, diaphoretic.

probably speculative, and we do not know if it was used in ways similar to those of the Egyptian physicians. Rapeseed oil, now called canola oil, contains nothing that might have led physicians to deduce the properties with which they credited it.

Dietetics and Modern Food Sciences

By about 1900, medical dietetics assumed new forms and goals in the wake of experimental laboratory investigations that permitted physicians to incorporate the concept of metabolic needs into their professional thinking. Although the identification and isolation of vitamins over the following three decades nearly completed that story, daily requirements for carbohydrates, fats, proteins, minerals, and vitamins are still being debated and modified. Many of today's medical concerns about foods are related to their statistical associations with specific illnesses. While such topics are explored elsewhere in this work, consideration of the transition from old to new concepts of medical dietetics is pertinent here.

The first foods to provide a true cure of any disease were citrus fruits, but the ready response they elicited in scurvy patients was not, at first, recognized as the result of replacing a substance that was missing from their diet. Indeed, James Lind's celebrated experiment with oranges and lemons on HMS *Salisbury* in 1747 was not the negatively controlled clinical trial it is often said to have been: He was only comparing six acids, including the fruits, because scurvy was thought to be a kind of fever and, therefore, treatable with almost any cooling acid. Some thought that excess alkalinity caused scorbutic fever, which led to the same therapeutic conclusion. Moreover, Lind did not argue that citrus fruits were the best protection against scurvy; indeed, he continued to recommend several other acids. Marine surgeons had recognized the antiscorbutic value of lemons by at least 1617, but not until 1795 did the British navy adopt limes as standard protection against scurvy (the U.S. Navy followed suit in 1812), as evidence of their efficacy continued to accumulate. Even so, navy surgeons knew only that lemons, limes, and oranges could prevent or cure the disease, not that they replenished the body's stores of a vital principle. When, in 1784, the Swedish chemist Karl Wilhelm Scheele discovered citric acid in lemons, he erroneously assumed that it was the active therapeutic principle, and it was not until the 1920s that the true antiscorbutic principle, ascorbic acid, was isolated and identified as essential to life (Estes 1979, 1985, 1990: 49, 116).

Studies of the physiology of digestion provided essential stepping-stones to the development of modern dietetic therapeutics early in the nineteenth century. In England, William Prout classified foods into the three major groups that are, in retrospect, recognizable as carbohydrate, protein, and fat. Friedrich Tiedemann and Leopold Gmelin reported from Heidelberg, in 1826, that the ingestion of any kind of food increased the amount of acid in the stomach, and that the acid could dissolve all foods. Some investigators continued to argue that lactic acid was the active principle of digestion, but in 1852 Friedrich Bidder and Carl Schmidt of the German university at Dorpat, Estonia – then emerging as the first academic center for the study of pharmacology – showed that the free hydrochloric acid discovered by Réamur was the only acid in gastric juice (Leicester 1974: 147, 161–3).

The experiments on gastric function performed by U.S. Army surgeon William Beaumont led him to conclude, in 1833, that although animal and grain products are easier to digest than most vegetable foods, the differences are attributable only to the relative sizes of their constituent fibers, not to their other properties. He emphasized this by pointing out that the action of the hydrochloric acid in gastric juice is the same on all foodstuffs (Beaumont 1833: 275–8), as Tiedemann and Gmelin had shown.

By the 1840s, digestive enzymes had been found in saliva, gastric juice, and pancreatic juice, and by 1857 Claude Bernard had demonstrated that the glucose that provides the body's energy is released from glycogen that has been synthesized and stored in the liver (Leicester 1974: 165–9). It was probably these discoveries that permitted the eventual abandonment of dietetic therapies that had originated in the ancient world, especially when it became apparent that food itself does not alter normal gastric acid or digestive enzyme secretion, although both were eventually shown to be altered in specific diseases.

In 1816, François Magendie of Bordeaux found that dietary sources of nitrogen, especially meat, are essential for health in dogs, and that all the nitrogen necessary to sustain life comes from food, not air (Leicester 1974: 146). His work prompted the studies of Justus von Liebig, of Giessen, in Germany, which by 1840 had laid the foundations for the study of metabolism and other aspects of human nutrition. He showed, for instance, that the nitrogenous substances present in meat and some vegetable foods are assimilated into animal tissues, while carbohydrates like starch and sugar are consumed during oxidative respiration. Liebig's work began to elucidate the complex chemical interactions of foodstuffs with the fabric of the body (Drummond and Wilbraham 1958: 285–6, 345; Holmes 1973). In 1866, his pupil Carl von Voit showed that carbohydrates and fats supply all the energy used by the body, while its chief nitrogenous components, the proteins, are themselves derived from dietary protein of both plant and animal origin (Leicester 1974: 192).

Perhaps with these discoveries in mind, in 1865 Liebig began to promote an "Extract of Meat" he had devised as a medicine for specific illnesses, such as typhoid fever and inflammation of the ovaries. He marketed it both as a proprietary remedy and, in Germany (but not Britain or the United States), as a prescription drug. Although it was shown almost immediately to lack meat's nutritive elements, the extract was a success in European, British, and American kitchens for many years afterward, especially when Liebig redirected its advertising toward over-the-counter consumers instead of physicians and pharmacists, who were unconvinced of its therapeutic value. The extract also prompted development of the first commercial formulations of infant foods, which were advertised as promoting growth and preventing disease (Apple 1986; Finlay 1992).

Like Liebig's Meat Extract and many botanical drugs, several foods were medically important in the eyes of nineteenth-century laymen, even if not in those of contemporary physicians. Some dietary lore was pure mythology, such as the aphrodisiacal properties imputed to nutmegs, tomatoes, quinces, and artichokes (Taberner 1985: 204–6, 60–3). However, many over-the-counter remedies or their ingredients had the imprimatur of regular medicine, as is evident in British and American home-medicine texts.

Such books evaluated not only the nutritive value of foods but also their specific physiological effects in health and disease. By way of example, when J. S. Forsyth prepared the twenty-second edition of William Buchan's *Domestic Medicine,* he moved the chapter on diet from near the end to the very beginning, and incorporated into it ideas he had developed in his own *Natural and Medical Dieteticon* (Buchan 1809: 413–31, 1828: 19–40). Forsyth began by explaining that the "constant use of bread and animal substances excites an unnatural thirst, and leads to the immoderate use of beer and other stimulating liquors, which generate disease, and reduce the lower orders of the people to a state of indigence" (Buchan 1828: 19). Moreover, he said: "The plethoric . . . should eat sparingly of animal food. It yields far more blood than vegetables taken in the same quantity, and, of course, may induce inflammatory disorders. It acts as a stimulus to the whole system, by which means the circulation of the blood is greatly accelerated" (Buchan 1828: 20). In other words, although a meat diet is best suited to the physiological needs of laborers, it predisposes them to intemperance and poverty.

Forsyth differentiated vegetables and meat in terms of their acidity and alkalinity. He said that plant foods are more acidic and lighter in the stomach; in addition, they mix more readily in the stomach with other foods, and are more constipating, than meat. By contrast, he thought that animal foods display the "greater tendency to alkalescency and putrefaction," which meant that they might cause diarrhea and dysentery, even if only rarely. Although in Forsyth's opinion they mixed less well with other foods during digestion, they did help keep the bowels regular. He concluded by pointing out that meat produces "a more dense stimulating elastic blood" than does a vegetable diet, because animal food "stretches and causes a greater degree of resistance in the solids, as well as excites them to stronger action" (Buchan 1828: 39–40). This explained the value of meat to the health of the workingman within the contexts of contemporary chemical knowledge and of the humoral and solidist medical traditions.

Although Buchan and his posthumous editor wrote for British readers in the first instance, their work found receptive audiences in the United States, where do-it-yourself medicine flourished more than in England. In 1830, John Gunn of Knoxville, Tennessee, explained to the people of America (he dedicated his book to President Andrew Jackson) that "[f]ood . . . is intended to support nature" (Gunn 1830: 124). According to Gunn, because the most nourishing food is of animal origin, it can overheat and exhaust the body, unlike vegetable foods. In this respect he went beyond Forsyth's caveats. Inasmuch as plant foods cause stomach acidity, flatulence, and debility if they are the only items in the diet, Gunn recommended a diet with balanced amounts of meat and vegetables.

Guides to diet as a way to health proliferated throughout the nineteenth century. Some were mixed with exhortations against alcohol or doctors' drugs, while others promoted the benefits of physical culture. Gymnastics enthusiast Dio Lewis, for example, published books specifically related to gastrointestinal health, including *Talks about People's Stomachs* (Boston, 1870) and *Our Digestion; or My Jolly Friend's Secret* (Philadelphia, 1874). The latter title alone suggests that the book focuses on how to avoid the unpleasant sour feeling that characterizes dyspepsia. Similar titles appeared in England, such as W. T. Fernie's *Meals Medicinal: . . . Curative Foods From the Cook; In Place of Drugs From the Chemist* (Bristol, 1905).

Some British writers had been promoting meatless diets for a century before Dr. William Lambe claimed, in 1806, that such diets are not hazardous, and could even cure tuberculosis. His work seems to have prompted Percy Bysshe Shelley, at the age of 21, to write a vegetarian tract that was republished many times between 1813 and 1884. But most physicians, a conservative lot, argued that plant foods are hard to digest, and would have agreed with Forsyth that meat is essential for maintaining strength and vitality (Green 1986: 46–7; Nissenbaum 1988: 45–9).

Thus, by the end of the nineteenth century, scientific studies of the chemistry of foods were being translated into professional texts and domestic health guides written by physicians. Most of the foodstuffs used as medicines during the 25 centuries between the era of Hippocrates and the discovery of pathogenic microbes in the 1870s quietly disappeared from pharmacopoeias in the early twentieth century, as did the vast majority of historic drugs. From then on, until the recent emergence of medical nutrition as a clinical subspecialty, regular medicine nearly abandoned the therapeutic application of diet to disease, save for patients with specific biochemical defects of intermediary metabolism or those with vitamin deficiencies.

In the meantime, however, some of the newly emerging information about foods (and distortions of it) was being exploited by promoters who functioned outside the mainstream of regular medicine, but who well understood the needs of mainstream Americans. They and their followers liked to think of themselves as innovators or "reformers."

Alternative Dietetics

A number of nineteenth-century American health reformers – many of them energetic entrepreneurs – mounted effective populist attacks on both traditional and modern medical ideas simultaneously. Their chief selling point was that their ideas were more prophylactic than curative, a highly liberal position in a proud new republic in which regular medicine was dominated by political conservatives.

The allure of do-it-yourself medicine for the traditionally self-reliant American public was quickened by Samuel Thomson, an itinerant New England healer who, beginning in 1805, found that his system of botanical medicine was more profitable than farming. Although the curative focus of his system revolved around a relatively small number of remedies made from indigenous plants, Thomson also emphasized the importance of proper diet for health. His own version of the Hippocratic concept of the humors presumed that all disease arises from disordered digestion, resulting in insufficient heat for maintaining normal body function (Estes 1992).

Regular physicians were privately incensed at the economic competition inherent in Thomson's system – one of his marketing slogans was "Every man be his own physician" – but in public they could only charge him with unscientific reliance on a single dogma, his insistence that all disease was caused by cold. Such notions were not entirely new. In 1682 an anonymous French writer who thought the large intestine was the primary seat of all disease had urged his readers to be their own physicians, and to use botanical remedies that grew in their own country (Thorndike 1958, 8: 409). But in the 1680s, such suggestions must have been seen as only adding to the surfeit of emerging medical ideas and not as heresy or competition.

The true fountainhead of the healthy diet in America was Sylvester Graham, a Presbyterian clergyman who preached the physiological benefits of abstinence from alcohol and sex, as well as dietary reliance on homegrown and homemade whole wheat bread. His medical notions were not entirely original, however. They stemmed largely from those of François-Joseph-Victor Broussais, a physician in Napoleonic France who had taught that all disease was caused by an irritation in the gastrointestinal tract. Therefore, said Broussais, almost any illness can be cured by removing the responsible stimulating irritation with bleeding and his version of a low diet.

Because of the historical association of meat eating with potentially pathogenic stimulation, vegetarian writers such as Graham associated avoidance of animal foods, alcohol, and sexual arousal with physical, moral, and spiritual health. The ideal diet he began advocating in the 1830s consisted of two small meatless meals daily that included whole wheat bread and cold water. Graham said that his regimen would preclude the exhaustion and debility that usually follow excessive stimulation (Nissenbaum 1988: 20, 39–49, 57–9, 126–7, 142–3).

His influence has persisted to the present in several guises. Graham certainly fostered the notion that a meat diet was the major cause of dyspepsia (Green 1986: 164). The self-sufficient Shakers, who farmed and sold medicinal herbs, adopted his teachings along with those of Thomson, and sold flour made to Graham's specifications. However, although the Shakers believed that dyspepsia was the quintessential disease of postwar America, they were not vegetarians themselves (Green 1986: 30–1; Estes 1991b).

The Grahamite proselytizing of Dr. Russell T. Trall has had the most lasting impact of all. He emerged in the 1840s as an energetic and prolific promoter of hydropathy, the water-cure techniques introduced in Austria by Vincenz Preissnitz, who, like Thomson, found healing more lucrative than farming (Armstrong and Armstrong 1991: 81–2). Preissnitz did not preach vegetarianism, but his American disciple did. Trall rationalized his therapeutic methods by updating the ancient four temperaments in what he said was a more "practical" classification.

He associated the nervous temperament with the nervous system, and the sanguine temperament with the arteries and lungs. He explained that these two temperaments were more active, or irritable, than the bilious temperament, which he paired with the veins and musculoskeletal system, or the lymphatic temperament, paired with the abdominal viscera. Thus, Trall described the gastrointestinal tract as torpid and incapable of irritation in persons with a lymphatic temperament (Trall 1852: 287–90).

Although he cited Liebig's differentiation of nitrogenous from non-nitrogenous foods, Trall based much of his dietary argument on his own reading of Genesis 1:29: "Behold, I have given you every herb bearing seed, which is upon the face of all the earth, and every tree in which is the fruit of a tree yielding seed; to you it shall be for meat." From this, Trall concluded that "the vegetable kingdom is the ordained source of man's sustenance" (Trall 1852: 399).

He went on to adduce anatomical, physiological, and "experimental" (actually, testimonial) evidence for the medical efficacy of a vegetable diet. He stated that the secretions of vegetable eaters are "more pure, bland, and copious, and the excretions . . . are less offensive to the senses," and that their blood is "less prone to the inflammatory and putrid diatheses." As a result, their "mental passions are more governable and better balanced," a conclusion that Graham would have seconded, although he might not have accepted Trall's association of any temperament with a nonirritable intestinal tract (Trall 1852: 410–12). Neither would Graham have tolerated Trall's opinion that certain boiled or broiled meats, white fish, and an occasional egg were acceptable. Still, the major item on the menu at Trall's water-cure establishments was unleavened bread made of coarse-ground, unsifted meal like Graham's (Trall 1852: 421–4).

Ellen G. White, who began the Seventh-Day Adventist movement in the late 1840s, at the time Graham and Trall were achieving fame, was interested in the teachings of both. The Adventists' continuing adherence to a vegetable diet today is presumed to be responsible, in large measure, for their lesser risk of major degenerative diseases (Webster and Rawson 1979).

In 1866, Mrs. White opened the Western Health Reform Institute in Battle Creek, Michigan, as an Adventist retreat that served its guests two vegetarian meals a day, modeled on those advocated by Russell Trall, along with the full range of water cures. Ten years later, Dr. John Harvey Kellogg became the Institute's medical director. There he invented and prescribed the original versions of "Granola" and peanut butter, and the rolled breakfast cereals that he developed in collaboration with his younger brother, Will Keith Kellogg. Not only were cereals nutritious, said the brothers, but they would also counteract the autointoxicants then being accused of causing many illnesses, and facilitate bowel movements.

Charles W. Post, a former patient at the Battle Creek Sanitarium (as J. H. Kellogg renamed it), followed suit with his own "Postum" (1895), "Grape-Nuts" (1898), and "Post Toasties" (1908). The Kelloggs had set up a company to manufacture their products, but it was after the brothers had parted ways that W. K. Kellogg in 1906 introduced "Corn Flakes." Although the Kelloggs and Post had many competitors among health-food manufacturers in the Battle Creek area alone, their products still dominate the marketplace for breakfast cereals. Their initial success was attributable largely to their advertised medical uses. Like other bran foods, W. K. Kellogg's "All-Bran" was first marketed as a relief from constipation. In 1931 Nabisco's "Shredded Wheat," a competing product, was proclaimed to offer "Strength in Every Shred" (Green 1986: 305–12; Whorton 1988; Armstrong and Armstrong 1991: 99–119).

A few other foods entered the realm of medical usage outside the framework established by Sylvester Graham. The most visible was probably the tomato, one of the most fleeting therapeutic discoveries in the history of medicine. Many Europeans had regarded it as inedible or poisonous after it was brought from the New World in the 1540s, because it belongs to the same family as the deadly nightshade. Its therapeutic value was reported in London as early as 1731, but when sent to North America soon afterward, it was only as an ornamental plant (Smith 1991).

In 1825, Dr. Thomas Sewall reported, in Washington, D.C., that tomatoes could cure bilious disease, probably because they have particles that are yellow, as is jaundice, produced by the accumulation of yellowish bile pigments in the skin as a result of liver or gall bladder disease. Then, in 1835, a brazen medical entrepreneur, John Cook Bennett, began telling Americans that tomatoes could cure diarrhea and dyspepsia. He claimed that Indians used them to promote diuresis, while others said they were good for fevers. The agricultural press spread Bennett's enthusiasm, and within five years several extracts of tomato had been marketed as typical panaceas (Smith 1991).

An 1865 advertisement claimed that "Tomato pills, will cure all your ills." However, reports of the hazards of tomatoes, as well as their lack of therapeutic efficacy, had already begun to resurface. Although the merits of tomatoes were being debated as late as the 1896 annual meeting of the American Medical Association, they had long since lost their medical appeal – but by then they had become firmly established in American cookery (Smith 1991).

The role of food as therapy is still central to several modern alternative-healing systems. Naturopathic healers (also known as naturists) cite Samuel Thomson as their chief source of authority, declaring that the "Naturist will be both dietician and herbalist." They, too, look on the stomach as "in almost every instance the seat of disease," and like Russell Trall, they cite Genesis 1:29 (Clymer 1960: 12, 33, orig. 1902). Some naturopathic regimens include coffee enemas, administered at two-hour intervals, to cleanse the intestines.

Occasionally, a small number of people will use a food for medical reasons despite evidence of the dangers of such usage. For example, unpasteurized milk has been promoted neither by advertising nor by any organization – its use seems to be inspired chiefly by folklore, supported by its consumers' supposition that it is a matter of freedom of choice. Those who persist in using raw milk, sometimes illegally, claim that it has more nutritive value than pasteurized milk, that it increases their resistance to disease and enhances their fertility, and that it contains unidentified substances, such as an "antistiffness factor" that helps prevent rheumatism (Potter et al. 1984).

When the word "macrobiotic" entered English usage in the early eighteenth century, it signified a diet or other rules of conduct that would prolong life. Its modern usage appeared in the early 1960s, when a Japanese, Georges Ohsawa, introduced a new concept in dietary therapy. He began with the premise that there is "no disease that cannot be cured by 'proper' therapy." His idea of "proper" therapy, which originated in ancient Chinese ideas of the balance between the complementary forces of yin and yang, was based on white grain cereals and on avoiding fluids. As much as 30 percent of the diet could be meat when the patient began the prescribed regimen, but by the time he or she had progressed through the entire ten-step sequence, which Ohsawa called the "Zen macrobiotic diet," the patient would be eating only grain products. In the 1970s, Michio Kushi revised Ohsawa's diet after its inventor had died, but without its meatless extremes. In addition, Kushi developed a cadre of "counselors" whose special training permits them alone to make diagnoses within the system. Many do so by iridology, which associates segments of the iris with specific parts of the body (iridology has also been practiced by chiropractors, among others). Because Ohsawa had said that the macrobiotic diet could cure any disease, it is sometimes resorted to by victims of cancer, who are instructed to chew each mouthful 150 times, to enhance the food's strengthening yang properties and to preclude overeating; healthy people need chew only 50 times (Macrobiotic diets 1959; AMA Council 1971; Simon, Wortham, and Mitas 1979; Cassileth and Brown 1988).

In the 1920s, a German physician, Max Gerson, developed a dietary cure for cancer based on his belief (which accorded with the pioneering studies of intermediary metabolism by Otto Warburg) that the rate of cancer cell growth depends on imbalances in the aerobic and anaerobic metabolic reactions of the malignant cells. Gerson said his diet would restore those balances to normal by, among other things, increasing potassium intake. It resembles the diet served at Russell Trall's water-cure establishments, with the addition of calves' liver, a mixture of special fruit juices, and coffee enemas. Gerson refined his regimen after emigrating to the United States, and it is still available from his heirs in Tijuana, Mexico (American Cancer Society 1990; Green 1992).

Other clinics in Tijuana offer diets that are said to cure cancer by strengthening the immune system and minimizing the intake of potential toxins. Such programs are often accompanied by vitamins, minerals, enzymes, and gland extracts and by stimuli to moral and religious health that are reminiscent of the activities provided at the Battle Creek Sanitarium (American Cancer Society 1991). Several diets and dietary supplements have been marketed without any medicalized rationalization beyond that used to promote five products sold by United Sciences of America, Inc.: "to provide all Americans with the potential of optimum health and vital energy" (Stare 1986).

Modern foods that originated in nineteenth-century efforts to improve the American diet are as healthful as their nutritional content allows. Nevertheless, today many of them – especially breakfast cereals – are fortified with vitamins and minerals, often to enhance their presumed acceptability to consumers. But no one has yet discovered a food or devised a diet that can be proved to cure diseases, such as arthritis, cancer, or any other illness that is not the result of a specific nutritional deficit.

Dietetics in Other Cultures

Important discoveries in the biochemistry of food began to appear in the twentieth century, many of them soon after the discovery of vitamins. Eventually they led to the somewhat contentious discussions of the influence of specific foods on human illness that are a recurrent feature of American culture today. We have few written records that permit detailed comparisons of the dietary medicine practiced in cultures other than those whose roots were in ancient Egypt, Greece, and Rome. But the broad outlines of medical dietetics in a few other cultures can be ascertained.

Among North American Indians

There is evidence that at least some Indian groups of North America had specific ideas of what constituted a proper diet, and that they took dietary precautions when they were sick, such as starving a fever. Colonists reported that New England Indians remained healthy so long as they continued to eat their usual foods, and that they rejected some English foods even when, as hunter-gatherers, they were at the mercy of an uncertain food supply (Vogel 1970: 251–3).

Several Indian societies put plant foods to differing therapeutic uses. Pumpkins were used by the Zunis to treat the skin wounds made by cactus spines, but by the Menominees as a diuretic. New England Indians thought that sarsaparilla was useful as food when they were on the move, whereas the Iroquois used it to treat wounds. The Penobscots of the East Coast and the Kwakiutls of the West Coast used sarsaparilla as a cough remedy, and the Ojibwas applied it to boils and carbuncles (Vogel 1970: 356–61). It seems clear that such uses were as much based on the *post hoc ergo propter hoc* fallacy as were those in the Hippocratic–Galenic tradition. The Aztecs found some uses for the indigenous flora of Mexico that resembled those of their unrelated neighbors north of the Rio Grande. Thus, both Aztecs and the Indians who lived in Texas used the pods and seeds of edible mesquite as a remedy for diseased eyes (Ortiz de Montellano 1990).

In the Far East

The Chinese diet was even more rigidly associated with physiological concepts than that of the Graeco-Roman tradition. Balance between the classical complementary forces of yin and yang dominated the structure and function of the body, and was as important to health as were balances among the Hippocratic humors. The basic digestive processes described in Chinese texts resemble those postulated by Aristotle, although only the latter based some of his conclusions on dissections. The Chinese assumed that food passes from the stomach to the liver, where it yields its vital forces to the muscles, and its gases to the heart (the origin of both blood and animal heat), while its liquid components move to the spleen, then the lungs, and finally the bladder (Leicester 1974: 45–9).

According to the teachings of Huang Ti, the mythical Yellow Emperor said to have reigned about 2600 B.C., but probably not written down before 206 B.C., proper medical treatment includes foods that can correct the patient's "mode of life." Because the Chinese recognized five elements – water, fire, wood, metal, and earth – the number five recurs throughout Chinese thought: They associated each of the five major organs – liver, heart, lungs, spleen, and kidneys – with one of the "five grains," the "five tree-fruits," the "five domesticated [meat] animals," and the "five vegetables," in terms of any organ's nourishment. In ancient China, as in the medieval European tradition, taste was correlated with a food's action, but within a different framework: Sweet foods were appropriate to the health of the liver, sour foods to the heart, bitter foods to the lungs, salty foods to the spleen, and pungent foods to the kidneys (Veith 1949: 1–9, 55–8).

The canonical sweet foods of Chinese dietetics (rice, dates, beef, and mallows) were believed to enter the body through the spleen, to produce a slowing effect. Sour foods (small peas, plums, dog meat, and leeks) enter via the liver, and produce an astringent, or binding, effect. Bitter foods (wheat, almonds, mutton, and scallions) enter via the heart, and strengthen, or dry, the body. Salty foods (large beans, chestnuts, pork, and coarse greens) enter through the kidneys, with a softening effect. And, finally, pungent foods (millet, peaches, chicken meat, and onions) disperse the smallest particles of the body after entering it via the lungs. One important precept that followed from these complex relationships was that a patient should avoid foods of the correlative taste whenever he or she had a disease in the organ through which that taste enters the body (Veith 1949: 199–207). The traditional Ayurvedic medical practices of India share many concepts with those of China, although their professional literatures differ in their underlying cosmological premises (Leicester 1974: 51–2).

Chinese medical dietetics loosened its adherence to strict rules as the centuries passed. For instance, although Ko Hung (under the nom de plume Pao-p'u Tzu) described basic principles for constructing healthy diets in about A.D. 326, he did not prescribe specific foods as cures, even if he did maintain that a patient's blood supply can be increased simply by eating more food (Huard and Wong 1968: 19–23). Yet eventually, as European dietary and medical notions penetrated the Far East, many traditional Chinese remedies disappeared – but not all of them.

By contrast, the medical lore of neighboring Tibet did not succumb to external influence. Along lines that Galen might have approved, Tibetan healers classified patients, in the first instance, as wind-types, bile-types, or phlegm-types, and, secondarily, by habitus, complexion, powers of endurance, amount of sleep, personality, and life span. For each patient type and subtype – they were all mutually exclusive – doctors prescribed specific medicines and foods, although their prescriptions show that they recognized more mixtures of the basic types than might have been supposed from their texts alone (Finckh 1988: 68–73).

Food or Drug? The Example of Garlic

Therapeutic descriptions by medical authorities since Dioscorides are still being cited in order to market some foods that were used as medicine in the ancient world. Such foods are not advertised as remedies; if they were in the United States, at least, they would be subject to the proofs of efficacy and safety required by the Food and Drug Administration. Nevertheless, they illustrate the continuing difficulty of devising mutually exclusive definitions of foods and drugs. The long history of garlic as a medical remedy is not only a case in point; it also exemplifies historical changes in medical theory.

Garlic in Ancient and Medieval Medicine

Garlic is the bulb of *Allium sativum,* a member of the lily family; the Romans derived the Latin genus name from a Celtic word for pungent bitterness. Ancient Egyptians did not use garlic as a remedy, but they did include it in a foul-smelling amulet designed to keep illness away from children (Sigerist 1951: 283). It was also found among Tutankhamen's burial goods – as a seasoning (Block 1985; Manniche 1989: 70–1). Modern Sudanese villagers, like some ancient Egyptians, place garlic in a woman's vagina to determine if she is pregnant; if she is, the characteristic odor will appear in her breath the next day (Estes 1989: 117). Ancient Mesopotamians prescribed garlic for toothache and painful urination and incorporated it in amulets against disease, as did the Egyptians (Levey 1966: 251). Traditional Chinese medicine associated garlic with the spleen, kidneys, and stomach, while Ayurvedic practitioners in India considered it a panacea, even if its specific actions were understood in the humoral and solidist traditions (Hobbs 1992).

The first-century testimonies of Dioscorides and Pliny the Elder provide similar pictures of the use of garlic in Graeco-Roman practice. The nearly complete text of its description by Dioscorides is given here because his book was the bedrock of virtually all herbal lore and prescription writing for the next 15 centuries. The translation is from the first – and still only – English version (1655) of his *Materia Medica:*

> It hath a sharp, warming biting qualitie, expelling of flatulencies, and disturbing of the

> belly, and drying of the stomach causing of thirst, & of puffing up, breeding of boyles in ye outsyde of the body, dulling the sight of the eyes. . . . Being eaten, it drives out the broade wormes, and drawes away the urine. It is good, as none other thing, for such as are bitten of vipers, or of the Haemorrhous [hemorrhoids], wine being taken presently after, or else that being beaten small in wine, & soe dranck. It is applyed also by ye way of Cataplasme [a watery poultice] both for the same purposes profitably, as also layd upon such as are bitten of a mad dogge. Being aten, it is good against the chaunge of waters. . . . It doth cleare the arteries, & being eaten either raw or [boiled], it doth assuage old coughes. Being dranck with decoction of [oregano], it doth kill lice and nitts. But being burnt, and tempered with hon[e]y it doth cure the sugillationes oculorum [black eyes], and Alopeciae [bald spots] being anointed [with it], but for the Alopeciae (it must be applyed) with unguentum Nardinum [an extract of *Nardostachys jatamansi*]. And with salt & oyle it doth heale [papular eruptions]. It doth take away also the Vitiligenes, & the Lichenes, & the Lentigenes, and the running ulcers of the head, and the furfures [purpural spots], & ye Lepras [other spots, not leprosy], with hon[e]y. Being boiled with Taeda [pine tar] and franckincense, & kept in the mouth it doth assuage the paine of ye teeth. And with figge leaves & [cumin] it is a Cataplasme for such as are bitten of the Mygale [shrew-mouse]. But the leafes decoction is an insession [insertion into the vagina] that brings downe the Menstrua & the Secundas. It is also taken by way of suffumigation [fumigation, in which the patient stands over the burning medicine so that its fumes rise into her vagina] for ye same purpose. But the stamping that is made of it and ye black olive together, called Myrton, doth move the urine & open ye mouths of ye veines & it is good also for the Hydropicall [edematous] (Dioscorides 1934: 188–91).

In short, Dioscorides says that garlic expels intestinal worms and skin parasites, protects against venomous animals, neutralizes internal and external inflammations of many kinds, relieves toothaches and coughs, reduces hemorrhoids, and stimulates menstruation. Most important of all for later writers, garlic removes excess fluid from the body by dilating blood vessels and stimulating the kidneys.

Pliny, on the other hand, was an inquisitive encyclopedist, not a physician. In his *Natural History* he lists many of the same uses for garlic. But whereas only Dioscorides says that it can move the urine, Pliny adds that garlic can cure epilepsy, cause sleep, stimulate the libido, and neutralize the poisonous effects of aconite and henbane (although such antidotal effects are unlikely) (Manniche 1989: 70–1; Hobbs 1992). Together, he and Dioscorides dictated the therapeutic uses of garlic for centuries.

Thus, al-Kindi, a royal tutor in ninth-century Baghdad, transmitted lessons he had learned from Greek and Roman sources when he said that garlic was good for inflamed ears (Levey 1966: 251). As Arabic works became available in European languages, ancient remedies were systematized within an increasingly rigid humoral framework. Consequently, the entry for garlic in a late-fourteenth-century *Tacuinum Sanitatis* says: "*Nature:* Warm in the second degree, dry in the third. *Optimum:* The kind that does not have too pungent a smell. *Usefulness:* Against poisons. *Dangers:* For the faculty of expulsion, and the brain. *Neutralization of the Dangers:* With vinegar and oil" (Arano 1976, plates 96–7). Such information changed from time to time, perhaps as doctors changed their minds, but also perhaps because of errors in transcribing manuscripts: A slightly later version of the same health handbook says exactly the same things about garlic, but describes it as warm in the fourth degree.

The most famous surgeon in sixteenth-century Europe, Ambroise Paré, based his therapeutic assessments on his own observations, perhaps because he had not learned his profession by scholastic disputation in a university. He thought garlic's major value was as a preventive against serious contagions:

> Such as by the use of garlick have not their heads troubled, nor their inward parts inflamed, as Countrey people, and such as are used to it, to such there can bee no more certain preservative and antidote against the pestiferous fogs or mists, and the nocturnal obscurity, than to take it in the morning with a draught of good wine; for it being abundantly diffused presently over all the body, fils up the passages thereof, and strengtheneth it in a moment (Paré 1634: 823–4, 1031).

Paré's therapeutic reasoning is obscure; he seems to have presumed an analogy between garlic and onions, both of which he classified among the hottest of all remedies, those warm in the fourth degree. Surgeons who agreed with his Galenic assumptions quickly adopted an onion poultice Paré had invented on the premise that onions "attract, draw forth, and dissipate the imprinted heate" (Sigerist 1944).

Throughout the seventeenth century, physicians and laymen alike employed garlic as a diuretic and for virtually all the other uses listed by Pliny and Dioscorides, as well as for its ability to protect against contagious diseases (Leighton 1970: 306–7; Hobbs 1992). It was the major ingredient in one of more than 50 prescriptions recommended by the eminent London physician Thomas Willis for treating serious respiratory disease, especially consumption (Willis

1692: 86). As late as the early nineteenth century, physicians still relied on the properties that Dioscorides had ascribed to garlic, as revealed by its description in an influential 1794 compendium of medical practice:

> The root applied to the skin inflames. . . . Its smell is extremely penetrating and diffusive; when the root is applied to the feet, its scent is soon discovered in the breath; and taken internally, its smell is communicated to the urine, or the matter of an issue, and perspires through the pores of the skin. This pungent root stimulates the whole body. Hence, in cold leucophlegmatic habits, it proves a powerful expectorant, diuretic, and if the patient be kept warm, sudorific; it has also been supposed to be emmenagogue. In catarrhous disorders of the breast, flatulent cholics, hysterical, and other diseases proceeding from laxity of the solids, it has generally good effects: it has likewise been found serviceable in some hydropic cases. . . . The liberal use of garlick is apt to occasion headachs, flatulencies, febrile heats, inflammatory distempers, and sometimes discharges of blood from the haemorrhoidal vessels. In hot bilious constitutions, where there is already a degree of irritation, and where there is reason to suspect an unsound state of the viscera, this stimulating medicine is manifestly improper [contraindicated], and never fails to aggravate the distemper. Garlick made into an ointment with oils, &c. and applied externally, is said to resolve . . . cold tumors, and has been greatly esteemed in cutaneous diseases. It has likewise been sometimes employed as a repellent. When applied in the form of a poultice to the pubis, it has sometimes proved effectual in producing a discharge of urine, when retention has arisen from a want of due action of the bladder; and some authors have recommended, in certain cases of deafness, the introduction of a single clove, wrapt in thin muslin or gauze, into the meatus auditorius [ear canal] (*Edinburgh New Dispensatory* 1794: 87–8).

The *Dispensatory,* which reflects contemporary therapeutic practices at the Royal Infirmary of Edinburgh, also points out that garlic has been reported to be an effective treatment for malaria and smallpox. William Buchan of Edinburgh described a garlic ointment for whooping cough that could be prepared at home:

> by beating [it] in a mortar . . . with an equal quantity of hog's lard. With this the soles of the feet may be rubbed twice or thrice a day; but the best method is to spread it upon a rag, and apply it in the form of a plaster. It should be renewed every night and morning at least, as the garlic soon loses its virtue (Buchan 1809: 212).

James Thacher presented selected aspects of the Edinburgh professors' views of garlic in his influential *American New Dispensatory* (Thacher 1813: 135–6). The first U.S. *Pharmacopoeia* (1820), which owed much of its content to its Edinburgh counterpart, included garlic among the remedies accepted by the American medical profession. Its 1905 edition listed it for the last time, but garlic as a recommended remedy remained in the United States as late as the 1936 edition of the *National Formulary* (Vogel 1970: 306–7).

Garlic during the Scientific Revolution

Solidist theories of pathophysiology melded well with the emergence of experimental chemistry in the eighteenth century. In 1822, Jacob Bigelow, a professor of medicine at Harvard, based much of his brief description of garlic's effects on those of its active principle, recently isolated as an oil:

> Garlic and other plants of its genus have a well known offensive odour and taste, which, however, in a weakened state, render them an agreeable condiment with food. These qualities depend on a thick, acrid, yellowish, volatile oil, which may be separated by distillation, leaving the bulbs nearly inert. Garlic is stimulant, expectorant and diuretic. It is given in the form of syrup in chronic coughs, and the secondary stages of pneumonia; also, in combination with other medicines, in dropsy. Externally the bruised bulbs, in the form of a poultice, act as rubefacients (Bigelow 1822: 58).

An important reference text published 50 years later describes the effects of garlic much as both Dioscorides and Bigelow had, but within the more explicit context of solidist physiology:

> Its effects on the system are those of a general stimulant. It quickens the circulation, excites the nervous system, promotes expectoration in debility of the lungs, produces diaphoresis or diuresis according as the patient is kept warm or cool, and acts upon the stomach as a tonic and carminative. It is also said to be emmenagogue. . . . Moderately employed, it is beneficial in enfeebled digestion and flatulence. . . . It has been given with advantage in chronic catarrh, and other pectoral affections in which the symptoms of inflammation have been subdued, and a relaxed state of the vessels remains. . . . If taken too largely, or in excited states of the system, garlic is apt to occasion gastric irritation, flatulence, hemorrhoids, headache, and fever. As a medicine, it is at present more used externally than inwardly. Bruised, and applied to the feet, it acts very beneficially, . . . in disorders of the

> head; and is especially useful in the febrile complaints of children, by quieting restlessness and producing sleep. Its juice . . . is frequently used as a liniment in infantile convulsions, and other spasmodic or nervous affections in children (Wood and Bache 1874: 87–9).

Although garlic was not among the materia medica of Thomson (Estes 1992), one of his followers, the prominent eclectic physician John King, described its efficacy as a gastric tonic, as an anthelmintic, and in respiratory illnesses, especially those of children (Hobbs 1992). Despite the Shakers' unreserved reliance on Thomson's teachings, they recommended garlic as a stimulating tonic to promote expectoration in upper respiratory conditions, and to promote both diuresis and bowel movements. They also applied it externally to relieve pulmonary symptoms, just as Willis and the doctors of Edinburgh had done (Miller 1976: 177).

Modern herbalists preserve some indications for garlic inherited from the ancient world, including its use in love potions and prophylactic amulets. Others also prescribe it for effects not recognizable among those mentioned in medical works of the past, such as for "life-prolonging powers," and improved memory and mental capacity (Huson 1974: 32–3, 53–4, 252, 279, 312).

Garlic in the Modern Laboratory

In 1844, Theodor Wertheim, a German chemist, distilled a strongly pungent substance from garlic oil. He called the chemical group associated with the characteristic odor "allyl," from the plant's scientific name. Exactly 100 years later, Chester J. Cavillito and his colleagues at Sterling-Winthrop Company laboratories in Rensselaer, New York, discovered the chemical structure of allicin, the compound in garlic that produces its odor.

Four years later, in 1948, Arthur Stoll and Ewald Seebeck, at Sandoz Company laboratories in Basel, isolated alliin (0.9 percent of fresh garlic), the molecule that is biotransformed to allicin (0.1–0.5 percent of fresh garlic, up to 0.9 percent of garlic powder), which represents a doubling of the alliin molecule. The reaction is mediated by the enzyme allinase (in association with the coenzyme pyridoxal phosphate, or vitamin B_6). Garlic does not emit its typical odor until it is crushed. Stoll and Seebeck found that crushing releases allinase from the bulb's cells, permitting it to act on alliin to produce the odoriferous allicin (as well as ammonia and pyruvate ion).

Finally, in 1983, Eric Block of New York and workers at the University of Delaware and at the Venezuelan Institute of Scientific Investigations in Caracas established the structure of ajoene (*ajo* is the Spanish word for garlic), formed by the condensation of two molecules of allicin in garlic cloves. Ajoene cannot be detected in proprietary preparations of garlic, only in fresh cloves (Block 1985; *International Garlic Symposium* 1991: 10–11).

Several potentially therapeutic effects have been attributed to garlic oil and its chemical constituents since the early 1980s. Some preparations reduce plasma concentrations of cholesterol, triglycerides, and low-density lipoproteins to a modest extent, while increasing high-density lipoproteins. These effects seem to be secondary to inhibition of an enzyme necessary for cholesterol synthesis (hydroxy methyl glutaryl coenzyme A reductase), and may be associated with the ability of the same preparations to reduce blood pressure in hypertensive animals and men. An aqueous extract of garlic has been reported to inhibit angiotensin converting enzyme; modern drugs that selectively inhibit that enzyme are highly effective as antihypertensive medicines. Garlic and its extracts also inhibit thrombosis by inhibiting platelet aggregation, decreasing blood viscosity, dilating capillaries, and triggering fibrinolysis (clot breakdown). Ajoene, which is about as potent as aspirin as an antithrombotic compound, blocks platelet fibrinogen receptors. Indeed, it is probably the major antithrombotic factor in garlic juice (Block 1985; *Lawrence Review* 1988; Auer et al. 1990; Kiesewetter et al. 1990; Mader 1990; Vorberg and Schneider 1990; *International Garlic Symposium* 1991: 9, 19–44).

In 1858 Louis Pasteur found that garlic has antibacterial properties. Later studies have shown that a highly diluted solution of its juice can inhibit the growth of several important pathogenic bacteria, including *Staphylococcus, Streptococcus, Bacillus,* and *Vibrio cholerae,* as well as pathogenic yeasts and other fungi. Since then, garlic has been reported to inhibit the in vitro growth of several species of fungi, gram-positive and gram-negative bacteria, and the tuberculosis bacillus, and to reduce the infectivity of viruses, such as influenza B. Because it is the malodorous allicin that is responsible for garlic's antimicrobial effects, it is no surprise that the Sandoz Company decided not to develop it as an anti-infective drug following the discoveries of Stoll and Seebeck.

Other studies have demonstrated garlic's antineoplastic activity in rodents, but this effect may be associated with the trace elements germanium and selenium, rather than with allicin or its metabolites. Finally, recent evidence suggests that garlic decreases plasma concentrations of thyroxine, thyroid stimulating hormone, and glucose (and increases the concentration of insulin) (Block 1985; *Lawrence Review* 1988; Horowitz 1991; *International Garlic Symposium* 1991: 28–39; Farbman et al. 1993).

Several preparations of garlic are available in the United States as "health foods," although no clinical indication other than "goodness" is advertised for them – thus exacerbating the problem inherent in the coined word "nutraceutical." Most research on the therapeutic effects of garlic has been carried out in Great Britain and Europe, where garlic's medical value is more widely proclaimed. Some commercial garlic preparations are said to lack the characteristic odor, which means they are probably incapable of the potentially beneficial effects that have been attributed to alliin, allicin, and ajoene. Moreover, even though garlic has been used for culinary purposes for many centuries with no known toxic effects, it is possible that concentrated preparations might have deleterious effects in patients with diabetes or those taking anticoagulant drugs, but no reports of such effects seem to have been published (*Lawrence Review* 1988). Several sulfur-containing compounds found in fresh garlic have been held responsible for the acute gastroenteritis that ingestion of large amounts of its buds may induce in young children, while chronic ingestion of garlic has been reported to produce goiter by inhibiting iodine uptake by the thyroid gland (Lampe and McCann 1985: 28–9).

Whatever the eventual fate of garlic in pharmacological therapeutics, its history well illustrates how medical concepts have often been adapted to fit newly emerging ideas, even in the absence of any validation of the revised medical notions – other than the evidence implicit in the average adult patient's 95 percent chance of recovering from any nondevastating illness. Until the twentieth century, physicians had no better evidence on which to base dietetic prescriptions and recommendations. As Marie-François-Xavier Bichat said about two centuries ago: "The same drugs were successively used by humoralists and solidists. Theories changed, but the drugs remained the same. They were applied and acted in the same way, which proves that their action is independent of the opinion of doctors" (Estes 1990: ix). Clearly, Bichat would have included foods – even garlic – within the meaning of his word "drugs."

J. Worth Estes

Appendix: Definitions of Drug Properties

Anthelmintic: A drug that expels worms from the intestines.
Antidysenteric: Relieves dysentery.
Antihysteric: A form of antispasmodic used to treat several conditions regarded as "hysteric."
Anti-icteric: For treatment of jaundice *(icterus).*
Antiseptic: To prevent putrefaction *(sepsis).*
Antispasmodic: Reduces spasms (including fast heart rate), but without inducing insensibility (as narcotics do).
Antitussive: Cough suppressant.
Aperient: A weak cathartic.
Astringent: Strengthens a body that is too relaxed, or reduces excessive evacuations; also see *Styptic.*
Attenuating: Thins and divides the humors into smaller particles.
Carminative: Expels gas from the intestines, especially in dyspepsia.
Cathartic: A drug that promotes defecation, or increases fluid secretion from the intestinal lining.
Cephalic: For disorders of the head.
Demulcent: Lubricates organ surfaces (especially of intestines).
Deobstruent: Removes obstructions to the free flow of urine, sweat, feces, phlegm, bile, and blood.
Detergent: Cleanses or purges.
Diaphoretic: A drug that increases sweating, by stimulating blood vessels in the skin.
Digestive: Improves digestion and, therefore, nutrition.
Diluent: Dilutes blood, facilitating diuresis and diaphoresis.
Diuretic: A drug that promotes urine by stimulating the kidneys.
Emetic: A drug that induces vomiting.
Emmenagogue: Promotes menstruation.
Emollient: Reduces tension in rigid or distended organs, and warms and moistens them.
Errhine: Increases discharge from the nose; induces sneezing.
Expectorant: Promotes secretion and ejection of mucus from the lungs and trachea.
Lactatogue: Stimulates lactation.
Laxative: A gentle cathartic.
Narcotic: Affects the brain, by sedating *or* stimulating it.
Nervine: In seventeenth century, an emollient unguent for the sinews; from the eighteenth century, a stimulating tonic for weak nerves.
Pectoral: For disorders of the chest and lungs; often an antitussive and/or expectorant.
Rubefacient: Reddens or irritates the skin.
Stomachic: Warms and strengthens the stomach.
Styptic: An astringent for external use.
Tonic: Strengthens the body by increasing the force of the circulation, animal heat, secretions, digestion, or muscular activity, especially in debilitating illness.

VI.17 Vegetarianism

Human populations often have been obliged to subsist on an all-vegetable diet because of a poverty or scarcity of animal foods. The term "vegetarianism," nevertheless, is usually reserved for the practice of voluntary abstention from flesh on the basis of religious, spiritual, ethical, hygienic, or environmental considerations. These in turn have led to still finer distinctions regarding exactly what nonmeat articles of diet are permissible, resulting in the fragmentation of vegetarians into several groups. The great majority of adherents are "lacto-ovo" vegetarians, who reject flesh but find dairy products and eggs acceptable. Smaller groups include "vegans," who admit no animal products whatsoever into their diet; "lacto-vegetarians," who consume milk but not eggs; "ovo-vegetarians," who allow eggs but not milk; "fruitarians," who eat only fruits and nuts; "raw foodists"; and "natural hygienists," who scorn even vegetable foods if these have been processed or refined. And because - for all those classes - vegetarianism implies a concern to persuade others to adopt meatless diets, the history of vegetarianism is, at core, the history of the development of arguments used to justify and to proselytize for a vegetable diet.

Vegetarianism in Eastern Religion

The most notable examples of a religious basis for vegetarianism are to be found in Asian culture. Hinduism, though not requiring a strictly vegetable diet, has fostered a significant tradition of vegetarianism among certain believers for more than two millennia. The practice is still more widespread in Buddhism, where the doctrine of ahimsa, or nonviolent treatment of all beings, forbids adherents to kill animals for food. Many Buddhists do, nevertheless, eat meat, supporting the indulgence with the argument that the animal was killed by others. Jainism, likewise, espouses ahimsa and specifically denies meat to any practitioners of the faith (Barkas 1975; Akers 1983: 157-64).

Vegetarianism has continued as a common practice down to the present in Asia, especially in India. In Western societies, religion has also been a factor in the history of vegetarianism, but there it has played a relatively minor role compared to philosophical and scientific influences. The Western rationale for a vegetable diet is, in truth, the result of a considerably more complicated evolution shaped by a variety of cultural forces, which are outlined in this chapter (Whorton 1994).

Vegetarianism in Antiquity

The term "vegetarianism" was coined relatively recently, in the mid-nineteenth century, as the consumption of a flesh-free regimen began to assume the form of an organized movement. As a practice, however, it dates to much earlier times. No later than the third century A.D., in fact, Porphyry could describe the doctrine as already "ancient," as well as characterize the self-image vegetarianism had long embraced and would retain: It was "a dogma . . . dear to the Gods" (Porphyry 1965: 22).

The antiquity of the dogma can be traced to Pythagoras, the Greek natural philosopher of the sixth century B.C., who founded a religious community in southern Italy in which vegetarianism is reputed to have been part of the rule of life. Pythagoras scorned the eating of meat because of his belief in the Orphic concept of the transmigration of souls: If human spirits were reborn in other creatures, animal souls must be of the same quality as human souls, and animals must be as deserving of moral treatment as people. The killing of an animal was equivalent to murder, and the eating of it akin to cannibalism (Dombrowski 1984; Spencer 1993).

Additional justifications of vegetarianism with arguments dear to the gods were forwarded by several authors in later antiquity. During the first two centuries of the Christian era, Ovid and Plutarch both denounced slaughter as vicious treatment of innocent animals: "O horrible cruelty!" the latter remonstrated, that "for the sake of some little mouthful of flesh, we deprive a soul of the sun and light, and of that proportion of life and time it had been born into the world to enjoy" (Plutarch 1898: 6). Plutarch's essay "Of Eating of Flesh," in fact, provided the most comprehensive yet concise statement against conventional diet to be penned before the Renaissance and offered several objections that would become stock components of the vegetarian rationale on to the present day. These included physical arguments to complement the spiritual ones.

Flesh foods, Plutarch asserted, "by clogging and cloying" the body, "render [men's] very minds and intellects gross" (Plutarch 1898: 9). People, furthermore, could not have been intended by nature to be meat eaters, "for a human body no ways resembles those that were born for ravenousness" (Plutarch 1898: 7); it lacks fangs, claws, and all the other predatory equipment of carnivores. Finally, meat was prejudicial to health, causing "grievous oppressions and qualmy indigestions," and bringing "sickness and heaviness upon the body" (Plutarch 1898: 14).

The last vegetarian treatise from antiquity was the third-century work of the neo-Platonist Porphyry, *On Abstinence from Animal Food,* an elaboration of earlier authors' objections to meat, with particular emphasis on vegetable diet for spiritual purification: "The eye of the soul will become free, and will be established as in a port beyond the smoke and the waves of the corporeal nature" (Porphyry 1965: 53). Nevertheless, as Plutarch had recognized, "it is indeed a hard and difficult task . . . to dispute with men's bellies, that have no ears" (Plutarch 1898: 10).

The despair of vegetarians throughout the centuries has been that, in most people, the stomach speaks more loudly than the conscience, and it demands flesh. Nor did the rise of Christianity to cultural dominance strengthen the voice of conscience in support of animal welfare. Although the medieval church harbored vegetarian sects such as the Manichees, the orthodox position was that presented by Aquinas, that humankind had been granted dominion over the animal creation to use to suit their needs. Aquinas's insistence on rationality as a requirement for the extension of moral consideration to a being overrode the notion of kinship between people and animals that had been put forward by ancient vegetarians (Aquinas 1989: 146, 188). To be sure, individual church luminaries – Saints John Chrysostom and Benedict, for example – forswore the consumption of meat; but their motivation was primarily the wish to suppress their own carnal appetites rather than to extend compassion to the animal creation (Dombrowski 1984).

The Seventeenth and Eighteenth Centuries

Not until the seventeenth century was there to be any expansion of the brief against meat eating, but then one encounters, in the works of Thomas Tryon, the most broad-based argument yet for the virtues of a vegetable diet (that an Englishman should revive vegetarianism was prophetic, for England would serve as the fountainhead of vegetarian thought well into the nineteenth century). In *The Way to Health, Long Life and Happiness* (1683: 447), this dissenting religionist-cum-health-reformer and sometime poet begged readers to consider,

> How shall they but Bestial grow,
> That thus to feed on Beasts are willing?
> Or why should they a long Life know,
> Who daily practice KILLING?

In those two couplets is expressed much of the modern rationale for a vegetarian diet. The killing of animals must be discountenanced both because it inflicts pain and death on "fellow creatures" and because scripture indicates that the original diet appointed by God for humankind was meatless (Gen. 1:29). Those who feed on meat will grow bestial in both mind and spirit, whereas those who actually carry out the slaughter of animals for food will become so hardened to suffering as to lose compassion for fellow humans as well, and even to commit crimes against them.

But Tryon's case against flesh food is most significant for raising the issue of physical health to a new level of emphasis. He did not merely declare that meat eaters would not know a long life or would in other ways suffer infirmity. Tryon proposed a distinct physical mechanism for flesh food's mischief, observing that "nothing so soon turns to Putrifaction" as meat, then adding that "'tis certain, such sorts of food as are subject to putrifie before they are eaten, are also liable to the same afterwards" (Tryon 1683: 376).

Meat, in other words, because it is highly putrescible even after ingestion, must "breed great store of noxious Humours" (Tryon 1683: 377). There was the pathological justification for Tryon's charge that had it not been for the adoption of a carnivorous diet, "Man had not contracted so many Diseases in his Body" (Tryon 1683: 446). Indeed, flesh eating produced so much sickness, and vice as well, that if it were abandoned, he suggested, society would have no need for physicians or lawyers (Tryon 1683; Ryder 1979).

Both the medical and the moral strains would remain central to vegetarian philosophy throughout the 1700s. Toward the end of that century, moreover, each would take on additional import. Greater attention to the moral implications of diet was encouraged by developments in two areas of inquiry in particular: physiology and religion. The former discipline had been dragged into the arena of philosophical dispute in the mid-seventeenth century by the physiological theories of René Descartes.

The Cartesian proposal that beasts were mere automata, utterly lacking in consciousness and sensation, had focused scientists' and philosophers' attention on the question of animal pain and provoked extensive debate over the morality of slaughter, vivisection experiments, and other uses of animals for human benefit (Cottingham 1978). It was generally agreed that Descartes had erred, that animals truly do experience pain; but it was also suggested that their pain is not felt as keenly as that of humans, and that, in any event, people are justified in using lower creatures to realize their own desires.

During the eighteenth century, however, studies of the nervous system demonstrated close structural similarities between humans and higher animals, sharply increasing the probability that brutes suffered pain as severely as people: "Answer me, mechanist," Voltaire sneered at the Cartesian physiologists, "Has nature arranged all the springs of feeling in this animal in order that he should not feel? Has he nerves in order to be unmoved?" (Voltaire 1962: 113). At the same time, and in England especially, several intellectual currents were fostering a stronger feeling of relationship to animals. The Enlightenment's promotion of natural rights and humanitarian sympathy for the less fortunate encouraged a heightened sensitivity to physical pain and abhorrence of cruelty that was being occasionally extended to lower creatures by the later 1700s.

Jeremy Bentham, the founder of utilitarianism, expressed the new solicitude for animal welfare in his refutation (1789) of the argument that brutes do not deserve kindness because they are not rational beings. "The question," he insisted, "is not, Can they *reason?* nor, Can they *talk?* but, Can they *suffer?*" (Bentham 1961: 380–1). That point was not necessarily an endorsement of vegetarianism; as Bentham observed, a butcher might give an animal a quicker and less painful death than it could expect from nature (implying that meat eating was actually the more humane diet) (Bentham 1961).

Nevertheless, every animal had a right – the word is Bentham's – not to be tormented. This concept of animal rights was, meanwhile, being advanced by several other Enlightenment authors, some of whom included the right not to be used as food. Simultaneously, English religious thought was entertaining the supposition that animals have souls and even a heaven, thereby at least suggesting a neo-Pythagorean condemnation of flesh eating (Stevenson 1956; Turner 1980: 1–14).

The Nineteenth Century

Regard for animal welfare was intensified still further at the beginning of the nineteenth century by a more politically directed religious movement. Evangelicalism, the outgrowth of John Wesley's determination to make Christianity a "social gospel," was dedicated through aggressive political action to relieving the miseries of society's downtrodden and exploited. Evangelicals succeeded in moving Parliament to legislate against the slave trade, child labor, Britain's barbaric penal code, and numerous other injustices. Among Evangelical good works was an animal protection campaign that attacked the mistreatment of animals used for labor or sport and resulted in Western society's first animal welfare legislation, a law passed in 1822 to protect work animals from abuse (Turner 1980: 15–38).

The new climate of distaste for animal cruelty gave vegetarianism added appeal, of course; and though it would remain the doctrine of a small fringe group, membership in the fold did increase significantly around the turn of the nineteenth century. Vegetarian literature grew apace, no longer just an occasional volume from an isolated eccentric but now a steady flow of treatises voicing outrage at the cruel ravages visited upon defenseless creatures. The title of the first major work in this new genre captures its prevailing sentiment perfectly: *The Cry of Nature,* as John Oswald named his book, *Or, an Appeal to Mercy and to Justice, on Behalf of the Persecuted Animals* (1791). Romantic sensitivity to the beauty and innocence of nature gushed through such volumes; Oswald's frontispiece, for example, portrayed a slaughtered fawn spilling its blood upon the earth while its mother tearfully called on it to rise. Nearby, an unclothed child of nature hid her face in shame. "Come," Oswald invited, "approach and examine with attention this dead body. It was late a playful fawn, which, skipping and bounding . . . awoke, in the soul of the feeling observer, a thousand tender emotions. But the butcher's knife hath laid low the delight of a fond dam, and the darling of nature is now stretched in gore upon the ground" (Oswald 1791: 22–3).

If the moral hideousness of slaying animals for food was the dominant theme of early-century vegetarianism, the physical repulsiveness of flesh food was hardly overlooked. Oswald requested readers to gaze upon the scene of carnage a second time: "Approach, I say, . . . and tell me, tell me, does this ghastly spectacle whet your appetite? Delights your eyes the sight of blood? Is the steam of gore grateful to your nostrils, or pleasing to the touch, the icy ribs of death? . . . or with a species of rhetoric, pitiful as it is perverse, will you still persist in your endeavour to persuade us, that to murder an innocent animal, is not cruel nor unjust; and that to feed upon a corpse, is neither filthy nor unfit?" (Oswald 1791: 22–3).

Filthy and unfit are moral terms, of course, but they have physiological connotations as well. What one sees here, and can find expressed still more overtly in subsequent vegetarian literature, is the suggestion that the revulsion produced by the sight of blood and the smell of gore is not simply an aesthetic reaction; it is also a physiological response to physical filth and physical unfitness, an indication that the human body is not designed to receive such food as nutriment.

Vegetarianism, Science, and Medicine

The physiological superiority of a vegetable diet was an especially critical point to demonstrate by the beginning of the nineteenth century. Enlightenment philosophy had elevated science to the position of an indispensable method of investigation and proof. Therefore, if the newly energized vegetarianism of the early 1800s was to legitimate itself in society's eyes, it had to prove itself nutritionally as well as spiritually.

It had to be demonstrated, first of all, that one could survive in reasonable health without flesh foods. It was generally assumed that meat, being most closely akin chemically to human muscle, must be more easily digested and assimilated than plants and provide greater strength and endurance. An all-vegetable diet, this reasoning supposed, must be debilitating, and surely self-preservation carried greater moral weight than kindness to other species.

Two English physicians were especially influential for presenting evidence that vegetarianism was not, after all, a form of slow suicide. The first was George Cheyne, one of the most widely read health writers of the eighteenth century. A high liver in his younger days, Cheyne turned to lacto-vegetarianism in the 1720s in order to reduce his now bloated and unwieldy 32-stone frame. But not only did he manage to shed considerable weight on his diet of milk and vegetables; various other complaints that had nagged him for years (headache and depression, for example) disappeared as well. Through subsequent observations of "my own crazy Carcase" (1734: xvi), as well as of numerous patients, Cheyne became convinced that flesh food "inflames the Passions, and shortens Life, begets chronical Distempers, and a decrepid Age" (Cheyne 1734: 94). His several guidebooks to health were the first to recommend vegetarianism almost exclusively for reasons of physical well-being and to back claims of health with clinical cases.

Still more clinical evidence of the healthfulness of a vegetable diet was presented in 1809 by another London practitioner, William Lambe. Lambe had relieved himself of long-standing illness three years earlier by removing meat from his table. He had then applied that diet to the care of his patients and succeeded in curing, he believed, numerous cases of asthma, tuberculosis, and other chronic complaints, including cancer. Although he insisted that "a strict vegetable regimen" was an "absolute necessity" in the management of chronic illness, he was less forceful in his advocacy of vegetarianism for the healthy. He proposed only that meat was unnecessary, and that "what is unnecessary cannot be natural, [and] what is not natural cannot be useful" (Lambe 1815: 172).

Lambe's branding of meat as unnatural food for humans did sway several individuals well known in English society to convert to vegetarianism. Most prominent of all among these was the Romantic poet Percy Shelley, who in 1813 produced an emotionally charged pamphlet titled *A Vindication of Natural Diet.* In this work, logic was subjected to a fair amount of violence, yet the *Vindication* did achieve a certain balance by assigning roughly equal weight to both the moral and the physical objections to a flesh diet.

On the one side, the bloody excesses of the French Revolution and the tyranny of Napoleon were credited to the Gallic appetite for rare meat. But on the other, there was the assurance that "the bile-suffused cheek of Buonoparte, his wrinkled brow, and yellow eye, the ceaseless inquietude of his nervous system" were incontrovertible proof that he had not "descended from a race of vegetable feeders" (Shelley 1884: 17). Meat, Shelley declared bluntly, is "demonstrably pernicious" (20), as clear a demonstration as any being the "easiness of breathing" (24) acquired by vegetarians, granting them "a remarkable exemption from that powerful and difficult panting now felt by almost everyone after hastily climbing an ordinary mountain" (24).

Realistically, of course, the uphill battle had to be fought by vegetarians. Not only was the weight of medical opinion still on the side of meat, so was public opinion and, even more important, popular taste: "The forbidding of animal food," Lambe had despaired, is "an injunction that sounds more unwelcome to English ears than any perhaps that could be given" (Lambe 1815: 130). For such prejudice to be overcome, meat had to be transformed into a positive menace by the construction of physical arguments that were more sophisticated than were warnings that flesh eaters make poor alpinists. The elevation of physiology to primacy in the ongoing formulation of a rationale for vegetarianism, however, was the work of American theorists rather than English or other European ones.

Vegetarianism in America

Vegetarianism was brought to the United States toward the end of the 1810s by William Metcalfe, an envoy of the Bible Christian Church. The first organization in modern times to make vegetarianism one of the requirements of membership, the Church had been founded in Manchester, England, in 1807 by the Swedenborgian minister William Cowherd (there is a Dickensian irony in the names of the vegetarian leaders of the early 1800s – Cowherd, Metcalfe, and Lambe all conjuring up visions of chops and roasts). Though motivated in part by humanitarian sentiment, Cowherd had been equally impressed by the writings of Cheyne, and he forbade his congregation meat (and alcohol too), largely for reasons of health (Forward 1898: 7).

The Bible Christian sect would continue in existence in England until the 1880s at least, but its greatest impact came early in the century and on American soil. About 1830, in the process of organizing a New World branch of his church in Philadelphia, Metcalfe caught the attention of Sylvester Graham, a Presbyterian minister turned temperance lecturer. Graham, at that time, was in the process of expanding temperance into an all-inclusive program of physical and moral reform, and Metcalfe's understanding of the virtues of a vegetable diet was in perfect philosophical harmony with the American's own view of health behavior generally.

Graham's popular health reform movement, the first stage of what would become an enduring tradition of hygienic extremism in America, operated on the assumption that the laws of health were as much the dictates of God as the Ten Commandments, and, therefore, the two sets of rules could not conflict: Physiology must be congruent with morality. Acting from this certainty, that any behavior that tarnished the soul must also injure the body, Graham and his health reform comrades bombarded the public of the 1830s to 1850s with health injunctions against alcohol, extramarital sex, late-night entertainments, and sundry other practices both hateful and hurtful; included among these, by necessity, was the consumption of meat (Whorton 1977, 1982).

Graham hardly labored alone in erecting more extensive physiological supports for vegetarianism. Numerous health reformers participated, most notably William Andrus Alcott, who in the late 1830s supplanted Graham as commander of the forces of health reform. One of the most prolific self-help writers of the entire nineteenth century, Alcott contributed an 1838 volume under the title *Vegetable Diet,* specifying in his subtitle that vegetarianism was *Sanctioned by Medical Men and by Experience in All Ages.* The book was intended, in short, to show that science corroborated Christian moral principles (or at least his interpretation of the spirit of compassion of the New Testament). Comparative anatomy was one of the sciences applied to the task, though the similarity of human teeth and intestines to those of herbivores had been pointed out by any number of earlier authors. Rather it was the still emerging science of nutrition that seemed to offer the most up-to-date demonstration that meat was a poison, and Alcott, Graham, and other health reformers mobilized an impressive array of entirely new nutrition-based arguments to prove their point.

The arguments were impressive, that is, for their quantity. Qualitatively, however, they were completely inadequate and scientifically invalid, both because of the period's severely limited understanding of nutrition and biochemistry and because of health reformers' determination to force science into the straitjacket of their moral preconceptions. The latter was facilitated by the adoption of the theory of pathology that had recently been formulated by French physician François Broussais, a theory that attributed all illness to overstimulation of body tissues, especially those of the digestive tract.

As stimulation was already a loaded word morally – to the Victorian mind, arousal of carnal appetites and animal passions was the root of all evil – Broussais's pathology offered an ideal foundation for the construction of a health reform version of vegetarianism. Consequently, stimulation arguments too numerous to recount were advanced by health reform apologists for vegetable diets throughout the antebellum period.

One effort, for example, interpreted the famous in vivo digestion experiments performed in the 1820s by William Beaumont on a man with a gastric fistula. Beaumont's studies included measurement of the digestion times required by various foods, accomplished by tying food samples to a string, introducing them into the stomach, and retrieving them hourly for inspection. Beaumont's conclusion was that, "generally speaking, vegetable aliment requires more time, and probably greater powers of the gastric organs, than animal" (Beaumont 1833: 36).

Graham objected, maintaining that greater speed of digestion is clearly an indication of a more intense response by the vital powers to the stimulus of food. The more intense a response, he reminded, the more intense the stimulus must be, so meat must be more stimulating – pathologically stimulating – than vegetables. There was additional evidence in the feeling of warmth experienced after a meal rich in meat. A later generation would attribute this to the specific dynamic action of protein, but for health reformers it was a "digestive fever" in which, according to Alcott, "the system . . . is inevitably worn into a premature dissolution, by the violent and unnatural heat of an over-stimulated and precipitate circulation" (Alcott 1840: 221).

Meat even stimulated itself, decomposing (as Tryon had noted two centuries earlier) in much less time than vegetables. It followed that human flesh constructed from the excessively stimulated molecules of meat must also be less stable and more subject to decay. That explained, in Alcott's opinion, why vegetarians smelled better. "The very exhalations of the lungs," he asserted, "are purer, as is obvious from the breath. That of a vegetable-eater," he had determined, "is perfectly sweet, while that of a flesheater is often as offensive as the smell of a charnel-house. This distinction is discernible even among the brute animals. Those which feed on grass . . . have a breath incomparably sweeter than those which prey on animals. Compare the camel, and horse, and cow, and sheep, and rabbit, with the tiger (if you choose to approach him), the wolf, the dog, the cat and the hawk. One comparison will be sufficient; you will never forget it" (Alcott 1838: 233–4).

Still more to the point, however, was that the unstable atoms of a carnivore's muscles must be subject to more rapid molecular turnover than a vegetarian's tissues and, hence, subject to accelerated aging and premature death. The mechanics of life could be summed up simply: "A man may not inaptly be compared with a watch – the faster it goes the sooner it will run down" (Cambell 1837: 291).

The condemnation of fast living was a double entendre, for try as they might to present their ideas as concrete science, health reform vegetarians could never stop moralizing. Alcott, for instance, immediately followed his alarm over the "violent and unnatural heat" of a flesh eater's digestive fever with the observation that a vegetable diet is cooling, and "has a tendency to temper the passions" (Alcott 1840: 221). Colleague Russell Trall was even more uneasy about untempered passions, warning that "no delusion on earth [is] so widespread [as] this, which confuses stimulation with nutrition. It is the very parent source of that awful . . . multitude of errors, which are leading the nations of the earth into all manner of riotous living, and urging them on in the road to swift destruction" (Trall 1860: 10).

To their credit, health reform vegetarians balanced their thrilling flights of theory with down-to-earth demonstrations by cases. The proof of the theory, after all, was in the state of health of those who practiced it, and history could offer robust vegetarians aplenty in evidence. The first to be recognized, predictably, were the antediluvians, those original folk whose simple diet kept them vigorous all the way to the end of their 900 years. But pagans could serve the cause as well, though, surprisingly, it was pagan soldiers, especially those of the Roman army, who were held up as paragons of hygiene, as they had marched to their greatest victories on plain vegetable rations.

The incongruity of the diet of gentleness and benevolence providing the strength for battlefield slaughter was missed by the health reformers in their excitement over the physical glory of the vegetarians of antiquity. Subsistence on vegetable food, according to an agitated Graham, was "true of all those ancient armies whose success depended more on bodily strength and personal prowess, in wielding warclubs and grappling man with man in the fierce exercise of muscular power, and dashing each other furiously to the earth, mangled and crushed and killed" (Graham 1839: 188).

More recent, and less brutal, examples were more convincing and suitable. Alcott allotted nearly 200 pages of his book on vegetable diet to the presentation of testimonials, including such samples of prodigious vitality as Amos Townsend, a graminivorous bank cashier, who could "dictate a letter, count money, and hold conversation with an individual, all at the same time, with no embarrassment" (Alcott 1838: 75–6).

The Establishment of Vegetarian Societies

That American vegetarians' more pronounced orientation toward health impressed European counterparts is evident from the deliberations associated with the founding of the first national vegetarian organization. On September 30, 1847, meat abstainers from all parts of England gathered in Ramsgate, Kent, to form the Vegetarian Society. It was at this organizational meeting that the term "vegetarian" was coined, being taken from the Latin "vegetus": lively or vigorous. The founding members then pledged themselves "to induce habits of abstinence from the flesh of animals as food, by the dissemination of information upon the subject, by means of tracts, essays, and lectures" (Forward 1898, 22).

When they next enumerated the "many advantages" of vegetable diet that would be presented through literature and lecture, the traditionally favored advantage, morality, was pushed to a subsidiary position; again, vigor was the emphasis, their list beginning with "physical" improvements. The Society's monthly, *The Vegetarian Messenger,* was launched two years later and granted the same prominence to the physical in its messages; by 1853, 20 physicians and surgeons were included among the organization's membership of more than 800 (Forward 1898: 22, 33).

The new group's unorthodox philosophy immediately attracted ridicule. *Punch,* for instance, reported that "a prize is to be given [by the Society] for the quickest demolition of the largest quantity of turnips; and a silver medal will be awarded to the vegetarian who will dispose of one hundred heads of celery with the utmost celerity" ("Vegetarian Movement" 1848: 182). An organized movement of vegetarianism did spread with celerity. American vegetarians quickly followed the English lead, forming the American Vegetarian Society in 1850. As with its predecessor, the very first resolution adopted by this society recognized the value of a vegetable diet for health, declaring "that comparative anatomy, human physiology, and . . . chemical analysis . . . unitedly proclaim the position, that not only the human race may, but *should* subsist upon the products of the vegetable kingdom" ("Proceedings" 1851: 6). Morality did nevertheless follow close behind, with the next three resolutions adopted claiming biblical and ethical sanctions for vegetarianism.

In the meantime, vegetarianism was undergoing a similar development on the European continent. There, treatises such as *Thalysie: ou La Nouvelle Existence (Thalysie: Or the New Existence)* by Jean Antoine Gleizes (1840), and *Pflanzenkost, die Grundlage einer neuen Weltanschauung (Vegetable Diet, the Foundation of a New Worldview)* by Gustav von Struve (1861), slowly raised public awareness of the dietary alternative and attracted followers.

The first national organization of vegetarianism on the continent was established in Germany in 1866, under the leadership of Eduard Baltzer. Vegetarian journals and magazines appeared during the midcentury, beginning in England with the *Vegetarian Advocate* (1848) and the *Vegetarian Messenger* (1849) and continuing in the United States with the *American Vegetarian* (1851), published by the American Vegetarian Society. During the decade of the 1870s, vegetarian restaurants were established in major European and American cities; London could boast of a dozen by the end of the century (Forward 1898: 102). Finally, the first international organization was launched in 1908: The International Vegetarian Union.

Henry Salt

Britain and the United States remained the centers of vegetarian philosophy and practice into the twentieth century. In the former, the cause of vegetable diets was advanced with particular eloquence by Henry Salt (Mohandas Gandhi, among others, credited Salt for his conversion to vegetarianism). Author of numerous books calling for reform of social injustices, Salt was nevertheless best known (or most notorious) for his advocacy of *Animals' Rights Considered in Relation to Social Progress,* the title of an 1892 volume that attacked every form of exploitation of the brute creation. There, and in his later *The Logic of Vegetarianism* (1899), Salt employed a thoroughly unsentimental approach to argue that philosophy and science, alike, required abstention from meat.

Philosophy, his *logic* of vegetable diet posited, could not support the common assumptions that human beings have no moral relationship or obligation to other creatures and that the killing of animals for food is a law of nature. The latter idea had become an especially popular justification for meat eating in the wake of Charles Darwin's explanation of nature's rule of survival of the fittest. The response of Salt, and other late-century vegetarians, was that cooperation among animals was as common a strategy for survival as competition, and that human cooperation with other species was positively enjoined by Darwin's theory that people had descended from animal ancestors: How could one justify the slaughter of creatures with whom humans shared a "bond of consanguinity" (Salt 1892, 1899: 50)? Just such a bond had, in fact, been suggested by Darwin himself in *The Descent of Man;* there he presented a sizable body of evidence to demonstrate that "there is no fundamental difference between man and the higher mammals in their mental faculties. . . . The difference in mind between man and the higher animals, great as it is, certainly is one of degree and not of kind" (Darwin 1874: 74, 143).

The Twentieth Century

John Harvey Kellogg

Evolutionary kinship with livestock was also a significant element in the case constructed by America's most influential spokesman for vegetarianism in the early twentieth century. John Harvey Kellogg, however, gave greater emphasis to medical than to biological theory and propounded what was clearly the period's most persuasive argument against the consumption of meat. Kellogg was bred, if not born, a Grahamite by virtue of his family's membership in the Seventh-Day Adventist Church, an institution that gave allegiance to Graham's hygienic system on the basis of the divine, health-related visions experienced by spiritual leader Ellen White (Numbers 1976).

Kellogg also received training in hydropathy, an alternative system of medical practice that treated all conditions with applications of water and exhorted all patients to abide by Graham's rules of health. (Kellogg's mentor, and the leading figure in American hydropathy, Russell Trall, was a founding member and officer of the American Vegetarian Society, and the author of a volume titled *The Scientific Basis of Vegetarianism* [1860]).

Kellogg also completed a program of orthodox medical training and then, in 1875, returned to his native Battle Creek, Michigan, to assume the directorship of a struggling hospital and health-education facility operated by the Adventist Church. Not only did he quickly transform the Battle Creek Sanitarium into a thriving business, he built it into the most famous health institution in the country from the 1880s until World War II. As part of the Sanitarium's dietary program, Kellogg, along with his brother Will, created an assortment of meat substitutes and other vegetarian health foods, including the breakfast cereals that have immortalized the family's name (Schwartz 1970; Whorton 1982: 201–38).

Kellogg also lectured tirelessly, from coast to coast, and wrote voluminously. In addition to editing the popular periodical *Good Health,* he authored several dozen books, addressing every aspect of personal health behavior from *The Evils of Fashionable Dress,* to *Plain Facts about Sexual Life,* to *Colon Hygiene.* The last topic, the health of the large bowel, represented Kellogg's most significant contribution to the updating of the nutritional argument for vegetarianism. Here, he elaborated the dietary implications of one of the grand pathology fads of the turn of the twentieth century – intestinal autointoxication.

In the 1880s, laboratory scientists had isolated several substances produced in the intestinal tract through the bacterial putrefaction of undigested protein. The compounds were determined to be toxic when injected directly into the bloodstream in animals, and it was quickly supposed they might be absorbed from the colon into the human bloodstream and then circulated to play havoc throughout the body. Since these agents of self-poisoning were products of bacterial activity, the theory of autointoxication could be seen as an extension of medical bacteriology. Thus clutching the coattails of the germ theory, autointoxication swept into professional and popular awareness at the end of the nineteenth century (Chen and Chen 1989; Whorton 1991).

For Kellogg, autointoxication theory provided enough ammunition to support several book-length attacks on meat eating. In such works as *Autointoxication or Intestinal Toxemia* (1918), *The Itinerary of a Breakfast* (1919), and *The Crippled Colon* (1931), he expounded time and again on how the common diet contained so much protein from its flesh components as to encourage the growth and activity of proteolytic bacteria in the colon. As the microbes operated on undigested flesh food, the body would be "flooded with the most horrible and loathsome poisons" (Kellogg 1918: 131) and brought to suffer headache, depression, skin problems, chronic fatigue, damage to the liver, kidneys, and blood vessels, and other injuries totaling up to "enormous mischief." Anyone who read to the end of Kellogg's baleful list must have been ready to agree that "the marvel is not that human life is so short and so full of miseries, mental, moral, and physical, but that civilized human beings are able to live at all" (Kellogg 1918: 131).

"Civilized" referred to the fiber content of the ordinary diet, too. Modern people, Kellogg chided, ate too concentrated a diet, with insufficient bulk to stimulate the bowels to action. A vegetarian diet, he added for the unaware, was high in roughage. Its other advantage was that it was low in protein. The high-protein diet common to flesh eaters was ideal fodder for the putrefactive microorganisms of the colon, whereas its low-fiber content reduced its rate of movement to a crawl that gave the microbes time to convert all unabsorbed protein to poisons. In the meat eater's sluggish bowels, Kellogg believed, lay "the secret of nine-tenths of all the chronic ills from which civilized human beings suffer" (1919: 87), including "national inefficiency and physical unpreparedness," as well as "not a small part of our moral and social maladies" (Kellogg 1919: 93).

Morality could be merged with medicine in other ways. In *Shall We Slay to Eat,* Kellogg applied a bacteriologic gloss to the age-old objection to the cruelty of slaughter. Reminding readers of the gentleness of unoffending cows and pigs (animals with whom humans were bound by evolution), Kellogg then forced them, Oswald-like, to look upon the "tide of gore," the "quivering flesh," the "writhing entrails" of the butchered animals, and to listen to their squealing and bleating as they died (Kellogg 1905: 145–67). What he counted upon ultimately to move his readers, though, was the abominable filth through which the tide of gore flowed. The Augean nastiness of the typical abattoir (here nauseatingly detailed a year before the publication of Upton Sinclair's much more famous *The Jungle*) ensured that meat must be infested with every germ known: "Each juicy morsel," Kellogg revealed, "is fairly alive and swarming with the identical micro-organisms found in a dead rat in a closet or the putrefying carcass of a cow" (Kellogg 1923: 107).

Alexander Haig

Even biochemistry, just then blossoming as a laboratory science, was recruited to the vegetarian campaign. The other major pathology fad of the early twentieth century was uricacidemia, a disease-inducing state discovered by London physician Alexander Haig. Through a process too involved to be recounted here, Haig convinced himself during the 1880s that his migraine attacks were due to excess uric acid in his blood. As so often happens when an enthusiast discovers the source of his own health problems, Haig was soon blaming uric acid for everybody's problems. Through selective use of biochemical data and oversimplification of biochemical theory, Haig was able to propose mechanisms by which uric acid could cause every complaint from flatulence to cancer. His presentation of that thesis, a 900-page opus called *Uric Acid As a Factor in the Causation of Disease,* passed through seven editions in the 1890s and early 1900s. Haig's notions were soon disowned by his medical brethren, but the public's fear of uric acid carried into the 1920s and brought greater popular attention to bear on vegetarianism.

It was not necessarily approving attention, for the uric-acid-free diet Haig recommended was a highly restrictive system of eating. It required, after all, the elimination of every food containing either uric acid or purines that could be metabolized into uric acid. That rule eliminated not only all meat but many vegetables as well – beans, peas, asparagus, mushrooms, and whole-grain cereal products. Haig was thus left with milk, cheese, some vegetables, fruit, nuts, and – a unique position for a food reformer – white bread. Additional blandness was imposed by the prohibition of coffee and tea on the grounds that they contained methyl xanthines (it was later determined that caffeine and similar compounds are not metabolized into uric acid). And any rejoicing that at least alcoholic beverages were free of uric acid–producing substances was quickly squelched by Haig's assurance that his diet removed any need for stimulation and thus destroyed the taste for strong drink (Haig 1892).

The physical advantage of Haig's diet was demonstrated by the extraordinary success of several athletes who adopted it. Indeed, as early-twentieth-century society became captivated by competitive sports, vegetarians of every persuasion turned to athletic conquest for practical proof of the nutritional superiority of their regimen. As a result, a remarkable record of vegetarian victories in all sports was compiled in the 1890s and early 1900s, from the cycling records established by England's aptly named James Parsley to the championships won by the tug-of-war team of the unfortunately named West Ham Vegetarian Society. (Among the flesh-abstaining champions was Haig's son Kenneth, who won prizes as an Oxford rower but eventually was removed from his boat for fear that "his diet would demoralize . . . the rest of the crew.") Carnivorus competitors refused to acknowledge the vegetarians' athleticism, however, crediting their triumphs not to diet but to the dedication and competitiveness bred by fanaticism (Whorton 1981).

The "Newer Nutrition"

If full-fledged vegetarianism was still being taken lightly, the early twentieth century did foster a new respect for the nutritional value of vegetables; though few accepted vegetable foods as wholly sufficient for a healthful diet, all did come to see the consumption of vegetables as necessary to health. The critical development was the growth of understanding of vitamins over the first two decades of the century, accompanied by the realization that vitamin-rich fruits and vegetables were badly neglected at most tables. The most prominent representative of the so-called newer nutrition, vitamin discoverer Elmer McCollum, estimated in 1923 that "at least 90 per cent" of the food eaten by most American families was restricted to the old standards of white bread and butter, meat, potatoes, sugar, and coffee. His call for nationwide dietary reform aimed at educating and converting the public to replace much of the traditional diet with what he called the "protective foods."

The resultant dietary education campaign made the 1920s as truly the decade of newer nutrition as of bathtub gin and jazz. Food educators bombarded the public through lectures, newspapers, magazines, textbooks, and comic strips and were gratified to see the national consumption of fruits and vegetables increase markedly. To note one of the more extraordinary examples, between 1925 and 1927, the spinach intake of schoolchildren in Fargo, North Dakota, grew tenfold (Whorton 1989).

Public consciousness of the nutritional virtues of plant foods was not limited to vitamin awareness. Another dominant health theme of the 1920s was the lack of bulk in modern society's diet of refined and processed foods. Bulk foods were needed, of course, to prevent constipation, and ultimately autointoxication, still an unsettling threat in the public mind. The Kelloggs, Charles W. Post, and other manufacturers of bran-containing breakfast cereals fostered popular anxiety over torpid intestines with grossly exaggerated advertising warnings, giving the 1920s as pronounced a fiber consciousness as any more recent decade. But there was also the disinterested promotion of a higher-fiber diet by altruistic health reformers, some of them physicians and scientists.

At the head of this group was Britain's archenemy of autointoxication, the renowned surgeon Sir William Arbuthnot Lane. Convinced that the upright posture and soft lifestyle of civilized people weakened the colon and produced "chronic intestinal stasis," Lane surgically removed the colons of hundreds of patients during the 1910s in order to save them from autointoxication. The risks of surgery, as well as criticism from his professional colleagues, forced Lane to stop doing colectomies in the 1920s. But he remained convinced that constipation was the fundamental disease of civilization and was responsible for a host of illnesses, including colon cancer and other neoplasms. Consequently, in 1926, he organized the New Health Society in London and dedicated the last 17 years of his life to lecturing and writing on the dangers of intestinal stasis. Through Lane, the New Health Society, and the magazine *New Health,* British and American consumers were repeatedly harangued about the importance of fruits and vegetables for maintaining bowel regularity and preventing more serious diseases (Whorton 1991).

Vegetarianism and Health

Frequently included in Lane's presentations were anecdotal reports of the relative freedom from autointoxication diseases enjoyed by the vegetarian populations of less-developed nations. But it was not until the late 1940s, after Lane had died and autointoxication had disappeared from orthodox medical theory, that epidemiological studies of so-called developing-world cultures began to verify Lane's anecdotes by demonstrating statistical correlations between a high intake of dietary fiber and low incidences of hemorrhoids, gallstones, colon cancer, and various other "Western diseases" (Trowell 1981). Although some of the specific conclusions associated with the dietary fiber hypothesis have sparked debate, not to say controversy, among nutritionists and other health scientists, fiber has been officially recognized as an essential dietary component, and the general public has clearly been impressed with the health benefits of a diet high in unrefined vegetable foods.

Highly publicized studies linking cholesterol and saturated fats with cardiovascular disease have similarly conditioned society to associate vegetarianism with health and have motivated physicians and nutritionists to study heart disease and longevity in vegetarian groups such as Seventh-Day Adventists and Trappist monks. Those studies, conducted from the 1950s onward and too numerous to cite specifically, have largely confirmed what early-nineteenth-century vegetarians initially proposed, that a vegetable diet not only is capable of sustaining health but may actually improve it as well (Hardinge and Crooks 1963; Amato and Partridge 1989: 10–15).

Vegetarianism and Ethics

Running parallel with the twentieth-century growth of medical support for vegetarianism has been the expansion of the diet's moral rationale. Until recently, this argument has been aimed almost exclusively at the pain inflicted on animals at the time of slaughter and the injustice of depriving them of life. Some attention has also been directed to the discomforts endured by livestock being driven or transported to market; this issue was introduced into deliberations in the mid–nineteenth century, as animals began to be shipped in crowded boxcars and ship holds. Although both types of objections continue, discussion has widened since the middle of the twentieth century to take in the treatment of meat animals throughout their lives.

The transformation of farming into agribusiness, including the adoption of economies of scale in stock raising, fostered a system of more intensive rearing methods – "factory farming" – that confined animals in unnatural environments from birth. Ruth Harrison's 1964 *Animal Machines* first directed public attention to the raising of chickens in overcrowded coops and the packing of pigs into "Bacon Bin" fattening houses. Photographs of veal calves penned in narrow wooden cages all the days of their short lives soon became a common feature in vegetarian appeals (outdone in emotional impact only by the pictures of bludgeoned baby seals used in anti-fur advertisements). The maintenance of hens under similar conditions has encouraged lacto-ovo vegetarians to give up eggs; some have abandoned milk products as well in protest of the dairy industry's practice of separating calves from their mothers soon after birth (and the subsequent transformation of those calves into veal). Thus, the ranks of vegans have grown considerably in the later twentieth century (vegans are sometimes referred to as "pure" vegetarians, but there is some question about the applicability of the term, since the word "vegetarian" was minted to refer to a diet that includes eggs and milk). Even meat eaters have been affected by the critique of factory farming, a sizable number now selecting "free range" animal products whenever they are available.

The Animal Rights Movement

Bentham's proposal that slaughtering an animal for food saves it from a more painful and protracted death in the wild has lost its cogency in the age of the factory farm; now an animal's entire existence might be seen as one long death. The morality of imposing such an existence on any creature has been raised to a higher level of discussion, moreover, by the animal rights movement of the last quarter century. Peter Singer's 1975 work, *Animal Liberation,* the chief catalyst of the movement, is a work in which the heavily sentimental tone of traditional vegetarian moralism is set aside in favor of a rigidly philosophical analysis that recognizes animals as sentient beings, capable of experiencing pain and pleasure, and concludes that they should, therefore, be accorded the same respect as humans in areas where their interests are affected. Various violations of those interests are attacked by Singer (and they are much the same as the ones assailed by Salt nearly a century before) – for example, the use of animals in experimental research and the raising of animals for fur.

Because of the sheer numbers involved, however, the worst example of "speciesism" – the practice of moral discrimination purely on the basis of biological species – is the raising and killing of animals for food: "the most extensive exploitation of other species that has ever existed" (Singer 1975: 92; Regan 1975). The most significant element in such exploitation, however, is regarded not as the unnatural conditions of life imposed upon livestock or even their physical suffering. Fundamental to the animals' rights analysis is the affirmation of a right to life for every creature. Thus, even if the animal is allowed a free-range existence and is slaughtered painlessly, the simple act of killing it for food constitutes an unjustifiable moral offense.

The arguments of Singer, Tom Regan, and other advocates of equal moral consideration for animals have elicited a serious response from the philosophy community. Over the past two decades, professional journals and conferences have given an extraordinary amount of attention to the issue of animal rights and its practical applications, including vegetarianism. To be sure, much of the reaction among philosophers has been critical. The Singer analysis has been faulted on grounds of logic and even attacked as a trivialization of civil rights, women's rights, and other movements promoting more moral treatment of fellow human beings (Francis and Norman 1978).

Yet a good bit of the discussion has supported the animal rights arguments, endorsing both the abstract proposition of an animal's right to life and older sentiments such as an intuitive appreciation that eating animals with whom people sense a bond of kinship is wrong (Diamond 1978). Speciesism has acquired an odious taint as well from the human exploitation of wild animals that has pushed many species to the brink of extinction, and by studies of communication in other mammals that have strengthened our feeling of relation to the rest of the animal kingdom.

Vegetarianism and the Environment

Not only have the moral and medical defenses of a vegetable diet grown stronger individually over the twentieth century, they have been buttressed in recent decades by environmental arguments. This is not an entirely new approach – eighteenth- and nineteenth-century vegetarians occasionally pointed out that less land would be needed for agriculture if people were fed on grain rather than meat – and it is a frequently cited truism in vegetarian literature today that 16 pounds of grain are required to produce 1 pound of meat. But with the twentieth century's rapid increase of human population, the ceaseless conversion of arable land into housing developments and shopping malls, and the dramatic expansion of industry and the spread of industrial pollution, the degradation of the environment has become an object of grave scientific and public concern. As attention has been focused ever more sharply on the multitudinous threats to the fragile environment of our shrinking globe, a flesh diet has been recognized as a significant contributor to environmental decline.

The ecology of meat eating was first explored thoroughly by Frances Moore Lappé, whose 1971 best-seller *Diet for a Small Planet* examined livestock farming's toll on the land, water, and air. Since Lappé, it has become commonplace for vegetarian literature to detail the soil erosion associated with the cultivation of livestock food crops; the excessive demands on water supplies to irrigate those crops; the pollution of waterways by field and feedlot runoff; the large amounts of fossil fuel energy expended in raising meat animals; even the contribution to global warming made by the methane released in cattle flatulence. Lately, the destruction of the tropical rain forest to provide more grazing land for beef cattle has been singled out as flesh diet's greatest threat to the viability of "spaceship earth." And in the end, ecology has returned to ethics. In the twentieth-anniversary edition of *Diet for a Small Planet* (1991), Lappé concentrated her criticisms on the immorality of growing grain for the fattening of cattle while millions of people worldwide starve.

A final characteristic of contemporary vegetarianism is its accomplishment of a joining of East and West. The Western counterculture's fascination with Asian religious traditions has been an important contributor to the growth of vegetarianism over the past quarter century, with vegetarian religious sects such as the International Society for Krishna Consciousness now widely distributed through North America and Europe. Voluntary vegetarianism remains the practice of a small minority of the world's population, of course; the number of practitioners, nevertheless, has risen to a historic high due to the combination of spiritual, ethical, medical, and environmental preoccupations resident in the mentality of the late twentieth century. In the United States, there are now approximately 9 million people identifying themselves as vegetarians, whereas another 40 million claim to have decreased their flesh food intake for reasons of health, morals, or ecological concern (Amato and Partridge 1989).

VI.18 Vegetarianism: Another View

Early Humankind

Vegetarianism is a cultural and social, rather than a biological, phenomenon. Anatomically and physiologically, the digestive organs of the human species are designed for both animal and plant foods. Moreover, a global cross-cultural survey demonstrates the fact that all cultures, past and present, have revealed a preference for at least some form of animal fat and protein and that none have ever been totally vegetarian (Abrams 1987b: 207-23).

Current paleoanthropological research indicates that humans have been on this earth for some 3 to 4 million years. For over 99 percent of that time, humans were hunters and gatherers (Cohen 1977: 15; Johanson and White 1979: 321-30). From the Australopithecines to the inception of agriculture, humans gradually developed more efficient tools to obtain food, especially for hunting game. *Homo erectus* pursued large game, and early *Homo sapiens,* the late Paleolithic humans, were even more dedicated in this regard.

Indeed, the availability of game may well have dictated human settlement patterns. As population pressure mounted in Africa, the original home of humankind, herds of game dwindled, forcing people further afield to follow other herds. This ultimately led to human settlements in Asia, Europe, the Americas, and Australia - in all of the continents except Antarctica.

About 10,000 years ago, beginning in the Middle East, people finally started to raise plant foods because of their own growing number, on the one hand, and because so many game animals were scarce or had been hunted to extinction, on the other. And with sedentary agriculture came political organization and formal religions.

Religion and Diet

As people settled into sedentary agriculture, meat-eating prohibitions gradually became part of the tenets of some of their religions, such as Hinduism. Ultra-orthodox Hindus and Jains, for example, are strict vegetarians, but as anthropologist Marvin Harris points out, in earlier times the Hindus were beef eaters. Later, beef eating was restricted, primarily, to the Brahman caste; and finally, the practice became prohibited for all Hindus.

Harris has argued that such a prohibition was the result of human population growth. Because cows were valuable as draft animals and as providers of milk and dung (as fuel for cooking), it was wasteful to use them for meat. In fact, Harris argues that the consumption of certain animals is prohibited in many cultures for pragmatic reasons (Harris 1977: 129-52) and that compliance is more likely when such prohibitions are codified as tenets of religion (Dwyer et al. 1973: 856-65; Mayer 1973: 32; Todhunter 1973: 286).

Other religious groups that today adhere to some type of vegetarianism include Buddhists, Seventh-Day Adventists, and orders such as the Roman Catholic Trappist monks. Justification of vegetarianism on religious grounds may be because it is more spiritual, or because it is more in harmony with nature, or because of the conviction that all animal life is sacred (Abrams 1980: 53–87).

Modern-Day Vegetarianism

A phenomenal escalation of vegetarianism, which began in the 1960s, has occurred in the Western world and has had little to do with religion (Erhard 1973: 4–12; Sonnenberg and Zolber 1973). The new vegetarians include a wide variety of individuals with concerns ranging from what animals are fed and injected with to environmental problems and world hunger to the indictment of cholesterol and animal fats as causative factors in the development of vascular diseases, cancers, and premature deaths.

There is also considerable variation in the practice of vegetarianism. At one extreme are the vegans, who exclude all types of animal protein from their diet and subsist solely on vegetables, seeds, nuts, and fruits. Moreover, their dietary beliefs are extended to other daily activities. Vegans shun clothing made of animal products such as wool, silk, leather, fur, or pearl (Erhard 1974: 20–7). They abstain from using consumer goods, such as soap or cosmetics made with animal fat or brushes of animal hair, and they refuse immunization from animal-derived sera or drugs, or toiletries whose safety has been determined by animal testing.

Vegetarians toward the middle of the continuum choose a wider variety of foods and include certain animal protein foods in their diets. Lacto-vegetarians, for example, use dairy products; ovo-vegetarians, eggs; pollo-vegetarians, poultry; and pesco-vegetarians, fish. Some will use more than one type of animal protein foods, such as lacto-ovo vegetarians, who consume dairy products and eggs along with other foods.

Opposite to the vegans on the vegetarian continuum are the red-meat abstainers, who consume all animal protein foods except beef, lamb, and pork (Fleck 1976: 408–27).

Extreme Vegetarianism and Health

One form of extreme vegetarianism is the final stage of the Zen macrobiotic diet. This vegetarian phenomenon attained some popularity in the Western world during the 1960s but has declined since its founder's death. The diet encompasses a life philosophy based on a loose reading of Buddhist symbolism and the ancient Chinese dualistic concept of yin and yang (Dwyer 1979: 1–2). Allegedly, humans achieve harmony in all of life's manifestations by reaching a balance between the cosmic forces of yin and yang, which oppose while they complement one another (Keen 1978), such as male/female; contraction/expansion; and fire/water. In terms of food, such dualities are manifested in complements such as animal versus vegetable; mineral versus protein and fat; bitter and salty versus sweet.

According to the philosophy behind the macrobiotic persuasion, disease results from yin/yang imbalances, which can be restored by an ideal diet. The individual must follow 10 stages of an elaborate dietary regimen, with the final stage consisting solely of brown rice, salt, and fluids such as herbal teas. Reaching this final stage, presumably, assures attainment of perfect health, freedom from all disease, and spiritual enlightenment. In this latter connection, macrobiotics has been especially popular. Some individuals have embraced it in a search for an alternative to drug experimentation in order to experience a "natural high" (Keen 1978).

Yet one account, *The Death Diet* (Christagu 1967: 43–7), has described the tragedy suffered by a young couple upon reaching the tenth stage of the macrobiotic diet. The health of the male was impaired severely, and the woman died. Her death certificate read, "Multiple vitamin and protein deficiencies precipitated the chain of events leading to her death" (Mayer 1975).

Total vegetarians are likely to suffer deficiencies of many of the chief nutrients, among them vitamin B_{12}. All foods of animal origin contain vitamin B_{12}, yet plant sources for this vitamin are unreliable. The human body stores at least a thousand times the Recommended Dietary Allowance (RDA) of vitamin B_{12}, which is an amount sufficient to maintain serum levels in some people for up to five years, although there are a wide range of serum levels associated with the deficiency. Thus, deficiency may not be apparent for some time while reserves of the vitamin are gradually being tapped (Ellis and Mumford 1967: 205; Ellis and Montegriffo 1970: 249). It can be difficult to detect vitamin B_{12} deficiency because of the high folic acid intake of vegetarians, which frequently masks symptoms of the condition (Brown 1990: 175). All of this is particularly unfortunate because early detection of the deficiency is vital to avoid irreversible neurological impairment.

Some vegetarians, although aware of the risk of vitamin B_{12} deficiency, depend nonetheless on plants for this vitamin, despite the unreliability of such foods as a source. When found in plants, vitamin B_{12} is present only because of bacteria growing on the plant or because the plant has been contaminated by bacteria, especially from fecal matter. Spirulina and tempeh, used frequently by vegetarians as vitamin B_{12} sources, have virtually none and in fact provide B_{12} analogues that actually block the metabolism of functional vitamin B_{12} (Bailie 1987: 98–105).

Vitamin B_{12} deficiency can result in megaloblastic anemia, a grave condition. In the mid-1970s, a high incidence of megaloblastic anemia was reported among orthodox Hindus who had emigrated from India to England. The phenomenon was puzzling. The orthodox Hindus did not have vitamin B_{12} deficiency while they lived in India, nor after they first emigrated, but developed the deficiency during their residence in England. Their diet was similar in both countries. But investigations revealed that the cause stemmed from differences in growing, processing, and packaging foods in the two countries.

In India, where crops had minimal applications of costly pesticides, many plants were insect-contaminated, and the insects, or their eggs and larvae, contributed a supply of vitamin B_{12} to the diet. Additional opportunities for insect contamination were provided by minimally processed or packaged food. Thus, in India, the orthodox Hindus had adventitiously obtained sufficient vitamin B_{12} to prevent deficiency, a finding that helps to explain why extreme vegetarians in other developing countries may escape it as well. But ironically, the privileged in those countries, who can afford to purchase imported foods that are highly processed and protectively packaged, may suffer from an inadequate vitamin B_{12} intake (Rose 1976: 87).

In addition to lacking vitamin $B_{12,}$ extreme vegetarian diets are often deficient in adequate proteins and even calories. Moreover, total vegetarian diets tend to be low in calcium and riboflavin (Raper and Hill 1973). Certain coarse, green leafy vegetables may be high in calcium, but the calcium is not well absorbed because of the high fiber content of the diet, and other minerals, including zinc, phosphorus, and iron, may also be poorly absorbed (Haviland 1967: 316–25; Reinhold et al. 1976: 163–80; Bodzy et al. 1977: 1139; Freeland, Ebangit, and Johnson 1978: 253).

Calcium absorption is also impaired by certain green leafy vegetables, such as spinach and Swiss chard, that contain oxalates. These compounds bind with calcium during digestion to form insoluble calcium oxalate, which is not utilized, and the calcium is excreted in the feces (Albanese 1980). Moreover, whole grains, frequently consumed in large quantities by many vegetarians, are high in phytates, and these substances, like the oxalates, interfere with calcium absorption (Hegsted 1976: 509). Similarly, vegetarians may have low zinc levels due to phytates and oxalates in their diets. In contrast, foods from animal sources provide dietary zinc, but they do not contain the inhibiting phytate and oxalate compounds (Prasad 1966: 225–38).

Zinc insufficiency is one of the greatest but least-known dangers of vegetarianism, according to the late Carl C. Pfeiffer, who commented wryly that "the light headed feeling of detachment that enshrouds some vegetarians can be caused by hidden zinc hunger, rather than by some mystical quality of the brown rice or other food consumed" (Pfeiffer 1975: 103). Among other things, low zinc levels are related to male infertility. In one study, mild zinc depletion in nine male volunteers resulted in decreased fertility, and the sperm count of the men fell to an infertility level after the men intentionally ate a zinc-deficient diet for about six months (Prasad 1982).

Obtaining sufficient iron can also be a problem for vegetarians, and women on strict vegetarian diets, especially during child-bearing years, may have real difficulties in this regard (Mayer 1973: 32). As with zinc, foods of animal origin are reliable iron sources, whereas foods of plant origin are not. Moreover, heme iron from foods of animal origin is absorbed and utilized far more efficiently than nonheme iron from plant foods: 10 to 30 percent can be absorbed from animal foods, compared with only 2 to 10 percent from plant foods; and finally, phytates and oxalates interfere with iron absorption (Finch 1969: 3).

Normal plasma estrogen levels are necessary for women's menstrual regularity. Because nutrition can affect hormone levels, dietary differences may affect menstrual patterns, as was shown in a study of evenly matched nonvegetarian and vegetarian premenopausal women at the Milton S. Hershey Medical Center in Hershey, Pennsylvania: Only 4.9 percent of the nonvegetarians experienced menstrual irregularities, whereas 26.5 percent of the vegetarians had difficulties. The probability of menstrual regularity was associated positively with protein and cholesterol intake and negatively with dietary fiber and magnesium intake (Pedersen, Bartholomew, and Dolence 1991: 879–85). Such results are consistent with the hypothesis that premenopausal vegetarian women have circulating estrogen concentrations (Lloyd, Schaeffer, and Walter 1991: 1005–10) and that these women may also have decreased reproductive capacity (Pedersen et al. 1991: 879–85). Another study at the Hershey Medical Center reveals that the frequency of menstrual irregularity was significantly higher in a lacto-ovo vegetarian group of women than in a matched group of nonvegetarian women (Lloyd et al. 1991: 1005–10).

Infants and children may suffer the most from extreme vegetarian diets. Commenting on this issue, the pediatrician George Kerr observed that "history has many examples of parents abusing children for the very best intention. . . . Specifically, should we start considering reporting these cases of growth failure on vegan diets to the authorities involved with child abuse?" (Kerr 1974: 675–6).

Infants breast-fed by women who are strict vegetarians have been found to be deficient in vitamin B_{12}, and such lactating women are advised both to take a vitamin B_{12} supplement and to include soybean milk or fermented soybean foods in their diets (Dwyer 1979: 1–2). Vegetarian infants and children tend to be smaller and to grow at a slower rate than do children from the general meat-eating population. One factor may be the high-bulk/low-calorie content characteristic of vegetarian diets (Erhard 1973: 11).

Pediatricians have expressed concerns about the vulnerability of infants and growing children who are especially at risk from extreme vegetarianism. "Kokoh," a special macrobiotic infant-feeding formula, was found to be capable of inducing kwashiorkor, one form of protein–energy malnutrition. Moreover, the

American Academy of Pediatrics (ACP) has reported that infants fed solely on this formula from birth usually are underweight within a few months and below average in total body length (Abrams 1980: 57).

Other research and clinical observations have also shown that infants fed no animal protein fail to grow at a normal rate and may develop kwashiorkor. Infants who are breast-fed and then placed on vegan diets do not grow or develop as normal infants, nor do they do as well as infants fed vegetarian diets supplemented with cow's milk (Erhard 1973: 10–12).

Vegetarianism and Chronic Diseases

Ancel Keys's seminal reports (Keys 1956: 364; Keys, Anderson, and Grande 1957: 959), followed by others, suggested a direct relationship between diet, especially animal fats, heart disease (Connor, Stone, and Hodges 1964: 1691–1705; West and Hayes 1968: 853; Anderson, Grande, and Keys 1976: 1184), and colon cancer (Burkitt 1971: 3, 1973: 274; Berg, Howell, and Silverman 1973: 915; Reiser 1973: 524, 1978: 865; Hill 1975: 31; Howell 1975; Nichols et al. 1976: 1384; Truswell 1978: 977–89). Conclusions drawn from these studies, however, remain controversial, and many other studies take issue with them (Mann et al. 1961: 31; Mann 1977: 644; Enstrom 1975: 432; Lyon, Klauber, and Gardner 1976: 129; Enig, Munn, and Keeney 1978: 2215; Glueck and Connor 1978: 727).

Nonetheless, the public has been led to believe that foods that contain saturated fat and cholesterol, such as eggs and red meats, are related to heart disease and colon cancer. In fact, some alarmed individuals have embraced a limited or total vegetarian diet in the belief that such measures will ward off these illnesses (Hardinge and Stare 1954: 83; West and Hayes 1968: 853; Ruys and Hickie 1976: 87; Sanders, Ellis, and Dickerson 1978: 805).

In truth, however, research has produced contradictory and puzzling findings. Seventh-Day Adventists, for example, have an educational health program for their members that advocates a well-balanced diet, including milk and eggs, along with other foods. In other words, these lacto-ovo vegetarians eat adequate amounts of animal protein foods, although they exclude red meats. Additionally, Seventh-Day Adventists have been found to have lower rates of cancer and coronary artery disease than the general American population (Wynder, Lemon, and Bross 1959: 1016–28). For cancer, they experience a 50 to 70 percent lower mortality incidence than the general population (Phillips 1975: 3513). For coronary heart disease, mortality was lower in males under 65 years of age than in the general population but not in males over 65, nor in females of any age (Phillips et al. 1978: S191).

Because Seventh-Day Adventists are red-meat abstainers, it was assumed that such abstention accounted for their lower incidence of heart disease than that of the general public. But other confounding factors may play important roles in preventing these diseases. For example, Seventh-Day Adventists abstain from tobacco, alcohol, and caffeinated beverages (Dwyer 1979: 1–2).

Members of the Church of Jesus Christ of Latter Day Saints (Mormons) provide another homogeneous group for study. Mormons are not red-meat abstainers, but the church urges moderation in lifestyle. Compared to the American average, Utahan Mormons were found to have a 22 percent lower incidence of cancer in general and a 34 percent lower incidence of colon cancer (Lyon et al. 1976: 129). However, Puerto Ricans, who eat large amounts of animal fats, especially pork, have very low rates of colon and breast cancers (Enig et al. 1978: 2215). Such contradictions practically leap off the pages of a comparative study of the incidence of breast and colon cancers conducted in Finland and the Netherlands. People in these two countries eat similar levels of animal fats per person per day, but despite this similarity, the incidence of breast and colon cancer in the Netherlands was nearly double that of Finland (Enig et al. 1978: 2215).

Nor are such contradictions confined to cancer. A study in western Australia has contradicted the notion that a high serum cholesterol level increases the risk of heart attack. Three groups of mothers and children were studied: those with high, those with medium, and those with low cholesterol levels. The groups had no significant differences in their daily dietary intake of proteins, fats, and carbohydrates, and obesity was ruled out as a factor, because cholesterol levels did not differ between the obese and the nonobese.

The conclusion reached was that diet did not appear to account for differences in cholesterol levels in a culturally homogeneous group. Furthermore, the "correlation between habitual diet and the average serum cholesterol level is good between contrasting populations (for example, people of Japan and Finland)" but "within a given culture, people eating the same kind of food can have different serum lipids. Those who develop coronary heart disease do not necessarily eat differently from those who do not" (Hitchcock and Gracey 1977: 790).

More recently, additional confounding evidence has been contributed by the so-called French Paradox. The eating habits of people in Gascony, in the southwest of France, were studied for 10 years. This area is noted as the world's leading producer of cholesterol-laden foie gras. People in Gascony consume goose and duck fat liberally, snack on dried duck skin, and eat more than twice as much foie gras as other French people and 50 times as much as Americans. Yet they were found to have the lowest incidence of death from cardiovascular disease in all of France. In Gascony, of 100,000 middle-aged men, about 80 die annually of heart attack, compared with 145 elsewhere in France and 315 in the United States (O'Neill 1991: 1, 22).

Fats

Because of the negative publicity that fats have received of late, we sometimes tend to forget that fat is essential for proper growth and development, even for life itself. Fat provides essential fatty acids necessary for cell membrane structure and for prostaglandins; it also acts as a carrier for the fat-soluble vitamins. Humans require different types of fats for different purposes, both structural and storage. Structural fats make possible the growth of the brain and the central nervous system and maintain cell membrane integrity. Structural fats are found inside the cell. Cell membranes are not mere envelopes but active parts of the cell, arranged as an orderly production line, creating some things, breaking down others, and transferring raw materials (nutrients) as needed from one place to another. Storage fats, no less important, are used for energy (Crawford and Marsh 1989: 120).

Vegetable Oils

It may be unfortunate that millions of people have been persuaded to change their choices of fat in the belief that oils from plants containing predominantly polyunsaturated or monounsaturated fatty acids are good, and fats from animals are bad. There is an argument that large amounts of polyunsaturated oils in the diet may be detrimental to health (Lyon 1977: 28–31). Although vegetable oils have been offered with promises of risk reductions for cardiovascular diseases, some authorities find these claims to be misleading and inaccurate (Pinckney and Pinckney 1973: 31–8; Moore 1989: 40–95).

Eggs and Cholesterol

Cholesterol has also gotten a bad press, which tends to obscure its vital roles in human health. It is needed for the transmission of nerve impulses throughout the body, and, in fact, the nervous system cannot function properly with insufficient cholesterol. In addition, cholesterol is needed to produce sex hormones. Indeed, it may well be because cholesterol is so crucial that the human body does not depend solely on dietary sources but also manufactures cholesterol. If dietary cholesterol is insufficiently supplied, then the body manufactures more to meet its requirements. Thus, Roger J. Williams turned current wisdom on its head when he observed that "anyone who deliberately avoids cholesterol in his diet may be inadvertently courting heart disease" (Williams 1971: 73).

In response to public concern about eggs and their cholesterol content, food processors have countered by concocting products that contain egg white (the noncholesterol component) but no yolk (the cholesterol-containing component). These products were intended for omelets and scrambled egg dishes. M. K. Navidi and F. A. Kummerow of the Burnsides Research Laboratory, University of Illinois, undertook an experiment to determine the nutritional value of such replacer eggs. They fed one group of lactating rats exclusively on fresh eggs and another group on Egg Beaters. They intended to run the experiment for 40 days, but all the rats on the egg substitute were dead in 17 days. They were underweight, were severely stunted in growth, and had mottled hair. All the rats on fresh whole eggs were healthy and normally sized (Navidi and Kummerow 1974: 565).

Diet and Primitive Societies

In using the term "primitive," we would note at the outset that there are no primitive peoples. The term, when used by anthropologists, denotes the development of technology used by cultures.

Not many hunting and gathering societies have survived to the present, and those that have are rapidly becoming acculturated. Yet the few still in existence have been extensively studied, with such efforts contributing considerably to our knowledge of the diet and health of past peoples.

Among other things, such knowledge disputes vegetarians who defend their practice with the claim that individuals in primitive societies (and presumably our ancestors) were herbivores who lived primarily on plant foods. The evidence is that most hunting-and-gathering peoples consume large amounts of meat and other types of animal protein whenever it is available.

The Eskimos constitute a classic example. They lived almost entirely on a traditional diet of raw sea and land mammals, fish, and birds, and so long as the traditional diet was followed, Eskimos remained in excellent health. Indeed, the raw meat and organs of these animals, including the liver and the adrenal glands, even provided an ample supply of vitamin C, so long as the meat was raw or cooked only a little. Being heat-sensitive, vitamin C is destroyed in meats by normal cooking (Stefansson 1960: 58).

Although it was obvious that Eskimos could thrive on a diet of raw meat (Stefansson 1937), the notion persisted that such a diet would probably harm Europeans, which led to an interesting experiment. Under the auspices of the Russell Sage Institute of Pathology at Bellevue Hospital (an affiliate of the Cornell University Medical College of New York), the anthropologist Vilhjalmur Stefansson and his colleague Karsten Anderson volunteered to eat a ratio of 2 pounds of raw lean meat to a half pound of raw fat and nothing else daily for a year. Both men thrived. After the year was up, Stefansson, who had previously lived for years on the Eskimo diet, continued on it for decades more and enjoyed sound health until his death at age 83. Similarly, Anderson was found to be in better physical condition after eating the traditional Eskimo diet for the year than when he began the experiment (Stefansson 1957: 60–89).

The Eskimo diet, then, also tends to confound the notion that meat and fats undermine human health. Paul Martin, for example, who spent years in the Arctic, discovered that although Eskimos consumed large amounts of animal fats, whale blubber, and seal oil, they did not have problems with cholesterol and, in fact, were remarkably free of degenerative diseases, especially those related to heart and to blood pressure (Martin 1977: 25–8).

Another observer of indigenous Eskimo culture concluded that the native diet of raw land and sea mammals and fish provided all the nutrients needed for excellent health (Schaefer 1971: 8–16). Unfortunately, with their adoption of industrialized foods since World War II, consisting mainly of refined carbohydrates (sugar and white flour), chemically altered fats, and other highly processed foods, the Eskimos began to suffer from those degenerative diseases common to the modern industrialized world (Schaefer 1971: 8–16).

George V. Mann, of Vanderbilt University Medical College, who challenged Keys's fat hypothesis, initiated several studies with the few available primitive societies still living largely on animal foods. He reasoned that if a high fat and cholesterol intake really did cause heart disease, then hypercholesteremia and coronary heart disease ought to characterize the health of groups of people living on high fat and cholesterol diets.

Mann first studied the Pygmies in the African rain forest. Almost untouched by civilization, these people have continued on a traditional diet of large amounts of meat, supplemented with plant foods. But Mann discovered that despite a high level of meat consumption, adult male Pygmies had the lowest cholesterol levels yet recorded (Mann et al. 1961).

Next, Mann observed the Masai of Tanganyika, a nomadic pastoral people living almost exclusively on meat, cow's blood, and milk. His examination of 400 Masai adult males revealed very little cardiovascular disease and no signs of arteriosclerotic disease. As a result of his investigation, Mann concluded that the widely held notion that meat and milk cause coronary heart disease is unsupported by the evidence (Mann 1963: 104).

Modern Nutrition and Tooth Decay

Tooth decay has been known throughout human history, but only in relatively modern times has it become endemic. The evidence shows that tooth decay was rare throughout the Paleolithic period, which spanned some 3 to 4 million years.

When the hunting-and-gathering way of life gave way to stable agriculture, though, the switch led, among other things, to increased tooth decay. And it would seem that dependence on high-carbohydrate foods, such as grains and other plant foods, began to seriously undermine the health of those who did not find a way to maintain a favorable dietary balance between high-quality animal protein foods and lower-quality plant protein foods (Page and Abrams 1974: 188–203, 214–26; Abrams 1976: 102–12, 1978: 41–55).

Skeletal remains of European populations reveal a slow, steady increase in tooth decay from the Neolithic period when agriculture first began until the present, when it escalated (Wells 1964; Abrams 1976: 102–12, 1978: 41–55). Such a deterioration in teeth is also vividly portrayed in the experience of the Lapps (Sami) of northern Europe, who until recently had hunted in a manner similar to that of the late Paleolithic age and lived mainly on reindeer meat. They consumed about a pound of meat per person each day and were renowned for their healthy teeth. Eighteenth-century skeletal remains show a cavity rate of only 1.5 percent in Lapp teeth. But gradually, Lapps adopted the industrialized diet, with the result that their cavity rate has soared to 85 percent (Pelto and Pelto 1979: 292–301).

Examination of the skulls of the ancient Norse, who subsisted almost entirely on fish, seafood, and animals, also showed that dental decay was rare (Page and Abrams 1974: 188–203, 214–26). But skeletal remains of prehistoric Indians in the California area, whose diet was primarily vegetarian, revealed that 25 percent of the population had some tooth decay (Pelto and Pelto 1979: 292–301). Substantially worse were the teeth of prehistoric Indians in New Mexico, whose diet was based on corn (maize), supplemented with a few other plant foods and small amounts of animal protein. Tooth decay was a problem for 75 percent of that population (Pelto and Pelto 1979: 292–301).

Such relationships between diet and dental decay, as well as other degenerative diseases, has also been well documented by Weston A. Price's pioneering efforts around the globe. He found, for example, that so long as the Australian Aborigine, Polynesian, Eskimo, and other peoples followed their traditional diets, consisting of animal foods and unrefined, unprocessed plant foods, they had an exceptionally low incidence of caries and other health problems. But after adopting an industrialized diet these same peoples developed rampant tooth decay and other degenerative diseases, as well as malformations in offspring (Price 1989: 59–72).

Animal experiments have yielded similar results that underscore observations on human populations. Protein-malnourished rat pups developed more caries than when protein was amply supplied. Rats fed adequate calories but no protein also had a high incidence of tooth decay (DiOrio, Miller, and Navia 1973: 856–65; Menaker and Navia 1973: 680–7; Navia 1979: 1–4). Clearly, such findings suggest that humans, especially infants and children, are more susceptible to tooth decay if deprived of adequate animal protein foods.

Diet and the Lower Primates

It is sometimes argued that the basic human diet should be plant food because closely related species of primates such as monkeys and apes are vegetarian. Yet, since World War II, ethological studies on primates in the wild have shown that monkeys and apes, despite a predominantly vegetarian diet, nonetheless seek out small animals, insects, insect eggs, and larvae as food (Abrams 1980: 75).

Marmosets and squirrel monkeys are especially fond of crickets and flies (Abrams 1980: 75). Baboons actively hunt, kill, and eat a variety of wild animals, and zoo marmosets have failed to mate until animal foods were added to their diets (Abrams 1978: 42–50). Jane Goodall has witnessed chimpanzees in the wild fashioning crude tools to gather termites as food and has observed them killing and eating arboreal monkeys, baby baboons, and other small animals (Goodall 1971).

Gibbons often eat rodents, birds, and small antelopes. Orangutans feed on larvae, beetles, nesting birds, and squirrels. And in captivity, gorillas show a preference for meat over vegetarian fare (Perry 1976: 165–85). In this connection, it should be noted that the desire of chimpanzees to eat meat does not stem from a lack of plant foods, which are abundant and constitute most of their diet (Eimerl and De Vore 1968: 142–52; Goodall 1971).

Such findings have made it necessary to reclassify monkeys and apes. Rather than being herbivores, these animals are now recognized as omnivores, and the reason that they do not eat more animal food than they do may be the result of a limited ability to provide it in great abundance. But in seeking the animal foods that they do consume, monkeys and apes are most likely driven by a basic need to meet nutritional requirements that are available only from animal protein (Abrams 1980: 76).

The tree shrew, the most primitive of all the living primates, is closest in structure to the fossil ancestors of the first primates, who date from about 70 million years ago. The tree shrew is almost exclusively an insectivore (Berg et al. 1973: 915). Such findings about the primate progenitors of humans strongly suggest that all primates, including humans, have a basic need for some animal protein in the diet (Abrams 1980: 76).

In moving away from lower primates to humans, we find that available paleontological and archaeological data can tell us much about the diet of humans for most of their time on earth.

Humans as Hunters

Fossil remains of *Australopithecus,* the first humans (Dart 1969: 42–189; Leakey 1971: 215–90), have been found over the savannas of South and East Africa (Leakey 1971: 215–90). They ate their food raw, but unlike other primates, they made and utilized crude stone tools to collect more food per unit of time. Their diet consisted of insects and small animals and plant foods that could be eaten raw as found in nature (Biegert 1975: 717–27). They scavenged, eating the remains of any large carcass they found, and apparently were able to obtain surprisingly large amounts of meat (Schaller and Lowther 1969: 307–34).

Through mutations and natural selections, about a million years ago a more advanced human, *Homo erectus,* evolved. These people developed far more efficient tools and techniques for hunting large animals and spread from Africa into Asia and southern Europe (Constable 1973: 29–37, 70).

Between 35,000 and 70,000 years ago, modern *Homo sapiens* evolved. The late Paleolithic *Homo sapiens* is exemplified by Cro-Magnon man (Prideaux 1973). *Homo sapiens* continued to improve hunting techniques and followed game from Africa to the far north of Europe and, finally, to Siberia, the Americas, and Australia. Cro-Magnon's religion and magic, reflected in extraordinary cave art, centered around the theme of the hunt for large game.

Both archaeological excavations and cave art reveal the variety of meat available. In Europe and Asia, for example, Cro-Magnon hunted for bear, cave lion, hyena, wild horse, bison, woolly rhinoceros, reindeer, chamois, ibex, woolly mammoth, and deer. In the Americas, the quarry became the dire wolf, mammoth, giant beaver, giant sloth, American camel, and more than 100 other species (Prideaux 1973: 12, 14, 42–78). But beginning about 40,000 years ago, many of the large animal species began to die out worldwide, and by approximately 10,000 years ago, numerous animals had been hunted to extinction (Martin 1967: 32–8). Anthropologist Sherwood L. Washburn has postulated that the quest for game was a significant factor in the evolution and intellectual development of humans. Beginning with the *Australopithecines* and continuing over eons until the domestication of plants and animals, humans increasingly learned to be ever more efficient hunters, to devise better and better strategies, and to invent and improve better and more effective tools as well as techniques for using them. That humans were forced to shift from hunting and gathering to sedentary agriculture because of a decreasing supply of large animals suggests that they were too successful in perfecting their hunting techniques (Washburn 1961: 299).

Nutrients in Plants and Animals

It should be clear by now that our ancestors, both of the lower primates and of humans, consumed much in the way of animal food and with good reason, for nutrients in meat are much more highly concentrated and are utilized more efficiently than those from plant foods. For example, venison provides 572 calories/100 grams of weight, compared with only 100 calories from a similar amount of fruits and vegetables (White and Brown 1973: 68–94). Humans, then, developed an ability not only to hunt an animal efficiently but also to digest it efficiently. Through natural selection both of these abilities afforded humans an adaptive advantage for survival in a changing environment (Bronowski 1972: 42–56).

A full day of foraging is required to obtain the amount of food value from plants that is found in one small animal. By eating animals that lived on grasses and leaves, humans could obtain a highly concentrated and complete food, converted from plants into meat. When humans moved into the cold regions of northern Europe and Asia, they had to rely on meat even more. Edible plant foods were available only seasonally, whereas game was available throughout the year (Campbell 1976: 253–302). Moreover, game did not need to be cooked, whereas many plant foods had to be prepared in this fashion to be edible. *Homo erectus* may have used fire to a very limited extent some 300,000 years ago, but the evidence is sparse and questionable. Fire's general use, according to both paleontological and archaeological records, began only about 40,000 to 50,000 years ago (Abrams 1976: 102–12).

The use of fire, extended to food preparation, resulted in a great increase and variety of plant food supply. All of the major basic domesticated plant foods, such as wheat, barley, rice, millet, rye, and potatoes, require cooking before they are suitable for human consumption. In fact, in a raw state, many plants contain toxic or indigestible substances or antinutrients. But after cooking, many of these undesirable substances are deactivated, neutralized, reduced, or released; and starch and other nutrients in the plants are rendered absorbable by the digestive tract. Thus, the use of fire to cook plant foods doubtless encouraged the domestication of these foods and, thus, was a vitally important factor in human cultural advancement (Abrams 1986: 24–9).

In summary, it seems clear that the natural diet of humans is an omnivorous one and that proteins from animal sources are vital to health and well-being. This is because proteins differ in quality, depending on the amino acids from which they are built. Some amino acids ("nonessential" or "dispensable") can be synthesized in the human body; others ("essential" or "indispensable") must be supplied by food. For optimal protein quality, all amino acids must be present and in optimal ratios with one another. No individual plant meets these requirements, whereas all foods of animal origin do.

The egg represents the ideal quality protein against which all other proteins are measured in terms of its protein efficiency ratio (PER). At the top of the PER scale, the egg is followed closely by proteins from other animal sources, both organ and muscle meats. The PERs for plant foods such as legumes, grains, and seeds are much lower on the scale because all are limited by a low level of one or more of the amino acids, which are not in good balance with each other. To obtain an amount sufficient to meet human requirements, one would need to consume enormous quantities of a plant food, and the total diet would become imbalanced.

Perhaps in the future, with genetic engineering and other scientific and technological advances, it will become possible to develop plant foods that will supply, in ideal balance, all the amino acids and other nutrients required for optimal health. Meanwhile, it seems prudent to keep the traditional dietary wisdom of our predecessors and apply it, insofar as possible, to modern life, meaning that humans should eat a varied, balanced diet consisting of both animal and plant foods, all in moderation.

PART VII

Contemporary Food-Related Policy Issues

The concern of Part VII is with the impact of economics, governments, politics, and special interest groups on diet in the twentieth century. It begins with the attention that nationalistic governments in the West belatedly paid to the nutritional health of their citizens at the turn of the twentieth century – the health of women, who provided offspring to strengthen the state demographically, and the health of men, who were called upon to fight for it. Mostly, however, Western governments have stopped short of active intervention in ensuring the food supply of individuals, and as the chapters on food entitlements and subsidies for infants and children make clear, such intervention – save for helping the very young – continues to be viewed with sufficient hostility that it is only grudgingly (and only partially) undertaken.

If governments are reluctant to underwrite food entitlements, however, they are much more willing to ensure the dissemination of nutritional guidelines, such as those discussed in the chapter dealing with recommended daily allowances of the chief nutrients and another treating recent food labeling requirements. Yet governments do not act in a vacuum, and the chapter on food lobbies in the United States (and elsewhere by implication) demonstrates the enormous ability of special interests to influence food policy, including the content of much of the nutritional information aimed at informing the public.

The question of the desirability of more or less government involvement in food matters runs deeply through the next few chapters. That food biotechnology may turn out to be a blessing, a curse, or both is a concern of considerable magnitude, and rightfully so, as the chapter on its politics and implications for policy makes evident. However, in what is becoming a roller-coaster look at new food technology, the chapter that follows on biotechnology and food safety seems more reassuring.

The chapter on food additives, which opens a window on the past and present of this fascinating world, is succeeded by another that portrays substitute foods and ingredients, such as margarine and artificial sweeteners, as superfluous at best and health hazards at worst. The author of the chapter on nonfoods as dietary supplements critically evaluates them by describing the history of three – bioflavonoids, dietary fiber, and carnitine – whereas the question of food safety is revisited one last time in the penultimate chapter with a look at the food toxins and poisons imparted by microorganisms.

The last chapter in Part VII takes us full circle by discussing a hypothesis much in the news from time to time – namely, that we modern humans need to be more mindful of the diets consumed by our Paleolithic predecessors so as to reduce our risk of cancer, coronary problems, and other chronic diseases. After all, so the message reads, in the short span of the 10,000 or so years that separates us from them, we have not had much of an opportunity to make biological adjustments so as to utilize foods obtained by farming as well as those secured by foraging.

VII.1 ◆ The State, Health, and Nutrition

Overview

The science of nutrition has influenced consumers in their choices about the kinds and optimal amounts of food to eat, but there are other influences as well, such as prosperity levels within a given population, the efficiency of transportation and distribution systems, and the standards of hygiene maintained by food producers, processors, and retailers.

One factor, however, that has not received much scholarly attention is the increased role of the state, either through direct or indirect means, in the production, distribution, and consumption of food. Only recently have historians addressed the development of food policies (mostly those in Europe) in order to understand the state's role in controlling and monitoring food supplies.

In early modern European societies, the maintenance of public order and the control of food supply were intimately related; religious and secular authorities alike had a vested interest in ensuring that production met the demands of consumption. The actions of these authorities (the distribution of food or price-fixing, for example) were largely responses to localized crises. What distinguishes modern food policies from their early modern antecedents are the intended goals of these policies, as well as the scientific nature of their implementation.

The rise of industrialization and urbanization in the nineteenth century prompted new concerns about food supplies. The competitive nature of an industrialized, capitalist food market increased popular anxieties about adulteration; one of the more important roles of the state was to regulate the hygienic quality of food supplies. The economic conditions of the nineteenth century provoked greater concern with population's risking dietary deficiencies and, therefore, poor health. Social reformers and scientific experts took a more active and deliberate interest in monitoring the health of the laboring classes through the measurement of food consumption levels.

It is not mere coincidence that the rise of modern European food policies paralleled the development of the science of nutrition. As physiologists and social scientists explored both the content of foods and the uses which consumers made of them, state policies utilized this information to safeguard public health, thereby increasing the productivity and longevity of the population. This chapter provides a schematic, comparative overview of state intervention in popular diet throughout the nineteenth and early twentieth centuries, a period when there was an increased recognition of the extent and effects of dietary deficiencies but no cohesive state programs to guarantee proper nutrition for all.

It was often for the sake of military strength that European governments showed interest in the nutritional status of their populations, but even then much of the burden for improving diets was placed on the nutritional education of housewives. World War I, as a contest of industrial and military strength, made necessary the efficient management of resources, including food. Governments were thrown into the roles of suppliers and distributors of foodstuffs, and much of food policy formation was piecemeal, at times chaotic, in nature.

Then, after the states had assumed new regulatory powers over food supplies, the question of whether continued intervention was necessary, or even desirable, formed the basis for interwar debates over the link between food policies, civilian health, and greater economic productivity. Although military and economic competition between nations continued to make civilian health important to national well-being, questions of degrees of state intervention to safeguard health were never adequately resolved. What was clear by the time of World War II, however, was that European states had become increasingly interested parties in matters of food consumption as they related to public health.

The Nineteenth Century

Throughout the nineteenth century, the twin processes of industrialization and urbanization brought dramatic changes to European food consumption habits. Decreased opportunity for domestic agricultural production placed populations, particularly urban ones, at the mercy of price fluctuations. Public discontent over food issues shifted away from riots and disturbances over food availability and toward forms of protest over wages, prices, and standards of living. The division of labor and the monetary economy in industrial capitalist societies brought the rise of commercial middlemen concerned with profits rather than increasing food supplies. This new business ethic spread fears of food adulteration and unscrupulous business practices for the sake of greater profits. Social scientists and reformers observed that in industrialized areas, the poorer segments of the laboring classes suffered from malnutrition, staving off their hunger with cheap carbohydrates such as those provided by bread, potatoes, liquor, and sugar.

Nonetheless, the nineteenth century can be characterized as one in which the quality and variety of diet slowly improved. In addition to sugar, new foodstuffs like wheaten flour, margarine, coffee, and chocolate became urban dietary staples as industrializing nations experienced what Hans Teuteberg has termed "the democratization of dietary gratification" (Teuteberg 1975: 79). By the latter half of the nineteenth century, the rationalization of agriculture, decreasing transport costs, and the industrial mass production of foodstuffs reduced food prices. In Germany, as household incomes rose, families consumed a richer diet and shifted their preferences from potatoes and grain to dairy products and meat, allotting less income for subsistence in relation to other expenditures (Offer 1989: 40).

This is not to say, of course, that meat was regularly consumed by everyone. Rural consumers might have eaten meat only once a week or on holidays. It is interesting to note, however, such changes in consumption patterns signaled new criteria for evaluating diet. In Great Britain, for example, the increase in meat and sugar consumption was seen as a shift to more energy-producing foods and therefore as more desirable for the average worker (Burnett 1966; Mennell 1985; Shammas 1990).

It was in the late nineteenth century that members of scientific communities began to shape dietary evaluation criteria. The science of physiology broke foods down into the essential components of carbohydrates, proteins, and fats. Social scientists, charitable organizations, and parliamentary committees documented the consumption habits of the laboring classes while evaluating standards of living and health. The scientific community also scrutinized some of the troubling effects of industrialization on dietary patterns. Levels of concern and scientific conclusions depended, of course, on national context. Italian physiologists, observing the effects of late-nineteenth-century industrialization on the population, noted that at the same time consumers could afford more nutritious foods, they could also afford alcohol, tobacco, sugar, and coffee, all of which could cancel out the beneficial effects of an improved diet (Helstosky 1996).

The term "diet," distinct from food or food consumption, indicated that there were new criteria for evaluating the place of food in everyday life. Diet implied a certain level of adequacy in food consumption patterns, whether measured by the emerging body of scientific knowledge about calories and nutrients or evaluated in terms of food's capacity to fuel laborers. Therefore, diet was simultaneously a prescriptive and descriptive term, denoting both current habits and a nutritional goal set by members of the scientific community. Statistical knowledge about actual dietary practice relied largely upon concrete records of consumption habits in the form of family budget studies. These studies ranged from government-funded inquests of large populations to studies of smaller groups, sometimes a single family, funded by universities and charitable concerns.

Generally, the period between 1850 and 1910 in western Europe was characterized by a broad range of state and private investigations into the living standards of agricultural and industrial workers (Porter 1986; Hacking 1990). One of the most influential of these, Frederic Le Play's *Enquete agricole* – commissioned by the French Ministry of Agriculture, Commerce, and Public Works – was published in 36 volumes between 1869 and 1870. In Le Play's analysis, dietary habits constituted only a small part of the standard of living; other factors such as literacy, wage rates, housing conditions, and delinquency, for example, also were given analytic leverage.

The European social scientific community followed Le Play's lead in structuring their own monographs; food consumption habits and spending were only parts of detailed works encompassing a wide array of social problems. Data on working-class family budgets from Belgium became the basis upon which the German statistician Ernst Engel formulated his famous law: The proportion of outgo used for food, other things being equal, is the best measure of the material standard of living of a population; the poorer the individual, family, or people, the greater must be the percentage of the income necessary for the maintenance of physical sustenance (Engel 1895).

Nineteenth-century determinations of living standards underscored the centrality of experts and the use of scientific criteria to define social problems. Such determinations also had the effect of emphasizing the importance of the relationship between dietary practice and the physical and social condition of a given population.

By the turn of the century, concrete budget studies of the laboring classes became the basis from which physiologists made nutritional recommendations for dietary intake. There was, however, little agreement over such recommendations. German physiologists like Carl von Voit and Jacob Moleschott defended high levels of dietary protein (between 100 and 130 grams per day), whereas American physiologist Russell Chittenden claimed the body could function adequately on only 60 grams of protein per day (Offer 1989: 39–44). There is no question that scientific recommendations reflected prevailing habits and consumption levels that varied from nation to nation. Uniform nutritional standards were not formulated until the Interallied Scientific Commission met in 1917 and recommended a daily intake of 145 grams of protein, 75 grams of fat, 490 grams of carbohydrates, and 3,300 calories for the average man of 154 pounds working at least an eight-hour day ("Scientists and the world's food problems" 1918: 493).

Debates over what did constitute an adequate intake of nutrients and calories, combined with tabulations of consumption habit by class and region, naturally led to questions of how to improve the nutritional quality of diet and who was to be responsible for such improvements. To some extent, European social scientists and physiologists looked to their governments to take a more active role in guaranteeing better nutrition for all. National governments sponsored investigations into living standards, and on the municipal and national levels, social welfare policies ameliorated poor living conditions through housing reform, consumer cooperatives, and health education programs.

There were no national food policies in the nineteenth century. There were, however, governmental actions that had the effect of improving nutritional standards, such as the adoption of standardized supervision against food falsifications and fraud, as well as assistance for specific populations at risk of dietary deficiencies. The first of these interventions, the regulation of the food market, was arguably one of the most important means of protecting public health. Yet most European governments were reluctant to intervene in the food market, even though in Great Britain, for example, works detailing fraudulent practices ranged from chemist Frederick Accum's *Treatise on the Adulterations of Food* (1820) to Henry Mayhew's *London Labour and the London Poor* (1861).

Such works provoked vigorous political and scientific debates over regulation, but in England there was no governmental attempt to intervene between producer, retailer, and consumer until the enactment of adulteration legislation in 1870 (Burnett 1966). Similarly, in Germany, controls for milk, one of the most commonly adulterated foods, were slow to develop, and it was not until 1879 that uniform food controls and punishments for adulteration were passed (Teuteberg 1994).

In Italy, regulations governing fraudulent retail practices were instituted in 1890 only to be judged ineffectual by the scientific community. As physiologist Adolfo Zerboglio noted in 1897, "[I]t is common knowledge that the poor are obliged to stave off their hunger with spoilt food . . . everyone knows how certain merchants will push poor quality food onto the poor, so as not to keep it in stock" (Zerboglio 1897: 12).

Similarly, governmental interventions to assist populations at risk, such as infants and children, were not fully organized and implemented until the turn of the twentieth century. Diet had improved for many as a result of the increased consumption of fresh fruits and vegetables, butter, and eggs. This was particularly true for Italy and Germany, where the effects of later industrialization were making themselves felt.

In Britain, the inadequate height of military recruits for the Boer War spawned a national debate focused on civilian health and fears of racial degeneration. The minimum height requirement for infantry recruits was lowered from 5 feet 6 inches to 5 feet 3 inches in 1883, and to 5 feet in 1902 (Drummond and Wilbraham 1939: 484–5). Although the stunted growth and malnourished physiques of urban dwellers was of considerable concern, more attention in the ensuing scientific and political debates was given to housing and sanitary conditions than to the influence of inadequate nutrition on public health. The Royal College of Surgeons and Royal College of Physicians were both reluctant to undertake an inquiry into the nutritional status of the population. However, an interdepartmental Committee on Physical Deterioration finally concluded that poor nutrition was in fact playing a role in the continued physical degeneration of the British people. The committee's findings, issued in 1904, focused considerable attention on the preference for refined, white bread among the working classes, but also concentrated on the feeding of infants and children; working-class mothers were found to be poorly nourished and therefore unable to breast-feed properly (Drummond and Wilbraham 1939: 485–7; Winter 1980).

Mercantilist demographic pressures, coupled with the growing fear of national degeneration, led to a more focused educational campaign to raise the nutritional status of the family. Both charitable organizations and eugenics societies undertook to instruct British women on infant nutrition. These efforts, however, generated feelings of anxiety and inadequacy among working-class mothers faced with the task of juggling household budgets to procure better-quality foods when the formidable appetites of their families demanded quantity (Davin 1978). Social scientists and reformers frequently noted that working-class mothers sacrificed their own health in order to feed their families properly, and pregnant women, younger mothers, and children often subsisted on a diet of bread with margarine and tea (Ross 1993).

Similarly, European-wide campaigns to increase infant birth weight (and reduce infant mortality) focused on the health of the mother without making positive contributions toward maternal nutrition. By the late 1870s, doctors had come to recognize that poor maternal health (including nutrition), as well as short intervals between pregnancies, contributed to low birth weights and consequently to low levels of infant health, and by the end of the century the practice of weighing and measuring newborns in hospitals had become common. Policy suggestions in Switzerland, Germany, the Netherlands, and France, however, focused not on improving maternal nutrition but rather on the importance of a period of rest for mothers before giving birth to increase birth weight and reduce infant mortality (Ward 1993: 24–5).

In Britain, concern for the physical health of the population continued through World War I because of the size and health of military recruits and resurfaced once again during the "hungry thirties" (Winter 1980; Mayhew 1988). During this period, scientific documentation of poor physical stature associated individual health with living conditions, whereas public debates over state intervention linked standards of living to national economic health and military strength.

Great Britain was by no means the exception; across Europe in the early twentieth century, solutions to the problem of popular welfare were debated at national and international conferences on population, eugenics, hygiene, infant mortality, and social work.

Such concerns may be understood as characteristic of modernity (Horn 1994: 3–5) and must be seen within a broader context of national and local governmental efforts to "regulate the social" (Steinmetz 1993). But state intervention to improve housing conditions and sanitation was less controversial than efforts to improve diets. European governments were fundamentally uneasy with direct interventions in the everyday life of the family, and any policy that sought to redress nutritional deficiencies for entire populations was not easily reconciled with either liberal democratic governments or capitalist markets.

Even nutritional assistance to populations at risk – infants, schoolchildren, and the poor – was fraught with tension. At the municipal level, assistance was meted out with few problems. In the northern regions of Italy, where pellagra was prevalent, municipal governments worked in conjunction with charitable societies to organize and extend soup kitchens to those consuming the monotonous, maize-based diet that caused the disease (Porisini 1979). And in Germany, socialist and women's organizations pressured municipal governments to experiment with consumer cooperatives and other means of making food more affordable for the working classes (Steinmetz 1993: 4).

On the national level, however, intervention to provide more nutritious foods for those in need was limited to the provision of school meals and milk. School feedings were justified on both economic and eugenic grounds: to guarantee proper nutrition to the neediest so as to ensure the health of future generations.

Under pressure from school boards, school feedings were incorporated into national education acts on the grounds that improperly nourished children could not perform well. In France, free and subsidized meals for children were considered to be an integral part of the school system, and in Norway, breakfast was offered to all children, rich or poor. In the Netherlands, however, the School Act of 1900 contained provisions that food and clothing be supplied to needy children – a policy judged less successful precisely because school feeding was linked to poverty and therefore tainted by paternalism and charity (den Hartog 1994: 71).

In Great Britain, school-feeding policies grew out of charitable initiatives like the Destitute Children's Dinner Society (1864), but the government was long reluctant to act on a national level for fear that the poor would become dependent on the state for sustenance and other material needs. National intervention, however, was finally justified by the turn-of-the-century debate over health, efficiency, and empire triggered by the small stature of many who served in the Boer War (1899–1902).

In twentieth-century Europe, such an extension of state responsibility for assuring nutritional adequacy has often resulted from military (rather than economic or social) considerations. School meals were no exception. As John Burnett recently observed, "War, the fear of it and the retreat of the danger of it, has been a major influence throughout the history of school meals" (Burnett 1994: 55). But although the state increasingly justified intervention on the grounds of national survival, local officials and others continued to view the provision of free or cheap meals and milk as an act of charity.

World War I

The circumstances of World War I dramatically altered the attitude of European governments toward promoting civilian health through food policies. They literally were forced by wartime conditions to provide enough food to keep their populations fit for military and civilian service. If the war was a watershed in the history of modern food policy, it was not because governments were able to promote scientific principles of nutrition. Although scientific knowledge about vitamins and other nutrients in food was developing, it was difficult to incorporate this into wartime policies based on expediency.

Within both belligerent and occupied nations, the consumption of proteins and fats declined, and food shortages developed even in the postwar period. In western Europe, malnutrition aggravated mortality from tuberculosis, nephritis, and pulmonary diseases, especially in Germany and Belgium.

Within the Allied nations, World War I further spread the "democratization of dietary gratification" by narrowing dietary distinctions between socioeconomic classes. The homogenization of consumption patterns has been an overall trend in the twentieth century; however, "the principal agency in narrowing the gap between the rich and the poor was the social effect of the war" (Oddy 1990: 262). Full employment provided regular as well as increased incomes, and the extension of state control over food modified the division of food on the basis of price. To some extent, food consumption levels improved in the Allied nations because military provisioning made more nutritious foods available to soldiers. In the case of Great Britain, "the nation which went to war in 1914 was still so chronically undernourished that for millions of soldiers and civilians wartime rations represented a higher standard of feeding than they had ever known before" (Burnett 1966: 217). There is little doubt that this was the case for soldiers, but to make a similar argument for civilians would be a more complicated matter.

Indeed, a comparison between Great Britain and Italy during the war demonstrates that food policies aimed at civilians had a complex effect on living standards and consumption habits. In both nations, histories of popular diet published after the war claimed that living standards had been so miserable that wartime rationing actually improved the nutrition of many (Bachi 1926; Drummond and Wilbraham 1939). But if these assertions were true, it was for different reasons: The malnourished in Britain comprised the urban poor and the industrial working class, whereas in Italy it was the rural "backwards" peasantry that was in the worst dietary shape. In both nations, full employment and higher wages were the most significant factors in improving living standards. Rationing policies sought to make more food available to all. However, as price was still the limiting factor in working-class consumption, allowances for more expensive goods like meat did not make much difference if consumers could not afford a full ration. And as one history of British food policy points out, scientific experts still used calories to judge the adequacy of diet, so it was entirely possible that experts would not detect an actual decline in nutritional standards based on food substitution (Barnett 1985: 180–1).

In Great Britain and Italy, bread was never rationed but made available in varying weights and consistencies at different, sometimes subsidized, prices. Yet ensuring the availability of cheap bread, as a matter of wartime food policy, made a significant difference in working-class consumption habits. Not only were consumers able to stave off hunger with as much bread (barring occasional shortages) as they could eat, but subsidized bread freed up more of the household budget to purchase other necessity and non-necessity items. Non-necessity items in these cases were often modest: a few extra eggs, dairy products, coffee, or alcohol.

Moreover, even after the war had ended, the public furor ignited by the termination of the Italian bread subsidy in 1919 demonstrates that consumers had come to view cheap staple foods as an entitlement. The postwar bread riots and disturbances in Italy differed from those of earlier times; consumers still clamored for cheap bread, but they did so now in order to afford more coffee, tobacco, and wine (Helstosky 1996). Thus, food policies in Britain and Italy did not transform consumption habits among the lower classes all that dramatically, although there were subtle dietary changes that were significant for those who experienced them. The increased consumption of eggs and dairy products and of refined wheat-flour bread were critical indicators of an improved living standard.

Although the war's duration called for tightly organized systems of food controls, food policies in Europe progressed on a piecemeal basis, were sometimes chaotic in organization, and mixed private voluntarism with state bureaucracy. The aim was to ensure the health of the labor and military forces, and even in the absence of legal governments, as in the case of Belgium, a national committee (the *Comité national de secours et d'alimentation*) attempted to coordinate food aid at different levels to guard the welfare of Belgian labor and thus assure future economic security (Scholliers 1994: 40–1).

Whereas national governments coordinated food imports, requisitioning, and shipments of food out to military forces, municipal governments were usually the first to institute policies important for consumers. In Italy, the national government responded to, and coordinated, prefectoral initiatives on price ceilings, rationing, and domestic trade controls. In wartime Berlin, the municipal government acted to control commercial practice in the interests of consumers and preserving domestic order (Davis 1993).

If the implementation of consumer-oriented policies had its origins in local politics, however, such policies branched out into national politics after 1917, when war weariness on both sides demanded a greater equalization of experience within populations, especially in terms of resource sharing and sacrifice. The most commonly discussed example of the shift from producer-oriented, paternalistic policies to consumer-oriented ones has been that of Germany (Kocka 1984; Offer 1989; Davis 1993). Increasing civil annoyance with the uneven distribution of food led to bitter criticism of food policies and mechanisms of distribution. Consumers chafed at the Reich's calls for a domestic truce *(Burgfrieden)* when they perceived disparities in the distribution and acquisition of food between regions and classes. The hardships experienced during the "turnip winters" of 1917 and 1918 led to civil unrest and attacks on commercial middlemen and contributed to a more generalized criticism of governmental war aims and military policy (Kocka 1984: 53–4).

As the war dragged on, Allied governments paid increased attention to consumption issues, primarily to keep civilian workers content and productive. Moreover, because the Allies borrowed both money and food from the United States, some consideration had to be given to managing consumption in order to extend food supplies. Voluntary measures urging austerity were common; wartime ministries resorted to rationing only as a last resort. Austerity campaigns forged a new bond between citizens, particularly women, and government. Budget management and providing the family with a more nutritious diet were tasks that fell upon the housewife, whether or not she worked. During the war, "economy could now be urged upon the housewife all the more strongly because it was justified on social rather than private grounds" (Mennell 1984: 249). It is likely that propaganda slogans like "food wasted is another ship lost" publicly reinforced women's intermediary roles as food preparers and paved the way for future negotiations between state and housewife for provisioning responsibilities.

The amount of food that Allied nations were able to conserve was never enough in the eyes of Herbert Hoover, U.S. Food Administrator after August 1917 (and later the director of U.S. relief efforts). Following the advice of his "diet squad" of American physiologists, Hoover suggested that Europeans do more to curtail consumption by reducing their intake and substituting foods (Offer 1989: 377). It was during the negotiations between U.S. food administrators and European officials that the idea of transforming scientific findings directly into food policies was debated.

The nutritional studies of American scientists claimed that a general reduction in calories lowered individual body weight and basal metabolism, leading to a more economical working of the body. Hoover and others urged a general reduction in food consumption in order to reduce Allied wheat consumption by one-fourth, thereby easing the wartime strain on U.S. grain stocks (Offer 1989: 378). The British Royal Society soundly rejected such a proposal, noting that any such policy of forced reduction would risk both industrial efficiency and political stability.

Wartime conditions brought about a contradictory situation with respect to popular diet. Although the salaries of workers rose to allow for increased consumption, shortages of supplies and pressure from the United States acted to deny it, and whether consumers were able to purchase more nutritious foods with their additional money is open to question. After the war, the Carnegie Foundation sponsored research that examined changes in living standards and food supplies that had occurred during the war. Authors of these books – mostly economists and agricultural experts – observed mixed results. Economist Riccardo Bachi's study of wartime Italy, for example, concluded that the war improved the nutritional quality of diet primarily because prewar consumption levels were so low (Bachi 1926). Italian physiologists, however, contradicted Bachi's findings, asserting that consumers used higher wages to purchase non-nutritive goods like tobacco, coffee, and wine, thus succumbing to what one scientist termed "alimentary sensualism" (D'Alfonso 1918: 28).

Dr. M. Demoor of Belgium's *Académie Royale de Médecine* rejected the possibility of any objective and scientific study of alimentation during the war: The incomplete documentation of living standards meant that nothing but speculation was possible (Henry 1924: 195). In France, the continuation of subsidized prices for special groups like pregnant women, families with more than two children, and the aged indicated that rations were still not adequate for all segments of the population (Augé-Laribé and Pinot 1927: 258–9). It is difficult, then, to generalize about the nutritional content of diet during and immediately after the war. There were few detailed monographs written on living standards, and those that were usually addressed the situation of workers in industrialized areas.

It is also difficult to generalize about the impact of state policy on food consumption habits, given the wide variation in national experience. Assessments of policy have as much to do with social scientific observations of living standards (which are sorely lacking in many cases) as they do with public perceptions of policy efficacy. Consumers in Germany, where essential foods were rationed and often unavailable, interpreted the effects of food policies far differently from the way that consumers did in Britain, where only sugar and meat were rationed and most goods were continuously available for purchase.

Despite the sometimes chaotic nature of food policy development, what seems clear is that European governments assumed a greater responsibility for civilian health over the course of the war. Whereas state intervention prior to the war was limited to the regulation of food distribution and assistance for the few, wartime policies sought to control the mechanisms of production, distribution, and consumption. The few scientific observations of changing living standards during the war, combined with the standardized nutritional recommendations of the Interallied Scientific Commission, led to an even greater awareness of dietary "averages" to be met as policy goals for the interwar period. There was no question that European governments had become more involved in matters of food consumption as a result of the war; the questions open for debate during the interwar period were whether intervention should continue and for what purposes.

The Interwar Years into World War II

Wartime consumption patterns – more dairy products, meat, fruits, and vegetables, as well as further increases in wheat consumption – were consolidated during the prosperous 1920s and reversed in the following decade of economic crisis. Generally, with the continued development of food processing and retailing in the interwar period, all social classes were enjoying a greater variety of foods. These included industrially created foods like margarine, breakfast cereals, preserves, and meat or fish pastes, along with canned fruits and vegetables. Scientific knowledge about food continued to advance, and vitamins as well as minerals were pronounced essential components of diet. Recommendations for caloric intake, however, fell slightly during this period because greater numbers of people were living more sedentary lifestyles.

Feeding populations at risk became more closely related to the promotion of commercial concerns. The "Milk for Schoolchildren" program in Britain, for example, was sponsored by the National Milk Publicity Council. Similarly, nutritional education programs for housewives and mothers, as well as domestic economy literature, counseled women to buy only standardized, commercial products they could trust (such as foods from Nestlé and Leibig or brand-name products such as Bovril or Kellogg's Corn Flakes). This was probably useful advice for many housewives, especially wherever consumers patronized local shops with less than ideal hygienic practices.

In terms of broader food policies, the most interesting changes in the interwar period reflected the wide-ranging turbulence created by competing systems of political economy. This was the era when both liberal democracies and authoritarian regimes alike took a greater interest in popular health, although their concerns manifested themselves differently. In Great Britain, dietary standards were debated in an effort to address chronic poverty, although, typically, the state ultimately balked at the idea of assuming broader powers of intervention. In Fascist Italy and Nazi Germany, by contrast, food production and consumption were more carefully controlled so that the dictatorships could successfully implement policies of greater economic self-sufficiency. The economic crisis of the 1930s sharpened both the impulse toward autarky and the debate over state responsibility for minimal versus optimal health.

In Great Britain, the publication of John Boyd-Orr's *Food, Health and Income* in 1936 and B. Seebohm Rowntree's *Poverty and Progress* in 1941 pushed the issues of dietary standards and civilian health into the political forefront. Boyd-Orr's study found that 10 percent of the working population during these depression years earned wages that were insufficient to purchase a nutritionally adequate regime. Moreover, he determined that half of the general population consumed a diet that satisfied hunger but was deficient in the nutrients that would maintain what he called optimal health (Boyd-Orr 1937: 8). Lower than optimal dietary standards, he believed, were a financial drain on the state, and he argued for greater state intervention in nutritional matters. Both the findings and the conclusions of Boyd-Orr, however, were roundly criticized in both political and scientific circles for having greatly exaggerated dietary deficiencies in the general population.

Politically, the debate focused on whether the state should work to ensure dietary improvements for all or simply continue protecting populations at risk, such as children. Fear of creeping socialism prevented drastic intervention, but both sides of the political spectrum agreed to focus on improving child nutrition, the left in the hopes of extending state welfare and the right because of eugenic concerns with degeneration (Oddy 1990: 276). The scientific debate over popular nutrition centered upon whether income or food preparation played a more important role in determining the nutritional quality of diet. Scientists were divided on whether malnutrition was a product of ignorance or insufficient income (Mayhew 1988: 450). Despite Boyd-Orr's calls for greater state involvement, responsibility for proper nutrition ultimately was shifted to consumers; as physiologist E. P. Cathcart of the University of Glasgow stated, "It has been our experience, as a result of repeated dietary studies, that one of the most prominent contributory factors toward defective and deficient dietaries is not so much the inadequacy of income as its faulty expenditure" (Pike 1985: 36).

Thus, Britain did not undertake more drastic measures to improve the overall quality of diet. Governmental involvement remained limited to the continued nutritional education of mothers, school feedings, and interventions to meet the needs of the economic crisis.

With economic and agricultural crisis also came more action from European governments to protect domestic agriculture. These interventions assumed the primary form of tariffs, and when tariffs alone were insufficient, the second line of defense consisted of import quotas and milling requirements for domestic grains. Great Britain abandoned laissez-faire agricultural policies by adopting import duties and creating marketing boards. France organized marketing boards for agricultural staples like wheat and wine; Denmark introduced domestic market supports; Nazi Germany instituted a comprehensive organization of production, marketing, and trade; Italy intensified domestic grain production and tightened controls over imports (Tracy 1989).

Such protectionist policies had indirect effects on food consumption habits in the sense that they made domestic staples like wheat more expensive. If staple goods came to occupy a greater portion of the household food budget, this meant that less money was available for the non-necessity items consumers had become accustomed to purchasing during and after the war.

The effect of economic policies on food consumption habits seems particularly important in light of the fact that an adequate standard of living was tied intimately to the promotion of economic and political systems. In Fascist Italy, for example, the regime founded the Committee to Study the Problem of Alimentation in 1928. One of the Committee's responsibilities was to organize, conduct, and publicize grand inquests into the living standard, in order to prove to the rest of the world that fascism as an economic system was leading the nation out of its backward status.

By contrast, sociologists in Belgium worked to measure the nutritional standard of the working classes and, as Peter Scholliers has observed, "[t]heir writings had ideological aims, stressing the fact that the capitalist system was, in the long run, capable of ensuring a decent standard of living for all people" (Scholliers 1992: 73). Although authoritarian regimes in Italy and Germany worked to exert tighter controls over food production, distribution, and consumption, the primary goal of such policies was not to improve nutritional standards. Rather, the motive was to ensure that populations could survive on less food, should there be another war or invasion.

The experience of World War II threw European governments back into the roles of providers and coordinators of food supplies. Rationing was implemented earlier and, because of the duration and severity of the conflict, was imposed on more food items than during the previous war. The struggle for adequate sustenance was a more difficult one in many areas, as exemplified by the extension of the black market in foodstuffs and the use of goods as viable currency throughout the continent. As in the case of World War I, European governments again acted out of expediency, making it difficult to ensure proper nutrition through a rationalized program of food controls. It would not be until after the war and well into the economic miracle Europeans experienced in the 1950s and 1960s that consumers in some nations would experience the culture of superabundance and confront for the first time the health problems associated with overconsumption.

Summary

State intervention in matters of nutrition during the nineteenth and early twentieth centuries in Europe can be characterized by a hesitancy and a reluctance to assume greater responsibilities for the overall health of the population. Governmental concern over popular diet had as much to do with mercantilist and militarist anxieties as it did with a growing public awareness about the importance of nutrition in building and maintaining health. Even when limited interventions – such as the feeding of schoolchildren – sought to safeguard the economic and military future of European nations, these actions were rooted in the voluntaristic paternalism that characterized charity in earlier periods. Pressure to guarantee optimal health for entire populations came mostly from the scientific and social-scientific communities, but it was only under wartime conditions that states acted with such broad measures to guarantee a minimal subsistence for all.

This is not to say, however, that state activities did not influence patterns of food consumption. Direct and indirect intervention in food markets affected the allocation of household budgets and therefore the nutritional composition of diets. Over the course of the nineteenth and early twentieth centuries, European governments demonstrated an increasing interest in safeguarding the health of populations through food consumption; but their limited range of activities demonstrates the political and economic constraints under which they functioned. Prior to the formation of the post-1945 welfare state, which ideally regarded optimal health as a right of citizenship, decisions to implement food policies as a means of building labor productivity, reducing mortality, or satisfying eugenic concerns depended upon economic and political circumstances as much as they did on the scientific knowledge of nutrition.

VII.2 Food Entitlements

Throughout the world there is enough food to feed every human being. Yet hunger and malnutrition persist. "Food security" – that is, access to culturally acceptable nutriments, through normal channels, in quantities sufficient for daily life and work – should be among the most basic of universal human rights. Hunger, poverty, and marginalization are caused by political and economic forces and decisions, which result in entitlement failures that undermine food security at the household level.

Having enough to eat depends upon access to at least a minimum "floor" level of the means of subsistence. In one sense, human history may be viewed as a gradual expansion of a sense of responsibility for others, which helps to secure that minimum "floor" for ever-increasing numbers of people. The concept of an entitlement to subsistence for households within one's own clan has been accepted for ages. Such "food security" became available to citizens of Greece and Rome thousands of years ago and was extended to most Europeans beginning about 200 years ago (Kates and Millman 1990: 398–9).

In spite of this record of progress, however, hundreds of millions of people throughout the world suffer unnecessarily from hunger and malnutrition, and, although the proportion of hungry people is diminishing, their total number continues to grow. Between 1990 and 2000, the absolute number of hungry people was projected to continue to increase and then gradually decline to a level of about 3 percent of the world's population in 2050. "In the meantime, half of the world's women who carry the seeds of our future may be anemic, a third of the world's children may be wasted or stunted in body or mind, and perhaps a fifth of the world's people can never be sure of their daily bread, chapati, rice, tortilla, or ugali" (Kates and Millman 1990: 405). Today, some 1 billion children, women, and men daily confront chronic hunger and, consequently, the specters of starvation, undernutrition, deficiencies of iron, iodine, and vitamin A, and nutrient-depleting diseases (Kates 1996: 4–6).

Among the shades of hunger, starvation is the most arresting to the observer and receives major, if often belated, coverage by news media when it occurs. In the latter twentieth century, the plight of refugees in central Africa has been a current and recurrent example. Famine-related food shortages threaten roughly 1 percent of the world's population with starvation every year.

Undernutrition, the most widespread form of hunger, is especially dangerous for children. It affects their ability to grow, their cognitive development, and their susceptibility to illness. Even relatively mild "chronic undernutrition," the typical form of hunger in the United States, can permanently retard physical growth and brain development and can reduce the ability of children to concentrate and perform complex tasks.

Nutritional anemia (a condition in which a lack of dietary iron causes a shortage of red blood cells) can cause an impaired capacity for work and intellectual performance as well as a decreased resistance to disease and an increased susceptibility to lead poisoning. Nearly one-fifth of pregnant women in the United States suffer from this condition.

A lack of vitamin A in the diet permanently blinds 250,000 children throughout the world each year and increases the chances that millions more will suffer from the three leading child killers – diarrheal disease, measles, and pneumonia. Iodine deficiency results in the birth of 120,000 brain-damaged children annually; millions more grow up stunted, listless, mentally retarded, or incapable of normal speech, hearing, or both. In addition, nutrient-depleting diseases such as diarrhea, measles, malaria, and parasitic infestations prevent millions of people from fully benefiting from the nutrients contained in the nutriments they do manage to take in.

Rights, Entitlements, and the Right to Food

Virtually every society develops a social compact – a set of values and behavior standards – that defines the rights and responsibilities of its members. From the sixteenth through the early nineteenth centuries, survival was considered in European societies to be largely an individual or family-based responsibility, with food and other necessities procured through work. But assistance was available for some of those not able to achieve self-reliance through work, and the various European nations enacted strikingly similar laws that separated needy people into two distinct categories – those who were deemed worthy and those considered unworthy of public aid.

In England, for example, only children, the blind, the disabled, and those elderly persons who could not work were thought worthy of relief under the Poor Laws. Destitute but able-bodied unemployed persons risked savage treatment at the hands of local authorities. They could be consigned indefinitely to workhouses or prisons. Adults and children were severely punished, sometimes even executed, for stealing food (Dobbert 1978: 187).

Today, in the United States and other industrialized countries, able-bodied persons are expected to earn their livelihoods. Often, there is debate over the extent to which the state should meet the needs of those who cannot work – whether because of age, or physical or mental infirmity, or because jobs paying a livable wage are unavailable. For some who cannot attain self-reliance through work, the condition is temporary, and only transitional support is needed. For others, age or infirmity makes the attainment of self-reliance unrealistic; these persons require lasting support.

Human Rights

Human rights are "enforceable claims on the delivery of goods, services, or protection by others" – meaning that people in need can insist upon the delivery of assistance, with recourse, if necessary, to legal or moral enforcement of their demand (Eide, Oshaug, and Eide 1991: 426). Such rights are based on social obligations that are accepted by all persons without reference to distinctions of race, gender, nationality, language, religion, or socioeconomic class. Human rights may be promulgated globally but must be implemented locally within nationally determined limits (Barker 1991: 105, 203; Eide et al. 1991: 415).

Some analysts separate such rights into two categories: civil/political rights and social/economic/cultural rights. Civil and political rights are basic "rights recognized in democratic constitutions, such as life, liberty, and personal security; freedom from arbitrary arrest, detention, or exile; the right to fair and public hearings by impartial tribunals; freedom of thought, conscience, and religion; and freedom of peaceful association" (Barker 1991: 105). Social, economic, and cultural rights include "the right to work, education, and social security; to participate in the cultural life of the community; . . . to share in the benefits of scientific advancement and the arts" (Barker 1991: 105), *and the right to eat.*

The protection of vulnerable groups, such as the poor, those with handicaps, and endangered indigenous peoples, is a major aim of social, economic, and cultural rights. Taking these rights seriously requires grappling with issues of social integration, solidarity, equality, and distribution of wealth. Perhaps as a consequence, although civil and political rights have received considerable attention, social, economic, and cultural rights have been relatively neglected at both the international and national levels (Eide and Rosas 1995: 17).

Those who separate human rights into two distinct categories argue that civil and political rights emphasize "freedom from" state interference; they are absolute, are immediately realizable at little financial cost to governments, and are capable of being adjudicated in court. In contrast, social, economic, and cultural rights are seen as claims on the state for protection and assistance; these are relative to the circumstances of one's society, are only gradually realizable at substantial financial cost to governments, and are dependent upon politics rather than the courts for such realization. Other analysts, however, view the two categories of rights as interrelated and as addressing "different aspects of the same three basic concerns: integrity, freedom, and equality of all human beings" (Eide 1995a: 21–2; Eide and Rosas 1995: 17).

Humans require basic necessities such as food, clothing, and housing (depending on the cultural conditions in which they live) to enable them to participate fully – without shame or unreasonable obstacles – in the everyday life of their communities. The right to a standard of living that supports such participation is, therefore, a basic social right (Eide 1995b: 90).

The three major components of such a standard of living are adequate food, care, and the prevention and control of disease. As a basic social right, this standard of living is a necessary foundation for an effective social compact, but it is not a solely sufficient one, as the compact must also provide for other social, economic, and cultural rights, as well as for civil and political rights. Thus, the right to adequate food is an essential – and perhaps the most important – building block in the foundation of a satisfactory social compact.

"Adequate food" means that every household can depend upon the availability of a stable supply of culturally acceptable, uncontaminated, good-quality food, which provides all necessary energy, nutrients, and micronutrients (such as vitamins and iodine). Food adequacy implies economic and social (as well as environmental) sustainability, which entails access to food through a combination of fair wealth distribution and effective markets, together with various forms (public and private, formal and informal) of supports and "safety nets" (Eide 1995b: 90–1).

According to the United Nations Administrative Committee on Co-ordination, Subcommittee on Nutrition, "care is the provision in the household and the community of time, attention and support to meet the physical, mental and social needs of the growing child and other family members" (Eide 1995b: 91). Such care implies, among other things, access to primary health care, protection from infection, medical assistance during illness, and assistance to meet the needs of disability and old age. Adequate care is necessary for everyone but is especially important for vulnerable groups such as young children, pregnant and lactating women, and the elderly (Eide 1995b: 91–3).

Adequate prevention and control of disease is essential to a satisfactory standard of living because of the close connection between disease and malnutrition. Therefore, immunization and breast-feeding campaigns, oral rehydration child survival programs, nutrition education, sanitation programs, and the like are important contributions to living standards (Eide 1995b: 93).

Entitlements and "Entitlement Failure"

An entitlement is a societal obligation to provide support as a right when people have insufficient resources to live in conditions of health and decency (Melnick 1994: 54–6). Entitlement to food is the ability to command food through the various forms of exchange relationships to which one has access (Sen 1981). Amartya Sen describes three basic forms of food entitlement: "(a) access to resources to collect or to produce food, (b) the exchange of resources (property, money, labor power) for food, and (c) the receipt of gifts or grants of food or the resources to procure food" (Sen 1981; Kates and Millman 1990: 397). An entitlement approach to food security "requires a shift in thinking from *what exists?* to *who can command what?*" (Eide 1995b: 95).

Many other rights interact with and affect the entitlement to food. The right to property supports the right to food both because ownership of land makes it possible to grow food and because ownership of assets makes it possible to produce items that can be exchanged for food. As property is often unevenly distributed, the right to work at a living wage is directly related to the right to the income necessary to purchase food, and, of course, the right to work is in turn affected by the right to an education. If a person lacks property and is unable to work because of age, disability, illness, lack of skill or training, scarcity of appropriate jobs, or because available work does not pay a living wage, a right to social security becomes necessary to secure access to food (Eide 1995b: 95–6).

Sen's three basic forms of entitlement have not changed over time. What has changed "is the mix: from a primary emphasis on household self-provision, to slave, servant, or serf status where labor is appropriated in return for minimal entitlement, to market exchange of labor and production, and most recently to the development of extensive safety-nets of food security" (Kates and Millman 1990: 398).

Sen's conceptualization of "entitlement failure" (Sen 1981; Drèze and Sen 1990a, 1990b, 1990c, 1991) has provided a powerful analytical tool with which to understand and intervene in the political economy of hunger. Most important, the concept helps avoid the pitfall of assuming that per capita food supplies that on average seem adequate will result in universal food security. Just as it is possible to drown in a stream that averages only an inch deep, it is possible to starve in a world, nation-state, region, or even household in which there is a seemingly sufficient average food supply.

When some people thrive but others do not – whether in the presence of food or faced with food shortages – one must ask *why* some have access to sufficient food and thrive, whereas others, lacking access, sicken or die. For Sen, "entitlement failure" is the central cause of hunger, starvation, and famine. People suffer malnutrition and die of starvation because of an inability to claim access to sufficient food resources to meet their nutritional needs. Such entitlement failure is a consequence of choices made publicly and privately at the international, national, state, community, and household levels.

Household Food Security

For a right to food to have meaning, it must be implemented where food is actually consumed, by individuals at the household level. The presence of food supplies in a nation or region is no guarantee of food security if households lack access to them. Household food security depends upon a household's "access to a basket of food which is nutritionally adequate, safe, and culturally acceptable, procured in a manner consistent with the satisfaction also of other basic human needs, and obtained from supplies, and in ways, which are sustainable over time" (Eide et al. 1991: 455).

Even if a household has access to a supply of food that, if equitably shared, could meet the needs of all of its members, that food may or may not be available according to individual needs. In many societies, for example, men and boys eat first, and women and girls wait to eat whatever the males leave.

Strategies for Food Security

Jean Drèze and Sen (1990a: 22–6) describe two contemporary strategies for replacing persistent want and hunger with food security: "growth-mediated security" and "support-led security." Growth-mediated security is based upon rapid economic expansion, with benefits shared through new jobs and higher wages, and use of growth-generated resources "to expand public support of health, nutrition, education, and economic security for the more deprived and vulnerable" (Drèze and Sen 1990a: 22). The "trickle-down" economics promoted by some politicians in the United States and the structural adjustment policies promulgated by the World Bank and the International Monetary Fund both assume the creation of growth-mediated benefits, but whether such benefits are shared with poor and marginalized people is a matter of public policy choices.

By contrast, support-led security involves providing "public support measures without waiting for the country to become rich through economic growth" (Drèze and Sen 1990a: 24). China, Sri Lanka, Costa Rica, Cuba, Chile, Jamaica, and the state of Kerala in India are all examples of governments that have followed the support-led strategy with considerable benefit to marginalized citizens.

Although there is a significant difference between the two approaches, public support plays an important role in each. "Indeed, in the absence of public involvement to guarantee that the fruits of growth are widely shared, rapid economic growth" can have a negative impact on the entitlements that secure sufficient food and other necessities of life. It is, according to Drèze and Sen (1990a: 26), essential to replace "unaimed opulence" with growth benefits targeted to the needs of the marginalized.

Moreover, Asbjørn Eide has argued that it is a mistake to assume that governments must have the primary responsibility to provide food to needy people through costly, potentially overgrown state bureaucracies. Instead, governments should work to maximize the capability of individuals to provide food for themselves and their households through their own resources and efforts (Eide 1995a: 36–8). This goal involves three levels of obligation. First, governments must respect individual freedoms and resources; for example, government actions to ensure the land rights of endangered indigenous peoples and to clarify smallholders' titles to their land enable such people to maximize self-reliance and their ability to earn an adequate living. Second, governments must protect the rights of less-powerful people against more powerful interests that may exploit them and reduce their ability to be self-reliant. Third, when no other possibilities exist, governments must fulfill rights by direct action, such as providing for basic needs through programs of food aid or social security (Eide 1995a: 36–8).

The Evolution of an International Entitlement to Food

The development of a right to food is the culmination of several centuries of struggle to affirm human rights and then extend them to people without property, such as former slaves, and women. The human rights from which the right to food has emerged are grounded in the philosophy of John Locke and Jean-Jacques Rousseau, in the 1690–1 British Bill of Rights, in the 1776 U.S. Declaration of Independence, and in the 1779 French Declaration on the Rights of Man and the Citizen (Dobbert 1978).

Until World War II, international law provided no basis for a right to food. The right could be claimed only by groups such as members of the armed forces (entitled to food in exchange for their willingness to fight) or the inmates of penitentiaries, almshouses, and similar public institutions, who were prevented from self-provision. Attitudes toward human rights, however, were fundamentally altered by the events surrounding World War II. The acute food shortages experienced by war-torn countries in Europe and elsewhere led to the emergence of the concept of a right to food as a universal right (Dobbert 1978: 188–9).

In 1941, in his well-known "Four Freedoms" State of the Union address, U.S. President Franklin D. Roosevelt introduced the concept of "freedom from want" into modern political discourse. Later that year, the Atlantic Charter – framed by Roosevelt and British Prime Minister Winston Churchill – called for international economic collaboration to secure "improved labor standards, economic advancement and social security" for all. Finally, in his 1944 State of the Union message, Roosevelt proposed an international "Economic Bill of Rights" recognizing that "true individual freedom cannot exist without economic security and independence." "People," he said, "who are hungry and out of a job are the stuff of which dictatorships are made" (Eide 1995a: 29).

International Conventions and Covenants

The Universal Declaration of Human Rights (UDHR), adopted by the General Assembly of the United Nations (UN) on December 10, 1948, is the foundation upon which efforts to realize an international right to food are based. In order to foster global freedom and democracy, the UDHR envisions worldwide human rights – to be monitored internationally and implemented nationally – for all people. Article 25(1) anticipates the right to food: "Everyone has the right to a standard of living adequate for the health and well-being of himself and his family, including food, clothing, housing and medical care and necessary social services" (Dobbert 1978: 192).

The UN Commission on Human Rights, which drafted the declaration, could not obtain the agreement of the United States and other nations of the industrial West to include both civil/political and social/economic/cultural rights in a single, legally binding convention. But subsequently, in 1966, 18 years after the promulgation of the UDHR, separate international covenants on civil/political rights and social/economic/cultural rights were adopted by the

UN General Assembly (Eide and Rosas 1995: 15). By 1995, 120 nations had ratified the international Covenant on Civil and Political Rights (CCPR).

The evolution of the international Covenant on Economic, Social and Cultural Rights (CESCR) has been more controversial. Article 11 contains the language most relevant to a right to food. By 1957, when most of the substantive language of the CESCR had been accepted, Article 11 stated simply that the nations party to the covenant "recognize the right of everyone to adequate food, clothing and housing" (Dobbert 1978: 191). In 1964, following a call by Dr. B. R. Sen, Director-General of the Food and Agriculture Organization of the United Nations, for a strengthening of the covenant, compromise language was adopted providing for a right to an adequate standard of living based on universal subsistence rights to adequate food and nutrition, clothing, housing, and necessary conditions of care (Dobbert 1978: 191–4). By 1995, the CESCR had been ratified by 118 nations. But although the U.S. government signed the covenant in 1976, it had still not been ratified by the U.S. Senate some 20 years later.

The actual enjoyment of these theoretically universal social, economic, and cultural rights still eludes many people throughout the world. Nevertheless, paying at least "lip service" to them provides an opportunity for advocates in all countries to press for their extension and implementation.

The Role of Intergovernmental Organizations

Several intergovernmental organizations (IGOs) have played important roles related to food security and contributed significantly to the conceptual evolution of a right to food but have been less successful in ensuring its realization. These include the Food and Agriculture Organization of the UN (FAO), the World Food Programme (WFP), the World Food Council (WFC), the International Fund for Agricultural Development (IFAD), the United Nations International Children's Emergency Fund (UNICEF), and the UN's World Health Organization (WHO) (Eide et al. 1991: 437–8).

The Food and Agriculture Organization was conceived during World War II and established in 1945, before the war ended. After the war, FAO made its headquarters in Rome, housed in the offices from which Italian dictator Benito Mussolini had hoped to rule an empire. The organization functions as a clearinghouse for scientific information on food and agriculture, but when it addresses structural causes of hunger, such as regulation of the world grain trade or issues of land reform, FAO risks conflict with its sponsoring governments.

FAO's role in promoting the right to food has varied from virtual inactivity to strong support, depending upon the bent of its directors. Although it was not until 1965 that the preamble to the FAO Constitution was amended to include "humanity's freedom from hunger," FAO played an important role in strengthening the CESCR. It was instrumental, too, in founding the World Food Programme and in initiating the 1974 International Undertaking on World Food Security, which recognized (paragraph I.1) "that the assurance of world food security is a common responsibility of the entire international community." In addition, the FAO worked to create the 1975 Food Security Assistance program to help developing countries implement national food-stock and reserve programs and was important in negotiating the nonbinding World Food Security Compact in 1985 (Tomasevski 1987; Eide et al. 1991). In 1996, FAO sponsored the International Food Summit in Rome.

The World Food Programme was founded by FAO and the United Nations in 1961. The WFP administers the food aid pledged by members of the United Nations for emergencies and development projects. When administered with careful attention to its effects on exchange entitlements, food aid can be very successful; by contrast, poorly targeted food aid can wreak havoc on entitlement relationships. The WFP has stressed the right to food "as the most fundamental of human rights, and a precondition to development" (Eide et al. 1995: 442–3).

The World Food Conference in Rome (held from November 5 to 16, 1974) focused global attention on the idea that hunger and malnutrition are solvable problems. It adopted the Universal Declaration on the Eradication of Hunger and Malnutrition, which proclaimed: "Every man, woman, and child has the inalienable right to be free from hunger and malnutrition in order to fully develop and maintain their physical and mental facilities" (Tomasevski 1987: 343). The declaration set a goal of eliminating hunger worldwide within 10 years and was subsequently endorsed by the UN General Assembly. Further activities intended to implement the declaration and the 22 resolutions of the conference included the establishment of the World Food Council, the FAO Committee on World Food Security, the International Fund for Agricultural Development, and the United Nations Administrative Committee on Co-ordination, Sub-Committee on Nutrition (ACC/SCN) (Tomasevski 1987).

The World Food Council was established by the UN General Assembly in December 1974 to coordinate the work of UN agencies related to "food production, nutrition, food security, food trade and food aid" (Tomasevski 1987: 346–7). In 1977, the WFC adopted the Manila Communiqué, an action program to eliminate hunger and malnutrition, and in 1979, it adopted the Mexico Declaration, which proposed, among other things, that countries "consider practical ways and means to achieve a more equitable distribution of income and economic resources so as to ensure that food production increases result in a more equitable pattern of food consumption" (Tomasevski 1987: 39–40). The ability of the WFC to serve as the UN's conscience on food security is, however, limited by its practice of operating on consensus, which precludes serious consideration of the more radical structural analyses offered by various country-groups. The WFC Secretariat has shown only moderate interest in promoting legal approaches to the right to food (Eide et al. 1991: 415).

The International Fund for Agricultural Development was established in 1976 with initial funding of $1 billion for programs to increase food production, reduce rural poverty, and improve nutrition in developing countries. IFAD gives priority to the poorest food-deficient countries and attempts to strengthen the entitlements of small and landless farmers. IFAD, then, is the IGO that works directly to reduce poverty among the most severely marginalized groups. Food security is now a major focus of its work.

The United Nations International Children's Emergency Fund was established in 1946 to promote health, education, and social services for children in developing countries and is actively employing in its work the Convention on the Rights of the Child (CRC), which was adopted by the UN General Assembly in November 1989. The CRC addresses rights to health (Article 24) and to social security (Article 25), whereas Article 27 recognizes "the right of every child to a standard of living adequate for the child's physical, mental, spiritual, moral and social development." The 1990 World Summit for Children sponsored by UNICEF to promote the CRC was attended by more than 70 heads of state, and by 1995, the convention had been ratified by 150 nations (Eide 1995a and 1985b). Until then, the United States was the sole major nonsignatory of the convention, and although the U.S. government at last signed the CRC (as a memorial to UNICEF executive director James Grant), it had not yet ratified the document by the end of the following year.

The World Health Organization, in response to worldwide activism against the irresponsible marketing of infant formulas, has worked to create awareness of infants' right to adequate nutrition. Its Code of Marketing of Breast Milk Substitutes was adopted by the World Health Assembly in 1981.

U.S.-Based Nongovernmental Organizations

During the 1970s and 1980s, a growing public awareness of the problem of hunger resulted in the establishment of a large number of antihunger nongovernmental organizations (NGOs). National and international NGOs based in the United States that have played substantial roles in the struggle to develop food security or the right to food include Oxfam America, Food for the Hungry, and the Campaign for Human Development (founded in 1970); Bread for the World (1974); Food First and World Hunger Year (1975); World Hunger Education Service (1976); the Hunger Project (1977); and Results (1980).

By 1985, the more economically developed countries supported an estimated 2,000 NGOs – mostly focused on development and self-help – throughout the world. Some were quite large; World Vision, for example, had 750,000 subscribers and raised an international budget of $300 million annually. Catholic Relief Services had a 1990 budget of $220 million, CARE $294 million, Lutheran World Relief $49 million, and Church World Service $43 million (Beckman and Hoehn 1992: 20–1).

Millions of U.S. residents have participated in episodic, short-term, hunger-relief activities in response to famines – such as aid concerts, "Hands across America," and the like (Millman et al. 1990: 326). In 1991, for example, "334,580 people participated in Church World Service 'CROP Walks' to raise money for anti-hunger efforts" (Beckman and Hoehn 1992: 15–18).

Development aid from the governments of developed countries increased from $7 billion to $48.1 billion between 1970 and 1988. "But most of this 'aid' is tied to political and commercial interests of the Northern governments, and often hurts rather than helps poor people in Southern hemisphere countries" (Beckman and Hoehn 1992: 22). Although the majority of U.S.-based NGOs focus on relief or development activities, Bread for the World and Results have mobilized substantial grass-roots constituencies lobbying for changes in U.S. public policy that will support food security.

Bread for the World (BFW) is an interdenominational Christian organization in the United States with about 40,000 members. BFW members lobby the U.S. Congress on policies that affect domestic and global hunger. In 1974, BFW mobilized its members to pressure the U.S. Congress to enact a "Right-to-Food Resolution." (H.R. 737 was passed in the U.S. House of Representatives with a vote of 340 to 61; S.R. 138 was passed in the U.S. Senate by voice vote.) The resolution by the House stated the sense of Congress as follows:

> (1) the United States reaffirms the right of every person at home and abroad to food and a nutritionally adequate diet;
> (2) the need to combat hunger shall be a fundamental point of reference in the formulation and implementation of United States policy in all areas that bear on hunger;
> (3) the United States should seek to improve domestic food assistance programs for Americans in need, to ensure that all eligible recipients have the chance to obtain a nutritionally adequate diet;
> (4) the United States should increase substantially its assistance for self-help development among the poorest people of the world with particular emphasis on increasing food production and encouraging improved food distribution and more equitable patterns of economic growth; this

> assistance should be coordinated with expanded efforts by international organizations, donor nations, and recipient countries to provide a nutritionally adequate diet for all. (U.S. House of Representatives 1976b)

Among its lobbying efforts, BFW has led successful attempts to increase U.S. allocations for intergovernmental child survival programs that save millions of lives annually. Through its Transforming the Politics of Hunger project, BFW is encouraging those in the voluntary feeding movement to take a more active role in affecting governmental antihunger policy (Beckman and Hoehn 1992).

The Results organization is a hard-headed, policy-focused spin-off of the Hunger Project begun in 1977, which seeks "to empower people to take actions against hunger" (Millman et al. 1990: 327). By 1987, the Hunger Project claimed to have enrolled more than 5 million members in 152 countries (Millman et al. 1990: 327). Mobilization efforts by Results have included generating support in the United States and several other countries for the World Summit for Children and the Convention on the Rights of the Child.

International Nongovernmental Efforts

There are several international efforts to strengthen and implement the right to food that should be mentioned. An October 1981 meeting – organized in Gran, Norway, by the United Nations University – resulted in the 1984 publication of *Food As a Human Right* (Eide et al. 1984). The book emphasized (p. ix) that human food supplies are "filtered through socioeconomic processes which deny an adequate supply of food to many while delivering a large over-dose to a 'lucky' few" and that meaningful intervention "will probably require deep structural changes" that will generate conflict.

The World Institute for Development Economics Research (WIDER) was established by the United Nations University in 1984. The following year, it began its program, "Hunger and Poverty: The Poorest Billion," and in 1986, it sponsored (in Helsinki) a Food Strategies Conference to identify feasible opportunities for affecting world hunger. The conference pursued an entitlement approach emphasizing public intervention to improve literacy rates, life expectancy, and infant mortality in low-income nations. Follow-up activities to the WIDER conference included publication of the three-volume work *The Political Economy of Hunger* (Drèze and Sen 1990a, 1990b, 1990c).

In June 1984, the Right to Food Project of the Netherlands Institute for Human Rights (SIM), with cosponsorship by the Norwegian Human Rights Project, brought together "42 lawyers, nutritionists, and development experts, from all parts of the world, and from both nongovernmental and intergovernmental organizations" (Alston and Tomasevski 1984: 215). Participants in the conference, "The Right to Food: From Soft to Hard Law," criticized discussions of world hunger as frequently oversimplified. Instead of being defined simply in terms of calorie/protein requirements, hunger, they contended, should be analyzed "in terms of economic, social, political, cultural, and other structural factors, which deprive some people of access to land, work and food" (Alston and Tomasevski 1984: 217). A wide range of discussions focused on causes (for example, land tenure and access to work and food), rather than on manifestations, of hunger. The conference proceedings were published as *The Right to Food,* which attempted, "for the first time, to make hunger a prominent issue on the human rights agenda and to put the right to food on the agenda of national and international human rights agencies" (Alston and Tomasevski 1984: 7).

The SIM conference called for a translation of the "soft law" norms of human rights into "hard law" capable of adjudication. Conferees proposed monitoring the implementation of the right to food through (1) an international system based on cooperation among the relevant UN agencies, (2) a redesign of the CESCR reporting system, and (3) an NGO network using an Amnesty International–style "mobilization of shame" approach (Alston and Tomasevski 1984: 220). The greatest need, according to the SIM conferees, was for:

> a network of support by and among NGOs which would include the mobilization of other private sector groups such as professional organizations of lawyers and doctors and churches in the fight against hunger. This network could strengthen existing NGOs, building and using human rights law and developing a concrete, realistic program of action on the right to food. (Alston and Tomasevski 1984: 220)

Five years later, in 1989, "a group of 24 planners, practitioners, opinion leaders, and scientists," brought to Bellagio, Italy, by the World Hunger Program of Brown University, adopted "The Bellagio Declaration: Overcoming Hunger in the 1990s." Its signers represented national or international agencies, organizations, universities, and research institutes in 14 countries, both northern and southern.

Whereas some advocates approach ending hunger incrementally, and others envision more fundamental structural changes, the Bellagio Declaration sought a "common middle ground" in which half of the world's hunger could be ended in a decade by appropriately applying the "better and the best" of current programs throughout the world. The Bellagio strategy included: (1) eliminating deaths from famine, (2) ending hunger in half of the poorest households, (3) cutting malnutrition in half for mothers and small children, and (4) eradicating iodine and vitamin A deficiencies (Kates and Millman 1990).

In December 1992, preceding the International Conference on Nutrition in Rome, a Task Force on Children's Nutrition Rights was established under the aegis of the World Alliance on Nutrition and Human Rights. The task force encouraged national workshops "designed to launch locally-based long-term campaigns to strengthen children's nutrition rights, giving attention to both their articulation in the law and the effective implementation of that law." Workshops were held in Guatemala and Mexico in 1993 and are being planned in several additional countries (Kent 1993a).

The Task Force on Children's Nutrition Rights is collaborating with the Foodfirst Information and Action Network (FIAN), an "international human rights organization for the right to feed oneself" (Kent 1993b: 10), which has chapters in several countries. At the June 1993 World Conference on Human Rights in Vienna, FIAN took the lead in advocating an optional protocol for the CESCR that would empower individuals to bring human rights complaints to the UN Committee on Economic, Social, and Cultural Rights (Kent 1993b).

In the 1990s, poor weather conditions reduced world grain reserves to a perilously low level and caused the price of grain to rise. Although this was a boon to farmers in grain-exporting countries like the United States, it played havoc with the economies of grain-importing countries throughout the developing world. Concurrently, total annual commitments of external assistance to agriculture in developing countries fell from about $16 billion in 1988 to about $10.7 billion in 1993.

Prompted by widespread food insecurity, the FAO made plans for the World Food Summit in Rome in 1996 to deal with problems of hunger and malnutrition. The summit, the first global conversation in 22 years that was focused specifically on food and hunger adopted the Declaration on World Food Security and Plan of Action, which reaffirmed the right to be free from hunger through universal access to safe and nutritious food and pledged to reduce the number of hungry people to 400 million by the year 2015.

The retreat from the 1974 World Food Conference goal of ending hunger worldwide in 10 years to the 1996 World Food Summit goal of reducing hunger by half in 20 years reflected diminished support by the United States and other developed countries for a legal right to food. During the two years of negotiations on the 1996 summit documents, U.S. representatives repeatedly expressed concern that a right to food could expose producing countries to lawsuits and trade complaints from the developing world. In opposition to the 1996 declaration, the U.S. delegation to the summit contended that the right to food is only an "aspiration" that creates no international obligation for governments.

Entitlement Failure: And the Right to Food

In light of this chapter's recitation of the resolutions, conventions, declarations, protocols, visions, and down-to-earth efforts of IGOs and NGOs to nurture recognition of the right to food and to implement food security, one might be tempted to ask why hunger and malnutrition persisted as the twentieth century came to a close. Is there any reason for hope that the right to food will become as commonly accepted as, say, entitlement to public education, and that the global right to food will become as commonly accepted as civil and political rights? Where must we go from here in order to attain the basic social justice reflected in a universal, implementable right to food security?

To speak only about the United States, the challenge seems especially daunting during a time in which public programs are under attack. Even with the present food-security safety net relatively intact, 4 million U.S. children under age 12 experience hunger, and every year another 9.6 million are at risk of hunger. In fact, 29 percent of U.S. children live in families that experience food shortage problems year after year (FRAC 1995: v–vi), and poor children in the United States have less access to food than poor children in 15 other industrial nations (Bradsher 1995). The U.S. welfare "reform" legislation of 1996, which replaced the entitlement to public assistance of families with dependent children with a time-limited, work-based program, might well push more than 1 million additional children below the U.S. poverty threshold.

The human costs of slow progress are great. The demise of hunger is not guaranteed. But hunger can be ended, if we choose. R. W. Kates and Sara Millman (1990: 404) describe the progress that has been made and the challenges we still face:

> In global terms, there is enough food to go around. In the 1960s the earth passed the first threshold of theoretical food sufficiency (enough to provide a near-vegetarian diet for all if distributed according to need) and [is] approaching a second threshold of improved diet sufficiency (enough to provide 10 percent animal products). But we are still a long way from a third threshold of a full but healthy diet with the choices available in industrialized nations. Projecting world food demand, under alternative assumptions of both diet and population growth, indicates that nearly three times the present level of production might be required for an improved diet and almost five times for a full, but healthy, diet, some 60 years from now.

In other words, there is cause for hope. Reduced contributions for development aid will harm, yet not cripple, development efforts. The dramatic strengthening of civil society in some developing countries is one of the major causes for hope.

Moreover, there is a deep-seated tradition in a number of the industrialized nations of caring for one's poorer neighbors. Widespread public opinion in the United States holds that no one should go hungry. Perhaps BFW and its antihunger-movement allies will succeed in transforming the politics of hunger and in energizing the feeding movement to affect the direction of national aid policies. A reenergized, populist, antihunger movement throughout the world, armed with appreciation of entitlement failure as the key to understanding the political economy of hunger, may yet succeed in transforming "soft" concern about hunger into the "hard law" of an enforceable, adjudicatory right to food.

VII.3 ~ Food Subsidies and Interventions for Infant and Child Nutrition

One hundred and fifty million children, or one in three, in the developing world are seriously malnourished (United Nations Development Program 1990). This includes 38 million children underweight, 13 million wasted, and 42 million stunted. In addition, 42 million children are vitamin A-deficient (West and Sommer 1987), 1 billion people, including children, are at risk of iodine-deficiency disease (Dunn and van Der Haar 1990), and 1.3 billion have iron-deficiency anemia (United Nations 1991).

Malnutrition, whether undernutrition per se or a specific micronutrient deficiency, is usually the result of an inadequate intake of food because households do not have sufficient resources. In a review of the income sources of malnourished people in rural areas, J. von Braun and R. Pandya-Lorch (1991) found that among households with a per capita income below $600 (U.S.), there was a close relationship between household food security and the nutritional status of children.

The problems associated with nutritional deprivation are compounded when access to sanitation is limited, because poor sanitation and hygiene results in increased morbidity. This condition is often accompanied by a reduction in food intake at the very time when energy and nutrient requirements are high. About one-third of the populations of developing countries has access to sanitation, and just over half have access to safe water, but there are large urban–rural differences. Ease of access to water is 48 percent lower in rural areas than urban areas, and overall access to sanitation is 77 percent lower in rural areas (United Nations Development Program 1990).

Although urban populations may appear better off than rural ones, the plight of the urban poor is getting worse. The average annual growth rate of urban populations in developing countries is 3.7 percent, whereas that of rural ones is 0.9 percent (Hussain and Lunven 1987). However, in urban slums and squatter settlements, the population of which represents one-quarter of the world's "absolute poor," the growth rate may exceed 7 percent per annum. This rapidly expanding population comprises people who often lack the resources to obtain an adequate diet for either themselves or their children.

There are also gender, social, and cultural inequalities in addition to urban–rural disparities. In the rural areas of Africa and the urban slums of Latin America, women commonly head the household. In many cases, these women are compelled to be employed, but in general their remuneration is low because they tend to work in subsistence agriculture or in the informal sector, where women's wages are lower than those of men. Social and cultural inequalities also often favor males over females, which is manifested in, for example, better health care and nutrition for males and neglect of female education. Irrespective of the environmental and political situation, social, economic, and cultural interactions exist that make improving the nutritional status of the poor a formidable task.

Targeting interventions so that those most nutritionally vulnerable, especially children, can benefit is important not only from an economic perspective but also in terms of the nutritional impact of the intervention program. Thus, although policy makers may be interested in improving the nutritional status of preschoolers, to focus solely on this age group is neither realistic nor practical (Berg 1986; Beaton and Ghassemi 1987). Indeed, in order to improve the nutritional status of infants and young children, it is more cost-effective to use programs that would benefit the entire household. The objective of a food-policy program aimed at the poor should be to improve their nutritional status by improving their access to food. However, unless nutritional considerations are explicitly stated in a food policy, it cannot be considered a food policy (Berg 1986).

Food policies can be based on *economic* and *nutrition* interventions. Specific economic interventions, which aim to stabilize food prices, may include those to increase agricultural and livestock production, to commercialize agriculture, to hold buffer stocks, and to subsidize consumer food prices. In addition to food policies, there are also other macroeconomic policies that influence the availability and consumption of food. An overvalued foreign exchange rate, for example, may discourage farmers from producing food because imported food can be cheaper. Similarly, food production can decline when industrial development is carried out at the expense of agricultural development.

Nutrition interventions, however, include food fortification, the use of formula foods, supplementary feeding programs, food-for-work and food-for-cash programs, and nutrition education. The boundaries between economic and nutrition interventions are not always distinct. Supplementary feeding and food-for-work programs, for example, can be considered as consumer food-price subsidies or as income transfers.

This chapter reviews the different economic and nutrition interventions that are used as policy tools to increase the energy and nutrient intakes of the poor, thereby increasing their household food security and the nutritional status of their infants and young children.

Economic Interventions

Agricultural and Livestock Production

Increased agricultural and livestock production are often prerequisites for food security because they generate additional amounts of both food and income. Increasing productivity, however, entails changing or modifying an existing production system to make it more cost-effective. This may be achieved in a number of ways: first, by increasing yields per unit of land area or worker; second, by ensuring the availability of sufficient inputs – fertilizer, pesticides, and so forth; and last, by establishing price relationships that can act as an incentive to both innovation and the mobilization of resources (Mellor undated).

Improved technology. The Green Revolution, through the use of improved technology, was instrumental in expanding world food production during the 1970s – in particular that of rice and wheat in Asia. Similar approaches are needed for the staple food crops grown in other parts of the world, especially in Africa. Specifically, attention needs to be given to root crops as well as to the more drought-tolerant cereals, such as sorghum and millet.

Expanding the area under cultivation and increasing cropping intensity are the means of increasing agricultural production, be it for home consumption or for sale. Outside of Africa, there is little scope to expand the area under cultivation. However, through the wider use of those improved crop varieties that are more resistant to pests and diseases, farm yields could be stabilized. The greater use of early-maturing varieties, which shorten the growing season, would also allow for multiple cropping. Intercropping, too, increases overall yields, stabilizes production, and allows food to be grown throughout a longer season. Management issues such as pest and disease control, the use of crop residues and animal manure as fertilizer, and soil conservation also help to augment yields and at the same time to lower the costs of production. Livestock productivity can be increased through better disease and parasite control. This not only results in farmers' getting a better yield of milk and a better price for their dairy products or meat but also improves the work performance of draft animals and thus the asset value of the animals themselves. An increase in agricultural and livestock production can result in an improvement in the nutritional status of households through increasing household food security, which can in turn reduce the risk of infants and young children from becoming undernourished.

Land reform. There is a great deal of evidence to show that small farmers are more productive per unit of land than are large farmers (Lipton 1985). This is because small farmers depend on family labor to grow high-value or double crops, to improve land in the slack season, to reduce fallow lands in area and duration, and to enhance yields through better cultivation practices. Large farmers tend to use imported machinery as a labor-displacing strategy, and such machinery depends on imported fuel and spare parts (Norse 1985; Longhurst 1987).

The inequality in both land ownership and tenure systems is the primary cause of poverty in the rural areas of Asia, Latin America, and, to a lesser extent, Africa (Norse 1985). Access to land clearly determines access to food and income (Braun and Pandya-Lorch 1991). Landless households that depend on the sale of their labor for survival are nutritionally the most vulnerable group. Sharecroppers and tenant farmers, who give part of their crop or work at peak agricultural times in lieu of rent, and very small farmers, are also extremely vulnerable nutritionally.

Availability of inputs and services. Unless soils are replenished, the production potential of land slowly declines as soil nutrients are depleted. Inputs, particularly fertilizer and water, are needed in order to maintain production levels. The money needed to finance these inputs, generated through credit, as well as an advisory service in the form of agricultural extension services, must be available. Both inputs and services should be available to women as well as to men because a great number of women are already involved in agriculture and dependence upon women's earnings increases as employment for men falls (Mencher 1986).

In addition to inputs and services, it is essential that the reliability and efficiency of the marketing infrastructure for both food and nonfood commodities be improved if farm income levels are to be raised. Distortions in policies that adversely affect the availability of agricultural inputs and services to the small farmer will limit any improvement in agricultural production and, ultimately, influence income and the nutritional status of young children.

Commercialization of Agriculture

The integration of small farmers into a market economy entails a shift from subsistence food crop to cash crop production. However, increasing the production of cash crops at the expense of domestic food crops can disrupt traditional economic and social relationships. This, in turn, may have an adverse impact on the income, food consumption, and nutritional status of the poor (Senauer 1990). The evidence to support this theory, however, is mixed, with some studies showing commercialization having a positive effect on nutritional status (Braun and Kennedy 1986; Braun 1989) and others showing either no effect (Kennedy and Cogill 1987) or a negative one (Pinstrup-Anderson 1985; Kennedy and Alderman 1987).

Commercialization of agriculture need not necessarily be detrimental to nutritional status for two reasons. First, even though the promotion of cash crop production may decrease domestic food production, the foreign exchange generated from agricultural exports can more than offset the cost of importing food for the domestic market. Second, nutritional problems are not necessarily the result of a lack of food, but may be caused by a lack of access to sufficient food, which in itself is determined by income levels and food prices. Thus, increasing the income of poor farmers, whether from food or nonfood crops, rather than simply increasing production, should be a priority for agricultural production programs.

In general, part of any increase in income is spent on food. Among the poor, the additional proportion spent on food may be quite high. This does not, however, necessarily mean that more energy will be consumed, because families may diversify their diet rather than increase the absolute quantity of the foods they already eat (Braun and Kennedy 1986). Thus, an increase in income alone will not necessarily result in better nutrition, and other interventions, such as nutrition education, are also needed.

Another aspect of commercialization is that income flow, as opposed to total income, is important in determining the impact of income on nutritional status. A lump sum of money, such as that generated from growing cash crops, is more likely to be spent on nonfood items such as school fees or housing, whereas continuous income is more likely to be spent on food (Kennedy and Alderman 1987).

The status of the person who controls the household's money may also be important. In many developing countries, the income generated from commercial crops is viewed as belonging to men, whereas that from food crops goes to women (FAO 1987). When women have some decision-making power, they are more likely than men to purchase food and health care (Kennedy and Cogill 1987). In some countries, such as India, the money earned by mothers has been found to have a greater impact on child nutrition than that from other income sources (Kumar 1979). Braun and Pandya-Lorch (1991) have claimed that women spend more of their income on food, whereas men spend their income according to personal taste on either food or nonfood items. This observation has important implications for programs that encourage expanding the cultivation of a particular crop that can change the way in which a household's land is allocated for food and nonfood crops. Any program that reduces the amount of land available for food production without altering the control and use of income can adversely affect nutritional status.

Type of income can also influence consumption patterns. In India, S. Kumar (1979) found that payment in kind, rather than in cash, was used for consumption. Likewise, J. Greer and E. Thorbecke (1983) noted that in Kenya, income from food production rather than from off-farm work was associated with increased food intake. E. Kennedy and H. Alderman (1987) suggested that income from home gardens and home production was more likely to increase household food intake than was an equivalent amount of cash income. This interpretation emphasizes the importance of the role of women in agricultural programs, given that, in general, they control the food produced for household consumption and the income generated from the sale of food crops. Obviously, their position has important implications for child nutrition.

Buffer Stocks

Buffer stocks are strategic food stores that are used to meet fluctuations in demand, or to accommodate fluctuations in supply, when there are no alternative sources of food. Buffer stocks are primarily used to stabilize prices – for example, at times of harvest failure or just prior to the harvest season when supplies are low.

In order to stabilize prices, buffer stocks should be released onto the market and sold at a controlled, or intervention, price once a predetermined consumer "ceiling price" has been reached. Over time, the intervention price, paid by the consumer, needs to fall, as does the producer price. In order to avoid a decline in production associated with the use of buffer stocks, grain has to be bought up when the producer price on the free market falls below a predetermined "floor price."

The margin between the floor price paid to farmers and the ceiling price paid by consumers is crucial to the stabilization desired from the use of the buffer stock. If the range is wide, so that the floor price is low and the ceiling price high, then net flows of food will be small and infrequent. This situation will allow stock levels to be relatively small, but the effect on the market will also be small. In contrast, if the margin is too narrow, then the floor price may rise above the producer price or the ceiling price below the consumer price. This will cause stock levels to fluctuate wildly. Thus, the narrower the margin the larger the food stock required to maintain it, but the greater the stability in prices.

Political pressure – from farmers (to increase producer prices) and from urban consumers (to keep consumer prices low) – can undermine a buffer-stock scheme, as can private commodity dealers. For buffer stocks to be effective in stabilizing prices, the operators must have foresight and knowledge about the different types of price fluctuations (regional, seasonal, annual, inflationary, and so forth). In addition, the administration of buffer stocks should be independent so as to resist political pressure. Finally, storage costs of the buffer stock should be low (Streeten 1987).

Buffer stocks are both difficult to administer and expensive to maintain. For example, 1 ton of buffer-stock wheat held in the Sahel can cost $500 (U.S.), as compared with a price of $200 (U.S.) per ton (including freight) for wheat purchased on the world market (Streeten 1987). Aside from capital costs (such as warehouses, staff training, and the initial cost of the grain) and recurrent costs (wages, pesticides, building maintenance, and so forth), buffer stocks incur such additional costs as the interest on the funds tied up in the stock, the value of losses caused by pests, and losses resulting from deterioration in quality. S. Maxwell (1988) suggests that these additional costs may be larger than the capital or maintenance costs, although they are rarely included in estimates of buffer-stock costs. In Sudan, for example, these additional costs were equivalent to 40 percent of the purchase price of sorghum.

Buffer stocks have been used as a means to get grain to food-deficient areas in Indonesia (Levinson 1982) and as a famine reserve in Ethiopia (Maxwell 1988). These programs were implemented with the assumption that the poor, who are the most nutritionally vulnerable, would not suffer from any further deterioration in nutritional status.

Consumer Food-Price Subsidies

Consumer food-price subsidies are essentially income transfer policies that enable consumers to buy food at a lower price. They exist because cheap food is often regarded as a nutritional as well as a political necessity (Pinstrup-Anderson 1985, 1988).

Food subsidies have been found to have a positive impact on nutritional status in a number of countries (Pinstrup-Anderson 1987). This impact has been achieved in three ways. First, food subsidies increase the purchasing power of households because their members can buy more food for the same price. Second, they may reduce the price of food relative to the price of other goods, thus encouraging households to buy more food. Third, they may make certain foods cheaper relative to others and thereby change the composition of the diet.

Food subsidies, however, are not necessarily the most economic means of increasing the food intake of the poor. This is because they benefit all income levels: The rich, who do not need the subsidy, gain more than the poor because the rich can afford to buy more of the subsidized food. In addition, households do not necessarily increase their intake of the subsidized food; they may instead use the savings from its availability to buy other food or nonfood items that may be of limited nutritional benefit.

There is evidence, however, that food subsidies do increase the real income of the poor. In one study, food subsidies represented the equivalent of 15 to 25 percent of total incomes of poor people (Pinstrup-Anderson 1987). Because poor households spend between 60 and 80 percent of their income on food, the economic benefit of subsidized food as a proportion of current income is larger for the poor than for the rich, even if the absolute value of the subsidy is greater for the rich.

Food-subsidy programs have also been found to increase energy intakes at the household level, although the effect at the individual level is not always apparent. In Kerala, India, Kumar (1979) found that the subsidized ration resulted in an increase in energy intake by the lowest income group of 20 to 30 percent.

Food subsidies are often considered more beneficial to urban than to rural populations. Alderman and Braun (1986) learned that the Egyptian subsidies on bread benefited the urban population more than did subsidies on wheat flour. However, the opposite was true in rural areas where there were fewer bakeries to sell subsidized bread. R. Ahmed (1979), in Bangladesh, found that although only 9 percent of the population lived in urban areas, two-thirds of the subsidized cereal went to urban consumers. In Pakistan, B. Rogers and colleagues (1981) discovered that ration shops, which sold rationed subsidized wheat flour, had no significant effect on the energy intake of the rural population, whereas that of the urban population was increased by 114 calories per capita. Clearly, the transportation and administrative costs involved in serving a scattered rural population may limit the extent of a subsidy network. In addition, the threat of political unrest in urban areas is often a reason for governments to pursue food-price subsidies.

The political and economic climate invariably determines who benefits from a food subsidy program and how the program is implemented. The effect of food subsidies on household food consumption and, ultimately, on the nutritional status of children will depend, in part, on whether there is a *general* food subsidy, a *rationed* food subsidy, or a *targeted* food subsidy. In addition, the choice of the food to be subsidized is important.

General food subsidy. A general food subsidy is one in which the subsidized price of a specified food (or foods), in the market is below that of supply. Although politically very popular, such programs may not be the most efficient or effective way to improve the nutritional status of the poor. General price subsidies are costly and may divert financial resources from other programs, such as employment creation and wage increases, that would increase the purchasing power of the poor (Reutlinger 1988). In addition, in order to help pay for the subsidy, the programs themselves may cause increases in the prices of other foods that are important in the diet of the poor.

Yet a number of countries have implemented general food subsidy programs, which, in spite of their costs, have benefited the poor. For example, wheat flour and bread are subsidized throughout Egypt at ration shops, with no restrictions on the amount that may be purchased. Oil, sugar, and rice are also subsidized, but the supply of these is rationed. In addition, there are government-controlled cooperatives that sell subsidized frozen meat, poultry, and fish. Alderman and Braun (1984) have reviewed the Egyptian program, in which over 90 percent of the population derived benefits. In 1980, the subsidies cost the government some $1.6 billion, which was equivalent to 20 percent of concurrent government expenditure. But along with the cost burden of the general subsidy, there were noticeable nutritional gains, as shown in the fact that per capita energy intake in Egypt was greater than that in any of the countries having a per capita gross national product (GNP) up to double that of Egypt.

Access to subsidized food, however, was biased toward the rich in Egypt for a number of reasons (Alderman, Braun, and Sakr 1982). First, the lack of refrigeration facilities in rural areas precluded cooperatives from operating there, although ration shops were omnipresent. Second, the wealthier neighborhoods of Cairo appeared to have better supplies of the subsidized commodities, such as rice, than did the poor areas. In addition, although subsidized rationed commodities, such as oil, were not always rationed in the rich neighborhoods, oil was not even always available in the poor areas. Third, in addition to the regular cooperatives, civil servants and workers had their own workplace cooperative shops (in locations where more than 200 people were employed), which received extra allocations of subsidized meat and poultry. Fourth, wealthier households could afford to employ servants to fetch and queue for the subsidized food. Last, wealthier households could afford to pay bribes to ensure preferential access to subsidized food.

The Egyptian study found that although there were large variations in access to the subsidized food and also inequalities in the distribution system, the poor did benefit from an effective increase in purchasing power as a result of access to cheap food. Indeed, food subsidies accounted for 12.7 percent of expenditures for the lowest income quartile in urban areas and 18 percent of total expenditures of the poorest households in rural areas.

Rationed food subsidies: Dual prices. A dual price system is one in which certain quantities of food are rationed at a subsidized fixed price, and unlimited quantities are available at the prevailing market price. Typically, a household's quota for a rationed food is less than the total amount required by the household, and the difference is made up from purchases in the open market, where prices are higher. This arrangement effectively allows households to increase their expenditure on food.

Dual price systems, utilizing ration shops, have been implemented in India for wheat, rice, and small amounts of coarse grains (Scandizzo and Tsakok 1985) and in Pakistan for the wheat flour known as "atta" (Alderman, Chaudhry, and Garcia 1988). The ration price in India was 60 percent, and that in Pakistan 51 percent, of the open market price.

Targeted food subsidies: Food stamps. A food-stamp program is one in which coupons are sold to a selected target group who may then buy specific foods of a stated value in authorized stores. The store cashes in the coupons at a bank and the bank is reimbursed by the government. The rationale behind food stamps, in contrast to cash transfers, is that households are more likely to increase food intake with transfers in kind rather than in cash (Kumar 1979). In other words, "leakage," meaning the purchase of nonfood items or more expensive "prestigious" food, is lower. Kennedy and Alderman (1987) noted that unless the value of the food stamps is more than that which a household would normally spend on food, there is no reason to expect the nutritional effect to be greater than that of giving a direct cash transfer. If, however, the cost of the coupons is close to that which the household would normally spend on food but the quantity of food that can be purchased with the coupons is higher, then the nutritional effect would be larger than that of a cash transfer. This is because, in addition to the income effect, food is cheaper at the margin. An example frequently cited is that of the U.S. food-stamp program, which until 1979 enabled a household to spend, say, $100 (U.S.) to receive $150 (U.S.) worth of food stamps.

Although it has been argued that food-stamp programs are costly to implement, S. Reutlinger (1988) has pointed out that the direct costs of administering a food-stamp program could be small because it brings in customers, so there would be no need for shops or banks to charge for processing the coupons. In addition, marketing costs may fall, which could lead to lower food prices because of an increased volume of shop sales. Thus, the only administrative costs are for printing the coupons, handling the distribution, and regulating against abuses.

As with all food-distribution programs, identifying the target group is not easy. Colombia, for example, has had a program in which only households in low-income regions with young children and pregnant or lactating women were eligible to participate. Coupons were distributed through health centers, where growth monitoring and nutrition education were carried out concurrently. The value of the food stamps was 2 percent of average income, but there was no evidence that the nutritional status of the target group improved (Pinstrup-Anderson 1987). In Sri Lanka, only households whose "declared" incomes were below a specified level could receive food stamps. However, this restriction meant that wage-earning workers on the tea estates where hunger was present did not qualify for food stamps even though they were one of the nutritionally most needy groups (Edirisinghe 1987).

In order to increase food intake and, thus, the nutritional status of the poor, the value of the food stamps must be indexed to inflation. This was not done in Sri Lanka, and so, over a four-year period, the value of the food stamps declined to 56 percent of their original value. The net result was that the already low total energy intake of the poorest 20 percent of the population declined by 8 percent.

Like other food-price subsidy programs, coupons do not necessarily result in increased consumption if the food issued does not meet the perceived needs of the household. The latter will depend on a household's composition and food preferences. In Colombia, for example, the foods that could be purchased with food stamps included highly processed foods not normally consumed by the poor.

In addition, the need for cash to buy the coupons often discriminates against the neediest households, which do not always have a regular source of cash. Moreover, even when a household does have income, it may not be sufficient to cover the cost of the coupons. But unfortunately, setting up a progressive program in which the price of the coupons is based on what a household can pay is not feasible in many societies (Pinstrup-Anderson 1987).

Choice of subsidized food. Most programs subsidize a staple cereal, and when the entire population consumes significant quantities of that staple, the cost can become prohibitive. In order to cover the costs and ensure that the poorest sections of the population benefit, the selection of the food to be subsidized is critical, particularly where more than one food is considered a staple. In Brazil, for example, C. Williamson-Gray (1982) found that subsidizing wheat bread resulted in a decrease in the energy intake of the poor. This was because the poor substituted the still more expensive subsidized bread for rice and other foods, thus decreasing their total intake of food. Williamson-Gray suggested that subsidizing cassava, rather than wheat, would have been better. Such a subsidy would have effectively increased the income of the poor because cassava is not prominent in the diet of the rich.

It has been pointed out that where "inferior" foods are subsidized, the subsidy program becomes self-targeting toward the group that consumes the "inferior" food. For this to happen, however, the "inferior" food must be consumed by a large proportion of the targeted population. Various studies cited by P. Pinstrup-Anderson (1988) indicate that subsidizing highly extracted wheat flour benefits the poor more than the rich largely because the latter perceive such flour as lower in quality because of its physical appearance.

As can be seen, a range of economic policies have been used, directly or indirectly, to improve food security among the poor. Undernutrition is inexorably linked with poverty, and unless poor households have the ability and resources to feed themselves, their infants and young children will suffer. For this reason, the focus of food-related economic policies has been at the household level.

Nutrition Interventions

Like economic interventions, nutrition interventions can be targeted or nontargeted. Once implemented, nontargeted interventions, such as food fortification, protect the entire population against a specific nutrient deficiency from an early age. Targeted interventions, such as the use of formula foods, feeding programs, and nutrition education, attempt to focus specifically on infants and young children, although many also include pregnant and lactating women. This section reviews the most commonly used nutrition interventions: food fortification, formula foods, supplementary feeding programs, and nutrition education.

Food Fortification

Food fortification is the addition of specific nutrients to foods. It can be used to restore nutrients lost in processing or to increase the level of a specific nutrient in a food. Examples of fortified food commonly consumed in developing countries include milk containing vitamin D (originally introduced to prevent infantile rickets) and salt to which iodine is added (to prevent goiter).

To ensure that the most vulnerable members of the population benefit from food fortification, the vehicle for fortification must be a staple food consumed throughout the year by a large proportion of people with relatively little inter- and intraindividual variation. Intake levels must be self-limiting to minimize the possibility of toxicity. The level of fortification must be such that it contributes significantly to nutritional requirements without altering the taste, smell, look, physical structure, or shelf life of the food vehicle. Because control and monitoring procedures must be adopted at the manufacturing level to ensure that fortification levels are adequate, legislation may be necessary (International Nutritional Anaemia Consultative Group 1977, 1981; Bauernfeind and Arroyave 1986; Arroyave 1987).

The advantages of food fortification are many. Such a procedure is socially acceptable; it does not require the active participation of the consumer; it requires no changes in food purchasing, cooking, or eating habits; and the fortified food remains the same in terms of taste, smell, and appearance. Because the product to be fortified should already be marketed and have a widespread distribution system, fortified food can be introduced quickly; its benefits are readily visible; legislation for compliance is possible; its use is relatively easy to monitor; it is the cheapest intervention for a government; and it is the most effective sustainable method of eliminating a micronutrient deficiency (International Nutritional Anaemia Consultative Group 1977, 1981; Bauernfeind and Arroyave 1986; Venkatesh Mannar 1986; Arroyave 1987).

The main disadvantage of food fortification is that although it is applied to a food that is processed and marketed throughout a society, only those who consume that food will benefit. Fortification, for example, will not benefit people who use only locally produced or unprocessed foods. Other disadvantages are that fortified food reaches nontargeted as well as targeted individuals and may not be the most economical way to reach the target group. Moreover, when the cost of fortification is passed on to the consumer, purchasing patterns may change adversely among those most intended to benefit. Fortification also involves recurring costs. Finally, political will, legislation, and mechanisms to enforce decisions to fortify foods are necessary to ensure the success of such programs (Bauernfeind and Arroyave 1986; Arroyave 1987).

Among the nutritional deficiencies of children for which the use of fortified foods has been advocated in the developing world are the control of xerophthalmia, or night blindness (International Vitamin A Consultative Group 1977), goiter (Dunn and van der Haar 1990), and nutritional anemia (International Nutritional Anaemia Consultative Group 1977, 1981; United Nations 1991). One example of the use of a specific commodity as a vehicle for vitamin A fortification to control xerophthalmia is sugar in Guatemala (Arroyave 1986, 1987). Another is the use of vitamin A–fortified monosodium glutamate in the Philippines (Latham and Solon 1986) and Indonesia (Muhilal et al. 1988), although large-scale programs have not been implemented. Iodization of salt to control goiter has been successfully introduced in China, India, and 18 countries in Central and South America, although in the latter case, some countries have had a recurrence of iodine deficiency due to a lack of continuous monitoring and control measures (Venkatesh Mannar 1986). Fortification of wheat flour with an iron salt to control nutritional anemia is being implemented in Grenada. Trials on other nonfortified foods have been implemented in a number of developing countries. In Thailand, for example, fish sauce, a widely used condiment, is fortified with an iron salt (WHO 1972). In South Africa, curry powder has been fortified with iron EDTA (ethylenediaminetetraacetic acid) (Lamparelli et al. 1987), and in Chile, reconstituted lowfat milk is fortified with an iron salt, whereas wheat biscuits have been fortified with bovine hemoglobin (Walter 1990).

Formula Foods

Formula foods are premixed foods made from unconventional sources. They may be made by combining a local cereal grain with a vegetable/pulse protein rich in the amino acids deficient in the cereal. Originally, formula foods were developed as low-cost milk substitutes to be fed to weaning children. Two classic examples are a milk substitute made from corn and cottonseed flour (INCAPARINA), and corn-soya-milk (CSM). CSM is an important food-aid commodity and a major staple of many ongoing supplementary feeding programs.

The advantages of formula foods are that they are cheaper than conventional sources of animal protein, vitamins, and minerals and can be formulated to meet the specific nutritional needs of a target group while providing energy at the same time. In addition, they do not require cold storage.

The disadvantages are that although the costs are less than those of animal protein supplements, they are higher than those of cereal staples because of manufacturing and distribution costs. The main beneficiaries of formula foods tend to be urban populations because the formula foods are generally sold through commercial channels and can become prohibitively expensive in rural areas. B. Popkin and M. C. Latham (1973) estimated that formula foods were priced at between 8 and 40 times the cost of homemade traditional foods on a nutrient-per-dollar basis. In addition, a lack of familiarity with formula foods may result in low levels of acceptability. Thus, on balance, the use and potential of such foods appear to be somewhat limited in terms of developing countries, particularly in rural areas.

Supplementary Feeding Programs

Supplementary feeding programs are conducted at health centers, schools, or community facilities, which have the advantage of keeping capital outlays low by using existing institutional infrastructures. They also facilitate decisions on intrahousehold food distribution in situations when food and income are limited. Politically, such programs are acceptable because they often generate support among the recipients.

There are, however, disadvantages involved in feeding programs. First and foremost is their cost. Apart from the possible cost of the food (which may or may not be donated food aid), there are the administrative and operational expenses of the program. These include those of transport, storage, wages, overhead, physical plant, fuel, and cooking utensils. In addition, the operation of feeding programs in health centers or schools imposes extra work on the staff, which may be detrimental to the institution's core concerns and thus is itself a hidden cost. Further questions include whether the intended beneficiaries actually participate in and benefit from the program, whether a feeding program based on imported food aid encourages black marketeering, whether the food is used for political ends, and whether feeding programs create psychological, nutritional, and political dependence.

Participation in any feeding program depends upon a number of factors, which ultimately determine the success of the program when that success is measured in terms of an improvement in nutritional status. Criteria for success include the quality and quantity of food reaching the recipients, the regularity of supply, the timing of meals, the nutritional status of the participants, and the degree of targeting.

The quality of foods served in a feeding program is important in enhancing the overall quality of the diet provided. For example, powdered milk fortified with vitamins A and D is preferable to unfortified milk. Where premixes are employed, the addition of sugar to an oil/cereal base or oil to a sugar/cereal base not only increases the energy density of the food but also renders it more palatable and, thus, increases the likelihood of its being eaten. The use of premixes has both advantages and disadvantages. On the positive side, leakage of one of the commodities (sharing or selling the commodity) is restricted, especially if a high value is put on a particular food. On the other hand, although premixes may be made up of foods that are consumed locally, the appearance and consistency of a cooked premix may be alien to the intended beneficiaries.

The quantity of food each participant receives is critical to the success of any feeding program. In general, "average" rations are based on the extent to which the general diet is deficient in both energy and specific nutrients. But no allowances are made for individual variation or for leakage. Thus, Kennedy and Alderman (1987), for example, cite a CARE review finding that in four feeding programs, 62 to 83 percent of the total energy gap was the fault of the supplementary foods. In yet another feeding program in India, sharing reduced the amount of the ration consumed by child beneficiaries by 50 percent.

Minimizing leakage through the use of increased rations, or by having on-site feeding programs, will inevitably add to costs, but these measures are more likely to encourage attendance and produce viable results (Kennedy and Knudsen 1985). One difficulty encountered in all supplementary feeding programs, regardless of leakage, is ensuring that children actually eat an adequate amount of food. Undernourished children are often anorexic. Their total intake is likely to be greater if they are fed on a "little and often" basis rather than at set meals. This means that on-site feeding centers need to operate beyond conventional working hours and may require additional staff.

The regularity of supply of supplementary food is essential for it to have an impact. Regularity, however, can be impaired by transportation and bureaucratic constraints. Any uncertainty in supply can result in a reluctance on the part of local administrators to invest either time, personnel, or resources in a supplementary feeding program. Uncertainty in supply may also jeopardize existing programs by generating ill will among the recipients, especially if they have to travel or wait for food that fails to arrive.

The timing of the issuance of supplementary meals is also important for two reasons. First, it influences how much food a child will eat, and second, it may determine the extent to which the supplementary meal is considered as a substitute for the home meal. A meal served early in the morning is unlikely to be fully eaten by a participant if the individual has already eaten at home. At the same time, it may deter a mother from giving her child an adequate meal first thing in the morning if she knows there will be one at the feeding center. The same consideration applies to other supplementary meals given near the times that meals would normally be eaten in the home. To overcome this effect, feeding programs in some countries (for example, Guatemala) changed the time at which the food was distributed so that it was perceived as a "snack" rather than a meal (Anderson et al. 1981; Balderston et al. 1981).

The initial nutritional status of the participants in a feeding program influences the success of the program. Indeed, the greatest benefit from a supplementary feeding program ought to be seen among the most undernourished children (Beaton and Ghassemi 1987). For this reason the "targeting" of feeding programs becomes very important (Kennedy and Knudsen 1985; Kennedy and Alderman 1987).

Yet targeted programs are often politically difficult to implement because they involve singling out one group of people, which may not be socially or culturally acceptable. Conversely, groups not in nutritional danger, who want to benefit from what is perceived as a "free handout," should be excluded. In order to target successfully, there must be some criteria with which to identify the intended beneficiaries (Anderson 1986). All too often, the data for doing this are limited (Cornia 1987).

Where undernutrition is widespread, feeding programs that are well targeted geographically can be effective in reaching the nutritionally disadvantaged population. This type of targeting is generally used in drought situations – for example, in Sudan and Ethiopia between 1984 and 1986. Geographic targeting is appropriate for areas in which there is a concentration of intended beneficiaries. Kennedy and Alderman (1987) have suggested that if less than 20 percent of households or children in an area are nutritionally needy, then geographic targeting on its own is unlikely to be an effective tool.

Once vulnerable individuals have been identified, targeting at the community level can be directed at households or individuals. This will largely depend on whether the program aims to improve the energy intake of vulnerable households or only that of vulnerable children and women. At the community level, targeting often relies on some arbitrary cutoff point using nutritional criteria such as weight-for-height, weight-for-age, and in some cases, middle-upper-arm circumference. Children are enrolled in and discharged from feeding programs based on nutritional status criteria. Once a child reaches and maintains an acceptable level of nutrition for a specified time period (at least one month), he or she can be discharged from the program.

Because undernutrition often involves not only a simple food deficit but also problems of sanitation and hygiene, it is important to address these factors as well so as to reduce the likelihood of children being caught in the undernutrition–morbidity cycle that inevitably ends in their being readmitted into a feeding program.

A feeding program must not overlook the importance of maintaining an improved nutritional status once it has met its objectives, and the causes of undernutrition have been removed (Pinstrup-Anderson 1987). G. H. Beaton and H. Ghassemi (1987) have suggested that although the implementation of a feeding program may improve nutritional status, it may also disrupt the equilibrium between a community and its environment. Because of this, when a feeding program is terminated, it is essential that it be phased out over a period of time in order to ensure that the positive results of the program are not lost and that the circumstances that led to the establishment of the program in the first place do not occur again.

Supplementary feeding programs fall into four categories: on-site, take-home, school, and community programs. Each of these can also be used as a vehicle for nutrition education, which is an essential component of any feeding program that hopes to modify nutritional behavior.

On-site and take-home feeding programs. On-site and take-home feeding programs are generally aimed at children 6 months to 5 years old, women in the last trimester of pregnancy, and women in the first six months of lactation. On-site programs involve the beneficiaries' attendance at a feeding center once or twice a day to receive food rations, whereas take-home programs distribute rations at regular intervals.

As previously mentioned, on-site programs tend to cost more than take-home programs, and although the beneficiaries of the former are more likely to consume the food themselves, the coverage of such programs is usually limited in both area and numbers. In addition, there is some evidence that the supplementary food is more likely to serve as a substitute (rather than a supplement) for the food that would otherwise be eaten at home (Beaton and Ghassemi 1987). Kennedy and Alderman (1987) point out that because a household operates as an economic unit, it attempts to promote the well-being of all its members. A child who receives food at a feeding center may be considered to have been fed already and is thus given less food at home, with a resulting net energy intake that is considerably lower than intended by the planners of supplementation. There is also the danger that when the responsibility for feeding a child is removed (albeit temporarily) from the mother, undernutrition may come to be regarded as a disease to be cured through outside interventions, rather than through a reallocation of resources within the household.

Take-home programs have more scope for leakage than do on-site programs because the food may be shared among the whole household or sold. M. Anderson and colleagues (1981) compared supplementary feeding programs in five countries and found that 79 to 86 percent of children attending on-site feeding centers ate their ration, whereas only 50 percent of children receiving a take-home ration did so.

Distributed food is more likely to be shared if it is a food that is widely accepted by the local population as appropriate for consumption. Indeed, Beaton and Ghassemi (1987), in their review of over 200 reports on feeding programs, found that sharing accounted for 30 to 60 percent of the food distributed, and the overall net increase in food intake of the target population was only 45 to 70 percent. The investigators concluded that on-site and take-home programs are not effective in reaching children less than 2 years of age, although such children are nutritionally a very vulnerable group. The reasons cited for failing to enroll children younger than 2 years included the use of unfamiliar weaning foods that are considered inappropriate by mothers, as well as the mothers' lack of knowledge about feeding children of this age.

Because of the time often required for travel to a feeding center, feeding programs may suffer from low participation and low attendance and have difficulties in reaching the most vulnerable groups. In their review of feeding programs, Beaton and Ghassemi (1987) found that participation rates were 25 to 80 percent of the intended level of distribution. Low participation and attendance result in part from the fact that mothers are often working, either domestically (collecting water or firewood, preparing food, looking after a large family, and so forth), or on their land, or in the informal sector. Participating children left with older siblings do not always benefit from the feeding program because the older children may not know how to prepare the supplementary food or not understand its importance. Indeed, experience in Sudan showed that older children were more interested in playing than in bringing an undernourished child to a feeding center on time or in attempting to feed a child who was anorexic.

School feeding programs. School feeding programs have been widely adopted in many countries. Such programs encourage school enrollment and attendance and improve school performance and cognitive development (Freeman et al. 1980; Jamison 1986; Moock and Leslie 1986). Many, however, operate only during the school year. School meals may replace, rather than supplement, meals eaten at home, although in situations when the mother is not at home during the day, it is questionable whether the child would get a midday meal anyway. In the latter situation, the advantage of the school meal outweighs the disadvantage of its possibly being a replacement meal. In India, school feeding programs were found to influence household expenditure patterns because school meals were cereal-based, which allowed households to spend less money on cereals and more on milk, vegetables, fruits, and nonvegetarian foods (Babu and Hallam 1989).

Among the poor, however, school-age children are often required to work to augment the household's meager income or to look after younger siblings while the adults work. Indeed, in many situations, children from the most vulnerable households are the least likely to be at school and, thus, the least likely to benefit from a school feeding program.

Community feeding programs. Strictly speaking, community feeding programs provide replacement or substitute rather than supplementary meals. Community-organized mass feeding programs, known as *comedores,* have been implemented in Lima, Peru (Katona-Apte 1987). There, members of a group of women take turns preparing morning and midday meals. Standardized portions are sold at set prices to participants, whose entitlement depends on household size. The money collected is used to purchase foods additional to those contributed by donor agencies. Households pay for meals depending upon their circumstances, although the *comedor* does limit the number of free meals it issues each day.

The advantage of community feeding programs is that they benefit from economies of scale. Thus, not only the quantity but the quality of the meals will most likely be nutritionally superior to that of meals that would have been prepared at home. Communal kitchens also afford participating mothers more time for other activities, and yet one more benefit of a community-based program is that it gives women the opportunity to interact with and help each other.

The disadvantages of community-based feeding programs are that they do not allow for individual food preferences and that they take the control and responsibility of feeding the family away from the household. This runs the risk of child undernutrition coming to be perceived as a problem that the household cannot solve.

Food-for-Work and Food-for-Cash Programs

Food-for-work (FFW) and food-for-cash (FFC) programs are indirect nutrition interventions involving labor-intensive employment programs. Such programs effectively subsidize labor through the provision of either food or wages as remuneration, thereby improving a household's access to food and reducing the risk of child undernutrition. The short-term outcome of such programs is the creation of employment for the poor, whereas the long-term one is income generation for both poor and nonpoor through the development of an asset base (Biswas 1985; Stewart 1987; Braun, Teklu, and Webb 1991; Ravallion 1991).

The participation and involvement of both the local community and government in the design and implementation of the program is essential if the poorest people, who generally have no power base, are to participate in and benefit from it. Payment, whether in cash or as food, must be determined by the prevailing food-market conditions (Braun et al. 1991). Poor people already spend a large proportion of their income on food, and any increase in income is generally translated into further food purchases (Alderman 1986; Braun and Kennedy 1986). In order to ensure that this change takes place, the existing food market must be such that it can cope with the increased demand without price increases that will negate some positive effects of the program.

There are numerous advantages to FFW or FFC programs in terms of improving household food security and, thus, nutritional status. First, because of their relatively low level of remuneration, they do tend to reach the poor and are, consequently, self-targeting. Second, they are relatively low-cost in relation to the jobs they create. Third, they develop and improve a much needed infrastructure. Fourth, they increase local purchasing power. Fifth, they increase food demand through the generation of income for the poor, which will stimulate the local market. Sixth, there is no notion of charity. Seventh, they enable communities to be involved in their own asset creation, including that of environmental sanitation, thereby reducing the morbidity–undernutrition risk. Eighth, they can be implemented in the slack agricultural season, thereby reducing seasonal fluctuations in income and, thus, dependency on moneylenders in rural areas (Biswas 1985; Stewart 1987; Braun et al. 1991).

The constraints of FFC and FFW programs are that many developing countries – particularly in Africa – do not have the institutional capabilities to set up, monitor, and maintain them. In many situations, it is not easy to determine the wage rate or to identify suitable small-scale infrastructural projects. In addition, the quality of the work carried out may be poor because of insufficient funds or inadequate work performance. Finally, the programs depend not only on the existence of surplus labor but also on the willingness of the laborers to be mobilized (Braun et al. 1991; Ravallion 1991).

Funds for FFW or FFC programs are generated through food aid, which can be used directly or indirectly, with the latter meaning that the food is sold and the proceeds are used to subsidize the program. As a result of administrative costs, food aid has been estimated to cost between 25 and 50 percent more than purely financial aid (Thomas et al. 1975; World Bank 1976), and food aid is not appropriate in rural areas with surplus agricultural production because it can depress local prices and incomes.

Nutrition Education

The main purpose of nutrition education is to change behavior patterns that determine the distribution of food within a household so as to reduce any intrahousehold inequality in nutritional status. However, without a proper understanding of the problems and constraints that households face, nutrition education on its own will have little impact. For example, if income is the most limiting factor, then education to reallocate income or food within the household is unlikely to be effective (Pinstrup-Anderson 1987). Indeed, nutrition education is likely to be useful only when households are capable of responding – for example, when a large proportion of the budget is spent on nonessential goods.

The most widely used themes in nutrition education are the encouragement of breast feeding; the introduction of appropriate food supplements for breast-fed infants between the ages of 4 and 6 months; the best use of scarce money to purchase the cheapest combination of nutritious food; the minimization of food wastage through improved food preparation and preservation; safer food preservation procedures; and ways to cook more efficiently, thereby saving on fuel costs (Manoff 1987). However, each theme cannot be treated as a discrete educational entity. For example, the promotion of breast feeding is related to the nutrition of both pregnant and lactating women, the introduction of weaning foods, the prevention and control of diarrheal disease, the adverse marketing practices of commercial breast milk substitutes, changes in hospital practices, and changes in policies such as paid maternity leave and provision of nurseries at the workplace.

Nutrition education techniques have relied largely on mass media campaigns and face-to-face communication through maternal-child-health clinics, women's groups, agricultural extension agents, and so forth. Few, however, involve the community, although R. C. Hornik (1987) and R. K. Manoff (1987) have suggested that unless communities develop the messages and undertake the administrative and financial responsibility for nutrition education programs on their own, it is unlikely that nutrition education will be effective on a large scale. If people pay for a service, however, they will use it and change their behavior.

Although the mass media has the potential to inform a large number of people, the number of people who can be reached in the lowest economic strata – nutritionally the most vulnerable – is generally not large. Irrespective of literacy levels, the majority of people in developing countries do not have access to newspapers, and there are only about 170 radios and 40 televisions per 1,000 people in the entire developing world (United Nations Development Program 1990). Moreover, in many developing countries there are multiple languages and dialects, as well as differing religious beliefs, ethnic groups, and cultural practices. Nationalized mass media messages may, therefore, not be very appropriate.

Women comprise the majority of the 870 million illiterate adults in the developing world (United Nations Development Program 1990). But mothers are not the only ones to whom messages need to be directed in order to effect a change in behavior. The medical profession, too, could play a much larger role than it currently does. In addition, schoolchildren, religious leaders, and the members of any institutionalized program have a role to play in nutrition education. If behavior is to be truly changed, however, the focus must be on ways to educate and communicate both relevant and appropriate nutrition advice.

The preceding sections show the range of nutrition policies that may be used to improve the nutritional status of infants and young children. Each policy has been analyzed in terms of its benefits and constraints, but it is difficult to ensure that the most nutritionally vulnerable children do, indeed, benefit from an intervention. For this reason, it is more appropriate to identify the vulnerable groups – that is, poor households with specific characteristics – than the vulnerable children. In short, to improve the nutritional status of infants and young children, economic and nutrition interventions must be aimed at poor households.

VII.4 ~ Recommended Dietary Allowances and Dietary Guidance

To view this topic in perspective, we need answers at the outset to two questions: "What are Recommended Dietary Allowances (RDA)?" and "What purpose do they serve?" RDA are a set of *dietary standards;* they are *reference values* for the amounts of essential nutrients and food sources of energy that should be present in human diets. Standards of this type, based on the best available scientific knowledge, are needed by policy administrators, public-health officials, physicians, dietitians, and educators who have responsibility for establishing food and health policy; for providing the public with reliable dietary advice; for planning nutritionally adequate food supplies for large groups of people; and for assessing the adequacy of diets consumed by individuals or populations.

Definition of RDA

RDA for essential nutrients are defined differently from RDA for food sources of energy. For essential nutrients, the RDA values are amounts judged to be high enough to meet the known physiological needs of practically any healthy person in a group that has been specified by age and sex. They exceed average requirements to ensure that few, if any, individuals who are consuming amounts of nutrients equivalent to the RDA will have inadequate intakes. In contrast, RDA values for food sources of energy are the *average* amounts needed by the members of each group. RDA are not, in themselves, general dietary recommendations, but as standards, they serve as the scientific basis for many aspects of practical nutrition and food and health policy (FNB 1989b).

Nomenclature

The name "Recommended Dietary Allowances" for these reference values was proposed by the Food and Nutrition Board (FNB) of the U.S. National Research Council (NRC) in 1941 when it first established a dietary standard (ADA 1941). As the term "RDA" was more and more widely used, it became evident that its meaning was not well understood. It was frequently used as a synonym for requirements or with the implication that RDA were dietary recommendations for use directly by the public. The response of the FNB was to increase the specificity of the definition in subsequent RDA reports and to include an introductory section explaining the uses of RDA (FNB 1974).

In an effort to distinguish more clearly between reference values and general dietary recommendations, some national and international committees have used other names for their dietary standards. A Canadian committee called its values simply a "Dietary Standard" (CCN 1940). The Food and Agriculture and World Health Organizations of the United Nations (FAO/WHO) have usually entitled their reports "Nutrient Requirements," with the dietary standards derived from the average requirements being designated as "Recommended Daily Intakes" (FAO/WHO 1970) or "Safe Levels of Intake" (FAO/WHO 1985). The United Kingdom adopted the term "Recommended Daily Amounts of Nutrients" (DHSS 1985). Canada (HWC 1983) and Australia (NHMRC 1990) have used "Recommended Nutrient Intakes." Recently, the United Kingdom adopted the terms "Dietary Reference Values for Food Energy and Nutrients" and "Reference Nutrient Intakes" (DHSS 1991). These are the clearest and most specific terms proposed. It is hoped that they will be widely accepted and thereby reduce misunderstanding about the meaning of dietary standards.

About 40 countries have established national dietary standards; at least 10 national committees have adopted the term "RDA," and several others the FAO/WHO standards (Truswell 1987, 1990). Although definitions of dietary standards differ slightly from one organization to another, and values for some nutrients differ from one national standard to another, the various sets of reference values (regardless of the names used for them) have all been designed for the same purposes. The term "RDA" is used for the most part in this chapter, but the equivalence of this and other terms for dietary standards should be kept in mind.

Historical Perspective

Prehistoric Knowledge of Food and Health

The essentiality of specific constituents of foods for human health and survival was discovered only during the nineteenth and early twentieth centuries. The concept of dietary standards and programs of dietary guidance based on knowledge of human needs for individual nutrients are, thus, of recent origin. However, as food is a basic biological necessity, our early ancestors undoubtedly learned through observation and much trial and error how to identify safe sources of nutriment from among the vast array of natural products available to them.

They discovered that some of these products were toxic and caused illness and even death. At the same time, they learned how to cope with several potentially dangerous foods and other dietary problems. For example, the indigenous peoples of the Amazon Basin found that the poisonous cassava root could be converted into a wholesome, edible product by steeping it in water, and peoples in the Arctic region discovered that scurvy, the debilitating and often fatal disease caused by a lack of ascorbic acid (vitamin C), was prevented or cured if they consumed extracts of evergreen needles (Clark 1968). Thus, the human species learned early to distinguish among natural products that were valuable sources of food, those that had medicinal properties, and those that contained poisons (Harper 1988). Oral transmission of such information can be viewed as the earliest form of dietary guidance.

In recent prehistoric times (12,000 to 5000 B.C.), the domestication of certain plants (especially cereal grains and legumes) and animals (sheep, goats, pigs, cattle) to provide safe and dependable sources of food (Cowan and Watson 1992) was undoubtedly based on this knowledge. Also, observations about the effects of certain foods and other natural products in treating diseases expanded and, by early historic times (3000 to 500 B.C.) in Egypt, Babylonia, India, and China, had become intimately associated with an organized practice of medicine. In all of these civilizations, extensive lists of prescriptions (pharmacopoeias) were compiled, and an immense number of natural materials, especially herbs (some of which have since been shown to contain effective medicinal components) but also some traditional foods, were used as remedies for a variety of ailments.

In Egypt, for example, the onion, a good source of ascorbic acid, was recommended as a cure for a disease resembling scurvy. At the same time, much of the accumulated knowledge about the use of natural products for the treatment of illnesses was subjective and unreliable and was intertwined with mythical and magical beliefs. Major diseases were attributed mainly to supernatural causes and restoration of health to the magical or supernatural powers of the remedy or the healer (Ackerknecht 1982). Apart from improved methods of obtaining a dependable supply of food and increased knowledge of the medicinal properties of natural products, concepts of foods and nutriture during the early historic period differed little from those of the prehistoric period.

Medical Dietetics – Hippocrates to the Renaissance

In Greece, a new attitude toward food and health began to emerge between 600 and 400 B.C. Physicians of the Hippocratic school of medicine in Cos rejected the belief that magical and supernatural influences determined human well-being. They accepted the viewpoint of the Ionian philosophers that the only reliable way to learn about the natural world was through direct observation and logical reasoning. Those physicians described the symptoms of their patients and the course of diseases in great detail with remarkable accuracy, and they recognized the recuperative powers of the body and the importance of food in maintaining or restoring health. They observed: "Growing bodies have the most innate heat; they therefore require the most food for otherwise their bodies are wasted. . . . In old persons the heat is feeble and they therefore require little fuel" (Adams 1952: 131).

Diet loomed large in both their diagnosis and treatment of diseases. The Greek physicians were concerned with what to feed, along with when, how much, and how often, and developed a complex system of dietetic medicine (Fidanza 1979). Despite their many astute observations, however, they believed that health depended upon the appropriate balance of four mystical humors – blood, phlegm, black bile, and yellow bile – and their associated qualities: warm, cold, moist, and dry. They believed that imbalances among these humors caused diseases (Ackerknecht 1982). They further believed that the basic elements of matter were fire, water, earth, and air – a concept proposed by Empedocles (490 to 430 B.C.) that remained the basis of theoretical chemistry until the eighteenth century (Brock 1993) – and that foods contained only a single source of nutriment: "aliment" (McCollum 1957: 63). These erroneous concepts of chemistry and human biology and reliance on subjective observations without controlled experimental studies prevented the early Greek physicians from achieving an understanding of the chemical nature of foods, the process of nutrition, and objective knowledge of relationships between diet and disease.

The Greek era of medicine culminated with Galen, who in the second century A.D. compiled an extensive record of Greek medical knowledge and his own contributions to it. He used the experimental method to establish that urine was formed in the kidney, not in the bladder, and recognized that food must undergo transformation in the body before it can be used to form tissues. But he, too, was limited by the chemical and biological concepts of the times. Of pertinence to the present topic, however, he codified rules of personal hygiene, of healthful living. He identified health-influencing factors over which the individual could exert some control – air, food and drink, activity, rest, sleep, evacuation, and passions of the mind – and he recommended moderation in all things (Whorton 1982).

Hippocratic and Galenic concepts dominated medicine in Europe until the seventeenth century, but they were gradually discarded as science progressed. The rules for healthful living, however, persisted and were a stimulus for many health movements in the eighteenth and nineteenth centuries (Burnham 1987), probably because they were compatible with the theology of the times in providing a moralistic solution for the sins of gluttony, sloth, and intemperance to which illness was attributed. Present-day dietary guidelines are a modern version of some of these rules. The objective remains the same – guidance for healthful living with moralistic overtones – but is now bolstered by scientific observations.

Knowledge of foods, nutrition, and relationships between diet and health advanced little for over 1,500 years following the death of Galen. With the decline of the Roman Empire and the rise of Christianity, interest shifted from the body to the soul; the social and religious environment was no longer conducive to investigations of natural phenomena. The concepts and teachings of the Greek philosophers and physicians became ossified, and it was only toward the end of the Renaissance that resistance to authoritarian doctrines and a rebirth of the scientific attitude opened the way for a new era of critical inquiry.

The nature of the transition is illustrated by the career of Paracelsus (1493–1541), a Swiss physician, alchemist, magician, and necromancer (Pachter 1951). He rejected the Galenic belief that diseases were caused by an imbalance of humors and proposed that they were caused by improper diet or defective body function. He taught that foods were sources of aliment, medicine, and poison, and asserted: It is the dose that makes the poison. Despite his enlightened approach, however, he accepted the magical "doctrine of signatures," the belief that potential remedies exhibited signs of the conditions for which they were effective – the shape of the leaves of the liverwort, for example, indicated its value for treating diseases of the liver. Thus, reading the efforts of Paracelsus to express his concepts of biological processes without knowledge of basic chemistry is reminiscent of viewing Michelangelo's unfinished statues, in which the partially formed figures appear to be struggling to break out of the blocks of marble.

The Enlightenment: The Impact of Science on Nutrition

By the beginning of the eighteenth century, the power of the scientific method to expand knowledge of natural phenomena had been demonstrated in the physical sciences through the investigations of Galileo Galilei (1564–1642) and Isaac Newton (1642–1727). The essentiality of a component of air for respiration had been established by Robert Boyle (1627–91) and his colleagues. The mystical elements assumed by the Greeks – Empedocles and Aristotle – and by the alchemists to be the basis of matter were being questioned. The anatomical observations of Andreas Vesalius (1514–64) had begun to undermine the authority of Galen, and William Harvey (1578–1657) made discoveries about the nature of blood circulation that opened up new approaches to the study of respiration (Wightman 1953). Yet knowledge of food and nutrition had advanced little. The Hippocratic belief that the state of health was determined by the balance of humors was still dominant in medicine, as was the concept that foods contained only a single source of nutriment.

There were, however, a few observations of links between foods, diet, health, and disease made during the seventeenth and eighteenth centuries that may be taken as harbingers of progress to come in nutrition (McCollum 1957; Guggenheim 1981). The effectiveness of citrus fruits and fresh vegetables as cures for scurvy was reported on several occasions during the seventeenth century (Carpenter 1988). Investigations of this disease by James Lind (1716–94) in 1753 led some 40 years later to the inclusion of citrus juice in the rations of sailors in the British Navy. Earlier Thomas Sydenham (1624–89), a prestigious London physician, had observed (in the 1670s) that a tonic of iron filings in wine produced clinical responses in anemic patients. Pellagra was noted by Gaspar Casal (1679–1759) to be associated with consumption of a poor diet, and in Germany, C. A. von Bergen noted in 1754 that liver, later found to be a good source of vitamin A, had been recommended in several places as a treatment for night blindness. But although Sydenham's observations could be taken as early evidence of the essentiality of iron (McCollum 1957), and the formal action of requiring citrus juice in the rations of British sailors as the initial example of a dietary standard (Leitch 1942), they were not recognized as such at the time, probably because success in treating diseases with foodstuffs was attributed to their content of medicinal substances.

The scientific contributions of Antoine-Laurent Lavoisier (1743–94) to our knowledge of the nature of gases, the process of oxidation, and the chemical structure of matter, which built on the discoveries of many of his predecessors and colleagues (Brock 1993), finally opened the way for an understanding of the composition of foods and the functions of individual food constituents in nutrition. After Lavoisier had shown that during combustion, various metals and carbon combined with oxygen and released heat, he and Pierre Simon de Laplace demonstrated (between 1770 and 1790) that respiration by guinea pigs and human subjects was an analogous process and that oxidation of carbon compounds by the body was accompanied by the release of heat (Lusk 1964). Foods, it was now evident, were not just a source of building materials for body substance but were also a source of energy for physical activity and other body functions.

In 1816, Françoise Magendie (1783–1855) concluded, from the results of experiments on dogs fed on diets that contained only carbohydrate or fat, that food was the source of nitrogen for the body. Although his experiments were less definitive than is often assumed (Carpenter 1994), his work led to the recognition that protein was an essential dietary constituent. During this time, the major constituents of foods had been separated and identified and, in 1827, William Prout (1785–1850), a London physician and scientist, proposed that the nutrition of higher animals was to be understood through consideration of the three major food components – carbohydrates, fats, and proteins. By 1850, largely through animal-feeding studies in Europe, particularly those conducted by Jean Baptiste Boussingault (1802–87) in France, five mineral elements – calcium, phosphorus, sodium, chloride, and iron – were known to be required in the diets of animals (McCollum 1957; Guggenheim 1981). The foundation for a science of nutrition had now been laid.

Nutrients As the Basis for Dietary Advice

After these advances, making dietary recommendations based on the chemical composition of foods was a concept finally approaching reality. During the 1830s, Boussingault in France, Gerrit Mulder (1802–80) in Holland, and Justus von Liebig (1803–73) in Germany had all proposed that the nitrogen content of a food could serve as an indicator of its nutritive value. Liebig began to teach that the "plastic" (nitrogen or protein) and "fuel" (carbohydrate plus fat) constituents of foods, together with a few minerals, represented the essentials of a nutritionally adequate diet. During the 1840s, Liebig and his colleagues in Giessen prepared extensive tables for predicting relative nutritive values of foods from their content of protein and energy-yielding constituents.

Mulder probably deserves credit for proposing the first dietary recommendations for a specific nutrient. In 1847, based on studies of Dutch army rations, he recommended 100 grams of protein daily for a laborer and 60 grams for a sedentary person (Todhunter 1954). In selecting a higher value for laborers, he was conforming with Liebig's erroneous belief that muscle protein was degraded during physical activity and was replaced by proteins from foods. During the 1850s, Lyon Playfair (1818–98), a professor of chemistry at Edinburgh who also accepted Liebig's hypothesis that muscular work involved breakdown of muscle protein, undertook extensive surveys of the diets consumed by men doing different types of work as a way of assessing protein needs. He took the results of his surveys (that laborers doing heavy physical work consumed much more protein than those who were less active) as support for Liebig's hypothesis. His results were not surprising. If food is readily available, individuals doing hard work will eat more than those working less vigorously and will therefore consume more protein whether or not they need it. Nonetheless, in 1865 he concluded that healthy adults should consume 119 grams of protein daily in a diet providing about 3,000 kilocalories of energy (Munro 1964).

This approach of basing dietary recommendations on estimates of the amounts and types of foods consumed by a generally healthy segment of the population was continued throughout the century. In Germany, Carl von Voit, a colleague of Liebig, on the basis of surveys of the diets of German workers in different occupations, reached essentially the same conclusions as Playfair, as did Wilbur Atwater (1844–1907), who had worked with Voit and later studied the diets of workers in the United States. But these recommendations were not actually dietary standards; all were based only on observed intakes of active healthy people, not on measured needs.

An exception was one set of recommendations by Edward Smith (1819–74), a British physician and scientist who had done extensive experimental studies of energy expenditure and nitrogen excretion by human subjects. During the depression of the 1860s, he was requested by the medical officer of the British Privy Council to determine the quantity and quality of food that would avoid "starvation-diseases" among the unemployed (Leitch 1942). He concluded from his experimental observations that a nutritionally adequate diet for working men should provide about 80 grams of protein and about 3,000 kilocalories of energy and recommended about 10 percent less for women. His recommendations were the first true dietary standards based on experimental evidence of human requirements (Todhunter 1961).

Throughout the nineteenth century, dietary recommendations were directed exclusively toward meeting needs for protein and energy, in large measure because of the prestige of Liebig, who had asserted strongly that protein and energy-yielding nutrients (fats and carbohydrates), together with a few minerals, were the essentials of a nutritionally adequate diet. This concept was the basis for dietary advice provided to the public by the U.S. Department of Agriculture (USDA) between 1890 and 1905. Yet, as early as 1849, J. Pereira (1804–53), a British physician and Fellow of the Royal Society, had questioned the validity of Liebig's views on the grounds that diets providing adequate quantities of protein and energy, but lacking variety, were associated with the occurrence of scurvy. Subsequently, several investigators in France, Britain, and Switzerland provided strong circumstantial evidence that foods contained many other unidentified substances essential for health (McCollum 1957; Guggenheim 1981). But it was only in the second decade of the twentieth century that Liebig's concept of a nutritionally adequate diet was generally acknowledged to be untenable. This came after experiments had demonstrated that modifications of diet or provision of dietary supplements could cure diseases such as beriberi in humans and scurvy in guinea pigs, and that supplements of small amounts of milk or egg could prevent growth failure in rodents fed a diet consisting of purified proteins, carbohydrates, fats, and minerals.

Evidence that several diseases associated with the consumption of poor diets were caused by nutritional deficiencies (MRC 1932) began to affect dietary recommendations toward the end of World War I. A Food Committee of the British Royal Society, besides recommending 70 to 80 grams of protein and 3,000 kilocalories of food energy for the "average man," stated that every diet should include "a certain proportion" of fresh fruits or green vegetables and that diets of all children should contain "a considerable proportion of milk" to protect against unknown dietary deficiencies (Leitch 1942). In response to this "newer knowledge of nutrition," the USDA in 1916 developed a food guide based on five food groups and recommended that diets be selected from a wide variety of foods to ensure that both known and unknown nutrients would be consumed in adequate amounts (Hertzler and Anderson 1974).

Between 1925 and 1935, the importance of consuming protective foods was also emphasized in reports of the British Medical Association (BMA) (1933) and a League of Nations committee on nutrition-related policy issues (1937). The objective of dietary recommendations prior to this time had been, first, to prevent starvation and malnutrition during periods of economic depression and, second, to maintain the working capacity of those in the labor force and the army (Leitch 1942). The new recommendations were designed to improve the health of the entire population but were framed only in general terms because knowledge of human requirements for specific nutrients was sparse.

Dietary Standards – A New Concept

During the depression years from 1929 to 1935, E. Burnet and W. R. Aykroyd (1935) prepared a report on diet and health for the League of Nations. In it they emphasized the inadequate state of knowledge of human nutrition and the importance of investigating human needs for nutrients to provide a reliable base for dietary recommendations. An important outcome of the discussion of their report by the Assembly of the League was a statement calling attention to the need for, among other things, public education about the principles and practice of nutrition and the need to establish dietary standards (Harper 1985). This was the first time that a clear distinction was made between recommendations that represented food and nutrition policy and standards to establish that policy.

Between 1920 and 1940, rapid progress was made in advancing knowledge of the newly discovered essential nutrients. Chemical structures of some of the vitamins were determined, the effects of several vitamin and mineral deficiencies were described, and human needs for essential nutrients were investigated (McCollum, Orent-Keiles, and Day 1939; Rosenberg 1945). The knowledge needed for establishing dietary standards was becoming available.

Hazel Stiebling of the USDA, who had been a U.S. representative at meetings of League of Nations committees on food and nutrition problems, proposed the first set of standards for ensuring that diets used in feeding programs during the depression of the 1930s would be nutritionally adequate (Stiebling 1933). This standard for several essential nutrients – vitamins A and C, calcium, phosphorus, and iron – was subsequently expanded to include values for the vitamins thiamine and riboflavin (Stiebling and Phipard 1939). The values were derived from estimates of human requirements (USDA 1939). It is noteworthy that Stiebling and E. F. Phipard made separate recommendations for children of various ages and that they set their recommended intakes 50 percent above the average requirement to allow for variability among the requirements of individuals.

During this time, the League of Nations Technical Commission on Nutrition (1938) published recommended intakes for calcium and iron in addition to energy and protein. The commission did not make quantitative recommendations for vitamins but emphasized consumption of "protective foods" – meat, milk, leafy vegetables, fruits, eggs, organ meats, and fish – as important sources of vitamins and minerals and included specific recommendations for pregnant and lactating women. In 1939, the Canadian Council on Nutrition (CCN) (1940) proposed a "Canadian Dietary Standard" that included reference values for energy, protein, fat, calcium, iron, iodine, and vitamins C and D. Thus, by 1940 the principles for developing dietary standards had been established.

In 1940, at the request of the U.S. government, the NRC established a Committee on Food and Nutrition, which, a year later, was given permanent status as the Food and Nutrition Board (FNB). One of the first actions of the FNB in fulfilling its obligation of advising the federal government on problems relating to national defense was to prepare a set of dietary standards for adequate intakes of essential nutrients. The process by which this was done has been described by Lydia Roberts (1944, 1958), chair of the committee that was assigned this task. The set of values for nine essential nutrients adopted by the FNB, and designated as Recommended Dietary Allowances, was approved by the American Institute of Nutrition (the professional nutrition society of the United States) and subsequently accepted at a national conference on nutrition convened at the request of President Franklin Roosevelt in 1941. The reference values for seven of the nine essential nutrients included in this standard did not differ appreciably from those proposed by Stiebling and Phipard; the other two nutrients, niacin and vitamin D, were new additions.

The RDA publication has been revised nine times since 1941; the tenth edition was published in 1989. The number of nutrients for which RDA or safe and adequate intakes are established has expanded from 9 (ADA 1941) to 26 (FNB 1989b). Changes in the first seven editions have been summarized by Donald Miller and Leroy Voris (1969). The International Union of Nutritional Sciences has compiled detailed information on many national and international dietary standards (Truswell 1983).

The Process for Establishing Dietary Reference Values

The process by which dietary standards are established is described in the various RDA reports and has been discussed by Gordon Young (1964), Alfred Harper (1987a, 1994), Stewart Truswell (1990), Roger Whitehead (1992), and others cited by these authors. It involves appointment of a committee that assumes responsibility for selecting age-sex groups for which RDA are needed, evaluating information about human requirements for nutrients, and then establishing procedures for deriving appropriate recommended intakes from knowledge of the requirements for, and utilization of, nutrients.

Committees on Dietary Standards

In the United States, a committee appointed by the NRC and reporting to the FNB is assigned the task of setting RDA. In most other countries, committees to establish Recommended Nutrient Intakes are appointed by departments of health. The committees usually consist of 8 to 12 scientists with both a broad general knowledge of nutrition and expertise in one or more special areas. In brief, in the United States, individual members or subcommittees prepare background papers on one or more nutrients based on a critical evaluation of the scientific literature on human requirements. These papers are reviewed by the entire RDA committee at several meetings over a period of three years, and problems are identified and resolved, sometimes with the aid of consultants or workshops. After revisions, the final draft of the report is submitted to the NRC for further review and revision before the final version is published.

The international agencies – FAO and WHO – follow a different procedure. Their reports deal with only a few nutrients at a time. One report, for example, may be on energy and protein (FAO/WHO 1985), whereas another may discuss vitamin A, iron, folate, and vitamin B_{12} (FAO/WHO 1988). The two organizations jointly appoint a committee of from 12 to as many as 20 scientists from various nations and a secretariat, consisting mainly, but not exclusively, of members of their staffs, to coordinate and facilitate the work of the committee. Its members (and those of the secretariat) prepare background papers on different aspects of requirements for the nutrients under consideration; they then meet together for about 10 days to discuss and resolve problems and prepare a draft report. This is circulated to the members for comment, after which a subgroup of the committee and the secretariat prepare the final report for publication.

Age-Sex Groups

The first step in setting RDA is to select age ranges and age-sex groups for which separate RDA values are needed and to specify body weights appropriate for each group. Most RDA reports currently include values for some 15 age-sex groups and for gestation and lactation. This number of groups is necessary for two reasons – first, because requirements for nutrients per unit of body weight decline as the growth rate declines and, second, because RDA for essential nutrients are expressed as amounts recommended daily per person in the specified group rather than as amount per unit of body weight. The range of ages included within a group must, therefore, be narrow during early life, when requirements per unit of body weight are high, and during adolescence, when body size is increasing rapidly. Also, requirements per person for females differ from those for males, mainly, but not exclusively, because of differences in body size, so that, except at young ages, separate groups are also employed for the two sexes. The age ranges and weights for groups frequently differ from one country to another, making exact comparisons among values from different reports difficult.

For individuals or groups whose weights deviate considerably from the specified weights, RDA should be adjusted on the assumption that they are proportional to body weight. For those judged to be substantially overweight, adjustment on the basis of lean body mass is thought to be more appropriate. Body weights for the age-sex groups are currently based on information obtained in national health surveys. They are not "ideal" or "desirable" weights. In the United States, the values are the median weights observed for the population (FNB 1989b); in Britain they correspond with the fiftieth percentile for body weight (DHSS 1991).

Establishing RDA for Essential Nutrients

The objective in establishing RDA for essential nutrients is to identify a level of intake high enough to ensure that the tissues of virtually all individuals in the population will contain enough of the nutrient to prevent impairment of health even if intake is inadequate for some period of time. The time differs from one nutrient to another, owing to differences in the ability of the body to store and conserve them. To accomplish this objective, the usual procedure is, first, to assemble and evaluate the information on human requirements for the different age-groups that have been studied; second, to estimate the variability among requirements of individuals; and, third, to assess the effects of various factors that influence nutrient needs, such as efficiency of absorption and utilization in the body, the bioavailability of the nutrient from major foodstuffs, and the contributions of precursors of nutrients in the food supply. The extent to which the last group of factors influences RDA differs from nutrient to nutrient and depends upon the nature of the foods consumed.

Estimation of Requirements

Methods that can be used for estimating requirements differ from one nutrient to another, and there is not always agreement as to the most appropriate criteria for establishing when a requirement has been met. Maintenance of a satisfactory rate of growth is accepted generally as an appropriate criterion for establishing that the requirements of infants and young children have been met. The amounts of nutrients consumed by infants growing well on a diet of human milk or a formula of proven quality are generally viewed as satisfactory, but not necessarily minimal, estimates of infant requirements.

With adults, several approaches have been used. In the case of nutrients for which naturally occurring dietary deficiencies have been encountered, the amounts needed to prevent or cure deficiency signs have been estimated both in practical studies and experimentally. These include thiamine, niacin, vitamins A and C, iron, and iodine. Experimental studies in which human subjects have been depleted of a nutrient until they develop signs of deficiency and then are replenished with different amounts until the signs disappear have been used to estimate requirements for ascorbic acid, vitamins A, E, and B_6, riboflavin, and folic acid. These methods are based on the assumption that body reserves are adequately restored when deficiency signs disappear. Balance studies have been used to estimate requirements for protein, calcium, magnesium, and zinc. In these the minimal amount of nutrient required to just prevent loss from the body is estimated from measurements of intake of the nutrient and excretion of the nutrient or its metabolites by human subjects whose intakes are increased incrementally.

The body content (usually called the body pool) of a few nutrients, for example, vitamin B_{12}, ascorbic acid, and iron, can be measured directly by isotopic methods; then, relationships among intake, rate of loss, and the development of signs of deficiency can be established. For several others, an indirect measure of the state of body reserves can be estimated from measurements made while intake is varied, of the rate of excretion of the nutrient or one of its metabolites in urine (niacin, vitamin B_6), the concentration in blood (vitamin A), or the activity of an enzyme or other protein of which the nutrient is a component (thiamine, selenium).

Confidence in estimates of requirements is increased when there is reasonable agreement between values obtained by two or more methods. With all of these methods, however, an element of judgment is required in selecting the point at which the requirement is met. What, for example, is the appropriate body pool size, blood level, or enzyme activity to equate with an adequate intake, especially when the responses to increasing or decreasing intakes of nutrients are characteristically curvilinear and do not have clear inflection points?

Appearance of deficiency signs is clear evidence of an inadequate intake and, thus, prevention of these signs provides a guide to the minimal amount required. But it is a matter of judgment when it comes to how much the body pool, blood level, or metabolic indicator should be above the value associated with the prevention of signs. As intake of most nutrients is increased, excretion of the nutrient or of its metabolic products increases, and a sharp rise in body losses serves as an indicator that intake is in excess of needs. But as intake of some nutrients (vitamins A and D, for example) is increased, they continue to accumulate to a point at which toxic reactions can occur.

The total numbers of subjects studied in experiments on requirements, and the total amount of information available, is less than desirable. For many nutrients, values for intermediate age-groups must be obtained by interpolation from what is known about the requirements of infants and young adults; this is because few subjects at other ages have been studied. Differences in the judgments of various national committees lead to differences in estimates of the requirement. For a few nutrients, such as ascorbic acid and calcium, such differences in judgment are wide. But as a rule, the similarity of the values determined by different committees is impressive.

Individual Variability of Requirements

Individuals differ considerably in their requirements for essential nutrients owing to genetic differences among them. Stiebling and Phipard (1939) originally suggested that an intake of 50 percent above the average requirement should meet the needs of those with the highest requirements. L. B. Pett, C. A. Morrell, and F. W. Hanley (1945) assumed that requirements follow a Gaussian distribution, so RDA values would have to exceed average requirements by about three times the standard deviation of the mean in order to meet the needs of all individuals in the population. M. H. Lorstad (1971) subsequently proposed that a value two standard deviations above the average requirements (which would cover 97 to 98 percent of the population) would be an appropriate practical dietary standard. His proposal was adopted by FAO/WHO and has since been accepted generally. In view of the tendency of RDA committees to be generous rather than parsimonious in the selection of values for requirements, and of the ability of the body to conserve nutrients if intake is somewhat below the requirement without impairment of health, this would seem to be an acceptable approach.

In practice, for many nutrients there are not enough individual values to permit reliable estimates of the variability of requirements. In the case of nutrients for which the procedure has been applied, requirements follow a Gaussian distribution with coefficients of variation (the standard deviation expressed as a percentage of the mean) of about 15 (10 to 20) percent (Beaton 1994). If it is assumed that requirements for other nutrients follow a similar pattern, increasing the average requirement by about 30 percent should give an acceptable estimate for setting RDA generally (FAO/WHO 1988; Beaton 1991). Iron requirements of menstruating women, which are skewed toward the upper end of the range, are an exception.

Other Considerations in Setting RDA

RDA are the amounts of nutrients that should be present in foods as they are eaten. Losses of nutrients that occur during processing and preparation are not taken into account in setting RDA, but factors that influence the utilization of nutrients in the food ingested are. These include the digestibility of the foods, the biological availability of the nutrient from the food, absorption, and the presence in foods of precursors of certain nutrients. The requirement for protein, for example, is a composite requirement for nine essential amino acids and for a nonspecific source of nitrogen. The requirement for protein, thus, depends upon the digestibility of the protein and the proportions of amino acids it contains. RDA for protein are based on requirements for protein of the highest quality.

Many plant foods contain carotenoids, precursors of vitamin A (retinol) that differ in vitamin A value. To take this into account, RDA for vitamin A are expressed as retinol equivalents. The contributions from the vitamin and its precursors will depend upon the nature of the food supply. The amino acid tryptophan is a precursor of the vitamin niacin, so the need for this vitamin will depend upon the tryptophan content of the protein consumed. Thus, the RDA is expressed as niacin-equivalents.

The biological availability of iron may range from as low as 3 percent for foods of plant origin to 20 percent for foods of animal origin; hence, RDA for this nutrient will depend upon the proportions of plant and animal products in the food supply. Differences in the biological availability of nutrients in national food supplies account for some of the differences in RDA for essential nutrients among countries. There is no evidence to suggest that physiological requirements for different racial groups differ significantly.

RDA for Food Sources of Energy

The RDA for energy, expressed as kilocalories or megajoules per day (1,000 kilocalories equal 4.184 megajoules), are actually requirements for the components of the diet that, upon oxidation in the body, yield energy – carbohydrates, fats, and proteins. Ordinarily the amount of food consumed by most healthy individuals is controlled spontaneously by the body, over time, to an amount that will provide just enough energy to balance the amount expended and maintain body weight relatively constant – often for a period of years. If the RDA for energy were set, as for essential nutrients, at the upper end of the requirement range, it would be a recommendation for overconsumption and, hence, overweight for most people, because intakes in excess of the amount needed are not excreted but stored. The RDA values for energy are, therefore, average requirements for each group, not reference values for each individual in the group.

Energy requirements of individuals can be estimated from knowledge of their resting (basal) energy expenditure, energy expended for physical activity, and energy lost as heat from the stimulation of metabolism after a meal (thermogenesis). Resting energy expenditure varies with body weight, age, and sex. It can be estimated from equations derived empirically from relationships among basal metabolic rate, body weight, age, sex, and height, which are based on measurements of energy expenditures determined directly by calorimetry. Energy required for activity is estimated using factors that are multiples of the resting expenditure appropriate for each activity, and then multiplying these by the amounts of time spent in different activities (HWC 1990; Warwick 1990). The total of energy required for activity and resting energy expenditure, with an allowance for thermogenesis, yields the final value. The amount of food energy consumed daily, averaged over a period of several days, provides a reasonable estimate of the energy requirements of adults who are maintaining a stable body weight.

Uses of RDA

The original purpose of RDA was to "serve as a goal for good nutrition" – to act as reference values for planning nutritionally adequate food supplies and diets for large groups of people, and for devising dietary guidance systems based on sound scientific principles for the public. They have since been used in many other ways, some of which they were not designed for and for which they have limitations that are not always recognized. The uses can be separated into two general categories: (1) "standards for dealing with practical applications of nutrition," and (2) "guidelines for food and nutrition regulations and policies." This distinction is somewhat arbitrary because practical applications may arise from, or even be the basis for, policy decisions. Uses of RDA have also been grouped in another, more technical, way. Those related to planning food supplies and diets, offering dietary guidance, and serving as standards for food regulations and economic assistance programs have been categorized as *prescriptive* uses. Those related to assessment of the adequacy of nutrient intake, diets, and food supplies have been termed *diagnostic* (Beaton 1994). The former classification seems more appropriate for the present purpose, even though the separation between the categories is less distinct.

In using RDA as reference values for different purposes a question arises as to whether they apply equally well to individuals and groups. For energy, the situation is clear. RDA for energy are average values for groups; for applications involving individuals, energy needs of each person must be estimated separately. For essential nutrients the situation is more complex. RDA for essential nutrients exceed the requirements of nearly all persons in the specified groups, so a food supply that meets the RDA should be adequate for an individual and, provided it is distributed equitably, for all members of a group as well. But when RDA are employed as standards for assessing the adequacy of essential nutrient intakes, the answer is less clear. The problems that arise are considered in the following sections.

Uses Related to Practical Applications of Nutrition

Planning food supplies and diets. The RDA are used to estimate the amounts of foods needed to provide large groups of people, such as the armed forces or populations of institutions, with nutritionally adequate diets. For this purpose, information is needed about the proportions of the population in various age-sex categories and about the composition of the available foods. The RDA for energy, being average requirements for each age-sex group, can be used to calculate directly the total amount of energy sources needed, as about half of the individuals in the group should consume more and half less than the RDA. The RDA for essential nutrients are then used as reference values to assure that foods selected and diets formulated provide the requisite amounts of essential nutrients. Allowance must also be made for losses that occur during food preparation. A similar procedure is used by international agencies to estimate the adequacy of both the quantity and quality of food supplies of nations in meeting the nutritional needs of their populations (FAO/WHO 1985).

It should be emphasized that the objective in planning food supplies and diets is not merely to provide amounts of essential nutrients needed to meet RDA. Diets should be composed of a wide variety of palatable and acceptable foods so that they will meet psychological and social needs and be eaten in the required amounts over long periods of time. In trying to accomplish this, the amount of vitamin A provided, for example, will ordinarily vary greatly from one day to another because relatively few foods are rich sources of this vitamin. Although RDA are specified as daily amounts, this kind of day-to-day variability in the provision of individual nutrients need not be of concern as long as the total amount of each nutrient, averaged over several days, meets the RDA.

Nutrition education. RDA are employed effectively by health professionals for planning nutritionally adequate diets, but they are not designed for use by the public. For people with limited knowledge of nutrition, RDA for nutrients must be translated in terms of foods. A common way of doing this is by first separating familiar foods into a few groups on the basis of the essential nutrients of which they are good sources, and then, using the RDA as reference values, estimating the number of servings from each food group that must be eaten daily to meet essential nutrient needs.

This has been the basis for a food guide, developed by Louise Page and Esther Phipard (USDA 1957), designed to explain how to obtain the required amounts of essential nutrients from a specified number of servings selected from four familiar groups of foods. The number of servings required by adults to obtain the foundation for a nutritionally adequate diet provided only 1,200 to 1,600 kilocalories daily and allowed for obtaining the needed extra energy from additional servings of any of a variety of foods.

The number and selection of servings were modified for children. Estimates of the nutrient content of model diets based on this food guidance system demonstrated that the principles underlying it are sound. The system has been widely used in nutrition education programs for teaching the principles of a nutritionally adequate diet. Many modifications have been proposed in order to adapt it for groups with different cultural backgrounds, lifestyles, and incomes (King et al. 1978). More recently, a modified version based on five food groups – the "food pyramid" (USDA 1992) – was designed as a guide for the total diet and for limiting fat consumption.

Therapeutic nutrition. Although RDA are standards for nutrient intakes of healthy people, they serve equally well as a guide to the nutritional needs of persons with medical problems that do not affect food consumption or nutrient utilization. They also provide a baseline for modifying diets to meet the special nutritional needs of individuals who are ill. Loss of appetite, associated with many types of illness, can result in the wasting of tissues and depletion of body stores of nutrients that must be replenished. Infections of the gastrointestinal tract, disorders that cause malabsorption, systemic infections, injuries, renal failure, certain inborn errors of the metabolism, and many other health problems alter nutritional needs in different ways and to different degrees, owing to the impairment of absorption or excretion or to increased metabolic wastage of nutrients. Dealing with the specific nutritional needs resulting from these conditions requires specific clinical and dietary management.

Designing new or modified foods. RDA are employed in formulating new food products composed of highly purified constituents, foods for special dietary purposes, or products designed as meal replacements, such as special diets for weight reduction, so as to ensure that these will provide appropriate amounts of essential nutrients. When RDA are used for this purpose, it is essential to remember that they are standards for amounts of nutrients to be consumed daily. In the case of products that are total diet replacements, especially those for weight reduction that provide restricted amounts of energy sources, the daily allotment should contain amounts of nutrients that meet the entire RDA.

Foods for general use should contain essential nutrients in reasonable proportion to the amount of energy derived from the product. The concept of "nutrient density" – the amounts of nutrients in the product expressed per 1,000 kilocalories – provides the basis of a method for accomplishing this goal (Hansen, Wyse, and Sorenson 1979). To provide a set of standards, RDA are expressed as units of nutrient required per 1,000 kilocalories of energy sources required. The quantities of nutrients in the product can then be adjusted to correspond with the standard.

Some shortcomings of this procedure should be recognized. In establishing standards for nutrient density, only a single RDA value is used for each nutrient – usually the value for the age-sex group with the highest requirement. For other groups, the standards therefore deviate in varying degrees from the RDA. Nutrient density values have also been proposed as guides to the relative nutritive values of foods. Caution should be exercised, however, in employing the nutrient density concept to compare the nutritive values of foods. The contributions of foods to meeting nutritional needs depend not just on differences in their nutrient content but also on differences in the amounts consumed. Two foods may have the same nutrient density, but if one is eaten in an amount only 10 percent that of the other, their contributions to meeting nutrient needs will differ by tenfold.

Assessing the adequacy of nutrient intakes – individuals. The amounts of essential nutrients consumed by individuals can be estimated from records of the quantities of different foods they eat and tables of food composition. The amounts of nutrients consumed can then be compared with the RDA. Unfortunately, comparisons of this type permit few firm conclusions about the adequacy of intakes. Because RDA exceed the requirements of most people, the probability of nutritional inadequacy is obviously remote for those whose intakes equal or exceed the RDA. But because requirements of individuals differ widely, it is not valid to conclude that an intake below the RDA is inadequate. All that can be said is that the further the intake falls below the RDA, the greater is the probability that the intake is inadequate. This is not a shortcoming of the RDA; dietary standards generally are not meant to be used for this purpose. The adequacy of essential nutrient intakes of individuals can be evaluated accurately only by clinical and biochemical assessment, not by comparing intakes with the RDA or with any other standard.

Inability to quantify the degree of nutrient inadequacy from knowledge of intakes below the RDA has, however, stimulated efforts to apply statistical methods (and the risk concept) as an alternative procedure for assessing the adequacy of essential nutrient intakes. Application of probability analysis, using information about *requirements* (not RDA) and intakes of essential nutrients, has been proposed as a way of obtaining a quantitative estimate of the *risk* of nutritional inadequacy (FNB 1986; FAO/WHO 1988; Beaton 1991, 1994).

From plots of the cumulative percentage distribution of *requirements* (assuming they are normally distributed) against intake, the probability that an intake below the highest requirement is inadequate can be estimated; for example, the probability that an intake equal to the average requirement is inadequate is 50 percent. Although a quantitative estimate of the probability (risk) of a particular intake being inadequate is obtained through this type of analysis, it does not establish whether the intake actually is inadequate. But it can help in deciding if an individual should be referred for specific biochemical tests.

Uses Related to Food and Nutrition Policy

Nutritional standards are needed both for many food and nutrition programs and regulations and to provide a reliable scientific basis for interpreting the nutrient intake information that is employed to establish food and nutrition policy. For some of these uses, RDA are appropriate standards, but for others they are too complex and must be modified, or they are too limited in scope and must be used in conjunction with other standards.

Assessment of nutritional adequacy – populations. Information about the adequacy of essential nutrient intakes in a population is used to identify potential health problems. In assessing the adequacy of intakes in a population, one must take into account not only the variability of requirements but also the variability of intakes. Food and, hence, nutrient intakes of individuals vary widely. Even in developed countries, where the average nutritional intake of the population exceeds the RDA, those of many individuals are found to be less – and some much less – than the RDA (USDHHS/USDA 1986). This may occur for many reasons, such as poverty, illness, and ignorance, but the point is that even if the average intake of a population is in excess of the RDA, there is no assurance that all individuals within that population are meeting their requirements. Moreover, the problem of estimating the proportion of persons who have inadequate intakes remains unresolved.

From the results of dietary surveys of representative samples of large populations, the proportions of the population with different intakes can be determined. Then, with this information about the distribution of intakes, the same type of analysis that is used to assess the risk of inadequacy for an individual can be employed to assess the probable incidence (risk) of inadequate intakes in the population (FNB 1986; FAO/WHO 1988). This problem has been analyzed in detail by G. H. Beaton (1994), who concluded that only if the average intake of a population exceeds the *average requirement* by more than twice the coefficient of variation of the *average intake* will the probability of inadequate intakes in the group be low. This raises a question as to whether RDA for groups should be higher than those for individuals. The answer is not clear, but because the problem is important in relation to policy decisions, it is important to be aware of it. The actual prevalence of nutritional inadequacy in a population, as in an individual, can be assessed accurately only through clinical and biochemical observations, not by comparing the average population intake with a standard.

It seems not to be sufficiently appreciated, as Beaton (1994) has emphasized, that estimates of the probability of intake being inadequate are based on the observed distribution of individual *requirements* around the mean. Inclusion of a table of average requirements in RDA reports would be more useful than the table of RDA for assessing the adequacy of nutrient intakes by probability analysis. As all committees use essentially the same information for establishing requirements, a higher degree of agreement might be anticipated in establishing average requirements than in establishing RDA. Having both sets of values published together would also draw attention to the need for a critical assessment of criteria, both for establishing when a requirement has been met and for evaluating the process used to derive RDA from requirements.

Difficulties in trying to assess the adequacy of nutrient intakes using RDA as standards have also stimulated interest in alternative standards. Separate standards that represent the lower limits of acceptable nutrient intake have been developed in New Zealand, Norway, and Australia. These are to be used only for evaluating the adequacy of nutrient intakes (Truswell 1990). The FAO and WHO (1988) have published separate reference values for "basal requirements" and "safe levels of intake" (essentially RDA) for iron and for vitamin A.

The major problems in evaluating the adequacy of nutrient intakes from dietary information are not resolved by establishing new standards. Conclusions about inadequacy can still be drawn only in terms of probability or risk. Moreover, individuals cannot be identified as having inadequate intakes from dietary assessment alone, but as Truswell (1990) notes, intakes below the lower standard are more likely to be associated with deficiency than are intakes at some arbitrary level below the RDA.

Food labeling. To provide consumers with information about nutrient contributions of foods, the U.S. Food and Drug Administration (FDA) established a standard based on the RDA. To use the RDA directly for this purpose would be unwieldy and complicated; in order to devise a standard with a single set of values for food labeling, the FDA selected the highest values from among the RDA for 20 nutrients and called these U.S. Recommended *Daily* Allowances (NNC 1975). Nutrient contributions of products have been listed on labels as percentages of the U.S. RDA per serving. (The different meanings of the terms "U.S. RDA" and "RDA" had created a measure of confusion.)

There are differing views about the purpose of food labels: According to one, the label should provide information that can readily be related to nutritional needs, and thereby serve as a tool for nutrition education; according to another, the main purpose of having nutrition information on the label is to enable the purchaser easily to compare the nutrient contributions of different products. The U.S. RDA are not useful guides to nutrient needs of the various age-sex groups for which RDA are set other than for the adult male. They do serve effectively, however, for the primary purpose for which they were designed – to provide an easy and simple standard for comparing products as to the per-serving percentages of the U.S. RDA that they contain. U.S. RDA are also appropriate standards for programs that fortify foods with nutrients judged to be low in the food supply.

The FDA has recently established new standards for food labeling and regulations. The basic standard for essential nutrients – Reference Daily Intake – is a population-weighted average of the 1989 RDA values for age-sex groups beyond 4 years of age. The amount of nutrient provided by a food product may be included on the label as a percentage of the Daily Reference Value – the amount of the nutrient that should be provided by a diet that yields 2,000 kilocalories. This system will permit simple comparisons of the nutrient contributions of different foods just as the earlier system did, but the values will not relate closely to the RDA. It is essentially a modified form of the nutrient density concept and, as such, may eventually find a niche in nutrition education programs.

Food assistance and welfare programs. Most economic assistance programs of government agencies in the United States are direct or indirect food assistance programs. They include programs such as school lunches, supplementary food for women, infants, and children, and nutrition for the elderly. RDA are used as reference values for many of these programs. To assure that foods or meals supplied through these programs will be of high nutritional quality, it is required that they contain specified proportions of the RDA for certain nutrients. RDA are appropriate standards for meeting needs for essential nutrients, but they are not appropriate as the sole standards for planning meals or diets. As mentioned in relation to diet planning generally, planning meals requires, in addition, consideration of palatability, acceptability, and variety of the food supply, so that diets will be eaten and enjoyed over prolonged periods of time.

Meeting RDA has been an important consideration in developing the food plan that has served as the basis for allotting coupons in the food-stamp program, for licensing and certifying nursing homes and daycare centers, and for establishing the poverty level of income. RDA are appropriate standards for meeting needs for essential nutrients, but even though they are employed in conjunction with other standards, their use in this way has resulted in economic assistance programs being viewed as nutrition programs. It may make such programs more politically acceptable, but it also diverts attention from the need for broader and more comprehensive standards for them. It also has led to efforts to include use of RDA for economic assistance programs as part of the basis for setting RDA values, a procedure that, if accepted, would undermine their scientific validity as dietary standards.

Dietary guidance for the public. The RDA-based food guide system, employed in teaching the principles of a nutritionally adequate diet in nutrition education programs, was developed originally by the USDA as part of that agency's response to the policy of providing dietary guidance for the public. Many aspects of such guidance, however, extend beyond the scope of RDA, such as desirable proportions in the diet of carbohydrates, fats, and other sources of food energy; maintaining a healthful body weight; and associations between diet and disease. These topics ordinarily are discussed in only broad terms in RDA publications, and some are addressed in dietary guidelines adopted jointly (as part of current health policy) by the USDA and the U.S. Department of Health and Human Services (USDHHS) (1990), by Canada (HWC 1992), and by many other countries (Truswell 1987).

To comply with current health policy, a modified food guide system for selecting the *entire* diet from five food groups and emphasizing food selections that will reduce fat and cholesterol consumption (USDA 1992) has been substituted for the earlier one, which provided *partial* guidance in selecting only 1,200 to 1,800 kilocalories from four food groups as a basic diet – to be supplemented with other selections. This new system represents a shift in public dietary guidance in the United States, whereas in Canada, the four-food-group system, with an emphasis on meeting essential nutrient needs, has been retained (albeit with new guidelines for reduced fat consumption) (HWC 1992). RDA continue, nonetheless, to serve as the scientific basis for selecting a nutritionally adequate diet in programs of dietary guidance.

RDA and Changing Health Policy

During the past 30 years, emphasis in health policy in the United States and many other developed nations has shifted toward the prevention of chronic and degenerative diseases. This shift has been accompanied by changes in dietary guidance that require a different base of knowledge from that for guidance based on the RDA. When the nature of the changes is examined, it is evident that this has implications for the concepts of RDA.

Changing Emphasis in Food and Nutrition Policy

Changing health status. Health has improved dramatically in the United States during the twentieth century while dietary advice has been based on the RDA (USDHEW 1979). Nutritional deficiency diseases have been virtually eliminated; mortality from infectious diseases has declined sharply; the proportion of infants born who live to age 65 or older has increased from less than 40 percent to 80 percent or more; height at maturity has increased; and life expectancy has risen from less than 50 to about 75 years. These improvements have occurred in association with improved sanitation, diet, and medical care and a higher standard of living. The extent to which they are attributable to better diets cannot be established, but increased infant and childhood survival and increased growth rates and height at maturity could not have occurred unless diets had been nutritionally adequate (Harper 1987b).

A consequence of the high rate of survival of the young to old age, with a stable, then declining, birth rate, is that the proportion of people 65 years of age or older in the population has increased from 4 to 12 percent. Such aging of the population has been accompanied in most developed countries by an increase in the proportion of deaths from cardiovascular diseases and cancer, from about 20 percent of total deaths during the early 1900s to about 70 percent today.

New directions in dietary advice. The emergence of chronic and degenerative diseases as the major causes of death, coupled with the perception that alterations in diet may increase life expectancy by delaying the onset of such diseases (the causes of which are poorly understood), has brought about a striking change in food, nutrition, and health policy. Much greater attention is now being given to dietary guidance for the "prevention" of diseases associated with aging than to advice on how to select a nutritionally adequate diet (USDHHS 1988; USDA/USDHHS 1990).

This change in policy evolved over a period of more than two decades (Truswell 1987), mainly in response to reports of associations between the type and quantity of fat in the diet and mortality from heart disease. Conclusions drawn from these associations and accepted as the bases for changes in health policy have, nonetheless, been controversial (FNB 1980), and skeptical views have been expressed by numerous experts.[1] Later observations that high intakes of vegetables and fruits are associated with lower mortality from certain cancers expanded interest in diet modification as a disease prevention measure (USDHHS 1988; FNB 1989a). The underlying bases for these associations have not been established, and claims that certain known plant constituents (such as carotenoids) may be among the effective agents have led to further controversy. Despite this, however, the recommendation for increased consumption of vegetables and fruits is accepted generally, on several grounds, as appropriate nutrition policy.

In 1980, as the culmination of an effort to achieve consensus among conflicting views over the role of diet in delaying the onset of chronic and degenerative diseases, the USDA and USDHHS jointly adopted (and later revised) a set of "Dietary Guidelines for Americans" (USDA/USDHHS 1990). Two of the seven guidelines – "Eat a variety of foods" (a nutritionally adequate diet), and "Maintain healthy body weight" – are the essence of the RDA-based dietary guidance initiated decades ago for variety and moderation in food consumption. The others, recommending a diet low in fat (and especially in saturated fat and cholesterol), with plenty of vegetables, fruits, and grains (providing fiber) and only moderate use of sugars, salt, and alcohol, were proposed as guidelines for reducing the risk of developing chronic and degenerative diseases, as is emphasized in the text of the publication.

The purpose of these guidelines is distinctly different from those based on the RDA. They are uniform dietary recommendations for the entire population, adopted to institute a health policy for the control of diseases that are not products of nutritional deficiencies and to which individuals differ greatly in susceptibility. They deal mainly with foods and food constituents that are not essential nutrients (energy sources, fiber, cholesterol) and are based on information that is beyond the scope of the RDA – indirect evidence of associations that cannot be accurately quantified. RDA, in contrast to these guidelines, are quantitative reference values for intakes of essential nutrients. They are part of the information base employed in developing programs to institute a policy of encouraging consumption of diets containing adequate amounts of nutrients, deficits of which will cause diseases in all individuals in the population. In a recently published revision of *Dietary Guidelines for Americans* (USDA/USDHHS 1995), although the guidelines themselves remain essentially the same, the text has been modified considerably. Much more emphasis has been placed on dietary guidance for maintaining health and much less on diet as a disease prevention measure. This change has improved the balance between dietary guidance based on well-established knowledge of the effects of essential nutrients (the RDA) and guidance based on evidence, much of it indirect, of probable health benefits from other components of foods (including unidentified substances).

The adoption of a policy that emphasizes dietary modification as a means of disease prevention has led to proposals that the RDA concept be modified to conform with the new direction in health policy (Hegsted 1993; Lachance 1993; IM 1994). To accomplish this, the RDA would be expanded to include all dietary constituents shown to influence susceptibility to chronic and degenerative diseases; some examples are carotenoids (plant pigments, some of which are precursors of vitamin A), cholesterol, and fiber (Lachance 1993, 1994). Moreover, observations that high intakes of certain vitamins (especially those that can function as antioxidants, such as vitamins E and C) may reduce the risk of heart disease and some cancers have given rise to proposals that such information be used in setting values for the RDA (IM 1994). Controversy over issues of this type delayed revision of the tenth RDA report for several years (Pellett 1988).

If the basis for setting RDA is modified to include consideration of the effects of substances (such as fiber) that cannot be quantified accurately, and of medicinal or pharmacological effects of vitamins or other nutrients (which require amounts well in excess of those that can be obtained from diet), the RDA will cease to be reliable reference values for meeting basic physiological needs (Truswell 1990; Harper 1994; Rosenberg 1994). Such a change would represent modification of a standard (the RDA) to conform with policy. The RDA, which are set on the basis of critical scientific evaluation, would become a vehicle for dietary guidance comparable to dietary guidelines, which are established by consensus. To maintain the independence and integrity of sources of information employed in making policy decisions, it is essential that the process of evaluating information used in setting policy be separated clearly from the process used to develop programs to institute policy. Continuing the approach used in most countries of maintaining a clear separation between the process for establishing dietary guidelines and that for setting dietary standards (Reference Nutrient Intakes; RDA) will accomplish this. Separate publication of dietary guidelines also provides an appropriate mechanism for presenting information about the potential health benefits (even tentative ones) of foods and food constituents independently of the RDA. Adoption of the British approach of calling the dietary standards "reference values" would be a further contribution toward maintaining such separation.

VII.5 ~ Food Labeling

In the United States, the past three decades have witnessed tremendous changes in the way the public views the foods it buys. Unlike counterparts in the developing world, where problems of food availability and food quantities still dominate, consumers in the United States (and the West in general) have become increasingly interested in the nutritional quality of the foodstuffs they are offered. As a consequence, nutrition labeling has emerged to play a key role in government regulation of the food supply, in informing consumers about the constituents of the foods they eat, and in the formulation and marketing of food products by the manufacturers.

The importance of food labels has come about in spite of the fact that during the last 20 years or so, policy decisions regarding the implementation of nutrition labeling have been made in a political environment that emphasizes nonintervention in the operation of market economies. Recent legislation in industrialized countries has taken, for the most part, a minimalist approach to the regulation of nutritional quality. But although still controversial, labeling is seen as an acceptable "information remedy" that requires relatively little market intervention, and most Western nations have established some form of legislative guidelines for the regulation of nutrition labeling. With the adoption of the Nutrition Labeling and Education Act (NLEA) in 1994 (Caswell and Mojduszka 1996), the United States is currently in the forefront of establishing a mandatory and comprehensive national nutrition labeling policy.

The growing interest in nutrition policy reflects the understanding that foods represent major potential risks to public health because of such factors as foodborne organisms, heavy metals, pesticide residues, food additives, veterinary residues, and naturally occurring toxins. But although these are very real health hazards, scientists believe that the risks associated with nutritional imbalances in the composition of the diet as a whole are the most significant in the longer run, particularly in industrialized countries, where the high percentage of fat in daily diets seems to significantly threaten public health (Henson and Traill 1993). The recognition of nutritional quality as a value in itself has led to a separation of the nutritional from other food safety issues and a growing tendency to develop legislation targeted specifically at nutrition.

The latter, along with a perceived need for nutrition labels, is a reflection of the social changes that are influencing how, where, and when, as well as what, people eat (Wilkins 1994). Perhaps the most important change is the growing number of households that consist of two working parents or a single parent. With such a change in family structure, more meals are consumed in restaurants, more foods are eaten at home that have been prepared elsewhere, and convenience items predominate among foods prepared at home. In addition, the traditional three meals per day are often replaced with ad hoc meals as consumers employ an even greater variety of "heat and eat" foods. As a result, the consumption of traditional staple foods, such as cereals and potatoes, has decreased, and in most industrialized countries, the consumption of meat, milk, and milk products has markedly risen. The percentage of fat in the diets of citizens in industrialized countries has thus grown substantially in the last half century. Whereas regional variations persist, these current trends in eating patterns have generally meant a much greater intake of fats as a percentage of calories, which many view as a major factor in increasing morbidity and mortality from so-called chronic diseases such as cancer and coronary artery disease (Helsing 1991).

Such linkages between diet and health, and the communication of this knowledge to the general public, have led to an increased demand for higher quality, to which producers and retailers have responded by extending the variety of foods offered for sale. The nutritional composition of many foods has improved as well as their labeling; this, in turn, has stimulated an even more intensive marketing of the nutritional attributes of food products, as producers have recognized that an informed public will pay for better nutrition. Thus, as growing numbers of scholarly studies show, nutrition labels have become vital to public knowledge about food and, consequently, to improving public health (Caswell 1991).

The Evolution of Labeling Regulation

Despite the recent importance that labeling has achieved, concerns with labeling food products according to safety and purity have a long history. For example, throughout the medieval and early modern periods, foods of all kinds were identified by origin and grade, and regulatory "marks" on bread go back at least to the reign of Henry III in thirteenth-century

Britain. Indeed, they were one of the most common forms of control imposed on food producers in the Middle Ages. Manufacturers also recognized the profitability of such regulation; the German "Brewing Purity Law" of 1516, imposed by the Bavarian court but readily adopted by German brewers, stands as an example that continues to this day as a marketing tool for beer.

The history of food regulation in its current form has its roots in aspects of late-nineteenth-century modernization and industrialization. Scientific chemical experimentation in the early 1800s made possible the sophisticated adulteration of food as well as tests of its quality. The later growth of international markets and transportation networks contributed to a decline of reliance on fresh food and advanced the increasingly impersonal aspects of food markets. The key to such markets was food durability, and as processing capabilities evolved through packaging, bottling, and canning in the nineteenth, and freezing in the twentieth century, so interests in marking and labeling food products by brand name and contents became increasingly important.

Because they presumably carried assurances of quality and consistency in an impersonal market, brand names substituted to some degree for the lack of face-to-face contact in modern retailing, and by 1900 food labels showing brand names were well established in the industrialized Western nations. In the United States, major brands dating from the late nineteenth century include those created by Joseph Campbell, H. J. Heinz, and P. D. Armour. By 1920, producers recognized that brand names were a significant factor in trade and worth protecting legally as the important "public face" of a company's product line (Wilkins 1994). Beyond displaying brand names that promoted company reputation and increased consumer recognition, food labels sometimes included frequently specious claims about the content, quality, and healthfulness of their products.

During the late nineteenth century, there was a growing government interest in regulating the food supply through inspection and control of such deceptive labeling. To some extent this was a response to varying national standards for the import of meat products, but it was also because of an increasing public recognition of the potential health hazard of processed food. In the United States, public and government concerns with food purity helped propel the outspoken Dr. Harvey Wiley, a chemist from Purdue University, into work on food safety with the Department of Agriculture in 1883. As leader of the Bureau of Chemistry, the forerunner of the U.S. Food and Drug Administration (FDA), Wiley worked on a variety of food- and health-related issues.

The Pure Food and Drug Act of 1906 for which he had labored long and hard (FDA 1993) marked a major step toward labeling regulation and offers a classic example of how interactions between consumers, government, and industry shape the food regulatory environment. Various attempts to pass food and drug legislation had languished in Congress for over 15 years, while food poisoning scandals and investigative reports appearing in the scientific and popular press called growing attention to abuses in the food industry. And public outcry against the unsanitary conditions in the meat-packing industry in Chicago was inspired by the publication of Upton Sinclair's 1905 novel, *The Jungle.*

All of this activity encouraged President Theodore Roosevelt to back legislation authorizing federal oversight of the food industry. The provisions of Wiley's Pure Food and Drug Act, along with an accompanying Beef Inspection Act, authorized the federal inspection of meat-processing plants, established controls on food additives and preservatives, and tightened controls on food labels (FDA 1993). The latter, in a major step forward, were now required to correctly identify the producer so as to facilitate consumer complaints. Food labels were also to honestly list package contents; descriptive superlatives, such as "best" or "superfine," had to be removed if the manufacturer could not prove the claim. If producers had products tested and registered by the Department of Agriculture, an official label could be used on these packages.

This provision, however, was weakened by the lack of postregistration oversight: Unless a consumer complained, producers could use official labels with impunity, even though product composition might have changed since initial registration. Thus, in a progression that became typical of industry reception of new food regulations, the powerful Chicago "Beef Trust" at first resisted the new legislation but then publicly adopted the federal stamp of approval in an effort to revive public confidence and increase flagging demand for its meat products (FDA 1993).

Other important regulatory measures were adopted in the United States during the following decades. In 1938 a new U.S. Food, Drug, and Cosmetic Act updated the 1906 Pure Food and Drug Act and tightened labeling regulations considerably. In addition to prohibiting statements that were false or misleading, the law prescribed that labels on all processed and packaged foods had to include the name of the food, its net weight, and the name and address of its manufacturer or distributor. A detailed list of ingredients was also required on certain products. The Food, Drug, and Cosmetic Act was subsequently updated, and in 1950, an Oleomargarine Act required clear labels on margarine spreads to distinguish them from butter. In 1957, the Poultry Act authorized the labeling of poultry products.

In 1969, the White House Conference on Food, Nutrition, and Health (FDA 1993) investigated dietary deficiencies in the United States and recommended that the federal government take a more active role in identifying the nutritional qualities of food, which set the stage for the differentiation of food safety from nutrition regulation. The 1970s saw an explosion of public interest in healthful foods, as fears of pesticides, food radiation, and mercury poisoning in fish, on the one side, and the rise of "health food," organic farming, and consumer watchdog groups, on the other, encouraged a more activist approach to nutrition policy and food labeling.

Recent Labeling Regulation in the United States

The United States, as the world leader in the regulation of nutrition labeling, moved from partial controls in the 1970s and 1980s on voluntary provision of nutrition information (on product labels) to mandatory nutrition labeling in the 1990s. No other Western nation has similar mandatory labeling regulations. This move was, in part, a response to heightened public awareness of nutrition-related health issues in the United States. But it represented, as well, an acknowledgment on the part of federal health agencies that a significant portion of the population had poor diets. At the same time, manufacturers discovered that nutritional claims on packaging labels could be powerful marketing tools.

In 1973 the FDA had issued rules requiring nutrition labeling on all packaged foods to which one or more nutrients had been added or on foods whose advertising included claims about their nutritional qualities and/or their importance in the daily diet. But for almost all other foods, nutrition labeling was voluntary. Voluntary nutrition labeling went into effect in 1975; if producers wished to include nutritional information on their packaging they could, but they were required to use a standardized, federally designed label, which remained in use until 1994.

From 1975 to 1984, food health claims for marketing purposes were prohibited; after 1984, however, some claims were allowed, following case-by-case review by the FDA for nutrient content and health claims (FDA 1993). However, this review process was lax, and little enforcement against deceptive claims took place, virtually inviting industry abuses. Examples included Salisbury steaks that were labeled "lowfat," even though the meat product derived 45 percent of its total calories from fat, and labels on potato chips that concealed high levels of cholesterol-elevating saturated fat.

In 1988, Surgeon General C. Everett Coop released a report on nutrition and health in which, for the first time, the federal government formally recognized the role of diet in the etiology of certain chronic diseases and proposed labeling policies. And after 1989, growing public interest in nutrition, and several publicized cases of label disinformation, led to stricter state and federal scrutiny of nutrient content and health claims on food labels. In 1990, negotiation between the FDA and the United States Department of Agriculture (USDA), often made tense by lobbying on the part of special-interest groups, led to the enactment by Congress of the Nutrition Labeling and Education Act (NLEA) (Gorman 1991). This legislation, which went into effect in 1994, makes nutrition labeling mandatory and strictly regulates nutrient content and health claims. Nutrition labeling, however, remained voluntary for raw foodstuffs (primarily fruits, vegetables, and meats), though grocery stores were allowed to post general nutrition information at the point of sale. Other exempted products from labeling included those destined for consumption away from home, as, for example, in restaurants, hospitals, and other institutions. Small producers, with annual gross sales under $500,000 or food sales under $50,000, were also exempt.

NLEA regulations changed the nutrients that must be listed on the redesigned "Nutrition Facts" panel, which appears on the back side of product packaging. The new list emphasizes fats, sodium, and cholesterol – nutrients that most consumers worry about having too much of rather than too little – and requires that manufacturers indicate percentages of the following macro- and micronutrients on food labels: total calories, calories derived from fat, total fat, saturated fat, cholesterol, total carbohydrates, sugars, dietary fiber, protein, sodium, vitamins A and C, calcium, and iron. Information on the content of these nutrients is presented in quantitative amounts and as percentages of standardized dietary reference values, stated as "Percent of Daily Value." Other nutrition labeling is permitted on a voluntary basis, including information on calories derived from saturated fat and polyunsaturated fat and listings on soluble fiber, insoluble fiber, potassium, and other essential vitamins and minerals.

The percentages given in the "Nutrition Facts" panel are based on standardized serving sizes to help consumers understand and compare the nutritional values of different foods. In fact, according to the NLEA, serving sizes are supposed to be consistent across product lines and close to the amounts people actually consume; the number and amounts of nutrients labeled is based on the serving or portion size supposedly eaten by an "average person" over the age of 4 and must be given in common household and metric measures. Packages that contain less than two servings are considered single-serving containers, and their nutrient contents have to be declared on the basis of the contents of the entire package.

In order to control the manipulation of food descriptors, the FDA has developed consistent and uniform definitions of nine nutrient content claims that expressly or implicitly characterize the level of a nutrient present in a product (such as the Quick Quaker Oats front label, which claims, in eye-catching yellow, that the product is a "lowfat food," a "good source of fiber," a "sodium-free food, and a "cholesterol-free food"). These nutrient content claims are allowed on a voluntary basis, but manufacturers can use them only when a food meets particular nutritional standards.

The nine descriptor terms include: free, low, high, source of, reduced, light (or lite), less, more, and fresh. Because these are key advertising terms and typically appear in marketing tag lines on product front labels, NLEA has encouraged producers to either reformulate their products or drop deceptive nutrient descriptors.

Until 1984, a food product making a claim about the relationship between a nutrient and a disease on its label was treated as a drug (FDA 1993). But in a major shift in nutrition regulatory policy, the NLEA, for the first time, allowed food labels to include voluntary health claims, linking a nutrient or food to the risk of specific diseases or health conditions. For example, within carefully defined limits, food labels are allowed to cite links between calcium and osteoporosis, sodium and hypertension, fat and cardiovascular disease, and fat and cancer (thus, the Quick Quaker Oats back label states in part that "[t]his product is consistent with the American Heart Association dietary guidelines" and that "diets low in saturated fat and cholesterol and high in fiber-containing grains . . . may reduce risk of heart disease").

Recognizing that labels were of limited value without an informed and educated consumer who could understand them, the FDA has also begun a multiyear food labeling education campaign that involves participation by consumer advocates, industry groups and corporations, and other government agencies. Its purpose is to increase consumers' knowledge and to assist them in making sound dietary choices in accordance with the USDA-designed "Dietary Guidelines for Americans." The latter promotes a diet balanced between basic food groups and is usually represented in the form of a food pyramid.

The FDA estimates that in the United States the new food label will cost food processors between $1.4 and $2.3 billion over the next 20 years. But measured in monetary terms, the potential benefits to the public may well exceed the costs; health benefits potentially include decreased rates of coronary heart disease, cancer, osteoporosis, obesity, high blood pressure, and allergic reactions to food (FDA 1993).

Thus, the effects of nutrition labeling go far beyond serving as a shopping aid for consumers. The NLEA is also expected to have a significant impact on the functioning and performance of the food industry because manufacturers will redesign food nutritional profiles to meet changing consumer demands. In other words, for food companies the implementation of mandatory labeling requirements is likely to have important effects on both consumer demand and the marketing of foods (Caswell and Mojduszka 1996).

Nutrition Labeling in Europe

In post–World War II Europe, agricultural and food industry policies were mainly shaped by criteria such as the welfare of industrial workers, economic implications for farmers, national employment, and military security. So long as nutrition experts advised Ministry of Agriculture officials in various European countries on the best crops to cultivate to overcome food shortages in the immediate postwar years, health and nutrition issues were rarely central considerations in agricultural planning but instead were seen as primarily relevant to developing countries.

In 1974, however, the World Food Conference stressed the need for all countries to adopt food safety and nutrition policies, regardless of their stage of development. In Europe, Norway was the first industrialized country to adopt such a policy. By the mid-1980s, a number of health departments in European nations, including West Germany, France, and Great Britain, had issued reports on nutrition and diet, and international organizations such as the World Health Organization (WHO) and the Food and Agriculture Organization (FAO) – both offices of the United Nations – also called attention to the role of nutrients in human health in industrialized societies, citing dietary problems associated with oils and fats.

By 1990, seven countries in Western Europe had established food safety and nutrition policies similar to those in the United States before NLEA (Helsing 1991). But although the majority of these programs recognized that information and public education were key components of a national nutrition policy, they stopped short of requiring labeling on all processed food products.

The regulation of food and nutrition labeling in Europe has taken place within the context of attempts to establish a common European market. In 1979, the European Community (EC) issued rules on food safety and consumer protection based on the "Principle of Mutual Recognition," intended to standardize food health regulations to facilitate international trade. Under this rule, no EC country was to prevent the importation of a food product legally produced and sold in another country, even though the product might not be legally produced according to standards established by the importing country's own laws. Such a rule eased trade restrictions in the EC but presented risks of lowered food quality and safety in countries with more stringent quality standards.

To address these concerns, the EC expanded regulation in the 1980s with new rules on product definition, quality differentiation, and labeling. Under these directives food labels were required to display information on product characteristics, including quality, quantity, and origin of ingredients. Producers are prohibited from making health claims that link their product to the prevention or treatment of diseases. EC labeling policy was intended to supply European consumers with adequate information on nutrition and food quality to help them make informed choices in the grocery store without setting up rigid labeling regulations that might place burdens on individual national economies (Worley et al. 1994).

The variety of nutrition policies in Europe underscores the way variations in regional dietary patterns and differing political environments affect governments' willingness to establish nutrition regulations and is illustrated by a brief examination of food policy in Norway, Denmark, and Poland. In Norway, government planners chose a carefully activist nutrition policy, unique in the extent to which it relied on government intervention. Norway's readiness to adopt interventionist policies reflects in part the relative limits of the country's domestic agricultural sector, based heavily on dairy and beef production, and its dependence on foreign imports of sugar and grains.

Adopted in 1975, Norway's "Food Supply and Nutrition Policy" acknowledged the relationship between public-health objectives and food supply planning. The stated aims of the policy included encouraging healthy eating habits in the population, implementing the recommendations of the World Food Conference of 1974, and maximizing the domestic production of food to ensure the stability, security, and quality of the national food supply. Specific dietary changes recommended for the population – to reduce fat intake to 35 percent of total dietary energy, to increase the consumption of cereal and potatoes, to increase the proportion of polyunsaturated fat in the diet, and to increase the consumption of fish – reflected concerns over the dietary level of fat but also posed a potential threat to Norway's domestic agriculture.

Acting with support from a coalition of industry, consumer, and government representatives, the Norwegian government used a variety of consumer food subsidies (many were already in place) together with agricultural policies intended to slowly raise domestic production of grains while lowering consumer consumption of saturated fats, so as to protect both consumer and industry interests. Information controls forbade misleading advertising, particularly for foods with poor nutritional profiles such as ice cream, chocolate, and soft drinks. Educational programs were also launched and special attention was given to the nutritional content of school courses at the nursery, primary, secondary, and higher levels. Voluntary nutrition labeling of processed foods aimed to better inform the population on the nutritional content of food products. By 1990 fat consumption had dropped to the 35 percent target level and overall agricultural production rose as planned, demonstrating the success of Norway's combination of interventionist and information policies (Gormley, Downey, and O'Beirne 1987; Helsing 1991).

In Denmark, by contrast, food and nutrition policy came relatively late, and was poorly promulgated and coordinated. Acting in response to consumer interest in diet and health, the government adopted a formal nutrition policy in 1984. Unlike Norway, Denmark's policy did not formulate specific nutrition policy goals or assign responsibility for coordination of policy activities. Although the government helped establish several research institutes focused on nutrition issues, little attention was given to providing nutrition information to the public. In 1990, Denmark's nutrient pattern failed to show the same dramatic improvements that had been seen in Norway (Helsing 1991).

Poland's experience with nutrition policy offers an exemplary case of the problems countries on the geographical and economic periphery of the European Union (EU) face in achieving standards deemed important by the Union. In Poland, as in other Eastern European countries with command economies before 1989, nutrition policy lags behind and creates problems for public health and international trade. Though the right of Polish consumers to truthful disclosure of information about the quality of food products was presumably guaranteed when the Polish government accepted United Nations Organization directives in 1985, advertising became the main – and not very satisfactory – source of information about food quality for most Polish people after 1989.

In April 1995, the Federation of Polish Consumers issued a report on "The State of Realization of Consumer Rights in the Polish Food Market" that called attention to shortcomings in the Polish regulatory system. The report made it clear that despite growing public awareness of nutrition issues, laws then in place that dealt with the nutritional composition of foods and their advertising were not effective because the Polish government lacked the power to enforce them. Thus, for example, it became impossible to fine manufacturers that used deceptive advertising because there was no government office to evaluate the nutritional claims made by advertisements.

An ineffective nutrition policy also affects foreign markets for Poland's agricultural products, and it would seem that food labeling policy is necessary to make Polish food acceptable and competitive in international markets as well as competitive with imports reaching Poland. The regulation of nutrition labeling would give Polish manufacturers incentives to quickly come into compliance with higher standards. Such a step would also provide Polish consumers with knowledge to protect themselves from risks posed by foods and save them from buying costly products whose quality is misrepresented. Like other central and Eastern European nations where agriculture and food production are key sectors of the national as well as the export economy, Poland faces the need to put in place effective regulations and enforcement policies that ensure the quality of food products and the reliability and usefulness of information provided on food labels.

An international comparison of nutrition regulation can also underline the importance of food labeling, not only for its value in public education and for encouraging better health but also as an increasingly important component of international trade. The stiffer regulatory environment in the United States poses potential barriers to the import of food from other countries, even those in Western Europe, where regulations are less strict (Worley et al. 1994). As countries in both Eastern and Western Europe and North America transform their regulatory requirements to comply with international trade agreements, informational approaches to food regulation will play a more significant role and will likely lead toward the gradual convergence of international regulatory policies.

This is a slow-moving process, largely because labeling policies evolve in different political climates and in response to different regional diets, but also because food manufacturers typically oppose mandatory nutrition labeling of foods. Changes in national nutrition-labeling regulation have to be carefully negotiated between consumer, government, and industry representatives and involve important policy issues.

Nutrition Labeling and Policy Issues

Since a better awareness of linkages between diet and health has been achieved, governments of many countries have been forced to confront the issue of market intervention in order to regulate food quality. There are two main approaches to the implementation of nutrition policies by central governments. The first, called the minimalist approach, stresses the responsibility of the individual in the attainment of a healthful diet. The role of government is limited to the development and advocacy of dietary guidelines and to the provision and monitoring of information available to the consumer on the nutritional composition of foods. The planned interventionist approach, in contrast, maintains that government should actively intervene in many sectors of the economy to achieve optimum nutrition for all citizens.

With the exception of Norway, however, developed nations have thus far adopted minimalist approaches to nutrition regulation that rely on market forces to ensure the nutritional quality of food products and the nutritious diets of their populations. Governments have many reasons for hesitating to adopt planned interventionist programs. The most common can be grouped under the headings "scientific/philosophical" and "political." Scientific/philosophical reasons include a lack of confidence in the scientific basis of most nutrition theories and thus a hesitation to intervene in nutrition-related health issues without "absolute" scientific proof. When combined with philosophical beliefs in the sufficiency of the market and a reluctance to interfere with the individual's freedom of choice, these reasons join to make a compelling argument for a minimalist approach.

Political reasons for the unwillingness of governments to adopt interventionist policies center primarily on the relative importance of the agricultural and food processing industry sectors in different countries. For example, in nations with economically highly ranked agriculture and food processing industries, like Denmark, the Netherlands, Ireland, and Belgium, politicians may be unwilling to interfere with food availability and choice because of resistance from powerful producers and various lobbies and a lack of a clear support from the public. Public demands for action, however, may encourage elected officials to address such issues (Gormley et al. 1987).

As already noted, though, even the implementation of a minimalist government nutrition policy has been politically controversial, especially in the United States and Great Britain, where the agricultural and the food processing industries were concerned that government efforts to implement dietary guidelines could threaten their survival. In fact, a successful implementation of the ideal dietary guidelines would imply reduced demand for meat, dairy products (two well-organized producer groups in the United States), eggs, fats, and sweets and increased demand for vegetables, fruits, cereals, and vegetable oils. This would represent a major shift in the diets of the populations and could potentially disrupt the food production sector. Not surprisingly, the regulation of nutrition has often been resisted by meat and dairy producers and other agricultural interests.

Nevertheless, despite the potential economic dislocation feared by advocates of a "hands-off" approach, there are compelling arguments for government intervention in nutrition regulation. Even though a degree of scientific uncertainty exists, most researchers agree that public health is well served by increased knowledge of nutrition and by the availability of nutritionally sound foods. Yet although it is true that producers will readily supply food with a positive nutrition profile if it is profitable for them to do so, the cost is a likely deterrent. Consequently, without some form of regulation to control the truthfulness of label claims, producers who do market higher-quality food face unfair competition from others offering less expensive, lower-quality products.

Following the philosophical assumptions surrounding belief in the "free market," some economists, policy makers, and food manufacturers have argued that relatively unregulated markets provide adequate information to consumers on the nutritional quality of foods, making government regulation of information disclosure unnecessary. In a perfectly operating market, product price will, theoretically, transmit all the information the consumer needs to make a rational, informed choice. A variety of products with different levels of quality and risks would be offered for sale at a variety of prices; higher nutritional quality would be signaled by higher prices. In a theoretically "free market," consumers would choose among a variety of foods based on their preferences for products and the attributes of those products (Caswell and Mojduszka 1996).

The actual marketplace, however, is rarely free or perfect in the theoretical sense and typically fails to provide either accurate nutritional information or foods with good nutritional profiles. Manufacturers are better informed about the content and nutritional profiles of their products than consumers. Consequently, if information on the nutritional quality of food is inaccurate, or if public perceptions about the risks or hazards associated with certain food products are incorrect, then consumers are exposed to health risks far greater than they would have been willing to face if they were able to make informed decisions. These factors imply that government should intervene in the marketplace to ensure the provision of nutritious food and, thus, enhance consumer health.

Governments in market economies have three basic instruments that can be used to influence the nutritional quality of the food supply: providing the public with more reliable information about nutrition, enhancing production standards at processing plants, and confronting manufacturers with pecuniary measures, including taxes, subsidies, and fines (Kramer 1990). Because the political and philosophical climate of the last two decades has favored minimalist approaches to market intervention, government agencies have focused mostly on the first of these. Information remedies can take a variety of forms: the mandatory disclosure of information about the nature of products by manufacturers; controls on claims made for product promotion; provision of public information and education; government subsidies for the provision of information; and control of product names. Such measures are undertaken in an attempt to encourage people to demand foods with a high nutritional profile and, as we have already noted, to inspire manufacturers to produce higher-quality foods. As we have seen, the NLEA, as promulgated by the FDA, leans heavily on information remedies.

Policy experts consider information regulation appropriate, and particularly valuable, in the case of nutrition because without it, it is generally impossible for consumers to determine either the health safety or the nutritional quality of food, even after the product has been bought and consumed. Advocates of the minimalist approach also assume that the regulation of information will encourage consumers to purchase more healthful food bundles, in turn compelling producers to improve the nutritional formulation of their products without direct legislative intervention in the production process.

Though the FDA contends that food prices will show little change as a result of mandatory nutrition labeling, reliance on information remedies to regulate food nutrition does impose other costs on consumers by forcing them to spend time reading labels and, of course, learning about nutrition. This can be something of a problem because minimalist information remedies do little to control food advertising beyond limiting false or misleading claims, and even under the relatively stringent NLEA rules, producers and marketers are able to sometimes use vague nutrition-related claims to powerfully influence consumer food choice. Finally, critics of the minimalist approach maintain that its intent is often severely weakened by a lack of formal government commitment to action. For example, educational or enforcement programs may have inadequate funding.

The effects of labeling regulation are difficult to measure. A 1996 survey in the United States showed mixed results: Whereas 58 percent of consumers polled said that they always read the nutrition label before buying a product for the first time (up from 52 percent in 1991), and more than half said they were trying to eat less fat, 46 percent agreed with the statement that "there is so much conflicting information about which foods are good for me that I'm not sure what to eat anymore" (Howe 1996).

Information remedies clearly have limits, and interventionist approaches, despite their current unpopularity, may ultimately offer consumers greater health protection by directly requiring producers to improve the quality of their foods. In a political climate that favors a minimalist approach, however, government adoption of nutrition regulation focused on information remedies can influence product design, advertising, consumer confidence in food quality, and consumer education about diet and health. The implementation of nutrition labeling regulation thus offers real health benefits to the general population and potentially improves both economic efficiency and public welfare (Caswell and Padberg 1992).

Conclusion

Before World War II, rules for information disclosure on food labels were generally understood as one component of more general food safety policies. After the war, nutrition was increasingly seen as an important factor in its own right, and by the 1970s, most developed countries had established nutrition policies that included provisions for consumer information and food labeling. Perhaps ironically, concerns with nutrition are greater in countries where there is abundant food for most citizens and malnutrition is a result of poor dietary habits rather than food shortages. In less developed countries, where nutrition deficits are often the result of a lack of food, regulation of nutrition through labeling may appear superfluous or unnecessary until supply problems are solved; in addition, neither consumers nor governments can afford the relatively high costs associated with labeling programs.

Nutrition labeling is only one of the possible policy tools available to governments as part of a modern program of nutrition and food safety regulation, but in an economic environment stressing free trade and nonintervention, it has become increasingly important. Product labeling and information disclosure requirements act as an interface between government requirements, manufacturer response, and consumer demand that encourages nonpunitive market incentives with relatively limited government interference. Nutrition labeling policies continue to evolve in an increasingly international environment and are now seen as possible nontariff barriers to the flow of international trade. Among the strongest incentives to modify nutrition labeling policy in the twenty-first century will be concerns with the compatibility of regulatory regimes across national boundaries.

Nutrition labels can provide an important benefit to the health of certain groups of consumers, but they also impose costs on consumers, producers, and government. The use of labels can require expensive monitoring programs in regulating industry and educational programs to encourage public awareness; producers may also be forced to invest in product reformulation and new label design. Labels are also something of a double-edged sword and, at times, have been used by manufacturers to misrepresent the nutrition profiles of certain foods in marketing campaigns. In the end, the success of nutrition labeling depends on a number of interacting factors, making effectiveness difficult to measure without broad studies that focus on changes in consumer awareness and dietary patterns, as well as on the introduction of new foods with more healthful nutrition profiles and improvements in the nutritional quality of existing food products.

VII.6 ~ Food Lobbies and U.S. Dietary Guidance Policy

In April 1991, the United States Department of Agriculture (USDA) withdrew from publication its *Eating Right Pyramid,* a new food guide for the general public. Despite official explanations that the guide required further research, its withdrawal was widely believed to have been prompted by pressure from meat and dairy lobbying groups who objected to the way the *Pyramid* displayed their products (Burros 1991b; Combs 1991; Sugarman and Gladwell 1991; Nestle 1993a).

This incident focused attention on a continuing political and ethical dilemma in American government: The rights of individuals guaranteed by the First Amendment to the Constitution versus the social good. In this case, the dilemma involved the inherent right of private industries to act in their own economic self-interests versus the best judgments of health authorities as to what constitutes good nutrition for the public. The *Pyramid* controversy also focused attention on the dual and potentially conflicting USDA mandates to protect U.S. agricultural interests and to issue dietary recommendations to the public (Nestle 1993b).

To address such dilemmas, this chapter reviews the history of dietary guidance and lobbying policies in the United States, describes the principal food lobbies, and presents examples of ways in which they have influenced – or have attempted to influence – federal dietary advice to the public. Finally, it discusses options for correcting improper, sometimes unconscionable, food lobby influence on U.S. nutrition policies.

U.S. Dietary Guidance

From its inception in 1862, the USDA was assigned two roles that have led to the current conflict of interest: to ensure a sufficient and reliable food supply, and to "diffuse among the people of the United States useful information on subjects connected with agriculture in the most general and comprehensive sense of that word" (USDA 1862). In the early 1890s, the USDA began to sponsor research on the relationship between agriculture and human nutrition and to translate new discoveries into advice for consumers. By 1917, the agency had produced at least 30 pamphlets that informed homemakers about the role of specific foods in the diet of children and adults.

The USDA's first dietary recommendations established principles that govern its policies to this day. The agency recommended no specific foods or combinations of foods. Instead, it grouped foods of similar nutrient content into five general categories – fruits and vegetables, meats, cereals, sugar, and fat (Hunt and Atwater 1917). Such a recommendation was intended to encourage the purchase of foods from the full range of American farm products, for by 1921, improvements in agriculture had led to greater availability of many different kinds of foods, any one of which was said to contribute to wholesome and attractive diets (Hunt 1921).

Thus, the recommendation was supported by food and agricultural producers who suspected that the market for their products was becoming limited as the U.S. food supply was already sufficient to provide adequate food to all of its citizens; consequently, any increase in use of one food commodity would have to occur at the expense of others (Levenstein 1988). During the next 35 years, the USDA produced many pamphlets based on the food group approach, all emphasizing the need to consume foods from certain "protective" groups in order to prevent deficiencies of essential nutrients (Haughton, Gussow, and Dodds 1987). The number of recommended food groups, however, varied over the years in no consistent pattern (Nestle and Porter 1990).

At least some of the variation in the number of food groups reflected concerns about the impact of dietary advice on consumer purchases. A Great Depression–era food guide, noting that producers want "to know how much of different foods may well appear in the diets of different consumer groups, and to what extent consumption may rise or fall as the economic situation changes," increased the number of food groups to 12 and included, for the first time, milk as a separate category (Stiebeling and Ward 1933).

In the 1950s, national nutrition surveys indicated that the diets of many Americans were below standard for several nutrients. To help the public choose foods more wisely, USDA nutritionists proposed a simplified guide based on four groups – milk, meats, vegetables and fruits, and breads and cereals – which, for the first time, would specify the number and size of servings.

Prior to its release, the USDA invited leading nutrition authorities to review the guide. Food industry representatives were also sent drafts because "it was felt that food industry groups would have a vital interest in any food guide sponsored by the government" (Hill and Cleveland 1970). Dairy organizations were pleased with the treatment given to milk and milk products, but "meat industry groups were unhappy about the serving size indicated for meat . . . [t]hey pointed out that this size is smaller than average" (Hill and Cleveland 1970). Despite these complaints, the controversial serving sizes (two daily portions of 2 to 3 ounces cooked meat) were incorporated unchanged into the final version of what became known as the *Basic Four* (USDA 1958). This guide remained the basis of USDA nutrition policies for the next 20 years (Figure VII.6.1). Except for the minor concern about portion size, food producer groups supported USDA efforts to promote consumption of more – and more varied – food products.

This relationship changed when policymakers became aware that nutritional deficiencies had declined in prevalence and had been replaced by chronic diseases related to dietary excesses and imbalances. Early reports on the role of dietary fat in atherosclerosis were published in the mid-1950s (Page, Stare, Corcoran et al. 1957), advice to reduce caloric intake from fat in 1961 (American Heart Association 1961), and recommendations for dietary changes and public policies to reduce coronary heart disease risk factors in 1970 (Inter-Society Commission 1970). These last recommendations called for significant reductions in overall consumption of fat (to 35 percent of calories or less), saturated fat (to 10 percent), and cholesterol (to 300 milligrams per day).

The 1977 Farm Bill (Public Law 95–113) specified that the USDA was to be responsible for a wide range of nutrition research and education activities, including dietary advice to the public. In 1988, in an effort to ensure that the federal government speak with "one voice" when it issues dietary recommendations, the House Appropriations Committee reaffirmed USDA's lead agency responsibility for this activity (U.S. House of Representatives 1988). As dietary recommendations shifted from "eat more" to "eat less," the USDA's dual responsibilities for protecting agricultural producers and advising the public about diet created increasing levels of conflict.

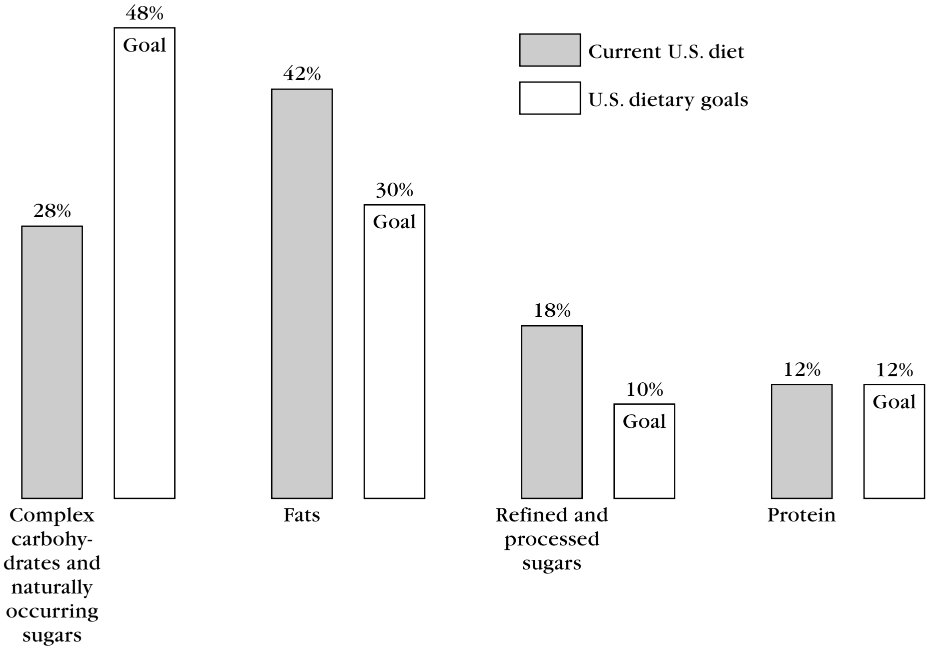

Figure VII.6.1. Meat and dairy groups approved as the 1958 *Basic Four*, as it emphasized the importance of their products in the U.S. diet. Meat producers complained, however, that the suggested portion sizes were too small. (From Hill and Cleveland 1970; USDA 1958.)

Although this conflict was often expressed in terms of the scientific validity of diet–disease relationships, it derived from the profound economic implications of dietary recommendations (Timmer and Nesheim 1979). Foods of animal origin – meat, dairy products, and eggs – have provided much of the total fat and saturated fat, and all of the cholesterol, in the U.S. food supply. In 1990, for example, meat provided 32 percent of the total fat and 40 percent of the saturated fat, and dairy products 12 and 20 percent, for a combined total of 44 and 60 percent, respectively (Raper 1991). Thus, advice to consume less fat and cholesterol necessarily translated into reduced intake of meat, dairy products, and eggs. By 1977, this message was well understood by nutrition scientists, dietitians, and consumer activists (U.S. Senate Select Committee 1977c) and was reflected in declining sales of whole milk and eggs (Putnam 1991). As these trends continued and as beef sales also began to decline, food producer lobbies became much more actively involved in attempts to discredit, weaken, or eliminate dietary recommendations that suggested using less of their products.

Lobbies and Lobbyists

In tribute to their level of influence, lobbies and lobbyists have been viewed as constituting a third house of Congress (Schriftgiesser 1951) or fourth branch of government (Berry 1984). But its members are appointed rather than elected, paid to represent private (and thus not always public) interests and to pursue those interests through activities that are often not in full view of the general public. Thus the actions of lobbies can and do raise concerns about their potential to corrupt democratic political processes (American Enterprise Institute 1980).

Definition of Lobbying

In the broadest possible sense, lobbying includes any legal attempt by individuals or groups to influence government policy or action; this definition specifically excludes bribery. All lobbying efforts involve three common elements: an attempt to influence governmental decisions, representation of the views of special interest groups, and communication with government officials or their representatives. Therefore, a lobbyist is an individual who communicates with a government official on behalf of a third party in the hope of influencing federal decisions. When surveyed, lobbyists have stated that their one common characteristic is similar to that of most others connected with the political process: They try to influence governmental decisions in some way (Milbrath 1963).

Lobbying in the United States

The history of attempts to control lobbying reflects basic tensions in the American political system. From its beginnings, this system has granted individuals the right to express political views publicly, to petition government regarding such views, and to organize on behalf of them. Elected officials of representative governments must listen to constituents, yet special interest groups constantly pressure the government to enact policies that may benefit relatively few constituents. Attempts to control such pressures, however, have been viewed as infringements of constitutionally guaranteed civil rights, and Congress has found it difficult to draft acceptable laws to curb lobbying abuses (Milbrath 1963). Despite substantial public and congressional concern about many lobbying activities, there is little consensus as to how such activities might be controlled (Berry 1984).

This dilemma appeared early in U.S. history. James Madison, writing of the "dangerous vice" of factions (the term he used for lobby groups), observed that they arise from causes inherent in human nature and in the unequal distribution of property. Relief from the "mischiefs of faction," according to Madison, would derive from the principles of majority rule proposed for the federal republic. A faction "may clog the administration, it may convulse the society," but under the terms of the Constitution, "it will be unable to execute and mask its violence" (Madison 1787: 45).

Indeed, from the earliest years of the new republic, public exposures of excessive and dishonest lobbying were followed by investigations and demands for regulation of interest groups. In response, Congress made sporadic attempts to control lobbying abuses. Proposed legislation typically passed in one house or the other but failed to become law. Congressional leaders were unable to agree on legislation that would curb dishonest lobbying yet permit individual rights to free speech and petition (Congressional Quarterly 1968).

Table VII.6.1 summarizes selected landmarks in the history of U.S. lobbying. As early as 1829, individuals who frequented the lobby of the state capitol in Albany in order to seek favors from New York legislators were called "lobby-agents." By 1832, Washington journalists were using the term "lobbyists" in the current meaning of the term. In 1877, frequent abuses led the state legislature of Georgia to declare lobbying to be a crime, and Massachusetts, Maryland, Wisconsin, and New York passed antilobby legislation between 1890 and 1905. Beginning in 1911, nearly every Congress attempted to probe and control lobbying and related activities. Between 1935 and the early 1940s, Congress enacted laws requiring employees of public utilities, the merchant marine, and foreign governments to register and report political contributions, and it prohibited labor unions from making such contributions. Such actions, however, failed to make any real progress in controlling lobbying abuses (U.S. Senate Special Committee 1957; Congressional Quarterly 1965).

Legislative Mandate

When Congress finally did address interest group practices, it made lobbying legal. The 1946 Federal Regulation of Lobbying Act protected lobbyists' rights and required only that persons paid to lobby, or the organizations paying them, disclose their identities and sources of funds. The act, which is still in force, requires lobbyists to register and to file with Congress sworn quarterly reports disclosing the amounts of

Table VII.6.1. *Selected landmarks in the history of U.S. lobbying*

1787	James Madison, in Federalist Paper No. 10, warns of the dangers of self-interested "factions" to government processes.
1792	First Amendment to Constitution guarantees right to free speech, assembly, and petition to Congress.
1829	The term "lobby-agent" is used to describe a person who frequents the lobby of the state capitol in Albany in order to seek special favors.
1832	Washington journalists first use the term "lobbyists."
1877	Georgia's constitution declares lobbying to be a crime.
1890–1900	Massachusetts, Maryland, Wisconsin, and New York pass anti-lobby legislation.
1907	Congress forbids corporations to make political campaign contributions in federal elections.
1919	Internal Revenue Service rules lobbying expenditures are not deductible from federal income taxes by businesses or individuals.
1935	Public Utilities Holding Company Act prohibits political contributions by utility companies and requires individuals who do make contributions to register and report.
1936	Merchant Marine Act requires similar registration and reporting.
1938	Foreign Agents Registration Act imposes registration and reporting requirements for political contributions.
1943	Smith-Connolly War Labor Disputes Act bars political campaign contributions in federal elections by labor unions during war emergency.
1946	Federal Regulation of Lobbying Act, adopted as Title III of the Legislative Reorganization Act of 1946 (P.L. 79-601), requires paid lobbyists to register and file financial reports.
1947	Taft-Hartley Act prohibits political campaign contributions by labor unions and corporations.
1954	Supreme Court upholds constitutionality of 1946 act in *U.S. v. Harriss;* limits law to individuals paid by a third party to communicate directly with members of Congress to influence legislation.
1956	In connection with a bribery attempt, Superior Oil Company attorneys become the first – and only – individuals to be convicted for failure to register under the 1946 act.
1957	Senate investigating committee finds 1946 act failing to achieve the disclosure aims that it was designed to accomplish.
1968	*Congressional Quarterly* lists 23 former senators and 90 former congressmen who have registered as lobbyists since 1946.
1974	Amendments to the Federal Election Campaign Act authorize the formation of Political Action Committees (PACs) to fund congressional campaigns.
1980	Congress attempts to revise the lobbying act.
1991	More than 7,000 individuals register as lobbyists.

money they receive or spend, the individuals to whom they pay funds, the purposes of these payments, and the specific legislation that they are supporting or opposing (Schriftgiesser 1951; Congressional Quarterly 1965). This law, considered vague by virtually all authorities (U.S. Senate Committee 1991), was reduced further in coverage by challenges in federal courts. In a 1954 case, *U.S. v. Harriss,* the Supreme Court upheld the constitutionality of the act, albeit through a narrow interpretation; it limited the law's applicability only to individuals who solicited or received money for the purpose of lobbying members of Congress (Congressional Quarterly 1965).

These decisions leave much room for ambiguity; they can be interpreted as permitting interest groups to lobby congressional staff or officials and staff of cabinet departments and their agencies, and to decide for themselves whether and how much they need to report. The act defines no special enforcement procedures, even though it specifies criminal penalties for noncompliance. In its entire history, the act has resulted in only one conviction (Congressional Quarterly 1968). Despite repeated attempts to strengthen its provisions (American Enterprise Institute 1980), the 1946 act remains in force only as modified by *U.S. v. Harriss.* Thus, the view that lobbying legislation is unenforced, unenforceable, and widely ignored continues to prevail (U.S. Senate Committee 1991).

Registered Lobbyists

The extent to which the lobbying act may be ignored is uncertain. During the 20 years following its passage, an average of 400 lobbyists registered and reported contributions that amounted to $4 to $5 million annually, but these figures were considered low because of the many loopholes in reporting requirements (Congressional Quarterly 1968). The number of registrations grew rapidly from 1960 to 1980, partly in response to expansion in the size and complexity of government. In 1963, the government included 10 major cabinet departments and 70 major agencies, and Congress employed 7,700 aides. By 1991, these numbers had increased to 14, 140, and 20,062, respectively. The number of registered lobbyists doubled between 1976 and 1986 (Browne 1988). At the beginning of the 1990s, 7,000 to 8,000 individuals registered as lobbyists, many representing multiple organizations or causes (Registered lobbyists 1991; U.S. Senate Committee 1991).

The interests represented by lobbyists encompass every conceivable aspect of American corporate and private enterprise: banks; corporations; legal, public relations, and life insurance firms; educational institutions; professional societies; advocacy groups; city, state, and national governments; defense, health, computer, energy, drug, chemical, paper, tobacco, transportation, travel, and, of course, food industries. They all pay individuals to represent their interests to Congress. There is no industry too small, no group too isolated, and no opinion too extreme to lack a professional lobbyist. Lobbying is a multimillion-dollar industry with enormous impact on government decisions (U.S. Senate Committee 1991).

Food Lobbies

The Agricultural Establishment

By the end of World War II, farmers and food producers had come to view the USDA as their department and its secretary as their spokesman. Producers, together with USDA officials and members of the House and Senate Agricultural Committees, constituted the "agricultural establishment" and ensured that federal policies in such areas as land use, commodity distribution, and prices promoted their interests (Paarlberg 1964). The control exercised by producer groups over USDA and congressional actions was so complete that both the secretary of agriculture and the president were said to be excluded from any significant role in policy decisions (Kramer 1979).

The perpetuation of this system was guaranteed by the congressional seniority system and the strong representation on agriculture committees of members from farm states. Committee membership rarely changed hands. Allen Ellender (D-La), for example, chaired the Senate Agriculture Committee for a total of 18 years, and his successor, Herman Talmadge (D-Ga), held the chair for 10 more. Jamie Whitten (D-Miss), first elected to Congress when Franklin Roosevelt was president, chaired the House Agricultural Appropriations Subcommittee for so long that he was referred to as "the permanent secretary of agriculture" (Morgan 1978b); he was elected to his twenty-seventh term of office in 1992 and resigned the committee chair he had held since 1949 when he finally left office in 1994 (Binder 1995).

By the early 1970s, this system weakened as new constituencies demanded influence on agriculture policies. A combination of bad weather, poor harvests in foreign countries, and massive purchases of U.S. grain by the Soviet Union had led to increased food costs and consumer complaints (Kramer 1979). Agriculture was gaining in importance in the U.S. economy, and the food industry was expanding to include processors and marketers as well as producers (Morgan 1978b). Responsibility for providing food assistance to the poor was assigned to the USDA (Morgan 1978a). In response to demands from these constituencies, the House expanded the membership of its Agriculture Committee to include representatives from urban areas in 1974, and, in 1977, the agriculture committees of both houses were assigned jurisdiction for policies and programs related not only to agricultural production, marketing, research, and development, but also to rural development, forestry, domestic food assistance, and some aspects of foreign trade, international relations, market regulation, and tax policies (Knutson, Penn, and Boehm 1983).

Food Lobbyists

The number of food lobbying groups reflected the expansion in constituencies. In the 1950s, 25 groups of food producers dominated agricultural lobbying, but by the mid-1980s, 84 groups lobbied on food issues (Browne 1988). In the early 1990s, food lobbies included a multiplicity of groups, businesses, and individuals attempting to influence federal decisions. They represent producers, growers, marketers, processors, and distributors of every imaginable fruit, vegetable, cereal, baby food, diet aid, nutritional supplement, sweetener, and product grown or manufactured at the local, state, or national level. They also represent manufacturers of pesticides, feeds, and fertilizers; professional and health organizations; and food, nutrition, antihunger, and welfare activists (Registered lobbyists 1991). Table VII.6.2 lists specific examples of such groups. The number of active food lobbyists is uncertain. A 1977 study identified 612 individuals and 460 groups lobbying on food and agriculture issues (Guither 1980). A cursory review of current lobbyist registrations suggests that 5 to 10 percent of lobbyists are concerned with such issues.

Lobbying Methods

Personal Contacts

No matter whom they represent, all lobbyists use similar strategies to gain access and influence. Of these methods, lobbyists rank personal contacts as the most effective means of gaining access to government officials. These contacts are established through office visits, meetings, participation on advisory boards, testimony at hearings, social occasions, fundraising sessions, and performance of favors, as well as through the engagement of other individuals and groups to perform such favors. Lobbyists also organize meetings, provide technical advice, contribute to election campaigns, stage media events, employ public relations firms, organize public demonstrations, and encourage lawsuits (U.S. Senate Special Committee 1957; Milbrath 1963; Browne 1988).

Technical Expertise

Virtually all blueprints for successful lobbying emphasize the importance of knowledge and credibility (deKieffer 1981; Berry 1984). These attributes establish lobbyists as technical experts who provide Congress with well-researched advice on issues related to proposed legislation. The value of this expertise is, in part, responsible for a congressional reluctance to control lobbying activities.

Financial Contributions

Individual and corporate contributions and gifts to members of Congress are strictly regulated by the Federal Election Campaign Act. Small items such as lunches, books, awards, liquor, samples, and theater tickets are considered acceptable (deKieffer 1981). Also considered legal are very large payments for administrative costs, fundraising events, travel expenses, and honoraria. Thus in 1991 several food and agriculture corporations legally donated $100,000 or more each to the Republican Party (Babcock 1991).

An analysis of privately funded travel among members of the House of Representatives in 1989–90 identified nearly 4,000 trips sponsored by lobby groups, two-thirds of them corporations or trade associations.

Table VII.6.2. *Selected examples of food lobbying groups*

Commodity producer organizations
American Soybean Association
American Sugar Beet Growers Association
Florida Sugar Cane League
National Association of Wheat Growers
National Broiler Council
National Cattlemen's Association
National Corn Growers' Association
National Fisheries Institute
National Milk Producers' Federation
National Peanut Growers Group
National Pork Producers Council
Rice Millers' Association
United Egg Producers
United Fresh Fruit and Vegetable Association
Processing, manufacturing, and marketing organizations
American Frozen Food Institute
American Meat Institute
Chocolate Manufacturers' Association of the U.S.A.
Corn Refiners Association
Food Marketing Institute
Grocery Manufacturers of America
National Food Processors Association
National Frozen Food Association
National Soft Drink Association
Peanut Butter and Nut Processors' Association
Public interest groups and professional societies
American Cancer Society
American Dietetic Association
American Heart Association
American School Food Service Association
Center for Science in the Public Interest
Food Research and Action Center
Public Voice for Food and Health Policy
Society for Nutrition Education
Private food producers
Cargill
ConAgra
Archer-Daniels-Midland
Mars
Pizza Hut
Safeway Stores
Ralston-Purina

Sources: Guither (1980) and Browne (1988).

In particular, agriculture lobbies sponsored 390 trips and paid more than $500,000 in honoraria to House members during the 101st Congress; of these trips, 239 went to members of the House Agriculture and Appropriations Committees. The most frequent corporate-sponsored traveler was Charles Stenholm (D-Tex), a senior member of the Agriculture Committee. Of his 50 paid trips, agricultural interest groups sponsored 37; they also provided $38,250 in honoraria (McCauley and Cohen 1991).

Election Campaign Contributions

In 1974, amendments to the Federal Election Campaign Act authorized formation of Political Action Committees (PACs) by corporations and other groups to collect and disburse voluntary campaign contributions. Although the law limits the amount of money that can be contributed to any one candidate, it does not restrict the number of candidates to whom contributions can be made or the number of PACs that can contribute to any one candidate. In 1974–5, 608 PACs contributed $12.5 million to election campaigns; by 1982, 3,371 PACs, nearly half of them corporate, were contributing $83 million (Berry 1984); and by the election of 1989–90, nearly 4,700 PACs were contributing more than $370 million to candidates (Federal Election Commission 1991b).

The size of the contribution to any one candidate typically varied from $500 to $2,000; however, such contributions could add up to substantial amounts. In 1989–90, Senators Robert Dole (R-Kan), Jesse Helms (R-NC), and Tom Harkin (D-Iowa), all members of the Committee on Agriculture, Nutrition, and Forestry, received respectively $308,000, $790,000, and $1.5 million in PAC contributions. These amounts all derived from contributions of $5,000 or less (Federal Election Commission 1991a).

Relatively few PACs represent food and agriculture interests. In 1978, 82 such PACs were identified, 46 of them producer groups contributing a total of $1.4 million. The largest contributor was the Associated Milk Producers PAC, which distributed a total of $456,000 among 37 candidates for the Senate and 185 candidates for the House (Guither 1980). PACs representing the dairy industry remain relatively large contributors; an analysis by Common Cause of Federal Election Commission data found that dairy groups contributed nearly $1.8 million to candidates in 1989–90. In comparison, beef PACs contributed just over $326,000 in that election. In the period from 1985 to 1990, dairy PACs contributed a total of $5.5 million and beef PACs $864,000 to election campaigns, but these amounts were greatly exceeded by the $25, $23, and $12 million donated by the real estate and construction, insurance, and banking industries, respectively (Common Cause, personal communication).

In the 1989–90 election campaign, food and agriculture PACs, though still in the minority, were well represented. Contributions came from the sugar, meat, dairy, egg, soft-drink, wine and liquor, rice, fruit, vegetable, seed, and snack food industries, as well as from PACs representing growers, distributors, manufacturers, and promoters. As an example, Table VII.6.3 provides a partial listing of food and agriculture PACs that contributed to the 1989–90 campaign of Senator Harkin. PACs representing consumer, health, or public interest groups are rare. As noted by Senator Dole in an earlier context, "there aren't any Poor PACs or Food Stamp PACs or Nutrition PACs or Medicare PACs" (Berry 1984).

Nevertheless, experts differ on whether the small amount of money contributed by any one PAC is sufficient to buy influence. Some political commentators believe that the power of PACs is overrated (Bowers 1991), whereas others view it as insidious, largely because members of the House and Senate who hold important positions on powerful committees become ". . . more beholden to the economic interests of their committee constituents than to the interests of their district residents or to the President or party" (Califano 1992).

One study found that members of the House of Representatives who received dairy PAC funds were almost twice as likely to vote for legislation to maintain price supports as those who did not; that supporters of maintenance received 2.5 times more PAC funds than opponents; and that the more PAC money members received, the more likely they were to support such legislation (Public Citizens' Congress Watch 1982). Most experts agree that PACs give the appearance of purchasing influence, whether or not they actually do so.

Revolving Door

The transformation of government officials into lobbyists and of lobbyists into government officials is commonly known as the "revolving door." By 1968, at least 23 former Senators and 90 former Congressmen had registered as lobbyists for private organizations (Congressional Quarterly 1968). Job substitutions between food producer lobbies and the USDA have been especially frequent and noticeable. At the USDA, as many as 500 agency heads and their staff members are chosen on the basis of political party, support from key politicians, and other political criteria rather than expertise. Such appointments are strongly influenced by special interest groups (Knutson et al. 1983).

In 1971, for example, USDA secretary Clifford Hardin traded places with Earl Butz, who was director of the Ralston Purina Company; Butz became USDA secretary and Hardin went to Ralston Purina. One report identified several assistant secretaries, administrators, and advisers who joined the USDA from positions with meat, grain, and marketing firms or who left the agency to take positions with food producers (Jacobson 1974). The chief USDA negotiator arranging for private companies to sell grain to the Soviet Union in 1972 soon resigned to work for the very company that gained the most from the transaction (Solkoff 1985). More recently, the appointment of JoAnn Smith, a former president of the National Cattlemen's Association, as chief of the USDA's food marketing and inspection division raised questions about apparent conflicts of interest when she approved the designation "fat-reduced beef" for bits of meat processed from slaughtering by-products and opposed an American Heart Association proposal to put a seal of approval on certain meat products low in fat (McGraw 1991).

Generic Advertising (Checkoff Programs)

In an effort to counteract declining consumption trends, Congress passed a series of food promotion and research acts that require producers of 15 specific commodities – among them beef, pork, dairy products, milk, and eggs – to deduct or "checkoff" a fee from sales. These strictly enforced fees are then used to promote the commodities (Becker 1991). Through these and more than 300 state programs, about 90 percent of all U.S. producers contributed more than $530 million to promote about 80 farm commodities in 1986 (Blisard and Blaylock 1989).

The two largest national checkoff funds are dairy and meat; they generated $194 and $84 million, respectively, in 1986 (Blisard and Blaylock 1989). About half the funds are distributed to state commodity boards and the other half to national promotion and research boards. The beef checkoff began as a voluntary program generating $31,000 in 1922. In the 1970s, as beef consumption began to decline, the National Cattlemen's Association started lobbying for a compulsory program through a campaign that involved PACs, letter writing, and personal visits to members of Congress by hundreds of cattle farmers. The legislation passed in 1985; beef lobbies are especially effective because cattlemen are distributed among a great many states, and beef sales amount to nearly $22 billion annually (Wilde 1992). The beef checkoff generated nearly $90 million in 1991 (Cattlemen's Beef 1991).

The various checkoff boards collect and spend the funds, award contracts, and sponsor advertising, research, and education programs. Although the legislation prohibits use of the funds for lobbying, the distinction between promoting a product to consumers and to lawmakers can be subtle. The boards are closely affiliated with lobbying groups (Becker 1991), some even sharing office space. The Cattlemen's Beef Promotion and Research Board, for example, shared an address with the National Cattlemen's Association, and the National Pork Board shared offices, staff, and telephone services with the National Pork Producers Council. The legislation actually specifies that a certain percentage of checkoff funds must be allocated to the commodity groups who nominate members of the promotion boards to be appointed by the USDA (Cloud 1989).

Although checkoff funds are supposed to be used for research as well as advertising, only a small fraction is used for that purpose. Between 1986 and 1989, the Beef Board spent nearly $106 million, of which only about 5 percent went toward research and only 1.4 percent toward development of leaner products. At the same time, the board paid more than $1 million each to movie stars Cybill Shepherd and James Garner for participating in a beef advertising campaign (Parrish and Silverglade 1990).

Checkoff programs attempt to convince consumers to choose one type of food product over another (Becker 1991). The Meat and Beef Boards, for example, aim to build demand for red meats and meat products (National Live Stock and Meat Board 1987); encourage consumers to view beef as wholesome, versatile, and ever lower in cholesterol; and educate doctors, nurses, dietitians, teachers, and the media about the nutritional benefits of beef (Cattlemen's Beef 1990). Similarly, the Dairy Boards promote consumption of cheese, milk, butter, and ice cream as the best sources of calcium and other nutrients (Westwater 1988). For the most part, studies have shown a positive relationship between such campaigns and sales for a wide range of commodities. From 1984 to 1990, for example, generic advertising was associated with significant increases in consumption of milk and cheeses (Blisard, Sun, and Blaylock 1991). The Beef Board has attributed the industry's increased relative strength to the checkoff program (Cattlemen's Beef 1991).

Checkoff supporters maintain that these programs benefit farmers at little cost to the USDA and provide useful information to consumers. Of concern, however, is the potential of checkoff programs to increase food costs and competition between commodity groups and to promote products high in fat, saturated fat, and cholesterol. Of even greater concern is the ability of lobbying groups to use the millions of dollars available from check-off funds to influence food and nutrition policies (Becker 1991).

Brand Advertising

In 1991, the annual cost of all food product advertising was $8 billion (Becker 1991). In that year, food companies that were among the top 100 U.S. advertisers spent $3.9 billion to promote their products. Three billion dollars of this amount was spent on television commercials, one-third of them for snacks and soft drinks. The leading national advertiser, Procter and Gamble, which sells food products, among others, spent nearly $2.3 billion on advertising, and McDonald's, eighth in rank, spent more than $764 million ("The 100 Leading National Advertisers" 1991).

Academic and Professional Support

Food companies routinely fund academic departments, research programs, individual investigators, and meetings, conferences, journals, and other activities of professional societies. For example, at least 16 food or nutritional supplement companies provide funding for the *Journal of Nutrition Education;* 22 support educational activities of the American Society for Clinical Nutrition; and Kraft General Foods supports a consumer hot line staffed by the American Dietetic Association.

One survey of university nutrition and food science departments identified frequent food industry payments to faculty for consulting services, lectures, membership on advisory boards, and representation at congressional hearings. This same study noted several departments receiving significant portions of their research budgets from food company grants. These faculty and departments may disclose corporate connections willingly but are rarely required to do so; they are usually grateful for the support and deny that it affects their views in any way (Rosenthal, Jacobson, and Bohm 1976).

Such conflicts of interest are not confined to the United States; a British study found that 158 of 246 members of national committees on nutrition and food policy consulted for, or received funding from, food companies (Cannon 1987). Such relationships naturally raise questions about the ability of academic experts to provide independent opinions on policy matters that might affect their sources of funding.

Food Lobbies in Action

Dietary Goals for the United States

Aware of evidence that diets high in fat, saturated fat, cholesterol, sugar, and salt were associated with chronic diseases, the staff of the Senate Select Committee on Nutrition and Human Needs, chaired by George McGovern (D-SD), held hearings on dietary determinants of obesity, diabetes, and heart diseases in 1973, and produced a report on nutrition and chronic disease in 1974. In July 1976, the committee held further hearings on the role of American food consumption patterns in cancer, cardiovascular disease, and obesity (U.S. Senate Select Committee 1977e).

On the basis of evidence presented at these hearings, the staff produced the February 1977 report *Dietary Goals for the United States.* Consistent with American Heart Association recommendations, the report established six goals for dietary change: Increase carbohydrate intake to 55–60 percent of calories; decrease fat to 30 percent, saturated fat to 10 percent, and sugar to 15 percent of calories; reduce cholesterol to 300 milligrams per day and salt to 3 grams per day. To achieve these goals, the committee advised consumption of more fruits, vegetables, whole grains, poultry, and fish, but less meat, eggs, butterfat, whole milk, and foods high in fat (U.S. Senate Select Committee 1977a).

Many groups objected to one or another of these recommendations, but the advice to "eat less" brought immediate protest from the groups most affected – cattlemen, the dairy industry, and egg producers. The cattle industry, especially in McGovern's home state, pressured the committee to withdraw the report. "Here, after all, was the Congress of the United States telling the public not to eat their products" (Broad 1979). Meat and egg producers demanded and obtained additional hearings to express their views. In these hearings, a pointed exchange between Senator Robert Dole and Mr. Wray Finney, president of the National Cattlemen's Association, established the basis for compromise on the key recommendation (No. 2) to eat less meat:

> *Senator Dole:* I wonder if you could amend No. 2 and say "increase consumption of lean meat"? Would that taste better to you?
> *Mr. Finney:* "Decrease is a bad word, Senator." (U.S. Senate Select Committee 1977d).

Committee members who represented states with large producer constituencies demanded changes in the report. McGovern "said he did not want to disrupt the economic situation of the meat industry and engage in a battle with that industry that we could not win" (Mottern 1978). The report was revised to state, "choose meats, poultry, and fish which will reduce saturated fat intake" (U.S. Senate Select Committee 1977b). These statements and later versions of recommendations concerning meat intake are listed in Table VII.6.4.

When Nick Mottern, the staff member who wrote the original report, objected to the changes, he was asked to leave his position (Mottern 1978). Shortly thereafter, McGovern was quoted as saying about McDonald's and other fast-food companies that "on the whole, quick foods are a nutritious addition to a balanced diet," leading one reporter to suggest that "still another industry has thrown its weight around" (Broad 1979).

Despite such compromises, the *Dietary Goals* report established the basis of all subsequent dietary recommendations and altered the course of nutrition education in the United States. This contribution, however, was the Select Committee's last. Shortly after release of the report, the Senate abolished the committee and transferred its functions to the Nutrition Subcommittee of the newly constituted Committee on Agriculture, Nutrition, and Forestry as of the end of the year (Hadwiger and Browne 1978). In 1980, McGovern lost his bid for reelection.

Table VII.6.4. *Evolution of federal recommendations to reduce dietary fat through changes in meat consumption*

Year	Report, Agency	Recommendation
1977	*Dietary Goals,* U.S. Senate	Decrease consumption of meat
1977	*Dietary Goals,* 2d ed., U.S. Senate	Choose meats . . . which will reduce saturated fat intake
1979	*Healthy People,* DHEW	Relatively . . . less red meat
1979	*Food,* USDA	Cut down on fatty meats (2 servings of 2–3 ounces each)
1980	*Dietary Guidelines,* USDA and DHEW	Choose lean meat
1985	*Dietary Guidelines,* 2d ed., USDA and DHHS	Choose lean meat
1988	*Surgeon General's Report,* DHHS	Choose lean meats
1990	*Dietary Guidelines,* 3d ed., USDA and DHHS	Have 2 or 3 servings, with a daily total of about 6 ounces
1991	*Eating Right Pyramid,* USDA	Choose lean meat (2–3 servings or 5–7 ounces)

Healthy People

In 1979, reflecting the emerging consensus among scientists and health authorities that national health strategies should be "dramatically recast" to emphasize disease prevention, the Department of Health, Education, and Welfare (DHEW) issued *Healthy People.* This report announced goals for a 10-year plan to improve the health status of Americans. Its nutrition section recommended diets with fewer calories; less saturated fat, cholesterol, salt, and sugar; relatively more complex carbohydrates, fish, and poultry; and less red meat. The report, noting that more than half the U.S. diet consisted of processed foods rather than fresh agricultural produce, suggested that consumers pay closer attention to the nutritional qualities of such foods (USDHEW 1979).

Because dietary advice to restrict red meat and be wary of processed foods was certain to attract notice, *Healthy People* was released in July without a press conference as one of the final official acts of Joseph Califano, who had been fired from his position as DHEW secretary by President Carter the month before. Nevertheless, the report elicited a "storm" of protest from the meat industry. The president of the National Live Stock and Meat Board was quoted as saying, "The report begins with 'the health of the American people has never been better,' and we think it should have ended right there" (Monte 1979: 4).

Healthy People became the last federal publication ever to suggest that Americans eat less red meat. When later asked about this issue, Surgeon General Julius Richmond speculated that subsequent editions of this report might advise a switch to lean meat rather than a decrease in intake of red meat in general (USDA and USDHEW 1980).

USDA's Food Books

Because USDA nutritionists found diets that met the *Dietary Goals* to be "so disruptive to usual food patterns," they developed a series of publications under the generic title *Food* to inform the public about ways to modify the calorie, fat, sugar, and salt content of diets (Wolf and Peterkin 1984). This first USDA publication to address diet and chronic disease, *Food: The Hassle-Free Guide to a Better Diet,* was notable for its caution:

> Many scientists say the American diet is contributing to some of the chronic diseases that hit people in later life. . . . Other scientists believe just as strongly that the evidence doesn't support such conclusions. So the choice is yours. (USDA 1979)

USDA staff revised the Basic Four to display the food groups in a vertical format with the vegetable/fruit and bread/cereal groups located above the dairy and meat groups. At the bottom, they added a fifth group of foods – fats/sweets/alcohol – that keep bad "nutritional company" and are high in calories but low in essential nutrients and fiber. To reduce fat intake, they suggested, "cut down on fatty meats."

Food was the most requested USDA publication in 1979 (Carol Tucker Foreman, personal communication). After the 1980 election, however, under pressure from representatives of the meat, dairy, and egg industries who objected to the negative advice about fat and cholesterol and the placement of their products below fruits, vegetables, and grains, *Food* was not reprinted and all action on subsequent publications in the series was suspended. Eventually, the USDA gave its completed page boards for *Food II* to the American Dietetic Association, which published them as two separate booklets in 1982 ("ADA to Publish" 1982). *Food* became the last federal publication to use the phrase "cut down" in reference to meat (see Table VII.6.4).

1980 Dietary Guidelines

In February 1980, the USDA and DHEW announced joint publication of *Nutrition and Your Health: Dietary Guidelines for Americans.* The recommendations were to eat a variety of foods; maintain ideal weight; avoid too much fat, saturated fat, and cholesterol; eat foods with adequate starch and fiber; avoid too much sugar and too much sodium. Those who consume alcohol should do so in moderation (USDA and USDHEW 1980). Because these guidelines had replaced the unacceptable "eat less" phrases with the vague "avoid too much," agency officials did not expect objections from food producers. As stated by USDA secretary Bob Bergland during the press conference: "They feared we might issue edicts like eat no meat, or eggs, and drink less whole milk. They have been waiting for the other shoe to fall. There is no shoe" (Greenberg 1980).

Indeed, the Food Marketing Institute (FMI) commented that the *Guidelines* are "simple, reasonable and offer great freedom of choice," and the American Meat Institute (AMI) called them "helpful," noting that they provide "a continuing and central role for meat" (USDA and USDHEW 1980). But for certain food producers, especially the meat industry, even these mild recommendations went too far; they lobbied Congress to end funding for the publication (Broad 1981). One commentator observed that the purpose of the USDA is to make it easier for farmers to make money, a goal that is not well served by permitting federal agencies "to run loose on such politically sensitive matters as red meat, butter, and eggs" (Greenberg 1980).

On the eve of Appropriation Committee hearings on the *Guidelines,* called in July by Senator Thomas Eagleton (D-MO), a coalition of 104 consumer and health organizations criticized producer efforts to suspend distribution of the publication (Haas 1980). In part, this coalition had been created in response to an attack from the quasi-federal National Research Council (NRC). In May 1980, just three months after release of the *Dietary Guidelines,* the NRC issued its belated response to the *Dietary Goals.* This report, called *Toward Healthful Diets,* immediately became notorious for its conclusion that advice to restrict intake of fat or cholesterol was unwarranted (NRC 1980). One explanation for this conclusion was that the report had been financed by food industry donations, and that at least 4 of the 15 Food and Nutrition Board scientists responsible for its development had been funded by egg, meat, or other food producers (Wade 1980). Shortly after the election, but before the Reagan administration assumed office, Congress established a committee to revise the *Guidelines.*

At this point, the demise of the *Guidelines* seemed virtually assured. The new USDA secretary, John Block, was an Illinois hog farmer who during his confirmation hearings had remarked that he was "not so sure government should get into telling people what they should or shouldn't eat" (Maugh 1982). Through the revolving door, two high-level USDA positions had been filled by a former executive director of the American Meat Institute and a lobbyist for the National Cattlemen's Association. In addition, one of Block's first acts had been to close USDA's Human Nutrition Center, a research unit remarkable for its promotion of consumer rather than producer interests and its linking of research to policies, such as the *Dietary Guidelines* (Broad 1981).

Further attacks on dietary recommendations followed the release of *Diet, Nutrition, and Cancer,* an NRC report that had been commissioned by the National Cancer Institute during the last year of the Carter administration (NRC 1982). Food producers objected to the recommendation to reduce fat to 30 percent of calories by decreasing intake of high-fat meats. Livestock prices had dropped following release of the report, leading one food industry representative to observe that advice on diet and cancer "could be very harmful long term to the meat industry" ("Livestock Prices Fall" 1982: 44). In response to a request from the National Pork Producers Council, seven members of Congress called for an investigation of the cancer report (U.S. General Accounting Office 1984), and USDA political appointees drafted a report rejecting the 30 percent fat recommendation (Zuckerman 1984).

1985 Dietary Guidelines

When the committee to revise the *Dietary Guidelines* was finally appointed, five of the six USDA nominees appeared to be closely connected to the food industry ("USDA Readies" 1983). When informed of the committee's composition, a prospective Department of Health and Human Services (DHHS) appointee threatened to resign, stating that he had "no intention of being part of a process that guts the guidelines" ("Dietary Guidelines Review" 1982: 6). To the surprise of critics, however, the committee eventually made only minor changes in the text (USDA and USDHHS 1985), and USDA secretary Block, joined by the National Cattlemen's Association, endorsed the *Guidelines,* admitting that "all of us have changed in our thinking" ("Reagan Administration" 1985: 2).

This change in views was principally the result of an increasing consensus on the scientific basis of diet and disease relationships, as expressed in three groundbreaking reports released in 1988 and 1989. The first was the NRC's *Designing Foods,* which recommended reducing fat intake to 30 percent of calories and challenged the meat industry to develop methods to raise leaner beef; remarkably, this report had been requested by the USDA and issued with the full cooperation of meat producers (NRC 1988). It was followed by the 1988 *Surgeon General's Report on Nutrition and Health* (USDHHS 1988) and the 1989 NRC *Diet and Health* study (NRC 1989). All three of these reports identified reduction of fat – particularly saturated fat – as the primary dietary priority. Because none of these reports elicited much critical comment, consensus on dietary recommendations appeared to have been achieved (Nestle and Porter 1990).

1990 Dietary Guidelines

Despite the apparent consensus among medical and scientific authorities, USDA political appointees argued that recent research had established a need to reexamine the *Dietary Guidelines.* Invoking the lead agency mandate, they pressed for and obtained appointment of a committee to write a third edition. As appointed, the new committee consisted of nine nutrition scientists and physicians with few apparent ties to the food industry. Of 13 groups who submitted written comments during committee deliberations, however, 10 represented food producers, trade associations, or organizations allied with industry (USDA 1990).

This process revealed that the current consensus on dietary recommendations had been achieved at the expense of clarity. To address concerns that certain foods are increasingly perceived as "bad" and unfit for inclusion in healthful diets, the committee altered the phrasing of the *Guidelines* to make their tone more positive. For the phrase, "avoid too much," it substituted, "choose a diet low in." For the phrase "choose lean meat . . . ," it substituted, "have two or three servings of meat . . . with a daily total of about 6 ounces." Its one significant achievement was to suggest upper limits of 30 percent of calories from fat and 10 percent from saturated fat – precisely those recommended by the 1977 *Dietary Goals.* Lest these figures appear too restrictive, however, the new edition emphasized:

> [T]hese goals for fats apply to the diet over several days, not to a single meal or food. Some foods that contain fat, saturated fat, and cholesterol, such as meats, milk, cheese, and eggs, also contain high-quality protein and are our best sources of certain vitamins and minerals. (USDA and USDHHS 1990)

Unlike the previous two editions, the 1990 *Dietary Guidelines* elicited no noticeable complaints from food producers.

The Food Guide Pyramid

In 1991, the interference of food lobbies in dietary guidance policy again came to public attention, this time over a food guide with a simple, pyramid-shaped graphic. This project had originated a decade earlier in response to criticisms that consumers would have difficulty planning menus that met dietary recommendations (Peterkin, Kerr, and Shore 1978). In the heat of the controversy over the 1980 *Dietary Guidelines,* USDA nutritionists had rushed a menu guide into print just prior to President Reagan's inauguration (USDA 1981).

With the *Guidelines* under revision, the nutritionists began to develop a new guide that would specify the numbers and sizes of food servings needed to meet its recommendations. They presented this guide in a wheel format for use in an American Red Cross course in 1984 (Cronin, Shaw, Krebs-Smith et al. 1987). Food industry experts objected to the study guides prepared for the course and requested extensive changes in the text (Zuckerman 1984); the wheel also proved difficult for the public to understand. Thus, USDA staff initiated a consumer research study to identify a more useful format; they continued to use the portion sizes and numbers presented in the wheel in subsequent publications such as the 1990 *Dietary Guidelines.*

The research demonstrated that consumers preferred the *Pyramid* over many other designs. Its graphic displays grains and cereals at the wide base, vegetables and fruits in the band above, meats and dairy foods in the narrow upper band, and fats and sweets in the narrow peak. The band width represents the number of portions of each food group recommended by USDA. But unlike earlier graphics, the *Pyramid* format indicates that the daily diet should include more servings of grains, fruits, and vegetables than of meats, dairy products, and fats and sweets.

Preparation of the *Pyramid* graphic and accompanying brochure began in 1988. During the next two years, these materials were reviewed extensively, publicized widely, and fully cleared for publication; they were sent to the printer in February 1991 ("A Pyramid Topples" 1991). In April, representatives of the National Cattlemen's Association saw a *Washington Post* report on the *Pyramid* (Gladwell 1991) and joined other producer groups to protest that it "stigmatized" their products and should be withdrawn immediately (Burros 1991b; Combs 1991; Sugarman and Gladwell 1991). Two weeks later, the newly appointed USDA secretary, Edward Madigan, a former

Republican congressman from Illinois, announced that the *Pyramid* required further testing on children and poorly educated adults and postponed its publication. His explanation for this decision, however, was widely disbelieved ("A Pyramid Topples" 1991). Instead, observers attributed his actions to a direct response to pressures from meat producer lobby groups.

During the following year, the USDA issued a new and far more expensive contract to retest alternative designs on children and low-income adults. While this research was in progress, newspaper and magazine reporters wrote repeatedly of the *Pyramid* incident as an example of the conflict of interest created by the dual mandates of the USDA to protect American agricultural interests and to advise the public about food choices; they also used the incident as an illustration of the excessive and heavy-handed influence of lobbyists in federal policy decisions (Nestle 1993a).

The research tested the impact of alternative designs – particularly bowl shapes – that were preferred by most food industry representatives. When the messages conveyed by bowl designs were tested against those conveyed by pyramid designs, the results were nearly indistinguishable. At that point, the USDA was faced with a dilemma; the agency could choose the original *Pyramid* and risk embarrassment over the delay, additional costs, and continued opposition from food producers, or it could choose the bowl design for what might be interpreted as political rather than scientific reasons. Eventually, the USDA chose the pyramid design, perhaps because press reports kept public attention focused on the issue.

In April 1992, USDA released its *Food Guide Pyramid.* This publication seemed quite similar to the previous version. Its most significant difference concerned the numbers of recommended servings. These were relocated outside the triangle and reset in boldface type that two to three daily servings of meat and dairy foods were still recommended (USDA 1992). This change, which gave no indication that the servings were meant to be small and an upper limit, pleased food producers who made no further complaints about this publication (Nestle 1993a).

1995 Dietary Guidelines

Lobbying from meat and dairy groups was noticeably absent during preparation of the fourth edition of the *Dietary Guidelines* (USDA and USDHHS 1995). The recommendation for meat was similar to that offered in previous editions – "Choose two to three servings of lean . . . meats" – and the accompanying text suggested the benefits of eating moderately from the meat and beans group and avoiding sources of saturated fat in the diet. For the first time, the *Dietary Guidelines* recommended meals with rice, pasta, potatoes, or bread at the center of the plate and included a section on vegetarian diets. Nevertheless, release of this report elicited no comments from meat producers, perhaps because the meat serving was defined as 2 to 3 ounces, in effect extending the recommended intake range to 9 ounces per day.

Concluding Comments

Classic studies have viewed lobbying as a healthy influence within the political system that keeps Congress informed about issues, stimulates public debate, and encourages participation in the political process. These views find undue lobby influence unlikely, as "it is virtually impossible to steal or buy a public policy decision of any consequence in Washington" (Milbrath 1963).

Nonetheless, the history of dietary guidance policy records the increasing involvement of food lobbies – and the incorporation of their views – into federal recommendations for chronic disease prevention. In 1956, USDA staff drafted the *Basic Four* and, as a courtesy, permitted industry representatives to review it. But since 1980, food industry representatives increasingly have participated in the design of dietary guidance materials as well as in their review. This change in role occurred as the goal of dietary recommendations shifted from prevention of nutrient deficiencies to prevention of chronic diseases and from "eat more" advice to "eat less," and as food lobbies more vigorously defended their products against such advice.

Through their connections in Congress and the USDA, and use of their strong financial base, food lobbies successfully convinced government policymakers to alter advice about meat, a principal source of dietary fat, from "eat less" to "choose lean" to "have 2–3 portions." Yet this policy shift occurred concurrently with increasing scientific consensus that reduced fat intake would improve the health of the public, that the 30 percent target level has been a political compromise, and that evidence all along has supported a level of 20 to 25 percent or less (Burros 1991a; Wynder, Weisburger, and Ng 1992). To some extent, it seems likely that contradiction between scientific consensus and federal advice is responsible for Americans' failing to reduce their fat intake (McGinnis and Nestle 1989; Putnam 1991; Nestle 1995).

It must be emphasized that lobbying strategies are entirely legal and available to consumer groups as well as to food producers. What should be clear from this discussion, however, is that producer groups possess far greater resources for lobbying activities than do either consumer groups or the federal government. The hundreds of millions of dollars available to the meat and dairy lobbies through checkoff programs, and the billions of dollars spent on food advertising, far exceed the $1.3 million spent by the USDA on dietary guidance and research in 1991 (USDA 1991). As one commentator stated, it is unfortunate that "good advice about nutrition conflicts with the interests of many big industries, each of which has more lobbying power than all the public-interest groups combined" (Jacobson 1974).

The controversy over the *Eating Right Pyramid* demonstrates that the connections between members of Congress, USDA officials, and food lobbies must continue to raise questions about the ability of federal officials to make independent policy decisions. Individuals concerned about such issues might consider whether the USDA's conflicts of interest have so impaired its ability to educate the public about diet and health that such functions should be transferred to an agency less tied to food industry groups. Also worth consideration is more forceful advocacy of consumer perspectives to Congress, reform of lobbying laws, reduced dependence on PAC expenditures, tighter restrictions on the revolving door, disclosure of funding sources by members of advisory committees, and education of the public on the extent of lobbying influence.

VII.7 Food Biotechnology: Politics and Policy Implications

Food biotechnology – the use of recombinant deoxyribonucleic acid (rDNA) and cell fusion techniques to confer selected characteristics upon food plants, animals, and microorganisms (Mittal 1992; Carrol 1993) – is well understood as a means to increase agricultural productivity, especially in the developing world. The great promise of biotechnology is that it will help solve world food problems by creating a more abundant, more nutritious, and less expensive food supply. This theoretical promise is widely appreciated and beyond dispute (Rogers and Fleet 1989; U.S. Congress 1992).

Nonetheless, food biotechnology has elicited extraordinary levels of controversy. In the United States and in Europe, the first commercial food products of genetic engineering were greeted with suspicion by the public, vilified by the press, and threatened with boycotts and legislative prohibitions. Such reactions reflect widespread concerns about the safety and environmental impact of these products, as well as about their regulatory status, ethical implications, and social value. The reactions also reflect public fears about the unknown dangers of genetic engineering and deep distrust of the biotechnology industry and its governmental regulators (Davis 1991; Hoban 1995).

Biotechnology industry leaders and their supporters, however, dismiss these public concerns, fears, and suspicions as irrational. They characterize individuals raising such concerns as ignorant, hysterical, irresponsible, antiscientific, and "troglodyte," and they describe "biotechnophobia" as the single most serious threat to the development, growth, and commercialization of the food biotechnology industry (Gaull and Goldberg 1991: 6). They view antibiotechnology advocates as highly motivated and well funded and believe them to be deliberately "interweaving political, societal and emotional issues . . . to delay commercialization and increase costs by supporting political, non-science-based regulation, unnecessary testing, and labelling of foods" (Fraley 1992: 43).

In the face of this controversy, industry leaders have concluded that their most important challenge is to find ways to allay public fears (U.S. Congress 1991a) and to "assure the public that the new food technologies are not only beneficial to society, but safe" (Gaull and Goldberg 1991: 9).

This divergence in industry and public viewpoints can be traced to the conflict inherent in the two basic goals of the food biotechnology industry: (1) to benefit the public by developing agricultural products that will solve important food problems, and (2) to benefit the industry itself through the successful commercial marketing of these products. Although development of genetically engineered food products might well be expected to meet both goals, such is not always the case. One problem is the lack of a viable market, which experts view as a major barrier to research on food problems of the developing world (Hodgson 1992). Another centers on industry needs for rapid returns on investment; such needs constitute a driving force in decisions about research and development and cause industry leaders to view legitimate public questions about the use, safety, or social consequences of particular food products as threats to the entire biotechnology enterprise.

This chapter examines the reasons why so potentially useful an application of molecular techniques to food product development has elicited so great a level of controversy in the United States and elsewhere. Using the situation in the United States as a case study, it reviews key issues of economics, marketing, and risk that have affected the development and implementation of regulatory policies for the commercial products of food biotechnology, particularly those that affect food safety, allergenicity, environmental impact, and intellectual property rights. It also addresses issues that have influenced public perceptions of these products and describes how these issues have affected industry and public responses to the first genetically engineered food products released in the United States. Finally, it suggests implications of the present controversy for future product development, industry actions, and public policies.

The Promise

There seems little doubt that biotechnology holds great promise for addressing world food problems, most notably the overall shortfall in food production now expected early in the twenty-first century (Fraley 1992). No theoretical barriers impede the use of the techniques of molecular and cellular genetics to improve the quantity and quality of the food supply, to increase food safety, and to reduce food costs (Reilly 1989; U.S. Congress 1992; Hayenga 1993). Table VII.7.1 lists the wide range of potential applications of food biotechnology that as of the mid-1990s were under investigation or are theoretically possible. Such applications could greatly increase world food production, especially given the conditions of poor climate and soil typical of many developing countries (Swaminathan 1982).

Table VII.7.1. *Theoretical and current applications of food biotechnology*

Improve the flavor, texture, freshness, or nutrient content of fruit and vegetables.
Modify seed storage proteins to increase their concentration of limiting amino acids such as lysine or tryptophan.
Alter the chain length and degree of saturation of plant seed oils.
Increase plant production of specialty chemicals such as sugars, waxes, phytooxidants, or pharmaceutically active chemicals.
Increase levels of vitamins and other nutrients in plant food crops.
Decrease levels of caffeine or other undesirable substances in plant food crops.
Increase resistance of crops to damage by insect or microbial pests.
Increase resistance of crops to "stress" by frost, heat, salt, or heavy metals.
Develop herbicide-resistant plants to improve weed control.
Enable crop plants to be grown under conditions of low input of fertilizers, pesticides, or water.
Enable major crop plants to fix atmospheric nitrogen.
Develop plant foods containing antigens that can vaccinate humans against disease.
Increase the efficiency of growth and reproduction of food-producing animals.
Create disease-resistant animals.
Develop animal veterinary vaccines and diagnostic tests.
Allow cows to produce milk containing recombinant human milk proteins that can be used in infant formulas.
Create microorganisms, enzymes, and other biological products useful in food processing.
Develop microorganisms capable of converting environmental waste products – plastics, oil, pesticides, or PCBs – into usable animal feeds.

The potential for such improvements in the food supply constitute the principal basis for industry and government conclusions that "biotechnology is the most important scientific tool to affect the food economy in the history of mankind" (Gaull and Goldberg 1991: 150), that "biotechnology promises consumers better, cheaper, safer foods" ("Biotechnology Promises" 1990: 1), and that "genetic engineering and biotechnology will create miracles to help us feed a hungry world efficiently and economically" (Sullivan 1991: 97).

Such promises, however, have not yet been fulfilled, nor are they likely to be realized in the immediate future (Messer and Heywood 1990), principally because many of the applications listed in Table VII.7.1 pose biological and technical problems of formidable complexity (Barton and Brill 1983; American Medical Association 1991). For example, many hundreds of as yet uncharacterized genes appear to be involved in the reproduction of corn (Kilman 1994b), and the more than 350 varieties of cassava (manioc) grown throughout the world seem especially resistant to transgenic transformations (Beachy 1993). But the slow progress of biotechnology in addressing world food problems should not imply that such problems cannot be solved. Given sufficient time, commitment, and funding support, the technical barriers almost certainly can be overcome.

Economic Issues

Costs and Benefits

Technical problems, however, are not the most important barriers to the application of food biotechnology to world agricultural productivity. Instead, the greatest barrier derives from the need of the industry to recover the costs of research and development and to maximize return on investment (Harlander 1989). Research costs are not trivial: The average genetically modified plant requires about $10 million (U.S.) to develop and about six years to become marketable (Ollinger and Pope 1995). Thus, the expected returns on such an investment need to be substantial (U.S. Congress 1991a). Although no products had as yet been brought to market, food biotechnology was considered in the early 1990s to have "a huge potential to make money" (Kim 1992a: B1). At that time some experts suggested that the value of the industry would increase to at least $50 billion by the year 2000 (Leary 1992a) and that the prices of biotechnology stocks would rise by 25 percent annually well into the 1990s (Somerville 1993).

To date, however, stock market returns have not reflected such projections. Although the biotechnology industry increased in sales, revenues, and numbers of companies and employees from 1989 to 1993, net losses also increased steadily during that period (Waldholz 1994). One notable exception has been the Monsanto Company; its stock prices gained 75 percent in 1995 (Fritsch and Kilman 1996) and another 70 percent in 1996 (Wadman 1996). Monsanto officials estimated that their products of plant biotechnology would earn $2 billion by the year 2000 and that sales would grow to $6 or $7 billion by 2005 and to $20 billion by 2010 (Feder 1996).

The generally poor performance of other food biotechnology stocks has been attributed to uneven management, corporate shortsightedness, and product failures (Hamilton 1994). It also has been attributed to lack of government investment. Although overall federal investment in biotechnology research exceeded $4 billion in 1994, only 5 percent of these funds supported agricultural projects; in contrast, 41 percent were applied to drug development (Caswell, Fuglie, and Klotz 1994). By the mid-1990s, only a few products had come to market, and their degree of acceptability was as yet unknown. The resulting uncertainties in profitability explain industry preoccupation with issues of federal regulation, intellectual property, and public perception (Fraley 1992).

The need for return on investment has encouraged the industry to focus on the development of products that are most technically feasible, rather than those that might be most useful to the public or to developing countries. To date, food biotechnology research has tended to concentrate on agronomic traits that most benefit agricultural producers and processors. These include control of insects, weeds, plant diseases, and ripening, and production of crops that will resist insects and tolerate herbicides (Office of Planning 1988; Olempska-Beer et al. 1993). Research also has focused on the development of foods that will last longer on the shelf and cost less to process (U.S. Congress 1991a; Barnum 1992). A 1988 survey of 74 food processing firms that used biotechnology methods found that of their research projects, 27 percent were devoted to enzymes (such as those used in cheese manufacture), 15 percent to sweeteners, 11 percent to flavors, fragrances, and colors for prepared food products, and 10 percent to better detection of contaminants; the remaining 37 percent were concentrated on product development and processing methods (Reilly 1989). A more recent study reported that chemical and pesticide companies have obtained 41 percent of all permits for field testing of genetically engineered plants (Ollinger and Pope 1995).

In 1990, the leading 36 agrochemical and agricultural biotechnology companies together spent nearly $400 million on such research and development, but an order of magnitude less ("puny" by comparison) on projects designed to address agricultural problems of the developing world (Hodgson 1992: 49). Such problems – and their biotechnological solutions – are well defined (Bokanga 1995; Knorr 1995). Although many sources of private and public funding are available to support biotechnology projects in developing countries (Chambers 1995), these are fragmented, poorly coordinated, and often promote donors' priorities rather than those of the recipients (Messer 1992). One well-established research institute dedicated to improving crops in developing countries reports little success in obtaining industry financing or support beyond the permission to use patent-protected techniques "for specific crops under certain circumstances" (Beachy 1993: 61). Such observations have led commentators to conclude: "Nearly 20 years into the gene-splicing revolution, the industry has ballooned to well over 1,000 public or private companies that have raised about $20 billion. Yet no one has cured cancer or produced a bioengineered miracle of loaves and fishes for a hungry Third World. The industry is still peddling dreams . . ." (Hamilton 1990: 43).

Marketing Barriers

To assure adequate returns on investment, the biotechnology industry must create and sell new products. These products, however, compete with other products in a market that is already highly competitive because the United States vastly overproduces food (Stillings 1994). In 1990, for example, the U.S. food supply made available an average of 3,700 kcal/day for every man, woman, and child in the country (Putnam and Allshouse 1996), even though adult men require two-thirds that amount, women about half, and children even less (National Research Council 1989). Because the amount of energy that any one person can consume is finite, such overproduction implies that a choice of any one food product will preclude choice of another.

Food marketers compete for consumer purchases through two principal means: advertising and new product development. Retail sales of food generated $791 billion in 1994. In the same year, food marketers spent $9.8 billion on direct consumer advertising and about twice that amount on retail promotion in trade shows, product placements, point-of-purchase campaigns, and other incentives. From 1984 to 1994, food companies introduced 125,000 new products into U.S. markets, more than 15,000 of them in 1994 alone (Economic Research Service 1994; Gallo 1995). Nevertheless, such efforts have failed to improve overall growth in the food processing sector, which has increased at less than 1 percent per year since the late 1940s, a rate considered stagnant by comparison to other industries. In so competitive an environment, biotechnology is seen as a crucial force for development of new products that will increase the country's overall economic productivity (Reilly 1989).

Risk Issues

Tryptophan Supplements

From the standpoint of the biotechnology industry and its supporters, genetically engineered foods are no different from foods produced by conventional genetic crosses. Therefore, industry supporters argue that any risks associated with these foods are extremely small and greatly outweighed by their benefits (Gaull and Goldberg 1991; Miller 1991; Falk and Bruening 1994). Critics, however, insist that food biotechnology raises safety concerns that in the absence of prior experience are difficult to define, predict, or quantify. They point, as an example, to the case of tryptophan supplements to illustrate the unknown hazards of commercial biotechnology.

In 1989, health officials linked tryptophan supplements from a single manufacturer to an unusual syndrome of muscle pain, weakness, and increased blood levels of certain white cells (eosinophils), a constellation of symptoms termed eosinophilia-myalgia syndrome (Centers for Disease Control 1989). Eventually, more than 1,500 cases of illness and nearly 40 deaths were attributed to the use of such supplements as a self-medication for insomnia and other conditions (Roufs 1992; Mayeno and Gleich 1994). Because tryptophan is a normal amino acid component of all proteins, investigators believed that toxic contaminants must have developed during the manufacturing process. This process involved the creation of a strain of bacteria genetically manipulated to produce high levels of tryptophan and extraction of this amino acid through a series of purification steps (Fox 1990).

To date, characterization of the toxic components remains incomplete (Mayeno and Gleich 1994). Although it appears unlikely that the genetic engineering methods were directly at fault (Philin et al. 1993), their use to modify a bacterial strain created a situation in which toxic products were formed, albeit inadvertently (Aldhous 1991). This example suggests that concerns about the unknown hazards of biotechnology have some basis in experience.

Allergenicity

Because genes encode proteins, and proteins are allergenic, the introduction of allergenic proteins into previously nonallergenic foods could be another unintended consequence of plant biotechnology. In a finding described as "Another shadow . . . cast over the agricultural biotechnology industry . . ." (Winslow 1996: B6), researchers have now demonstrated that an allergenic protein from Brazil nuts can be transferred to soybeans, and that people with demonstrable allergies to Brazil nuts react similarly to soybeans that contain the Brazil-nut protein (Nordlees et al. 1996).

The Brazil-nut soybeans were developed as a means to increase the content of the amino acid methionine in animal feeds, which must otherwise be supplemented with methionine to promote optimal growth. The Brazil-nut protein is especially rich in methionine and its gene was a logical choice as a donor. Nuts, however, are often allergenic, and the investigators happened to have collected serum samples from people known to be allergic to Brazil nuts. Thus, they had in place all the components necessary to test for allergies to Brazil-nut proteins. Such components are rarely available for testing other potentially allergenic proteins, however.

Adverse reactions to food proteins can be documented in just 2 percent of adults and 8 percent of children (Sampson and Metcalfe 1992), but many more people are expected to develop food sensitivities as proteins are increasingly added to commercially prepared foods. Soy proteins, for example, already are very widely used in infant formulas, meat extenders, baked goods, and dairy replacements. Most biotechnology companies are using microorganisms rather than food plants as gene donors. Although these microbial proteins do not appear to share sequence similarities with known food allergens (Fuchs and Astwood 1996), few of them have as yet entered the food supply. At the present time, their allergenic potential is uncertain, unpredictable, and untestable (Nestle 1996).

As discussed in the following section, allergenicity raises complicated regulatory issues. Under a Food and Drug Administration (FDA) policy established in 1992, the manufacturer of the Brazil-nut soybeans was required to – and did – consult the FDA about the need for premarket testing. Because testing proved that the allergenic protein had been transmitted, the company would have been required to label its transgenic soybeans. Because the company had no simple method in place to separate soybeans intended for animal feed from those intended for human consumption, it withdrew its transgenic soybeans from the market. This action was interpreted by supporters of the FDA policy as evidence of its effectiveness.

Others, however, viewed this event as further evidence that the FDA policy could not protect consumers against lesser-known transgenic allergens to which they might be sensitive and, therefore, favored industry. The lack of a requirement for labeling was of particular concern, as avoidance is often the only effective way to prevent allergic reactions. In 1993, the FDA requested public comment on whether and how to label food allergens in transgenic foods (FDA 1993). Then, in 1994, the FDA drafted a rule that would require companies to inform the agency when developing new transgenic foods, in part to help resolve safety issues related to allergenicity. Implementation of such a rule seemed unlikely, however, especially because the biotechnology industry demanded that any such requirement be limited in scope and "sunset" after three years ("Bio Favors" 1994). To date, the FDA has not reported or acted on the public comments related to labeling of transgenic allergens.

Policy Issues

Regulation

Current debates about the regulation of food biotechnology center on a conflict between issues of safety on the one hand and a broad range of ecological, societal, and ethical issues on the other. For the industry and its supporters, safety is the only issue of relevance. Because the safety of most genetically engineered products is well supported by science, regulations appear to create unnecessary barriers to further research and economic growth (Gaull and Goldberg 1991; Miller 1991). For critics, however, regulations must be designed to protect the public not only against known safety risks but also against those that cannot yet be anticipated (Mellon 1991). In addition, as discussed in the next sections, critics view safety as only one component of a far broader range of concerns about the impact of biotechnology on individuals, society, and the environment – issues that might also demand regulatory intervention. For government officials, regulation of food biotechnology must find the proper balance between oversight of the industry and encouragement of its efforts to develop and market new food products (U.S. General Accounting Office 1993). Thus far, the balance achieved by existing regulatory policies has satisfied neither the industry nor consumer groups.

Table VII.7.2 outlines key historical events in the development of policies for regulation of food biotechnology. This history has resulted in current regulatory policies that affect three key areas of concern: food safety, environmental protection, and intellectual property rights.

Table VII.7.2. *Key events in the history of the commercialization of food products of biotechnology in the United States*

1930	Congress passes Plant Patent Act, extending protection to distinct, asexually propagated varieties.
1970	Plant Variety Protection Act extends patent rights to new sexually propagated plant varieties.
1973	Cohn and Boyer clone insulin gene using rDNA technology.
1975	Asilomar Conference suggests guidelines for rDNA research.
1976	Genentech established as the first company dedicated to exploitation of rDNA technology. NIH publishes safety guidelines for rDNA research.
1980	U.S. Supreme Court rules that microorganisms may be patented (*Diamond v. Chakrabarty*); first patent issued for rDNA construction to Cohn and Boyer. Genentech stock sets Wall Street record (share price rises from $35 to $89 in 20 minutes). Congress passes amendments to Patent Acts allowing nonprofit institutions and small businesses to retain titles to patents developed with federal funds.
1982	Recombinant insulin approved for use. Transgenic plant prodcued using *agrobacterium* transformation system.
1983	A plant gene is transferred from one species to another. Executive order permits large businesses to hold title to patents developed with federal funds.
1985	The Environmental Protection Agency (EPA) issues use permit to Advanced Genetic Sciences for release of organisms genetically engineered to lack ice-nucleation proteins. Patent Office extends protection to corn with increased levels of tryptophan (*ex parte* Hibberd). FDA authorizes sales of meat and milk from cows treated with recombinant bovine somatotropin (rbST); reaffirms safety of these foods in 1988, 1989, and 1990.
1986	Office of Science and Technology Policy issues Coordinated Framework for the Regulation of Bio-Technology, partitioning regulatory responsibility among USDA, EPA, FDA, and, to a lesser extent, NIH (51 FR 23302, June 26).
	Congress passes Technology Transfer Act permitting companies to commercialize government-sponsored research. USDA develops transgenic pigs carrying the gene for human growth hormone.
1987	Tomatoes with a gene for insect resistance are field-tested. USDA requires field-testing permits only for genetically engineered organisms that present risks to plants (52 FR 22892, July 16).
1988	Patent Office extends patent protection to genetically engineered animals.
1990	Food and Drug Administration (FDA) approves recombinant chymosin (rennet) as generally recognized as safe (GRAS). NIH issues statement that rbST is safe.
1992	FDA announces policy on foods derived from new plant varieties (57 FR 22984, May 29). USDA grants Calgene, Inc. permision to field-test the Flavr Savr tomato.
1993	FDA requests data and information on labeling issues related to foods derived from biotechnology (58 FR 25837, April 28); approves rbST for commercial use (58 FR 59946, November 12); requests public comment on whether and how to label food allergens in transgenic foods. Congress issues moratorium on use of rbST. Patent Office resumes granting patents on genetically engineered animals.
1994	Congressional moratorium on rbST expires.
	USDA reaffirms policies that genetically engineered livestock and poultry are subject to existing regulations for slaughter, research, and inspection (59 FR 12582, March 17).
	FDA publishes interim guidance on voluntary labeling of milk from cows treated with rbST and forbids statements such as "rbST-free" (59 FR 6279, February 10); concludes consultation with Calgene, Inc., finding no significant difference between the Flavr Savr and other tomatoes with a history of safe use (59 FR 26647, May 23); approves use of aminoglycoside 3'-phosphotransferase II (the kanamycin-resistance gene) for use in developing new varieties of tomatoes, oilseed rape, and cotton (59 FR 26700, May 23); concludes consultation approving seven other genetically altered plants, including tomatoes, squash, potato, cotton, and soybeans.
	EPA announces that federal pesticide laws will apply to toxins and other substances introduced into crop plants through genetic engineering (59 FR 60496, November 23).
1996	Congress requires USDA to discontinue its advisory committee on food biotechnology and close its Office of Agricultural Biotechnology.
	Allergen from Brazil nuts is transmitted to transgenic soybeans; transgenic herbicide resistance is transmitted to weeds, raising environmentalist concerns.
	Monsanto plants Bt cotton, herbicide (Roundup)-resistant soybeans. Ciba-Geigy plants herbicide-resistant corn. Both encounter consumer resistance in Europe. The European Union approves the soybeans, requires committee discussion of the corn, approves the corn but requires labeling of transgenic crops.

Table VII.7.3. *Safety issues raised by food biotechnology*

Unanticipated health effects resulting from genetic manipulations.
Increase in levels of naturally occurring toxins or allergens.
Activation of dormant toxins or allergens.
Introduction of known or new toxins, allergens, or antinutrients.
Adverse changes in the composition, absorption, or metabolism of key nutrients.
Increase in antibiotic-resistant microorganisms through use of antibiotic marker genes.
Transmission of herbicide resistance to weeds.
Adverse changes in the nutrient content of animal feed.
Increased levels of toxins in plant by-products fed to animals.

Food Safety

From the first, gene cloning experiments elicited safety concerns, mainly focused on the potential hazards of releasing new organisms with unknown properties into the environment. At a conference in 1975, scientists suggested stringent guidelines for research studies employing recombinant DNA techniques. The following year, the National Institutes of Health required researchers to follow similar guidelines. In subsequent years, as understanding of the techniques improved, concerns about safety diminished and the guidelines were modified accordingly. Nevertheless, common genetic methods for food modification involving, for example, bacteria that cause crown gall (a plant disease), marker genes for antibiotic resistance, and insertion of genes from one living species into another, continued to elicit debate about the known and unknown hazards of such techniques (International Food Biotechnology Council 1990). Table VII.7.3 summarizes the principal safety issues that have been raised by the use of food biotechnology.

In 1986, the White House Office of Science and Technology Policy (OSTP) developed a "Coordinated Framework" for regulating biotechnology based on the premise that its products were no different from those developed through conventional techniques, and that existing laws and agencies were sufficient for their regulation. OSTP specified the distribution of regulatory responsibility among the various federal agencies. Under laws then in effect, responsibility for the regulation of food biotechnology involved no less than three offices reporting directly to the president; four major federal agencies; eight centers, services, offices, or programs within agencies; and five federal committees – all operating under the authority of 10 distinct acts of Congress (U.S. Congress 1992).

As might be expected, critics immediately identified a substantial lack of coordination, duplication of effort, overlapping responsibility, and gaps in oversight in this regulatory framework (Mellon 1988; Fox 1992). Because the principal laws affecting food safety were written before biotechnology became an

issue, they did not necessarily apply to the new methods (Browning 1992). Thus, the confusing and uncertain regulatory status of recombinant products stimulated the food biotechnology industry to demand more precise guidance from the FDA. The President's Council on Competitiveness, a group dedicated to reducing regulations that impede industry, strongly supported such demands (Leary 1992b).

In response, the FDA developed a formal policy for the regulation of plant foods produced through biotechnology (FDA 1992). The agency designed this policy to be "scientifically and legally sound and . . . adequate to fully protect public health while not inhibiting innovation" (Kessler et al. 1992: 1832). This policy framework is summarized in Figure VII.7.1. The policy presumed that foods produced through rDNA techniques raised no new safety issues and could be regulated by the FDA's postmarket authority for foods "Generally Recognized as Safe" (GRAS). Therefore, safety evaluation would focus on changes in the "objective characteristics" of foods – new substances, toxins, allergens, or nutrients – and not on the techniques used to produce them. Under this policy, the FDA would invoke its testing requirements for new food additives, and would require industry consultation, only if the transgenic foods contained unusual or potentially toxic components (e.g., allergens). This new biotechnology policy required no premarket safety evaluation, premarket approval by the FDA, or special labeling of the new foods.

The response of the industry to these "election-year efforts by the White House to provide . . . as much regulatory relief as possible," was enthusiastic and viewed as "a very strong incentive for investment in the agricultural/food biotechnology area" (Ingersoll 1992: B1). One investment analyst summarized the new policy as an "assurance that after all a company's planning for a picnic, the government won't rain on it" (Kim 1992b: B3).

By contrast, consumer groups criticized the policy as inadequate to protect public safety and threatened to respond with mail campaigns and legal challenges (Hoyle 1992). A group of leading chefs in New York City called for an international boycott of genetically engineered foods, with one quoted as saying:

> I don't want a biotechnician in a lab coat telling me it's a better tomato . . . I think mother nature does a great job on her own. These people are tampering with the ecosystem and will cause problems. But what is most disturbing to me is the idea of selling the food without a label. ("Chefs Urge Boycotting" 1992: C6)

Critics of the policy were especially concerned about the lack of requirements for premarket testing and labeling (Hopkins, Goldburg, and Hirsch 1991). Commentators wondered whether this policy of "least regulatory resistance" actually might increase public suspicion of genetically engineered foodstuffs (Hoyle 1992), especially in light of increasing press attention to "Frankenfoods" (O'Neill 1992). In response to such concerns, a federal study recommended formal review of the entire federal regulatory framework for food biotechnology in order to establish a better regulatory balance between promotion of the industry and protection of the public (U.S. General Accounting Office 1993).

Despite the controversy, the FDA implemented its policy. By late 1994, the agency had approved the marketing of tomatoes genetically engineered to reach optimal ripening after they were picked, milk from cows treated with a recombinant growth hormone, a virus-resistant squash, an insect-resistant potato, an herbicide-resistant cotton (used to make seed oil for animal feed), and herbicide-resistant soybeans (Associated Press 1994).

Environmental Impact

The "Coordinated Framework" affirmed that the U.S. Department of Agriculture (USDA) and the Environmental Protection Agency (EPA) were the primary agencies responsible for regulating agricultural biotechnology (see Table VII.7.2). Under the authority of two laws – the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and the Toxic Substances Control Act (TSCA) – the EPA was authorized to regulate genetically engineered organisms used to control insects and other pests, including those viral and bacterial, as well as any genetically engineered chemicals that might be hazardous to humans or to the environment. The EPA classified rDNA as such a substance and began to require biotechnology companies to obtain permits prior to the manufacture or release of their agricultural products (Caswell et al. 1994).

EPA policies were designed to address concerns that widespread agricultural use of new kinds of living species might present direct risks to human health. Such risks, however, are seen as minimal by environmentalists as well as by experts sympathetic to the industry (Mellon 1988; Miller 1994). Instead, the chief concern of environmental advocates is that agricultural biotechnology poses uncertain – but potentially grave – ecological risks. They offer considerable evidence to support the possibility that biotechnological organisms might displace existing plants and animals, create new plant pathogens, disrupt ecosystems, reduce crop diversity, and change climate patterns (Mellon 1988; Rissler and Mellon 1993). In addition, environmentalists are even more concerned about the impact of biotechnology on ongoing efforts to promote more widespread use of sustainable agricultural practices. They note, for example, that a large proportion of agricultural biotechnology research is dedicated to the development of herbicide-resistant crops, and that such research stimulates reliance on chemical herbicides to manage pests (Goldburg et al. 1990).

Thus, the EPA's 1994 decision to apply federal pesticide laws to toxins and other pesticidal substances introduced into crop plants through rDNA techniques was especially controversial. The biotechnology industry opposed it as an anachronistic and scientifically indefensible decision and noted that the EPA should instead have considered a risk-based regulatory system focusing on the organisms themselves rather than on the processes by which they were created. For the industry, the EPA decision would undoubtedly "exert a profoundly negative effect" on research into biological pest management strategies, particularly those unlikely to provide a sufficient financial return (Miller 1994: 1817).

Environmental advocates, although "pleased that EPA plans to regulate such crops the way it regulates traditional chemical pesticides," were also dissatisfied; they noted that the EPA rules focused "too narrowly on the development of genetically engineered, toxin-producing crops," and were insufficiently attentive to the potential hazards of herbicide-resistant crops that were virtually certain to bring about increases in the use of potentially damaging herbicides (Environmental Defense Fund 1994: 1). The marketing by the Monsanto Company of soybeans genetically engineered to be resistant to Roundup, a widely used herbicide also produced by that company, has only heightened such concerns (Feder 1996; Fritsch and Kilman 1996).

Environmentalist doubts about the adequacy of EPA regulatory policies were further stimulated by two events in 1996. That year, farmers planted 2 million acres with cotton engineered by the Monsanto Company to contain Bt *(Bacillus thuringiensis),* a soil bacterium that produces a compound toxic to cotton bollworms and other common insect pests. Bt has long been a key component of pest management in sustainable agricultural systems. When the Bt crop failed to protect thousands of acres of cotton against bollworms, observers feared that so large a planting had induced selection for insects resistant to Bt, thereby rendering the toxin useless for sustainable or any other type of agriculture (Kaiser 1996). EPA officials were reported to have asked Monsanto to test the surviving bollworms for Bt resistance, but to have admitted ". . . that further evaluation of the crop is entirely dependent on Monsanto's own reporting" (Benson, Arax, and Burstein 1997: 68).

Also in 1996, researchers reported that oilseed rape (canola) plants genetically engineered to resist herbicides readily transmitted herbicide resistance to related weed plants – plants that could reproduce rapidly (Mikkelsen, Anderson, and Jorgensen 1996). This report led critics to charge that transgenic crops could lead to the creation of "superweeds" and, therefore, to "ecological catastrophe." Despite this charge, federal officials continued to argue that monitoring of herbicide resistance should not be their responsibility: ". . . it is the developer of the product that has the interest in assuring that resistance does not build up" (Kling 1996: 181). Well before the time this statement was published, however, Congress had removed the USDA from involvement in biotechnology policy by eliminating funding for its advisory committee on biotechnology research and its Office of Agricultural Biotechnology (Fox 1996).

Intellectual Property Rights

United States intellectual property laws grant rights to patent owners to exclude everyone else from making, using, or selling the protected product for at least 17 years. Patents were first granted to plant varieties developed through asexual propagation in 1930. In 1970, Congress extended these rights to new varieties of plants developed through traditional genetic methods of sexual propagation. In 1980, the Supreme Court granted patent rights to microorganisms developed through rDNA techniques, and the Patent Office issued the first patent for such an organism. Patent rights were further extended to genetically engineered plants in 1985 and to animals in 1988 (U.S. Congress 1989, 1991a).

The patenting of biotechnological microorganisms and plants provided a major incentive for the growth of the food biotechnology industry, and patent rights are believed to have greatly stimulated such growth during the 1980s. Within just a few years, however, patent awards were challenged by industry and government officials in the United States, Canada, and Europe. By 1995, the U.S. Patent Office had issued 112 patents for genetically engineered plants. Among these were exclusive patent rights to one company for all forms of bioengineered cotton and to another for all uses of the "antisense" genes that were used to create the Calgene tomato (see later section on the "Flavr Savr" tomato). The breadth of such patents ". . . stunned the agricultural biotechnology community . . . It was as if the inventor of the assembly line had won property rights to all mass-produced goods . . . ," and numerous lawsuits were soon filed (Stone 1995: 656).

The patenting of animals has generated even greater debate, particularly from animal-rights organizations and other groups concerned that the genetic engineering of farm animals might adversely affect family farmers, be cruel to animals, and endanger other living species (U.S. Congress 1989). The principal arguments for and against the patenting of transgenic animals are summarized in Table VII.7.4 (U.S. Congress 1991a).

Perhaps in response to concerns about such issues, the Patent Office ceased issuing patents for transgenic animals in 1988. In 1993, it resumed processing of the 180 animal patent applications that had accumulated during this "self-imposed moratorium" (Andrews 1993). By that time, far fewer companies were attempting to patent farm animals, largely because persistent technical problems and concerns about costs had encouraged them to shift to more

Table VII.7.4. *The principal arguments for and against the patenting of transgenic animals*

Arguments for patenting transgenic animals
Patent laws regulate inventiveness, not commercial uses.
Patenting is an incentive to research and development.
Patenting enables the biotechnology industry to compete in international markets.
Patenting is preferable to trade secrets.
Patenting rewards innovation and entrepreneurship.

Arguments against patenting transgenic animals
Metaphysical and theological considerations make patenting untenable.
Patenting involves inappropriate treatment of animals.
Patenting reflects inappropriate human control over animal life.
Patenting disturbs the sanctity and dignity of life.
Most other countries do not permit patenting of animals.
Patenting could cause adverse economic effects on developing countries.
Patenting promotes environmentally unsound policies.
Animal patents will increase costs to consumers and producers.
Animal patents will result in further concentration in agricultural production.
Patent holders will derive unfair benefits from royalties on succeeding generations of patented animals.

Sources: U.S. Congress (1989) and Fox (1992).

profitable areas of research. But lobbyists against animal patents, such as Jeremy Rifkin, a leading antibiotechnology advocate, continued to protest Patent Office policies on both philosophical and economic grounds:

> We believe the gene pool should be maintained as an open commons, and should not be the private preserve of multinational companies . . . this is the Government giving its imprimatur to the idea that there is no difference between a living thing and any inert object . . . it's the final assault on the sacred meaning of life and life process. (Andrews 1993)

International Trade

Soybeans are used in more than 60 percent of all the processed foods sold in European markets (Wolf 1997). Transgenic, herbicide-resistant soybeans constituted 2 percent of the 59 million tons grown in the United States in 1996, their first year of production (Ibrahim 1996). Corn exports to Europe were valued at $500 million in 1995 (Wadman 1996). Transgenic Bt corn, also herbicide-resistant, was expected to account for half of the nearly $25 billion in annual sales in the United States within just a few years (Wolf 1997). Clearly, any action interfering with acceptance of transgenic crops would have grave economic consequences.

But European consumers were highly resistant to the idea of transgenic foods. This resistance has been attributed in part to memories of Nazi eugenics during World War II (Dickman 1996), in part to concerns that the antibiotic-resistance marker gene used in constructing the corn might spread to animals and to people, and in part to fears generated by the 1996 food-safety crisis over "mad cow" disease in England. The transmission of antibiotic-resistant bacteria from animals and milk to people had been demonstrated some years earlier (Holmberg et al. 1984; Tacket et al. 1985) but did not involve plants. The transmission of "mad cow" disease, although poorly understood, also did not appear to involve plants (Smith and Cousens 1996). European consumers, however, also were reacting to broader issues related to what they viewed as the arrogance of American officials who were claiming the superiority of their food safety criteria and were attempting to control trading policies through sanctions against European countries conducting business with Iran, Libya, or Cuba.

The transgenic soybeans and corn were approved as safe by the governments of the United States, Canada, and Japan. The European Union (EU) approved the import and processing of transgenic soybeans in April 1996. It referred the approval of the transgenic corn to scientific committees in June, thus raising the possibility that Europe might refuse corn from the United States and thereby cause a "corn war" (Wadman 1996). In October, Jeremy Rifkin announced the initiation of a worldwide boycott of genetically engineered crops produced in the United States. Rifkin was joined in this effort by an official of EuroCommerce, a trade association representing a large number of retail and commerce groups in 20 European countries, who called for separation and labeling of products using these grains so that European consumers could decide whether to buy them (Jones 1996). As the official later explained:

> Our message from our customers is that for whatever reason they would prefer not to have it in their foodstuffs . . . I am telling the American exporters to please, in this season, if you are wise, don't ship those soybeans to Europe because you may trigger a lasting reaction. And, if you must, separate and label them. (Ibrahim 1996: D1)

Surveys reported that 85 to 90 percent of European consumers wanted genetically engineered foods to be labeled as such (Ibrahim 1996: D24). Labeling, however, would require strict separation of genetically engineered from the usual varieties of corn or soybeans. Producers considered such separation impractical. If consumers refused to buy transgenic corn, or the European Union banned its import, U.S. producers would lose more than half a billion dollars in corn sales alone. This situation generated "tremendous interest" in a small company in Iowa that was marketing a test that could identify soybeans, corn, and other plants that had been genetically engineered (Wadman 1996). In December, the EU approved the genetically modified corn, leading the biotechnology industry to be ". . . optimistic that Europeans will come around to the benefits of genetically engineered crops" (Wolf 1997: 8). The EU ruling required labeling of genetically modified foods, however: "We must not miss this opportunity to repeat our clear signal that better labeling is one of the ways forward in this area" ("EU Approves" 1997: 1).

In Canada, a proposal to establish a central biotechnology regulatory agency met with opposition from farm, consumer, and industry groups, all of which viewed the current system of joint regulation by the departments of health and agriculture as satisfactory. Industry groups were especially concerned that government policies provide explicit regulations for the development and introduction of new plant varieties. Consumer proposals for labeling were opposed by the Canadian Federation of Agriculture:

> Canada must be in step with our major partners to ensure that Canada's labeling policy does not conflict . . . and thereby reduce the competitiveness of Canadian producers . . . The development of labeling regulations must recognize that the imposition of a labeling regime that is not based on science would have a negative trade implication for Canada. (Elliott 1996: 3)

Public Perceptions

Because food is overproduced in the United States and the West generally, and because the food industry is so competitive, biotechnology industry leaders view consumer acceptance of their products as an issue of critical importance: "Both the industrial and scientific communities have lagged in their understanding of the importance of the public's attitude toward biotechnology . . . It is the consumer – the poorly informed and uninitiated average individual – who holds the key to our future" (Walter 1995: 216).

Consumer surveys do indeed document a fundamental public misunderstanding of basic food safety issues. Many surveys have reported a large proportion of respondents to be deeply concerned about the hazards of pesticides or irradiation, whether or not they believe these hazards to be more important (Food Marketing Institute 1994) or less important (Lynch and Lin 1994) than the far greater dangers of microbial contamination.

Because of the importance of consumer attitudes to the future of the industry and to federal regulatory efforts, various agencies in the United States and Canada have conducted surveys designed specifically to reveal consumer perceptions of food biotechnology. The methods used to obtain this information have varied among the surveys, and their results are not strictly comparable. Nevertheless, the results of such surveys have proven remarkably consistent over time, and they reveal an internally consistent logic of considerable predictive value.

At least three surveys have examined public attitudes toward agricultural biotechnology in the United States. In 1986, the Office of Technology Assessment commissioned the Harris organization to conduct focus groups and to administer a telephone survey of a national probability sample of 1,273 adults on perceptions of science, genetic engineering, and biotechnology (U.S. Congress 1987). In 1992, the USDA commissioned a telephone study of the attitudes of 1,228 consumers, along with a series of focus groups (Hoban and Kendall 1993; Zimmerman et al. 1994). In addition, Rutgers University researchers conducted a telephone survey of 604 New Jersey residents in May of 1993 (Hallman and Metcalfe 1993).

The results of these surveys are summarized in Table VII.7.5. Despite differences in method, population, and year, they yielded virtually identical responses that provide a consistent picture of public attitudes toward food biotechnology. Although respondents to all three surveys displayed a limited understanding of science and technology, they expressed high levels of interest in those fields, as well as high expectations that food biotechnology would produce benefits for them and for society as a whole. The respondents were concerned about the potential and unknown dangers of genetically engineered foods, but they believed that the benefits of biotechnology outweighed any risks, and they strongly supported continued federal funding of food biotechnology research.

It is especially noteworthy that the survey participants preferred some genetically engineered food products to others. They were most likely to accept products that appeared to be beneficial to health or society, to save money or time, to be safe, or to improve the environment.

Safety considerations, although often the focus of biotechnology debates (Hopkins et al. 1991), did not emerge in these surveys as the most important public concern. Instead, survey respondents appeared most troubled by ethical issues related to food biotechnology. Thus, they were more willing to accept genetically engineered foods that involved plants rather than animals, that did not harm animals, and that did not involve the transfer of animal genes into plants. These views derived from value systems that encompassed issues extending far beyond food safety (see Table VII.7.4), and the importance of such value systems to consumer perceptions of biotechnology cannot be overestimated:

> Whatever the actual saliency of these ethical charges and critiques, obviously fundamental social, cultural, and religious values are at stake, arising out of broad cultural traditions and interests. Animal biotechnology, coupled to the engines of corporate economics, is felt to threaten fundamental and traditional moral, religious, and cultural orientations (Donnelley, McCarthy, and Singleton 1994: S21).

Table VII.7.5. *Public perceptions of food biotechnology*

Respondents express	U.S. Congress (1987)	Hoban and Kendall (1993)	Hallman and Metcalfe (1993)
Great interest in food biotechnology	✓	✓	✓
Limited understanding of science and techniques	✓	✓	✓
Expectations that food biotechnology will benefit them and society	✓	✓	✓
Concerns about unknown risks	✓	✓	✓
Expectations that benefits will outweigh risks	✓	✓	✓
Belief that government should continue to fund food-biotechnology research	✓	✓	✓
Greater willingness to accept products that			
Directly benefit health, consumers, or society	✓	✓	✓
Save money or time	–	✓	✓
Are safe	✓	✓	✓
Help improve the environment	✓	✓	✓
Involve plants rather than animals	✓	✓	✓
Do not harm animals	✓	–	✓
Do not involve transfer of animal genes into plants	–	✓	–
Distrust of government credibility related to science and technology	✓	✓	✓
Distrust of government regulatory ability	✓	✓	✓
Distrust of the biotechnology industry	✓	✓	✓
Belief that food biotechnology should be regulated	✓	✓	✓
Belief that biotechnology-derived food products should be labeled	✓	✓	✓

All three surveys confirmed substantial public distrust of government credibility in scientific and technical safety matters and in the ability of government to regulate food biotechnology appropriately. Respondents were equally skeptical of the ability of the biotechnology industry to make decisions in the public interest. For these reasons, all three surveys indicated that the large majority of respondents wanted genetically engineered food products to be labeled as such. A 1993 survey conducted in Canada reported similar results (Walter 1995).

Industry leaders have tended to interpret such results – scientific misunderstanding, fear of unknown dangers, concern about animal welfare, distaste for transgenic experiments, and demand for regulation and food labeling – as evidence for public irrationality (Gaull and Goldberg 1991; Walter 1995). They and others further interpret these survey results as strongly supporting the need for comprehensive education campaigns to inform consumers about the safety and benefits of biotechnology (Bruhn 1992; Hoban and Kendall 1993; Walter 1995).

Such interpretations miss the most strikingly useful conclusion to be drawn from these surveys: Consumer acceptance of food biotechnology is entirely product-specific. The survey results clearly demonstrate that the public will readily accept genetically engineered products that are perceived as filling important needs: "People appear to be far more focused on the characteristics of products than the process used to create those products. People may be willing to overlook their objections to genetic engineering if its products produce specific benefits" (Hallman and Metcalfe 1993: 3).

The results of the Canadian survey further support this conclusion:

> The Canadian public tends to consider biotechnology products individually, based mainly on their potential benefits. For example, the general concept of transferring genetic material from one plant to another was accepted by 51% of the respondents. This support jumped to 70% if the transfer improved plant nutritional value, though it slid to only 36% if the transfer only improved plant color . . . Products with laudable goals were strongly supported, while those with dubious benefit were rejected. (Walter 1995: 216)

Such results demonstrate that the key issue in consumer acceptance of genetically engineered foods is the value of the specific product to public health and welfare. The implication of these results is equally clear: If the food biotechnology industry wants consumers to accept its products without protest, it must market products worthwhile to the public as well as to the industry.

Predictive Implications: U.S. Case Studies

The survey results also suggest an analytical framework for predicting the degree of difficulty with which a given genetically engineered food is likely to achieve public acceptance in the United States. This

Table VII.7.6. *Analytical framework for predicting public acceptance of a food product of biotechnology*

1. Is the food valuable? Will it
    - Increase nutrient content?
    - Increase food availability?
    - Decrease food cost?
    - Improve food taste?
    - Grow better under difficult conditions?
    - Reduce use of herbicides and pesticides?
2. Is the food safe for people and for the environment?
3. Is the food ethical? Does it avoid
    - Harm to animals?
    - Insertion of animal genes into plants?

analysis presumes that consumer acceptance is predicated on the importance of a product, its safety, and its ethical value. To predict whether a product will be acceptable, one need only ask the questions listed in Table VII.7.6. If the answers to all three questions are affirmative, the product is highly likely to be accepted by the great majority of consumers. To the extent that the answers are negative or equivocal, consumer resistance is likely to increase. Consumer responses to the genetically engineered products that have been approved for marketing in the United States constitute case studies that illustrate the predictive value of such questions.

Pharmaceuticals

By the early 1990s, the FDA had approved at least 15 recombinant drugs for use in human subjects. Recombinant insulin, for example, was the first to receive approval, in 1982. This drug is of unquestioned utility (U.S. Congress 1991a). It solves problems of scarcity and quality, as it can be produced in unlimited quantities. Its amino acid structure is identical to that of human insulin, and it is, therefore, superior to insulin obtained from the pancreas of pigs or cows. It is safe and raises no ethical issues. Recombinant insulin readily meets all three criteria for consumer acceptance, and it is neither surprising nor inconsistent that activists against biotechnology in the United States have never protested its use.

Chymosin

Recombinant enzymes used in food manufacture also have been accepted readily. Chymosin, an enzyme used to coagulate milk to make cheese, was traditionally extracted from the stomachs of calves and sold as part of a mixture called rennet. The enzyme was difficult to extract, varied in quality, and was scarce and expensive. Through rDNA techniques, the gene for chymosin was transferred to bacteria that can be grown in large quantities. Chymosin derived from this process was approved for food use in 1990 (U.S. Congress 1991a). This action elicited no noticeable complaints from biotechnology critics, not only because the manufacturer saw "little to gain from waving the biotech flag," but also "because the alternative is slaughtering baby calves" (Kilman 1994b: R7). This product also meets the three criteria for consumer acceptance: It is more useful, more ethical, and just as safe as the product it replaced.

The "Flavr Savr" Tomato

Americans have come to expect tomatoes to be available on a year-round basis. The market for fresh tomatoes was estimated at between $3 and $5 billion annually in the early 1990s (Fisher 1994; Hilts 1994). In 1993, American farmers produced nearly 16 pounds of fresh tomatoes per capita and another 77 pounds per capita for processing (Putnam and Allshouse 1994). But supermarket tomatoes, bred for disease resistance, appearance, and durability, have long been the bane of consumers longing for "backyard" taste and freshness (Mather 1995).

Beginning in the mid-1980s, Calgene, a California-based biotechnology company, invested $25 million and eight years of effort to develop a tomato with a reversed (and, therefore, blocked) gene for ripening. This process was designed to permit it to be picked and marketed at a more mature stage of ripeness and taste (U.S. Congress 1991a). Calgene expected this "Flavr Savr" tomato to capture at least 15 percent of the market for fresh tomatoes as soon as it became available (Kim 1992b). The company planned to market – and label – the tomato as genetically engineered to taste better.

As the first company to develop such a food, Calgene voluntarily sought FDA guidance on the tomato's regulatory status in 1989, long before it was ready to market. In 1990, Calgene requested an FDA advisory opinion as to whether the gene for resistance to the antibiotic kanamycin, used as part of the genetic engineering process, could be used as a marker in producing tomatoes and other crops. The following year, Calgene requested a more formal FDA "consultation" on whether the Flavr Savr would be subject to the same regulations as conventional tomatoes, and, in 1992, the company published a comprehensive report on the tomato's safety and nutrient content (Redenbaugh et al. 1992).

The following year, Calgene filed a petition with the FDA to approve the kanamycin-resistant gene as a food additive. The FDA reviewed this request under its 1992 policy and also requested an opinion from its Food Advisory Committee (FDA 1994a; Hilts 1994). In its review, and during the committee hearings, the FDA insisted that the discussion focus exclusively on safety questions. Consumer and other representatives on the committee said they were ". . . frustrated by a debate that, to them, ignores other key issues that affect consumers' preferences for foods, such as religious, ethical, or aesthetic criteria . . . They also say that such foods should carry labels" (Fox 1994: 439).

The FDA decision, in 1994, that "all relevant safety questions about the new tomato had been resolved"

(FDA 1994a) was greeted as "terrific news for the industry," and the price of Calgene stock increased slightly (Fisher 1994: B7). Consumer groups, however, charged that the FDA review of the tomato had been an anomaly because the approval system had been entirely voluntary. Certain antibiotechnology advocacy groups threatened picket lines, "tomato dumpings," boycotts, and legal challenges (Leary 1994). Most analysts, however, believed that consumers would accept the tomato if they perceived its improved taste to be worth what it would cost (O'Neill 1994). Although the price was originally expected to be twice that of conventional varieties (Sugawara 1992), the cost of the tomato was reduced in test markets to compete with locally grown products (Biotech 1994). By the summer of 1996, however, supplies of the tomato were still too limited to determine its level of acceptance.

From the answers to the questions in Table VII.7.6, some consumer resistance should be expected. Although the Flavr Savr is demonstrably safe, it raises issues related to its impact on small tomato growers. Its benefit to the public is restricted to taste. Perhaps most important, its higher costs identify the Flavr Savr as a luxury product targeted to an upscale market.

To Calgene, however, the tomato was well worth the huge investment of time, money, and effort; indeed, it was said that part of the effort involved providing members of Congress with bacon, lettuce, and Flavr Savr sandwiches (Stix 1995). FDA approval of the tomato paved the way for subsequent approval of the company's seed oils, herbicide-resistant cotton, and other genetically engineered crops, raising hopes that Calgene would at last obtain a return on its investment. The company was reported to have lost more than $80 million since its formation in the early 1980s (McMurray 1993), and it continued to report losses during 1994. In June 1995, Monsanto, the manufacturer of recombinant bovine somatotropin (see next section), purchased 49.9 percent of Calgene, thus becoming the leading supplier of fresh tomatoes in the nation (Fisher 1995).

Bovine Somatotropin

The story of recombinant bovine somatotropin (rbST), the first food product to be approved by the FDA under its 1992 policy, best illustrates how issues of societal benefit, safety, and ethics contribute to consumer resistance to biotechnology. The product, a growth hormone that increases milk production in cows by at least 10 to 20 percent (Pell et al. 1992), has elicited an extraordinary level of debate. Its very name is controversial: Most proponents use its scientific name, rbST, whereas critics tend to use its more readily understandable common name, Beef (or Bovine) Growth Hormone, abbreviated rBGH (Daughaday and Barbano 1990). For purposes of consistency, this chapter employs the term rbST.

The Monsanto Company developed rbST in the mid-1980s and promoted it as a means to make dairy farming more efficient. Although such efficiency would seem to be of great benefit to consumers, critics soon raised questions about the product's effects on human health, animal welfare, and the economic viability of small dairy farms (U.S. Congress 1992). They also raised issues related to consumers' freedom of choice in the marketplace: When the FDA ruled that milk from cows treated with rbST cannot be so labeled.

For the industry and its supporters, concerns about factors other than safety were seen as irrelevant and highly threatening to the future of agricultural biotechnology; if rbST failed in the marketplace, the entire industry would be in jeopardy (Schneider 1990). Accordingly, this hormone and an equivalent product for pigs were extolled as:

> Biotechnological miracles that would give consumers more for their money at less cost to the environment. Yet these and other long-tested products . . . are likely to be mired in continuing controversies instigated more by ignorance, nostalgia and a Luddite view of technology than by understanding and actual fact . . . whether such improvements will ever reach the marketplace will depend largely on how well consumers accept BST (Brody 1993: C17).

Yet rbST was controversial almost from its inception. By 1989, during periods of testing on commercial farms and research centers in nearly every major dairy state (Schneider 1989, 1990), rbST had become the target of groups concerned about family farms as well as of those suspicious of genetic engineering (Sun 1989). As a result, supermarket chains announced that they would not carry milk from rbST-treated cows, and dairy companies such as Ben and Jerry's stated that their products would carry label statements that opposed the use of rbST (Schneider 1989). The state legislatures of Wisconsin and Minnesota temporarily banned the sale of rbST, an action considered extraordinary in the case of a product not yet approved for commercial use (Schneider 1990). By 1992, four major supermarket chains, two large manufacturers of dairy products, and the nation's largest dairy cooperative had joined the boycott (Miller 1992), as had many small farmers, dairy cooperatives, and groceries (Day 1994). Such a level of protest might easily have been anticipated, as rbST raised many of the issues suggested by the questions in Table VII.7.6.

Safety issues. Bovine somatotropin stimulates milk production, and the natural hormone is always present in cow's milk in low concentrations. Milk from rbST-treated cows contains both the natural hormone and rbST; these are almost identical and cannot easily be distinguished, complicating efforts to require labeling. The hormone is unlikely to be harmful to humans, even though its concentration is higher in milk from treated cows. Its protein structure differs from that of the human hormone and it is biologically inactive in humans. Moreover, like all proteins, the cow hormone is largely broken down in the human intestinal tract. The hormone had been tested on 21,000 cows, and described in more than 900 research papers by 1992, with no indication of untoward effects on human health (Miller 1992).

Despite this evidence, critics continued to raise doubts about safety because of concerns about two factors that might be present in rbST milk: insulin-like growth factor-I (IGF-I) and antibiotics (Blayney 1994). Treatment with rbST increases concentrations of IGF-I in cows' milk, raising concerns that this factor might stimulate premature growth in infants and cancers in adults. Proponents of rbST argue that the factor appears to be relatively inactive in rats, is denatured in infant formulas, and seems unlikely to be absorbed by the human digestive tract in sufficient amounts to be harmful (Juskevich and Guyer 1990). A federal study has confirmed that IGF-I concentrations are indeed higher in rbST-treated cows but concluded that more research would be needed to determine whether the higher levels posed any risk (U.S. General Accounting Office 1992b).

The second concern arose because cows treated with rbST develop udder infections (mastitis) more frequently than untreated cows. Such infections are treated with antibiotics that can appear in milk and meat and, theoretically, contribute to human antibiotic resistance. Although federal regulations require testing for antibiotic residues in milk, the FDA tests for only a small fraction of animal drugs in common use – just 4 out of 82 in one study – leading to charges that the agency lacks a comprehensive strategy for monitoring animal drugs (U.S. General Accounting Office 1992a). These concerns led yet another federal committee to recommend discontinuation of rbST marketing until antibiotic risks could be evaluated; at the same time, the committee called for development of a feasibility study of rbST labeling to provide information to the public (U.S. General Accounting Office 1992b). As discussed here, these recommendations were not implemented.

In 1990, Monsanto-sponsored scientists reported in a leading medical journal that rbST milk was safe for human consumption and that FDA studies had answered all safety questions (Daughaday and Barbano 1990). That same year, FDA scientists reviewed more than 130 studies of the effects of rbST on cows, rats, and humans and concurred in the conclusion that the hormone did not affect human health (Juskevich and Guyer 1990). The publication of this last report in a prestigious scientific journal was judged "unprecedented," as it gave the appearance of a conflict of interest: The FDA seemed to be acting as a proponent of a drug that it had not yet approved (Gibbons 1990). Critics viewed the report as "part of a campaign by the four companies developing the drug and portions of the dairy industry to calm the public's concern. . . . The review could not have been conducted without the permission of the manufacturers to disclose their own confidential studies on the safety of the drug" (Schneider 1990: A18). Nevertheless, a panel of experts recruited by the National Institutes of Health (NIH) also concluded that milk from rbST-treated cows was essentially the same – and as safe – as milk from untreated cows (Office of Medical Applications 1991).

Animal welfare. Because treatment of cows with rbST increases milk production, concerns have also been expressed about the effect of the drug on the health and reproductive ability of the animals. In addition to increasing cases of mastitis, injections of rbST have been reported to produce localized reactions at the injection sites in some cows (Pell et al. 1992; U.S. General Accounting Office 1992b). Despite FDA and industry assertions that appropriate herd-management practices can minimize such problems, they are nonetheless regularly reported. Between March 1994 and February 1995, for example, more than 800 farmers filed complaints with the FDA about animal health problems related to the use of rbST. Yet, according to the FDA, such reports "raise no new animal health concerns" ("Over 800 Farmers" 1995: 6).

Dairy farming. In the opinion of many, arguments about the safety of rbST have tended to obscure "the real issue – the economic impact of BGH once it hits the market" (Sun 1989: 877). For years, dairy production has exceeded demand, resulting in large surpluses of milk, butter, and other dairy products; such surpluses are purchased by the government to maintain prices (Schneider 1989). Common use of rbST will almost certainly increase milk production, but the effects of this increase on prices to farmers and costs to consumers and the government are difficult to predict. One estimate has suggested that the use of rbST will lead to a 2 percent decrease in prices paid to farmers and, therefore, to a 1 percent decline in farm income by 1999 (U.S. Congress 1991b). Any decline in milk consumption, coupled with increasing supplies, might be expected to accelerate trends toward the elimination of small dairy farms (Schneider 1994b). Federal spending on dairy price supports might also increase, although such an increase could be offset by the lower costs of federal commodity distribution programs (Blayney 1994).

Whether rbST milk will cost less is uncertain. The industry contends that the use of the hormone will reduce farm production costs because equivalent amounts of milk can be produced by fewer cows. Although it might seem logical that creation of milk surpluses would lead to lower prices, any price decline stimulates higher levels of federal spending to protect farm incomes (Kilman 1994b). Most commentators – but not all (U.S. Congress 1991b) – believe that at least some dairy farmers will be forced out of business.

Regulation. In 1985, the FDA permitted Monsanto to use the drug on an experimental basis (Schneider 1989). The agency reaffirmed the safety of rbST milk and meat in 1988, 1989, and again in 1990 (Miller 1992), as did the NIH in 1990 (Office of Medical Applications 1991) and the Office of Technology Assessment in 1991 (U.S. Congress 1991b). FDA approval of rbST as a new animal drug product appeared imminent (Miller 1992), but in August 1993, Congress enacted a 90-day moratorium on rbST sales. In fact, the Senate, concerned about the fate of small dairy farms, had approved a moratorium lasting an entire year, but House opposition forced this compromise ("BGH Moratorium" 1993).

After lengthy deliberations, advisory committee consultations, and public hearings, the FDA approved Monsanto's rbST as a new animal drug in November 1993. In announcing the decision, the FDA commissioner stated: "There is virtually no difference in milk from treated and untreated cows . . . in fact, it's not possible using current scientific techniques to tell them apart . . . we are confident this product is safe for consumers, for cows and for the environment" (Schneider 1993: 1).

FDA approval applied only to the Monsanto product, although approval of products from other companies was expected to follow ("FDA Approves" 1993). Industry representatives hailed the FDA decision as a strong signal that the administration intended to reduce regulatory barriers, as a victory for Monsanto, and as a "banner day for agricultural biotechnology" (Schneider 1993: 9). The actual effect of the ruling, however, would not be seen until the moratorium on sales ended. In the meantime, Monsanto was reported to be giving the product to farmers at no cost ("FDA Approves" 1993).

Because dairy companies, concerned about consumer reactions to rbST, had been labeling their products as "BGH-free," industry groups requested FDA guidance on the labeling of dairy products derived from untreated cows. In February 1994, the FDA stated that it did not have the authority to require special labeling and ruled that companies might voluntarily inform customers that they were not using rbST, provided "that any statements made [we]re truthful and not misleading." Because all milk contains some bST, milk could not be labeled as "BGH-free." Because bST and rbST are indistinguishable, milk also could not be labeled as "rBGH-free." However, these designations could be used if accompanied by a statement that put them in proper context: "[N]o significant difference has been shown between milk derived from rbST-treated and non-rbST-treated cows" (1994b: 6280).

Nevertheless, the state of Vermont passed legislation requiring the labeling of milk from rbST-treated cows, in conflict with FDA rulings: "Vermonters have the right to know what is in the food they eat . . . In particular, there is a strong public interest in knowing whether or not rBST has been used in the production of milk and milk products" (Schneider 1994d: A16). By 1996, however, industry groups had successfully challenged this law in the courts ("Court Strikes Down" 1996).

Moreover, two major milk marketers launched new brands certified as coming from untreated cows. In response, Monsanto warned dairy companies that such labels were misleading and "might create the impression that something is wrong with milk from treated cows" (Kilman 1994a: B7). By May 1994, Monsanto had sued at least two dairy companies to force them to comply with the FDA ruling. Because the dairies lacked resources as extensive as Monsanto's, they seemed certain to lose the suits. As one report stated, "Everyone is terrified of Monsanto . . . it is quite ominous" (Burros 1994: C4).

International implications. The European Community (EC) has long been skeptical about the use of growth hormones in cattle. This is the result of 1980 incidents in which consumption of baby foods containing veal from cows treated with diethylstilbestrol was associated with cases of premature sexual development in infants. Despite such skepticism, in 1987 Monsanto Europe requested approval of rbST from the EC's Committee for Veterinary Medicinal Products (Vandaele 1992). The following year, however, the EC banned nontherapeutic use of hormones in the domestic livestock industry and soon extended the ban to countries that exported meat to the EC.

This action raised trade issues related to the use of rbST (Krissoff 1989). In 1991, the Veterinary Products Committee decided that rbST met requirements for quality, efficacy, and safety and posed no risk to consumers or cows. But this decision was overruled by the EC Directorates General, an action seen as a "blow to agricultural biotechnology" (Vandaele 1992: 148). Indeed, the EC executive committee proposed a seven-year ban on rbST use because it feared that the hormone might undermine efforts to reduce farm surpluses.

Thus, rbST became caught in a "policy paradox"; it would be manufactured by Monsanto in Europe, where it could not be sold, and then exported to the United States, where its use was permitted (Aldhous 1993). In 1995, the United States successfully persuaded the EC to declare that all Codex Alimentarius international standards for food additives, including animal drugs, should be based on science (i.e., biological safety). This was clearly an effort to force the EC to permit the use of rbST-derived milk and meat. But a straightforward motion by the United States for EC approval of rbST as posing no health risk fared less well; it was postponed until the Codex meeting scheduled for 1997 (Leonard 1995).

Industry actions. As early as 1987, rbST was expected to become agricultural biotechnology's first billion-dollar product (Sun 1989). In 1989, the market for rbST was estimated at $100 to $500 million annually (Schneider 1989); more recent estimates have been somewhat higher (Millstone, Brunner, and White 1994; Schneider 1994a). The potential for such a large return on investment helps to explain Monsanto's unusually aggressive sales tactics (Feder 1995) and heavy-handed political actions to protect and promote this and its other products (Benson et al. 1997). Certainly the company took full advantage of its connections in government. FDA employees with ties to Monsanto played key roles in the agency's review of rbST (Schneider 1994e; U.S. General Accounting Office 1994), and Monsanto enlisted an influential former congressman, to whom the secretary of agriculture owed his appointment, to encourage the USDA to prevent Congress from studying the economic effects of rbST (Engelberg 1994).

Monsanto leveled charges of plagiarism against independent researchers who had used company data to analyze counts of white blood cells ("pus," according to critics) in rbST-treated milk, thereby preventing publication of their report (Millstone et al. 1994). The company used legal and political strategies to resist demands for labeling and recruited dairy industry executives to help persuade the FDA to establish favorable labeling guidelines. In addition, Monsanto was reported to have recruited at least two Washington law firms to monitor dairies for advertising and labeling violations and to instigate legal action against milk processors who had "inappropriately" misled customers (Schneider 1994c).

To some extent, these efforts succeeded. By March 1995, Monsanto claimed to have sold 14.5 million doses of rbST during the previous year and stated that 13,000 dairy farmers, or 11 percent of the potential market, were customers (Feder 1995). Sales were said to be especially strong in the state of New York, with 10 percent of dairy farmers reported to be using rbST. But in Wisconsin, where milk is the foundation of a $10 billion dairy industry, only 5 percent of the state's 29,000 dairy farmers were said to be using the hormone (Schneider 1994c), and 90 percent were reported as hoping that the drug would never be widely adopted. Overall sales for the first year were estimated at $70 million, far short of what had been anticipated (Feder 1995).

Consumer responses. The degree of consumer acceptance of rbST was also uncertain in 1995. A telephone survey of 1,004 adults suggested that use of rbST would have no impact on milk consumption, as most respondents had never heard of the drug. However, the phrasing of the survey questions, which used the term somatotropin rather than "growth hormone," and emphasized safety rather than issues of ethics and values, may have led respondents to more favorable answers. For example, respondents answered positively (scoring 6.18 on a scale where 10 is strongly positive) to this question:

> The National Institutes of Health, the American Medical Association, and several other independent medical groups have found milk from cows that receive BST is unchanged, safe, and nutritionally the same as milk currently on grocery store shelves. Given this information, how acceptable do you find the use of BST. . . ? (Hoban 1994: 8)

The lack of labeling of rbST dairy products complicates understanding of consumer acceptance. Despite FDA rulings, surveys demonstrate overwhelming consumer support for special labeling of rbST products (Blayney 1994). Supporters of rbST have argued that the marketplace should be allowed to decide the commercial fate of the hormone (Sun 1989), but without labeling, consumers cannot easily make their opinions known.

Implications. Public skepticism about rbST relates to nearly all of the areas of concern listed in Table VII.7.6. Given the strength of these concerns, this product seems an unfortunate first choice for commercialization. United States farmers already overproduce milk, and rbST offers no clear benefit to consumers in availability, price, or quality. It will not even create more manufacturing jobs, as most rbST will be made and packaged in Europe (Hansen and Halloran 1994). That the product affects milk itself is also unfortunate: "Is there any product in the world that has tried harder to sell itself as wholesome and pure than milk? . . . It is a food for innocent, trusting children, culturally laden with symbolism. Any adulteration of milk . . . is seen as taboo" (Kolata 1994: E13).

The primary gainers from rbST, therefore, appear to be its manufacturers and the large dairy farmers who can best exploit its use. As summarized by the head of a dairy company that refuses to use rbST:

> We do know that the use of BGH will increase the supply of milk at a time when we already have a tremendous surplus. It does not make any sense to exacerbate this problem with a product about which there are so many legitimate doubts, a product whose principal beneficiaries will be chemical companies and corporate agribusiness. (Cohen 1993: 1)

Policy Implications

This history indicates that the controversy over food biotechnology derives from the conflict between the industry's need to be profitable and the desire of consumers for products that are economically and socially valuable, as well as safe. Therefore, to frame the debate about food biotechnology in terms of rational science versus an irrational public is to do a disservice to both.

Biotechnology is not inherently dangerous, and it is capable of doing much good. The public is not inherently irrational and is quite capable of judging whether genetically engineered products are worth buying. Few consumers demand that biotechnology "pack up its test tubes"; they support industry efforts to impart to food plants desirable qualities such as resistance to diseases and pests to food plants. At the moment, however, many view the great promise of biotechnology as having been betrayed (Hamilton 1990: 43).

Thus, the open contempt of policymakers and industry leaders for public misunderstanding of science and technology misses an important point. As this analysis has indicated, public views of biotechnology in the United States are product-specific and, as such, are logical, consistent, and predictable. Analysts of biotechnology policy who are aware of this logic recommend that regulators and the public decide the risks and benefits of each new product on a case-by-case basis (Davis 1991). They agree with industry that the marketplace should be allowed to determine the success of these products. They suggest that the products be labeled so that the public can make informed decisions in that marketplace and believe that if industry is producing valuable products, the label will encourage the public to purchase them.

Although it is always useful to educate the public about the benefits of science and technology, education alone will not solve problems of consumer acceptance. The analysis presented here suggests that it will continue to be difficult to convince the public that genetically engineered food products are necessary or safe as long as the principal beneficiary of food biotechnology is the industry itself. If the food biotechnology industry wants to convince the public that its products are beneficial, it will need to place far greater emphasis on the development of truly useful products, those that foster sustainable agriculture, drought- and pest-resistance, and improved nutrient quality.

This analysis also argues in favor of the development of federal regulatory mechanisms capable of addressing a much broader range of issues than just food safety. As noted by one commentator, regulations should be based on a comprehensive analysis of policy and assessment of technology that examines the full range of social and environmental consequences of technological change (Brown 1991).

That the agricultural biotechnology industry would benefit from such an analysis is evident from recent events. Developing-world countries are moving quickly to develop recombinant crops that will solve their local food problems. These efforts, which derive directly from the need to produce more food, are focusing on improvements in disease resistance and nutritional quality, especially among native plant species (Moffat 1994; Bokanga 1995). Such efforts deserve much support and should encourage food biotechnology companies in industrialized nations to focus research and development efforts on products that will benefit individuals and societies as well as the companies' investors.

VII.8 Food Safety and Biotechnology

The ready availability of safe, wholesome food is often taken for granted by citizens of modern societies. However, maintaining the safety of a large, diverse food supply is a challenging undertaking that requires coordinated effort at many levels. In this chapter, the principles of food safety are discussed first with regard to traditional foods and then again as they concern novel foods developed through genetic modification.

Definitions and Priorities

The term "food safety," as used today, encompasses many diverse areas, including protection against food poisoning and assurance that food does not contain additives or contaminants that would render it unsafe to eat. The term evolved mainly in the context of preventing intoxication by microbial poisons that act quickly (within hours to a day or two of exposure) and often induce such serious symptoms as convulsive vomiting and severe diarrhea, or respiratory failure and death (Cliver 1990). An example of the former is staphylococcal food poisoning, caused by the proteinaceous enterotoxins of the pathogenic bacterium *Staphylococcus aureus* (Cliver 1990). Botulism is an example of the latter, caused by the neurotoxins synthesized by *Clostridium botulinum* (Cliver 1990).

Both staphylococcal food poisoning and botulism result from ingesting toxins that are preformed in the implicated foods. For illness to ensue, it is necessary only to ingest the toxin, not the microbe itself. Food poisoning may also follow the ingestion of certain pathogenic bacteria, such as *Salmonella,* which produce gastrointestinal (GI) infections, and *Escherichia coli* 0157:H7, which produces an infection and a potent toxin within the GI tract (Cliver 1990). The infection results in bloody diarrhea, while the toxin enters the bloodstream and induces kidney damage.

Given the foregoing, it should come as no surprise that the Food and Drug Administration (FDA), the lead federal agency charged with ensuring the safety of the food supply in the United States, considers foodborne microbial pathogens and the toxins they produce to be the most important of the various food safety risks (Table VII.8.1). Unfortunately, evidence indicates that the public often tends to focus too much on pesticide residues and food additives, wrongly believing that the risk from these materials is as great as that from pathogenic microorganisms (Pariza 1992c).

Table VII.8.1. *Ranking food safety risks*

1. Food-borne disease.

Table VII.8.2. *Summary of reported food-borne disease outbreaks in the United States, 1983–7*[a]

Etiologic agent	Percentage of cases	Percentage of outbreaks[b]
Pathogenic bacteria[c]	92	66
Viruses[c]	5	5
Parasites[c]	<1	4
Chemical agents[d]	2	26

[a] During this time period, 91,678 cases and 2,397 outbreaks of foodborne illness were reported to the Centers for Disease Control (CDC). The etiologic agent was identified in 38 percent of the outbreaks. These data are summarize in this table.

[b] An outbreak is the occurrence of two or more cases of illness transmitted by a single food.

[c] Pathogenic bacteria, viruses, and parasites are all classified as microorganisms.

[d] Some instances of chemical poisoning were actually due to chemical toxins produced by microorganisms. No instances of illness traced to synthetic chemicals were identified in the report.

Source: Bean et al. (1990).

Microbial Foodborne Illness

Table VII.8.2 shows a summary of foodborne illness in the United States, compiled by the Centers for Disease Control (CDC), from 1983 to 1987 (Bean et al. 1990). But according to both the CDC and the FDA, the reported cases and outbreaks account for only a tiny fraction of the total foodborne illnesses that occurred during that period. It is estimated that several million cases of microbial food poisoning actually occur in the United States each year (Archer and Kvenberg 1985).

Foodborne illness is caused by a relatively small number of bacterial species. All raw foods contain microorganisms, some of which may be pathogens. Whether or not this becomes a problem is determined largely by how the food is handled prior to consumption. Pathogen growth depends on a number of factors. The most important of these are (1) the levels of salt and other electrolytes present in the food; (2) the types and amount of acid in the food; (3) the amount of available water; (4) the presence of microbial inhibitors (both naturally occurring and synthetic); (5) storage conditions; and (6) cooking conditions. Safe food processing depends on understanding these factors and effectively utilizing the basic principles of microbiology as they apply to foods.

In addition to precipitating illness and soaring medical costs, foodborne illness can also bring economic devastation for producers of an implicated product (Todd 1985). A dramatic example occurred in 1982, when two Belgians developed botulism after sharing a can of Alaskan salmon. One of them subsequently died of the illness.

The problem was traced to a can press that was used at the processing plant to form the can in question. The press was defective and had produced a tiny rupture in the wall of the implicated can. The rupture, which was virtually invisible, nonetheless permitted a small amount of nonsterile water to be drawn into the can during the cooling step that followed heat processing. The water was contaminated with spores of *Clostridium botulinum* which, once inside the can, germinated and produced the toxin that induced the illness. Fears that other cans might have been similarly damaged prompted voluntary recalls of much of the canned Alaskan salmon produced that year. In all, 60 million cans were recalled and discarded (Hayes 1983).

Foods provide a medium for the growth of specific pathogens, but they can also be passive carriers for virtually any pathogen capable of producing infection via the oral route. In this case the pathogens do not actually have to grow in the food. They need only to survive. Good examples are the foodborne viruses, such as the virus that causes hepatitis A. These cannot grow in the foods that carry them, yet illness follows ingestion of the contaminated food.

It should be noted that food spoilage and food safety are not related in a direct manner. A food may be spoiled but nonetheless safe. Alternatively, however, a food can contain bacterial toxins at deadly levels yet appear perfectly "normal." And finally, it is important to recognize that not all microbes in food are bad. Rather, harmless microorganisms are an integral part of many traditional foods. One could not produce bread, cheese, yoghurt, soy sauce, sauerkraut, beer, or wine without specific yeasts, bacteria, and molds. Such microorganisms are needed to induce desirable changes in the food through a process called "fermentation." Besides providing characteristic flavors, fermentation is also an important, effective method of food preservation. The harmless fermentation microorganisms produce microbial inhibitors and otherwise change the ecology of the food in ways that discourage subsequent pathogen growth.

Risks from Synthetic Chemicals

The data summarized in Table VII.8.2 indicate that the risk of developing foodborne microbial illness is far higher than the risk of becoming ill because of exposure to toxic chemicals in food. The instances of chemical poisoning reported in Table VII.8.2 represent almost exclusively naturally occurring toxins or contaminants. Only one approved food additive (monosodium glutamate) was reported as possibly causing illness in two outbreaks that occurred in 1984, involving a total of seven persons. In no instance was a synthetic chemical identified in the CDC report as a cause of illness (Bean et al. 1990). The data summarized in Table VII.8.2 refer to clinical illness, almost all of which is acute (that is, there is only a short time interval between exposure and onset of symptoms). Of course, questions about risks from "chemicals" in food often center on chronic effects, such as cancer, which in humans takes many years to develop.

The causes of chronic illness are much more difficult to determine because of the long time intervals between initial exposure and the onset of symptoms. Nonetheless, there is an extensive toxicology data base against which hypotheses can be tested. For example, based on these data, one may conclude that it is highly unlikely that synthetic pesticide residues or food additives pose a cancer risk to consumers (Ames, Profet, and Gold 1990; Pariza 1992a, 1992b).

Risks of Naturally Occurring Pesticides

Plants lack the defenses that animals possess (mobility, claws, and teeth), and so they must rely on passive defenses that are effective in situ. Accordingly, evolution has provided plants with the ability to synthesize naturally occurring toxins. In a very real sense, plants are practitioners of chemical warfare against potential predators.

The natural toxins that plants produce are usually nonspecific in nature; that is, they act against a variety of potential pests, including mammals as well as insects. The pathways regulating the synthesis and expression of these toxins tend to be under general control, meaning that any number of stresses, from insect infestation to drought, can "turn on" the entire spectrum of chemical and biological defenses that a plant possesses.

In this context, crop breeding can be seen as a means of controlling unwanted wild traits, such as toxin production, in plants destined for the table. Experience has shown that this is a relatively easy matter, even without any knowledge of the underlying science, doubtless because toxin production is not an inherent part of the growth and reproductive processes. Humans select and artificially propagate variants that would not otherwise survive but that nonetheless exhibit desirable traits. Because of the genetic linkage within the generalized protective mechanism pathways, increased expression of traits that humans deem desirable will usually be accompanied by decreased toxin expression (International Food Biotechnology Council 1990).

Unfortunately, selected traits that make a plant desirable as human food also make it desirable to insects. This, in fact, is why synthetic pesticides are used: They replace the naturally occurring pesticides and related survival traits that have been bred out of food plants.

Yet, although the natural pesticide levels of food plants have been lowered considerably through breeding, they have not been totally eliminated. Rather, the data in Table VII.8.3 show that many commonly consumed food plants and plant products contain naturally occurring pesticidal carcinogens. Moreover, unlike synthetic chemicals, which must be rigorously tested before regulatory agencies will approve them for food-related use, the toxins made naturally by plants are not ordinarily subjected to any sort of testing (Ames et al. 1990). For some individuals, however, it is unsettling to learn that many of those substances that have been tested have proved to be carcinogenic in rat or mouse feeding studies.

Yet it is important to put these findings into perspective by a consideration of (1) the relative exposure of the public to natural versus synthetic carcinogenic pesticide residues, and (2) the relative risk of cancer from these exposures.

With regard to exposure, FDA data indicate that the average daily intake of synthetic pesticides per person in the United States is 0.09 milligrams (mg) (Ames et al. 1990). About half of this intake (0.04 mg) comes from four chemicals that were not carcinogenic in high-dose rodent feeding studies. Thus, assuming that all of the remaining exposure is to carcinogenic pesticides (an unlikely assumption), the maximum exposure to synthetic carcinogenic pesticide residues is 0.05 mg per person per day.

Table VII.8.3. *Some natural pesticidal carcinogens in food*

Rodent carcinogen	Plant food	Concentration, ppm
5-/8-methoxypsoralen	Parsley	14
	Parsnip, cooked	32
	Celery	0.8
	Celery, new cultivar	6.2
	Celery, stressed	25
ρ-hydrazinobenzoate	Mushrooms	11
Glutamyl r-hydrazinobenzoate	Mushrooms	42
Sinigrin (allyl isothiocyanate)	Cabbage	35–590
	Collard greens	250–788
	Cauliflower	12–66
	Brussels sprouts	110–1560
	Mustard (brown)	16000–72000
	Horseradish	4500
Estragole	Basil	3800
	Fennel	3000
Safrole	Nutmeg	3000
	Mace	10,000
	Pepper, black	100
Ethyl acrylate	Pineapple	0.07
Sesamol	Sesame seeds (heated oil)	75
α-methylbenzyl alcohol	Cocoa	1.3
Benzyl acetate	Basil	82
	Jasmine tea	230
	Honey	15
Catechol	Coffee (roasted beans)	100
Caffeic acid	Apple, carrot, celery, cherry, eggplant, endive, grapes, lettuce, pear, plum, potato	50–200
	Absinthe, anise, basil, caraway, dill, marjoram, rosemary, sage, savory, tarragon, thyme	>1000
	Coffee (roasted beans)	1800
Chlorogenic acid (caffeic acid)	Apricot, cherry, peach, plum	50–500
	Coffee (roasted beans)	21600
Neochlorogenic acid (caffeic acid)	Apple, apricot, broccoli, brussels sprouts, cabbage, cherry, kale, peach, pear, plum	50–500
	Coffee (roasted beans)	11600

Source: Ames, Profet, and Gold (1990).

By comparison, it is estimated that Americans consume 1.5 grams of natural pesticides per person per day, or about 15,000 times more than the amount of synthetic pesticides. Moreover, many of these natural pesticides are also carcinogenic in high-dose rodent feeding studies (Table VII.8.3). Clearly, the public is exposed to far higher levels of naturally occurring pesticides, and, in fact, when compared to naturally occurring pesticides, synthetic pesticide exposure is trivial (Ames et al. 1990).

Moreover, toxicology is not just about exposure levels to toxic substances, because animals, including humans, have numerous biochemical and physiological resources to defend against such exposure. These defenses include enzymes that detoxify toxins and repair toxin-induced damage to DNA and other important biological structures, as well as the continual shedding of cells at epithelial surfaces that are most exposed to toxic insult (that is, cells at the surface of skin, eyes, and gastrointestinal tract). In short, humans have layer on layer of protection against the toxic dangers of "natural" environments.

Because of the immense number and variety of potential toxins, the defense systems must by necessity be general in nature. In this regard, there is nothing unique about synthetic pesticides. The protective mechanisms that act against naturally occurring toxins also act against synthetic toxins. These protective mechanisms are, of course, even more effective when the dose is exceedingly low as is the case with exposure to synthetic pesticide residues on produce. Moreover, it is important to note that the biological effects produced in animals by naturally occurring pesticides and other potential toxins are not always adverse. Rather, paradoxically, many of the substances shown in Table VII.8.3 that cause cancer when fed to rodents at excessively high levels seem to protect against cancer when fed at the lower, more realistic levels encountered in a normal diet (Pariza 1993).

One implication of this paradox is that unrealistically high dose cancer tests have been responsible for indicting the naturally occurring substances shown in Table VII.8.3. In fact, this consideration has led many experts to reexamine the entire framework through which we detect and regulate "carcinogens" (Ames et al. 1990; Pariza 1992c; National Research Council 1993).

The Safety of Novel Foods

There are many kinds of novel foods. In the simplest sense, a food may be novel in one locale and a dietary staple in another. Examples include the many foods that crossed the Atlantic Ocean between Europe and the Americas in the years following Columbus's voyages (Goldblith 1992). Corn, potatoes, tomatoes, and cacao (chocolate), which today are common throughout the world, were novelties for everyone on earth, save the Native Americans, just 500 years ago.

At the other end of the spectrum are novel foods developed by using recombinant DNA technology (for example, Calgene's flavr savr tomato). The recombinant DNA process is defined as "cutting and recombining DNA molecules to remove segments from or otherwise modify an organism's genetic material, or to combine segments of DNA from different types of organisms" (International Food Biotechnology Council 1990:).

Discovered and refined only since the 1970s, recombinant DNA methods represent a revolutionary means of controlling the introduction of new traits into plants, animals, and microorganisms. It should be stressed, however, that the "revolution" is not the process itself. There is ample evidence that gene transfer between different species has occurred throughout the history of life on this planet (International Food Biotechnology Council 1990). Rather, the revolution is that humans are able to control the process. For the first time in history, it is possible to direct the transfer of DNA from one species to another. It is also possible to create entirely new genes that, seemingly, have not existed before and transfer them into living hosts where the new genes will then replicate along with the host's genetic material.

The incredible power of this technology has led some to conclude that to prevent misuse, the process itself must be carefully regulated. Others argue that the process is simply a scientific tool and that the focus of regulation should be on the products of biotechnology, not on the process.

With specific regard to food, most experts agree that the focus of safety evaluation should be on the novel foods themselves, and not on the process whereby novel foods are developed (International Food Biotechnology Council 1990; Kessler et al. 1992). The rationale for this reasoning is that recombinant DNA technology is no less safe than plant breeding or any other traditional means of genetic manipulation. In all cases, one is (or should be) concerned with the expression of genetic information.

For example, in traditional plant breeding, one should determine if unexpected traits that bear on safety are expressed by the new cultivar. Such unexpected traits may arise directly from the genetic material itself that has been transferred in the cross may result because the transferred genetic material affected a regulatory element, thereby inducing the expression of an undesirable new trait (for example, the expression of a toxin).

In any attempt to establish the safety of a novel food, the same procedures should be followed to assure that the gene being transferred produces a safe product and that the gene does not induce changes in the recipient that bear on health and safety issues.

Addressing the first concern (whether the gene that is being transferred produces a safe product) is a relatively straightforward matter. This is because the gene can be completely defined. If the gene codes for a protein, it, too, can be completely defined and studied directly for toxigenic potential.

The second concern (whether the transferred gene induces changes in the recipient that bear on health and safety issues) is somewhat more problematic, as it is with traditional methods of genetic modification.

For example, the data of Table VII.8.3 indicate that many food plants naturally produce potentially carcinogenic compounds. As already discussed, the expression of such natural pesticides does not occur at a constant rate irrespective of other considerations. Rather, these substances are under genetic control, which in turn is influenced by environmental factors, such as insect infestation and drought. A pertinent example shown in Table VII.8.3 concerns celery.

Celery produces a class of natural pesticides called psoralins, which are light-activated mutagenic carcinogens. Ordinarily, the concentration of psoralins in celery is about 0.8 parts per million, which is too low to produce evidence of adverse effects in persons who consume the vegetable. However, through the use of traditional breeding methodology, an insect-resistant celery cultivar was developed that contained about 10 times the concentration of psoralin typically found (Table VII.8.3). This level was sufficiently high to produce skin irritations in consumers (Ames et al. 1990). Ordinary celery, subjected to stress, contains still higher levels of psoralin.

The increased psoralin content of the new celery cultivar was the result of genetic manipulation via traditional crop breeding techniques. It represents a reversal of the more commonly observed trend of decreased levels of naturally occurring toxicants in plants as they are "domesticated" through crop breeding (International Food Biotechnology Council 1990). In this particular case, however, the breeder's goal was to select for enhanced insect resistance so as to minimize the need for synthetic pesticides. Hence, the outcome of increased levels of psoralin (celery's natural insecticide) is not surprising. It should be noted that when the excessive psoralin problem was discovered, the cultivar was quickly withdrawn from the market (Ames et al. 1990).

This example offers insight into the evaluation of the safety of novel foods. The issue is whether introducing the new gene into the recipient triggers a response by the recipient that bears on health and safety. One of the main considerations is the possibility of increased synthesis of a toxicant synthesized naturally by the recipient plant (such as psoralin in a hypothetical novel celery).

There is considerable information on naturally occurring toxicants that are produced by food plants (International Food Biotechnology Council 1990). Such information can provide the framework for comparing the natural toxin levels in a novel food with those in its traditional (unmodified) counterpart – for instance, the psoralins in the hypothetical novel celery versus those in ordinary celery. A given plant species produces only a limited number of the known naturally occurring toxicants (usually restricted to a specific chemical class). Hence, it is not necessary to analyze each plant for every known, naturally occurring toxin. Rather, effort can be concentrated on the potential toxicants with which the plants in question are known to be associated. Such assays can take the form of specific chemical analyses, possibly coupled with judicious, limited animal testing (International Food Biotechnology Council 1990; Kessler et al. 1992).

The concept of comparative toxicology – assessing safety of a novel food by comparing it with its traditional counterpart – is central to the food safety assessment schemes developed by the International Food Biotechnology Council, a food and biotechnology industry-sponsored group (International Food Biotechnology Council 1990) and the FDA (Kessler et al 1992). In addition to assays for specific toxins, one should also consider changes in composition that might affect pathogen growth (Pariza 1992b).

Conclusion

With the advent of biotechnology, the production and availability of food is entering a new era of great promise for improved human welfare. Procedures and methodologies are available to ensure the safety of the novel foods that have been and will be developed through biotechnology (International Food Biotechnology Council 1990; Kessler et al. 1992). These procedures and methodologies are not fundamentally different from those used now to assure the safety of traditional foods developed though traditional means of breeding and improvement.

VII.9 Food Additives

Foods are biological products and, therefore, incorporate complex physical and biochemical systems. Many vegetables, fruits, and (sometimes) meat and fish are eaten raw, but in general they are cooked. And cooking induces profound chemical and physical changes. Some changes, such as the denaturation of protein and the gelation of starch, render food more digestible and are beneficial; others, by improving appearance, color, flavor, and texture, are also desirable. But some that cause heat damage to proteins, the loss of vitamins, or the formation of carcinogens on the surfaces of roast and barbecued meats are deleterious. Cooking leads to the use of one system, or a component of it, in the establishment of another. An example would be the role of egg yolks in emulsifying oil and water (vinegar) to make mayonnaise and to color it. Cooking also permits the use of major and minor ingredients and, thus, infinite variation in the final dish, but it also opens the way for the entry into food of nonfood substances derived from utensils and containers, and from the kitchen itself.

Food processors operate highly organized and sophisticated kitchens, and they apply detailed scientific knowledge of the raw materials to the production and packaging of products in response to market demands for variety, safety, wholesomeness, nutrition, and reasonable price. In effect, food processors are "super-cooks," but if in making mayonnaise they use lecithin (emulsifier) and beta-carotene (color) instead of egg yolk, or if they add acetic or citric acids instead of vinegar, then they are using additives.

Put simply, a food additive is a substance deliberately added to food by the processor to facilitate processing or to improve appearance, texture, flavor, keeping quality, or nutritional value. By contrast, any unwanted substance that finds its way into food is a contaminant. This may be defined even more widely as a substance that is not normally present in that food in its natural form; or is present in concentrations not normally found; or is not permitted under the food regulations to be present; or, being an additive as defined under the regulations, exceeds the concentration permitted.

Unfortunately, practice denies such simplicity, and the Codex Alimentarius Commission uses the following definition:

> "Food additive" means any substance not normally consumed as food by itself or not normally used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food results, or may be reasonably expected to result, (directly or indirectly) in it or its by-products becoming a component of or otherwise affecting the characteristics of such foods. The term does not include "contaminants" or substances added to food for maintaining or improving nutritional qualities (Codex Alimentarius Commission 1979).

There are gaps and uncertainties in such a definition. The key word in the Codex definition is "intentional." This excludes substances in which residues are inevitably present that are legitimately used in the production and processing of food. Strictly speaking, these residues are contaminants, but they are variously described as adventitious, indirect, incidental, or unintentional additives and are treated by most regulatory authorities in the same way as substances added for functional purposes to the food itself. They include pesticide residues, processing aids, sanitizers, boiler water additives, and packaging migrants and are quite different in kind, and often in concentration, from industrial contaminants, such as the notorious mercury contamination of the fish in Minimata Bay, Japan, and polychlorinated biphenyls (PCBs). For the purposes of this discussion, then, substances permitted by the Codex definition, together with such nutrients as vitamins and minerals, will be considered to be additives.

Food Additives in History

There is nothing new about the concept of food additives. The ancient Chinese unknowingly used traces of ethylene and propylene from burning paraffin to ripen fruit, although additives were probably used originally simply to preserve food. Smoking is an ancient method of food preservation, usually for meat or fish, which relies partly on drying and partly on the preserving chemicals in the smoke.

Similarly, the resins added to Greek wine act as mild preservatives, and in classical times, the pitch linings of amphorae contributed substances that helped to preserve the wine carried in them. More recently, the practice of burning sulfur in empty wine barrels not only fumigated the barrel but also adventitiously ensured that the wine filling the barrel would be treated with sulfur dioxide, still the preservative of choice in the industry.

It is possible, however, that the first additive deliberately used to preserve foods was salt. Salted foods, especially fish, were known in antiquity. Salt was used lavishly as a preservative; the Romans made a fish sauce, liquamen, in which the fermentation, as well as the keeping quality, was controlled by adding salt. Salt is, however, so familiar and is used so much in such proportions that we now think of it as an ingredient, in contrast to an additive.

The same could be said of sugar, which emerged much later, possibly from India. Salt, however, is a simple inorganic chemical, whereas cane (or beet) sugar is a rather more complex organic molecule. White granulated sugar is a very pure chemical of great value in food preparation, whether in the home or factory. In honey and dried fruits, the sugar present acts as a preservative as does cane sugar in jams – the value of sugar as a flavoring is obvious. Sugar is a functional additive, but today, like salt, it too is thought of as an ingredient. However, saltpeter (sodium nitrate), which has been used from ancient times as a preservative, is *not* considered an ingredient but is firmly classified as an additive and is subject to continuing scrutiny.

Fermentation was long used as an empirical method of preservation. Alcoholic fermentation is itself a kind of preservation, and alcohol, in the form of brandy, was used in brandied wines as an additive. The production of lactic acid by fermentation, as in cheese, yoghurt, certain cured sausages, and sauerkraut, is another historical example of the formation of a preservative in situ by fermentation. And the acetic acid of vinegar was used by the Romans as a preservative for fruits and vegetables. A modern parallel is the surface treatment of meat with acetic acid to prolong shelf life.

The use of spices as flavorings is very old, as is the Western spice trade with the East. Even if the popularity of spices in Europe was really the result of an efficacy in masking the flavors of salted and tainted meats, the demand for them was established, and it is now known that they also act as mild preservatives. Some 600 years ago, hops were added to beer as a flavoring, which was not at first appreciated; but it was then noted that hopped beer kept better than unhopped ale. Hop resins, too, function as preservatives, but both spices and hops also are today classified as ingredients.

Before the factory production of food, preservation and flavor seem to have been more important than color. Nonetheless, saffron was used as a food color in ancient Egypt, and upper-class Romans had a preference for white bread, which was produced for them by sieving the flour and then adding alum, a practice that persisted until the end of the nineteenth century. Food coloring became popular in medieval times but was confined to the kitchens of the castles and great houses whose chefs used many colors of plant origin. These included indigo, alkanet from the root of borage, sanders from sandalwood, saffron from crocuses, marigold, and turmeric; greens came from the chlorophyll of sage and spinach, and pinks, blues, mauves, and violets from petal extracts.

In the seventeenth century, cochineal (from the dried insect *Coccus cacti*) and annatto (from the seeds of the shrub *Bixa orellana*) reached Europe from the New World. The latter was used to color butter and cheese, although in the eighteenth century butter was colored with saffron. In addition, the greening of vegetables by cooking in copper vessels was well known. No food-processing industry existed, however, and additives were confined to the kitchen and to farmhouse and village technology – that is, to butter, cheese, wine, and cider making, and to brewing, baking, and milling. Because there was no food industry, there were no processing aids, sanitizers, boiler water additives, or packaging migrants; nor were there any agricultural chemicals. But there was lead, an outright contaminant that came from the pipes of water systems; from cooking, eating, and drinking utensils; and from ingredients.

The Romans employed lead for collecting and distributing water, and their methods persisted. Even today lead pipes are used for water reticulation in many old houses and buildings in Britain and Europe. In the ancient world, food was cooked and stored in vessels of lead, leaded bronze and brass, and pewter and was served on lead and pewter plates and dishes. The Romans lacked sugar and, for a sweetener, used grape juice concentrated by boiling in lead vessels, because of the extra sweetness derived from the lead salts (Nriagu 1983).

So high was the lead content of the food and drink (especially wine) consumed by the upper-class Romans that lead poisoning has been confidently proposed as one of the major causes of the decline of the Roman Empire (Gilfillan 1965; Nriagu 1983).

Lead acetate ("sugar of lead") itself, and other lead compounds, were used as sweeteners in wine well into the nineteenth century (Christison 1835; Johnson 1989). In 1767 the disease "Devonshire colic" was identified as lead poisoning and traced to lead fittings on cider presses and lead-lined tanks to hold the apple juice, which, because of the malic acid content, readily picks up lead (Baker 1767, cited in Smith 1986; MAFF 1983). Also during this period, warnings were issued about the danger of the solution of lead from the glazes on earthenware (Drummond and Wilbraham 1957), but as late as the 1870s, lead salts, especially chromate, were being added as colors to confectionery (Dunn 1878). Thus, by 1905, when the Australian state of Victoria introduced food regulations, the first of those regulations included the prohibition of lead in or in contact with food.

The attempts of governments, however, to regulate food additives had a long history. In the late Middle Ages, for example, saffron was used by pastry cooks to simulate eggs, and by the seventeenth century, butter was being colored with annatto. But in 1574 the authorities in the French city of Bourges acted to prohibit egg simulation, and in 1641 Amsterdam prohibited annatto coloring in order to protect May butter, which, because of its color, enjoyed a premium (Meijer 1961; Truhaut and Souverain 1963).

In England in the eighteenth century, claims that chalk and ground bones were added to bread to whiten it were successfully refuted (Drummond and Wilbraham 1957). But there is no doubt that alum was used in this capacity. Calcium carbonate in the form of marble, chalk, or shells was added to beer and cider to counteract acidity; bean flour and isinglass were used as clarifiers; and copperas (iron sulfate) was added to produce a "head" (Drummond and Wilbraham 1957).

With the emergence of factories during the Industrial Revolution, adulteration increased dramatically. Most of this had to do with cheaper substitutes, but some of it involved what would now be called additives: colors, flavors, thickeners, and so forth. In 1820, F. Accum, for example, reported among other things the whitening of bread with alum, the greening of pickles with copper salts, the coloring of Gloucester cheese with red lead, and the flavoring of beer with *Cocculus indicus*. By midcentury, alum, black lead, Prussian blue, lead chromate, copper carbonate, red lead, vermilion, and copper arsenite were all being used in food and confectionery (Mitchell 1848; Hassall 1855; Campbell 1990). One example of such usage involved spent tea leaves that were "faced" with a mixture of Prussian blue and turmeric to permit their resale as green tea (Cochran 1870).

At least as early as the 1840s, sodium nitrate was employed to preserve butter (Anon. 1843). From the 1830s to the 1870s, attempts were made in Australia to preserve meat with sulfites, phosphoric and lactic acids, acetates, nitrates, and nitrites for shipment to Britain (Farrer 1980). Boric and salicylic acids emerged later in the century as flavored preservatives for sausages, milk, and cordials, and in the United States, this led eventually to the "Poison Squad" of volunteers set up by H. H. Wiley, Chief Food Chemist of the U.S. Department of Agriculture, to test the safety of preservatives then in use.

Similar concerns had surfaced elsewhere. In Canada, a report to a meeting of the British Medical Association in Toronto in 1905 resulted in the Adulteration Act, under which the first list of additives prohibited for use in food was published (Pugsley 1959). In Australia, a report by the Victorian Government Analyst covered (among other things) colors, preservatives, flavors, saccharin, and alum. This led at the end of 1905 to the aforementioned Pure Food Act (Farrer 1980).

In 1856 William Perkin's accidental discovery of mauveine initiated the dyestuffs industry, which by the beginning of the twentieth century made available a large number of synthetic colors, some 80 of which were being used in food (Noonan and Meggos 1980). Their tinctorial properties were such as to require only very small concentrations to obtain the desired result, and thus they were perceived to be, and were, much safer than the lead, copper, and even arsenic salts that had been used for so long. In 1906, the United States listed 7 colors permitted to be used in foods, and in the interests of commercial rationalization, the number of dyes of "food grade" were soon limited elsewhere by manufacturers. In the period up to World War II, the American list was extended, and lists of colors permitted to be used in foods were adopted by various other countries.

Also in the early years of the twentieth century, borates and salicylates fell into disuse as preservatives and were largely replaced with sulfites and benzoates. For thickening and stabilizing, regular flour was employed (that is, the starch in it), along with corn flour, gelatin, and gums, and the natural lecithin of egg yolk was a common emulsifier. Changes came only after the World War II, when the carcinogenicity of additives and even of ingredients became an issue, and when large numbers of new functional additives became available.

Food Additives in Processing

The appearance, flavor, texture, and keeping quality of foods have always been important, and as noted, additives have long been used to improve them all. By enabling food to be presented in new, attractive, stable, and convenient ways, modern food additives have raised consumers' expectations to the extent that the demand for the advantages that food additives confer may be said to be sociological rather than technological.

Some may argue that it is the food technologist who has created such a demand, but at best this would be only half true. Colors, flavors, and preservatives have been used for centuries. Gelatin for jelly making, for example, was laboriously prepared in medieval times, and no doubt earlier, from calves' feet and hartshorn. Chemical aerators for baked goods have been dated from 1842 when Abel Conant obtained a patent for a baking powder. The role of the food technologist has been to simplify the preparation of many of the traditional additives and to offer better, more reliable, and safer alternatives to other older additives, while simultaneously providing and responding to the demand for greater variety, more convenience, and better keeping quality in the food products themselves.

Functional Additives

Table VII.9.1 is by no means a complete summary of food additives and the functions they perform, and it is readily apparent that some of them serve more than one purpose. The discussion that follows will concentrate not so much on the additives themselves as on the properties modified by them.

Organoleptic properties: Color and flavor. Color has a great deal to do with food selection and appreciation, and thus the argument in favor of the addition of food colors to processed foods is primarily aesthetic. Nonetheless, there are three technological justifications: (1) to intensify natural colors considered by manufacturer and consumer to be too weak; (2) to smooth over color variations in the raw material and thus to ensure standardization of the product in the marketplace; and (3) to replace color lost during processing by heating, chemical reaction (for example, bleaching with sulfur dioxide used as a preservative), or light.

Although all three justifications could be considered extensions of the aesthetic argument, they are part of the fulfillment of consumer expectations and therefore of importance to both manufacturer and consumer. Many natural colors are included in the various permitted lists; some are synthetic but their number is slowly diminishing.

No matter how tempting a food may look, however, if its flavor is found to be unacceptable it will not be bought a second time. Apart from confectionery and beverages (specifically, soft drinks), which are special cases, the arguments for the addition of flavors to foods are the same as those for adding colors. In addition, there is a fourth justification, which is (4) to make flavorful and attractive an otherwise unin-

teresting formulated product, such as a meat analogue from spun vegetable protein.

Natural flavorings have always been used, and by far the largest proportion of food flavors employed today are of natural origin. Because of the chemical complexity of flavors and the low concentrations normally required, it has been difficult to classify and control them, but they are generally recognized as falling into a few categories: (1) aromatic, but natural, raw materials of vegetable or animal origin, such as spices and meat extract; (2) natural flavors that are concentrates of materials in the first category; and (3) natural flavoring substances isolated from them. Then there are (4) flavoring substances that are synthesized or isolated; and finally, (5) artificial flavoring substances that simulate natural flavors but are not found in them. All flavors in the first three categories contain dozens, sometimes hundreds, of separate, naturally present, and identifiable chemical compounds.

Flavorings are sold in solution, and the *solvents* used, very often alcohol, are subject to the same scrutiny as the flavors themselves. *Flavor enhancers* are compounds that, apart from salt, have little flavor of their own but have the property of intensifying other flavors. Monosodium glutamate (MSG), possibly the best known of these, was identified early this century from a seaweed preparation known in antiquity for its property of intensifying other flavors.

Some *enzymes* are very useful in establishing flavor profiles. These substances are of natural origin and are able, among many other things, to split fats, proteins, and carbohydrates. Those associated with flavor development are usually lipases ("fat splitters") and proteinases ("protein splitters"). They are, perhaps, most obviously active in cheese. Some, in purified form, may be used to develop flavor in other products. Food acids, *acidulants,* have long been known in the form of vinegar (acetic acid), lemon juice (citric acid), and the juices of other fruits, such as verjuice from grapes and the malic acid of apples. Their influence on flavor is well known, and many products are flavored with, say, citric or acetic acids.

Nonnutritive sweeteners (as distinct from sugars) are a special group of flavors. The oldest is saccharin, which is hundreds of times sweeter than cane sugar but leaves a slightly bitter aftertaste. More recently, the cyclamates and aspartame were introduced, but the former, probably unfairly, fell under a cloud of suspicion. The latter is now well established, and although these compounds cannot exactly duplicate the taste of sugar, they are valuable in making a useful range of products available to diabetics and people on weight-reduction diets.

Pouring and slicing: Texture. Many different substances are variously classified as *modifiers and conditioners.* Between them they contribute to all the qualities of food except nutritive value – especially to appearance and texture. They ensure that emulsions do not break, that salad dressings pour satisfactorily, that baked products do not collapse in crumbs, that crystals of ice, salt, or phosphate, do not form where they are not wanted, and so forth.

Emulsifiers facilitate the dispersion of water and oil in each other to form the emulsions of such things as cake batters, salad dressings, ice cream, processed cheese, and some meat products. Gums of vegetable origin and thickeners and stabilizers, such as gelatin, starches, and modified starches, are then used to stabilize the systems. *Humectants* maintain the texture of such items as fruitcake and Christmas puddings, by preventing them from drying out, and *anticaking agents* ensure that salt, milk powders, and the like will run freely when poured.

Aerators have been used traditionally in baked goods to establish the desired texture, in this case, crumb structure, and in so doing have contributed to appearance. Yeasts, as well as yeast food to stimulate fermentation, make up a biological system of aeration, but chemical aerators also are common. They consist of slow-acting acidulants and baking soda and are designed to liberate carbon dioxide slowly enough to enable the desired texture to develop. *Enzymes* are used to modify texture in many products, and the oldest application may well be the use of rennet to set the curd for cheese making. Other applications are the tenderizing of meat, modification of gluten in dough making, digestion of pectin in fruit products to reduce gelling, and reduction of haze in beer.

Shelf life: Preservatives and antioxidants. Food, by its very nature, is perishable because it supports the growth of microorganisms, such as molds, yeasts, and bacteria. As they grow, these organisms can destroy food and render it unfit for human consumption. Yet sometimes, before its unfitness is apparent, such food can be positively dangerous to health. The empirical *preservatives* of history – salt, sugar, wood smoke, burning sulfur, and the alcohol and acid of fermentation – have been discussed, as have the chemical preservatives that came into use during the nineteenth century.

Modern methods of food processing, especially heat processing and refrigeration, have greatly reduced the need for chemical preservatives, although it is sometimes necessary to include one to protect a product once the container has been opened. This is particularly the case in tropical countries where many do not have home refrigeration. In addition, some modern packaging techniques rely on preservatives. For example, the flexible packaging material used for cheese frequently carries the antimycotic, sorbic acid, to inhibit the growth of the mold spores that are inevitably present on cheese surfaces.

Preservatives are also important in some processes. When meat, for example, is comminuted (as in the making of sausage), heat is generated in it, and the inclusion of a preservative, usually a sulfite, is necessary to stop the growth of microorganisms. Wine making is more difficult without the help of sulfur dioxide to control unwanted microbial growth, and for the same reason this preservative is used frequently in fruit juices.

Nitrates have long been associated with the preservation of meat, and it is now understood that nitrate reduces readily to nitrite, which inhibits the growth of *Clostridium botulinum,* the most deadly of all food-poisoning organisms. It is also the case that nitrates, via the nitrites, may give rise to nitrosamines that have proved carcinogenic in rats. Yet the benefit of the inhibition of *Cl. botulinum* outweighs the very low risk associated with nitrosamine formation.

That oils and fats develop rancidity is well known. This is a common flavor defect caused by oxidation that can also produce unacceptable colors and textures. These oxidation defects may be delayed (but not corrected or ultimately prevented) by the addition of *antioxidants,* and these compounds can, thus, be regarded as a special class of preservatives. In addition, because rancidity is promoted by traces of copper and iron, it is sometimes beneficial to add a *sequestrant* to an oil, which locks up such trace metals and eliminates their catalytic effect.

Some antioxidants, such as ascorbic acid (vitamin C), the tocopherols (vitamin E), and natural phospholipids (lecithin, for example), occur naturally in fruit and vegetables, whereas others, like the gallates, are synthetic compounds. Antioxidants may be used in oils and fats, as well as in other food products where their use has been shown to prolong shelf life. Also it has been suggested that some antioxidants in food may offer protection against certain forms of cancer of the alimentary tract.

The acidity (or alkalinity) of a biological system is an extremely important property, usually expressed as pH within a range from 1 (very acid) through 7 (neutral) to 14 (very alkaline). *Acids,* such as the vinegar used in salad dressings, send the pH down, whereas *alkalis* move it up. If it is necessary to hold the pH steady, a *buffer* is added. This is a substance that has the ability to "soak up" the acidity or alkalinity. Phosphates are the most common buffers used in food systems. The pH of most phosphates ranges from about 3 (some salad dressings) to about 8. Low pH (high acidity) inhibits microbial growth; conversely, higher pH, either slightly acid or on the alkaline side of neutral, favors such growth, meaning that meats and some cheeses are more vulnerable to microbial spoilage than, say, tomato products. Clearly then, the keeping quality of food products may frequently be improved by lowering the pH.

Nutritive value. Vitamins and minerals are added to foods for a number of reasons, the most important being to protect or improve nutritive value. The invention of margarine in 1870 introduced a new product that lacked the vitamins A and D of butter. This deficiency was not, of course, discerned until after the discovery of vitamins early in the twentieth century, and when eventually sources of A and D were commercially available, it became obligatory for the margarine manufacturers to add them to their products. This is a good example of the addition of a nutrient to a substitute (or analogue) in order to match the concentration found in the natural product.

A fine example of the rectifying of processing losses that could otherwise endanger the health of whole communities is found in the addition of B vitamins (especially thiamine) to rice after it is stripped of a vitamin-rich husk in a polishing process intended to improve keeping quality. Similar examples include the addition of calcium to the British national loaf in wartime; the addition of vitamin D to milk; the addition of iodine to salt or to bread for the prevention of goiter; and the addition of fluoride to water for the prevention of dental caries. All are illustrative of government additive programs in the interests of their constituents.

Rather different, however, was the addition of nutrients for purely commercial reasons – an initiative that dated from the late 1940s, when vitamins became freely available as ordinary items of commerce. A rash of advertising claims were made to the effect that the addition of large "unnatural" concentrations of vitamins, and some minerals, made products more "healthy." As a result of such exagerated claims, some countries now limit the addition of vitamins and minerals to specific products and in specific concentrations.

During the processing of food, it is inevitable that (as in the kitchen) vitamins and minerals will be lost to a greater or lesser extent. The example of polishing rice is a special case, but in both kitchen and factory, losses resulting from leaching and heat are common, which is the reason for the addition of sufficient quantities of vitamins to replace these losses. Similarly, the concentrations of some vitamins will fall during storage, and additions ensure that at the end of the stated shelf life of the product the vitamin activity claimed or expected will still be present. There might also be reason to standardize a product made from variable raw material, so that it contains the level of a vitamin or a mineral that would normally be expected of it.

Indirect Additives

Additives from the field. Many chemicals are used in agriculture, horticulture, and animal husbandry, and it is inevitable that traces of them will find their way into foods. Because of this result, some regulatory authorities subject such chemicals to the same close scrutiny as is given to additives proper. Of these substances, the most important are pesticides, which are used directly on food products. Traces large or small, usually depending on the way in which instructions for harvesting are observed, will be found on almost all raw food materials, and regulations governing the concentrations of pesticides permitted in food offered for sale have been introduced throughout the world since the 1950s. It is fortunate that the development of the wide range of chemical pesticides available today coincided quite closely with the discovery and application of modern methods of chemical analysis, which permit the measurement and detection of pesticides in very low concentrations.

Additives from the factory. Many substances are legitimately used in the food factory to facilitate processing and to clean and sanitize both plant and equipment, and these may be found in foods in minute amounts. For example, traces of boiler water additives to prevent the buildup of scale in steam boilers can be transferred in droplets of water in wet steam. Processing aids that may enter foods include flocculants and clarifying agents, enzymes, lubricants (such as medicinal paraffin on packaging machinery), and talc (on certain types of confectionery), along with quick-release agents in the baking industry. In addition, because cleanliness and the highest hygienic standards are essential, detergents (which sometimes must be quite specialized) and sanitizers used daily in food factories, can also enter foods.

Additives from the package. The first packages in modern food technology were Nicolas Appert's glass jars of the 1780s, which were followed by tin cans in 1810. The former contribute little to the food packed in them. But the latter may transfer tin, iron, and (in the past) even lead from the solder used to seal the can, although recent concern over lead in food has resulted in the development of the welded can (to eliminate the soldered side seam). Canned foods inevitably pick up some tin. This metal has not been a cause of significant concern, but the amount that might reach the consumer has been reduced, even though it occasionally imparts a desirable flavor, as with canned asparagus.

The wide use of plastics, both rigid and flexible, in the packaging of food products has focused attention on traces of residual monomers, plasticizers, colors, and so forth that may find their way from the package into the food, especially oily and fatty products. Some of these substances are potentially dangerous, and industry worldwide has collaborated with regulators to develop strict guidelines for plastics that come into contact with foods.

Control of Food Additives

The English "Assize of Bread," which remained in force from 1266 until the Bread Act of 1822, controlled weight and price but not additives. The French "Livres des Métiers" of 1268 sought to protect both the pocket and the health of the consumer and touched upon additives by forbidding the flavoring of beer. The appointment of German wine inspectors for Swabia and Alsace dates from 1488, and measures were taken at about this time by companies in England, the Netherlands, and France to protect their good names by controlling the misuse of certain additives.

In 1701, the government of Denmark issued an order against food that was tainted or unwholesome or that could cause sickness. This was a vague regulation with only the faintest implication of additive control, but a list of colors permitted for use in food was issued in Denmark in 1836, well before the first dye was synthesized. In 1887 the use of harmful colors in foods was forbidden by the German "Color Act" (Hinton 1960; Uhl and Hansen 1961; Hamann 1963; Truhaut and Souverain 1963).

In England, additive control was inextricably linked with the control of adulteration. Accum's 1820 treatise dealt primarily with adulteration, and only with modern eyes can it be seen as an indictment of the abuse of additives. Similarly, the search for pure food in the United Kingdom, which has been well documented by I. Paulus (1974), was only incidentally related to additive control. Regulations under the Victoria (Australia) Pure Food Act of 1905 and those flowing from the American Pure Food and Drug Act of 1906 were not primarily directed at additives, although as noted, concern over lead incidentally finding its way into food was a factor. The French, too, early in the twentieth century, accepted the possibility of dangerous metals (lead, zinc, arsenic, antimony) entering the food from utensils or kitchen equipment (Truhaut and Souverain 1963), and up to World War II many countries placed limitations of one kind or another on colors, preservatives, and heavy metals in foodstuffs.

Concern over food additives, first by governments and then by consumers, began to intensify in the 1950s. There were four reasons:

1. Results from animal tests in the late 1930s strongly suggested that a so-called coal tar dye used to color butter and margarine was carcinogenic; this finding converged in the late 1940s with a growing awareness of environmental links with some forms of cancer, and a 1952 lecture by A. F. J. Butenandt on the carcinogenicity of some food colors was taken up by the press (Hamann 1963).
2. Food technology had emerged during the war as an important new subject of study, and industry was offering a range of substances that could simplify the preparation of many existing products and permit the formulation and manufacture of new ones.
3. Analytic chemistry was on the threshold of enormous advances, and the detection and measurement of additives and the like was fast becoming easier.
4. There were new needs and, through United Nations agencies, new opportunities for the international regulation of food.

Governments in a number of countries appointed committees and developed mechanisms to study and propose regulations for food additives. In 1956, the United Nations Food and Agriculture and World Health Organizations set up a Joint Expert Committee on Food Additives (JECFA) for the same purpose. JECFA adopted a set of principles as follows:

- Food additives should not be used to disguise faulty processing or handling techniques, nor to deceive the consumer with regard to the nature or quality of the food.
- Special care should be exercised in the use of additives in foods that may form a major part of the diet of some sections of the community, or that may be consumed in especially large quantities at certain seasons.
- The choice of food additives should be related to the prevailing dietary patterns within a community. The availability of essential nutrients and their distribution in the various foods consumed should be taken into account before the true significance of making a further addition of a particular nutrient (e.g., calcium or phosphorus) or of using an additive that may change the pattern of nutrients in a food (e.g., an oxidizing agent) can be assessed.
- The specifications needed for each food additive have been compiled with three main objectives in mind: to identify the substance that has been subjected to biological testing; to ensure that the substance is of the quality required for safe use in food; to reflect and encourage good manufacturing practice (JECFA 1957).

In 1953, Australia had adopted similar principles (Farrer 1990). In Canada, the Adulteration Act of 1884 had included four general principles related to food additives, and in 1906 a report to the Canadian government made six recommendations, which, though directed specifically at preservatives, were the first related to the use of food additives (McGill 1906). The four general principles called for toxicological safety, technological need, labeling, and, where there is no provision for their use, exclusion. In effect, these are the principles that govern the use of food additives today.

Expert committees in many developed countries and the Scientific Committee for Food (SCF) of the European Community (EC) gather and assess information from many sources before deciding whether to recommend a specific additive for use in food and, if so, under what conditions. In some countries the technological need for a given additive in a given product must be demonstrated. But the SCF makes the questionable assumption that a request for permission to use an additive is prima facie evidence of technological need and concerns itself only with toxicological safety. In both cases, if there is any doubt about the toxicological safety of the additive in the way it is to be used, it will not be recommended. JECFA has a key role in establishing toxicological safety, and the information it seeks is detailed and stringent. Full details of the substance are required: how it is made, likely impurities, its method and rate of use, what happens to it in food, its effect on nutrients, and the substitute additives available.

Much detailed toxicological and pharmacological information about the additive also is sought: the no-observable-effect level (NOEL) of additives – that is, the concentration in the diet expressed as mg/kg of body weight that may be consumed over several generations without producing any discernible effect;

acute and chronic toxicity; the results of studies on carcinogenicity, mutagenicity, and teratogenicity, and of changes induced in cells and the nervous system; and whether the additive triggers or exacerbates an effect caused by another substance or alters the balance between naturally occurring substances. The 1980s saw a heightened awareness of the allergenic properties of some additives, and it is possible that in the future, more questions will be asked about neurotoxicity. The results obtained from all these studies are important, but equally important are the methodologies, which also must be reported.

From all the information generated by these investigations and using a safety factor of, usually, 100, JECFA calculates an Acceptable Daily Intake (ADI). This is "the amount of a chemical which may be ingested daily, even over a lifetime, without appreciable risk to the consumer in the light of all the information available at the time of the evaluation" (JECFA 1957). *Without appreciable risk* is taken to mean the practical certainty that injury will not result after a lifetime exposure (Vettorazzi 1975). If the data are insufficient to satisfy the committee, a "Temporary ADI" may be adopted, or it may be a case of "No ADI Allocated." Substances of very low toxicity are classified as "ADI not Specified," and the designations "Not to be used" and "Decision postponed" speak for themselves. JECFA assessments are very thorough, and its recommendations count for a great deal with both national and international regulatory authorities. They are reflected in the International Standards of Codex Alimentarius, which are of increasing importance in the world trade of food products.

In some countries, permitted additives have been listed for use in all foods, as, for example, substances classified in the United States as GRAS (Generally Recognized as Safe). In others, such as the United Kingdom, the tendency has been to let the courts decide what is "harmful," although the Public Health Regulations 1925 (Preservatives etc. in Food) limited preservatives to sulfur dioxide, sulfites, benzoic acid, and benzoates, and their use to 20 categories of food (nitrates were excluded from the definition of "preservative").

The trend now is to limit additives to specified products and limit them up to specified concentrations. These limitations combine the concepts of technological need and toxicological safety-in-use. In addition, former blanket labeling provisions (for example, the general statement "Artificially Colored") are being replaced by explicit requirements for the naming of each additive, or at least inclusion on the label of identifiable codes, such as the numbering system used in Europe and elsewhere. These requirements make it possible for persons who show idiosyncratic responses to avoid substances that are safe-in-use for the vast majority of people.

Because the evidence relating to substances proposed for use as food additives is freely available all over the world, lists of permitted additives and their concentrations are very similar. Nevertheless, there are differences, most of which reflect likes, prejudices, cultural differences, and politics. In the latter case, the range is from the influence of pressure groups (those of both consumers and industry) to the widespread effect of the American "Delaney Clause." Enacted by the U.S. Congress in 1958, this clause prohibits the use in food of any substance that has been shown to cause cancer when ingested by humans or any animal.

Ostensibly unchallengeable, this clause has caused untold difficulty in America and in many other countries as well. It takes into account no qualifying circumstance, such as dose levels (that is, amount of substance in a serving), variations in the responses of different animal species, the size of the animal, the frequency of consumption of the substance, and so on. Moreover, in the words of one commentator, "this clause has generated much controversy because of recognition by most scientists that the continued existence of mankind is silent witness to the fact that low levels of carcinogens can be tolerated" (Wodicka 1980). Fortunately, no other country is so legally constrained as the United States. There was recourse to the principle of *de minimis non curat lex* ("the law is not concerned with trifles"), which enabled some scientific evaluations to be made (Middlekauf 1985), but only for a few years. In 1992 a court decision in the United States ruled that the Delaney Clause meant *no* levels of carcinogens were permissible (Winter 1993). Because of the extreme sensitivity of modern methods, this definition has created a difficult (some would say, impossible) situation.

Food Additives in Popular Culture

Late-twentieth-century food-additive usage has a foundation of scientific evaluation that is not readily apparent to the casual observer. Newspaper articles, radio and television programs, books, even school teachers, inveigh against food additives as "chemicals added to our food." Some individuals class as contaminants certain substances that add quality to processed food products, and reject additives without any understanding of their functions. Nor is it generally understood that more fearsome substances occur naturally in foods than are ever added by humans.

Some food manufacturers have sought to profit from public uneasiness by advertising their products as free from all, or at least free from stipulated classes of, additives. One result has been to reinforce many consumers' uncertainties while creating unjustified suspicion of other products.

For many people, the most damning thing about food additives is that they are "chemicals," and chemicals are perceived as something to be avoided. Unfortunately, the chemical nature of food and of life itself is generally unappreciated. The body contains thousands of chemicals from the simple, such as water and salt (sodium chloride), to the complex, such as hemoglobin and cholesterol, and all are necessary for life itself. Water, salt, and many others must be supplied in the food, whereas hemoglobin and thousands more such compounds are made by the body as required. In addition, there are substances such as cholesterol, which is both manufactured in vivo and supplied in foods, such as eggs. And then, there is monosodium glutamate (MSG), which is naturally present in some foods, manufactured in the body from others, *and* also used as an additive.

For generations, cooks have used potassium hydrogen tartrate and sodium hydrogen carbonate. Better known as cream of tartar and baking soda, respectively, both are chemicals and both are food additives. There are many such examples of additives with familiar names; but there are others, known only by intimidating chemical names, that are no less safe. Similarly, many examples could be given of chemical reactions that occur in food during cooking and processing and of others that go on continuously in the body to permit such simple operations as breathing or typing these words.

Late-twentieth-century opponents of food additives cite several concerns. A major one relates to possible long-term and cumulative effects of their consumption, and the further possibility of interactions in vivo of additives with each other, with other food constituents, and with body components. Another concern is that toxicologically innocuous substances may cause nutritional imbalance or the physical obstruction of some biological process. Certainly, none of these possibilities should be unequivocally dismissed, but the detailed and exhaustive testing of substances proposed as food additives is intended to ensure that in the circumstances in which they are eventually permitted to be used, they will be safe; that is, they will be "safe-in-use."

Early in the sixteenth century, the Renaissance physician Paracelsus wrote that all substances are poisons and it was the right dose that differentiated a poison from a remedy. This truth is the clue to the understanding and acceptance of food additives. It is a statement of what is now called dose–response, of which probably the most familiar modern example is the effect of alcohol. For each person there is a limited number of drinks ("units" of alcohol) that produce no visible response in his or her behavior, but once that limit is passed there is a clearly visible response.

Put another way, given time, it is conceivable that the body can cope with any dose, but some substances can quickly swamp the body's capability to deal with them. Cyanide is well known as a deadly poison, but marzipan contains cyanide. It is, however, in such a small concentration that the body can deal with it without visible response, and in some countries, cyanide is specifically permitted by regulation to be present in marzipan up to a specified (very low) level. Dose–response, knowingly or not, is considered by everyone who drinks fermented liquids, and it is at the heart of food-additive usage. So, too, is risk–benefit analysis.

Certainly there is risk in food consumption, but the greatest risk is not that of food additives but, rather, that of food poisoning. This is a microbial risk, and it is increasing as people eat out more often and as an increasing number of housewives work and find themselves taking shortcuts in the kitchen. It has been calculated that the risk of food poisoning is 100,000 times greater than any risk from food additives (Truswell et al. 1978).

Nonetheless, the community has the right to expect that food-additive usage is fully explained and is as safe as it can be. And government, industry, and food technologists have the responsibility to see that it is.

VII.10 Substitute Foods and Ingredients

Substitute Foods

Substitute foods mimic their traditional counterparts: margarine as butter; nondairy products as milk, cream, and cheese; or extruded soybean mixes as bacon, beef, poultry, or fish. But although substitute food products may resemble their traditional counterparts, they are also likely to be composed of substances from totally different sources. The substitutes are partitioned and restructured, whereas the traditional foods are intact.

In the past, substitute foods were frequently developed as inexpensive replacements for more costly primary foods. An example is a cheese replacer. However, in recent years, substitute foods have been introduced and promoted for health reasons associated with reducing the intake of saturated fat, cholesterol, and calories. Examples are nonfat frozen desserts, egg replacers, and reduced-calorie baked goods.

On occasion, a substitute food, first launched as an inexpensive replacer, has become more expensive than its traditional counterpart. An example is margarine, originally offered as an inexpensive substitute for butter. But later it was promoted as more healthful than butter, and some special margarines became more expensive than butter (Sanford 1968).

Margarine as a Paradigm

Margarine was the first successful substitute food. A search for a butter substitute began in the early 1800s, and commercial production of margarine was launched in 1873.

Normally, the predominantly unsaturated oils used in margarine manufacture would soon oxidize and turn rancid when exposed to air. But the process of hydrogenation employed in its manufacture modifies the oils and makes them more saturated and durable. The raised melting point improves the fat's consistency and color for the deep-frying of foods, and it protects both the fats and the foods made with them from developing off-flavors. These qualities made hydrogenated oils suitable for the manufacture of margarine and other solid shortenings and for use in numerous processed foods.

Although hydrogenation serves a technological purpose, there are biological and nutritional consequences. Hydrogenation converts the *cis* form of fatty acids, naturally present in oils, to a trans form. The original molecular pattern is rearranged, and the biological quality has become nutritionally inferior. Normally, trans isomers are not present in human tissues. If present, they are less well utilized in the human body. They do not circulate in the blood, nor do they move through the tissues as liquids. They may disrupt the permeability characteristics of the membranes of the body's cells and prevent normal transport of nutrients into and out of cells (Emken 1984).

By the mid–1950s, warnings were sounded about the health risks of consuming hydrogenated fats and oils. A leading article in the *Lancet* predicted that "[t]he hydrogenation plants of our modern food industry may turn out to have contributed to the causation of a major disease" (Fats and Disease 1956: 55).

Shortly thereafter, Dr. Hugh Sinclair, at Oxford University's Laboratory of Human Nutrition, reported that hydrogenation of fats produced a deficiency of essential fatty acids (EFAs) by destroying them, or resulted in abnormal toxic fatty acids with an antiEFA effect both in animal experiments and with clinical human studies. Sinclair demonstrated that a deficiency of EFAs is "a contributory cause in neurological diseases, heart disease, arteriosclerosis, skin disease, various degenerative conditions such as cataracts and arthritis, and cancer" (Sinclair 1957: 33).

Additional reports and critical assessments of trans fatty acids in margarine and processed foods containing hydrogenated fats and oils were made by others (Bicknell 1960; Kummerow et al. 1974; Enig, Munn, and Keeney 1978; Enig et al. 1983; Keeney 1981; Enig, Budowski, and Blondheim 1984).

By the 1980s, a Canadian government task force had noted the apparent cholesterol-raising effects of trans fatty acids (Beardsley 1991). The group recommended that margarine manufacturers should reduce the amounts by modifying the hydrogenation process.

A turning point was reached in 1990, when a study directed attention to the hypercholesterolemic effect of trans fatty acids in margarine (Mensink and Katan 1990). The researchers found that these isomers raised levels of unfavorable low-density lipoproteins (LDLs) and lowered levels of favorable high-density lipoproteins (HDLs) to an even greater extent than did saturated fat. Trans fatty acids increased the lipoprotein risk profile. The researchers recommended avoidance of trans fatty acids by those at risk of atherosclerosis.

Additional incriminating evidence was revealed. At an epidemiology conference in 1993 sponsored by the American Heart Association, a team of Harvard University researchers reported the results of a survey of 239 heart attack patients and 282 healthy controls. After having analyzed the eating patterns of their subjects, the investigators had calculated the trans fatty acid intake. Even after adjustments for numerous factors, the association of trans fatty acids with heart attacks remained highly significant. Individuals who consumed more than two and a half pats of margarine daily had a nearly two and a half times greater risk of heart attack than did those who never used margarine (Ascherio 1993).

Release of the Nurses Health Study in 1993 corroborated these findings (Willett et al. 1993). For eight years, 85,000 nurses had been monitored for margarine intake. Women who ate products that contained hydrogenated fats and oils had increased their risks of heart attack by 70 percent. Those who ate more than four teaspoons of margarine daily in all products, and especially in white breads and cookies, were at far greater risk of coronary heart disease (CHD) than those who consumed margarine less than once a month. The researchers noted that as a result of pressure from well-intentioned but unenlightened activists, fast-food restaurants had switched from beef tallow to partially hydrogenated vegetable oils for deep-fat frying. The quantity of trans isomers in beef tallow is 3 to 5 percent; in hydrogenated vegetable oils, it is 30 percent.

The history of margarine can serve as a paradigm for the risk inherent in the use of all substitute foods. Indeed, the European Community Commission has proposed that novel foods and ingredients be regulated. At a toxicology forum, members described the need to evaluate them as a "burning and timely issue. . . . We need to look at them from both toxicological and nutritional viewpoints. It's a whole new era" (Somogyi 1993: 18).

Substitute Ingredients

Similar to substitute foods, ingredients, too, have been developed as inexpensive replacements for more costly or scarce ingredients. Examples are imitation vanillin, substituted for vanilla flavoring; inexpensive trash fish used in making surimi "sea legs" to simulate lobster; or the simulated maple taste in pancake blend syrup, in lieu of maple syrup.

In recent years, many substitute ingredients, like substitute foods, have been developed in response to concerns regarding certain health risks inherent in the industrialized diet, such as undesirable high levels of calories, fat, cholesterol, and sodium, or undesirable low levels of dietary fibers. One such effort has been to find a substitute for sugar.

Sugar Substitutes

The search for sugar substitutes has been driven by forces that involve health considerations. At first, the search was to meet a medical need: an acceptable sweetener that was tolerated by diabetics. Later, the driving forces were for sugar substitutes that were noncariogenic (to avoid tooth decay) and noncaloric or low caloric (to control weight).

Gradually, these specific health considerations became more generalized. A recent survey found that the main incentive for consumers to choose low-caloric products was to maintain overall health, rather than merely to reduce weight (Wilkes 1992).

In 1978, some 42 million Americans consumed low-calorie foods and beverages. By 1986, the number had more than doubled, to 93 million; and in 1991, it reached 101 million. In 1993, a national survey disclosed that the number had risen to 136 million, and low-calorie foods and beverages were being consumed by 73 percent of the total U.S. adult population (Fat Reduction in Foods 1993). The most popular low-calorie foods and beverages are soft drinks, consumed by 42 percent of all adults; sugar substitutes in other beverages and foods, consumed by 31 percent; sugar-free gums and candies, used by 28 percent; and sugar-free gelatins and puddings, eaten by 18 percent (Wilkes 1992).

Saccharin: An early substitute. Saccharin, an early sugar substitute, has been in continuous use as a noncaloric sweetener since the turn of the twentieth century. At present, however, it competes against more recently introduced noncaloric and low-caloric sweeteners. In fact, it was saccharin's beleaguered history of use in the United States that gave impetus to the development of alternatives (National Academy of Sciences 1975). In 1977, saccharin was found to be carcinogenic in rats, and the Food and Drug Administration (FDA) attempted to ban its use under the Delaney Clause in the 1958 Food Additives Amendment to the 1938 Food, Drug, and Cosmetic Act (U.S. House of Representatives 1977). However, the U.S. Congress enacted a moratorium on the ban, and the moratorium was renewed several times. Then, in 1991, the FDA announced its decision to withdraw the proposed 1977 ban. Thus, saccharin continues to be used in the United States food supply, and currently, it is also employed in more than 90 other countries (Wilkes 1992; Dillon 1993; Giese 1993).

Aspartame: A low-caloric substitute. Aspartame, approved by the FDA in 1981 for table use, represented the first sugar substitute approved in America in more than 25 years. Aspartame consists of two amino acids, L-phenylalanine and L-aspartic acid, and is 180 to 200 times sweeter than sucrose. Hence, it can be used at such a low level that it contributes only 4 calories per gram, and is regarded as a low-caloric sweetener (also known as a high-intensity sweetener).

Soft drinks account for 80 percent of aspartame's use in the United States. However, since aspartame's original approval, its use has been extended to thousands of food and beverage products, including carbonated soft drinks, refrigerated fruit juices, milk beverages, ready-to-drink teas, and frozen desserts, puddings, fillings, and yoghurt products, in addition to its use as a table sweetener (Wilkes 1992; Dillon 1993; Giese 1993).

The United States now accounts for approximately 80 percent of the global market for aspartame, although it is predicted that worldwide consumption will more than double by the end of the twentieth century. Aspartame is approved for use in more than 90 countries and is available, worldwide, in more than 5,000 products (Wilkes 1992).

Like saccharin, aspartame has been indicted for producing various adverse health effects, especially among heavy users (U.S. Senate 1987). These include numerous central nervous system and digestive system disturbances (Centers for Disease Control 1984; Monte 1984; Yokogoshi et al. 1984; Wurtman 1985; Drake 1986; Walton 1986; Koehler and Glaros 1988; Lipton et al. 1989; Potenza and El-Mallakh 1989; McCauliffe and Poitras 1991).

In 1984, the Centers for Disease Control conducted a four-month review of 517 consumer complaints relating to aspartame usage. The conclusions were that the complaints "do not provide evidence of the existence of serious widespread adverse health consequences attendant to the use of aspartame." However, further monitoring was advised (Centers for Disease Control 1984: 607).

Acesulfame K: A low-caloric substitute. The most recently introduced low-caloric sugar substitute is acesulfame K. Presently, it is used in about 600 food products in more than 50 countries. In 1988, the FDA approved its use for tabletop sweeteners, chewing gums, dry beverage bases, and dry dessert bases. Future approvals may be extended for confectionery products, baked goods, soft drinks, and other liquid beverages (Giese 1993).

Glycyrrhizin: Flavorant and sweetener. Glycyrrhizin, in the root of the licorice plant, is an intensely sweet triterpenoid saponin. It is from 50 to 100 times sweeter than sucrose. Extracts are used to flavor and sweeten confectionery products (Cook 1970). Glycyrrhizin is on the FDA list of GRAS (Generally Recognized as Safe) substances as a flavorant but not as a sweetening agent. However, food manufacturers have increasingly been using glycyrrhizin for its sweetening quality.

Metabolic studies have shown that glycyrrhizin can be hydrolyzed by human intestinal microflora to release glucuronic acid, a sugar that is almost completely metabolized. Moreover, glycyrrhizin has corticoid activity, influencing steroid metabolism to maintain blood pressure and volume and regulate glucose–glycogen balance. At high levels, glycyrrhizin is capable of producing a variety of health problems, including hypokalemia, high blood pressure, and muscular weakness (Chamberlain 1970; Robinson, Harrison, and Nicholson 1971; Blachley and Knochel 1980; Edwards 1991; Farese et al. 1991).

Other available sugar substitutes. Numerous low- or noncaloric sugar substitutes are in use elsewhere in the world but await approval in the United States. Sucralose, for example, was approved in 1991 for use in Canada, and shortly thereafter in Australia, Mexico, and Russia. Sucralose is 600 times sweeter than sucrose, and it does not break down in the body. It is manufactured by a multistep process that involves the selective chlorination of sucrose. Although a food-additive petition for sucralose use in 15 food and beverage categories was submitted to the FDA as early as 1987, the data are still under review. Applications are pending also in the United Kingdom and the European Community (Lite Sweeteners Maneuver 1989; Canada First Country 1991; Canada Clears Sucralose 1991; U.S. Department of Agriculture 1991).

Alitame, a low-caloric sugar substitute awaiting FDA approval, is 2,000 times sweeter than sucrose. It is formed by two amino acids, L-aspartic acid and D-alanine, and 2,2,4,4-tetramethylthietanyl, a novel amine. The aspartic acid component is metabolized normally; the alanine amide goes through the body with minimal metabolic changes. In the United States, a petition was filed for use of alitame in a broad spectrum of food products as early as 1986. But although alitame has been approved for use in Australia, New Zealand, and Mexico, the FDA is still reviewing the data (Alitame 1990; U.S. Department of Agriculture 1991).

Oligofructosaccharides (FOS) are natural sugar polymers that are potential sugar replacers. They contribute only 1.5 calories per gram and can be manufactured from sucrose by means of a fungal enzyme. They are reported to stimulate the growth of healthy bifidobacteria in the human intestine. At present, they are used in Japan (Mitsuoka 1990; Modler, McKellar, and Yaguchi 1990; Fat Reduction in Foods 1993). In the United States, interest in FOS is focused more on their value as dietary sweeteners than on their therapeutic benefits.

Potential botanical substitutes. Numerous substitute sweeteners can be derived from botanicals. Many have had a long history of use elsewhere but lack regulatory approval in the United States.

Dihydrochalcones are derived from two flavones, naringin and neohesperidin, found in citrus peels, and are several hundred times sweeter than sucrose. Many studies have confirmed their safety. The Scientific Committee for Food of the Commission of the European Community has allocated for dihydrochalcones an Acceptable Daily Intake (ADI) of 5 milligrams per kilogram of body weight. Currently, this sugar substitute is approved for use in Belgium and Argentina. The FDA has requested additional toxicological tests (New 'Super Sweeteners' 1970; McElheny 1977).

Stevia *rebaudiana* is a South American plant that yields several sweet compounds. Purified glycoside components of this plant have been employed for many years in South America. Currently, the main consumers of steviosides are the Japanese. Dental research suggests that *S. rebaudiana* may suppress the growth of oral microorganisms (Shock 1982).

The red serendipity berry (*Dioscoroephyllum cuminsii* Diels) from Africa contains a sweet component, monellin. A sweet herb from Mexico *(Lippia dulcis)* has hernandulcin, an intensely sweet sesquiterpene. Some plants commonly grown in the United States also have sweet constituents. Leaves of the herb, sweet cicely *(Myrrhis odorata),* known as the candy plant, have been used as a sweetener and flavor enhancer in conserves and to sweeten tart foods. The dried leaves of the big-leafed hydrangea (*Hydrangea macrophylla* var. Thunbergii) and the rhizomes of the common fern (*Polypodium vulgare* L.) also contain sweet constituents.

A final sweetener from botanicals is *Lo Han Kao* (*Momordica grosvenori* Swingle), a fruit from southern China. The purified sweetener from the dried fruit is about 400 times sweeter than sucrose (Inglett 1981).

Alternative approaches for substitutes. One innovation in the search for sugar substitutes is the utilization of molecules that are mirror images. Natural sugars usually occur in the so-called D-form, which is metabolized. The mirror image, which rarely occurs in nature, is in the L-form and is not metabolized. This feature makes L-sugars attractive candidates as noncaloric sugar substitutes. Currently, 3 of the 10 known L-sugars have been selected for safety testing and scale-up production studies (Process Yields No-Cal 1981; The Use of Sucrose 1982; L Sugars 1989; Giese 1993).

Another approach is to attach small molecules of sweeteners that are normally absorbed to much larger polymer molecules that are not absorbed. The sweetening agent leached to the polymer passes intact through the intestinal tract and is excreted unabsorbed (In the 1980s 1979).

The introduction of noncaloric and low-caloric sugar substitutes has not lessened the consumption of caloric sweeteners. On the contrary, there has been a steady increase in the use of *all* types of sweeteners – caloric, noncaloric, and low caloric (U.S. Department of Agriculture 1988). By 1993, the annual consumption of caloric sweeteners had reached 144.8 pounds per person in the United States (U.S. Department of Agriculture 1993).

Concomitantly, obesity continues as one of the most common and important medical conditions in the United States. More than one-third of all adults in the population are significantly overweight (Najjar and Rowland 1987; Sichieri, Everhart, and Hubbard 1992). The prevalence of obesity in some minority groups, especially Native Americans, African-Americans, and Hispanic women, reaches as high as 50 percent of these populations (Williamson et al. 1990). Although the problem of obesity is multifactorial, caloric intake is an important aspect. Clearly, the sweetening substitutes have not alleviated this problem; rather, they offer increased possibilities for food technologists to create a range of highly processed foods and beverages that further encourage poor food choices.

Fat Substitutes

The growing interest in fat and cholesterol reduction gained impetus in the 1980s and led to a multiplicity of developments for partial and total fat substitutes. In 1989 some 450 new food products introduced in the U.S. marketplace were labeled "low fat" or "nonfat." By 1992, 519 new low-fat or low-cholesterol products had been launched. Fully one-third of these products were dairy foods. Others included baked goods, condiments, meats, and snacks (Mancini 1993).

By 1993, more than two-thirds of all American adults were consuming low- or reduced-fat foods and beverages, and they expressed the desire to have still others available. It was predicted that, eventually, a low-fat version of virtually every type of food would become available (Mancini 1993).

Hydrocolloid-based fat substitutes. Many partial fat substitutes are made from cellulosics. Some are hydrocolloid stabilizers, such as cellulose gel from microcrystalline cellulose (MCC) isolated from plants (Cellulose Gel Helps 1990); powdered cellulose, a by-product of the pulp paper industry (Powdered Cellulose Reduces 1990); and semi- or totally synthetic celluloses that are nonabsorbable (Klose and Glicksman 1968).

Carbohydrate-based hydrocolloid fat substitutes consist of water-soluble polymers from vegetable gums, such as carrageenan and guar (Starches Replace Fat 1989; Fat Substitutes 1990). The polymers are also derived from plant starches, such as those from potato and corn (Potato Starch Replaces 1989); from dextrins, such as those in tapioca (Potato Starch Replaces 1989); and from maltodextrins, such as those in hydrolyzed cornstarch (Get Rid of Unwanted Fat 1989). Some of these complex carbohydrates are absorbable, whereas others are not (Klose and Glicksman 1968).

One cereal-based fat substitute, "oatrim," has notable characteristics as a fat substitute. It is derived from soluble oat fiber and from beta-glucans – complex carbohydrates contained in oat and other cereal grains – that have been found useful in lowering cholesterol. Thus, oatrim not only serves as a fat substitute but also as a cholesterol reducer.

Oatrim is made by treating oat bran and oat flour with alpha amylases. The starches are converted to amylodextrins, which, along with the beta-glucans, go into solution. The process yields a smooth, bland, white gel that can be used in numerous types of foods, such as extra-lean ground-beef mixtures, luncheon meats, cookies, muffins, and nonfat cheeses.

Consumption of oat bran had been promoted because of its ability to reduce cholesterol. However, it was found that the amounts needed were too great and could lead to gastrointestinal problems. In contrast, oatrim retains the cholesterol-reducing properties of oats and can be useful for this purpose at realistic levels of consumption (McBride 1993; American Chemical Society 1990).

Oatrim has been honored as being among the hundred most significant new technologies of 1993 (Hardin 1993). George E. Inglett and his associates at the U.S. Department of Agriculture's National Center for Agricultural Research at Peoria, Illinois, patented Oatrim in 1991. Several national and multinational food companies have obtained licenses to manufacture and use oatrim in food products.

Microparticulated protein. Several protein-based low-fat substitutes have been developed. The first to win FDA approval (1990) was Simplesse, developed by NutraSweet, a subsidiary of Monsanto. Simplesse contains only 1.3 calories per gram of food, compared to 9 calories in traditional fats. It is composed primarily of milk and egg white proteins, with added vegetable gum, lecithin, sugar, acid, and water. The molecules of the proteins are rearranged in a process called microparticulation. The resulting proteins consist of extremely small spherical particles, about one-thousandth of a millimeter in diameter. In this shape and size, the particles roll over one another, are perceived as being fluid, and mimic the mouthfeel and appearance of real fat (Fat Substitutes on the Horizon 1988).

Although the FDA concluded that Simplesse is safe because it consists of common food components, such an assumption has been challenged. The decreased particle size and homogenization of milk and egg white proteins may influence free cholesterol absorption. The technique creates stereochemical changes of amino acids and peptides, which could alter ratios of neurotransmitters and induce hyperinsulinemic responses (Roberts 1989).

In addition, concerns have been expressed about the potential sensitizing properties of Simplesse for individuals who have egg and/or milk intolerance. Dr. Ronald A. Simon, a member of FDA's Ad Hoc Advisory Committee on Hypersensitivity, warned of the possibility of unique antigens in Simplesse that might be sensitizing and induce allergenicity. He urged that careful studies be conducted prior to sanctioning Simplesse for general use to determine what reactivity-sensitivity there might be, and encouraged allergenicity tests for both the product and any metabolic breakdown products (Allergy Specialist Expresses Concern 1988; see also Zikakis 1974 and Roberts 1989).

Another fat substitute based on egg and milk is under FDA review. Kraft General Foods has petitioned for approval of its product Trailblazer, which is a modified protein texturizer. It consists of a mixture of dried egg white and whey protein concentrate or skim milk, changed in form, and combined with xanthan gum and food-grade acid. Vitamin A, normally present in milk fat, is absent from this mixture, and Kraft announced that it would add vitamin A to any frozen dessert products made with Trailblazer (Dziezak 1989).

Emulsifier-based fat substitutes. Emulsifiers to reduce fat levels were introduced as early as the 1930s, in "superglycerated" shortenings. In recent years, the application of emulsifier technology, in conjunction with other functional ingredients, has made it possible to achieve greater fat reduction (Fat Reduction in Foods 1993).

Emulsifiers themselves may be fat derivatives, with mono- and diglycerides constituting a major category. By changing the positions on the glyceride molecule, emulsifiers can be made to function differently in the body (Richard 1990). Every emulsifier has both hydrophilic and lipophilic portions, which makes the characteristic oil-and-water interface possible. The hydrophilic-lipophilic–based emulsifiers have a fat-derived component, usually one or more fatty acids attached to the hydrophilic portion of such substances as glycerine, sorbitol, sucrose, or propylene glycol. These emulsifiers, usually combined with water, can replace fat in food products. Some, such as the polyglycerol esters (PGEs), with or without added fat, offer the mouthfeel of fat. The PGEs have been used to provide about one-third fewer calories than traditional fats in food products (Richard 1990).

Due to their chemical composition or molecular weight, some of the emulsifiers (although fat derived), are poorly metabolized and absorbed. Similarly, some PGEs, which are complex molecules of glycerine and fatty acids, may be so large that they are hydrolyzed only partially in normal fat metabolism. Thus, they are not absorbed fully by the body (Richard 1990). Medium-chain triglycerides (MCTs) are metabolized by a different pathway, and normally are not stored in the body. Rather, they are burned as energy (Richard 1990).

Future synthetic fat substitutes. Sucrose polyester (SPE) functions and tastes like fat. Its molecules are too large to be broken down by the body's enzymes, and so it is neither digested nor absorbed. SPE is a mixture of hexa-, hepta-, and octa-esters that form when sucrose is esterified with long-chain fatty acid molecules derived from a fat, such as soy oil (Inglett 1981). Under development for several decades, SPE was accidentally discovered by researchers at Procter and Gamble (P&G) who were searching for fatty acids more easily digestible by premature infants than were those found in milk. It was patented by P&G in 1971 (The Use of Sucrose 1982).

In 1987, P&G petitioned the FDA to approve its SPE product (Olestra) for use as a fat substitute to replace up to 35 percent of traditional oils and shortenings for home and commercial uses, such as grilling; seasoning of vegetables, meats, and fish; and making doughnuts, sauces, and salad oils. It also replaces up to 75 percent of traditional oils and shortenings used in deep-fat frying in foodservice outlets. Another use is in the commercial manufacture of snack foods, such as potato chips (McCormick 1988).

Researchers have suggested that in addition to such SPE features as its escape from digestion and absorption, other characteristics may also prove beneficial. By interfering with cholesterol absorption, SPE might lower blood cholesterol and prevent or retard the development of atherosclerosis and bowel cancer. Moreover, it was thought that SPE might help block absorption of such toxins as DDT (dichlorodiphenyltrichloroethane) and other harmful compounds that remain in the body's fatty tissues for long periods, and might also help to expedite the excretion of such toxins from the body (Glueck, Mattson, and Jandecek 1979; Progress with Sucrose Polyester 1980; The Use of Sucrose 1982; Mellies et al. 1983; Sucrose Polyester 1983).

In human tests, however, SPE produced some adverse effects, such as gastrointestinal distress, including bloating, flatulence, nausea, diarrhea, soft oily stools, anal leakage, and increased urgency or frequency of bowel movements (Mellies et al. 1983). To avoid these problems, researchers modified the product's chemical structure. Another problem was that SPE blocked absorption of vital fat-soluble vitamins, especially A and E. Thus SPE could produce serious vitamin deficiencies (Mattson, Hollenbach, and Kuehlthau 1979).

The FDA classified Olestra as a food additive, and, legally, this classification required P&G to demonstrate that the substance was safe under conditions of its intended use (Definition of the Term 1985). After this classification, safety questions were raised by a panel of a dozen scientists organized by the Medatlantic Research Foundation, a private research group. The panel requested the FDA to require additional studies on the long-term health effects of Olestra and its possible absorption by humans (Swasy 1989). In 1989, P&G initiated additional safety tests to avoid having the FDA delay any further review by several years and secured approval for Olestra in 1996.

Meanwhile, other fatty acid–based fat substitutes are being developed. Among them is phenylmethylpolysiloxane (PS), a polymeric liquid oil that is chemically inert and nonabsorbable (Braco, Baba, and Hashim 1987). Another is dialkyl dihexadecylmalonate (DDM), a synthetic fat substitute with potential applications for high-temperature use with fried snack foods. DDM is reported to be minimally digested and absorbed (Fat Substitute Menu 1990; Spearman 1990).

In addition, work is proceeding on an esterified propoxylated glycerol (EPG) nonabsorbable fat substitute intended for cooked and uncooked food products (Dziezak 1989). Under investigation are alkyl glycoside fatty acid polyester (AGFAP) (Schiller, Ellis, and Rhein 1988); raffinate polyesters (trisaccharide fatty esters) (Schiller et al. 1988); and trialkoxytricarballylate (TATCA) (Fat Substitute Menu 1990), a nonhydrolyzable noncaloric oil-like compound.

Fat substitutes and safety concerns. The prospect of many food products with fat substitutes raises safety concerns. Many of the fat substitutes, such as SPE, are regarded by the FDA as food additives, and, as a rule, a food additive represents only a very small percentage of a food product, at most only 1 or 2 percent. But with synthetic fat substitutes, the percentage is far higher. As replacers of fat – a macronutrient in the diet – these substances might replace up to 40 percent of calories consumed daily.

In this event, it seems clear that present safety tests are inadequate, and new ones need to be devised that go beyond the traditional guidelines, which in this instance would mean guidelines that address more than 100 percent of the test diet. For widely used fat substitutes, the traditional margins of safety – between no effect levels in animals and estimated exposure levels in many humans – may need to be reduced. The FDA needs to find ways of modifying the traditional safety factor and, at the same time, to assure that food additives are safe (Scarbrough 1989).

Fat substitutes and nutritional concerns. It has been suggested that low-fat diets might compromise the intake of adequate amounts of certain nutrients, including essential fatty acids, calcium, iron, and zinc (Rizek, Raper, and Tippett 1988). Unfortunately, few feeding studies have been conducted with fat substitutes. Some trials suggest that they are ineffective for weight control, because individuals fed a meal that contained a lower than usual amount of caloric fat tended to compensate by eating more food at the next meal (Stark 1988).

Similarly, in animal studies, decreased carbohydrate intake made the subjects more hungry and resulted in an increased total food intake (Gladwell 1990). All of this, of course, raises the question of whether a decreased fat intake will result in a similar compensatory mechanism if fat substitutes gain widespread use.

Many health professionals are wary about the trend toward extensive use of fat substitutes. For years, public health programs have attempted to modify dietary habits. Americans have been encouraged, repeatedly, to increase consumption of nutrient-rich vegetables, fruits, whole-grain products, and lean foods of animal origin, while decreasing consumption of high-fat and high-sugar foods.

Thus, some health professionals are concerned that the availability of numerous low-fat and nonfat products (as well as those with low-caloric and noncaloric sweeteners) will lure consumers away from healthful nutrient-dense foods to poorer selections. A spokesperson for the American Heart Association cautioned that Simplesse, the first of the newly approved fat substitutes, "may do little but reinforce the country's taste for high-fat foods" (Fat Substitute Rolled Out 1990: 39).

Food products made with fat substitutes may follow a consumption pattern similar to that of the sugar substitutes. The latter originally were hailed as the great hope for banishing obesity. However, this condition is more of a problem than ever. Will the fat substitutes, which offer a similar promise, also prove ineffective?

VII.11 Nonfoods as Dietary Supplements

Food: A substance (of natural origin) ingested to maintain life and growth.

Diet: The habitual pattern of consumption of food and drink.

Supplement: That which supplies a deficiency or fulfills a need.

The semantically inclined will, no doubt, perceive an element of inconsistency in the title of this contribution. Any food(stuff) ingested for a nutritional purpose is, it could be argued, ipso facto a dietary component. To refer to "nonfood dietary supplements" would, therefore, be meaningless.

On the other hand, foods are often defined in traditional- historical terms, and it is apparent that there are a substantial number of "nutritionally significant" substances which, although not ordinarily components of a diet, may nevertheless be ingested in special circumstances. Whether such "foreign" substances are then described as food(stuffs) or as dietary nonfood(stuffs) is very much a matter of opinion.

The issue is further clouded by a tendency to regard foods as being of natural origin, whereas certain dietary supplements, although having a clearly definable nutritional role, may nevertheless have a "nonnatural" (synthetic) origin. And whereas "true" foods are rarely challenged in terms of potential toxicity, this is not the case with supplements – as evidenced, for example, by the American report on the safety of amino acids used as dietary supplements (Anderson, Fisher, and Raiten 1993).

Again, one must distinguish between nonfoods as dietary supplements and nonfoods as dietary components. Geophagists, picaists, and drug addicts may, in certain circumstances, ingest large amounts of nonfood materials, but these fall outside the scope of this discussion. Supplementation implies that the additional material is introduced intentionally for an avowedly dietary reason and is a substance that could not, in normal circumstances, be supplied by realistic dietary manipulation.

Since the purpose of dietary supplementation is to improve the nutritional status of the subject (thus distinguishing dietary supplements from pharmacological treatments), its practice must be congruous with generally accepted nutritional thought – which, in turn, implies that the intentional use of dietary supplements is a development of fairly recent origin. Consequently, the significance attributed to many nonfood supplements has, in recent years, ebbed and flowed, thereby reflecting the kaleidoscopic nature of orthodox nutritional thought itself.

By the same token, it is equally apparent that the concept of nonfood dietary supplements is a relative one, with the lines of categorization shifting from community to community. Thus dietary fiber, a widely advocated nonfood dietary supplement in the Western European diet, would have no such status in many African communities. Equally difficult to define is the distinction between the use of a supplement in a dietary capacity and its use as a pharmacological agent. Megadoses of ascorbic acid (vitamin C) may, in this respect, be contrasted with the more moderate levels used for orthodox dietary supplementation; and the use of arginine to modify immunity and intestinal carrier systems could, it may be argued, reflect a pharmacological, rather than a nutritional, role for supplementation (Hirst 1993; Park 1993).

By the late nineteenth century, the categorization of foods in functional terms had progressed considerably. Foods were described as "body-building" (nitrogenous) or "energy-forming" (nonnitrogenous), and there was, consequently, a tendency to simplify dietary concepts and to limit precepts to recognizably bona fide members of these two groups. However, by the turn of the century, the recognition of the role of vitamins – nonfoods in a quantitative sense – and the blurring of the lines of demarcation between "energy" and "growth" foods provided a more flexible conceptual framework for the proliferation of ideas about the usefulness of nonfood supplementation.

This chapter therefore deals with substances that, without falling into the conventional categories of dietary components (protein, energy sources, vitamins, and minerals), are nevertheless believed to enhance dietary effectiveness. They would not, in normal circumstances, be supplied by customary dietary components – either because the foods containing them are ingested in supposedly inadequate amounts (as in the case of dietary fiber in certain communities) or because the substance in question is not readily available from food(stuff) sources. This latter category is, in evolutionary terms, less likely to exist and, it could be argued, implies more of a pharmacological relationship than a nutritional one. Perhaps with this in mind, Michele Sadler, in a recent discussion of dietary supplements, has referred to them as "Functional Foods" and has defined them as lying between foods and pharmaceuticals (1993).

Three examples of "nonfood" dietary supplements are discussed below. All have achieved, at different times, some significance as supplements during the last 40 years or so, and they represent three "etiologically" different categories.

Bioflavonoids

The term "bioflavonoids" has been widely used to refer to those flavonoids that are believed to have pharmacological or nutritional properties. They have no apparently essential role in nutrition and, consequently, no daily requirement can be specified. Nevertheless, for a period of some 30 years they were held to have an "adjuvant" role in maintaining good health – possibly by enhancing the activity of vitamin C.

The flavonoids are a large group of plant compounds based on a $C_6C_3C_6$ skeleton. They are of widespread distribution in the plant kingdom, being virtually ubiquitous in angiosperms and also existing in more primitive groups, such as green algae, and Bryophyta, including Hepaticae. It has been estimated that in the West, the average per capita daily intake of bioflavonoids is approximately 1 gram (g) (Middleton 1988). Higher animals have, perforce, evolved in an environment in which, of necessity, their feeding habits exposed them to a wide range of flavonoid material, ingested as "secondary" components of foodstuffs. It is, therefore, quite conceivable that this evolutionary exposure to a wide range of flavonoids has elicited physiological and biochemical responses in higher animals. Certainly some bioflavonoid features, such as their ability to chelate with metals and the antioxidant activity associated with hydroxyl groups, indicate a considerable potential for biochemical involvements.

Bioflavonoids first attracted the attention of nutritionists in the 1930s when Hungarian workers reported that certain vegetables and fruits (notably citrus) contained substances capable of enhancing the antiscorbutic properties of ascorbic acid (vitamin C) and even of partially substituting for it. It was claimed that "the age-old beneficial effect of fruit juice is partly due to its vitamin P *[sic]* content" (Bentsáth, Rusznyák, and Szent-Györgyi 1937: 327); it was also suggested that "citrin," a flavonoid preparation, could prolong the survival period of scorbutic guinea pigs and that extracts of *Citrus limon* and *Capsicum annuum* could correct capillary fragility – a condition characteristic of ascorbic acid deficiency (Bentsáth, Rusznyák, and Szent-Györgyi 1936). The new factor(s) was regarded as separate from vitamin

C and was designated "vitamin P" (Rusznyák and Szent-Györgyi 1936), and sometimes was named, primarily by French workers, the "C_2" factor. However, the true nature of the relationship (if any) between the bioflavonoids and vitamin C was unclear, and later work indicated that some of the earlier results were probably attributable to traces of vitamin C in the flavonoid preparations. Nevertheless, by the late 1930s the bioflavonoids had acquired a niche, albeit a minor one, in the annals of vitaminology. But considerable reservations remained about their real nutritional significance (Harris 1938: 28).

In 1949 Harold Scarborough and A. L. Bacharach published an important review article summarizing the work done between 1935 and 1949, and dismissing any suggestion that vitamin P could generally substitute for vitamin C. They centered their attention on the influence of bioflavonoids on capillary resistance and quoted with approval an earlier statement that "guinea pigs placed on a scorbutic diet supplemented with adequate amounts of ascorbic acid show a decline in capillary strength . . . restorable by vitamin P" (Scarborough and Bacharach 1949: 11).

The consensus of opinion in 1950 was that flavonoids were of physiological significance and that their main influence (on capillary resistance) was mediated independently of vitamin C. Nevertheless, the Joint Committee on Biochemical Nomenclature (United States) recommended in 1950 that the term "vitamin P" be replaced by the designation "bioflavonoids"; and in 1980 the (U.K.) Committee on Dietary Allowances of the Food and Nutrition Board (COMA) indicated that the bioflavonoids should be regarded as pharmacological, rather than as nutritional, agents.

Interest in the possible nutritional significance of bioflavonoids forged ahead during the 1950s (see Table VII.11.1), with a continuing emphasis upon their possible adjuvant relationship with vitamin C. It is interesting to note that almost half of the bioflavonoid papers published during the period from 1948 to 1957 dealt with the specific bioflavonoid rutin (quercetin-3-rutinoside). Rutin was widely used at the time in model experimental systems and is still sold as a dietary supplement, sometimes in the form of extracts of buckwheat *(Fagopyrum esculentum),* one of its principal natural sources. Other specific compounds to receive attention by nutritionists were quercetin and hesperidin.

Table VII.11.1. *Publications during 1930–90 relating to the nutritional significance of (a) bioflavonoids and (b) carnitine*

	Bioflavonoids	Carnitine
1930–9	29 [53]	0
1940–9	51 [102]	0
1950–9	60 [172]	9 [25]
1960–9	35 [132]	9 [35]
1970–9	19 [85]	23 [104]
1980–9	7 [30]	93 [384]

Source: Based on papers abstracted in *Nutrition Abstracts and Reviews* and expressed per 20,000 total nutrition papers; the figures in brackets refer to the "uncorrected" total number of publications on bioflavonoids and carnitine, respectively.

Work on bioflavonoids was extended in the 1950s and 1960s to include a wide range of supposed physiological and biochemical involvements. Possibly for historical reasons, workers in Eastern European countries were particularly active in this respect. K. Böhm, in his 1968 monograph, cited some 40 definable influences of flavonoids in humans – although the evidence for many of these was weak and sometimes contradictory. M. Gabor, in his 1972 monograph, dealt almost exclusively with one of these suggested areas, namely the supposed anti-inflammatory effect of flavonoids. Other, and more overtly nutritional, areas where bioflavonoids were believed to have a role were hepatic detoxication and lipid utilization (Hughes 1978).

Nonetheless, by the 1960s, interest in a nutritional role for bioflavonoids had peaked, along with their associated use as dietary supplements (see Table VII.11.1). Thereafter the main nutritional interest in bioflavonoids centered on their supposed synergistic relationship with vitamin C and their possible role as antioxidants. There was substantial evidence that bioflavonoids could "enhance" the ascorbic acid status of hypovitaminotic C guinea pigs, and much work in the 1960s and 1970s was aimed at elucidating the nature of this relationship. Discussions centered on whether bioflavonoids could actually substitute for (or synergistically assist) vitamin C in some of its roles, or whether they increased the availability of vitamin C either by protecting it from oxidative breakdown in the tissues or by enhancing its absorption from the gastrointestinal tract (Hughes and Wilson 1977).

Two aspects of flavonoid metabolism attracted some attention – their antioxidant capacity and, in some cases, an apparent mutagenicity. But studies of the nutritional significance of these features gave inconsistent and difficult-to-interpret results. For example, one study dealing with mice indicated that, whereas a dietary supplement of quercetin shortened life span, a flavonoid-rich extract of black currants (containing quercetin together with other flavonoids) extended it (Jones and Hughes 1982). Moreover, none of these studies provided any incontrovertible evidence of an essential role for bioflavonoids in nutrition, and a recent reviewer opined that their function in health and disease as natural biological response modifiers still needed to be determined (Middleton 1988). M. M. Cody, in a contribution to the *Handbook of Vitamins,* dealt with bioflavonoids under the heading "Substances without vitamin status" (Cody 1984: 578–85).

Nonetheless, there remains a certain amount of residual evidence favoring the use of bioflavonoids as a dietary supplement to enhance the absorption of vitamin C from the gastrointestinal tract and, possibly, its subsequent retention by the tissues (Hughes and Wilson 1977). As a consequence, to advocate the ingestion of "natural" vitamin C (as, for example, in the form of bioflavonoid-rich black currant juice) – rather than the synthetic "tablet" form of the vitamin – by persons otherwise recalcitrant to vitamin C absorption (such as the elderly) is not entirely without experimental basis.

For the decade 1980–9, however, only 30 "nutritionally orientated" bioflavonoid publications could be identified, and general interest in the erstwhile suspected nutritional role of bioflavonoids and in their consequent use in dietary supplementation would now appear to be waning.

The recent COMA report dismissed them as an "unnecessary substance" and made no recommendation for their use as a supplement.

Dietary Fiber

There were many "latent" references to dietary fiber before it was identified and characterized as a specific dietary component. Early writers on diet, such as Thomas Elyot (*The Castel of Helth* . . . [1541]), Ludovicus Nonnius (*De Re Cibaria* [1645]), and Thomas Moffet (*Health's Improvements* [1655]), who referred to the laxative property of whole-meal bread (when compared with lower-extraction-rate breads), were in reality commenting on the fiber content.

Thomas Cogan, the Elizabethan dietitian, wrote in his *The Haven of Health:* "Browne bread made of the coursest of wheate floure, having in it much branne . . . shortly descendeth from the stomacke [and] . . . such as have beene used to fine bread, when they have beene costive, by eating browne bread and butter have been made soluble" (1612: 25).

Similarly, Thomas Venner, the Bath physician, wrote of whole-meal bread in his *Via Recta ad Vitam Longam* that

> by reason of some part of the bran which is contained in it, it doth sooner descend and move the belly, for there is a kind of abstersive [laxative] faculty in the bran: wherefore for those that are healthy, and yet subject to costiveness, and also for such as would not wax grosse, it is most profitable (1638: 25).

This comment is curiously congruous with the standpoint adopted by present-day fibrophiles.

Hugh Trowell, in his extensive bibliography *Dietary Fibre in Human Nutrition* (1979), mentions a paper written in 1919 as the earliest to deal with definable fiber (cellulose) per se. Arthur Rendle-Short, a British surgeon, argued in the 1920s that epidemiological evidence suggested a relationship between lack of dietary cellulose and the incidence of appendicitis. The earliest title in Trowell's bibliography to contain the term "fibre" was one by M. A. Bloom, published in 1930.

It was not until the 1970s, however, that a wide interest emerged in the nutritional significance of what had been regarded, until then, merely as dietary "roughage," or waste material. Three names are usually associated with this phase in the history of fiber. One is that of T. L. Cleave, a British naval doctor, who argued (1974) that a number of pathological conditions were probably attributable to an increased intake of refined sugar and starch. Although Cleave did not emphasize the mirror image of his thesis – namely, that an increasingly refined diet was in reality a low-fiber one – he has, nevertheless, been widely, and somewhat incorrectly, hailed as a pioneer of current dietary fiber hypotheses.

A more overt and direct link between fiber lack and disease was promulgated in the 1970s by Hugh Trowell (1979; see also 1985) and by Denis Burkitt (1971), and the genesis of modern fiber studies has become almost synonymous with their names. Burkitt himself, in tracing the early history of thought on fiber, has included a fourth name, that of A. R. Walker of South Africa. The number of identifiable publications on the subject of dietary fiber rose from an annual average of 10 in the late 1960s to 125 in the early 1970s; 10 years later (in 1983), the average had risen to well over 500. Trowell's original thesis (1960) stemmed from his observation that a number of diseases that appeared to be characteristic of affluent Western technological communities were rare or absent in the more "primitive" parts of Africa with which he was familiar. He drew particular attention to the differential incidence of diseases of the gastrointestinal tract and suggested that a high consumption of fiber-rich foods was protective against noninfective diseases of the large bowel. Similarly, and independently, Burkitt (in 1971) published his evidence that dietary fiber might be protective against colorectal cancer.

At that time, however, there was no generally accepted definition of dietary fiber, and much confusion stemmed from the use of values for "crude" fiber (the residue left after serial extraction with acid and alkali). This was a measure that excluded the bulk of the cellulose and hemicellulose material, both important components of dietary fiber. The problem of definition was, of course, inextricably linked to difficulties in the development of a method for the accurate determination of fiber (Englyst and Cummings 1990). Trowell, in 1971, defined dietary fiber as the plant cell material that was resistant to digestion by the gastrointestinal enzymes, and this became the accepted definition. More recently the term "dietary fiber" has been displaced by the resurrected form "nonstarch polysaccharide material," which reflects current analytic procedures.

The original "dietary fiber hypothesis" was soon extended by other workers to embrace suggested relationships between dietary fiber and nongastrointestinal diseases, particularly cardiovascular disorders (for example, Judd 1985; Kritchevsky 1988). Epidemiological studies indicated a negative correlation between fiber intake and the incidence of cardiovascular disease, and experimental studies showed that certain types of dietary fiber were potent hypocholesterolemic agents. However, relationships of this type posed a problem. By definition, dietary fiber was a substance that did not leave the gastrointestinal tract. How then could one explain its supposed "extragastrointestinal" effects?

Nor was it always easy to distinguish between a direct protective effect of fiber and a displacement effect on "harmful" dietary components. Mechanisms based on a fiber-mediated inhibition of cholesterol absorption or an increased bile acid excretion were among those mooted. But much of the epidemiological work related to fruit and vegetable intake and not to intake of fiber per se. M. L. Burr and P. M. Sweetnam (1982), however, found that in Wales, a vegetarian lifestyle could be correlated with a reduced incidence of heart disease, but fiber intake could not.

The picture was further complicated by the interrelationships now known to exist between dietary fiber and the intestinal flora. This is a complex two-way relationship. Not only are certain types of fiber subject to degradation by colonic bacteria, but there is also increasing evidence that fiber itself may, in turn, modify the nature and metabolic activity of the colonic flora, with consequent modifications to the formation and absorption of a wide range of metabolites. Considerations of this type have led to suggestions that dietary fiber may modify the estrogen status in females, with consequent implications for a protective role for fiber in breast cancer and, possibly, other cancers (Hughes 1990; Adlercreutz 1991).

The current consensus would appear to favor an increased fiber intake in the Western-type diet, but an optimal intake has yet to be clearly delineated. Appeals to primitive dietary patterns are of little help in this respect, as the fiber intake of humans has fluctuated substantially during their stay on earth. Estimates based on coprolite analysis have indicated substantially higher ingestion of dietary fiber by primitive peoples than by their present-day descendants, with daily intakes of 100 to 200 grams occurring at certain periods. In addition, there have been significant changes in fiber intake at critical points in the socioeconomic development of humanity, such as during the "neolithic transition" (Eaton 1990).

Fifteen years after the birth of the fiber hypothesis, Rodney H. Taylor, in a leading article in the *British Medical Journal* (1984), questioned the prophylactic usefulness of high-fiber diets except for improving colonic function and alleviating constipation. Recent dietary precepts are almost equally noncommittal in their advocacy of dietary fiber. The most recent COMA recommendation (1991) echoed Taylor's doubts. Although advocating an increase in NSP (nonstarch polysaccharides) from the current average intake of 13 g/day to 18 g/day to improve bowel function, the committee was unable to find sufficient evidence for a direct mediating influence of fiber in other suggested areas, such as diabetes and cardiovascular disease. Moreover, the increased intake, it was suggested, should be attained by dietary manipulation, rather than by overt supplementation. It is possible that after a quarter of a century of often frenzied investigative activity, the dietary fiber movement is beginning to disintegrate.

Carnitine

Carnitine was discovered at the beginning of this century when its presence in Liebig's meat extract – at the time a popular dietary supplement – was reported. Twenty years later its structure was elucidated, and it was shown to be (beta-hydroxy-gamma-(trimethylamino)-butyric acid. But it attracted little biochemical or nutritional attention until the late 1950s when its role in the metabolism of fats was described. Reviewing the situation at that time, G. Fraenkel and S. Friedman wrote that "a small amount of evidence has been pieced together indicating that carnitine may be active in the metabolism of fats or their derivatives" (1957: 104).

Subsequent, in vivo studies with labeled fatty acids confirmed this conclusion, and within a few years the role of carnitine in stimulating the mitochondrial oxidation of fatty acids was generally accepted (Olson 1966). Subsequent investigations revealed the nature of the mechanism of this stimulation when it was shown that carnitine acts as a transport molecule for the movement of long-chain fatty acid molecules into the mitochondrial matrix. A number of situations in which carnitine has a derived or secondary role as a buffering agent for acyl groups have also been described (Cerretelli and Marconi 1990).

A lack of carnitine, or a reduced or defective activity of one or more of the transport enzymes, would therefore reduce the availability of fat as a source of energy. This could be significant in cases where it is believed that a substantial proportion of the energy metabolism is derived from fat – as in the newly born infant or in cardiac muscle metabolism. It would appear, however, that in the short term, substantial falls in carnitine are required before an impairment of fatty acid oxidation becomes apparent (Carroll, Carter, and Perlman 1987).

The body is able to biosynthesize carnitine, and by the 1980s the biosynthetic pathway had been elucidated. It was shown that the precursor molecules were lysine and methionine, two essential dietary amino acids. The lysine is methylated by the methionine to form the protein-bound trimethyllysine, which is then hydroxylated to form beta-hydroxy-N-trimethyllysine. This is converted, first to gamma-butyrobetaine and then to carnitine (Rebouche and Paulson 1986).

Carnitine deficiency diseases, resulting from a defect in the biosynthetic pathway, have been described. Such a condition was first reported by A. G. Engel and C. Angelini in 1973, and since then a number of apparently different types of carnitine deficiency have been noted and discussed in the literature. Two basic types are sometimes recognized – systemic carnitine deficiency (characterized by a general reduction of carnitine in the tissues, including the liver) and muscle or myopathic deficiency, in which the reduction in carnitine occurs in the muscles. In such cases, carnitine replacement therapy is a recognized mode of treatment; supplementation must take the form of L-carnitine, the DL/D form being ineffective and, in some cases, further exacerbating the condition.

There are also a number of secondary or noncongenital syndromes that respond to treatment with carnitine, some of which are side effects of other clinical conditions (Rebouche and Paulson 1986; Smith and Dippenaar 1990). Carnitine levels are, in general, lower at birth than in adulthood, and there is evidence that some newly born infants may have a reduced capacity for carnitine biosynthesis. At birth, too, fatty acids become increasingly important as an energy source (Smith and Dippenaar 1990), and it has been suggested that all infants should receive carnitine supplements at least until the end of their first year of life (Olson, Nelson, and Rebouche 1989; Giovannini, Agostoni, and Salari 1991). A recent COMA report accepted that carnitine supplements could be necessary "for low birth weight or preterm infants" (Committee on Medical Aspects of Food Policy 1991: 135). Barbara Bowman, in a recent review, has pointed out that carnitine "appears to be a conditionally essential nutrient in malnutrition and in newborns, pregnant and lactating women, patients receiving dialysis or total parenteral nutrition, and patients with liver disease" (1992: 142).

Many of these examples of carnitine supplementation presumably stem from the correction of an abnormal feature of carnitine metabolism or by restoring a defective carnitine status to normal. Others are more overtly pharmacological than nutritional in nature. A striking example of the pharmacological use of [acetyl]carnitine was the report of a double-blind, randomized, controlled clinical trial in which the progression of Alzheimer's disease was significantly delayed by the ingestion of 2 grams of acetylcarnitine daily for a year (Spagnoli et al. 1991).

Whether carnitine supplementation has a role in normal or "nonclinical" nutrition is more debatable. Much of the discussion in this respect has centered on the possibility of using carnitine supplements to enhance aerobic power and the capacity for physical exercise (Cerretelli and Marconi 1990). Theoretically, such supplementation could be advantageous in a situation characterized by an increased demand for "physical energy" and, more specifically, in circumstances characterized by (1) an increased use of fatty acids as an energy source, and (2) a depression in the biosynthetic capacity of the body.

A depressed biosynthetic capacity might, in turn, result from a reduced availability of the essential nutrients involved in the biosynthetic pathway. This latter consideration – the influence of other dietary factors on carnitine status – could be of some significance and is central to the concept of carnitine as a conditionally essential nutrient.

The hydroxylation reactions in the formation of carnitine from lysine and methionine require ascorbic acid (vitamin C) as a cofactor; in addition, two members of the vitamin B complex (niacin and pyridoxine) are involved, as is iron. The endogenous formation of carnitine, therefore, involves the participation of six obligatory dietary components – a requirement that places it in a "high risk" category with respect to inadequate supporting diets. A review has underlined this point:

> If the exogenous supply of carnitine is temporarily cut off, and provided the subject is not suffering from protein hypo- or malnutrition (as may happen in vegetarianism) plasma carnitine concentrations do not shift . . . [but] however, drop sharply if the co-factors essential for carnitine synthesis are lacking (Giovannini, Agostoni, and Salari 1991: 88).

Of the essential cofactors, lysine (often the limiting amino acid in poor-quality diets and frequently present in a physiologically unavailable form [Helmut 1989]) and ascorbic acid (vitamin C) are probably the most critically important ones. There is evidence, both experimental and circumstantial, that a reduced availability of one or both of these essential nutrients results in a fall of carnitine and possibly a reduction of carnitine-mediated energy release. Thus, the intake of three compounds – preformed carnitine, lysine, and vitamin C (the three forming the "carnitine base") – will determine the carnitine status of an individual, and one can point to a number of historically significant situations where a reduced carnitine base has resulted in the emergence of a stage consistent with what we now know to be the physiological consequences of carnitine deficiency: primarily a reduced capacity for sustained muscular exercise (Hughes 1993).

Thus, there are grounds for believing that the fatigue and lassitude, invariably present in the early stages of scurvy, could have resulted from the impairment of carnitine synthesis, which in turn would have resulted from a deficiency of vitamin C (Hughes 1981, 1993; see also Figures VII.11.1 and VII.11.2). It is tempting to speculate that the lowered aptitude for physical

394 OF THE SCURVY.

ſome food; or any diſeaſe which greatly weakens the body, or vitiates the humours.

SYMPTOMS.——This diſeaſe may be known by unuſual wearineſs, heavineſs, and difficulty of breathing, eſpecially after motion; rottenneſs of the gums, which are apt to bleed on the ſlighteſt touch; a ſtinking breath; frequent bleeding at the noſe; crackling of the joints; difficulty of walking; ſometimes a ſwelling and ſometimes a falling away of the legs, on which there are livid, yellow, or violet-coloured ſpots; the face is generally of a pale or leaden colour. As the diſeaſe advances, other ſymptoms come on; as rottenneſs of the teeth, hæmorrhages, or diſcharges of blood from different parts of the body, foul obſtinate ulcers, pains in various parts, eſpecially about the breaſt, dry ſcaly eruptions all over the body, &c. At laſt a waſting or hectic fever comes on, and the miſerable patient is often carried off by a dyſentery, a diarrhœa, a dropſy, the palſy, fainting fits, or a mortification of ſome of the bowels.

Figure VII.11.2. Another eighteenth-century description of scurvy suggestive of carnitine deficiency. (From Buchan 1791.)

labor displayed by potato-eating Irish and by vegetable-eating French peoples and commented on by a number of observers in the last century was, at least in part, attributable to a reduced carnitine base (Young 1780; Lewes 1859; Bennet 1877; Williams 1885). A diet that centered almost exclusively on potatoes (as was eaten in Ireland during the nineteenth century) would contain virtually no preformed carnitine. Moreover, 20 pounds of potatoes would have to be eaten to obtain the amount of lysine present in half a pound of meat.

The remarks of George Henry Lewes in 1859 are interestingly pertinent in this respect. Describing the relative capacities of the French and the English for physical work he wrote:

> It is worth noting that the popular idea of one Englishman being equal to three Frenchmen, was found by contractors to be tolerably accurate, one Englishman really doing the work of two and a half men; and M. Payen remarks that the consumption of mutton in England is three times as much as that in France. . . . [B]y giving the Frenchmen as ample a ration of meat as that eaten by the Englishman, the difference was soon reduced to a mere nothing (1859, 1: 174).

Lewes's reference to mutton was, in this respect, a strikingly apt one, for of all meats and fishes analyzed to date, mutton has by far the highest carnitine concentration (Smith and Dippenaar 1990).

The belief in a positive correlation between animal protein intake and capacity for physical work was a central feature of dietary thought until disproved by the biochemical reductionism of the post-Liebigean era. H. Letheby summarized some of this anecdotal evidence in his Cantor Lectures in 1868:

> [T]here is always a relation between the amount of nitrogen contained [in] the food and the labor value of it. Carnivorous animals, for

> example, are . . . stronger and more capable of prolonged exertion than herbivores. . . . The bears of India and America, says Playfair, which feed on acorns, are mild and tractable whilst those of the polar regions, which consume flesh, are savage and untameable. The Peruvians whom Pizarro found in the country at its conquest were gentle and inoffensive in their habits, and they subsisted chiefly on vegetable food; whilst their brethren in Mexico, when found by Cortes, were a warlike and fierce race, feeding for the most part on animal diet. . . . The Hindoo navvies also who were employed in making the tunnel of the Bhore Ghat Railway, and who had very laborious work to perform, found it impossible to sustain their health on a vegetable diet; and being left at liberty by their caste to eat as they pleased they took the common food of the English navigators, and were then able to work as vigorously (1870: 79).

About seventy years later, Robert McCarrison (also in a series of Cantor Lectures) made almost the same point by comparing the diets and physical capabilities of different Indian races (McCarrison 1944). In general, however, by the beginning of the twentieth century, advances in our knowledge of muscle biochemistry were beginning to undermine the belief in a necessary relationship between animal protein intake and physical activity (Hutchinson 1902: 38).

It is interesting to note that the same biochemical reductionism that dismissed the supposed relationship between activity and a "strong" (animal protein) diet now prompts us to reconsider this anecdotal evidence from the standpoint of "carnitine base" status. Many of the "weak" or "poor" diets referred in this section would almost certainly be found wanting in this respect. By the same token, it has been suggested that certain significant socioeconomic changes could imply a change in carnitine base availability. Thus the "Neolithic transition," although leading to an improved supply and availability of food, almost certainly resulted in a reduction in dietary quality and, particularly, in that of the "carnitine base" (Cohen 1990; Hughes 1993).

Such considerations are of direct interest vis-à-vis carnitine supplementation. In more general terms, they underline the importance in supplementation studies of considering each situation on its own merits. Any reduction in one or more of the components of the dietary carnitine base could indicate a need for carnitine supplementation. A sudden fall in the animal protein intake or in the availability of the lysine component or in vitamin C intake (as would appear to occur in the institutionalized elderly where the tissue concentrations of vitamin C are significantly below those believed to be functionally desirable in younger subjects) could result in a reduction in endogenously formed carnitine (Hughes 1993).

General Observations

The entire issue of dietary supplementation is clouded by adventitious circumstances and considerations. Thus it will be apparent that certain intellectual environments or passing paradigms of scientific thought can be particularly favorable to the concept of dietary supplementation. The burgeoning interest in bioflavonoids in the late 1940s and 1950s (and in fiber in the 1970s) was probably not unassociated with two acceptable features of nutritional thought at the time: (1) the belief in "subclinical" manifestations of deficiency diseases (which, in some undefined way, were believed to exist despite a normal intake of accepted nutrients); and (2) the conviction that supplementation of foodstuffs with micronutrients was nutritionally appropriate – a belief that, in cases such as the supplementation of low-extraction flour, carried the seal of government approval.

It is true that there have always been those who advocated supplementation for scientifically inadequate reasons. Such persons belong to the same category as those who, also for nonscientific reasons (such as folklore or romantic naturalism), favored brown (whole-meal) bread rather than low-extraction breads (McCance and Widdowson 1956). Where arguments for supplementation stem from external sources of this nature and are, consequently, difficult to accommodate within the current framework of scientific thought, they should always be treated with proper scientific skepticism and subjected to the appropriate scientific scrutiny. If it turns out that the advocacy of a supplement is consonant with current biochemical thought, then the arguments for its use can be that much more convincing.

The three examples outlined in this essay represent, in this respect, cases of dietary supplementation with three quite different origins. The suggested use of bioflavonoids stemmed, in essence, from a mixture of folklore and weak anecdotal evidence, supported originally by unconfirmed laboratory reports, and was enthusiastically embraced by believers in the value of natural foods as contrasted with manufactured ones. There are many other erstwhile dietary supplements that belong to this category – "vitamin B_{15}" (pangamic acid), "vitamin B_{17}" (laetrile), sea salt, and a host of herbal preparations. These supplements, for the most part, entered the nutritional field, as it were, from "outside" and for nonscientific reasons. Their alleged efficacy was, consequently, more easily disproved by accepted experimental and statistical techniques, and their use was frequently subjected to criticism and, sometimes, ridicule by scientifically orientated "establishment" nutritionists (see, for example, Bender 1985).

Fiber belongs to a somewhat different category of nonfood supplements, as its appearance as a candidate for dietary status was the consequence of epidemiological studies, although it must be admitted that in a nutritional context, it is not always easy to distinguish between "strong anecdotal evidence" (as presented, for example, by Trowell in his early studies) and statistically acceptable epidemiological evidence. Unlike the bioflavonoids, however, dietary fiber has achieved a foothold in current nutritional thought mainly because of strong correlative evidence coupled with the results of some experimental studies. Dietary intervention studies with fiber have been somewhat less successful, and accommodating the purported advantages of fiber supplementation within the current ambit of biochemical thought still poses considerable problems.

Carnitine represents a third etiologic category of potential dietary supplements. Its emergence as a factor of possible nutritional significance, in contrast to the two other examples discussed, was an "internal" event; it was not thrust upon nutritional thought, as it were, from the outside. Arguments for its acceptance in certain circumstances as a dietary supplement placed no conceptual strain on contemporary nutritional thought. In scientific terms it belongs, therefore, to a more acceptable category than the other two examples discussed. Other putative supplements whose emergence has reflected the current state of the art, rather than external and unrelated circumstances are taurine (which, alongside carnitine, receives conditional acceptance as a supplement in the current COMA report), inositol, para-amino benzoic acid, and specific amino acids. In all such cases of putative dietary supplements, the final verdict must await extensive experimental work and intervention studies.

This brief survey of the recent history of three "nonfood" dietary supplements should serve to illustrate three important and cautionary facts. First, it is useful, as far as possible, to distinguish between a pharmacological role and a nutritional role for supplements. Second, one should exercise caution before accepting claims based on anecdotal evidence or derived from statements or arguments external to (and sometimes in open contradiction to) current scientific thought. Third, and most importantly, dietary supplementation must be defined in terms of lacunae and imbalances in the existing dietary pattern, rather than in terms of absolute requirements – the concept of "conditional essentiality."

Classical nutrition derived much of its strength (and lately, some of its weaknesses) from generalizations based on an essentially reductionist and unitary approach to dietary components. A necessary condition for its success was the virtual exclusion of any conceptually extraneous matter, such as the possible importance of nonobligatory dietary components, the significance of dietary interactions, and the importance of the changing balance between tissue demands and nutrient availability. There are signs that current nutritional thought is shedding at least some of its traditional absolutism (Hughes 1993: 40–1). Future studies will presumably be designed not so much to prove in absolute terms the usefulness of specific supplements but to define the nutritional circumstances in which such conditionally essential nutrients as carnitine and fiber would be deemed to be necessary.

VII.12 Food Toxins and Poisons from Microorganisms

The Processes Affecting Toxicity

Rather than undertaking a categoric examination of the myriad toxins in food, this essay highlights various considerations that should provide a sense of perspective in viewing toxins as a whole. It is important to realize that toxic substances must negotiate the various degradation and propulsive properties of a gastrointestinal tract in order to be absorbed and exert a harmful effect on the body. The ability of the toxin to be absorbed helps determine the amount of a substance that must be ingested before toxic effects become manifest. Moreover, the handling of ingested toxins by an immature gastrointestinal tract of a premature or term newborn infant may be different from that of the fully developed gastrointestinal tract.

Development of the tract begins during the first 12 weeks of gestation as it matures from a straight tube to one that is progressively convoluted, and the surface area for absorption increases. Over the next six months, the gut acquires a sophisticated immune system and the capacity to digest complex carbohydrates, fats, and proteins. Not all of these mechanisms, however, are fully functional until several months after birth.

The extent to which ingested substances, including food and toxins, are absorbed by the intestine is dependent on the capabilities it has developed to deal with carbohydrates, fats, proteins, water, and ions. These are highly complex issues about which varying amounts of information are understood. Nevertheless, a general concept of how absorption occurs may help put the discussion of food toxins in context.

Carbohydrates constitute the nutrients that provide the largest proportion of calories in the Western diet. Carbohydrate intake, in an adult diet, is approximately 400 grams per day. The major ingested carbohydrates are starch, sucrose (table sugar), and lactose (milk sugar) as 60 percent, 30 percent, and 10 percent, respectively, of the total digestible carbohydrates.

Starch is broken down by enzymes acting within the lumen or tube of the small intestine. The smaller molecules of sugar are digested (broken down) to molecules consisting of one to a few linked sugar molecules, and most are transported across the intestinal wall and into the blood by an energy-requiring "pump" enzyme system in the cell membrane (Van Dyke 1989).

Proteins undergo initial digestion in the stomach and are broken down further by pancreatic enzymes in the small intestinal lumen until they become either individual amino acids or small multiamino acid units called oligopeptides. The intestine has evolved separate transport mechanisms for absorption of different types of amino acids as well as oligopeptides.

Digestion of fat begins in the mouth but is primarily accomplished in the upper small intestine where bile acids from the gallbladder emulsify the fat, permitting the efficient action of the pancreatic enzyme lipase to break down the fats into free fatty acids. Because fats are poorly soluble in water, they are transported by micelles, made of bile acids and fat, to the surface of the upper small intestinal wall where they are absorbed as free fatty acids across the intestinal wall. There they enter either the blood, bound to proteins, or the lymphatic system. Many of the toxic substances in food are absorbed by the protein or fat digestion mechanism (Van Dyke 1989).

Other than the processes of digestion and absorption, intestinal factors that may affect the toxicity of substances in foods include the rapid turnover and sloughing of the intestinal epithelial cells in direct contact with toxins. Persons with intestines in which cell turnover has been slowed, as with those in developing countries suffering from protein–energy malnutrition, may be at greater risk of absorbing toxins from dietary staples.

Another factor is the motility of the gastrointestinal tract. Rapid transit, such as in diarrhea, may minimize the contact of foreign substances with the small intestine and thus reduce the opportunities for absorption (Silverman and Roy 1983). An additional consideration that has not been well studied is the presence of a variety of ingested substances in the intestinal lumen that may interfere with the ability of a toxic substance to come into contact with the intestinal absorptive surface. Thus, for example, the ingestion of phytates from various crops may interfere with the absorption of metals, such as zinc and calcium (Alpers 1989; Wallwork and Sandstead 1990).

Sometimes the ingestion of large quantities of one metal can inhibit the absorption of another. Such an inverse relationship exists between copper and zinc (Li and Vallee 1980). Furthermore, the porosity of the gastrointestinal tract is greater in young infants than in older children and adults (Silverman and Roy 1983). This allows the direct passage of intact proteins, and perhaps other substances as well, from the intestinal lumen into the blood, which could make infants more vulnerable to various toxins than older individuals.

The Concept of Bioavailability

Collectively, those factors that regulate intestinal absorption of toxic substances in foods, as well as of required nutrients, determine the *bioavailability* of the toxin. Although the bioavailability of many of the food toxins has not been clearly defined, it is important to consider this aspect of food toxins, because bioavailability will influence the amount of a substance that must be ingested before its toxicity becomes manifest. It is also a consideration in devising specific therapies for the ingestion of known toxins, such as the use of activated charcoal to bind a toxin in the intestinal lumen or the induction of vomiting to empty the stomach of a potential toxin.

An example of how bioavailability influences the degree to which toxic substances can produce harm is that of aluminum. Aluminum is the third most abundant element on earth and is a contaminant of many foods and medicinal products (Alfrey 1983). When it enters patients as a contaminant of solutions used for hemodialysis or intravenous feeding (total parenteral nutrition), it accumulates in bones, causing reduced bone formation and mineralization (Klein 1990). In addition, it interferes with hemoglobin synthesis, producing anemia, and in patients with kidney failure, it can accumulate in the brain causing progressive dementia and convulsions (Alfrey 1983). By contrast, oral intake of aluminum in normal individuals without damaged kidneys is well tolerated.

Excessive aluminum ingestion, as with long-term consumption of aluminum-containing antacids, may bind phosphate in the intestine and produce phosphate deficiency (Klein 1990). However, ingestion of aluminum in quantities present in normal Western diets (Alfrey 1983) or in currently manufactured infant formulas (Sedman et al. 1985) poses no threat to health so long as the kidneys function normally. The reason for this appears to be that the intestinal absorption of aluminum is very poor, probably less than 0.5 percent of intake, and the kidneys are efficient in eliminating that which is absorbed, leaving very little to accumulate in tissues (Klein 1990). Thus, oral intake of even large quantities of aluminum is not generally harmful because the bioavailability of aluminum in food is very low.

Metabolism

Once ingested, toxins that are absorbed are metabolized. The substances in question undergo biochemical transformation, largely in the liver, by a series of enzymes known as microsomal mixed function oxidases. Some of the reactions involving processes such as oxidation, reduction, or hydrolysis may increase or decrease the activity of the substances.

Other reactions, termed conjugation, involve coupling between the toxin and an endogenous molecule, such as a carbohydrate or an amino acid. These conjugation reactions often result in inactivation (Goodman and Gilman 1980). The fate of the particular toxin in the body will be determined by the relative rates of increased activation and inactivation. The enzymes involved in these reactions are subject to a wide range of individual variability in which genetics, age, body temperature, and nutritional status play important roles.

In general, very young children have a reduced quantity of microsomal enzymes, compared to older individuals. An increase in body temperature produces an increase in all aspects of metabolism, including microsomal enzyme activity, and protein–energy malnutrition depresses the activity of microsomal enzymes (Goodman and Gilman 1980).

The substances themselves may alter the activity of selected microsomal enzymes. Thus, such metals as aluminum, cadmium, and lead have been reported to reduce selectively some microsomal enzyme activity, although these same metals may increase the activity of some conjugating enzymes (Bidlack et al. 1987). Therefore, the variability resulting from the interaction of all the factors influencing metabolism of ingested toxins makes it extraordinarily difficult to predict the fate of any individual substance once absorbed.

It should be evident that both the bioavailability and metabolism of food toxins are very poorly understood variables, and the ensuing discussion of the nature of food toxins must be viewed in light of the highly complex response of the body to these substances, either alone or in combination.

Food Toxins

Food toxins can be generally categorized as plant pesticides (natural and synthetic), mycotoxins, metals, and animal toxins, as well as toxins present in foods as the result of industrial contamination. Each category is considered in turn in this section.

Plant Pesticides

Plant pesticides may be synthetic or natural. In recent years, synthetic pesticides have aroused public concern about possible health effects, especially carcinogenicity. Data gathered by the U.S. Food and Drug Administration (FDA) and reported by B. Ames, M. Profet, and L. Gold (1990a) showed that the average dietary intake of synthetic pesticide residues was 0.09 milligrams (mg) per person per day, compared to 1.5 grams per person per day of natural pesticides. Of the 0.09 mg, four chemicals not carcinogenic in rodents – ethylhexyl diphenyl phosphate, chloroprophan, malathion, and dicloran – constitute approximately half the intake, leaving 0.05 mg synthetics, primarily polychlorinated biphenyls (PCBs), as the only possible carcinogens consumed.

FDA monitoring for pesticides in food samples for a one-year period between 1986 and 1987 revealed that exposure of the American population to PCBs and other synthetic pesticides was consistently less than limits set by the U.S. Environmental Protection Agency (EPA), with less than 1 percent of samples containing pesticide residues exceeding the regulatory limits imposed by the FDA (Ames, Profet, and Gold 1990a).

In 1981, R. Doll and R. Peto estimated that approximately 35 percent of cancer cases could be attributed to the human diet. If true, and if synthetic pesticides account for such a small quantity of dietary intake, it is reasonable to cast suspicion, as do Ames, Profet, and Gold (1990b) and R. Beier (1990), on the natural pesticides.

These phytotoxins, as they are called, constitute a wide variety of chemical compounds produced by plants in response to injury from insects, fungi, climate, animal predators and physical damage. Although synthetic pesticide residues may be present in plants in the parts per billion range, natural pesticides may be present in plants in the parts per million or even parts per thousand range. Thus, they are present in much greater concentration than are the synthetic residues.

As an example, glucobrassicin, a polycyclic hydrocarbon, has a breakdown product called indole carbinol. Glucobrassicin is found in large quantities in vegetables, such as broccoli and Brussels sprouts. When these vegetables are chewed (cooked or raw), they release an enzyme that breaks down the glucobrassicin to indole carbinol. This substance acts biochemically in a manner similar to dioxins, some of which may be a carcinogenic synthetic residue. However, although the EPA has set an acceptable human dose limit for dioxin of 6 mg per kilogram (kg) per day, 100 mg of broccoli is estimated to contain 5 mg of indole carbinol (0.1 mg/kg/day) (Ames et al. 1990a).

Despite the large number of natural pesticides, relatively few have been tested for toxicity. Ames and colleagues (1990a, 1990b) estimate that they abound in the tens of thousands, existing in every edible vegetable and fruit to varying degrees. Yet it has also been estimated that only about 2,800 chemicals have been tested in laboratory animals, mainly rodents, for toxicity (Ames et al. 1990b).

The main categories of toxicity include (1) the potential to cause chromosome breakage in vitro, (clastogenicity); (2) the potential to cause genetic mutations (mutagenicity); (3) the potential to produce birth defects (teratogenicity); and (4) the potential to produce tumors (carcinogenicity). The vast majority of tests done using laboratory animals are carried out in rodents and at "maximum tolerated" (near-toxic) doses given chronically. B. N. Ames and colleagues (1990a) cite data showing that of 340 natural pesticides administered to rodents in conventional chronic high-dose protocols, approximately 70 percent were either carcinogens, mutagens, or both. Yet data on toxicity of these natural pesticides for humans are sparse. In addition, some of these natural pesticides (phytoalexins) have other properties that cause more acute toxicity in humans and animals without necessarily being carcinogenic.

Examples of natural chemicals that are harmful to humans include those found in a variety of Asian herbs containing pyrrolizidine alkaloids, which can be toxic to the liver. Thus, Indian herbal teas are known to cause hepatic veno-occlusive disease. Similarly, comfrey tea, made of the leaves and roots of the Japanese comfrey herb, are hepatocarcinogenic in rats, although insufficient data are available for humans. However, as much as 26 mg of pyrrolizidine alkaloids could be consumed in a cup of comfrey tea (Beier 1990).

Another instance of natural pesticides being harmful to human beings is the case of the white potato. Introduced into the Western diet as a result of the Spanish conquest of Peru, the white potato contains two major glycosteroid alkaloids, alpha solanine and alpha chaconine. Both are cholinesterase inhibitors, and thus have the potential to interfere with autonomic nervous system function.

Several outbreaks of a syndrome resembling gastroenteritis with a headache have been attributed to these alkaloids when the concentration of alpha solanine ranged from 100 to 400 micrograms per gram (μg/g) potato. Since not only the consumption of potatoes but also that of their skins (the site of peak alkaloid concentration) is increasing in restaurants, and at least one company is manufacturing a potato chip made from skins, it is possible that further outbreaks of alpha solanine poisoning will be seen. This is of special concern because these alkaloids appear to be resistant to cooking and frying. Some snack foods contain more than 7 times the safe limit of glycoalkaloids (limit of 200 μg/g potato) (Beier 1990).

Potatoes also contain nitrates with an average level of 119 μg/g fresh weight. Nitrates can react with various amine compounds to form N-nitroso compounds, which are carcinogenic and mutagenic in rodents. Potatoes supply 14 percent of the per capita ingestion of nitrates in the United States (Beier 1990).

In addition, there is epidemiological evidence suggesting that the glycoalkaloids in potatoes may be teratogenic in human beings. Attempts to breed strains more resistant to the potato blight fungus have led to an increase in the amount of natural pesticides produced by new strains of potato. L. Penrose (1957) has pointed out that Ireland has weather conducive to the growth of the blight fungus and also the world's highest incidence of anencephaly (congenital absence of the cranial vault) and spina bifida. Other areas of the world that have developed varieties of potato more resistant to blight have undergone as much as a doubling of the frequency of anencephaly (Beier 1990).

The risk of anencephaly is not eliminated by avoiding the consumption of potato during pregnancy. That the theoretical risk remains is suggested in the report by R. Beier (1990) that solanium, the aglycone derivative of alpha solanine, is stored in the body for a long time and could possibly be released during periods of increased metabolic demand, such as pregnancy. Although evidence supporting a role of the potato glycoalkaloids in the pathogenesis of anencephaly is only circumstantial, a case can surely be made for the need to determine more definitively the relationships of these natural pesticides to human birth defects.

The example of celery being harmful to humankind is more clearly established than that of the potato. The parsley plant group, most prominently celery, contains phytoalexins known as furanocoumarins. These are photosensitizing toxins that will cause both contact dermatitis and photodermatitis. Grocery workers subject to repeated handling of apparently healthy celery have experienced photodermatitis.

The problem stems from attempts to breed a more naturally pest-resistant form of the plant that have produced an elevation in its furanocoumarin content (Beier and Oertli 1983). In the epidemic of photodermatitis in grocery store workers, the linear furanocoumarin content was 14 times higher in the celery in question than in other celery varieties; psoralen, the most photosensitizing of the linear furanocoumarins, was 19 times higher than in other varieties of celery (Beier 1990).

Other evidence of harm to humans done by photosensitizing furanocoumarins are anecdotal. Psoralen ingestion followed by ultraviolet light exposure can produce cataracts in animals and humans (Lerman 1986). Severe, even fatal burns may occur in individuals ingesting psoralen and then visiting tanning parlors (Beier 1990).

These same linear furanocoumarins also are found in citrus and fig plants, which contain furanocoumarin in the peels that are used as flavorings for candies, soft drinks, and baked goods. D-limonene, a psoralen and coumarin derivative, is sold as an insecticide to control pests on household pets (Beier 1990). Fig photodermatitis is seen in fig handlers: In Turkey, 10 percent of fig handlers reportedly contract it (Beier 1990).

In addition, some crops are cultivated in developing countries because they are hardy and do not need the protection of expensive synthetic pesticides. However, they do require extensive processing to detoxify them. For example, much of the cassava root in South America and Africa contains cyanide in high concentrations and is edible only following washing, grinding, scraping, and heating (Beier 1990). Ataxia, or neuromuscular incoordination, due to chronic cyanide poisoning is prevalent in many of the areas of

Africa where cassava is consumed (Cooke and Cock 1989). Similarly, in India the pest-resistant grain *lathyrius sativas* is grown with its seeds containing a potent neurotoxin, B-N-oxalyl-amino alanine, the cause of a crippling nervous system disorder, neurolathyrism (Jayaraman 1989).

As an alternative to plant breeding and use of synthetic pesticides, "organic" farmers claim to use only natural pesticides from one plant species against pests that attack a different species. Thus, phytoalexins, such as rotenone, employed in India as a fish poison, or pyrethrins from chrysanthemum are used. These naturally derived pesticides have not been studied in sufficient detail to determine carcinogenicity in rodents (Ames et al. 1990a, 1990b).

Inasmuch as there are so many natural pesticides in virtually all our edible produce, one might wonder how it is that we are protected against them. Given the complexities in evaluating the effects of bioavailability and tissue metabolism of these toxins, this becomes a very difficult question. But it does seem that what is true for rodents may not be true for humans. Thus, species differences in the bioavailability and metabolism of naturally occurring toxins may account for differences not only in the minimum ingested quantity but also in the time course necessary to produce toxicity in humans. It is possible that humans rapidly metabolize natural pesticides to nontoxic metabolites or are not so susceptible to their toxic actions as laboratory rodents.

Secondly, even within the scope of rodent testing, doses of phytoalexins lower than the maximum tolerated dose may be protective or anticarcinogenic. Examples of this include limonene, caffeic acid found in coffee bean and potatoes, and indole carbinol (Ames et al 1990a). Often, feeding rodents large quantities of cruciferous vegetables, such as broccoli, cabbage, and Brussels sprouts, before their exposure to known carcinogens, such as aflatoxin, decreases the incidence of tumors and increases the rate of survival (Ames et al. 1990b). In contrast, if the experiment is performed in reverse and rodents are given the carcinogen prior to feeding on cruciferous vegetables, the incidence of tumors is increased.

Thus, in summary, the naturally occurring phytoalexins in our foods and medicinal herbs have not been subject to the same intensive scientific scrutiny as have the synthetic pesticides. But the public's current health concerns, the United States government recommendations that more fiber and starch be included in the American diet, and the popularity of "natural" foods and remedies sold in health-food stores combine to make mandatory an increasing amount of scientific study of the safety of such chemicals in the Western diet.

Furthermore, the continued prescription of herbal remedies without scientific basis, on the one hand, and consumption of agricultural staples high in natural pesticides by people in developing countries, on the other hand, pose both real and potential hazards of global dimensions.

Mycotoxins

Perhaps the reverse of the production of natural pesticides by plants responding to infestations and physical damage is the manufacture of toxic metabolic products by the invaders of the plants (that is, fungi). One example is the production of fungal toxins or mycotoxins. Mycotoxin poisoning was noted in ancient times in China and Egypt, and an epidemic identified by some as ergotism (one form of such poisoning) was recorded in Sparta in 430 B.C. (Beier 1990).

The mycotoxin thought to be most responsible for human disease is aflatoxin. Some others also implicated in human toxicity are ochratoxin A, trichothecenes, zearalenone, deoxynivalenol, citrinin, stergmatocytin, and ergot. These mycotoxins are relatively small molecules, with which humans most likely come in contact through contaminated foods.

The Food and Agriculture Organization of the United Nations (FAO) has estimated that 25 percent of the world's food crops are contaminated by mycotoxins, including 10 to 50 percent of the grain crops in Africa and the Far East (Mannon and Johnson 1985). Aflatoxins are primarily found in corn, peanuts, cottonseed, and tree nuts; ergot alkaloids, in rye and wheat; ochratoxin and T-2 toxin, in a variety of grains including barley, oats, corn, soybeans, wheat, and rice; penicillic acid, in corn and dried beans; and zearlenone, in corn and wheat (Beier 1990). Of all the fungi producing mycotoxins, only *aspergillus flavus* and *aspergillus parasiticus* produce aflatoxin, which is the most highly publicized fungal toxin affecting human health (Beier 1990).

Acute aflatoxicosis in humans has been reported from Taiwan and Uganda (U.S. Council for Agricultural Science and Technology 1989). The syndrome is manifested by abdominal pain, vomiting, liver necrosis, and fatty infiltration, as well as the accumulation of fluid in the lungs (pulmonary edema).

In 1974 in western India, unseasonal rains and food scarcity were responsible in over 200 villages for the consumption of corn contaminated with aflatoxin as high as 16 parts per million. Of 994 patients examined there were 97 fatalities (mostly due to gastrointestinal bleeding). However, the presence of other mycotoxins in the corn could not be ruled out, and consequently the epidemic may have been the work of multiple mycotoxins.

This example, along with other reported cases among children in Thailand, combine to suggest a serious risk of acute aflatoxicosis in developing countries where contaminated grain is more likely to be marketed for human consumption than in developed countries. A report by the U.S. Council for Agricultural Science and Technology (1989) suggests that acute aflatoxicosis poses a low risk in Western diets due to the apparent rarity of heavily contaminated grain in the food supply.

Conversely, aflatoxin B_1 has produced liver tumors in several species of experimental animals and is listed as a probable human carcinogen by the International Agency for Research on Cancer (U.S. Council for Agricultural Science and Technology 1989). Thus, there is concern about chronic low-level exposure of humans to aflatoxin despite the low risk of massive doses. The 1989 report by the U.S. Council for Agricultural Science and Technology has reviewed epidemiological studies from both Asia and Africa and concluded that the incidence of liver cell cancer is higher in regions where there is high chronic exposure to aflatoxin. However, there is no evidence that this correlation represents cause and effect.

In fact, a study of rural white males from different sections of the United States (Stoloff 1983) found that despite an estimated 1,000-fold difference in the intake of aflatoxin among men in different regions, the risk of death from liver cell cancer was only 6 to 10 percent higher in the most exposed population. Moreover, Chinese males living in the United States have a high incidence of liver cell carcinoma despite a low likelihood of exposure to aflatoxin (Stoloff 1983). Therefore, the risk of aflatoxin B_1 to humans as a probable carcinogen is still uncertain, at least with consumption of Western diets.

In addition to the encouragement of proper harvesting, drying, and storing methods, attempts are currently being made with a variety of techniques to degrade or otherwise chemically alter aflatoxin in grains (Beier 1990). Thus, as with aflatoxins, other mycotoxins probably pose a greater threat to human health in developing countries than in the more developed countries. In the former, the scarcity of food and the increased likelihood of grain contamination combine to magnify the likelihood of human consumption of tainted food products. Nevertheless, contaminated grains that may, from time to time, enter Western markets constitute at least a theoretical risk and mandate continued vigilance by governmental regulating agencies over national food supplies.

Fish Toxins

Endogenous toxins produced by fish may be less of a public health problem than industrial contaminants entering the food chain via fish or other foods. However, ciguatoxin, saxitoxin, and tetrodotoxin are acknowledged food hazards, and mention of them should be made. Ciguatera poisoning was described as early as the 1600s in the New Hebrides (now Vanuatu), and in 1774, the British navigator Captain James Cook reported an outbreak of apparent ciguatera poisoning in New Caledonia (Hokama and Miyahara 1986).

Ciguatoxin is of low molecular weight and belongs to a class of organic compounds called polyethers. It is one of the most potent toxins known, yet associated with few fatalities because its concentration in fish flesh is very low (Tachibana et al. 1987). The toxin is synthesized by a species of flagellate called *Gambierdiscus toxicus* and is passed through the aquatic food chain from herbivorous to carnivorous fish and then to humans, usually by consumption of certain reef fishes encountered around islands in the Caribbean and in the Pacific (Hokama and Miyahara 1986).

The onset of toxic symptoms may begin 10 minutes to 24 hours after consumption with gastrointestinal symptoms, such as diarrhea, vomiting, and abdominal pain. Neurological symptoms are caused by ciguatoxin's disruption of ion transport mechanisms that aid in the transmission of impulses along nerve axons (Hokama and Miyahara 1986). The symptoms include increased sensitivity to cold, which produces a painful tingling sensation, dilatation of the pupils, weakness, unsteady gait (ataxia), and abnormalities in deep tendon reflexes. With a large dose of ciguatoxin, respiratory depression may occur, and neurological symptoms can persist for months. Cardiovascular effects of ciguatoxin include abnormalities in blood pressure and heart rate, initially low, then sometimes too high, with an occasional irregular heart rhythm. These effects usually disappear within 48 to 72 hours. Of interest and concern, however, is that multiple poisonings of an individual generally increase his or her sensitivity to the toxin, resulting in more severe clinical effects with repeated ingestion.

Saxitoxin, like ciguatoxin, is produced by one or more species of flagellates (Valenti, Pasquini, and Andreucci 1979). These toxins, however, are often found in mollusks, which concentrate them. Saxitoxin is found, for the most part, in the Alaska butter clam and in mussels and scallops, especially during the warm months of the year. An epidemic of saxitoxin poisoning that occurred in Italy in October 1976 was attributable to the consumption of contaminated shellfish (Valenti et al. 1979).

Like ciguatoxin, saxitoxin is an organic compound of low molecular weight that acts as a neurotoxin by blocking the channels for sodium ion to cross the membranes of excitable nerve cells, thus blocking transmission of neuromuscular impulses. Symptoms usually appear within 30 minutes of ingestion. These include numbness around the mouth, lips, face, and extremities; a broad-based gait with neuromuscular incoordination, accompanied by nausea and vomiting and diarrhea; loss of voice; impaired swallowing; and respiratory impairment, which can lead to death within 12 hours.

A lethal dose of saxitoxin is reported to be 1 to 2 milligrams, whereas the concentration for saxitoxin in affected mollusks consumed in Italy ranged from 556 to 1479 micrograms per 100 grams pulp. Thus, there must be individual variation in the susceptibility to the effects of saxitoxin, because very large quantities of pulp are normally consumed.

Tetrodotoxin was first isolated in 1894 from the fugu (also called puffer) fish. It is found primarily in fish inhabiting the waters of Japan, China, and Polynesia and is one of the most potent toxins known. Ingestion of 2 grams of fish eggs can kill a person (Valenti et al. 1979). Female fish appear to produce greater amounts of toxin than males. Balloon fish, shellfish, toad fish, and globe fish also are known to produce tetrodotoxin. Like saxitoxin, tetrodotoxin is a rapid-acting sodium-ion channel poison that blocks neuromuscular conduction (Valenti et al. 1979).

The onset of symptoms occurs between 10 and 50 minutes following ingestion, with vomiting, spreading numbness, voice loss, swallowing difficulty, and respiratory depression. In Japan, more than half the victims die within an hour of ingestion, and 100 percent of those that die do so within 24 hours. Those ingesting only a minimal amount of tetrodotoxin recover without residual problems (Valenti et al. 1979).

The fugu fish is considered a delicacy by the Japanese, and restaurant chefs must have a special license from the government to prepare it in such a way that tetrodotoxin is inactivated. There are some anecdotal reports in the medical literature claiming that rapid administration of anticholinesterase drugs, such as edrophonium, can immediately reverse the paralytic effects of tetrodotoxin (Torda, Sinclair, and Ulyatt 1973; Chew et al. 1984).

Food Poisoning from Microorganisms and Their Toxins

Food poisoning is, regrettably, more than an occasional public health problem, usually resulting from either unhygienic food preparation or food storage or both. Spoiled food is contaminated primarily by toxins produced by strains of clostridium and staphylococcus. Salmonella may itself contaminate certain foods, but it does not produce a toxin, according to present knowledge. The causative organism for anthrax is among a group of other microorganisms found in spoiled food. The disease results from the ingestion of contaminated undercooked meat and is manifested by bloody diarrhea, pain, and occasionally shock. Anthrax is seldom a problem in the West and is more often encountered in underdeveloped countries (American Academy of Pediatrics 1991).

Bacillus cereus, a spore-forming gram-positive rod, may be present in a variety of foods. In fried rice (where it frequently occurs) it causes vomiting, and in meat and vegetables it causes diarrhea. The spores are relatively heat resistant, and the organism can grow and produce toxins in the intestine. The course is usually mild and resolves spontaneously within 24 hours (American Academy of Pediatrics 1991).

Two forms of clostridial food poisoning are noteworthy, that originating from *Clostridium botulinum* (botulism) and that generated by *Clostridium perfringens.* Botulism is a neurological disorder produced by neurotoxins A, B, E, and F of *Clostridium botulinum.* The toxins create a flaccid paralysis of the muscles of swallowing and phonation, as well as double vision, blurred vision, and slurred speech. Infant botulism, which occurs primarily in those less than 6 months old, is manifested by constipation, loss of muscle tone, a weak cry, poor feeding, a diminished gag reflex, and ocular palsies.

The neurotoxins are found in improperly preserved foods, especially those that are home processed and canned (American Academy of Pediatrics 1991). Illness occurs when the neurotoxins in unheated food are consumed. Most cases of infant botulism do not have a known source for the clostridial spores. However, honey is one identified source, corn syrup another. The American Academy of Pediatrics (1991) recommends withholding honey and, perhaps, corn syrup from an infant's diet for the first 6 months of life.

The cramping abdominal pain and watery diarrhea that develop 8 to 24 hours following ingestion of beef, poultry, gravy, and, notoriously, Mexican food usually result from a heat-labile enterotoxin produced by type A *C. perfringens.* The infection is generally acquired at places where food is prepared in large quantities and kept warm for long periods. Thus schools, camps, caterers, restaurants, and public markets where cooking is done would be typical sources of the infection. As in the case of infection by *B. cereus,* the symptoms usually resolve spontaneously within 24 hours (American Academy of Pediatrics 1991).

Caliciviruses are RNA viruses that can cause gastroenteritis-like symptoms lasting approximately four days. Outbreaks have been reported in children in institutional settings in Japan and the United Kingdom. Contaminated shellfish and cold foods are thought to be vehicles of transmission (American Academy of Pediatrics 1991).

Campylobacter jejuni, one of the most common organisms causing bloody diarrhea, has been isolated from the feces of turkeys and chickens. Transmission occurs by intake of contaminated food, including unpasteurized milk and improperly cooked poultry (American Academy of Pediatrics 1991).

Vibrio cholerae and its toxin can be acquired from ingestion of contaminated shellfish. The recent cholera epidemic in Peru and other parts of South America was originally attributable to "ceviche" (raw fish treated with lime juice) that was contaminated by *V. cholerae.* Adequate cooking eradicates the organism from foodstuffs.

Listeria monocytogenes is a cause of neonatal and perinatal infection. During outbreaks it has been traced to maternal intake of unpasteurized cheese or contaminated cole slaw, and milk has also been implicated.

Norwalk viruses can produce a gastroenteritis along with muscle aches, fever, and crampy abdominal pain. These RNA viruses are implicated in epidemics of gastroenteritis, and outbreaks are associated with eating contaminated shellfish and salads (American Academy of Pediatrics 1991).

Salmonellosis, or gastroenteritis produced by nontyphoid strains of salmonella, can be contracted from improperly processed meat or unpasteurized milk. Food handlers who carry salmonella are additional sources of outbreaks (American Academy of Pediatrics 1991).

Staphylococcus aureus and, occasionally, staphylococcus epidermitis can produce a variety of heat-stable enterotoxins: A, B, C_{1-3}, D, E, and F. The enterotoxins, if present in such foods as egg and potato salads, cream-filled pastries, poultry, and ham can produce abdominal cramping pain, nausea, vomiting, and diarrhea from 30 minutes to 7 hours after ingestion. The symptoms are severe but self-limited (American Academy of Pediatrics 1991).

Yersinia enterocolitica, an infection that may mimic other gastrointestinal diseases, including Crohn's disease (a chronic inflammatory bowel disease) and lymphoma, may be contracted by the consumption of contaminated food, especially uncooked pork and unpasteurized milk (American Academy of Pediatrics 1991).

Finally, one of the routes of transmission of toxoplasmosis, caused by a multi-organ protozoan pathogen with multiple disease manifestations, is by the consumption of poorly cooked meat. The same is true for trichinosis, caused by the nematode *Trichinella spiralis*. It too can cause anything from mild gastroenteritis to severe multiorgan disease and death.

Contamination of Food by Industrial Products

Industrial human-made toxins that contaminate foods include the heavy metals, such as lead, cadmium, and mercury, as well as lighter metals such as aluminum, dealt with in the section "The Concept of Bioavailability." Other industrial contaminants include halogenated hydrocarbons used as pesticides. The following section cites several examples of these contaminants as industrial disasters, as well as potential hazards.

Metal Contamination

Cadmium. In the Japanese prefecture of Toyama in the Jinzu River basin, postmenopausal women became ill after eating cadmium-contaminated rice. The illness, known as "itai-itai disease" was characterized by bone pain, osteoporosis, X-ray appearance of bone thickening overlying an incomplete fracture, and kidney disease as manifested by protein and sugar in the urine. Cadmium ingestion has also been the result of leaching from cadmium-plated containers by acidic drinks, such as fruit juices. These types of containers are now prohibited by law in many parts of the United States (Klein and Snodgrass 1993).

Cadmium may be deposited in soil and water near industrial plants that utilize it in metallurgy, plastics stabilizers, nuclear reactor rods, battery plants, and semiconductors. Because cadmium concentration in the soil can be high in these areas, crops grown in such soil may have high cadmium levels (Klein and Snodgrass 1993). Such may have been the case with itai-itai disease. Cadmium can also enter the aquatic food chain, especially through plankton, mollusks, and shellfish.

Mercury. Two major disasters have been reported as a result of epidemic mercury ingestion. One of these, in Japan, involved two episodes of methyl mercury ingestion as a result of waste dumping by an acetaldehyde manufacturing plant that discarded mercury into Minimata Bay. In 1956 and again in 1965, many infants of mothers from the cities surrounding the bay were born with brain malformations. They, and older individuals, developed irreversible neurological disease known in the literature as "Minimata disease."

In Iraq, a similar set of neurological problems developed following the 1971 consumption of bread made from wheat contaminated by a mercury-containing fungicide. The neuropathies resulted from degeneration of the nervous tissue caused by the mercury. Symptoms in exposed infants included cerebral palsy, psychomotor retardation microcephaly, spastic or flaccid paralysis, visual disorders, and convulsions. In older individuals, muscle weakness and visual and hearing impairment were prominent (Klein and Snodgrass 1993).

Lead. Although there are no recent major disasters on record for lead such as those reported for cadmium and mercury, it is now recognized that ingestion of even small quantities of lead, especially by children, may result in both behavioral and learning disorders. This finding is the work primarily of H. L. Needleman and colleagues (1990). The main source of lead ingestion by children has been lead-based paint that chips off the walls in run-down inner-city housing. However, it is apparent that other sources of lead ingestion include foods. In many cases, this is because agricultural vehicles, which are not required to use unleaded gasoline, release lead-containing exhaust onto crops, and lead accumulates most prominently in green, leafy vegetables. In addition, acidic foods can leach lead from the lead solder in cans (Klein and Snodgrass 1993).

Aluminum. Aluminum contaminates many foods in our diet, with the average adult consuming from 2 to 5 milligrams per day (Alfrey 1983). The Joint Food and Agriculture Organization/World Health Organization Expert Committee (1989) has indicated that a provisional tolerable weekly intake is around 7 mg per kilogram body weight.

Aluminum accumulation in bone has been associated with reduced bone formation and mineralization, in some cases leading to fractures and severe skeletal pain (Alfrey 1983, Klein 1990). It has also been implicated in a progressive dementia affecting uremic patients (Alfrey 1983). As we mentioned, the intestinal absorption of dietary aluminum is very low, about 0.5 percent (Klein 1990).

In recent years, the detection of large quantities of aluminum in some infant formulas has caused concern (Sedman et al. 1985). This has prompted the American Academy of Pediatrics to caution against the use of soy-based formulas (which have a high content of aluminum) for premature infants because of their immature kidney function (American Academy of Pediatrics Committee 1986). The source of the aluminum contamination in these soy formulas is the calcium and phosphate salts added to them, as well as the soy-protein isolate itself. The calcium and phosphate salts make up the chief sources of aluminum contamination of intravenous feeding solutions in use in hospitals (Sedman et al. 1985).

Chlorinated Hydrocarbons

There are numerous reports of halogenated, primarily chlorinated hydrocarbons contaminating the food chain, either via intake by fish or contamination of livestock feed. According to several reports, fish have been contaminated with DDT (dichlorodiphenyltrichloroethane) and other organic compounds, such as PCB (polychlorinated biphenyls), resulting in high human adipose tissue concentration of these chemicals (Kreiss et al. 1981; Ansari et al. 1986). It is also clear that these chlorinated hydrocarbons can concentrate in human breast milk to levels that may reach 20 times their concentration in cow's milk, with large dosing of infants a potential result (Fytianos et al. 1985).

Although all of the health implications (including carcinogenicity) of these ingestions are not understood, there is a report of more than 3,000 patients who developed porphyria in southeast Turkey following ingestion of hexachlorobezene fungicide added to wheat seedlings. Many of the breast-fed infants in this exposure under 1 year of age died as a result (Cripps et al. 1984).

In Michigan in 1973–4, there was a large environmental exposure because of the erroneous mixing of approximately one ton of polybrominated biphenyls (PBBs), a commercial flame retardant, into livestock feed. By mid-1974 virtually every Michigan resident had been exposed to these polybrominated biphenyls by consuming contaminated meat, milk, eggs, and other dairy products. Approximately 300 farm family members who consumed contaminated products from their own farms were followed for study (Anderson et al. 1979; Meester 1979).

Although no specific disease was identified, many of the exposed individuals complained of fatigue, visual problems, skin rashes, reduced resistance to infection, reduced tolerance of alcoholic beverages, and reduced libido. Several individuals complained of migratory arthritis, and one patient had aplastic anemia. The amount of polybrominated biphenyls in the subcutaneous fat did not correlate with symptoms, nor was there any kind of a dose–response relationship. The potential for carcinogenicity is uncertain although animal data suggest this is a risk in high-dose, long-term exposure (Groce and Kimbrough 1984). Furthermore, G. Lambert and colleagues (1990) have found that the hepatic microsomal enzymes of individuals exposed to PBBs remain activated up to 10 years following exposures. These activated enzymes are capable of producing carcinogenic metabolites from drugs and other organic compounds.

Conclusion

This chapter is intended to point out the variability of human defenses against the toxic substances we ingest; to illustrate the scope of our dietary exposure to toxins and putative toxins; to suggest our relative ignorance of the potential for harm caused by the myriad chemicals we consume with our food; to indicate that the majority of these are natural and not synthetic; and to show that industrial mishaps can indeed affect our food supply.

Although the public generally has confidence in the food with which it is supplied, there is a need for further scientific study of the effects of natural chemicals on our health, as well as a need for vigilance on the part of both industry and government to ensure that our food supply is neither needlessly nor irresponsibly contaminated.

Finally, in less-developed areas of the world, where the food available for human consumption is scarce and less subject to official scrutiny, the problem of toxic ingestion is magnified and its true extent probably unknown at the present time.

Gordon L. Klein
Wayne R. Snodgrass

The authors would like to express appreciation to Douglas E. Goeger, assistant professor of preventive medicine and community health at the University of Texas Medical Branch at Galveston, for the provision of key references as well as helpful comments. They would also like to thank Wilma L. Nance for manuscript preparation.

VII.13 ❧ The Question of Paleolithic Nutrition and Modern Health: From the End to the Beginning

A conviction has been growing among some observers that contemporary human health could be substantially improved if we would just emulate our hunter–gatherer ancestors in dietary matters. A look at this contention seems an appropriate way to bring this work to a close because the subject takes us full circle – linking contemporary issues of food and nutrition with our Paleolithic past. In addition, it offers an opportunity for some summary, and, finally, it provides a chance to remind ourselves of how ephemeral food and nutritional dogma can be.

In fact, in retrospect we call such fleeting tenets "Food Fads" (see the treatment by Jeffrey M. Pilcher, this work chapter VI.12), and in the United States at least, it was not very long ago that vitamin E capsules were being wistfully washed down in the hope of jump-starting sluggish libidos (Benedek, this work chapter VI.15). Not long before that, the egg was enshrined as the "perfect" food, with milk in second place, and cholesterol, now an apparently significant ingredient in the gooey deposits that plug heart arteries, was not a word in everyday vocabularies (Tannahill 1989).

In those "B.C." (before cholesterol) days, meat was in, and the starchy foods (potatoes, breads, and pastas), although full of fiber, were out – considered bad for a person's waistline and health, not to mention social standing. Garlic had a similarly dismal reputation – only foreigners ate it – and only winos drank wine. Who could have foreseen then that we would soon toss all of that nutritional lore that guided us into the ash heap of history and embrace its polar opposite – the "Mediterranean Diet" (Keys and Keys 1975; Spiller 1991; see also Marion Nestle, chapter V.C.1).

This, however, leads us back to the just-mentioned "growing conviction" among some students of current science and distant history that a fundamental flaw in our present approach to nutrition is a failure (or refusal) to realize that our diets were programmed at least 40,000 years ago and thus we are, to a very important extent, what our ancestors ate. Moreover, these same students believe that it is our obliviousness to the obvious that will prove most baffling of all to future observers of our nurture and nature (Eaton, Shostak, and Konner 1988a, 1988b; Nesse and Williams 1994; Profet 1995).

The purveyors of *The Paleolithic Prescription* (Eaton et al. 1988a; see also their "Stone Agers in the Fast Lane" [1988b]) belong to a group that subscribes to what has been labeled "Darwinian medicine" – a school of thought that has called into question many of the notions we have about nutriments and nutrients, as well as many practices in the practice of medicine.

Illustrative is the medical treatment of fever, routinely but perhaps mistakenly lowered with pain relievers. Fever, it is argued, is a part of a highly evolved defense system for combating pathogens. When fever is artificially lowered, that system is impaired, and recovery may take longer and be less perfect (Kluger 1979).

Another example is "morning sickness," said to arise from a mechanism evolved in the distant past to produce sufficient queasiness in newly pregnant women that they avoid foods – like slightly overripe meat, or cruciferous vegetables – that could be mildly toxic and, therefore, harmful to fetuses, which are especially vulnerable during the first trimester of pregnancy. If such ideas are correct, then it is possible that treating this Stone Age condition with modern nausea-preventing drugs increases the risk of birth defects (Profet 1995).

A final example from the medical side of the Darwinian thinkers' agenda has to do with what have become alarmingly high rates of breast and ovarian cancer. The Darwinians suggest that contemporary women endure an estimated three times more days with menstrual cycles than their hunter–gatherer ancestors because the latter averaged more children over a lifetime and breast-fed each for about three years – all of which suppressed menstrual cycles. The condition of modern women means three times the exposure to surges of estrogen that occur during those cycles – and estrogen has been implicated in the generation of female cancers (Nesse and Williams 1994).

No less disturbing are the nutritional implications that emerge from similar lines of reasoning that reach back into Paleolithic times. As we saw in Part I of this work, written by bioanthropologists, our hunter–gatherer forebears may have enjoyed such variety in viands that they fared better nutritionally than any of their descendants who settled down to invent agriculture; indeed, in terms of stature, it would seem that they did better than practically everyone who has lived ever since (see Mark Nathan Cohen 1989 and this work chapter I.6; Clark Spencer Larsen, this work chapter I.1).

Data on both stature and nutrition indicate that human height began to diminish with the transition from collecting to growing food, finally reaching a nadir in the nineteenth century. It has only been in the twentieth century that humankind, at least in the West, has started to measure up once again to our ancestors of at least some 25,000 to 10,000 years ago (Eaton et al. 1988a; Harris, this work chapter VI.5).

Proof of the early decline in stature and health, along with soaring rates of anemia and infant and child mortality, lies mostly in the skeletal remains of those who settled into sedentary agriculture. Such remains also bear witness to deteriorating health through bone and tooth lesions – caused on the one hand by an ever-more-circumscribed diet and on the other by the increased parasitism that invariably accompanied sedentism (Larsen 1995).

Paradoxically, then, enhanced food production, made possible by the switch to herding and growing, resulted in circumscribed diets and nutritional deficiencies. Thus it would seem that the various Neolithic revolutions of the world, which invented and reinvented agriculture and are collectively regarded as the most important stride forward in human history, were actually backward tumbles as far as human health was concerned. Moreover, when we remember that the superior nutritional status of the hunter-gatherers over that of their sedentary successors was achieved and maintained without two of the food groups – grains and dairy products – that we now call "basic" but which only came with the Neolithic Revolution, the hunter-gatherers' superiority seems downright heretical in the face of current nutritional dogma.

In longitudinal terms, humans have been on the earth in one form or another for a few million years, during which time they seem to have perpetuated themselves with some efficiency. About 1.5 million years ago, they shifted from a diet of primarily unprocessed plant foods to one comprised of increasing amounts of meat, some of which was scavenged. Approximately 700,000 years ago, humans began the deliberate hunting of animals, and Homo sapiens, who some 100,000 years ago had brains as large as ours today, became expert at it, judging from the frequent discoveries of abundant large-mammal remains at ancient sites (Larsen, this work chapter I.1). Meat may have constituted as much as 80 percent of the diet of those proficient at hunting, but they also ate wild vegetables and fruits; and certainly, as the Darwinists point out, it was these foods – meat, vegetables, and fruits – that constituted the diet from 25,000 to roughly 10,000 years ago (Eaton et al. 1988a).

In light of this nutritious past, it can be argued that humans are best adapted to these "old" food groups. Certainly, one piece of evidence in such an argument seems to be that humans are among the very few animal species that cannot synthesize their own vitamin C – an ability made superfluous by the great amounts forthcoming from the fruits and vegetables in the diet, and apparently lost along the evolutionary trail (Carpenter 1986; see also R. E. Hughes, this work chapter IV.A.3).

The other side of that coin, however, is that humans may not be well adapted to the "new" foods – dairy products and grains – and it is worth noting that from a nutritional standpoint, hunter-gatherers seem to have gotten along better nutritionally without these two food groups than the sedentary folk who created them and have used them ever since.

Recently, of course, meat – one of the old food groups – has become a primary suspect in the etiology of chronic illnesses, especially that of coronary artery disease, and it has been pointed out that modern-day hunter-gatherers (for example, the !Kung San in and around Africa's Kalahari desert) take in much more meat and, thus, more cholesterol than medicine today recommends. The traditional !Kung San and other modern-day hunter-gatherers, however, have very low blood-cholesterol levels and virtually no heart disease. Similarly, the Inuit of the Arctic and Subarctic, until recently at least, consumed mostly animal foods with the same lack of deleterious effects. It has only been with their switch to the foods the rest of us eat that their health has begun to deteriorate (Eaton et al. 1988a; see also Harold H. Draper, this work chapter VI.10; Linda Reed, this work chapter V.D.7).

It is true that hunted animals as a rule have only a fraction (about one-seventh to one-tenth) of the fat of their domesticated counterparts, along with a better ratio of polyunsaturated to saturated fats. Consequently, it has been estimated that our hunter–gatherer ancestors got only about 20 percent of their calories from fats, whereas fats deliver about 40 percent of the total calories in modern diets. But because the amount of cholesterol in meat is little affected by fat content, it would seem that our ancestors, like the !Kung San, also consumed more cholesterol than we do today and more than is recommended by nearly all medical authorities (Eaton et al. 1988a; see also Stephen Beckerman, this work chapter II.G.10).

It is interesting that a group of researchers in the United Kingdom has argued that cholesterol may not be the culprit – or at least not the only culprit – in bringing about coronary artery disease. Their search for its causes entailed the systematic and painstaking gathering, in all of Europe, of data on diets and deaths from heart disease, and analysis of this data has revealed one positive correlation: People living in the four European countries with the highest rates of heart disease (all in northern Europe) take in far more calcium than people in the four countries with the lowest rates (all in southern Europe) (see Stephen Seely, this work chapter IV.F.4).

Of course, that which is a significant correlation to some is merely an interesting speculation to others. But it may be the case that calcium can be harmful, depending on its source. During hunting-and-gathering times, calcium came mostly from plant foods, and bone remains indicate that our ancestors got plenty of it. Since the Neolithic, however, dietary calcium has increasingly been derived from dairy products, such as cheese and yoghurt – and milk, for those who can tolerate it.

Indeed, "tolerate" is the key word as far as milk is concerned, and, presumably, much of the reason for the difference in calcium intake between northern and southern Europeans is that the latter are less likely to consume milk after weaning because they are more likely to be lactose intolerant (cheese and yoghurt are less of a problem because when milk is fermented, lactose is converted to lactic acid) (Kretchmer 1993; see also K. David Patterson, chapter IV.E.6). Northern Europeans, by contrast, collectively constitute a lactose-tolerant enclave in a largely lactose-intolerant world, and, not incidentally, the point is made that white North Americans, whose ancestral homeland was northern Europe, are also able to tolerate milk and also suffer high rates of coronary artery disease (Seely, this work chapter IV.F.4).

One might then argue that in an evolutionary scheme of things, dairy products are newfangled: Allergies to cow's milk are common among children, and milk-based formulas can be deadly for infants (Fauve-Chamoux, this work chapter III.2). It may be true that lactose intolerance is Nature's way of preventing the consumption of much in the way of dairy foods that can calcify the arteries, and the heart attacks suffered by adult northern Europeans and their progeny in other parts of the world are the price of overcoming this trait. It is interesting to note that areas in Europe where oats are consumed are also those with the highest rates of coronary disease, and oats contain a great deal of calcium (Seely, this work chapter IV.F.4), which moves us to grains – the other "new" food group.

As with dairy products, it may be that humans are not well adapted to grains either. People with celiac disease – caused by the proteins in wheat and some other grains – most certainly are not. And perhaps significantly, this relatively rare genetic condition has its highest frequency in those regions that spawned the most recent major wheat-producing societies (see Donald D. Kasarda, this work chapter IV.E.2). Is it, therefore, possible that celiac disease is a holdover from earlier times, when the body evolved a mechanism to prevent the consumption of toxic wild grains? One trouble with such an argument, of course, is the need to explain how it was that the Neolithic Revolution ever got off the ground in the first place if people were genetically incapable – at least initially – of digesting the crops they grew.

One answer that has been proposed is that grains were not originally grown because of a need for food but, rather, because of a taste for alcohol (Katz and Voigt 1986; see also Phillip A. Cantrell, this work chapter III.1). It appears that barley-ale was being produced at least 7,500 years ago, and the records of the ancient Sumerians, for example, show that a staggering (no pun intended) 40 percent of their grain production went into brewing (Tannahill 1989). And ale making did precede bread making, so perhaps there was a time when grains were mostly for drinking, and only later was there a shift toward eating them.

The rise to prominence of grains that tended to narrow the diet – wheat in temperate Asia and Europe, rice in tropical and semitropical Asia, millet and sorghums in Africa, and maize in the Americas – was perhaps the most important factor in the previously mentioned decrease in human stature and significant deterioration of dental and skeletal tissues. This is because these so-called "super" foods are super only in the sense that they have sustained great numbers of people; they are far from super nutritionally. Almost all are poor sources of calcium and iron; each is deficient in essential amino acids, and each tends to inhibit the activities of other important nutrients (Larsen, this work chapter I.1, upon which the following paragraph also is based).

Rice, for example, inhibits the activity of vitamin A, and if its thiamine-rich hulls are pounded or otherwise stripped away, beriberi can be the result. The phytic acid in wheat bran chemically binds with zinc to inhibit its absorption, which, in turn, can inhibit growth in children. Zein – the protein in maize – is deficient in three essential amino acids, which, if not supplemented, can also lead to growth retardation; moreover, because the niacin contained in maize is in bound form, many of its consumers have suffered the ravages of pellagra. In addition, maize (along with some other cereals) contains phytates that act against iron absorption and also has sucrose, which – we are continually reminded – exerts its own negative impact on human health (significantly, dental caries were exceedingly rare in preagricultural societies). In short, it is arguable that humans may not be programmed for the newfangled grains either.

Much firmer ground, however, is reached with the assertion that humans are definitely not programmed for the quantities of sodium chloride many now take in. Even the most carnivorous of our ancestors, on an 80 percent meat diet, would have ingested less than half of the average per capita daily salt intake in the United States, and of course, excessive dietary salt has been linked with stomach cancer and hypertension, the latter disease a major contributor to heart attacks, kidney failure, and especially strokes. Modern-day hunting-and-gathering populations that consume little sodium (meaning amounts comparable to those of our hunter–gatherer forebears) suffer no hypertension – not even, it is interesting to note, the age-related increase in blood pressure that medicine has come to believe is "normal" (Cohen, this work chapter I.6).

In the case of sodium chloride, as in that of lactose absorption, western Europeans, once again, pioneered in the attempt to reprogram the Stone Age metabolism, although in this case they were joined by East Asians. All mammals normally consume less sodium than potassium, which complements bodily mechanisms that strive to conserve sodium, because the mineral is, after all, crucial to life itself. But not the Europeans – at least not after salt became an inexpensive commodity some 1,000 years ago. They preserved foods with salt, cooked them in salt, then added more salt at the table, with the result that over the ages, their bodies seem to have learned to some extent to rid themselves of sodium with brisk efficiency through urine and perspiration (Kiple 1984;

Eaton et al. 1988a; see also Thomas W. Wilson and Clarence E. Grim, this work chapter IV.B.7).

By contrast, it has been argued that those not of western European (and probably eastern Asian) ancestry and, thus, without a long history of heavy salt consumption, such as African-Americans (whose ancestral lands were poor in salt, whose ancestral cooking habits did not call for it anyway, and whose bodies seem still to treat the mineral as something precious to be conserved), are in considerable peril in cultures where sodium is routinely added at almost every step in food preservation, processing, preparation, and consumption (Wilson 1987; Wilson and Grim, this work chapter IV.B.7). Moreover, because potassium is progressively leached out during these procedures, people in affluent countries have now turned the Stone Age potassium-to-sodium ratio upside down and are consuming some 1.5 times as much sodium as potassium (see David S. Newman, this work chapter IV.B.6). Modern-day hunter-gatherers, by contrast, are said to have potassium intakes that exceed sodium by 10 times or more (Eaton et al. 1988a).

Another controversial, but fascinating, avenue of investigation traveled by some of the Darwinian thinkers has to do with iron, an essential mineral found in all cells in the body and a key component of hemoglobin, wherein can be found about 70 percent of all our iron. The remaining 30 percent is stored in the spleen, the liver, and especially in bone marrow, where it can be called upon as needed. Iron-deficiency anemia is the most common form of anemia worldwide and is especially prevalent in developing countries, where the diet is likely to contain little meat (from which iron is most efficiently absorbed) but much vegetable food (from which iron is poorly absorbed). Moreover, some dietary substances in vegetable foods, such as oxalic acid and tannic acid, actually interfere with iron absorption (Eaton et al. 1988a; Bollet and Brown 1993).

As a few of the authors in the present work point out, however, the presence of pathogens also affects iron levels, and the impact of this presence is more profound than that of dietary imbalance. Helminthic parasites, such as the hookworm, make their living on human blood and the iron it contains, and they frequently cause anemia when they prosper to the point that they become too many, taking too much advantage of a good thing (see Susan Kent, this work chapter IV.D.2; Kent and Patricia Stuart-Macadam, this work chapter IV.B.3; Nevin S. Scrimshaw, this work chapter VI.3).

What is of interest in addition to helminthic parasites, however, is a recently demonstrated and much more subtle interaction of iron and smaller parasites. Bacteria and viruses also need iron to multiply. To forestall such multiplication, or at least to slow it down, our bodies have developed the knack of reacting to pathogenic presence by drawing down the iron supply in the blood and putting it in storage – in effect, starving the pathogens – until the danger has passed, whereupon iron levels in the blood are permitted to rise again (Kent, this work chapter IV.D.2). But it would seem that only a small percentage of physicians are aware of this phenomenon, with the result that they may mistake bodily defenses for anemia and issue prescriptions for iron that can hurt the patients while helping the pathogens (Kent, this work chapter IV.D.2; see also Nesse and Williams 1994).

Moreover, studies in Polynesia, New Guinea, and West Africa have demonstrated that infants given iron have a much higher incidence of serious infectious diseases than those who are not given iron, and that discontinuing the administration of iron in itself lowers the incidence of infections. Thus, it is urged that health workers be reeducated to understand that, in many instances, the high incidence of anemia in the developing world does not mean a dietary failure that requires iron administration; rather, it means that an important bodily defense is at work, combatting high rates of parasitism (Nesse and Williams 1994; Kent, this work chapter IV.D.2).

In the developed world, the argument continues, the extent to which iron may be a threat to health is compounded, and the body confounded, by the indiscriminate and massive iron fortification of many cereal products and the regular use of iron supplements. This may be especially serious in countries like the United States, where elderly men and postmenopausal women have the highest incidence of anemia – which, it is contended, is really anemia defending against the chronic diseases to which these groups are most vulnerable, including neoplastic cells that, like pathogens, also need iron for multiplication. In addition, evidence is accumulating that high iron levels play a significant role in coronary artery disease (Kent, this work chapter IV.D.2).

Another recently recognized bodily mechanism that evolved with humans has to do with an unfortunately tenacious ability of the body to maintain a certain level of fat, even if it is an unhealthy level. A recent Rockefeller study (Leibel, Rosenbaum, and Hirsch 1995) indicates that the body has a preset level of fat that it strives to maintain by changing the efficiency with which it metabolizes food, so that it can either reduce or increase the amount of fat going into storage. What this means – to put the Rockefeller study together with the so-called thrifty-gene theory first advanced by the geneticist James Neel (1962) – is that those who try to lose weight seem to be up against Stone Age "thrifty genes" that probably evolved during the glacial epochs. Then, nutrition under harsh climatic conditions often would have been a matter of feast and famine, and individuals who, during times of feasting, could most efficiently store excess calories as fat to ride out famines would have enjoyed a considerable survival advantage over those lacking this ability (see Leslie Sue Lieberman 1993 and this work chapter IV.E.7).

Today, however, these thrifty genes are blamed directly for diabetes and gallstones and indirectly for all conditions in which obesity is a contributing factor. Apparently, here is another Stone Age mechanism that is troubling modern humans, particularly when today's diets give us calories in such compact forms that we can easily get more than we need before ever feeling comfortably full. It has been estimated that, in hunter-gatherer days, 5 pounds of food were required to provide 3,000 calories; today, 5 pounds of food may deliver upwards of 9,000 calories - some 3 times as many (Eaton et al. 1988a; Lieberman 1993).

Such a caloric conundrum presents an especially serious hazard to some groups of humans in transition. Studies of Native Americans, Australian Aborigines, Pacific islanders, and Alaskan Eskimos all have reported precipitous declines in health, suffered upon the abandonment of traditional diets and patterns of exercise (Lieberman 1993; Kunitz 1994). North American Indians, along with Polynesians, Micronesians, and native Hawaiians, have some of the highest rates of diabetes mellitus in the world. In sub-Saharan Africa, hypertension rates are rising alarmingly in the cities, where salt-laden prepared foods are replacing the foods of the villages. And coronary artery disease and hypertension are becoming commonplace in the Pacific, where just decades ago they were unknown (Wilson 1987; Lieberman 1993; Kunitz 1994; Draper, this work chapter VI.10; see also Nancy Davis Lewis, this work chapter V.E.3).

By way of concluding, it remains to be seen how much blame for current chronic diseases can be laid on Paleolithic nutritional adaptations. Another factor, of course, is that to some extent, humans have also been shaped by the requirements of more recent ancestors. Those who settled into cold and damp places, for example, chose diets that were rich and fatty and that helped build fat to insulate against the weather. In warm climates, where evaporating perspiration served to cool the body, strong herbs and spices that encouraged sweating were consumed; and much liquid was drunk to replace lost fluids. Today, central heating obviates the need for a fatty diet, and air conditioning reduces the need to sweat. But there are many dietary holdovers from those old days, too, that do humans no good and, in tandem with Stone Age genetic mechanisms, perhaps a great deal of harm. For example, it was not all that long ago that the author of a late-eighteenth-century cookbook picked a quarrel with a competing writer who called for 6 pounds of butter to fry 12 eggs. One-half that amount of butter was plenty, she primly assured her readers (Tannahill 1989).

Yet, hardly anybody wants to return to a hunting-and-gathering lifestyle. And although history sheds no light on an ideal diet, it does, in a way, defend those grains and dairy products that have just been examined and which, it can be argued, at least have been consumer tested for the past 8,000 to 10,000 years.

Nonetheless, what our authors and others have had to say on matters of Paleolithic nutrition has been well researched, well reasoned, and well received in many quarters. In other words, their work is not wild speculation, and their point, namely that natural selection has not had time to revise our bodies to cope with modern diets, is a good one. But about all Darwinian nutrition can actually do for us at this point is to remind us of the wisdom of moderation in food consumption and nutritional supplementation from yet one more perspective.

PART VIII

A Historical Dictionary of the World's Plant Foods

This final portion of the book is perhaps the most ambitious. It was initially conceived of as a dictionary of the exotic plants mentioned in the text, which our authors would otherwise be called upon to identify in their chapters and, in so doing, interrupt their narratives.

The expansion of Part VIII began when it was decided to include entries on *all* plant foods mentioned in the text and continued when it became apparent that the various fruits of the world do not lend themselves to generalized essays, because many have been mostly seasonal items in the diets of relatively few – and often unrelated – people. For example, the ancient Malaysians ate the "Java apple" (*Eugenia javanica*) when it was ripe, whereas, on the other side of the world, Native Americans of Brazil did the same with their "pitanga" (*Eugenia uniflora*). The plants that produce these two fruits are both in the same genus of the family Myrtaceae, but there is little that historically connects their human consumers (unlike the consumers of maize or wheat or potatoes). Thus, save for a few staples (bananas and plantains, for example), fruits really did not seem to belong in the earlier parts of the work dealing with staple foods, and when it was decided to treat fruits in individual dictionary entries – and not as botanical families, or even, as a rule, as genera – there seemed no question that these entries should be included in Part VIII.

More expansion ensued when our students, researching the gathered foods mentioned in a number of the chapters (such as those dealing with hunters and gatherers, early North America, the ancient Near and Middle East, and Australia and New Zealand), began making their own discoveries of gathered foods not covered in those chapters. These were subsequently included as entries in the dictionary, with the result that Part VIII also offers a glimpse of the myriad wild foods that sustained our hunting-and-gathering ancestors during almost all of humankind's time on earth – a glimpse of especial interest to those of us whose diets are generally limited to a relatively few commercialized plant foods. Among other things, these dictionary entries might be viewed as collectively questioning the wisdom of the progressive limiting of viand variety in the human diet that began with the invention of agriculture.

A final effort, which also expanded the size of Part VIII, was an attempt to include as many as we could identify of the common names (and synonyms) for food plants in English (and some in other languages). We hope that this labor will help researchers in sorting out items mentioned in the world's various spice trades; others who might find it useful to know that words like "colewort" (in Old English texts) would today mean cabbage (with "coleslaw" a reminder of the earlier name); and still others who might be interested to learn, for example, that "pigweed" can mean amaranth, goosefoot, lamb's-quarter, purslane, *quelites,* and quinoa (which in turn is also "quinua" and begins another long list of common names).

We have, in addition, attempted to provide something of the history of the more than 1,000 plant foods treated in Part VIII whenever such information was available. However, much of such history remains speculative, because although individual species may have evolved in discrete locations, many plants were moving across continents and even oceans – on their own or with human help – long before the dawn of recorded history.

Plant names constitute perhaps the single most daunting obstacle to an enterprise like Part VIII. Obviously, different languages and cultures have assigned their own common names to plants, so that well-traveled plants will generally have a host of them, and much-used names may well refer to multiple plants – as the previously mentioned example of "pigweed" illustrates. Scientific names – generally Latinized botanical terms drawn from Greek and Latin – were intended to remedy this problem so that at least the scientific community concerned with plants could speak the same language despite differences in plants' common names. But languages change, and change can be vexing. Disagreements about classification mean that equivalents are frequently used in the realm of scientific names designating genus and species (we indicate this with an equals sign [=] whenever we have turned up the information). Illustrative are some plants of the genus *Eugenia* that have also been assigned to the genus *Syzygium,* so that, for example, the fruit with the common name "rose apple" is both *E. jambos* and *S. jambos.* In addition, new scientific names may have come into use that were not employed by the sources we consulted. It was only at the last minute, for example, that we became aware that *Lens culinaris* was now an acceptable designation for lentils, previously called *Lens esculenta* (hence, *Lens esculenta* = *L. culinaris*). We have dealt as best we could with such taxonomic tribulation, but because we are not botanists, we have doubtless misunderstood, misinterpreted, and mistreated such information at various points, and for this we apologize.

Virtually all of the entries in Part VIII were written "in-house" by the editors, with plenty of research help from the members of our staff, led by Stephen V. Beck, all of whom are credited in the work's general acknowledgments. At this point, however, we would like to acknowledge and thank Charles B. Heiser, who contributed the entry on the "Jerusalem Artichoke," and Jeffrey M. Pilcher, who wrote some of our Mesoamerican entries. Both of these scholars also made contributions elsewhere in this work, and we are most grateful for their extra effort.

A

Abalong – *see* **COCOYAM**

Abata kola – *see* **KOLA NUT**

ABIU – A native of lowland South America, the abiu (*Pouteria cainito*) is a relative of the sapodilla, the mamey sapote, and the canistel. The abiu is a small yellow fruit, which grows on a tree that can reach upward of 30 feet in height. Like its better-known relatives, the abiu contains a sticky latex within its skin. Although the fruit is appreciated locally, it is generally not commercially exploited in its homeland; however, some varieties that have been introduced into South Asia and Australia reportedly have commercial possibilities.

Abóbora – *see* **CALABAZA (SQUASH)**

Abyssinian banana – *see* **ENSETE**

ACACIA – There are a number of species of (chiefly tropical) trees belonging to the genus *Acacia,* with some (especially *A. senegal*) exuding from their trunks a gum – called "gum arabic" – that has a wide variety of commercial uses, including many in food manufacturing and processing. In much of the tropical world, the gum as well as the leaves, pods, and seeds of acacia trees have food uses. The pods and seeds are dried and ground into a flour used for bread-making. In Mexico, the pods of the prairie acacia (*A. angustissima*) were consumed by Native Americans, as were those of the catclaw acacia (*A. greggii*) in what is now the southwestern United States. Acacia has a multitude of other names, including "wattle," "mimosa," and "Egyptian thorn."

Common names and synonyms: Catclaw acacia, Egyptian thorn, mimosa, prairie acacia, wattle(s).

ACEITUNA – Also called "olivo" and "paradise tree," the aceituna (*Simarouba glauca*) is a tree native to tropical America. It is prized for its oil seeds and for its edible fruit pulp, which is normally eaten raw. The aceituna is found in most produce markets of Central America, especially in El Salvador, where the trees are grown commercially. In addition to Central America and Mexico, the tree can be found throughout the Caribbean region, in Florida, and in Hawaii.

Common names and synonyms: Olivo, paradise tree.

ACEROLA (*see also* **CHERRY**) – Also known as the "Barbados cherry" and the "West Indian cherry," the acerola is so called because of its supposed resemblance to the Mediterranean azarole. The original habitat of the best-known species of acerola (*Malpighia glabra*) included the Caribbean region, southern Texas, Mexico, and Central America; today, however, it can be found in South America and throughout the southern United States as well. The fruit is borne on thick, quick-growing bushes and trees that reach from 6 to 25 feet in height. With its small size and bright red coloring, it bears a superficial resemblance to a cherry. Unlike a cherry, however, the acerola contains three seeds and has vertical grooves in its skin. Rich in vitamin C, the unripe acerola far surpasses all other fruits as a source of this nutrient, containing an incredible 20 times the ascorbic acid of an orange. Too tart for consumption as a fresh fruit, it finds many uses in the preparation of jellies, jams, preserves, and baby foods (in combination with other fruits to increase the amount of vitamin C), as well as in the pharmaceutical industry.

Common names and synonyms: Barbados cherry, *huesito,* Surinam cherry, West Indian cherry.

Acha – *see* **FONIO**

Achee – *see* **ACKEE**

Achiote – *see* **ANNATTO**

ACHIRA – Plants of the genus *Canna* are most often cultivated for ornamental use. The fleshy rhizomes of the achira (*Canna edulis*), however, produce a yellow starch that has long been a foodstuff consumed in the Andean region. It probably originated in the area that is now Peru, where remains of the plant – dating back to 2500 B.C. – have been excavated. Today, *C. edulis* is grown and marketed for human consumption in an area ranging from Chile to Venezuela in South America, on some islands in the Caribbean, to a lesser extent in Java and northern Australia, and, finally but not least, in Vietnam, where, during the past three decades, large areas have been devoted to its cultivation in order to make the highly prized transparent noodles that are an indispensable part of that country's cuisine. The plant has also been cultivated in subtropical Hawaii as a feed for cattle and pigs.

Common names and synonyms: Australian arrowroot, canna, gruya, Queensland arrowroot, *tous-les-ois.*

Achis – *see* **AMARANTH**

Achita – *see* **AMARANTH**

Achokcha – *see* **KORILA**

Achotillo – *see* **SOUARI NUT**

ACKEE – A West African plant, the ackee (*Blighia sapida*) reached the West Indies during the latter part of the eighteenth century and spread from there to most of tropical America. Some have credited its introduction to Captain William Bligh (hence the genus name *Blighia*), but most agree that it reached the Caribbean aboard slave ships. In fact, the presence of ackee in Jamaica has been dated from 1778, when the first known ackee slips were purchased from the captain of a slave ship by a local physician/botanist. In any event, the plant's introduction was a welcome one, as it occurred during a period in which warfare and hurricanes had triggered a desperate search for new foodstuffs for the slaves on English plantations. The large, shrublike ackee tree grows almost anywhere in the tropics, bears red- or orange-colored fruits in its fourth year, and will then bear fruit twice a year for the next half century or so. Despite the tree's West African origin, the main focus of ackee cultivation, consumption, and exportation today is in the West Indies. When cooked, the fruit has an appearance and taste that have been compared to those of a fine omelette – or brains (a nickname is "vegetable brains"), depending on the point of view. The classic use of ackee is in its famous gastronomical marriage with salted codfish. The fruit, which splits open when ripe, consists of pink pods, black seeds, and a fluffy yellow pulp. Only the yellow pulp is edible, however; the pink tissue contains a toxic peptide. All unopened (and thus unripe) ackees are toxic. Historically, this toxicity has been responsible for a number of deaths among Jamaican children, who ate fallen fruit picked up from the ground. Because of its potential danger to the unwary, ackee is generally only available in cans outside of the regions where it is grown. The fruit is a good source of beta-carotene and vitamin C.

Common names and synonyms: Achee, akee, vegetable brains.

ACORN – Technically, an acorn is the fruit of any oak tree (genus *Quercus,* of which there are some 400 to 500 species). The oak is native to all the continents except Australia, and edible acorns may be found in Europe and Asia as well as in North America. Yet even the so-called sweet acorns have a high content of tannic acid, meaning that all acorns are best leached and roasted before eating. In North America, sweet acorns from the white oak (*Q. alba*) have been the most popular. Today, acorns – which constitute an annual crop larger than all other nut crops put together – constitute a vastly underexploited resource that is utilized mostly as feed for hogs. In the past, however, acorns have been a staple food for many people (they were doubtless among the wild foods that humans gathered over many millennia), and they are still widely eaten in southern Europe. In North America, acorns sustained many Native American groups, who exploited some 20 species and ground the nuts to make breads and porridges, thereby supplementing diets composed largely of smoked fish and meat. Throughout the Middle Ages and since, acorns have been extensively used for meat production, and hogs were annually herded into forests during the oak mast. Acorns entered the diets of the first Europeans to reach North American shores, and during the Civil War, when blockades and wartime conditions in general made coffee scarce, ground acorns were discovered to be a serviceable substitute. Very sophisticated methods of employing acorns can be found in the areas around the Mediterranean from Turkey to Spain, as well as in Japan. The nuts have a high carbohydrate content and are relatively high in protein. It is interesting to note that some acorns are technically (and correctly) referred to as "beechnuts."

Common names and synonyms: Beechnut.

ACORN SQUASH (*see also* **SQUASH AND PUMPKIN**) – An American native – and one of the most familiar squashes in North America – the acorn squash (*Cucurbita pepo*) is so called because it is shaped something like an acorn. It is a winter squash with a hard, ridged rind which makes it difficult to peel, but it is easily cut in half for stuffing and is excellent for baking. The acorn squash has a mild, nutty flavor and delivers a good deal of calcium but (in view of its orange-colored flesh) surprisingly little beta-carotene.

See in addition: "Squash," Part II, Section C, Chapter 8, and "Squash and Pumpkin" in this section.

Adam's-needle – *see* **YUCCA**

Adlay millet – *see* **JOB'S-TEARS**

Advance – *see* **LOQUAT**

Adzuki bean – *see* **AZUKI BEAN**

Aerial yam – *see* **AIR POTATO**

African bitter yam – *see* **BITTER YAM**

African horned cucumber – *see* **KIWANO**

African horned melon – *see* **KIWANO**

AFRICAN LOCUST – The genus *Parkia* – named for Mungo Park, the famous late-eighteenth-century explorer of West Africa – is comprised of a number of leguminous trees of tropical Africa. Among them is the African locust (*Parkia africana*), which has pods containing edible seeds that are generally roasted. A close relative is *P. biglandulosa,* which bears very rich seeds that are usually boiled and made into cakes.

AFRICAN LOCUST BEAN – A tall tree of the West African tropics, the African locust bean (*Parkia filicoidea*) has leaves that are cooked and used as a vegetable. When the seeds are ripe, they are considered by some to be an aphrodisiac. The seeds are also pressed for a cooking oil.

African pumpkin – *see* **OYSTERNUT**

AFRICAN RICE (*see also* **RICE**) – African rice (*Oryza glaberrima*) is one of the two cultigens of the genus *Oryza.* The other, of course, is common or Asian rice. Although the two are similar in many respects, the latter has been far more successful in terms of consumer appeal and as a market commodity of global proportions.

It has been theorized that *O. glaberrima* was domesticated from the wild annual *O. barthii,* which grew in the flood basin of the central Niger delta, and that cultivation of the crop was under way as early as 3,500 years ago. From the Niger delta, it was introduced into other parts of West Africa, where farmers further developed the grain into diverse cultivars that could thrive in deepwater basins, water holes in savannas, forest zones, swampy areas, or dry highlands.

African rice, like its better-known relative, is an outstanding source of energy and important vitamins and minerals. It surpasses whole wheat and maize in terms of protein, is devoid of cholesterol, and is low in sodium and fat. Most varieties have a reddish color, which is perhaps one of the reasons that the more polished, white, Asian types have largely replaced *O. glaberrima* – even in regions where for many centuries it was both an important component of cherished rituals and an essential food. Another reason is that the Asian types of rice are more easily produced, harvested, and milled. Those who continue the cultivation of African rice are generally small-scale farmers, frequently in remote areas, who prefer the grain's distinctive taste, aroma, and coloring; consequently, the crop is grown mostly for local use. Such cultivation occurs on the "floating fields" of the flood plains of Nigeria, in Mali on the Niger's inland delta, and, to a lesser extent, on the hills near the Ghana–Togo border and in Sierra Leone.

African rice is prepared in the same manner as Asian rice, but traditional African uses include fermenting the grain to make regionally popular beers, as well as converting it to flour to make a variety of baked goods. The rice also still figures prominently in a number of West African rituals.

See in addition: "Rice," Part II, Section A, Chapter 7.

African spinach – *see* **AMARANTH**

African tea – *see* **KHAT**

AFRICAN YAM BEAN – Also known as the "wild yam bean," the African yam bean (*Sphenostylis stenocarpa*) is cultivated in West Africa and equatorial Central Africa and grows wild in the African tropics. The pods, seeds, and tubers of the African yam bean are all eaten, and its leaves are cooked as a vegetable.

Common names and synonyms: Wild yam bean.

AGAR (*see also* **SEAWEED**) – Called "agar-agar" in the past, agar is a gelatin obtained from seaweed – especially seaweeds belonging to the genera *Euchema* and *Gelidium.* It has reportedly been used in China since A.D. 300, and perhaps somewhat later in Japan (where it is called *kanten*). Many kinds of jellied sweets that are sold in tropical Asia retain their firmness because of agar, which is employed to thicken other foods as well. Agar also finds its way into vegetable dishes and salads and, in addition, has a number of medical uses.

Common names and synonyms: Agar-agar, *kanten.*

See also: "Algae," Part II, Section C, Chapter 1.

Agar-agar – *see* **AGAR, LAVER, SEAWEED**

Agati – *see* **SESBAN**

AGAVE – Any of numerous American plants of the genus *Agave* go by this name as well as "maguey" or "century plant." The latter term implies longevity and is the name of one variety (*A. americana*) that is common in the deserts of northern Mexico and the southwestern United States. This plant flowers only after 20 to 30 years of life, and then dies. Agaves are evergreens with fleshy, lance-shaped leaves. They were used as food by Native American peoples, who roasted the leaves and grilled the "heart" of the plant. In fact, remains found in the caves of Tehuacán indicate that agave was already an important food source by 6500 B.C. The 2-meter-long leaves also served as shelter material and as fuel, but perhaps the most common use of the plant was the fermentation of the sweet liquid that accumulates inside (up to 1,200 liters in a single plant) to make a thick alcoholic beverage called *pulque.* Later, the fermented juice was distilled by Spanish settlers to make *mescal* and tequila. Current Mexican law stipulates that tequila must be made from blue agave plants (*A. tequilana*) grown in the state of Jalisco, where the town of Tequila is located. The agave worm (also called the maguey worm or *gusano*) was formerly added to bottles of tequila to provide a measure of quality and potency – a weak alcohol content allowed the worm to rot. Nowadays, however, the outrageous prices offered for *gusanos* have forced small distillers to substitute slivers of maguey or sugarcane.

Common names and synonyms: Blue agave, century plant, maguey.

Agnus castus – *see* **CHASTE TREE**

Aguacate – *see* **AVOCADO**

Ague bark – *see* **HOPTREE**

Aguweed – *see* **BONESET**

Ahipa – *see* **AJIPA**

Ahuacatl – *see* **AVOCADO**

Ahuyama – *see* **CALABAZA (SQUASH)**

Aibika – *see* **SUNSET HIBISCUS**

Airelle de myrtille – *see* **CRANBERRY**

AIR POTATO (*see also* **YAMS**) – A native of South Asia that later spread to the South Pacific region and is now cultivated throughout the world's tropics and subtropics, the "air potato" (*Dioscorea bulbifera*) is also called the "potato yam" and the "aerial yam." Its name derives from the fact that its edible, potato-like tubers do not all form underground; instead, many are produced at the junction of the leaves and the stem of this tall, climbing herb.

Common names and synonyms: Aerial yam, potato yam.

See in addition: "Sweet Potatoes and Yams," Part II, Section B, Chapter 5.

Aiwain – *see* **AJOWAN**

AJÍ (*see also* **CHILLI PEPPERS**) – This chilli pepper (*Capsicum baccatum*) is of the Andes region of South America, where it is understandably known as *ají* because (in western South America and the West Indies) the word *ají* means chilli. The pepper called *ají* is – at least when fresh – a thin, tapered chilli, some 3 to 4 inches in length, with green or red flesh, which provides considerable heat for salsas and cooked dishes. When dried, the pepper is known as *ají mirasol* or *ají amarillo,* because its ripe red color turns yellowish. In this form, the pepper is used in a variety of sauces and also to make *ceviche* in Peru. Another pepper called *ají* is *ají panca,* a mild pepper that dries to a chocolate brown color and is used to make chilli sauces and various cooked dishes – generally featuring fish.

Common names and synonyms: Ají amarillo, ají mirasol, ají panca.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Ají amarillo – *see* **AJÍ**

AJÍ DULCE (*see also* **CHILLI PEPPERS**) – In western South America and the Caribbean, the word *ají* frequently connotes all chilli peppers – and *dulce* would seem to suggest a sweet pepper. But this member of the genus *Capsicum* (*C. chinense* Jacq.) is not the mild-mannered chilli pepper its name implies. Rather, it is an aggressive Venezuelan relative of the fiery habanero pepper (also of the species *C. chinense*), which it resembles somewhat in shape, although it is quite a bit larger.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Ají mirasol – *see* **AJÍ**

AJIPA (*see also* **LEGUMES**) – Like jícama, ajipa (*Pachyrhizus ahipa*) is a legume that develops swollen roots. Also called a "yam bean," it is unknown outside of South America, where it was grown by ancient Native Americans. The white tubers are often eaten raw in salads, to which they add a crispness and a sweet taste. The tubers are also boiled or steamed like potatoes.

Common names and synonyms: Ahipa, yam bean.

Ají panca – *see* **AJÍ**

AJOWAN – A native of southern India, ajowan (*Carum ajowan*) is also grown in an area that extends westward from Afghanistan, across Iran, and into Egypt – and doubtless has been for thousands of years. Although its whole or ground seeds have a taste similar to that of thyme, the plant is actually related to caraway and is used in much the same way as the latter in breads and pickles and with legumes.

Common names and synonyms: Aiwain, ajwain, bishop's-weed, *omam, omum.*

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Ajwain – *see* **AJOWAN**

Aka-suguri – *see* **CURRANT(S)**

Akee – *see* **ACKEE**

Alcachofa – *see* **ARTICHOKE**

Alecost – *see* **COSTMARY**

ALEXANDER – There are a number of plants called alexander, alexanders, or alexander buds. One is *Smyrnium olusatrum* – a European plant with the name of "alexanders" that resembles celery and was cultivated in the past as a potherb. Alexanders is also a name that was applied in the past to various members of the parsley or carrot family (Umbelliferae). Finally, alexanders can mean any plant of the genus *Zizia,* especially golden alexanders (*Z. aurea*), a native of eastern North America. This plant has yellow flowers and can be found in moist woods and meadows. The young umbels of the flowers were eaten by Native Americans just as they began to bud.

Common names and synonyms: Alexander buds, alexanders, golden alexanders.

Alexander buds – *see* **ALEXANDER**

Alexanders – *see* **ALEXANDER**

ALFALFA – A native of Eurasia, alfalfa (*Medicago sativa*) is a tall, cloverlike plant belonging to the pea family. It is now grown in North America (frequently as a cover crop to reduce erosion) and used for fodder. Its other uses are also mostly nonculinary:The fiber is employed in the production of paper; the drying oil derived from the seeds goes into paints; and the plant is a commercial source of chlorophyll. After the introduction of alfalfa into the New World, its tiny seeds were consumed by some Native American groups and are still used for sprouting by many concerned with health foods. The seeds are high in the minerals calcium, magnesium, and potassium, and the leaves (also edible) are high in vitamins A, C, D, E, and K.

Common names and synonyms: Lucerne, sativa.

Algae – *see* **SEAWEED**

Algarroba – *see* **ALGARROBO, CAROB, MESQUITE**

ALGARROBO – A native of Peru and Ecuador, the algarrobo (*Prosopis pallida* – also called "algarroba") is a tree that has been naturalized in Puerto Rico and Hawaii (where it is called "kiawe"). Its sweet pods are made into a syrup used in various drinks. The algarrobo blanco (*Prosopis alba*), which is found in subtropical Argentina, Uruguay, Paraguay, and southern Brazil, has pods that have been toasted to make a coffee substitute and are also used to make other beverages as well as flour.

Common names and synonyms: Algarroba, algarrobo blanco, ibope, igope, kiawe, tacu, white algarrobo.

ALICANTE BOUSCHET (*see also* **GRAPES**) – A cross between Grenache and Petite Bouschet, the Alicante Bouschet grape (*Vitis vinifera*) is deep purple in color with a thick skin. The latter attribute made these grapes extremely popular during the days of Prohibition in the United States, because they could withstand rough handling when shipped to the homes of aspiring private wine makers. The Alicante Bouschet is used primarily for blending.

See in addition: "Wine," Part III, Chapter 13.

ALKANET – A European plant, alkanet (*Alkanna tinctoria*) yields a dye from its roots that is used to color some cheeses and improve the color of inferior ports and other wines.

Alligator pear – *see* **AVOCADO**

Allouya – *see* **GUINEA ARROWROOT**

ALLSPICE – Unlike most spices (which are indigenous to the tropics of southern China, southern India, and the East Indies), allspice (*Pimenta dioica*) is a berry of the New World, native to the West Indies and Central America. A member of the myrtle family, allspice was used by the Taino and Carib Indians (and quite possibly also by those of the Mesoamerican mainland) long before the Europeans reached the Americas. The small, aromatic, tropical tree and its berries were among the many early "discoveries" of Spanish explorers, who mistook the pea-sized berries for peppercorns. In fact, even today the Spanish word *pimenta* refers to allspice. The Spaniards introduced the spice into Europe in the sixteenth century, and in both whole and ground forms it has subsequently become a part of the cuisines of many peoples across the globe. Allspice, which begins as a purple berry but turns brown when sun-dried, acquired its English-language name because of its versatility: Its taste is like a combination of nutmeg, cinnamon, and clove. It is best in sweet and savory dishes and is used frequently in mulled wines and for pickling, not to mention in fruitcakes and spice cakes. Commercially, allspice is important in the production of catsup, sauces for meats, sausages, and cured meats. Today, allspice remains American – it is grown exclusively in the Western Hemisphere, especially in Jamaica (where it still thrives in the wild). That island, with its limestone soils, is the biggest allspice producer, and the Jamaicans also use the berries to make a kind of rum.

Common names and synonyms: Jamaica pepper, myrtle pepper, *pimenta,* pimento.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

ALMOND (*see also* **CUDDAPAH ALMOND, JAVA ALMOND, MALABAR ALMOND**) – Almonds are the fruit seeds of *Prunus dulcis* (formerly *P. amygdalus*) = *Amygdalus communis*, a tree closely related to the peach and the plum, and are said to be native to the Mediterranean region and western Asia, where (like many other wild nuts) they doubtless helped to sustain our hunting-and-gathering forebears. Perhaps the oldest, as well as the most widely known, of the world's nut crops, almonds were first cultivated in Europe by the Greeks, are mentioned frequently in the Old Testament, and were a favorite of the Romans, whose sugared almonds may have been among the first sweetmeats in history. Recipes incorporating almond "flour" date from the Middle Ages in Europe, a period when almond "milk" was also used – as a liquid substitute for milk and eggs on days of fasting. The Spaniards brought the almond to the New World, where it is now grown extensively in California, and that state has joined Spain and Italy as a leading producer of the most important nut in the world nut trade. There are two types of almonds: sweet and bitter. Nuts of the latter type contain prussic acid and thus are toxic when raw; these must be blanched and roasted before being processed into an oil, a paste, or an extract that is used to flavor liqueurs and some confections. Sweet almonds, by contrast, are eaten whole, as well as blanched, slivered, chopped, diced, and ground for pastries and for meat and vegetable dishes. Almond paste is the soul of macaroons and marzipan. An almond tree will bear nuts for a half century or more, producing between 25 and 40 pounds annually. Almonds contain more calcium than any other kind of nut and are also a source of the B vitamins and vitamin E. They provide a small amount of protein and are high in fat.

ALOCASIA (*see also* **TARO**) – As members of a genus belonging to the family Araceae, *Alocasia* species are related to taro (*Colocasia esculenta*). These plants are cultivated in tropical areas throughout Asia, and their roots are starchy and nutritious. The "giant taro" or "giant alocasia" (*A. macrorrhiza*) and the "Chinese taro" (*A. cucullata*) have tubers that are eaten as cooked vegetables, whereas *A. indica* is used in Indian curries.

Common names and synonyms: Ape, Chinese taro, elephant-ear plant, giant alocasia, giant taro, *pai.*

See in addition: "Taro," Part II, Section B, Chapter 6.

Alpine strawberry – *see* **WILD STRAWBERRY**

Alverja – *see* **PIGEON PEA**

AMALAKA – Also known as "emblic," the amalaka (*Phyllanthus emblica*) is a large tree, native to Malaya but cultivated throughout South and Southeast Asia and now grown in Puerto Rico as well. It produces small, walnut-sized, green-to-yellow fruits, which are sour and are generally used for jams, pickles, and chutneys. The fruits are very high in vitamin C.

Common names and synonyms: Amalaki, emblic, Indian gooseberry, Malacca tree, myrobalan.

Amalaki – *see* **AMALAKA**

Amarante – *see* **AMARANTH**

AMARANTH (*see also* **CHENOPODIUM, CHINESE AMARANTH**) – Hernando Cortés, the Spanish conqueror of Mexico, prohibited the cultivation of the amaranth grown in Mesoamerica (*Amaranthus hypochondriacus* and *A. cruentus* – a third species, *A. caudatus,* was cultivated in the South American Andes) because it was used for religious as well as culinary purposes. The result is that this legendary plant of the Aztecs, which they called *huautli,* has only recently been rediscovered by the West, although it has long been grown in India and tropical Africa – in fact, in most of the world's tropical areas – and the Mexican descendants of the Aztecs have continued its cultivation on their *chinampas.* Because the tiny, usually yellowish (but sometimes red) amaranth grains do not come from a member of the grass family, they are technically not grains at all. Rather, the plant is a member of the chenopod family – related to lamb's-quarter and tumbleweed – and grows well (to about 6 feet in height) in hot and sunny locations. But whether it is a weed or not, the sesame-like amaranth seed, with its pleasant nutty flavor, is packed with calcium, magnesium, and iron, delivers a considerable amount of folacin and riboflavin, and has a high protein content. In addition to the seeds, the leaves are also eaten (much like spinach) wherever amaranth is extensively cultivated. Amaranth seeds are usually boiled and eaten as a porridge or used as an ingredient in soups and stews. In addition, they can be popped and used to make *alegría,* a popular sweet in Mexico. Amaranth sprouts are also good to eat.

Common names and synonyms: Achis, achita, African spinach, amarante, *bledos,* bondue, bush greens, *ckoito, coimi, coyo, cuime,* green leaf, *huautli,* Indian spinach, Joseph's-coat, kiwicha, livid amaranth, love-lies-bleeding, *millmi,* pale-seeded amaranth, pigweed, princess-feather, purple amaranth, quintonil, redroot, spinach-grass, Surinam spinach, wild beet, wild blite.

See in addition: "Amaranth," Part II, Section A, Chapter 1.

Amarelle – *see* **CHERRY**

Ambarella – *see* **GOLDEN APPLE**

Amber – *see* **AMBERSEED**

AMBERCANE (*see also* **SORGHUM**) – Grown especially in South Africa, ambercane (*Sorghum dochna* or *S. bicolor*) is a grain crop much like millet and is used in much the same manner.

See in addition: "Sorghum," Part II, Section A, Chapter 9.

AMBERSEED – Also called "ambrette" and "musk seed," amberseed is the seed of the abelmosk (*Hibiscus Moscheutos*), which is a bushy herb. Native to tropical Asia and the East Indies, amberseed has long been used as a flavoring in coffee and in perfumery.

Common names and synonyms: Amber, ambrette, musk seed.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Ambrette – *see* **AMBERSEED**

American angelica – *see* **PURPLESTEM ANGELICA**

American beech (tree) – *see* **BEECHNUT**

AMERICAN BITTERSWEET – Also known as "false bittersweet," "climbing bittersweet," and a host of other common names, American bittersweet (*Celastrus scandens*) is a woody vine that grows on trees and fences. It has clusters of greenish flowers and a yellow fruit in the form of a yellow capsule, neither of which is edible – in fact, the entire plant is toxic. But the twigs and inner bark were used as food by Native Americans, who discovered that boiling eliminated the poison.

Common names and synonyms: Bittersweet, climbing bittersweet, false bittersweet. American black walnut – *see* **WALNUT**

American horsemint – *see* **BEE BALM, BERGAMOT**

AMERICAN LINDEN – Also called "basswood" and other common names, the American linden (*Tilia americana*) is a forest tree that is especially common in mountainous terrain from Canada to Georgia. Native Americans harvested its sap for a beverage and ate its inner bark. The young leaves can be made into a salad, cooked as a vegetable, and added to soups and stews. The red berries of the tree are also edible, making it a year-round food source.

Common names and synonyms: Basswood, linden, whitewood.

American mandrake – *see* **MAYAPPLE**

American storax – *see* **SWEET GUM**

American styrax – *see* **SWEET GUM**

American taro – *see* **MALANGA**

American wormseed – *see* **EPAZOTE**

Amra – *see* **HOG PLUM**

ANAHEIM (*see also* **CHILLI PEPPERS**) – This member of the genus *Capsicum* (*C. annuum*) is named for the city of Anaheim, California, where the pepper was first grown at the beginning of the twentieth century. Another name, "California chilli," honors its home state. It is actually, however, a "New Mexican chilli," which is another of its aliases, along with "long green chilli" and "long red chilli." The Anaheim is a relatively mild pepper (although some can be hot), is frequently seen in produce markets, and is one of the most commonly used peppers in the United States. As its various names imply, the Anaheim pepper is green while still maturing and red after it has matured. It is eaten in both forms (the red is the sweeter of the two), is often roasted or pickled, and – when stuffed – is the star of the Mexican classic *chillis rellenos.* Anaheims are also dried and made into a powder called *chilli colorado.* A *pasado* is a red Anaheim that has been roasted, peeled, and dried.

Common names and synonyms: California chilli, Chile Colorado Anaheim, Chile Verde Anaheim, *chilli colorado,* long green chilli, long red chilli, New Mexican chilli, *pasado,* Red Chile Anaheim.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Anana – *see* **PINEAPPLE**

Anana del monte – *see* **POSHTE**

Ananás – *see* **PINEAPPLE**

Ananas de Mexico – *see* **MONSTERA**

Anato – *see* **ANNATTO**

Ancho – *see* **POBLANO**

ANDEAN LUPIN (*see also* **BEANS, LEGUMES**) – Known also as the "South American lupin" and "lupino," as well as a number of other names such as *chocho* and *tarvi,* the Andean lupin (*Lupinus mutabilis*) is a leguminous plant with large seeds (as a rule, bigger than lima beans) that served as food for ancient, pre-Incan peoples of the central Andean region. The Andean lupin is still widely cultivated there, even though the seeds contain alkaloids that must be leached out by a complex procedure. As with so many other poisonous plants, one can only wonder how the Andean lupin ever came to be widely used – or even used at all. The seeds are rich in protein and oil, are used in soups and stews, and can be made into a flour.

Common names and synonyms: Chocho, lupino, South American lupin, *tarvi.*

ANEMONE GREENS – Some greens from plants of the genus *Anemone* are used for food and medicinal purposes. The leaves of *A. flaccida* are eaten in Japan and China, whereas Eskimos eat the leaves of *A. narcissiflora* raw, fermented, or in oil. The crushed leaves of *A. hepatica* yield anemone camphor, which is used as a tonic. × *A. hupehensis* Hort. Lemoine var. *japonica* is cultivated in China for its roots, which are believed to be useful in treating heart disease. When collected during flowering, the dried plant *A. patens* is used to increase appetite and restore digestion.

ANGELICA (*see also* **PURPLESTEM ANGELICA**) – One of the tallest growing of the herbs, angelica (*Angelica archangelica*) provides stems as well as roots and leaves that are boiled and eaten as a vegetable. Angelica has a long history of use for medicinal purposes – indeed, its name (Latin for "angel") was assigned because of its healing properties. Angelica was one of the so-called scurvy grasses that were thought either to drive the disease away or to keep it at bay, and (until well into the twentieth century) after long winters, Icelanders dug up the roots to cure their bleeding gums. Today, oil from the roots and seeds is used for flavoring liqueurs, and the herb is used mostly in candied form. The stems are crystallized with sugar and employed in fruitcakes, as a flavoring in jams, and as a decoration for pastries.

Common names and synonyms: European angelica, garden angelica, Japanese angelica, scurvy grass, wild angelica.

Angel's-trumpet – *see* **MOONFLOWER**

ANGLED LUFFA – Also called "Chinese okra" because it is shaped like okra, the angled luffa (*Luffa acutangula*) is a dark green cucurbit native to India and has been grown (often on trellises) for many thousands of years for its tasty young fruits (the mature fruits become bitter). It is used mostly in China as a vegetable. Another more fibrous species, *L. aegyptiaca,* is dried and its fibrous skeleton used as a sponge. The United States is a major consumer of luffas and imports millions each year. But although it is called the "sponge gourd," *L. aegyptiaca* is also a food, and its flowers, buds, leaves, and young fruits are all eaten.

Common names and synonyms: Chinese okra, loofah, smooth loofah, sponge gourd, vegetable sponge.

ANGOSTURA – The bitter and aromatic bark of either of two Brazilian trees (*Galipea officinalis* and *Cusparia trifoliata* = *C. febrifuga*) is used to make a tonic called "angostura," named after a river town in Venezuela that is now called Ciudad Bolívar. "Angostura" is also the name of a proprietary brand of bitters made in Trinidad.

Common names and synonyms: Bitters.

ANISE (*see also* **CICELY, FENNEL, STAR-ANISE, SICHUAN PEPPERCORN**) – Also called aniseed, anise (*Pimpinella anisum*) is a native of the Mediterranean region (it grows wild in Greece and Egypt) and is one of the oldest of the spices. Anise was used by the ancient Greeks, Romans, and Hebrews, who viewed it as a powerful medicine, and today is grown in an area extending from southern Russia across South Asia, as well as in Mexico. Anise is a relative of dill, chervil, coriander, and cumin and has a licorice-like taste (after the seeds are dried) that is used to flavor liqueurs such as the Pernod of France, the ouzo of Greece, the anisette enjoyed in Spain, and the arrack of the eastern Mediterranean. Oil of anise has medicinal properties and is employed in cough syrups and lozenges. As a spice in the kitchen, anise is added to salads, pastries, fruit dishes, sauces, meat dishes, and fish and shellfish.

Common names and synonyms: Aniseed, *jintan,* sweet cumin.

See in addition: "Spices and Flavorings," Part II, Section F, Chapter 1.

Aniseed – *see* **ANISE**

Anise-pepper – *see* **SICHUAN PEPPERCORN**

Anise root – *see* **CICELY**

ANISILLO – A member of the New World genus *Tagetes* (which includes the garden marigold), anisillo (*T. minuta*) is an annual herb that grows to a height of from 3 to 6 feet. Throughout much of Latin America, it is dried and used to make a tealike beverage that is flavorful both hot and cold and is also thought of as a medicine. The dried plant is also added to rice dishes and stews for flavoring.

Common names and synonyms: Chilca, chinchilla, chiquilla, suico, wild marigold.

Anjou (pear) – *see* **PEAR**

ANNATTO – The bright red or yellow-brown fruits of the annatto plant (*Bixa orellana*), an American spice, have been employed more for their color than their flavor. Indeed, Native Americans of the Caribbean and Mesoamerica decorated their bodies with dyes made from the pulp that surrounds the seeds of this rough, berry-like fruit. The seeds are used – whole or ground – to color (and flavor) dishes such as Jamaica's famed ackee-fish-and-rice and the popular Mexican chilli powders. Annatto was carried by the Manila galleons to the Philippines, where the seeds have become important in many dishes. In Europe, annatto is used to color cheeses, butter, and oils.

Common names and synonyms: Achiote, anato, arnato, bija, bijol, *bixa,* lipstick tree, roucou.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Annual bunch grass – *see* **TEF**

Anon – *see* **SWEETSOP**

Anona – *see* **CHERIMOYA, CUSTARD APPLE**

Anona blanca – *see* **ILAMA**

Anu – *see* **MASHUA**

Ao-Togarashi (chilli pepper) – *see* **ASIAN CHILLIES**

Ape – *see* **ALOCASIA**

Apio – *see* **ARRACACHA**

APIOS – Also called "potato bean" and "groundnut" (but not to be confused with the peanut), apios (*Apios americana* or *A. tuberosa*) is a legume native to and found throughout eastern North America. Its edible underground tubers, roots, and seeds were gathered and widely consumed by Native Americans long before the Europeans arrived, but the plant was probably never cultivated. Apios is a twining vine with flowers ranging in color from pink to purple. It may have been taken to Europe as an ornamental as early as the end of the sixteenth century, and – later – there were thoughts of employing it as a potato substitute during the mid-nineteenth-century Irish potato famine. The idea was dropped, however, as disease-resistant lines of potatoes were developed. Among tubers, apios is very high in protein as well as carbohydrates, with a crude protein content about three times that of the potato. In addition, apios is unique among root and tuber crops for its ability to fix nitrogen. It nonetheless remains a neglected crop.

Common names and synonyms: Bog potato, groundnut, Indian potato, potato bean, Virginia potato, wild bean, wild potato.

Appalachian tea – *see* **WINTERBERRY**

APPLE (*see also* **CRAB APPLE**) – This fruit of legends – ranging from the tale of an apple as the cause of the Trojan War to the steady hand and eye of William Tell – is classified, along with the pear, as a pome fruit (meaning one with a compartmented core), and in fact "pome" means apple in Latin. Over 7,000 varieties of the apple (*Pyrus malus* or *Malus domestica*) are grown worldwide, and no wonder, for apple trees are valued not only for their fruit but also for their beauty in gardens and on lawns. Once the tree begins to bear fruit (after some 5 to 10 years for regular trees, but only 2 to 3 years for dwarf trees), it will continue to do so for upward of a century. Cultivated apples are descendants of wild or crab apples and are believed to have originated in Southwest Asia and the region around the Mediterranean. However, because crab apples still grow wild in Central Asia and Europe, some would widen the area of origin. Evidence indicates that this fruit, reputed to be the forbidden fruit of the Garden of Eden, was being cultivated and stored at least 5,000 years ago, and probably long before that. Apples were grown by the Etruscans, the Egyptians, the Greeks, and the Romans and, as with so many other food plants, were spread about Europe within the Roman Empire and thus have been cultivated there for at least 2,000 years. Apples reached the Americas in the seventeenth century with the early colonists, and today about 2,500 varieties are grown in the United States alone. Only 16, however, account for over 90 percent of the total U.S. production, about half of which goes into apple products such as cider, juice, applesauce, and the like. The leading 8 of the top 16, which account for 80 percent of U.S. production, are as follows:

- Golden Delicious, which when ripe is yellow and is the most widely consumed apple in the world. It was developed by accident in West Virginia toward the end of the nineteenth century.
- Granny Smith, a pale green apple, originated in Australia at about the middle of the nineteenth century. It is good eaten raw, is used for juice, and is suitable for general baking, for stuffing, for chutneys, and for salsas.
- Jonathan, a dark red and juicy apple, is used for juice and applesauce as well as for baking and stuffings.
- McIntosh is a greenish red apple that is good eaten raw and is used for juice and applesauce.
- Red Delicious, a red apple with crisp, juicy flesh, is the most popular apple in the United States.
- Rome Beauty, a red or red-striped apple, is favored for baking but is a bit mealy for eating out of hand.
- Stayman is a purplish apple for all-purpose use.
- York, also called York Imperial, is another good baking apple. It has a pink skin.

Other apples have somewhat specific uses. The Gravenstein is used mostly for applesauce; the Northern Spy is good for pies; the Winesap is a favorite for making cider. The sour crab apple is used for making jellies.

Most apples have a high sugar content, are low in tannin, and are slightly acidic. They are only a fair source of minerals, but they provide some vitamin A and have a good measure of vitamin C in their peels. Because apples are high in sugar, they are also high in carbohydrates.

Common names and synonyms: Cider apple, cooking apple, crab (wild) apple, dessert apple, Golden Delicious, Granny Smith, Gravenstein, Jonathan, McIntosh, Northern Spy, pippin, pome(-fruit), Red Delicious, Rome Beauty, Rome Delicious, Russet, Stayman, Winesap, Yellow Delicious, York, York Imperial.

Apple banana – *see* **BANANA**

Apple cactus – *see* **CACTUS APPLE**

Apple mint – *see* **MINT**

Apple-of-love – *see* **EGGPLANT**

Apple pear – *see* **ASIAN PEAR**

Apricock – *see* **APRICOT**

APRICOT – A sweet-sour fruit, the apricot (*Prunus armeniaca*) was long viewed as a kind of plum – and one that came from Armenia. In truth, it is a stone fruit (a drupe) of the same family as the peach, plum, almond, nectarine, and cherry and apparently originated (despite its scientific name) in China, where it has been cultivated for some 5,000 years. From China, the apricot traveled by way of northern India, finally reaching the Near East. After this, both Alexander the Great (356–323 B.C.) and, later, Roman legionnaires are credited with carrying the fruit to Europe. From Greece and Rome, apricots spread throughout Europe, and the Spaniards introduced them to the New World, where today they grow from Chile to California, with the latter area accounting for most North American production. In Europe, Spain is the leading producer of apricots. These walnut-sized fruits, which resemble peaches with their copper-colored flesh, are versatile in that they can be eaten fresh, dried, or canned and may be worked into rolls (apricot "sheets"), made into jelly, grilled, and poached. The kernels are a source of oil (although those of some varieties are poisonous), and the leaves can serve as fodder for sheep and goats. Apricots are an excellent source of beta-carotene, vitamin C, and potassium; when dried, they also are a good source of iron.

Common names and synonyms: Apricock.

Apricot vine – *see* **MAYPOP**

Arabian tea – *see* **KHAT**

ARAÇÁ-BOI – A fruit that is practically unknown outside of the Amazon Basin, the *acraçá-boi* (*Eugenia stipitata*) has a pleasant appearance. It is also sweet smelling but has such a fiercely sour taste that its juice must be sweetened before consumption.

ARAÇÁ-PERA (*see also* **GUAVA**) – A wild guava of the Amazon, the *araçá-pera* (*Psidium angulatum*) provides a sour juice that must be both diluted and sweetened to make it palatable.

Arbor-vitae – *see* **CEDAR**

Archiciocco – *see* **ARTICHOKE**

Areca nut palm – *see* **BETEL NUT**

ARGAN – An evergreen tree native to North Africa (probably Morocco), the argan (*Argania sideroxylon*) has fruits with a high oil content. About the size of plums, they are pressed for an oil much appreciated by the Moroccans for its aroma and as a cooking medium. The oil can be found in specialty stores in the United States, but at a considerable price.

ARMENIAN CUCUMBER (*see also* **CUCUMBER**) – With other common names like "snake melon" and "snake cucumber," the Armenian cucumber (*Cucumis melo*) is – not surprisingly – very long (up to 3 feet) and very narrow (up to 3 inches in diameter). But it is not a cucumber. Rather, it is a melon, like the muskmelon (also *C. melo*), and a native of the Old World tropics. The Armenian cucumber, however, is not eaten as a melon but is used mostly for preserves.

Common names and synonyms: Japanese cucumber, snake cucumber, snake melon.

See in addition: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

Arnato – *see* **ANNATTO**

AROIDS (*see also* **COCOYAM, TARO**) – The inclusive common name for all plants belonging to the Araceae family, the term "aroids" denotes over 1,000 genera and approximately 2,000 species, 90 percent of which are tropical in origin and grown largely as ornamentals. The exceptions are staple crops such as cocoyam and taro (genus *Colocasia*), which are cultivated in Southeast Asia, Malaysia, and the Pacific Islands. *Poi,* a Hawaiian dish, is made from taro. Monstera fruits, also part of the Araceae family, are edible as well.

Arracach – *see* **ARRACACHA**

ARRACACHA – A root of the Andean region of South America, arracacha (*Arracacia xanthorrhiza* or *A. esculenta*) is a staple for many of the Native Americans living there and, indeed, may be one of the oldest of the cultivated plants in that region. It stands in place of the potato in the diet and, in fact, was domesticated prior to the potato. Also called the "Peruvian carrot," arracacha is related to celery and – aboveground – resembles it. But belowground it has carrotlike roots that are boiled. Their flavor, according to expert Noel Vietmeyer, combines the tastes of celery, roasted chestnuts, and cabbage. No longer confined to the Andean region, arracacha is consumed throughout much of Latin America.

Common names and synonyms: Apio, arracach, arracacia, fecula, Peruvian carrot, Peruvian parsnip, r'accacha, white carrot.

Arracacia – *see* **ARRACACHA**

ARROW ARUM – A hardy North American perennial marsh plant, arrow arum (*Peltandra virginica*) is also called "green arrow arum," "Virginian tukahoe," "Virginian wake-robin," and "tukahoe." Native Americans in what is now the eastern United States ate the roots, stems, and flowers as vegetables.

Common names and synonyms: Green arrow arum, tukahoe, Virginian tukahoe, Virginian wake-robin.

ARROWHEAD – Arrowhead plants (genus *Sagittaria*) are widespread in the shallow waters of ponds, streams, and marshes, and those that are edible have roots that are cooked like potatoes or dried for flour. Some Native Americans used *S. latifolia* extensively, often acquiring it by discovering caches of the plants stored away by muskrats. *Sagittaria sinensis* is cultivated extensively in parts of China and Japan. Its root is similar to a lily bulb in appearance, has a bland, sweet taste, and is used in the same way as a potato.

Common names and synonyms: Arrowleaf, duck potato, swamp potato, wapata, wapato, wapatoo.

Arrowleaf – *see* **ARROWHEAD**

ARROWROOT – A perennial plant of the American tropics, arrowroot (*Maranta arundinacea*) is native to South America and the Caribbean and has been naturalized in southern Florida. It is also cultivated in Southeast Asia, Australia, and South Africa. The plant grows to a height of 3 to 5 feet, has long, very pointed leaves and small white flowers, and is cultivated for its starchy roots, which yield an edible starch that makes both a flour and a very smooth jelly or paste. The flour is almost all starch, is easily digested, is often employed as a thickener, and is prized by many chefs for making sauces. Both flour and jelly are used in infant foods, puddings, ice cream, and arrowroot biscuits, as well as in the manufacture of cosmetics and glue. Because Native Americans believed that the root absorbed poison from arrow wounds (hence its name), the plant has long been thought to have medicinal properties.

Starchy products from other plants are often subsumed under the general rubric of the term "arrowroot," and some can substitute for arrowroot. *Tacca leontopetaloides,* for example, is known as "Polynesian arrowroot."

Common names and synonyms: Polynesian arrowroot, tapioca, yuquilla.

Arrugula – *see* **ARUGULA**

Artichaut – *see* **ARTICHOKE**

ARTICHOKE – Although at least three vegetables are called artichokes, the globe or French artichoke (*Cynara scolymus*) has little relationship to either the Jerusalem artichoke or the Chinese artichoke. This is fortunate, because there is confusion enough created by the numerous varieties of the globe artichoke grown around the world. In Europe, the leaves are often reddish in color, but in the United States the only variety normally encountered in produce departments is the Italian Green Globe, with most of these grown in California. The artichoke appears to have originated in North Africa (where it still exists in a wild state). It subsequently became a wild thistle in Sicily, where its bitter leaves as well as its flower heads were gathered for food. The Greeks and Romans began its cultivation, and the parts of the immature flower head – artichoke leaves (tender and fleshy at the base) and bottoms ("hearts") – have been enjoyed at least since Roman times. The artichoke became an important part of Italian gastronomy and was subsequently imported to France by Queen Catherine de Médicis. Artichokes did not reach the United States until the nineteenth century. Today, the Spaniards, French, and Italians are the most fervent artichoke enthusiasts on the European continent, and California, Belgium, France, and the Mediterranean countries are the vegetable's most prolific producers. Similar to a miniature cabbage in appearance, the artichoke has leaves that are steamed and eaten with a dipping sauce, and the "hearts" and "bottoms" are sautéed, steamed, pickled, and cut into salads. Artichokes may be purchased fresh, frozen, and canned, and "baby" artichokes are frequently available marinated in jars. Artichokes are a good source of vitamin C and dietary fiber.

Common names and synonyms: Alcachofa, archiciocco, artichaut, articiocco, baby artichoke, *carciofo,* French artichoke, globe artichoke, Italian Green Globe, *karzochy.*

Articiocco – *see* **ARTICHOKE**

ARUGULA – Also known as "rocket" and "garden rocket," this native of Europe and western Asia (*Eruca sativa*) is a cruciferous plant that has long provided tender, slightly bitter, mustard-flavored greens for the salad bowls of southern Europeans and Italian-Americans. Lately, it has become widely available in the United States, where it has been naturalized. Its leaves resemble those of the radish, which is a close relative. The seeds of arugula are also eaten, and they yield an oil that is used for culinary purposes, as a lubricant, and in medicines. Arugula is loaded with vitamins A and C and – like many greens – provides much iron and calcium as well.

Common names and synonyms: Arrugula, garden rocket, jamba oil, Mediterranean rocket, rocket, rocket salad, roka, roquette, rucola, rugala, rugela, rugula.

See also: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Aruhe – *see* **BRACKEN FERN**

Arvi – *see* **COCOYAM**

ASAFETIDA – Asafetida (ass-uh-feh-TEE-da; *asa* from the Persian "gum" and *foetida* from the Latin "stinking") is a spice made from a notoriously bad-smelling plant (*Ferula assa-foetida*) of the carrot family, which can grow to 10 or even a dozen feet in height. The plant is a native of Iran and Afghanistan, is related to fennel, and is commonly used in Indian and – to a lesser extent – other Asian and Middle Eastern cuisines. Because of its fetid odor (some say it is like that of garlic), the Germans called it *Teufelsdreck,* which can be translated as "devil's-dung." But in the past asafetida was worn around the neck as an amulet to ward off disease and during medieval times to ward off witches. Asafetida was also prized in the ancient world for its alleged contraceptive powers, and the Romans regarded it as a substitute for silphium, an herb that became extinct about the time of Nero. Fortunately, the plant's odor, caused by sulfur compounds, disappears during cooking, and the leaves and stems are eaten as a vegetable. The spice, made from the milk-like juice of asafetida, usually comes in ground form and is added very sparingly to dishes such as meatballs and to pickles for its truffle-like flavor. It is also an ingredient in the venerable Lea & Perrins Worcestershire sauce.

Common names and synonyms: Asafoetida, assafetida, assafoetida, devil's-dung, food-of-the-gods, *hing,* stinking gum, *Teufelsdreck.*

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Asafoetida – *see* **ASAFETIDA**

Assafetida – *see* **ASAFETIDA**

Assafoetida – *see* **ASAFETIDA**

ASAM GELUGUR – A fruit from a tall tree that is native to Burma and Malaya, *Garcinia atroviridis* is orangish to yellow when ripe, round, about 3 inches in circumference, and very tart. As a rule, the fruit is sun-dried and used in curries. Immature fruits are incorporated in chutneys.

ASIAN CHILLIES (*see also* **CHILLI PEPPERS**) – Although all members of the genus *Capsicum* are native to the Americas, Asian peoples have enthusiastically adopted chilli peppers (which first reached Asia via the trading empires of Spain and Portugal) and incorporated them into the respective cuisines of the region. Many of the chillies, such as jalapeños, serranos, and Anaheims, would be familiar to Westerners, but others, now associated firmly with Asian cooking, would not. Among these are the tiny, red or green "bird's-eye" or "bird" chillies, which (frequently in dried form) give Thai cuisine its well-deserved reputation for fiery tastes. Another chilli, called "Thai" (this one about an inch and a half in length, and pointed), is also often dried, comes in green and red, and delivers significant heat (that lingers). A close relative of the Thai pepper is the Korean chilli, which is employed to put a bit of bite in *kimchee. Togarashi* chillies (often called by the Spanish *Japonés* in markets) are the Japanese equivalent of the Thai bird's-eye and, like it, are intensely hot. By contrast, the small, green *Ao-Togarashi* chillies have a mild flavor, as do the long, deep red Kashmiri chillies, which are employed for their color.

Common names and synonyms: Ao-Togarashi, bird chilli, bird's-eye, *Japonés,* Kashmiri chilli, Korean chilli, Thai chilli, Tien-tsin, *Togarashi.*

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

ASIAN PEAR (*see also* **PEAR**) – A wide variety of seemingly different fruits are called "Asian pears" (*Pyrus ussuriensis* or *Pyrus pyrifolia*). Many of these now grow in the western part of the United States – having been brought there by Chinese immigrants during the nineteenth century – but have been widely marketed only in the past few decades. Among these are "apple pears," "sand pears," "Chinese pears," and "Oriental pears" that range in size from very small to quite large. These fruits often resemble a cross between an apple and a pear and come in a wide variety of colors. But all are juicy and so crisp that they can be sliced very thinly. Like other pears, they are eaten raw as well as cooked. There are more than 25 varieties of Asian pears in U.S. markets (where the most popular one is the "Twentieth Century") and more than 100 varieties available in Japan. Asian pears are a good source of vitamin C and fiber.

Common names and synonyms: Apple pear, Chinese pear, Japanese pear, *nashi,* Oriental pear, salad pear, sand pear.

Asiatic aubergine – *see* **EGGPLANT**

Asiatic yam – *see* **LESSER YAM, WATER YAM**

ASPARAGUS – A member of the lily family (which includes leeks, garlic, onions, and other relatives of the grasses), this perennial (*Asparagus officinalis*) was doubtless an important gathered food for our Stone Age ancestors. There are about 300 species of asparagus native to a region that extends from Siberia to southern Africa (and possibly species native to South America as well). Some, mostly of African origin, are poisonous and are grown only for ornamental purposes; these include the ubiquitous "asparagus fern" or "florist's fern." Wild asparagus grows like a weed on English seacoasts, in the southern parts of eastern Europe, and on the steppes of the tundra, where horses and cattle graze on the vegetable. Asparagus has long been praised for both its culinary merit and its alleged medicinal properties, especially in the case of the kidneys. It has been cultivated since at least the time of the ancient Greeks and was a favorite of the Romans.

Asparagus can be green or white; the latter is the product of a method whereby soil is heaped on the growing stalks so as to block the sunlight necessary for chlorophyll production. White asparagus, with a stronger and somewhat more bitter flavor, is much more appreciated in Europe (especially in Spain and certain parts of France) and Argentina than in the United States, where commercial growers are mostly concerned with green asparagus. Although asparagus has a fairly short growing season in the United States, fresh spears can be purchased year-round because of South American production. France and Italy are also large producers. Frozen and canned asparagus is available, with the frozen close to the fresh in taste and nutritional value. The fresh green spears and green spears with white butts are frequently braised but are also excellent when steamed. Most canned asparagus is blanched white. Fresh asparagus has a large amount of vitamin C, although much can be lost during storage and preparation as well as during canning procedures. Asparagus is also high in vitamins A and E. Asparagus seeds have served as a substitute for coffee.

Common names and synonyms: Asparagus fern, florist's fern, garden asparagus, green asparagus, special bean, white asparagus, wild asparagus.

Asparagus bean – *see* **COWPEA, WINGED BEAN**

Asparagus broccoli – *see* **CALABRESE, CAULIFLOWER**

Asparagus lettuce – *see* **LETTUCE**

ASPARAGUS PEA – A native of southern Europe, the asparagus pea (*Lotus tetragonolobus*) is frequently confused with Africa's winged bean (*Psophocarpus tetragonolobus*) because of its winged pod. Asparagus peas are enjoyed as young edible pods that have an asparagus-like flavor and are prepared and served much like asparagus.

ASSAM AUR AUR – A native of Malaysia, and a fruit that has long grown wild in Southeast Asia, assam aur aur (*Garcinia hombroniana* Pierre) is now regarded as a candidate for cultivation as a specialty fruit. It is a close relative of the mangosteen, and its major culinary use involves its dried, crimson-colored rind – used as a relish in curries. In the past, the pulp of assam aur aur was fermented into a vinegar.

Assam – *see* **TEA**

Assfoot – *see* **COLTSFOOT**

ATEMOYA – A delicious dessert fruit that was created in the American tropics and subtropics, the atemoya (genus *Annona*) is a hybrid resulting from a cross between the cherimoya and the sweetsop. The fruit, which grows on small trees, is cultivated in southern Florida, the West Indies, and Central and South America in the New World. It has spread to Australia, New Zealand, and the Philippines in Oceania and to India, Israel, and South Africa in the Old World. The fruit looks somewhat like an artichoke on the outside; inside, it is pudding-like, creamy, and sweet. The taste of the atemoya resembles that of vanilla custard. It is a fine source of vitamins C and K as well as potassium.

Aubergine – *see* **EGGPLANT**

Auguweed – *see* **BONESET**

Australian arrowroot – *see* **ACHIRA**

AUSTRALIAN BLUE SQUASH (*see also* **SQUASH AND PUMPKIN**) – Although all squashes and pumpkins have an American origin, the Australian Blue squash (*Cucurbita maxima*) was developed in Australia. Also called the Australian Queensland pumpkin, it looks like a blue-gray-green pumpkin that is flat on both ends. Its soft flesh and mild flavor contribute to its frequent use in soup and bread making.

Common names and synonyms: Australian Queensland pumpkin.

See in addition: "Squash," Part II, Section C, Chapter 8.

AUSTRALIAN CARROT – A wild, dark-rooted carrot – native to Australia – the Australian carrot (*Daucus glochidiatus*) belongs to the same genus as the common carrot, which is domesticated in much of the rest of the world. The Australian version of the vegetable was one of the many foods gathered by the Aborigines.

AUSTRALIAN CHESTNUT – Also known as the "Moreton Bay chestnut" and the "bean tree" (because its fruits come in long pods), this big, evergreen, leguminous tree belongs to the pea family. The Australian chestnut (*Castanospermum australe*) produces large brown seeds that have long been an important food for the Aborigines. Like true chestnuts, these seeds are generally roasted before consumption.

Common names and synonyms: Bean tree, Moreton Bay chestnut.

Australian corkscrew tree – *see* **SESBAN**

AUSTRALIAN CURRANT – A small tree or shrub, *Leucopogon richei* is native to Australia and has white, edible fruits. These were among the many gathered fruits that sustained the Aboriginal population.

Australian desert kumquat – *see* **AUSTRALIAN DESERT LIME**

AUSTRALIAN DESERT LIME – Also known as the Australian desert kumquat, the Australian desert lime (*Eremocitrus glauca*) is a fruit – related to the orange – that grows on a shrub (an Australian native) about 8 to 10 feet in height. The pale yellow fruits are egg shaped and are made into beverages, jams, and preserves.

Common names and synonyms: Australian desert kumquat.

Australian nut – *see* **MACADAMIA NUT**

Australian Queensland pumpkin – *see* **AUSTRALIAN BLUE SQUASH**

Autumn olive – *see* **ELAEAGNUS**

Avens – *see* **HERB BENNET**

AVOCADO – The avocado (*Persea americana*) apparently originated in Central America, where it was cultivated as many as 7,000 years ago. It was grown some 5,000 years ago in Mexico and, by the time of Christopher Columbus, had become a food as far south as Peru, where it is called *palta.* Legend has it that Hernando Cortés found avocados flourishing around what is now Mexico City in 1519. The English word "avocado" is derived from the Aztec *ahuacatl,* which the Spaniards passed along transliterated as *aguacate.* Other names for the avocado are "alligator pear" and "butter pear," probably because of its green, leathery rind and buttery-, nutty-tasting flesh. Avocados are classified into three races, Guatemalan, Mexican, and West Indian, among which the Mexican is the least popular. Avocados have been grown in California and Florida since the middle of the nineteenth century, and – although there are more than 20 varieties of avocados on the market – for North Americans, they basically fall into two categories: those from California (a Guatemalan–Mexican hybrid and others of the Guatemalan race) and those from Florida (the West Indian race). Among those from California are Bacon, Zuttano, and Fuerte, and especially the Hass variety (by far the most abundant and, many say, the best tasting), a darker, bumpy-skinned, and considerably smaller fruit than the green, smooth-skinned Florida kinds (such as Lulu, Booth, and Waldin), which can look like pale green melons. The Florida avocados are lower in fat and calories than those grown in California but also have less texture and taste. Because avocados (along with olives and coconuts) contain high amounts of oil (avocado oil is similar to olive oil), their green, white, or yellow flesh doubtless played an important role in the otherwise lowfat diets of pre-Columbian peoples. Indeed, a recipe for guacamole – mashed avocados with spices – comes to us from the Aztecs. The Spaniards ate avocados with sugar, salt, or both, and introduced them into other parts of the Americas as well as other tropical parts of the world. But until the end of World War II, avocados were virtually unknown in Europe. This is no longer the case, however, as advertising has paved the way for their entrance into European produce markets everywhere. Today, avocados are considered a "fruit-vegetable," meaning that they go with both fruit and vegetable salads, are great with poultry and pasta, and make a nice sandwich as well. Avocado orchards stretch from California to Florida and from the Caribbean to Peru in the Americas. Avocados are grown in West Africa, in the countries surrounding the Indian Ocean, and in Israel, which supplies much of the European demand. In addition to its fat content, the avocado is fairly high in beta-carotene, is poor in vitamin C, is high in the B vitamins, and delivers a number of minerals.

Common names and synonyms: Aguacate, ahuacatl, alligator pear, avocado pear, *avocat,* Bacon, Booth, butter pear, Fuerte, Guatemalan avocado, Hass, Lulu, Mexican avocado, *palta,* Waldin, West Indian avocado, Zuttano.

Avocado pear – *see* **AVOCADO**

Avocat – *see* **AVOCADO**

AZAROLE – Native to North Africa and the Middle East, the azarole tree (*Crataegus azarolus*) is also known as the "Spanish pine," and its fruit as the "Neapolitan medlar" – both names suggesting its popularity in the Latin countries. By contrast, the fruit reached England in 1640 but never caught on there or in northern Europe. Azarole fruits range from red to yellow in color, are about the size of a crab apple, and make excellent preserves and marmalade as well as wine. The tree's flowers were once used to make a liquor, and its young buds and leaves are ingredients in salads. Azarole fruits are high in vitamin C and the B complex.

Common names and synonyms: Neapolitan medlar, Spanish pine.

AZUKI BEAN (*see also* **BEANS**) – This small, red bean (*Phaseolus angularis* – also known as the adzuki bean) is almost square in shape. It is native to China, where – as in Japan and Korea as well – it is grown extensively. Azuki beans are mostly dried and prepared by boiling, but they are also available canned in many countries around the world. The beans are generally used in dessert dishes. They are made into a paste for stuffing pastries, and pureed, they become a part of ice cream.

Common names and synonyms: Adzuki bean.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

B

BABACO (*see also* **PAPAYA**) – A native of Ecuador, the babaco (*Carica pentagona*) – a close relative of the papaya (*Carica papaya*) – is a cross between the mountain papaya (*C. pubescens*) and the chamburo (*C. stipulata*). We have, however, no idea of the antiquity of the fruit, which was discovered in the 1920s by European botanists. It is oblong in shape and has a yellowish green edible skin and pale yellow flesh. In the early 1970s, the fruit was introduced into New Zealand, where it has become yet another South American adoptee. Babaco is very high in vitamin C.

Babricorn bean – *see* **SWORD BEAN**

Bachang – *see* **HORSE MANGO**

Bachelor's-button – *see* **CORNFLOWER**

Bacon – *see* **AVOCADO**

Bactrian typha – *see* **MAIZE**

BACURÍ – A South American native, the bacurí (*Platonia esculenta* or *P. insignis*) is a yellow fruit that grows on a tall timber tree. A relative of the mangosteen, the fruit has creamy, white, and sweet flesh. The bacurí is commercially grown – and rather intensively so – in the Amazon Basin.

Common names and synonyms: Bacury, bakuri.

BACURIPARI – A small tree, native to the Amazon region of South America, the bacuripari (*Rheedia macrophylla*) produces a fruit of the same name that is somewhat like the mangosteen, a close relative. Its flesh is white and creamy, with a fine flavor, quite similar to that of the bacurí.

Bacury – *see* **BACURÍ**

Badian anise – *see* **STAR-ANISE**

BAEL FRUIT – Also known as the "bel-fruit" and "Bengal quince," the bael fruit grows on the bael tree (*Aegle marmelos*), a native of India that is now grown throughout much of South and Southeast Asia. The tree reaches about 40 feet in height, and its fruits are generally about 2 to 5 inches across. The Portuguese called them *marmelos* because they have the flavor of marmalade and can be eaten raw. Bael fruits are also used to make a refreshing beverage.

Common names and synonyms: Bael tree, bel-fruit, Bengal quince, Indian bael, *marmelo.*

Bahama whitewood – *see* **WHITE CINNAMON**

Bajra – *see* **MILLET**

Bakeberry – *see* **CLOUDBERRY**

Baked-apple berry – *see* **CLOUDBERRY**

BAKUPARI – Also known as *pacura,* the bakupari (*Rheedia brasiliensis*) is a Brazilian tree that produces an edible, orange-colored fruit with snow-white flesh. The fruit is slightly acid and is eaten out of hand as well as made into jellies and jams.

Common names and synonyms: Pacura.

Bakuri – *see* **BACURÍ**

BALANITES – Members of *Balanites,* a small genus of Old World tropical trees that is part of the family Zygophyllaceae, are cultivated from Africa to Burma for the acorn-like drupes they produce. The nuts are sometimes used for food but are mostly employed for the production of an oil used in cooking.

Balata – *see* **MIMUSOPS**

Balazo – *see* **MONSTERA**

Balloonberry – *see* **STRAWBERRY-RASPBERRY**

Balm mint – *see* **LEMON BALM**

Balm-of-Giliad tree – *see* **BALSAM FIR**

BALSAM APPLE – A tropical vine, native to the Old World, the balsam apple (*Momordica balsamina*) has yellow flowers and a warty, orange fruit that is eaten raw, boiled, and fried. Also called the "wonder apple," it grows in the tropics of India, New Guinea, and the Philippine Islands.

Common names and synonyms: Wonder apple.

BALSAM FIR – A North American tree that provides an inner bark once used by Native Americans for food, the balsam fir (*Abies balsamea*) is also known as the "Canada balsam" and the "balm-of-Giliad tree." The balsam or pith was also eaten, but the bark – often used to make a kind of bread – was so important to some tribes that it could almost be called a staple.

Common names and synonyms: Balm-of-Giliad tree, Canada balsam.

Balsam herb – *see* **COSTMARY**

Balsam pear – *see* **BITTER MELON**

BAMBARA GROUNDNUT (*see also* **LEGUMES**) – This leguminous plant (*Voandzeia subterranea* or *Vigna subterranea*) develops underground, nutlike fruits. Similar to peanuts, the fruits are encased in pods and are rich in starch and protein. Grown in the arid lands of Africa, Asia, and South America, they are most popular in Zambia and Madagascar. Bambara groundnuts are eaten fresh or boiled and have a taste similar to peas. They are also dried, ground into flour, and used for baking.

Common names and synonyms: Bambarra, Bambarra nut, Congo goober, ground pea, voandzou.

Bambarra nut – *see* **BAMBARA GROUNDNUT**

Bamboo – *see* **BAMBOO SHOOT(S), WATER BAMBOO**

BAMBOO SHOOT(S) – Plants of the bamboo tribe (*Bambusaceae*) are among the tallest of the grass family, occasionally reaching heights of 100 feet. Bamboo "shoots" are their young stems. Bamboo plants and their shoots are native to the warmest parts of Africa, the Americas, and, of course, Asia. As any zoo aficionado knows, these are the favorite (and practically the only) food of China's pandas. Bamboo is also important in the cuisines of Asia's humans, who add the shoots to dishes for a crunchy texture and also pickle and candy them. Outside of Asia, the shoots are generally available only in canned form, although they can be found in some Asian-style markets. Fresh bamboo shoots deliver good amounts of thiamine, potassium, and vitamin B_6, but the canning process robs them of most of their nutrients.

Common names and synonyms: Takenoko, tung sun.

Bamia – *see* **OKRA**

BANANA (*see also* **BANANA FLOWER, ENSETE, PLANTAIN**) – The various forms of the banana (*Musa paradisiaca*) are probably native to South and Southeast Asia and doubtless helped feed hunter-gatherers for hundreds of thousands of years. The banana is among the oldest plants that humans have used, was one of the first to be cultivated, and today constitutes one of the most important food crops in the world. The identity of the exact homeland of the banana has been blurred by the plant's ability to spread rapidly throughout the tropics. By way of an example, when bananas reached the tropical New World (apparently with Spanish explorers), they propagated with such rapidity that some of the earliest chroniclers thought that the fruit was an American native. And bananas apparently reached tropical Africa and Polynesia much earlier (c. A.D. 500 and 1000, respectively) than they did the New World.

The banana "tree" is really a giant herb that can grow to 20 or more feet in height in only a year, even though it sprouts from a rhizome or corm. Suckers rise in clumps from the rhizome and, as they grow, form groups of flowers that can become bunches (called "hands") of bananas. One "hand" may consist of as many as 400 bananas, but that is all the plant will ever produce; after producing one bunch, it dies, although another sucker may grow from the rhizome to take its place. Bananas did not become commercially important for export until the nineteenth century (with the advent of refrigerated ships), and today Brazil is the biggest exporter and the United States the biggest importer of the fruit. But most bananas – about 80 percent – are consumed in their respective African, Asian, Caribbean, or Central and South American regions of production, where the fruit is often an important staple food.

Bananas – with some 200 varieties – come in different shapes, sizes, and colors. *Manzanos* (also called finger or apple bananas) are about the length of a finger and turn from yellow to black when ripe. Saba and Brazilian bananas are medium-sized, tart, and straight rather than curved, whereas red bananas are sweeter. The Cavendish, with its color ranging from green through yellow to black (indicating its degree of ripeness), is the banana most commonly encountered in the produce markets of North America. Other common varieties are the Martinique, the Jamaica, the Gros Michel, and the Bluefield. Bananas can be baked, fried, and grilled, although roughly one-half of those produced are simply peeled and eaten out of hand. Bananas are easily digestible, can be used at various stages of ripeness, and are an excellent source of carbohydrates, potassium, and vitamins A and C.

Common names and synonyms: Apple banana, Bluefield, Brazilian banana, Cavendish, dwarf banana, finger banana, Gros Michel, Jamaica, *manzano,* Martinique, *pisong jacki,* red banana, Saba, Silk Fig.

See in addition: "Bananas and Plantains," Part II, Section B, Chapter 1.

Banana chilli – *see* **WAX PEPPERS**

Banana de brejo – *see* **MONSTERA**

BANANA FLOWER (*see also* **BANANA**) – The banana fruit is not the only edible part of the banana plant (*Musa paradisiaca*). The male flowers – the compact, purple, pointed heads at the end of a forming bunch of bananas – are also eaten, often on the site where the bananas are grown. They are used as a vegetable and garnish in the countries of Southeast Asia, where they are available in local markets.

Common names and synonyms: Banana blossom, banana bract, banana bud, banana heart(s), *jantung pisang,* Silk Fig.

See in addition: "Bananas and Plantains," Part II, Section B, Chapter 1.

Banana heart(s) – *see* **BANANA FLOWER**

Banana pepper – *see* **WAX PEPPERS**

BANANA SQUASH (*see also* **SQUASH AND PUMPKIN**) – A sometimes huge squash, weighing upward of 30 pounds, the banana squash (*Cucurbita maxima*) is often sold in smaller pieces at produce counters. It is perhaps the most bland of this American species that was domesticated in South America. The banana squash has an orange flesh that is high in beta-carotene as well as vitamin C.

See in addition: "Squash," Part II, Section C, Chapter 8.

BAOBAB – A huge tree, native to tropical Africa, the baobob (*Adansonia digitata*) is famous for its trunk, which often reaches 30 feet in diameter. Also grown in India, the tree has an edible-fleshed fruit sometimes called "monkey-bread." The fruit is about 9 inches in length, oval, and hard-shelled, and has a fibrous, floury white pulp. Its juice is also consumed – after sweetening – and in the past was used to treat tropical fevers. The leaves of the tree are eaten as a vegetable.

Common names and synonyms: Monkey-bread.

Barbados cherry – *see* **ACEROLA**

Barbados eddoe – *see* **COCOYAM**

BARBADOS GOOSEBERRY (*see also* **BERRIES**) – A member of the large cactus family, the Barbados gooseberry (*Pereskia aculeata*) is native to the West Indies. Its edible yellow fruit resembles the gooseberry in appearance and has a fine taste. Also called the "lemon vine," this cactus has leaves that are edible as well; they are usually consumed raw.

Common names and synonyms: Leafy cactus, lemon vine.

Barbary fig – *see* **PRICKLY PEAR**

Barbe de capucin – *see* **CHICORY**

BARBERRY (*see also* **BERRIES**) – There are numerous different species of shrubs of the genus *Berberis* that bear small orange or red berries similar to currants. They can be found in Asia, Europe, North Africa, and North and South America, growing best where there is plenty of sunlight. A very popular barberry is *B. thunbergii,* a native of Japan, and there are other popular varieties native to Korea and Japan. In France, famous jams are made from the seedless barberry. The bright red berries ripen in the fall in North America and are especially abundant in New England. In the western United States, the barberry is called the "wild Oregon grape," or just "Oregon grape." The berries are generally very tart and are the basis of fine jellies and preserves. They were doubtless another food employed by hunting-and-gathering Native Americans, as were barberry leaves, which go nicely in salads and can be cooked as a vegetable.

Common names and synonyms: California barberry, holly-leaved barberry, Oregon grape, pepperidge, Rocky Mountain grape, seedless barberry, trailing mahonia, wild Oregon grape.

BARLEY (*see also* **WILD BARLEY**) – Barley (*Hordeum vulgare*) originated in western Asia, and, as our hunter–gatherer ancestors settled into sedentary agriculture during the Neolithic Revolution, it became one of the first grains to be cultivated. This grain has the advantage of a relatively short growing season and – because it matures quickly – has adapted to a considerable variety of environments. Barley was important in early Egypt and China but was displaced by wheat in ancient Rome. Like rye, it became a staple in northern Europe during the Middle Ages. Barley has also long been a source of drink as well as food. Malt is made from barley by soaking the seeds until they sprout. In the process, the proteins in the bran change into enzymes that convert starches – first into sugars and then into alcohol. As with other grains, barley is refined by milling to the point that many nutrients are stripped away. Pearl barley, for example, has had the entire outer husk removed. Pot or Scotch barley is much less refined and is good in soups. Barley flakes and grits are used in breakfast cereals. Barley has a nutlike flavor, is high in carbohydrates, and contains phosphorus, calcium, and some of the B-vitamin complex. In North America and Europe, most barley either is used for the production of beer, ale, and whiskey or becomes feed for animals. But in less-developed countries, such as many of those in Africa, barley is still an important part of the human diet, and it remains a staple in the Middle East.

Common names and synonyms: Barleycorn, barley flakes, barley grits, malt, naked barley, pearl barley, pot barley, Scotch barley, six-row barley, two-row barley.

See in addition: "Barley," Part II, Section A, Chapter 2; "Beer and Ale," Part III, Chapter 1.

BARREL CACTUS – There is some taxonomical dispute concerning the genera of these two cacti (*Ferocactus wislizenii* and *Echinocactus,* especially *E. grandis*) known as "barrel cactus." They are also called "visnaga." Both are natives of the southwestern United States. The barrel cacti provided stem pulp that served as food for Native Americans, as did their fruits.

Common names and synonyms: Fish-hook cactus, southwestern barrel cactus, visnaga.

Basil – An herb that is part of the mint family, is native to India (and possibly Africa as well), and is known as the tomato's best friend, basil (*Ocimum basilicum = O. americanum*) comes in many types – and more than a few colors – that are now distributed worldwide. Closing in on becoming the world's most popular herb, basil was virtually unknown outside of Europe 30 years ago. It is sometimes classified as either "sweet basil" or "bush basil." Sweet basil has a larger leaf that is more aromatic and flavorful. Bush basil (*Satureja vulgaris* or *Ocimum minimum* – also called "wild basil"), although native to the Old World, is widely naturalized in the Americas. Basil was used by the ancient Greeks, and the Greek word *basilikon,* meaning "royal," perhaps suggests that the herb was reserved for royalty. The Romans spread the herb around Europe, where basil's heart-shaped and aromatic leaves have long been a favorite of the Italians and the Provençals – indeed, in Italy the leaves are considered symbols of love. Basil is best fresh, is often used in soups and pâtés, is vital to Italian pesto, and is a natural companion for tomatoes in sauces and salads. Dried basil does not retain the same delicate flavor as the fresh leaves, but it is frequently added to sauces nonetheless. Many people preserve their fresh leaves in olive oil in a tightly sealed jar. Basil is also employed to flavor the liqueur Chartreuse.

Common names and synonyms: Basilic common, *basilico,* bush basil, sweet basil, wild basil.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Basilic common – *see* **BASIL**

Basilico – *see* **BASIL**

Basswood – *see* **AMERICAN LINDEN**

Batata dulce – *see* **SWEET POTATO**

Batavian endive – *see* **ENDIVE AND ESCAROLE**

BAYBERRY (*see also* **BERRIES**) – The shrubs *Myrica pensylvanica* and *M. cerifera* are North American plants that produce gray, waxy berries, which have historically been melted down into wax for candles. Bayberry leaves, however, have culinary applications. They are pickled and dried for use as a less pungent bay leaf in soups, stews, and the like.

Bay laurel – *see* **BAY LEAF**

BAY LEAF – The aromatic leaves of the bay laurel tree (*Laurus nobilis*) are regarded by many as an indispensable flavoring herb in the kitchen. The leaves come from a small evergreen that apparently was a native of Asia Minor but has been scenting the air of the Mediterranean region for so long that it is also thought of as native there. Indeed, the Romans used laurel leaves for fashioning garlands to honor soldiers, athletes, and poets – hence the term "laureate," which still persists to indicate preeminence. In earlier times, the laurel leaf also had a reputation for warding off evil. Aromatic bay leaves are among the most versatile herbs used in Mediterranean cooking and, in fact, are popular in most cuisines throughout the world. If used fresh, they are first crumbled; if dried, they can be used either whole, crumbled, or ground. Bay leaves are good (often with thyme) in almost any soup, stew, sauce, or meat dish (including pâtés) and are one of the principal ingredients in a bouquet garni. They are also important in pickling and are added to vinegars, marinades, and puddings. Laurel leaves are now produced in areas of North Africa and North America as well as in their traditional regions of cultivation.

Common names and synonyms: Bay laurel, Grecian laurel, laurel, sweet bay, sweet laurel.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

BEACH PEA (*see also* **LEGUMES**) – A number of the fruits of the leguminous plants of the genus *Lathyrus* were used for food in the past by hunter-gatherers. Along the coasts of North America – including those of the Great Lakes – the immature seeds of the beach pea (*L. maritimus*) were eaten like sweet peas, and ripe ones were ground into a flour. The inflorescences of the sweet pea (*L. odoratus*), a popular garden flower originally from the Mediterranean region, may also have served as food in the past. Today, the plant is grown commercially for its flowers, which yield an essential oil used in perfumes. Other species have been used as food by Europeans and Asians over many millennia.

Common names and synonyms: Sweet pea.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

BEACH PLUM (*see also* **PLUM**) – The beach plum (*Prunus maritima*) is a seacoast shrub that bears an edible plumlike fruit. This plant ranges along the east coast of North America from the province of New Brunswick in Canada to as far south as Virginia. It is a strange plant that frequents only seemingly infertile areas like sand dunes, and its fruit, which ranges from red and purple to yellow, can be sweet and delicious or so tart as to be inedible. The beach plum is used mostly for making a jelly that goes well with duck and venison.

Common names and synonyms: Shore plum.

Beaked hazel – *see* **HAZELNUT AND FILBERT**

Bean tree – *see* **AUSTRALIAN CHESTNUT**

BEANS (*see also* the various bean entries) – Beans were among the first (and most important) foods to be gathered. In Afghanistan, the Himalayan foothills, and central Asia, *Vicia faba* – the fava bean, broad bean, or Windsor bean – was food for hunter-gatherers tens of thousands of years ago, as was *Cicer arietinum* (the chickpea or garbanzo) – in western Asia. These were gradually brought under cultivation in an area encompassing much of Asia, the Middle East, and Egypt and had become staples in the diets of many long before the ancient Greeks employed them as counters for balloting. The Phoenicians are credited with carrying the chickpea to the western end of Europe, where "garbanzos" became entrenched in the diet of the Iberians and have continued as an important staple to this day. Moreover, in prehistoric times, three species of the genus *Lupinus* were brought under cultivation in the Mediterranean region and later embraced enthusiastically by the Greeks and Romans. These were the white lupine (*L. albus*), the blue lupine

(*L. angustifolius*), and the European yellow lupine (*L. luteus*). In addition to their splendid pink-and-blue flowers, lupines provide very nourishing seeds, but around the time of the Renaissance they began their disappearance from culinary use. To this day, however, large lupine seeds are preserved in brine by many peoples of the Mediterranean, who simultaneously strip them of their thick skins and pop them in the mouth, eating them as a snack.

Meanwhile, in the New World, a vast range of beans of the genus *Phaseolus* had, as in Europe, initially been gathered and later brought under cultivation. The first species to be domesticated was the common bean (*P. vulgaris*), which archaeological evidence from the Peruvian Andes suggests occurred about 8,000 years ago (findings from the Tehuacán Valley in central Mexico indicate domestication there about 1,000 years later). Varieties of the common bean were subsequently cultivated from southern South America to as far north as the St. Lawrence River. Among them were seeds we know today as turtle beans (black beans), kidney beans (including the white cannellini), Lamon beans, chili beans, cranberry beans, pinto beans, red beans, "great northern" beans, string (snap) beans, Romano (Italian green) beans, flageolets, and other round white beans ranging from the large marrow bean to the small pea or navy bean.

A second New World species is *P. lunatus,* comprised of the lima and sieva beans and so called because of the lunar – actually half-moon – shape of the seeds of some varieties. Archaeological evidence shows that, like common beans, lima beans (named after Peru's capital city) were in use in the Andean highlands some 8,000 years ago. However, they do not appear in the archaeological record of Mexico. The smaller sieva beans, by contrast, were apparently never in Peru but were grown in Mexico about 1,200 years ago, all of which has prompted the conclusion that the two varieties had a common ancestor but were domesticated independently by Andean and Mesoamerican farmers. In Peru, there is much evidence to indicate that lima beans were playing a major role in the diet 5,000 years ago. Today, the large lima beans are called "Fordhooks" or "butter beans," and the smaller sievas are called "baby limas." Other names for members of *P. lunatus* are "Madagascar bean" and "Towe bean."

The scarlet runner (*P. coccineus*), today often grown as an ornamental climber in the United States (but much appreciated at the table in Great Britain), is the third New World species. These beans were gathered about 9,000 years ago and were cultivated in Mexico at least 1,500 years ago (there is disagreement as to whether pods dating from about 4000 B.C. were gathered in the wild or were domesticated). Both the purple-seeded and white-seeded varieties are frequently cultivated around poles (thus, "pole beans") to keep them from "running."

The fourth New World species of bean is the now obscure tepary bean (*P. acutifolius*). Of the four species, this one had the northernmost area of origin: Central Mexico, where teparies were cultivated about 5,000 years ago, and what is now the U.S. Southwest, which they reached by about 1,200 years ago. Apparently, the major use of teparies was to grind them into flour for more or less "instant" bean dishes.

The American beans began to travel after the arrival of the Iberians in the Americas. In the Far East, their reception was lukewarm because of local favorites such as the azuki bean (*P. angularis*), the mung bean (*P. aureus*), the cowpea (*Vigna unguiculata*), and, of course, the soybean (*Glycine max*) – today the most widely consumed bean in the world. Similarly, the West Africans had their own beans, such as the cowpea or black-eyed pea (actually a bean), and the winged bean (*Psophocarpus tetragonolobus*). But the American beans found ready acceptance in East Africa and in almost all of Europe.

Experimentation in bean breeding in Europe has produced considerable confusion. Native Americans probably consumed some beans as immature pods despite their stringiness, but the beans' major use was in the dried form, which was easily stored. The Europeans, however, sorted through the American beans and selected (and developed) many for use as snap beans. Thus, when the Europeans settled North America, they brought American beans back to their home hemisphere, but the green pods had become "French" beans – presumably because the French had given American beans the name *haricot.* In France, any bean of the genus *Phaseolus* is called an *haricot* whether fresh or dried, but in England "haricot" generally means a dried bean, whereas fresh pods are called French or green beans. Much breeding has finally removed the strings from string beans so that now they are known as "snap" beans, a category that includes green snap beans, green haricots, the Romano bean, the wax bean (the common name for the yellow snap bean), the purple wax bean, pole beans, scarlet runners, and even cowpeas when immature.

Some of the world's great dishes are based on beans. Among the first were the succotash of the Native Americans and the various "fabadas" (stews and soups made with fava beans) of Europe. Then there is the *cassoulet* of France, the *feijoada* of Brazil, the chile con carne of Texas, the "hoppin' John" of the U.S. South (and the three-bean salad of the United States in general), the hummus of the Middle East, the minestrone of Italy, the refried beans of Mexico, and, of course, Boston baked beans.

Beans are nitrogen-fixing, which means that when the plants are plowed under they become "green manure." Indeed, when beans are planted in rotation with wheat and barley, almost no fertilizer is required. Beans are cholesterol-free and high in vitamins, minerals, and soluble fiber. Long called "poor-man's-meat," they are also very high in protein.

Common names and synonyms: Azuki bean, baby lima, black bean, black-eyed bean, black-eyed pea, blue lupine, broad bean, butter bean, cannellini, chickpea, chile bean, chili bean, common bean, cowpea, cranberry bean, European yellow lupine, *faba,* fava, flageolet, Fordhook, French bean, *garbanzo,* great northern bean, green bean, green haricot, green snap bean, *haricot,* Italian green bean, kidney bean, Lamon bean, lima bean, lupine, Madagascar bean, marrow bean, mung bean, navy bean, pea bean, pinto bean, pole bean, poor-man's-meat, purple-seeded pole bean, purple-seeded scarlet runner, purple wax bean, red bean, Romano bean, scarlet runner, sieva bean, snap bean, string bean, tepary bean, Towe bean, turtle bean, wax bean, white bean, white cannellini, white lupine, white-seeded pole bean, white-seeded scarlet runner, Windsor bean, winged bean, yellow lupine, yellow snap bean.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3; "Soybean," Part II, Section E, Chapter 5.

BEAN SPROUTS (*see also* **BEANS, MUNG BEAN, SOYBEAN**) – Typically from mung beans (*Phaseolus aureus*) or soybeans (*Glycine max*), the early shoots of these plants are widely used in Asian cooking. The 1- to 2-inch-long sprouts are tender and rich in vitamin C. They are usually eaten raw, although they can be lightly cooked and still retain their nutritive value.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3; "Soybean," Part II, Section E, Chapter 5.

BEARBERRY (*see also* **BERRIES, HEATHER**) – Also known as "kinnikinnick" and "crowberry," the red bearberry comes from several North American shrubs (genus *Arctostaphylos*) that have small evergreen leaves and white or pink flowers. The eastern black bear is said to be fond of them, and they were among the many wild foods gathered by Native Americans.

Common names and synonyms: Crowberry, kinnikinnic, kinnikinnick.

Bearss – *see* **LEMON**

Bear's-weed – *see* **YERBA SANTA**

BEE BALM (*see also* **BERGAMOT**) – There is considerable confusion surrounding bee balm, balm, and melissa. Balm is a Eurasian native known as *Melissa officinalis* or melissa, from the Latin and Greek meaning "bee" and from "honey" or *meli* (consider the word "mellifluous") – the whole suggestive of the attraction that the flowers of this plant have for bees. Confusion began with one of the early Spaniards in the New World, Nicolas Monardes, a physician and naturalist, who seems to have been the first European to describe a close relative, *Monarda didyma,* an American native that was subsequently named for him. This plant is called bergamot but is very commonly named bee balm and melissa as well – hence the confusion. Both plants are sweet, herbal members of the mint family. In the case of the American native (the Eurasian cousin is now naturalized in North America), the leaves were used by the Oswego Indians to make a kind of tea, and when rebellious North American colonists could no longer obtain tea through British channels, they copied the Indians in making what they called "Oswego tea." In the case of the Eurasian plant, it is still used today to flavor liqueurs such as Benedictine and Chartreuse. The leaves of both "bee balms" are also used fresh and dried to flavor pork dishes, cooked vegetables, salads, stews, and poultry.

Common names and synonyms: American horsemint, balm, bee herb, bergamot, garden balm, horsemint, melissa, Oswego tea, wild bee balm.

Beech mast – *see* **BEECHNUT**

BEECHNUT – Beech trees (genus *Fagus*) belong to the family that also includes oak and chestnut trees. Their bark is smooth, light colored, and easily scratched or carved upon; consequently, the European beech (*F. sylvatica*), in particular, served as a "bulletin board" for eons prior to the advent of paper. In Europe, beechnuts (referred to as "mast" or "beech mast") were employed – historically as well as today – in fattening hogs and for oil. During both of the twentieth-century world wars, however, beechnuts were used extensively by humans as a survival food. The American beech (*F. grandifolia*) is native to the eastern part of the United States, where many consider its nut to be among the best tasting of all. The flavor of this small nut is somewhere between that of chestnuts and hazelnuts. It can be eaten raw and is also often roasted, made into nut "butter," and pressed to yield a fine oil. It is interesting to note that the nuts produced by certain kinds of oak trees are technically known as beechnuts rather than acorns.

Common names and synonyms: American beech, beech mast, European beech, mast.

Beech wheat – *see* **BUCKWHEAT**

Beefsteak fungus – *see* **MUSHROOMS AND FUNGI**

BEEFSTEAK PLANT – Also called *shiso* by the Japanese, the beefsteak plant (*Perilla arguts*) – a member of the mint family – is native to Burma, China, and the Himalaya Mountains. Both the red and green varieties are cultivated for garnishes, sprouts, and use as a vegetable.

Common names and synonyms: Shiso.

Beef tongue – *see* **MUSHROOMS AND FUNGI**

Bee herb – *see* **BEE BALM, LEMON BALM**

BEET (*see also* **MANGELWURZEL, SWISS CHARD**) – All of today's beets are descended from a wild forebear whose green tops doubtless nourished our own prehistoric forebears. Indeed, the first cultivated beets were apparently tended only for their leaves (eaten like spinach), and it was not until the early Christian era that their roots became appreciated. The commercially most important descendant of the wild beet (*Beta maritima*) is the European sugar beet (*B. vulgaris* L. ssp.), which was developed to produce sugar and became a serious competitor of sugarcane in the nineteenth century. However, the red, yellow, and white edible roots of some of the other native European *B. vulgaris* varieties (beetroots as they are called in the United Kingdom) find their way to the dinner table. The red garden beet, essential to borscht, is also the ingredient of the famous Harvard beets dish (named and perhaps created because of the university's crimson colors) and is prominent as a pickled vegetable as well. In much of Europe, however, the yellow variety has historically been prized because of a sweeter taste and greater suitability for pickling. The white-rooted beet is important for its leaves and stalks, which can be put to use as substitutes for, respectively, spinach and asparagus. Still another beet, the mangelwurzel, with a very large bulb, is employed as animal fodder. Unfortunately, many (especially middle- and upper-class Europeans) feel that *all* beets are essentially animal food – or, at best, peasant food. Beet greens are a source of riboflavin, iron, and vitamins A and C. The roots are high in folacin and vitamin C. Beets are available fresh, pickled, and canned.

Common names and synonyms: Beetroot, chad, chard, European sugar beet, garden beet, Harvard beet, mangel, mangelwurzel, red beet, red-beet leaf, red garden beet, spinach beet, sugar beet, Swiss chard, white-rooted beet, wild beet, yellow beet.

Beetle-bung – *see* **BLACK GUM**

Beggar's-button(s) – *see* **BURDOCK**

Beldobes – *see* **QUELITES**

Bel-fruit – *see* **BAEL FRUIT**

BELGIAN ENDIVE (*see also* **CHICORY**) – Also called "French endive," Belgian endive (*Cichorium endivia*) is known in Europe as *witloof* and is a relative of both escarole and chicory. It is a smooth, pale, elongated, and slightly bitter vegetable, which has been forced from roots that have been covered with soil and kept in darkness – hence its pale color. Belgian endive is used in salads and is braised as a vegetable.

Common names and synonyms: French endive, red Belgian endive, white endive, *witloof.*

BELIMBING – A relative of carambola, the belimbing (*Averrhoa bilimbi*) is also known as the "sour finger carambola" and the "cucumber tree." The fruit is light green to yellow in color, about 3 inches in length, and is much like a small, unripe mango in appearance. It is much too sour to eat raw, and in Malaysia, Thailand, Indonesia, and the Philippines, it is stewed and added to curries to impart a sour taste. Belimbings are very high in vitamin C.

Common names and synonyms: Bilimbi, blimbling, cucumber tree, sour finger carambola.

Benjamin bush – *see* **SPICEBUSH**

BENOIL TREE – Although originally native to the Indian subcontinent, benoil trees (*Moringa oleifera* and *M. pterygosperma*) are now found throughout the Old World tropics. The leaves and roots of this tree taste like horseradish and, chopped up and mixed with water or milk, are made into a sauce that is thought to aid digestion. The seeds yield an oil that is used for industrial purposes and also contain a sweetening substance. In short, virtually all parts of this tree are eaten or used in some way. The young seedpods – long and slender like drumsticks, and probably the source of the nickname "drumstick tree" – are eaten as a vegetable or used in curries. The roots may easily substitute for horseradish. The leaves – perhaps one of the richest sources of calcium in the plant world, and rich as well in vitamins, minerals, and proteins – are cooked and served as a vegetable and are also used as a flavoring and an animal feed.

Common names and synonyms: Drumstick tree, drumstick vegetable, horseradish tree, moringa nut.

Ber – *see* **DESERT APPLE**

BERGAMOT (*see also* **BEE BALM**) – The fruit called bergamot fruit comes from a small spiny tree (*Citrus bergamia*). It is called the bergamot orange, or mellarosa, and is halfway between an orange and a lemon. It is sour, and its leaves, flowers, and pear-shaped fruits are used mostly in perfumery. However, the oils from the rind are also employed in flavoring liqueurs, and the fruit goes into an Italian preserve, *mostarde di frutta.* The bergamot orange is grown mostly in the southern Italian province of Calabria.

Another plant called bergamot is wild bergamot, a name given to the leaves of any of several American plants of the genus *Monarda.* These are also known as "bee balm" and "American horsemint" and are made into tea.

Common names and synonyms: American horsemint, bee balm, bergamot herb, bergamot orange, horsemint, mellarosa, wild bergamot.

Bergamot lemon – *see* **LEMON**

Bergamot orange – *see* **ORANGE**

BERRIES (*see also* the various berry entries) – Berries were, arguably, among the very first human foods. Certainly they were a sweet seasonal staple for our hunting-and-gathering ancestors for scores of millennia. And at some point in the past, humans learned to dry them and store them for use in the winter, to make them into various kinds of preserves, and to mix them with meats and fats to become pemmican, as did the Native Americans. Wild berry gathering remains a popular activity in Europe as well as North America, but most berries encountered in stores have been cultivated. There are several species of blackberries and raspberries (with segmented fruits) belonging to the genus *Rubus,* some of which have been cultivated since the seventeenth century or so. Smooth-skinned blueberries and cranberries are members of the genus *Vaccinium* that have been cultivated commercially for a century or more in the United States. Strawberries (*Fragaria* species), of course, are the most popular berries and are widely cultivated, as are currants (genus *Ribes*). Most berries are very rich in vitamin C and potassium. Berries come fresh, frozen, canned, and in some cases (for example, that of cranberries) as a juice.

BETEL NUT – The orange- to scarlet-colored fruit of a palm that is native to tropical Asia, betel nut (*Areca catechu*) is processed by boiling and drying, then mixed with betel leaves and lime and chewed by many people for its slight narcotic effect. Those who chew it believe that betel nut sweetens the breath, strengthens the gums, and promotes digestion.

Common names and synonyms: Areca, areca nut palm, betel(nut) palm, *catechu, pinang.*

Betel(nut) palm – *see* **BETEL NUT**

Bhindee – *see* **OKRA**

Bhindi – *see* **OKRA**

Bible leaf – *see* **COSTMARY**

Bible-leaf mace – *see* **COSTMARY**

Bigarade – *see* **ORANGE**

Bigarreau – *see* **CHERRY**

BIG GREEN PLUM (*see also* **PLUM**) – Known also as the wild plum, the big green plum (*Planchonella pohlmaniana*) is an edible fruit of Australia and one of the many that sustained its hunting-and-gathering Aboriginal population over millennia.

Common names and synonyms: Great green plum, wild plum.

BIG-LEAFED HYDRANGEA – A native of China, the deciduous shrub *Hydrangea macrophylla* is the ancestor of most of our garden hydrangeas. Its dried rhizomes and roots have been used as both a food and a medicine.

BIGNAY – Also called *buni,* "Chinese laurel," and "salamander tree," the bignay (*Antidesma bunius*) is a small tree – native to Australia and India – that is widely cultivated in Indonesia for its red and somewhat sour fruits (about half an inch in diameter) that grow in clusters. They are eaten raw as well as made into preserves, jellies, and syrups. They are also used to flavor brandies, and to make a sauce for fish.

Common names and synonyms: Buni, Chinese laurel, salamander tree.

Bija – *see* **ANNATTO**

Bijol – *see* **ANNATTO**

BILBERRY (*see also* **BERRIES**) – A European relative of the blueberry, the bilberry (*Vaccinium myrtillus* – also known as the whortleberry in Europe) seems its identical twin (the Australians call bilberries blueberries), save that they have differently shaped flowers and that the bilberry is a bit darker than the blueberry. Perhaps the result of a natural hybridization, the bilberry is the focus of northern European berry pickers as well as their counterparts in northern North America during the summer and fall months. But it also grows in California and the American Southwest, where it is wrongly called huckleberry as well as blueberry. Bilberries were an important food for many Native American tribes.

Common names and synonyms: Blueberry, huckleberry, *myrtille,* whortleberry, windberry.

Bilimbi – *see* **BELIMBING, CARAMBOLA**

Billion-dollar grass – *see* **JAPANESE MILLET**

Bilsted – *see* **SWEET GUM**

Bindi – *see* **OKRA**

Bindweed – *see* **ROUGH BINDWEED**

Bird vetch – *see* **TUFTED VETCH**

BIRIBÁ – Native to northern South America and the West Indies, the biribá (*Rollinia deliciosa*) grows on a small tree and is most appreciated in northern Brazil, where it is grown commercially. It is a round, yellow, sweet, and juicy fruit that can weigh up to 3 pounds when mature. It is consumed fresh and made into juice.

Birthroot – *see* **TRILLIUM**

Bishop's-weed – *see* **AJOWAN**

Bistort – *see* **KNOTWEED AND SMARTWEED**

Bitter button(s) – *see* **TANSY**

Bitter cucumber – *see* **BITTER MELON**

Bitter gallberry – *see* **WINTERBERRY**

Bitter gourd – *see* **BITTER MELON**

BITTER MELON (*see also* **MELON**) – The fruit of a tropical vine, which is also known as "bitter cucumber," "balsam pear," and "bitter gourd," the bitter melon (*Momordica charantia*) originated in the Old World – possibly in Africa, but more likely in India – and was carried by the Portuguese to Brazil in the sixteenth or seventeenth century. Although now widespread in the tropical world from the Philippines to the Caribbean, the bitter melon is most highly regarded in much of Asia, where it is thought to have medicinal properties (it does contain quinine, which accounts for its bitter taste); it is believed to purify the blood and cool the body.

But the bitter melon is also cultivated as a food in China and South and Southeast Asia. The fruit has a skin that is light to bright green, wrinkled, and shiny, and it turns yellow as it ripens. Consumers look for the green skin because bitter melon is deemed best when it is immature. Like the cucumber, which it resembles, this fruit is usually prepared by halving it and scooping out the seeds. The Chinese braise or steam the bitter melon, whereas in India it is used in curries, pickled, frequently boiled and fried, and sometimes eaten raw after being steeped in water to remove the bitter taste.

Common names and synonyms: Balsam pear, bitter cucumber, bitter gourd, *kerela.*

See in addition: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

Bitter oca – *see* **OCA**

Bitter orange – *see* **ORANGE**

BITTER POTATO (*see also* **WHITE POTATO**) – The bitter potato (*Solanum* × *juzepczukii* or *S.* × *curtilobum*) is an ancient food of the high Andean plateau spanning Peru and Bolivia, where its cultivation dates from at least 8,000 years ago. Early Spanish chroniclers mentioned potatoes that were processed by freezing, thawing, and drying to make *chuño* – a life-sustaining staple. Although bitter potatoes were not the only potatoes that were "freeze-dried" in this fashion, in their case such processing was essential to remove their glycoalkaloids. Both black and white versions of *chuño* are made; the former is a thoroughly dehydrated product that keeps well, and the more expensive white *chuño* is available in markets and consumed on festive occasions.

See in addition: "Potatoes (White)," Part II, Section B, Chapter 3.

Bitterroot – *see* **VALERIAN**

BITTER ROOT – A western North American plant, *Lewisia rediviva* was named for Meriwether Lewis of the Lewis and Clark expedition across the continent in 1806 and 1807. The plant has white flowers and fleshy, edible roots that were roasted or boiled and consumed by Native Americans in the western part of the country. They also dried and ground the roots into a meal.

Bitters – *see* **ANGOSTURA**

Bitter tomato – *see* **LOCAL GARDEN EGG**

BITTER VETCH (*see also* **VETCH**) – This Mediterranean herb (*Vicia ervilia* or *Ervum ervilia*) is widely cultivated as fodder for livestock. Care must be taken with bitter vetch, however, because its seeds are considered poisonous for pigs and dangerous when moist and mature. Occasionally, it is eaten in soups. Found in Europe, Asia, and the United States, bitter vetch is also known as ervil.

Common names and synonyms: Ervil.

Bitterweed – *see* **RAGWEED**

BITTER YAM (*see also* **YAMS**) – Also called "African bitter yam," the bitter yam (*Dioscorea dumetorum*) is a native of tropical Africa, where it has remained because of the bitter taste its name proclaims. The reason that it is cultivated at all (mostly in Nigeria) is that it apparently has a higher yield than most other African yams. It is usually boiled in soups and stews.

Common names and synonyms: African bitter yam, cluster yam, trifoliate yam.

See in addition: "Sweet Potatoes and Yams," Part II, Section B, Chapter 5.

Bixa – *see* **ANNATTO**

Black alder – *see* **WINTERBERRY**

BLACKBERRY (*see also* **BERRIES**) – There are numerous species of blackberries (genus *Rubus*), which are divided into those that grow on brambles and those that grow on trailing vines; the latter are often called "dewberries" in the southern United States. Together, the blackberry and the dewberry constitute the most important of the wild berry crops in the United States. As a rule, these berries are indeed black or purplish black and outwardly resemble raspberries (also of the genus *Rubus*) in that each berry looks like a cluster of very tiny berries. Blackberries are an autumn crop that was harvested far back in prehistoric times. Their remains have been found in excavations of the earliest European habitations. Blackberries were known to the ancient Greeks and were another of the many gathered foods that sustained Native Americans, who may also have used them medicinally. The berries are said to be good blood cleansers and useful in combating dysentery as well as colds, and the leaves have been employed against sore throats. Some hybrid varieties of the blackberry, such as boysenberries, loganberries, and olallieberries, have been developed. Like all berries, the blackberry is a fine source of vitamin C. It also provides a good deal of iron.

Common names and synonyms: Boysenberry, bramble(s), dewberry, loganberry, olallieberry.

Black-cap – *see* **RASPBERRY**

Black caraway (seed) – *see* **NIGELLA**

Black cumin – *see* **NIGELLA**

BLACK CURRANT (*see also* **CURRANTS**) – Called *cassis* by the French, the black currant (*Ribes nigrum*) is employed to make the cordial *crème de cassis* and an aperitif called "Kir"; it is also used as a garnish with ice cream.

Common names and synonyms: Cassis, European black currant.

Black dhal – *see* **MUNG BEAN**

Black diamond (truffle) – *see* **TRUFFLE(S)**

Black drink – *see* **YAUPON**

Black-eyed pea – *see* **BEANS, COWPEA**

Black gram – *see* **MUNG BEAN**

BLACK GUM – Also called "sour gum," "pepperidge," and "tupelo," the black gum (*Nyssa sylvatica*) is a tree of eastern, central, and southern North America. It produces small, blue-black, plumlike fruits that were among the many foods gathered by Native Americans.

Common names and synonyms: Beetle-bung, pepperidge, sour gum, tupelo.

BLACK HAW (*see also* **BERRIES**) – Also known as "sweet haw," "sheepberry," "nannyberry," and "stagbush," these trees have two different scientific names depending on where they are found. On the east coast of the United States, the black haw is known as *Viburnum prunifolium,* whereas in the Midwest and on the Pacific coast it is *Crataegus douglasii.* The trees are usually planted for ornamental purposes, although their small, blue-black fruits can be made into preserves; the leaves, too, are edible, as Native Americans well knew. The black haw is also known for the medicinal uses of its bark. Containing the bitter resin viburnin, it is used as a sedative, uterine relaxant, and diuretic.

Common names and synonyms: Hawthorn, nannyberry, sheepberry, stagbush, sweet haw.

Black Indian hemp – *see* **HEMP DOGBANE**

BLACK MONKEY ORANGE – Native to southern Africa, *Strychnos madagascariensis* bears fruits that average a little over 3 inches in diameter and change from blue-green to yellow upon ripening. A thick shell protects the pulp, which is frequently made into a kind of jam by the Zulu people. In Zimbabwe, the pulp is dried in the sun or over a fire to serve as a nutriment during times of food shortage. The oil of the pulp is used as a medicine for dysentery.

Black nightshade – *see* **WONDERBERRY**

Black oyster-plant – *see* **SCORZONERA**

Black persimmon – *see* **BLACK SAPOTE**

Black salsify – *see* **SCORZONERA**

BLACK SAPOTE (*see also* **WHITE SAPOTE**) – A number of different fruits are called sapote (or sapota), which can produce considerable confusion. One might expect to find, for example, that the white sapote and the black sapote – both tropical American natives – are different-colored specimens of the same fruit. But they are not even of the same family: The white sapote belongs to the family Sapotaceae, and the black sapote to the family Ebenaceae. The black sapote (*Diospyros digyna* – a relative of the persimmon) does, however, resemble the sapodilla in form, although it has a sweet, soft, dark brown flesh. It is a highly prolific tree, grown throughout the New World tropics and subtropics, as well as in Hawaii and California, and the fruit is principally used in desserts.

Common names and synonyms: Black persimmon, black sapota, chocolate-pudding fruit, *zapte negro.*

Black snakeroot – *see* **WILD GINGER**

Black tamarind – *see* **VELVET TAMARIND**

Blackthorn – *see* **HAW, SLOE**

BLADDER CAMPION – There are a number of plants of the genus *Silene* that are called "campion" – especially "bladder campion" (*S. cucubalus = S. vulgaris*). It is a European green gathered in the spring for use as a potherb, particularly in the south of France.

Bladder weed – *see* **KELP, SEAWEED**

Blanc Fumé – *see* **SAUVIGNON BLANC**

Blé de Turquie – *see* **MAIZE**

Bledos – *see* **AMARANTH**

Blessed herb – *see* **HERB BENNET**

Blimbling – *see* **BELIMBING**

BLOOD ORANGE (*see also* **CITRUS FRUITS, ORANGE**) – A very large variety of sweet orange, the blood orange (*Citrus sinensis*) has juice that is usually of a burgundy hue, which along with the red color of its flesh, accounts for its name. Blood oranges (also called pigmented oranges) are a favorite in Europe (especially in countries along the Mediterranean coastline) but have not really caught on in the United States, although the "Ruby Blood" and "Moro" varieties are grown in California and Florida. Blood oranges come mostly from Spain and Italy; important European varieties include the Spanish *Sanguinella* and the "Maltese Blood." The English call these fruits "Maltese oranges," the French "*Maltaise oranges,*" and it is from the latter people that a hollandaise sauce – with the addition of the grated rinds of blood oranges – received the name "maltaise sauce." Like other oranges, the blood orange is a good source of vitamin C and provides some fiber as well. Its red color, however, does not come from carotene, which is one of the many exceptions to the rule that red and orange coloring of fruits and vegetables is a promise of beta-carotene.

Common names and synonyms: Maltaise orange, Maltese Blood, Maltese orange, Moro, pigmented orange, Ruby Blood, *Sanguinella.*

BLUEBERRY (*see also* **BERRIES, BILBERRY**) – Blueberries come from any of a number of shrubs of the genus *Vaccinium* that grow wild over much of the globe and can be found in the Western Hemisphere from Alaska to the jungles of South America. Those indigenous to North America are either highbush (especially *V. corymbosum* – also called the swamp blueberry) or lowbush (*V. angustifolium* – sometimes called the sweet blueberry). The former type has been commercially cultivated in the United States throughout most of the twentieth century and is considerably larger than its wild counterparts. Blueberries, which look almost the same as huckleberries, keep longer in storage than other berries – in both fresh and frozen forms. Blueberries were an important food for Native Americans, who used them in stews and dried and stored them for winter use. The Indians of Alaska have traditionally preserved them in seal oil for consumption in the winter. Blueberries are frequently eaten alone as a fruit, but are also popular in muffins, pies, cobblers, jams, and jellies and are made into wine. They are an excellent source of vitamins A and C as well as fiber.

Common names and synonyms: Highbush blueberry, huckleberry, late sweet blueberry, late sweet bush, lowbush blueberry, low sweet bush, rabbit-eye blueberry, swamp blueberry, sweet blueberry, whortleberry.

Blueberry elder – *see* **ELDERBERRY**

Bluebottle – *see* **CORNFLOWER**

BLUE COHOSH – A plant with a number of common names, such as "papoose root," "squawroot," and "blue ginseng" or "yellow ginseng," the blue cohosh (*Caulophyllum thalictroides*) is found in eastern North America and is especially common in the Allegheny region. Its seeds have been roasted and used as a substitute for coffee, and its large leaves consumed after boiling, but its blue berries are said to be poisonous. Its rootstock, which contains an alkaloid, is used medicinally.

Common names and synonyms: Blue ginseng, papoose root, squawroot, yellow ginseng.

Blue ginseng – *see* **BLUE COHOSH**

Blue lupine – *see* **BEANS**

Blue mountain tea – *see* **GOLDENROD**

BLUE-STEM – A grass of the western United States, blue-stem (*Andropogon furcatus*) is also called "blue-stem wheatgrass" and "western wheatgrass." Today it is used for hay; in the past both the stems and the seeds provided food for Native Americans; the plant also was used as a medicine for indigestion.

Common names and synonyms: Blue-stem wheatgrass, western wheatgrass.

Blue-stem wheatgrass – *see* **BLUE-STEM**

BLUE VERVAIN – A North American member of a genus that includes species scattered around the globe, blue vervain (*Verbena hastata*) grows as a weed throughout southern Canada and here and there in the United States – from Florida to Arizona. Native Americans processed the seeds of the plant by roasting and grinding them into a flour.

Common names and synonyms: False verbain, verbain, verbena, vervain, wild hyssop.

Blue water lily – *see* **LOTUS**

Bochweit – *see* **BUCKWHEAT**

Boechweite – *see* **BUCKWHEAT**

Bogbean – *see* **BOG MYRTLE**

BOG HEATHER – Also called cross-leaved heath and cross-leaf heath, bog heather (*Erica tetralix*) is a European shrub of bogs and marshes. Some varieties have dark, rose-red flowers with stems and petals that are said to be edible.

Common names and synonyms: Cross-leaf heath, cross-leaved heath.

BOG MYRTLE – Also called "Scotch gale" and "sweet gale," bog myrtle (*Myrica gale*) grows in bogs throughout the north temperate zone and has bitter-tasting leaves that are used as a potherb. In the past, before the use of hops, bog myrtle was widely employed in western Europe for flavoring beer, and it is still used on occasion for this purpose in England, where hopped beer has always met with some consumer resistance. Another plant known as bog myrtle and similarly used is the buckbean (*Menyanthes trifoliata*).

Common names and synonyms: Bogbean, buckbean, marsh trefoil, Scotch gale, sweet gale.

Bog potato – *see* **APIOS**

Bog rhubarb – *see* **COLTSFOOT**

BOK CHOY (*see also* **CABBAGE AND CHINESE CABBAGE**) – This member of the cabbage family is an East Asian native and a mainstay in the diets of the region. But bok choy (*Brassica rapa*) is also available in the markets of Europe and North America. It is sometimes called Chinese cabbage or Chinese mustard cabbage, which leads to confusion with the real Chinese cabbage (napa). In appearance, its nonheading stalks and leaves (both are eaten) resemble Swiss chard, or celery without the ribs. The taste of the stalks is something like that of romaine lettuce, whereas the leaves have a definite cabbage-like flavor. Bok choy is a favorite among the stir-fry vegetables and, in addition to being a fine source of vitamins A and C, also provides some calcium.

Common names and synonyms: Celery cabbage, Chinese cabbage, Chinese mustard cabbage.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

BOLETE (*see also* **MUSHROOMS AND FUNGI**) – Several of the mushroom members of the genus *Boletus* are poisonous, but not *Boletus edulis,* also called *porcino,* cep, *cèpe de bolete,* and *cèpe de Bordeaux.* These are wild mushrooms – easily recognized by the presence of spongy tubes instead of gills under their brownish-colored caps – and are highly prized throughout much of Europe. Although this mushroom also grows in North America, it tends to be moldy and is often a prey of insects. But in the spring and again in the fall the Italians hunt and consume their *porcini* with gusto, as do the French their *cèpes,* and the Germans their *Steinpilze.* A delicious mushroom that is generally eaten fresh – but wonderful as well when dried – it is also powdered and preserved in oil. *Boletus edulis* provides some vitamin D and a little of the vitamin B complex. It is also a good source of fiber.

Common names and synonyms: Cep, *cèpe, cèpe de bolete, cèpe de Bordeaux,* king bolete, *porcini, porcino, Steinpilz.*

See in addition: "Fungi," Part II, Section C, Chapter 7.

Bonavist bean – *see* **HORSE GRAM**

Bondue – *see* **AMARANTH**

BONESET – Any of several plants of the genus *Eupatorium* – and especially *E. perfoliatum* – are called boneset, along with a host of other colorful names, such as "auguweed," "feverwort," and "sweating plant," all suggestive of past medicinal uses. Some species, like *E. dalea,* have been used as a vanilla substitute in the American tropics. The leaves and flowering tops of others are cooked as greens in Asia, and in North America, where *E. perfoliatum* is a common weed, these parts of the plant served Native Americans as a wild food. One North American species (*E. rugosum*) – called "white snakeroot" – is toxic. This is the infamous weed that caused trematol poisoning in the cattle that grazed on it and "milk sickness" in the humans who drank their milk – a surprisingly frequent cause of death in the early decades of the nineteenth century.

Common names and synonyms: Aguweed, auguweed, feverwort, sweating plant, white snakeroot.

BONIATO (*see also* **SWEET POTATO**) – In Cuba, *boniato* (*Ipomoea batatas*) means sweet potato. This term is not to be confused with the Puerto Rican *boniata,* which means sweet yuca. Yet even the Cuban meaning is hazy, because white-fleshed sweet potatoes are preferred on that island, so that *boniato* has come to signify only the light-colored varieties that spread from their American homeland to Europe and throughout Asia – the latter region now grows some 90 percent of the world's production. A kind of cross between the orange sweet potato and a white potato, the *boniato* is a fair source of vitamin C and the B-vitamin complex. The whiter-fleshed varieties are not, however, good sources of beta-carotene, and some contain absolutely none.

Common names and synonyms: Cuban sweet potato, sweet potato, white sweet potato, yam (U.S.).

See in addition: "Sweet Potatoes and Yams," Part II, Section B, Chapter 5.

Bonnet pepper – *see* **HABANERO AND SCOTCH BONNET PEPPERS**

Booth – *see* **AVOCADO**

BORAGE (*see also* **INDIAN BORAGE**) – A native of the Middle East and Mediterranean regions, where it still grows wild, borage (*Borago officinalis*) has azure, nectar-filled flowers that bees love. The name derives from the Latin *burra* – meaning "rough hair" – and refers to the "hairs" that protrude from the stems and leaves of the plant, which taste something like unripened cucumbers. The Chinese stuff the leaves of borage in much the same way that Greeks stuff grape leaves. In France and Italy, the leaves are employed fresh in spring salads, are added to stews, and are used as a base for borage soup. In Germany, borage is often used in salads with dill, and in Britain and North America the leaves and flowers are sometimes added to cold drinks. Borage is also an ingredient in Pimm's No. 1, a gin drink of England. The flowers are added to salads and are frequently crystallized.

Borassus palm – *see* **WINE PALM**

Boreal vetch – *see* **TUFTED VETCH**

Borecole – *see* **COLLARDS, KALE**

Botoko plum – *see* **GOVERNOR'S PLUM**

BOTTLE GOURD (*see also* **CALABASH, SQUASH AND PUMPKIN**) – Although apparently a native of Africa, the bottle gourd (*Lagenaria siceraria*) spread to both Asia and the Americas in prehistoric times. In Mexico, bottle gourd remains dating from 7000 B.C. have been found, but how the Atlantic crossing was achieved is one of the mysteries surrounding the movements of plants in the distant past. The bottle gourd is so called because, when dried, it can be scooped out and employed as a container; such gourds were probably among the first utensils used by some human groups and, of course, are still in use as dipper gourds today. Although not well known as a food plant, bottle gourds are regularly consumed in India, China, and Japan and are similar in taste and texture to summer squashes. In India, the bottle gourd is called *doodhi,* and its flesh is added to stews and curries. In Japan, it becomes *kampyo* – the flesh is cut into ribbon-like strips that are dried and used as edible ties for packaging sushi. Bottle gourds are also employed as food in some of the countries of Latin America.

Common names and synonyms: Doodhi, hue, kampyo.

Bounce berry – *see* **CRANBERRY**

Box thorn – *see* **MATRIMONY VINE**

BOYSENBERRY (*see also* **BERRIES, BLACKBERRY**) – The boysenberry (*Rubus loganobaccus*) is the creation of twentieth-century American horticulturalist Rudolph Boysen, who in about 1920 created this huge blue-black hybrid berry by crossing the loganberry, the raspberry, and the blackberry. The boysenberry resembles the latter two in taste and has been assigned to the genus *Rubus.*

BRACKEN FERN – Also known simply as bracken or brake, this fern (*Pteridium aquilinum*) is well distributed throughout the world's temperate and tropical regions and has found use in such diverse corners of the globe as North America, Europe, Asia, the South Pacific, and the Canary Islands. The fronds are used for thatching and as fodder, but young ones are also cooked and eaten as a vegetable and made into soups. The rhizomes of the plant are roasted and ground into flour used in bread making. Native Americans steamed the fern in fire pits.

Common names and synonyms: Aruhe, bracken, brake.

Brake – *see* **BRACKEN FERN**

BRAMBLE(S) (*see also* **BERRIES, BLACKBERRY, BOYSENBERRY, CLOUDBERRY, DEWBERRY, JAPANESE WINEBERRY, LOGANBERRY, RASPBERRY, SALMONBERRY**) – An overarching name for any prickly plant or shrub of the genus *Rubus* is "bramble" or "brambles," which embraces blackberries, boysenberries, loganberries, and raspberries as well as other lesser-known species and varieties.

Brazilian cherry – *see* **PITANGA**

Brazilian grape tree – *see* **JABOTICABA**

BRAZILIAN MALAGUETA (*see also* **CHILLI PEPPERS**) – A small, greenish, tapered chilli pepper, the Brazilian malagueta (*Capsicum frutescens*) is not so narrowly confined as its name implies. It is actually a widely grown pepper, and its territory reaches north through Central America as far as Louisiana, where a variety called tabasco is grown.

Common names and synonyms: Bird pepper, tabasco pepper.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

BRAZIL NUT – This three-sided nut (*Bertholletia excelsa*) with a hard, dark shell grows in bunches of from one to more than two dozen nuts inside coconut-like shells (called *cocos* in Portuguese) on evergreens that tower over the Amazon rain forest. These nuts, which are native to Brazil and Guiana, take about 14 months to ripen after the flowers fade, and one tree can yield more than a half ton of fruit. There are some Brazil-nut plantations, but most are still harvested in the wild. And because the trees attain a height of upwards of 150 feet, and the *cocos* weigh about 5 pounds, and they are gathered only after they fall to the ground, harvesting these missiles can be hazardous work. It it interesting to note that Brazil nuts are not much consumed in Brazil, save for medicinal purposes. Rather, fairly early in the nineteenth century, the country began exporting almost the entire crop, and Europe and the United States became and remain the major importers. Because attempts have failed to cultivate the tree elsewhere, Brazil has a monopoly on more than the name. Brazil nuts have a high oil content and, consequently, are high in calories. But they are also a good source of calcium, thiamine, vitamin E, selenium, and sulfur-containing amino acids.

Common names and synonyms: Cream nut, para nut.

BREADFRUIT – The breadfruit tree (*Artocarpus altilis = A. communis = A. incisus*), which grows to about 40 feet in height, is native to the East Indies and the tropics of the South Pacific. It was carried eastward as far as the Hawaiian Islands by migrating Polynesians and is known to have been cultivated for more than 2,000 years as a staple food for Pacific peoples. Breadfruit was first described (for Europeans) by the English navigator William Dampier, who found it growing on Guam in 1688. About a century later, Captain James Cook observed the plant in Tahiti. This occurred in the aftermath of the American Revolution, which had resulted in much French interdiction of England's shipping to its colonies in the Caribbean and, consequently, much hardship for slaves on English sugar plantations. In 1787, the British government dispatched HMS *Bounty,* commanded by Captain William Bligh (who had been Cook's lieutenant), to Tahiti to collect breadfruit and other plants that might be useful for feeding slaves. The notorious mutiny on the *Bounty* prevented Bligh from accomplishing this first attempt at his mission, but later – in 1793 – he succeeded in carrying to the West Indies a cargo that included young breadfruit trees. The slaves, however, refused to eat breadfruit, which resembled nothing they had known in either West Africa (the "breadfruit" there is *Treculia africana*) or the West Indies, and for a half century or so the fruits of *A. altilis* were a food mostly for hogs. Yet following the end of slavery, breadfruit finally found its way into human diets in the Caribbean. Not really a fruit, the breadfruit comes in many varieties, some with seeds and some without. The seeded varieties are known as "breadnuts" and can be roasted like chestnuts. Breadfruit is baked, boiled, roasted, fried, and dried to make flour. When utilized as a completely green vegetable, the breadfruit – which can attain the size of a cantaloupe – is hard like a raw potato; when a bit ripe (it does not keep well), it is more like a baked potato. Breadfruit absorbs the flavors of other foods and thus can stretch the taste of meats, fish, and fowl. Like cassava, however, it is lacking in most nutrients, save some calcium and vitamin C. Unfortunately, the latter is largely destroyed by the heat of cooking.

Common names and synonyms: Breadnut, *fruit à pain, pana de pepita, sukun.*

BREADNUT – Also called *ramón,* the breadnut is the fruit of *Brosimum alicastrum,* a tree native to the West Indies and Central America. The tree grows to some 75 feet in height and produces a heavy yield of edible fruit, either a large, somewhat flavorless, red variety or a smaller, better-tasting, yellow one. The Maya prepared the fruit in the same manner as maize – grinding it on a stone and patting it into a flat bread similar to a tortilla. The seeds were made into gruel after cooking in ash water to remove the bitterness of their latex outer coating. The Maya call the breadnut "food of the ancestors," and some experts believe it was the staple food of many Mesoamerican Indians before the Spanish conquest. Its English name came about because the fruit is round and nutlike and can be ground to make a substitute for wheat flour. But the word "breadnut" is also used to describe the seeded varieties of breadfruit (not a relative), and it is important not to confuse the two. Today, the breadnut remains a part of certain Mayan religious rituals, but on an everyday basis it is usually fed to pigs.

Common names and synonyms: Ramon, *ramón.*

BREADROOT (*see also* **INDIAN TURNIP**) – Also called "prairie turnip," *tipsin,* "Indian breadroot," and "breadroot scurf pea," breadroot (*Psoralea *esculenta*) is a North American native that can be found on the plains from the Northwest Territories of Canada to Texas. Its thick, brown, edible starchy root was a staple for Native Americans and later sustained explorers and immigrants.

Common names and synonyms: Breadroot scurf pea, Indian breadroot, Indian potato, Indian turnip, prairie potato, prairie turnip, *tipsin.*

Breadroot scurf pea – *see* **BREADROOT**

Brinjal – *see* **EGGPLANT**

Bristle grass – *see* **MILLET**

Broad bellflower – *see* **CAMPANULA**

Broad-leaved tea-tree – *see* **CAJEPUT**

BROCCOLI (*see also* **BROCCOLI RAAB, CABBAGE, CALABRESE, CAULIFLOWER, CHINESE BROCCOLI**) – A member of the mustard family, and doubtless a descendant of the wild cabbage (*Brassica oleracea*), broccoli (*Brassica oleracea* var. *italica*) began as a wild-growing native of the Mediterranean region. Like all cabbages, broccoli was originally eaten for its stems, with the flowering heads a later development. Although broccoli is believed to be the forerunner of cauliflower – a vegetable known in Europe by the sixteenth century – it trailed behind cauliflower by about a century in culinary usage, save perhaps in Italy. The Italians claim broccoli as their own: The name comes from the Italian *brocco,* meaning "sprout" or "shoot," which, in turn came from the Latin *brachium,* meaning "arm" or "branch" – a succinct description of this plant with its many thick and fleshy stalks. Broccoli was introduced into England (where the term "broccoli" refers to cauliflower) around 1720 and was probably brought to North America soon thereafter, during colonial times. However, although much of the latter region offers the abundant moisture and cool climate that broccoli thrives within, the vegetable was not commonly grown in the United States until the twentieth century and only became popular after World War II – when returning GIs, who had eaten broccoli abroad, created a demand. It has subsequently become one of the most important frozen foods in the world. The green, unopened flower end is the part that is generally eaten, usually after steaming or boiling, although the leaves and tender parts of the stem can also be consumed. Broccoli is packed with vitamins and minerals, is an especially good source of vitamins A and C, and, as a cruciferous vegetable, is thought to be in the front line of foods that fight cancer.

Common names and synonyms: Asparagus broccoli, calabrese, Italian asparagus, sprouting broccoli.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

BROCCOLI RAAB (*see also* **BROCCOLI, CABBAGE**) – A favorite of the Italians (who call it *rapini*), broccoli raab (*Brassica napus*) is related to the turnip (some call broccoli raab "turnip broccoli") as well as being a member of the family that includes cabbage, cauliflower, and broccoli. It has dark green leaves, and its stalks resemble thin broccoli stalks. It is cooked and eaten like broccoli or kale; its taste, which is pungent and somewhat bitter, seems to encompass all of the most zesty flavors of its relatives and can certainly enliven bland foods. Like most greens, this especially aggressive representative is a good source of vitamins A and C as well as calcium and iron.

Common names and synonyms: Broccoli rab, broccoli rabe, broccoli rape, *brocoletti di rape, brocoletto,* Italian turnip, rape, *rapini,* turnip broccoli.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Broccoli rab – *see* **BROCCOLI RAAB**

Broccoli rabe – *see* **BROCCOLI RAAB**

Broccoli rape – *see* **BROCCOLI RAAB**

Brocoletti di rape – *see* **BROCCOLI RAAB**

Brocoletto – *see* **BROCCOLI RAAB**

Broken Orange Pekoe Fannings – *see* **TEA**

BROMELIA – *Bromelia* is the type genus of the family Bromeliaceae, which comprises plants often subsumed under the genus *Ananas,* such as the pineapple and the pinguin.

BROOKLIME – Also known as brooklyme, brooklime is any of several species of the genus *Veronica,* such as the Eurasian *V. beccabunga* and the American *V. americana,* which are edible aquatic or semiaquatic plants similar to watercress.

Common names and synonyms: Brooklyme, speedwell.

Brooklyme – *see* **BROOKLIME**

Broomcorn – *see* **SORGHUM**

BRUSH CHERRY – An Australian shrub or tree, the brush cherry (*Eugenia myrtifolia* or *Syzygium paniculatum*) is also called native myrtle (in Australia) and rose apple. Its edible red fruit has a sweet-tasting white flesh that is sometimes made into jelly. The fruit has helped to feed the Aborigines over many millennia.

Common names and synonyms: Native myrtle, rose apple.

BRUSSELS SPROUT(S) (*see also* **CABBAGE**) – Members of the mustard family that descended from the cabbage (*Brassica oleracea*) and were named for the capital of Belgium, Brussels sprouts (*Brassica oleracea* var. *gemmifera*) are immature buds, shaped like tiny cabbages, that cluster on the main stem of the plant they grow on. Although the cabbage is native to the Mediterranean region (where it has been cultivated for some 2,500 years), Brussels sprouts were developed in northern Europe (the cabbage was carried there by the Romans) around the fifth century – or perhaps even later. One source claims that the plant was cultivated near Brussels in the thirteenth century; another places the first recorded description of Brussels sprouts in 1587; still another claims that they have been widely grown in Europe only since the seventeenth century; whereas at least one more source insists that they have become popular in Europe only since World War I. Of course, these claims are not necessarily contradictory. But surely, in view of its name, the plant must have been grown around Brussels at some time. Brussels sprouts reached North America with French settlers, who grew them in Louisiana, but they have been popular in the United States only during the twentieth century, with most grown in the states of New York and California. Brussels sprouts brim with vitamins. They are an especially good source of vitamins A and C and, like other members of the cabbage family, enjoy a reputation for lowering low-density lipoprotein and for preventing cancer.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Buckbean – *see* **BOG MYRTLE**

BUCKEYE – Also called "horse chestnuts," buckeyes come from any of several trees of the genus *Aesculus.* Although poisonous when raw (because they are rich in saponin), buckeyes become edible when roasted and leached with water for a few days – a procedure with which Native Americans were familiar. They also used buckeyes raw as a fish poison. The seeds of local species are still consumed in Asia today.

Common names and synonyms: Horse chestnut.

BUCKTHORN – A number of shrubs and trees of the genus *Rhamnus* are called "buckthorn." They have berry-like fruits, and these – along with the bark and sap of the plants – have been mostly used as purgatives. However, the fruits of *R. crocea* in what is now southern California were eaten by Native Americans, as were those of *R. caroliniana* in the southeastern portion of North America.

Common names and synonyms: Redberry.

BUCKWHEAT – Grown extensively in China for millennia (although thought to be a native of Manchuria and Siberia), "buckwheat" is any plant of the genus *Fagopyrum,* especially *F. esculentum.* It is neither a true cereal nor a grass but constitutes a family of its own. Buckwheat was introduced into Europe toward the end of the Middle Ages. It does well in areas where the climate is cool and moist and became important in some northern and eastern European areas that had not only such a climate but also soils in which other grains did not thrive. In the Netherlands, the plant was called *boechweite* or "beech wheat," perhaps because the grains are shaped a bit like beechnuts. The Dutch, in turn, carried the grain to the New World, where the name became buckwheat. Another name, *kasha,* acquired from the Slavic mediators between Asia and Europe, is today applied to roasted and cracked buckwheat. Finely ground buckwheat is called buckwheat grits, whereas buckwheat groats are whole kernels that are either unroasted and white, or roasted and brown. In addition, the grain is turned into buckwheat flour for pancakes. The plant also serves as an animal feed, and its flowers and leaves yield a substance used in the treatment of hypertension. Today, the countries of the former Soviet Union (especially Russia) are collectively the main producers of buckwheat, of which there are three major varieties: Silverhull, Tartary, and Japanese.

Common names and synonyms: Beech wheat, *bochweit, boechweite,* buckwheat grits, buckwheat groats, Japanese buckwheat, *kasha,* Silverhull, Tartary.

See also: "Buckwheat," Part II, Section A, Chapter 3.

Buddha's-hand – *see* **CHAYOTE**

BUFFALO BERRY (*see also* **BERRIES**) – Two North American shrubs, *Shepherdia argentea* and *S. canadensis,* yield the silver buffalo berry and the russet buffalo berry respectively. Resembling currants (and sometimes called "Nebraska currants") as well as barberries, buffalo berries have long been a part of the Native American diet on the Great Plains and in western North America. The shrubs grow wild along streams and are one of the few plants that do well in a dry and rocky environment. *Shepherdia canadensis* (also known as the Canadian buffalo berry) produces the smaller of the two berries and is relatively tasteless. The berries of *S. argentea,* by contrast, are flavorful and used in jellies. Buffalo berries are a fine source of vitamin C.

Common names and synonyms: Canadian buffalo berry, Nebraska currant, russet buffalo berry, silver buffalo berry.

BUFFALO GOURD (*see also* **SQUASH AND PUMPKIN**) – A large plant with a bad smell, the buffalo gourd (*Cucurbita foetidissima*) grows wild in the south-central and southwestern United States as well as in northern Mexico. The fruits were sometimes used as rattles by Native Americans and reportedly were cooked and eaten at times, although today they are considered inedible. The seeds, however, were regularly consumed, generally after roasting and grinding them into a kind of mush. Oil was also obtained from the seeds. The pulp of the fruits and the huge root (which can weigh over 200 pounds) of the buffalo gourd contain saponin and were therefore employed as soap.

Common names and synonyms: Calabazilla, Missouri gourd.

See in addition: "Squash," Part II, Section C, Chapter 8.

Bulbine lily – *see* **YAM DAISY**

Bulghur – *see* **WHEAT**

Bullace grape – *see* **MUSCADINE**

Bullace plum – *see* **DAMSON PLUM**

Bullbrier – *see* **GREENBRIER**

Bull-dog – *see* **TURKEY FRUIT**

Bullock's heart – *see* **CUSTARD APPLE**

Bullrush – *see* **BULRUSH**

Bullsfoot – *see* **COLTSFOOT**

BULRUSH – A versatile food source in the wilderness, bulrushes (genus *Scirpus*) are grassy sedges that grow in wet places. These wild marsh plants have young shoots and juicy stem bases that can be boiled as greens or consumed raw in salads. In addition, the rhizomes are edible (they were often dried and ground), and the pollen was gathered by Native Americans to mix with flours for porridges and cakes. The seeds of some species are also edible. Most bulrushes are American natives, but Europe and Asia also have their own species – indeed, a bulrush constituted the Old Testament papyrus – and in East Asia the young stems of *S. fluviatilis* are still consumed today. Bulrush, broadly speaking, can also mean cattail, especially in Britain.

Common names and synonyms: Bullrush.

Bunchberry – *see* **CORNUS**

BUNCHOSIA – *Bunchosia argentea* is called the "peanut butter fruit" for the excellent reason that its flesh has both the consistency and the flavor of peanut butter. It is a native of tropical South America and is also grown in Florida, but it is uncommon almost anywhere else. The trees grow to more than 30 feet tall and bear flowers and fruit almost all year long. The small fruits are yellow or red, are oblong, and hang in clusters. Their flesh is the color of cream and, although sweet, is often too tart to be enjoyed fresh. The fruit may be made into preserves, but it is more frequently employed as a flavoring.

Common names and synonyms: Ciruela, peanut-butter fruit.

Buni – *see* **BIGNAY**

Burbank's spineless – *see* **PRICKLY PEAR**

BURDEKIN PLUM (*see also* **PLUM**) – The fruits of the Australian trees *Pleiogynium timoriense* and *P. solandri* are called "Burdekin plums." Both are plum-sized and edible, but the fruit of *P. timoriense* is purple, whereas that of *P. solandri* is red. They are not sweet and today are used mostly in jellies and jams. However, the fruits have long served as food for the Aborigines.

BURDOCK – Also known as "great burdock" and originally from Siberia, burdock (*Arctium lappa*) is cultivated for its long (up to 4 feet), slender, carrot-shaped taproot. The Japanese, who use burdock as others do carrots, are its foremost producers and consumers, although it can also be found in the markets of Taiwan and Hawaii. The roots are grated or cut into pieces and stir-fried or added to various dishes – especially soups – to which they contribute a somewhat earthy taste. The plant grows wild in North America and Europe, producing burrs that attach themselves to the clothing of those who cross meadows. Nutritionally, burdock offers mostly minerals, such as potassium and magnesium, although it is not a bad source of folacin.

Common names and synonyms: Beggar's-button(s), clotbur, edible burdock, *gobo,* great burdock, harlock.

BURMA MANGROVE – An evergreen tree of the Old World tropics, the Burma mangrove (*Bruguiera gymnorhiza*) produces edible, berry-like fruits. In some places, the bark is used as a flavoring; in others, the leaves are cooked as a vegetable.

BURNET – The name "burnet" comes from the Middle English and Old French *brunette,* which describes the brownish red flowers of the several species of this European native, now also commonly found in North America. One kind of burnet, *Poterium sanguisorba,* with cucumber-tasting leaves, was once a popular herb but is not much used anymore save in a few Italian and French dishes. In the past, however, especially in Elizabethan England, its leaves were frequently added to salads and sauces. There is confusion between this burnet and great burnet (*Sanguisorba officinalis*), also known mistakenly as bloodwort because of its reputation for stopping bleeding. Asian burnet and Japanese burnet are also different species.

Common names and synonyms: Garden burnet, lesser burnet, pimpinel, salad burnet, small burnet.

Burning bush – *see* **DITTANY**

BUSH CURRANT – A small tree or shrub that is also called the "currant bush," the bush currant (*Antidesma ghaesembilla*) is a wild plant of Australia that produces small edible purple or black berries.

Common names and synonyms: Currant bush, gucil.

Bush greens – *see* **AMARANTH**

Bush okra – *see* **JEW'S-MALLOW**

BUTTERCUP SQUASH (*see also* **SQUASH AND PUMPKIN**) – So called because of their turbanlike caps, the orange-fleshed and green-skinned buttercup squash and other moderate-sized varieties of *Cucurbita maxima* are also sometimes referred to as Kabocha-type squashes. These include the Black Forest, the Hokkaido (also Red Kuri), and Honey Delight varieties, all of which make good purees, soups, and pies.

Common names and synonyms: Black Forest, Hokkaido, Honey Delight, Kabocha, Red Kuri.

See in addition: "Squash," Part II, Section C, Chapter 8.

BUTTERFLY WEED – A plant mostly of eastern North America, the butterfly weed (*Asclepias tuberosa*) is the only one of the milkweeds that does not contain milky juice. Its roots were baked and eaten by Native Americans, as were its orange flowers, shoots, and leaves.

Common names and synonyms: Indian posy, orange milkweed, orange root, pleurisy root, tuberroot.

BUTTERNUT – *see also* **WALNUT**

BUTTERNUT SQUASH (*see also* **SQUASH AND PUMPKIN**) – Along with the acorn squash, the butternut (*Cucurbita moschata*) is the most common squash on the tables of North America. It is a winter squash that generally weighs from 2 to 4 pounds and has a tan skin, a long neck, and a swollen bottom. This squash is usually roasted, and its yellow flesh is high in beta-carotene.

See in addition: "Squash," Part II, Section C, Chapter 8.

Butter pear – *see* **AVOCADO**

Butterweed – *see* **HORSEWEED**

C

CABBAGE (*see also* the various *Brassica* entries) – Sources indicate that the cabbage (*Brassica oleracea*) is an ancient vegetable of the European Old World, but cabbages in China were mentioned by Confucius (d. 497 B.C.), which suggests that the plant traveled quite widely in the distant past. Certainly the wild cabbage must long ago have provided sustenance for those of our hunting-and-gathering ancestors who sought the vegetables out. The wild cabbage was a small plant that grew around European coastal areas (especially those of the Mediterranean) and – like broccoli – was first eaten for its stem. But by the time of the Romans, the head had become larger and more rounded, and the subsequent encouragement of various characteristics has resulted in some 400 varieties, such as numerous head cabbages, broccoli, Brussels sprouts, cauliflower, collards, kale, and kohlrabi, to name but a few. Moreover, the various Oriental species of the cabbage family include the Chinese cabbage (napa) and bok choy.

In general, cabbages have trouble with hot weather, although the ability of some (such as the frost-resistant green and red varieties) to thrive in cool climates made them important long ago in central and eastern Europe. Legend has it, however, that the technique of pickling cabbage to preserve it (as sauerkraut) reached Europe from China via the Tartars. In light of such widespread use, it is interesting to note that cabbages have never been uniformly accepted nor very highly regarded. They were not a part of the diet in the Neolithic Near East and, although apparently appreciated by the Greeks and Romans (at least for alleged medicinal qualities), were subsequently viewed in Europe as an unsophisticated food that gave off a bad smell when cooked and provoked flatulence when eaten.

Today, however, this remarkable group of vegetables is said to promote health by lowering cholesterol, preventing cancer, and providing the consumer with fiber and a number of important vitamins and minerals, especially vitamin C. Round cabbages have traditionally been boiled with meats and potatoes or beans in countless cultural versions of the "boiled dinner," and, because these vegetables were called cole cabbage and colewort in the past, we continue to refer to another means of cabbage preparation as "coleslaw," often without knowing why. Round cabbages include white, green, and red varieties with smooth leaves, as well as those with wrinkled leaves, such as the Savoy cabbage. European spring cabbages are one example of pointed cabbages, as is Chinese cabbage. Brussels sprouts are cabbages with hypertrophied buds. An example of a cabbage with dense flowering is the cauliflower, and a cabbage with its flowering in spears is broccoli.

Common names and synonyms: Cole cabbage, coleslaw, colewort, common cabbage, European spring cabbage, green cabbage, head cabbage, pointed cabbage, red cabbage, round cabbage, sauerkraut, Savoy cabbage, wild cabbage.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Cabbage palm – *see* **HEART(S) OF PALM**

CABBAGE TREE – "Cabbage trees" (*Cordyline terminalis* and other species) are shrubs or small trees that are cultivated in India and the Pacific Islands, where the plant is also known as *ti,* ti palm, and palm lily. In Hawaii, the roots – high in sugar content – are fermented to make a beverage, and the long, sword-shaped leaves are exploited for making skirts and for other decorative purposes. The leaves are also used to wrap foods for baking in Polynesia, and in New Zealand fibers from the leaves are employed as a source of twine. Finally, the leaves are also used as plates, and young leaves are eaten as a potherb.

Common names and synonyms: Palm lily, *ti,* ti leaf, ti palm, ti root.

Cabbage turnip – *see* **KOHLRABI**

CABERNET (*see also* **GRAPES**) – There are two varieties of the cabernet grape (*Vitis vinifera*) – Cabernet Sauvignon and Cabernet Franc – both of which are red grapes employed in making the fine wines of Bordeaux and California. Indeed, Cabernet Sauvignon is the most important red wine grape in the world and is also grown in Australia, South Africa, and New Zealand, as well as in other European countries besides France.

Common names and synonyms: Cabernet Franc, Cabernet Sauvignon.

See in addition: "Wine," Part III, Chapter 13.

Cabernet Franc – *see* **CABERNET**

Cabernet Sauvignon – *see* **CABERNET**

CACAO – The cacao tree (*Theobroma cacao*) produces the pods that yield the oblong beans that are dried, pressed, and ground to produce cocoa butter and a reddish brown powder, cocoa. That it has been a well-appreciated substance is evident from the tree's scientific name, which in Greek means "food for the gods." A member of the same family as the kola nut of West Africa, cacao is native to the American tropics (and still grows wild in the Amazon rain forest as well as in the forests of Central America) but is now raised commercially in many other tropical regions of the world. It was apparently the Maya who first domesticated the cacao tree. Columbus encountered the plant in the West Indies and took it to Spain at the end of his second voyage. Hernando Cortés, however, has been credited with properly introducing cacao in Europe because he knew what to do with it (mix the powder with vanilla), having learned from the Aztecs whom he had just conquered. Beginning in Spain and then throughout the rest of Europe, cocoa preceded coffee and tea as a stimulating drink (it contains caffeine), and by the end of the seventeenth century there were chocolate houses all over the Continent. The chocolate industry was under way, and the Spaniards began to spread cacao cultivation around the world. Plants were taken to the island of Fernando Po off the west African coast, after which they entered Africa. Cacao traveled west from Mexico via the Manila galleons to take root in the Philippines, and its cultivation was subsequently extended throughout the East Indies by the Dutch. Chocolate (as opposed to cacao) production began in North America in 1765, and in 1779 Dr. James Baker (whose name is practically synonymous with chocolate in the United States) entered the business. In 1828, the Dutch invented a press that would remove much of the cocoa butter, and a bit later the techniques for making chocolate bars were developed. In 1876, the Swiss, by mixing cocoa powder and powdered milk, developed milk chocolate (which is still considered the best chocolate), and in 1900 Milton Hershey introduced the first "Hershey Bars" in the United States. Soon afterward, he began construction of a chocolate factory near Harrisburg, Pennsylvania, and there quickly grew up a town that was named Hershey, Pennsylvania, in 1903. In addition to the culinary uses of cacao, cocoa butter is employed in the manufacture of cosmetics and pharmaceuticals. The shells – left over after processing the cacao beans – serve as a source of theobromine (a mild stimulant) and vitamin D and are often used as animal feed.

Common names and synonyms: Chocolate, cocoa.

See also: "Cacao," Part III, Chapter 3; "Spices and Flavorings," Part II, Section F, Chapter 1.

Cachira – *see* **ICE-CREAM BEAN**

CACTUS APPLE – A large, treelike, thorny cactus native to South America, the cactus apple (*Cereus peruvianus*) produces edible fruits that are known as *pitaya* fruits to Latin Americans. *Pitayas* range in color from yellow to red and have a white flesh with small edible seeds.

Common names and synonyms: Apple cactus, *pitaya* (fruit).

Cactus fig – *see* **PRICKLY PEAR**

Cactus pad – *see* **NOPALES**

Cactus paddle – *see* **NOPALES**

Cactus pear – *see* **PRICKLY PEAR**

Cactus-spoon – *see* **SOTOL**

Caihua – *see* **KORILA**

Cail – *see* **KALE**

Caimito (fruit) – *see* **STAR-APPLE**

Cajá – *see* **TAPEREBÁ**

CAJEPUT – An East Indian tree, the cajeput (*Melaleuca quinquenervia* or *M. cajuputi*) has a bark that has long been used for sacred writing, and it yields a pungent oil that some call "tea-tree oil," which has had myriad nonfood uses – from a painkiller in dentistry, to a killer of fleas and lice, to a mosquito repellent. But the oil is also used as a flavoring in foods ranging from baked goods through desserts to meat products and soft drinks.

Common names and synonyms: Broad-leaved tea-tree, punk tree, tea-tree oil.

CALABASH (*see also* **BOTTLE GOURD, XICALL**) – Also called the "tree gourd," this green fruit of the calabash tree (*Crescentia cujete*) has a hard outer rind that encloses a white pulp containing seeds. Probably both the sweetish fruit and the seeds have been eaten (and the pulp used medicinally), but the main use of the calabash has been as a container for food and beverages. In Africa, the name "calabash" has been applied to the bottle gourd (*Lagenaria siceraria*), which grows on a vine instead of a tree but has served many of the same functions as *C. cujete.*

Common names and synonyms: Bottle gourd, *calabaza, calebasse,* tree gourd.

CALABAZA (SQUASH) (*see also* **CALABASH, SQUASH AND PUMPKIN**) – *Calabaza* means "gourd" in Spanish, and the word is often intended to mean "calabash." But it has also come to mean a usually bright orange squash variety of the *Cucurbita moschata* species, which has flowers that – like its skin – range from creamy white to yellow to deep orange. This squash is a native American plant that can be found daily in the markets of the West Indies and Central and South America. Because it tends to grow to the size of a large pumpkin, it is often sold in pieces, but – like the pumpkin (a close relative) – the calabaza also comes in smaller sizes. Reportedly, this squash was an important food for the Indians of Florida when the Spaniards first reached that peninsula, and it has seemingly always been a favorite of Cubans and many other natives of the Caribbean islands. Calabaza goes well in stews, and pureed calabaza makes a fine soup. Many fry the raw squash in strips, and in Mexico pieces of young, green calabaza are sautéed with chicken. Calabaza is a fine source of vitamin A, folic acid, and potassium. Like pumpkin seeds, those of the calabaza are wonderful when toasted.

Common names and synonyms: Abóbora, ahuyama, crapaudback, Cuban squash, giraumon, toadback, West Indian pumpkin.

See in addition: "Squash," Part II, Section C, Chapter 8.

Calabazilla – *see* **BUFFALO GOURD, CABBAGE**

CALABRESE (*see also* **BROCCOLI**) – A variety of broccoli, calabrese (*Brassica oleracea* var. *italica*) is apparently named for Calabria, a region in the toe of Italy about to kick Sicily. Noted for its tightly packed green (or purple) flower heads, calabrese was introduced into France and England in the eighteenth century but was rare in the United States until after World War II. Today, however, California is a big producer of calabrese. The vegetable is high in vitamin C and some of the B vitamins as well as many of the trace minerals. Along with other members of the family Cruciferae, calabrese may be important in cancer prevention.

Common names and synonyms: Asparagus broccoli, sprouting broccoli.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Calabur – *see* **CAPULIN**

Calalu – *see* **CALLALOO**

CALAMONDIN (*see also* **CITRUS FRUITS**) – Thought by many to be a naturally occurring hybrid between the Mandarin orange and the kumquat, the orange-hued calamondin grows on a small evergreen tree (now designated as × *Citrofortunella microcarpa,* although in the past it was called *Citrus mitis* or *Citrus reticulata*) and is also known as the "musk lime," "Panama orange," and "calamondin orange." The fruits are about 1.5 inches in diameter and look like tangerines. There is some debate as to whether the calamondin is a Philippine native or originated in China, but in any event it is today widely cultivated in the Philippines and also in Hawaii and Florida in the United States. Calamondins are made into marmalades, jellies, and beverages, are used to flavor teas, and are also eaten raw. They are a good source of vitamin C.

Common names and synonyms: Calamondin orange, China orange, musk lime, Panama orange, Philippine orange, to-kumquat.

Calamus – *see* **SWEET FLAG**

Calebasse – *see* **CALABASH**

California chilli – *see* **ANAHEIM**

CALLALOO (*see also* **COCOYAM, TARO**) – The name of a soup made in many islands of the Caribbean, callaloo is also the name of the large, wide, green leaves that go into it. One of these greens is amaranth (genus *Amaranthus*) – either "Surinam amaranth" (with an African origin) or "Chinese spinach" (which is probably native to the West Indies). The other kind of green is the leaves of dasheen or taro (*Colocasia esculenta*). Collectively called callaloo – and in some places "sagaloo" – the leaves resemble spinach or sorrel and are cooked as a vegetable dish. Fresh callaloo leaves can be found in West Indian markets in the summer months, and they are available canned throughout the year.

Common names and synonyms: Calalu, callalou greens, Chinese spinach, dasheen, sagaloo, Surinam amaranth, taro.

See in addition: "Amaranth," Part II, Section A, Chapter 1; "Taro," Part II, Section B, Chapter 6.

Caltrop – *see* **WATER CHESTNUT**

Calvance pea – *see* **CHICKPEA**

CAMAS – The bulbs of "camas" herbs (*Camassia scilloides* or *C. leichtlinii* and *C. quamash* or *C. esculenta*) constituted an important food for Native North Americans of the West and Northwest. Indeed, both were named by these peoples who originally roasted, baked, and boiled them. Their consumption required some caution, however, for camas bulbs can be confused with the "death camus" (*Zigadenus* spp.), which, as its common name suggests, is toxic and can be lethal. In fact, it frequently poisons grazing animals in the western United States. Camas is also called "wild hyacinth."

Common names and synonyms: Camash, camass, commas, common camass, quamash, sqamash, wild hyacinth.

Camash – *see* **CAMAS**

CAMBUCÁ – A rare fruit, the cambucá (*Marlierea edulis*) grows on a tree with a range that is mostly confined to the coastal forests of the Brazilian states of Rio de Janeiro and São Paulo. The cambucá is a relative of the guava and the jaboticaba, and its yellowish fruit has a good flavor. It is eaten raw and made into juice.

Camomile – *see* **CHAMOMILE**

Camote – *see* **SWEET POTATO**

CAMPANULA – The genus name for numerous species of plants known as "bellflowers" or "Canterbury bells" is *Campanula* (meaning "bell" and referring to the shape of the flowers). Found in temperate zones, especially in the Mediterranean and tropical mountains, three species have been used as food. In the past, the fleshy roots and leaves of *C. rapunculoides* were cultivated to be eaten in England, and the plant was carried to North America, where it is now naturalized. Rampion (*C. rapunculus*) – another European native – was also grown for its roots and leaves in centuries past. It has an edible root that is used in salads and shoots that are cooked like asparagus. In addition, the leaves of *C. versicolor* have been used in salads.

Common names and synonyms: Bellflower, broad bellflower, Canterbury bell(s), harebell, rampion.

Canada ginger – *see* **WILD GINGER**

Canada pea – *see* **TUFTED VETCH**

Canada snakeroot – *see* **WILD GINGER**

Canada sweetgale – *see* **SWEET FERN**

Canadian turnip – *see* **RUTABAGA**

Cañahua – *see* **CAÑIHUA**

Canary grass – *see* **MAYGRASS**

Candleberry – *see* **CANDLENUT**

CANDLENUT – Also called "candleberry" and "Indian walnut," the candlenut tree (*Aleurites moluccana*), native to tropical Southeast Asia, produces a seed kernel that is roasted and eaten. The seeds are more used, however, for their oil, which presumably at one time or another has been used for candle making.

Common names and synonyms: Candleberry, Indian walnut.

Candy plant – *see* **CICELY**

Canella – *see* **WHITE CINNAMON**

CAÑIHUA (*see also* **CHENOPODIUM, QUINOA**) – A native of the Andean regions of southern Peru and Bolivia, cañihua (*Chenopodium pallidicaule*) is a cold-resistant grain known also as "quañiwa" and "cañahua." It is used much like quinoa, but does better in high regions because it is tolerant of both frost and drier soils. In addition, it has a higher protein content. Cañihua was first cultivated by ancient settlers in the region and continues to be grown today, but botanists think that its domestication is not yet complete. The grain is used to make a flour called *cañihuaco* and to make soups, stews, and desserts. It is even employed to flavor drinks.

Common names and synonyms: Cañahua, quañiwa.

CANISTEL – The fruit of a tropical tree, canistel (*Pouteria campechiana*) probably originated in Central America (Costa Rica or Belize) but has now spread throughout the Caribbean. It is sold in Florida and is a favorite in the markets of Havana and Nassau. The fruit is oval, hard, and green, changing to soft, orange, and glossy when ripe. The flesh has the texture of a hard-boiled egg (another of its names is eggfruit) and a taste similar to that of a sweet potato. It is eaten raw with lemon juice, is good in salads, and is made into custards and ice cream. It is extremely rich in beta-carotene.

Common names and synonyms: Eggfruit (tree).

Cankerroot – *see* **GOLDTHREAD**

Canna – *see* **ACHIRA, BERRIES**

CANNELLINI BEAN (*see also* **BEANS**) – Much used in Italian soups and stews and often appearing as an antipasto dressed with olive oil, the cannellini bean (*Phaseolus vulgaris*) is a "common bean" of American origin. It is, in fact, a white kidney bean that may have been developed in Italy. Cannellini beans are generally sold in canned form.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

Canola oil – *see* **RAPE**

CANTALOUPE AND MUSKMELON (*see also* **MELONS**) – A variety of muskmelon, the cantaloupe (*Cucumis melo*) belongs to the squash family and is a member of the genus that includes cucumbers. The places of origin of most melons are uncertain, but Africa (the home of the watermelon), the Near East, and India appear to be the most likely candidates. The muskmelon (*Cucumis melo*) probably entered Europe from the Muslim world via Spain, and during the Renaissance, monks developed the cantaloupe from muskmelons in the garden of the papal villa at Cantalupo, located close to Rome. It was muskmelon seeds, however, that were carried to the New World by Columbus and later planted by the Spaniards in California – so that today it is muskmelons that are generally consumed by North Americans, even if they mistakenly call the fruits "cantaloupes." The cantaloupe, also known as the "sugar melon," has remained mostly a European melon, is somewhat larger than the muskmelon, and has a warty or scaly rind, in contrast to the raised netting that characterizes the rind of the muskmelon. The orange flesh of both provides plenty of beta-carotene and vitamin C as well as potassium.

Common names and synonyms: Sugar melon.

See in addition: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

Cantarela – *see* **OKRA**

Canterbury bell(s) – *see* **CAMPANULA**

CAPE GOOSEBERRY (*see also* **BERRIES**) – Also called the "Peruvian cherry" and the "Peruvian groundcherry," the cape gooseberry (*Physalis peruviana*), with pale-yellow blooms, is a native of tropical America and very closely related to the tomatillo (*Physalis ixocarpa*), also American in origin. Nonetheless, it is named the "cape gooseberry" because of a round-the-world journey that took it to, among other places, South Africa, where it was cultivated at the Cape of Good Hope. When first introduced in Australia, it was called the cape gooseberry, and the name stuck. Long before this, however, the berries grew wild and were important to many Native American groups, who ate them fresh and also dried them for winter use. The cape gooseberry has additional relatives, such as the Chinese lantern plant and the groundcherry (and, indeed, any of the plants of the genus *Physalis,* all of which have a parchment-like husk). Cape gooseberries are yellowish and juicy and a good source of beta-carotene, vitamin C, the B complex, phosphorus, and iron. They are frequently made into jams and jellies.

Common names and synonyms: Goldenberry, golden husk, groundcherry, Peruvian cherry, Peruvian groundcherry, strawberry tomato, winter cherry.

Cape periwinkle – *see* **PERIWINKLE**

CAPER(S) – A spiny trailing shrub, the caper bush (*Capparis spinosa*) grows to between 4 and 5 feet in height. It is native to the Mediterranean region and possibly to the Middle East as well. Its flower buds, which are picked and pickled in vinegar, are the capers that have been used since at least the time of the ancient Greeks as a condiment to add a salty-sour flavor to sauces, cheeses, salad dressings, stews, and various other meat and fish dishes. The caper bush grows wild and thrives in southern Europe, where Italy and Spain are the biggest caper producers.

Common names and synonyms: Caper berry, caper bud, caperbush, caper fruit, *cappero, kápari,* smooth caper, spiny caper, *tapèra.*

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Cappero – *see* **CAPER(S)**

Capucine – *see* **MASHUA**

Capuli – *see* **CAPULIN, CHERRY**

CAPULIN (*see also* **CHERRY**) – Both the Mexican tree *Prunus capuli* and the Central and South American tree *P. salicifolia* are called "capulin" or "capuli." *Prunus capuli* is sometimes thought to be a form of the black cherry (*Prunus serotina*). Its edible cherries are consumed raw and in jellies, and their pits are ground to make flour. *P. salicifolia,* also known as the "tropical cherry," has edible purple cherries, which are also eaten out of hand or in preserves. Another fruit called "capulin" is the downy groundcherry (*Physalis pubescens*), which is also edible. Still another "capulin" is the Mexican wild plum (*Prunus capollin*), which is eaten both raw and cooked and turned into a juice that is combined with cornmeal and fried as cornmeal cakes. All of these fruits were important in the diet of Native Americans long before the arrival of Columbus. A final "capulin" is the small red fruit of *Muntingia calabura,* also called "calabur," "Panama berry," and "Jamaican cherry." This capulin has culinary applications like the others, but in addition, its leaves can be used to make a refreshing tea.

Common names and synonyms: Calabur, capuli, downy groundcherry, Jamaican cherry, Mexican wild plum, Panama berry, tropical cherry.

Carageen – *see* **CARRAGEENIN**

CARAMBOLA – The carambola (*Averrhoa carambola*) is also known as the "star fruit," and with good reason. It has an elongated yellow (sometimes white) body with five ribs that produce star shapes when it is sliced. Its native region was probably Malaysia, but the fruit now belongs to the world. Averrhoës, whose name it bears, was a twelfth-century Arab philosopher and physician who translated the works of Aristotle into Arabic. The word "carambola," however, is a Native American name for the fruit, and today it is cultivated in Asia, the West Indies, Florida, Hawaii, and Central and South America. The carambola has a fragrance reminiscent of quince and crisp, juicy flesh that can be either sweet or sour: Both tastes work well when applied to the appropriate salads, cooked dishes, and drinks. The carambola is also delicious eaten raw and provides the consumer with plenty of vitamin C.

Common names and synonyms: Belimbing, bilimbi, Chinese star fruit, five-angled fruit, star apple, star fruit.

CARAUNDA – Also known as "karanda," the caraunda (*Carissa carandas*) is an evergreen shrub or small tree of the East Indies that has a somewhat acidic fruit. In India, these reddish berries are eaten raw when ripe and pickled when not mature.

Common names and synonyms: Karanda.

CARAWAY – An herb native to Europe and Asia, caraway (*Carum carvi*) still grows wild on both continents. It is also a plant closely associated with the Arab world, where it is called *karawya,* and has traveled sufficiently widely to have become naturalized in the Americas. Its slightly sharp- and peppery-tasting seeds, which are ready for harvesting when they turn brown, have been used as a spice for at least 5,000 years, and there is reportedly evidence of their culinary use even prior to the Neolithic Revolution. Caraway seeds were an ancient item of importance in the spice trade and have been much in demand for the preservation of foods such as sauerkraut. Caraway was once enormously popular in English cookery. Shakespeare mentions "a dish of caraways," and at Trinity College, Cambridge, the tradition of serving roasted apples with caraway continues. Today, caraway is most frequently used in northern European – especially German and Austrian – cooking. The seeds are a common ingredient in rye breads, sauerkraut, potato salads, cabbage dishes, goulashes, cheeses, cakes, and the German liqueur *Kümmel,* the name of which means caraway.

Common names and synonyms: Jintan, karawya, Kümmel.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Carciofo – *see* **ARTICHOKE**

CARDAMOM – A member of the ginger family, cardamom (*Elettaria cardamomum*) is a plant native to South Asia, and the Cardamom Hills in India were named for the cardamom growing there. The seeds of the plant, which come in triangular capsules, have been used as a spice since ancient times. They found their way to Europe along the caravan routes and were an important commodity in the Greek spice trade with the East as early as the fourth century B.C. Cardamom was a popular spice in Rome and presumably radiated out from there to those other inhabitants of Europe who could afford it. Today, there are cardamom plantations in much of the tropical world, including Central America, although southern India remains the largest producing region. The biggest consumers of cardamom are the diverse peoples of Scandinavia and India. Scandinavians use the sweetness of the seeds to flavor fruit dishes, gingerbread, and Swedish meatballs. The Indians use the dried and ground seeds as one of the essential ingredients of curry powder. In addition, cardamom is crucial to the flavored coffees of the Arab world, and an oil derived from the plant is employed in flavoring liqueurs. "Cardamom" is also the name of an East Indian plant (*Amomum cardamomum*) whose seeds are used as a bad substitute for true cardamom seeds.

Common names and synonyms: Cardamon, cardamum.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Cardamon – *see* **CARDAMOM**

Cardamum – *see* **CARDAMOM**

Cardi – *see* **CARDOON**

Cardoni – *see* **CARDOON**

CARDOON – One of the edible thistles, the cardoon (*Cynara cardunculus*) is a relative of the globe artichoke. It is celery-like in appearance, with silvery gray stalks. The plant is native to the Mediterranean region, where it has been cultivated since the days of the Romans and where it remains a popular vegetable in Spain, France, and Italy. Cardoons were cultivated for a time in the United States but were never much appreciated save by Italian-Americans, in whose markets the vegetables can still be found. It is unfortunate that cardoons are not more widely known because they have an excellent flavor. They are frequently eaten raw in a sauce of olive oil, anchovies, and garlic; when cooked (usually blanched), the stalks taste bittersweet – something like celery and something like artichokes. Cardoons are a good source of potassium, iron, and calcium.

Common names and synonyms: Cardi, cardoni, common cardoon, Paris cardoon, red-stemmed cardoon, Spanish cardoon, Tours cardoon.

CAROB – Carob pods grow on a leguminous tree (*Ceratonia siliqua*) of the pea family that can rise upward of 50 feet above the ground. Carobs are native to the eastern Mediterranean region (and possibly western Asia as well), where they were grown in ancient times by the Greeks, who also introduced their cultivation into Italy. The pods (which are sweet and are enjoyed by animals and humans alike) are probably the proverbial "locusts" eaten by John the Baptist during his stay in the wilderness and thus are called "Saint-John's-bread." They were also a staple in the diet of the Duke of Wellington's cavalry during the Peninsular War. The pods grow up to a foot in length, dry on the tree, and are harvested when they fall to the ground. They contain seeds whose weight is believed to have been used by early jewelers to determine the carat. Today, the seeds are utilized to make locust gum, which is employed in the food industry as a thickener, in the preparation of cheese and meat products, and to stabilize ice cream. A pulpy material from the pod is dried to become carob powder, a substance that is roasted and used as a substitute for cocoa and chocolate as well as coffee. Carob has far fewer calories than chocolate or cocoa and does not contain caffeine or cause allergies.

Common names and synonyms: Algarroba, locust, locust bean, Saint-John's-bread.

Carolina tea-tree – *see* **YAUPON**

CAROLINA VANILLA – An herb of the southeastern United States that reaches 2 to 3 feet in height, Carolina vanilla (*Trilisa odoratissima*) has leaves that are employed in large amounts to flavor tobacco. The leaves, which have a pleasing vanilla odor, are also used to make a fragrant tea.

Common names and synonyms: Deertongue, vanilla leaf, vanilla plant.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

CARRAGEEN AND CARRAGEENIN (*see also* **SEAWEED**) – Also called "Irish moss" and "pearl moss," carrageen (*Chondrus crispus*) is a type of purple seaweed that frequents the coasts of the North Atlantic from the British Isles on the European side to the Maritime Provinces and New England on the American side. Most is harvested commercially for a gelatin used in food processing. It has also been used for clarifying beer, and some carrageen is employed in thickening soups and chowders and making jelly. Carrageenin is an extractive of carrageen and other red algae (such as *Gigartina mammillosa*), used mostly as a suspending agent in foods. It is also called "Irish moss extractive."

Common names and synonyms: Carrageen, carragheen, Irish moss, pearl moss.

See in addition"Algae," Part II, Section C, Chapter 1.

CARROT – A root vegetable of the Umbelliferae family – and thus related to parsley, dill, and celery – the carrot (*Daucus carota* ssp. *carota* when wild and ssp. *sativus* when domesticated), although originally native to Afghanistan, is now found all over the world in many shapes, sizes, and colors. It grows best in moist soils and mild climates, and its taproot is the edible portion of the plant. Early varieties were red, black, or purple, and today carrots in Asia can look much like beets to Westerners, who would also probably approach with caution one carrot variety in the Far East that grows up to 3 feet long. Carrots were cultivated by the Greeks and the Romans but not used very widely in Europe until the Middle Ages. In the sixteenth century, a yellow strain began to develop, and, in Holland of the seventeenth century, the orange type now familiar in the West arose. After the carrot reached the Americas, it frequently escaped cultivation to become the wild carrot known as "Queen-Anne's-lace." Like so many other vegetables from Europe, carrots became popular in the New World only after Americans had occasion to visit the Continent in large numbers and become familiar with the foods there. In the case of this vegetable, the occasion was World War I, after which Michigan and California became the biggest carrot producers in the United States. Carrots are available fresh, canned, frozen, dehydrated, and as a juice. They are eaten raw and often added to salads, as well as becoming an important ingredient in dishes such as carrot cake. Cooked, they make an excellent ingredient in stews and soups. In addition, the seeds contain an oil that is expressed for flavorings and for perfumes. The carrot has a great reputation as a source of beta-carotene (the precursor of vitamin A) and vitamin C, and it joins other vegetables as an apparent cancer fighter, cholesterol lowerer, and fiber provider.

Common names and synonyms: Queen-Anne's-lace.

CASABA (MELON) (*see also* **MELONS**) – Also spelled "cassaba," the name casaba designates a variety of winter melon (*Cucumis melo*) named for Kassaba, itself a former name of Turgutlu, Turkey. The fruit has a yellow rind and sweet, whitish flesh that contains much vitamin C.

Common names and synonyms: Cassaba, winter melon.

See in addition: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

CASCABEL (*see also* **CHILLI PEPPERS**) – In Spanish, *cascabel* means to jingle or rattle – and when this green or red pepper (about the size and shape of a small tomato) is dried and turns a brownish red, it becomes translucent and its seeds rattle about inside. Rarely used fresh, the dried *cascabel* (*Capsicum annuum*) is prized for the rich, smoky heat that it imparts to any dish or sauce in which it is simmered. Cascabel peppers are grown in Mexico but are available in the United States.

Common names and synonyms: Chilli bola.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

CASHEW – A kidney-shaped nut that grows in a double shell at the end of a strongly sweet-smelling, pear-shaped fruit, the cashew (*Anacardium occidentale*) is a very unusual nut. The largest part of the fruit is the juicy, pear-shaped fruit called the cashew "apple," which is eaten raw or fermented to become alcohol. The nut itself grows at the lower end of the "apple," but one never sees cashews sold in the shell for a very good reason. The cashew is related to poison ivy and poison sumac, and the shells contain an irritating oil that must be gotten rid of by heating before the nut can be extracted. The tree is a native of South America, but in the sixteenth century the Portuguese introduced it in the East African and Indian parts of their empire, and these areas are today the biggest exporters of cashews. Although lower in total fat than most nuts, cashews are high in saturated fat. They are a good source of folacin, iron, protein, and vitamin C. The cashew apple is also high in vitamin C and is used in beverages and to make jelly.

Common names and synonyms: Cashew apple, cashew fruit, cashew nut.

Cashew apple – *see* **CASHEW**

Cassaba – *see* **CASABA (MELON)**

Cassabanana – *see* **CUCUMBER**

Cassava – *see* **MANIOC**

Cassia – *see* **CINNAMON AND CASSIA, INDIAN BARK, SAIGON CINNAMON**

Cassina – *see* **YAUPON**

Cassine – *see* **DAHOON HOLLY**

Cassis – *see* **BLACK CURRANT**

CASTORBEAN – A native of Africa, the castor-oil plant (*Ricinus communis*) produces the castorbean – a poisonous seed – from which oil is extracted. The tree now grows throughout the tropical world, and its oil has many valuable industrial uses, but save for doses of the infamous castor oil, it is not consumed by humans.

Common names and synonyms: Castor-oil plant.

Castor-oil plant – *see* **CASTORBEAN**

Cat – *see* **KHAT**

CATARINA (*see also* **CHILLI PEPPERS**) – Grown in Texas and northern Mexico, the catarina chilli (*Capsicum annuum*) is red, some 1 to 2 inches in length, and can be either tapered or broad and oblong. Like its relative the cascabel, when the catarina is dried, its seeds rattle. Its moderate heat makes it an excellent ingredient in salsas.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

CATAWBA (GRAPE) (*see also* **GRAPES**) – The catawba is an American wine grape (*Vitis labrusca*) used to make Catawba wines. Called "one of the most celebrated of native American wines, at the beginning of the twentieth century, at century's end these heavy and somewhat sweet wines were virtually unknown. Most Catawba wines were white, and the highest priced were of the "sparkling" type. Some red Catawba was made, along with "sweet Catawba," which was a rich, fortified wine.

See in addition: "Wine," Part III, Chapter 13.

Catbrier – *see* **GREENBRIER**

Catchweed – *see* **GOOSEGRASS**

Catclaw acacia – *see* **ACACIA**

Catechu – *see* **BETEL NUT**

CATJANG (*see also* **COWPEA**) – One of the cowpeas of the genus *Vigna,* the catjang (*V. unguiculata*) is a relatively primitive form, cultivated mostly in Asia but also in Africa. Its main use is as animal feed, but people also use the seeds for food in both fresh and dried forms.

Common names and synonyms: Catjang pea.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

Catjang pea – *see* **CATJANG**

Catmint – *see* **CATNIP**

Catnep – *see* **CATNIP**

CATNIP – A perennial herb native to Eurasia, catnip (*Nepeta cataria*) is now widely naturalized in North America. Usually regarded as a weed, it has flowering tops, grows to about 3 feet in height, and has long been associated with cats, which are attracted by its odor. But the leaves and roots of catnip have also been used medicinally and as food for millennia. Indeed, they are still regularly consumed in parts of East Asia.

Common names and synonyms: Catmint, catnep.

Cat's-eye – *see* **LONGAN**

CATTAIL – A familiar roadside sight along drainage ditches, cattails – of the genus *Typha* – are marsh-dwelling plants that are scattered about the world, and their various parts have been used as food by hunter-gatherers since time immemorial. Native Americans, for example, ate the tender shoots and leaf bases raw, dried and ground the rhizomes into flour, and even roasted and ate the tops like corn on the cob. The seeds are also edible, and the flowers provide a pollen that can be added to flour. Cattails and bulrushes are sometimes lumped together, but they belong to different genera.

Common names and synonyms: Reed-mace.

Cattley guava – *see* **STRAWBERRY GUAVA**

CAULIFLOWER (*see also* **CABBAGE**) – The cauliflower (*Brassica oleracea* var. *botrytis*), another – and many would say the most elegant – member of the sprawling cabbage family, is a direct descendant of the original wild cabbage and a close relative of broccoli. The kind of cauliflower usually found in vegetable hors d'oeuvres has a white head, achieved by growers who cover the flower head in its outer leaves so as to block sunlight and, thus, prevent the formation of chlorophyll. There is also a purple type, called cauliflower broccoli. The cauliflower (the name is probably from the Italian *caolifiori,* meaning "cabbage flowers") was apparently known in much of Europe during the Middle Ages, but then disappeared and had to be reintroduced to the rest of the Continent in the sixteenth century. This was accomplished by the Italians, probably from Cyprus, where the plant had reached from Asia. In Europe, where much cauliflower is consumed, Italy has long been the major producer. The vegetable could be found in U.S. markets from the turn of the twentieth century onward but consumption only became significant following World War II. Cauliflowers are very low in calories but rich in vitamin C, the B complex, and vitamin K (which helps to clot blood).

Common names and synonyms: Asparagus broccoli, broccoli (British), cauliflower broccoli.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Caulorapa – *see* **KOHLRABI**

Cava – *see* **KAVA**

Cawesh – *see* **POSHTE**

Cayenne – *see* **CAYENNE PEPPER**

Cayenne cherry – *see* **PITANGA**

CAYENNE PEPPER(*see also* **CHILLI PEPPERS**) – Today, the term "cayenne" is synonymous with red pepper and can mean any of the ground, hot, red chilli peppers of the *Capsicum* species that are native to the Americas. And recipes from areas as diverse as Mexico and China, Louisiana and India, call for it. Originally, however, the pepper in question (*C. annuum*) was ground into powder in Cayenne in French Guiana (it is also called the ginnie pepper and guine pepper), and the term "cayenne" was meant to signify the hottest ground red pepper available. Cayennes are very hot, bright red when mature, long (some 4 to 6 inches) and slender, and generally are dried. These pointed red pods make an excellent addition to sauces, and when green they are incorporated in salsas. But their major use is in the production of powdered cayenne pepper (also designated hot red pepper). In addition, cayenne peppers have long been the primary ingredient in all of the Louisiana hot sauces except the Tabasco brand. The *de árbol* is a close relative of the cayenne pepper (and looks like it) and also is ground into powdered form. Another, smaller (about an inch long) close relative is the red *Pico de Pajaro* or "bird's-beak" – so named because of its beaklike shape. Today, cayenne peppers are grown in Mexico; Louisiana; South, Southeast, and East Asia; and West Africa.

Common names and synonyms: Bird's-beak, cayenne, *de árbol,* ginnie pepper, guine pepper, hot red pepper, *Pico de Pajaro.*

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Caygua – *see* **KORILA**

Caymito – *see* **STAR-APPLE**

Cayua – *see* **KORILA**

Ceci – *see* **CHICKPEA**

CEDAR – The name "cedar" embraces a number of trees of various genera, including those of the genus *Thuja,* which helped to feed Native Americans. In the northwestern portion of North America, the inner bark of the giant or western red cedar, *T. plicata,* provided food in much the same fashion as the inner bark of the slippery elm. In the Northeast, it was the white cedar (*T. occidentalis* – also known as northern white cedar, yellow cedar, featherleaf cedar, and arbor-vitae) that provided young shoots and leaves that were cooked like vegetables and made into tea.

Common names and synonyms: Arbor-vitae, featherleaf cedar, giant cedar, northern white cedar, western red cedar, white cedar, yellow cedar.

Ceiba – *see* **KAPOK TREE**

Celeriac – *see* **CELERY AND CELERY ROOT**

CELERY AND CELERY ROOT (*see also* **CELERY SEED**) – A member of the parsley family, and native to the Mediterranean region and the Middle East, wild celery (*Apium graveolens*) was one of the first vegetables to appear in recorded history. From the writings of Confucius, we know that celery (probably wild) was in use in China before 500 B.C. The ancient Egyptians gathered the plant for its seeds – used as seasoning – as well as for its stalks and leaves, whereas in ancient Greece celery had a medicinal as well as a culinary reputation.

Two types of celery have subsequently been developed. One is the so-called true celery (*Apium graveolens* var. *dulce*), with green or blanched stems that are eaten raw, sliced into salads, and cooked as a vegetable, and the seeds of which are still used as seasoning. The most common variety is the medium-green Pascal celery, which was first cultivated in Italy and, by the seventeenth century, in France. In the United States, commercial cultivation of Pascal celery dates from 1874, when Dutch farmers near Kalamazoo, Michigan, passed out free samples to train passengers to popularize the vegetable. Celery comes in both blanched form (celery hearts) and green with large, fleshy ribs, the difference being that the former is kept away from the sun to ensure whiteness. Celery leaves are sometimes cut up and dried to be added as an herb to stews, soups, and other dishes. Celery is reputed to lower blood pressure, is very low in calories, and provides a respectable amount of vitamin C and folacin.

The other type of celery (*Apium graveolens* var. *rapaceum*), cultivated for its starch-storing root rather than for stalks, is commonly called celery root or celeriac. It appears as an ugly sort of foodstuff – a gnarled, turnip-like form with dangling rootlets – ranging in size from an orange to a cantaloupe. But its zesty taste of celery and parsley intermingled has long been a part of French salads (often with a remoulade sauce) as well as an important ingredient of soups, stuffings, purees, and the like in Russia and the countries of northern Europe. Also called "knob celery" and "turnip-rooted celery," the root is a fair source of iron and calcium and makes a small contribution to the B-vitamin intake.

Common names and synonyms: Celeriac, *céleri rave,* celery heart(s), Hamburg celery, knob celery, Pascal celery, true celery, turnip-rooted celery, wild celery.

Celery cabbage – *see* **BOK CHOY, CHINESE CABBAGE**

Celery mustard – *see* **PAKCHOI AND KAI CHOY**

CELERY SEED – Celery (*Apium graveolens* var. *dulce*) was developed in seventeenth-century Europe from its wild predecessor and was first recorded as a plant in 1623 in France. The tiny brown seeds from celery impart a mild celery flavor to dishes in which the use of the stalks would not be appropriate, such as bread dough and sauces and some soups, salads, stews, and potato salads. Ground celery seeds also flavor celery salt, salad dressings, and the like.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Celtuce – *see* **LETTUCE**

Century plant – *see* **AGAVE**

Cep – *see* **BOLETE, MUSHROOMS AND FUNGI**

Cèpe – *see* **BOLETE, MUSHROOMS AND FUNGI**

Cèpe de bolete – *see* **BOLETE**

Cèpe de Bordeaux – *see* **BOLETE**

Ceriman – *see* **MONSTERA**

Ceriman de Mexico – *see* **MONSTERA**

CEYLON GOOSEBERRY (*see also* **BERRIES**) – Also known as *ketembilla,* and *quetembilla,* the Ceylon gooseberry (*Dovyalis hebecarpa*) is a fruit of tropical Asia that grows on a bushy shrub. The berries are maroon to purple in color and resemble gooseberries in appearance and taste. Today, the berries are cultivated throughout tropical Asia, and especially in India. Ceylon gooseberries are also commercially cultivated on a small scale in Florida and California. They are eaten fresh and made into preserves and jellies.

Common names and synonyms: Ketembilla, quetembila.

Ceylon spinach – *see* **MALABAR SPINACH, TALINUM**

Chaco – *see* **CHAYOTE**

Chad – *see* **BEET**

Chago – *see* **MAUKA**

CHAMBURO (*see also* **PAPAYA**) – A relative of the papaya, and papaya-like in appearance, the chamburo (*Carica pubescens*) is a native of northern South America that is now cultivated along the Andes as far south as Bolivia at altitudes of about 3,000 feet. The yellow fruit is tart, even when mature, and is generally made into juice or preserved instead of eaten raw.

CHAMOMILE – The dried flowers of chamomile (*Anthemis nobilis*) are used as an herbal infusion for baths and tisanes. They deliver a pungent, grassy flavor, and chamomile (also camomile) is said to be good for the digestive system. Chamomile teas were much consumed by Victorian ladies hoping to restore vitality. The herb was also employed historically as a gargle for sore throats.

Common names and synonyms: Camomile.

Champignon d'Paris – *see* **MUSHROOMS AND FUNGI**

Chan – *see* **HYPTIS**

CHANTERELLE (*see also* **MUSHROOMS AND FUNGI**) – The yellow or golden (although occasionally black or white) trumpets of the chanterelle (*Cantharellus cibarius*), a wild mushroom of the woodlands, are found in both Europe and North America. This edible fungus is gathered in abundance in the Pacific Northwest but has been especially appreciated in Europe, where it is known by many names, including *chanterelle* (French), *Pfifferling* (German), and *girolle* (Italian). The chanterelle has yet to be cultivated and thus is only gathered. Its taste varies widely – from delicate to fairly intense. The chanterelle is a good source of vitamins A and D and makes a contribution to the intake of the vitamin B complex.

Common names and synonyms: Chantarelle, forest mushroom, *girolle,* golden chanterelle, *Pfifferling.*

See in addition: "Fungi," Part II, Section C, Chapter 7.

Chard – *see* **BEET, SWISS CHARD**

CHARDONNAY (*see also* **GRAPES**) – The great white Burgundian wines of France, such as the light and dry Pouilly Fuissé, are made almost exclusively with Chardonnay grapes (*Vitis vinifera*), which are now grown all over the world. In the climate of Oregon, this grape grows so well that the state has become well known for its Burgundy-style wines. In California and Australia, Chardonnay is used to make dry wines as well as serving as a base for sparkling wines. It is a very expensive grape.

See in addition: "Wine," Part III, Chapter 13.

Charnushka – *see* **NIGELLA**

CHASTE TREE – Cultivated in both the New and the Old Worlds, this aromatic shrub or tree (*Vitex agnus-castus*) has a reputation for anaphrodisiac qualities – hence its name. But it is also called "wild pepper" and "monk's-pepper," and its seeds have served as a spice. The leaves of other *Vitex* species are used for tea, and some produce fruits that are consumed throughout the world's tropical zones.

Common names and synonyms: Agnus castus, hemp tree, Indian spice, monk's-pepper tree, sage tree, wild pepper.

Chawa – *see* **SWEET PEPPERS AND WAX PEPPERS**

CHAYA – Also called the "spinach tree," chaya (*Cnidoscolus chayamansa*) is found throughout Mesoamerica and the West Indies. In Mexico, this plant, which can attain the height of a human, has large leaves that are boiled and eaten as a vegetable and used to wrap tamales. The leaves must be boiled to render harmless a toxin they contain, and many varieties have stinging hairs on the leaves, which makes some cooks less than enthusiastic about their preparation.

Common names and synonyms: Spinach tree.

CHAYOTE (*see also* **SQUASH AND PUMPKIN**) – A member of the gourd family (Cucurbitaceae), this well-traveled, spiny vegetable (*Sechium edule*) originated in the American tropics. Called *chayotli* in Nahuatl, it was domesticated in what is now Mexico, was spread throughout South America after the Spanish conquest, and is now found in places as diverse and distant as North Africa and Indonesia. Such peregrinations doubtless account for its myriad names, a few of which are vegetable pear, mirliton, *pepinella, xuxu,* christophene, *chocho,* custard marrow, and *sousous.* The taste of this usually green, pear-shaped, vine-growing vegetable resembles that of other cucurbits such as zucchini and the summer squashes; unlike these, however, the chayote must usually have its skin removed before cooking. Most parts of the plant are edible, and the leaves and vine tips are eaten as vegetables. The tuberous roots, which are generally peeled and boiled and taste similar to a Jerusalem artichoke, are an important source of starch. The fruit is used like a squash. It is boiled, baked, fried, steamed, stuffed, pureed in soups, and made into desserts; many consider the seed a delicacy as well. Chayote is a fair source of vitamin C and potassium.

Common names and synonyms: Buddha's-hand, *chaco, chayotli, chinchayote, chocho, choko,* christophene, christophine, *chuchu,* custard marrow, *guispui,* mango squash, mirliton, *pepinella, sousous, tallon, tallote,* vegetable pear, *xuxu.*

Chayotli – *see* **CHAYOTE**

CHE (*see also* **BERRIES**) – A native of eastern Asia that was long ago naturalized in Japan and more recently introduced in Europe and the United States, che (*Cudrania tricuspidata*) is related to the mulberry and is sometimes called the "Chinese mulberry." Its fruits are relatively large, develop a bright, reddish color when ripe, and are reportedly delicious. In China, che leaves serve to feed silkworms when there is a shortage of mulberry leaves.

Common names and synonyms: Chinese mulberry, cudrang, mandarin melon-berry.

Checkerberry – *see* **WINTERGREEN**

Chekkurmanis – *see* **SWEET-SHOOT**

CHEMPEDAK – Probably native to Indochina, the chempedak tree (*Artocarpus integer*) is an ancient cultivar. Its yellowish to brown, oblong fruits are large – reaching a foot or more in length. The custard-like pulp is sweet and eaten raw, and the seeds are consumed after boiling.

CHENOPODIUM (*see also* various *Chenopodium* entries) – A large genus of herbs, *Chenopodium* includes the goosefoots and other plants that are found throughout the world's temperate regions – today mostly as weeds. Species raised in the pre-Columbian Americas that are still in cultivation include quinoa (*C. quinoa*), mostly grown in Ecuador, Peru, and Bolivia, and *cañihua* (*C. pallidicaule*), confined to the high Andes. In addition, *C. bushianum* appears to have been cultivated by Native Americans in eastern North America prior to the arrival of the Europeans, and *C. nuttalliae* was domesticated in Mexico. Since 1492, *C. huauzontle* has also been domesticated in Mexico, and both the Mexican grains are called *chia.* All of these plants were (and are) cultivated primarily for their seeds, which are ground to make breads, gruels, and – in the Andean regions – *chicha,* a beer. This does not mean, however, that the green, fleshy parts of the plants were not consumed, and other chenopods – for example, lamb's-quarter (*C. album*) and the wild spinach "Good-King-Henry" (*C. bonus-henricus*) – were gathered for their flower buds and greens. Still others, such as *epazote* (*C. ambrosioides*), called "Mexican tea" in Mexico and *paiko* in Peru, have served for thousands of years as seasonings.

Common names and synonyms: Chenopod, *chia, epazote,* goosefoot, lamb's-quarter, *paiko,* quinoa.

CHERIMOYA – No wonder the cherimoya (*Annona cherimola*) is sometimes called a "custard apple." When ripe, this heart-shaped, scaly, pulpy fruit has smooth, cream-colored flesh and tastes like a custard made from tropical fruit. Although much smaller than a watermelon, it has similar large, black seeds. The cherimoya's name comes from the ancient Quecha language, and the fruit is of American (specifically, the South American highlands) origin but has been grown for many centuries in Central America and the Caribbean region for local use. It has also moved as far as Iberia to the east and to Australia, New Zealand, and Malaysia in other parts of the globe. In the United States, the cherimoya is grown in California and Florida. But because it does not keep well in shipping, it is not generally available in produce markets, and those who cannot find this fruit must order it through specialty catalogs for an exotic treat. The cherimoya, of the same family as the sweetsop and the sugar apple, provides a good measure of vitamin C and some iron.

Common names and synonyms: Anona, chirimoya, custard apple, sherbet-fruit.

Chermai – *see* **OTAHEITE GOOSEBERRY**

CHERRY (*see also* **CAPULIN, CHERRY LAUREL, CHIMAJA, CHOKECHERRY, SAND CHERRY, SOUR CHERRY**) – Cherries come from any of several trees that belong to the genus *Prunus* and are part of the rose family. The small, rounded fruits are – along with apricots, peaches, and plums – "stone fruits," or "drupes." The cherry originated in temperate Europe and Asia, and doubtless wild cherries played a role in the human diet eons before the invention of agriculture and the beginning of recorded history. Our Neolithic ancestors extracted – and presumably fermented – cherry juice before it was discovered how to make wine from grapes.

The sweet cherry (*Prunus avium*) and the sour cherry (*P. cerasus*) are the two main cultivated types; such cultivation apparently stretches back at least to the ancient Greeks. Cherries were very popular in Germany, France, and England toward the end of the Middle Ages, and they reached the Americas with early immigrants. The bulk of the world's cherries is still produced in Europe. One important exception is the sour cherry, which is mostly cultivated in North America despite its historical background in the world of Rome (it is named for Cerasus in Pontus, the city where the Roman general Lucullus defeated Mithradates and Tigranes, after which he took their cherry trees back to Italy).

Various cultures have provided many names for the hundreds of varieties of cherries that are consumed fresh, canned, and frozen and used (among other things) for candies, jams, tarts, pie fillings, liqueurs (especially kirsch), and flavoring medicines. In parts of the Old World, the powder of ground cherrystones has been employed as a spice.

The bing cherry is perhaps the best known of the sweet varieties in the United States, and the Montmorency the best known of the sour. In addition, of course, there are wild red and black cherries. The wild black cherry, also known as the chokecherry (*Prunus virginiana*), was exploited by Native Americans in the eastern part of North America for both food and medicine long before the Europeans arrived. In fact, this cherry is still used in both capacities; it is a principal ingredient in cough medications, including the venerable "Smith Brothers'" cough drops. Wild black cherries also find their way into some rums. Cherries are high in potassium and, like all red fruits, contain vitamins A and C along with B vitamins.

Common names and synonyms: Amarelle, Bigarreau, bing cherry, bird cherry, black cherry, capuli, Capulin, chokecherry, Gean, Guigne, klarbar, Mazzard, Montmorency, pie cherry, red cherry, sour cherry, sweet cherry, tart cherry, wild black cherry, wild red cherry.

Cherry birch – *see* **SWEET BIRCH**

CHERRY LAUREL (*see also* **CHERRY**) – An evergreen plant of Europe, and now naturalized in North America, the cherry laurel (*Prunus laurocerasus*) bears small black fruits that have little taste. But its thick, glossy leaves have a flavor like bitter almond and are used in cooking – especially for flavoring dessert puddings.

Cherry pepper – *see* **HUNGARIAN CHERRY PEPPER**

CHERRY PLUM (*see also* **PLUM**) – Also known as the "myrobalan plum," the cherry plum (*Prunus cerasifera*) is an Asiatic fruit now used extensively in Europe for stock to bud domestic varieties. The European plum (*P. domestica*) is thought to be a hybrid of the cherry plum and the sloe. Cherry plums are yellow, red, or purple; they are juicy but not especially tasty.

Common names and synonyms: Myrobalan plum.

Cherry tomato – *see* **TOMATO**

CHERVIL – There is an annual chervil (*Anthriscus cerefolium*) and a biennial (*Chaerophyllum bulbosum*); the latter is also called "turnip-rooted chervil." Both are related to the carrot family and to parsley (which the annual variety resembles). The latter is native to western Asia and the Balkans (it grows wild in Iran and southwestern Russia) and derives its name from a Greek word meaning "cheer-leaf." The Romans used chervil for its aromatic, parsley-tasting, anise-smelling leaves and are credited with introducing it into western Europe and then spreading it about the continent. Chervil has parsley-like leaves, used for seasoning, that were long popular in England and today are especially appreciated in France. It is one of the fines herbes (along with parsley, chives, and tarragon) employed in salads and as potherbs. In addition, chervil is used much in the same way as parsley in fish and shellfish dishes, omelettes, soups, and sauces. The leaves are available both fresh and dried. The biennial, which is native to Europe, is grown for its carrot-like root.

Common names and synonyms: Garden chervil, leaf chervil, salad chervil, sweet cicely, turnip chervil, turnip-rooted chervil.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

CHESTNUT – Members of the beech family, chestnut trees are native to the world's temperate regions, and there are several trees of the genus *Castanea* that bear nuts enclosed in a prickly burr. The name, said to derive from a town – Kastanéa – in Asia Minor, has been preserved in most of the countries of Europe where chestnuts are enjoyed (*Kastanie* in German and *châtaigne* in French, for example), and the aroma of roasting chestnuts during the holiday season has long been an indelible memory for most city dwellers of Europe and North America. In the early twentieth century in North America, the native chestnut (*Castanea dentata*) was almost totally destroyed by a blight – a destructive fungal bark disease that may have killed 3 billion or more chestnut trees between the turn of the century and

1940. Because Asiatic varieties of the chestnut tree proved resistant to the blight, an attempt has been made to substitute Chinese trees (and European varieties), but thus far practically all chestnuts that are roasted or boiled and chopped into dressings to accompany birds and game in America have been imported from Europe. They are not, however, European "horse chestnuts" (*Aesculus hippocastanum*), which are bitter and mildly toxic, unlike the American and other European varieties, which have a mild, sweet, nutty taste. Chestnuts have a mealy consistency reminiscent of roasted cassava or potatoes. They were mentioned and used by the ancient Greeks and Romans and have served some people very much as a staple crop. Indeed, dried chestnuts were historically ground into flour for making breads, and in some places chestnuts constituted the most important food for whole populations. The chestnut is the only nut high in vitamin C, and it is also a good source of the B vitamins. A bonus is that it is low in fat and calories.

Common names and synonyms: American chestnut, *châtaigne,* Chinese chestnut, dwarf chestnut, European chestnut, European horse chestnut, Japanese chestnut, *Kastanie,* Spanish chestnut, sweet chestnut.

See also: "Chestnuts," Part II, Section D, Chapter 1.

Chestnut bean – *see* **CHICKPEA**

CHIA – A species of sage that produces pods filled with tiny seeds, chia (*Salvia columbariae*) long provided Native Americans of southwestern North America with a grain substitute. In addition, the Aztecs, farther south, used these seeds and those of a Mexican chia (*Salvia hispanica*) to make a refreshing drink. The seeds are gathered much like grain and are then parched and ground into meal for baking flat breads and making porridges. Chia seeds were also often stored for future use.

Common names and synonyms: California chia, ghia, Mexican chia.

Chiccory – *see* **CHICORY**

Chich-pea – *see* **CHICKPEA**

Chickling grass – *see* **CHICKLING VETCH**

Chickling pea – *see* **CHICKLING VETCH**

CHICKLING VETCH (*see also* **LEGUMES**) – Also known as "grass pea" and "European grass pea," chickling vetch (*Lathyrus sativus*) is a pea cultivated in Europe for its seeds and for animal forage.

Common names and synonyms: Chickling grass, chickling pea, European grass pea, grass pea.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

Chickory – *see* **CHICORY**

CHICKPEA (*see also* **BEANS**) – Known as *garbanzo* in Spanish, *ceci* in Italian, "gram" in India, and often as just plain "pulse" across the globe, the chickpea (*Cicer arietinum*) is an ancient pulse that originated in western Asia and was domesticated there some 7,000 years ago. The tan, hazelnut-sized seeds, with their wrinkled surfaces, nutty flavor, and crisp texture, soon became popular from the Mediterranean to India (as culinary traditions make clear) and today are practically universal. In the Near East, the chickpea is the basic ingredient for hummus and falafel and is frequently incorporated in couscous. In India, as the country's most important legume, the chickpea is roasted, boiled, and fried, is made into flour, and is part of a *dhal.* In the Mediterranean region, the chickpea figures prominently in the "poor cuisine" – as a staple in the diet of poor people, a substitute for meat (and sometimes for coffee as well), and an ingredient in the boiled dinners (*cocidos*) of Iberia.

Exactly when the chickpea reached Spain and Portugal is unclear – perhaps with the Phoenicians, certainly with the Romans. The Portuguese call the chickpea *grão do bico* ("grain with a beak") because of the little horn on the pea. From Iberia, chickpeas traveled to the Americas, where they achieved fame in Cuban bean soup and in menudo. The vegetable has also become a standard item on practically every salad bar in North America, a region where it can also be purchased dried or canned (but seldom fresh) in markets. Like almost all legumes, the chickpea is high in protein and the B-vitamin complex. Moreover, the chickpea and others of its relatives have recently come to be viewed as cholesterol fighters.

Common names and synonyms: Bengal gram, calvance pea, *ceci,* chestnut bean, chich, chich-pea, dwarf pea, garavance, garbanza, *garbanzo,* gram, gram pea, *grão do bico,* pulse, yellow gram.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

CHICKWEED – So called because they are eaten by chickens, chickweeds (any of the various plants of the genus *Stellaria,* especially the common chickweed, *S. media*) have enjoyed something of a reputation for medicinal use. In fact, a synonym, "stitchwort," was assigned because of an alleged ability to cure pains in the side. Native to Europe, *Stellaria* species were given the Latin word for star as a name in view of the shape of their flowers. Several species of chickweed are eaten in Japan. In North America, *S. media* (introduced from Europe) has a reputation for making an excellent salad with its tender leaves and stems. The seeds are also edible. Today, chickweeds are used mostly as a potherb, but because they are so hardy, growing even throughout the winter months, and because they can be cooked as a green, they doubtless served for millennia as food for hunter-gatherers and also for those caught in famine circumstances, even in the colder seasons. The term chickweed can also refer to plants of the genus *Cerastium.*

Common names and synonyms: Common chickweed, stitchwort.

Chicle (tree) – *see* **SAPODILLA**

Chico – *see* **SAPODILLA**

CHICORY (*see also* **BELGIUM ENDIVE, ENDIVE AND ESCAROLE**) – Semantic problems abound with chicory (*Cichorium intybus*) – also called succory, radicchio, and red chicory), endive (*Cichorium endivia*), and escarole, which is the broad-leafed variety of endive. All three are members of the dandelion family, but there the resemblance ends. *Cichorium endivia,* native to India, was the ancestor of endive and known to the Egyptians as well as to the ancient Greeks and Romans. By contrast, *C. intybus* is native to Europe, but the names nonetheless remain confused. In the United States, chicory is generally called Belgian endive, although this is also referred to simply as endive. The French, too, call it endive (and call endive *chicorée*), and radicchio is chicory's Italian name. The Flemish name for Belgian endive is *witloof* or "whiteleaf," because it was grown in cellars in dim light, which produced both the plant's whitish leaf color and its elongated leaves as they stretched out to seek light – indeed, modern methods of growing this pale, cigar-shaped vegetable follow the same principle. If part of the confusion is semantic, part also stems from the different uses of the plants. Chicory as well as endive roots are ground to become a natural coffee substitute (especially in France and French-influenced areas) or an addition to regular coffee for added flavor and reduced caffeine. However, the tight hearts of Belgian endive and radicchio are also attractive and slightly bitter ingredients in salads; in addition, their braised leaves can be a vegetable dish in their own right. Radicchio, although a relative newcomer to the U.S. culinary scene, is now grown domestically in New Jersey and California as well as in Italy and Mexico. Nonetheless, it remains a very expensive produce item.

Common names and synonyms: Asparagus chicory, *barbe de capucin,* Belgian endive, chiccory, chickory, endive, radicchio, *radicchio di castelfranco, radicchio di chiogga, radicchio di treviso, radicchio di Verona, radicchio rosso,* red chicory, red-leafed chicory, red treviso chicory, red Verona chicory, *rosso di Verona,* succory, *witloef, witloof.*

Chico sapote – *see* **SAPODILLA**

Chico zapote – *see* **SAPODILLA**

Chihli cabbage – *see* **CHINESE CABBAGE**

Chiku – *see* **SAPODILLA**

Chilaca – *see* **PASILLA**

Chilca – *see* **ANISILLO**

Chilean cranberry – *see* **CHILEAN GUAVA MYRTLE**

CHILEAN GUAVA MYRTLE – Also called the Chilean cranberry, the Chilean guava myrtle (*Myrtus ugni*) is a small evergreen shrub with delicious mahogany red, sphere-shaped fruits that are an inch or more in diameter. The plant is a native of Chile; its fruits are used for jelly, and its fragrant leaves as well as the fruits are employed in flavoring water and making perfumes.

Common names and synonyms: Chilean cranberry, *ugni.*

CHILEAN PINE – Also known as the "monkey-puzzle," the Chilean pine (*Araucaria araucana*) is a South American native. It bears the name of Native Americans (the Araucana) who fought the Spanish conquistadors to a standstill in what is now Chile, and the tree also bears nuts that are eaten raw as well as boiled or roasted.

Common names and synonyms: Monkey-puzzle (tree).

Chile caballo – *see* **MANZANA**

CHILHUACLE PEPPERS (*see also* **CHILLI PEPPERS**) – The three *chilhuacle* chillies (*Capsicum annuum*) are all grown only in southern Mexico (Oaxaca and Chiapas). The *rojo* (colored a deep red), the *negro* (oxblood to almost black in tone), and the *amarillo* (with a reddish yellow hue) average some 2 to 3 inches in length and appear like miniature bell peppers (which are members of the same species), although the *chilhuacles* can also taper somewhat. The *chilhuacles* are moderately hot, are almost always dried, and generally are employed in mole sauces. Of the three, the *chilhuacle negro* is the most highly prized and thus the most expensive.

Common names and synonyms: Chilhuacle amarillo, chilhuacle negro, chilhuacle rojo.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Chilhuacle rojo – *see* **CHILHUACLE PEPPERS**

Chili (pepper) – *see* **CHILLI PEPPERS**

Chilli bola – *see* **CASCABEL**

Chilli colorado – *see* **ANAHEIM, NEW MEXICO CHILLIES**

Chilli negro – *see* **PASILLA**

CHILLI PEPPERS (*see also* **SWEET PEPPERS**) – All chilli peppers belong to the genus *Capsicum* and are mostly varieties of two species – *C. annuum* and the generally smaller and hotter *C. frutescens.* Chilli peppers are native to the Americas, where they were cultivated for many thousands of years as they spread from South America north to Mesoamerica, the Caribbean, and the North American Southwest. When the Europeans reached the New World, chillies were the most common spice used by Native Americans. But after this they were no longer a secret from the rest of the world. Columbus called them *pimientos* after the *pimienta* or black pepper he had hoped to find and carried them to Iberia, whereupon they began to spread. Peppers also radiated to the East via the Spaniards' Manila galleons (trading between Mexico and the Philippines) and traveled with the Portuguese, who introduced the plants into West and East Africa, India, and the East Indies. The wildfire spread of chillies took place so quickly in the sixteenth century, and they became so well naturalized, that many in Africa, India, East and Southeast

Asia, and elsewhere began to think of the plants as native to their own regions of the world. The "fire" of chillies, which comes from the alkaloid capsaicin, is imparted in dozens of hot sauces throughout the world from Thailand (*nam prik*) to Mexico (*salsa*) to Tunisia (*barissa*), and chillies are vital in the cuisines of China, India, and Africa – south as well as north of the Equator. Chillies are green, yellow, red, or black in color and range in shape from long, skinny, hot, green chillies – or Anaheims – to the squat habaneros and jalapeños, to the plump, elongated serranos and banana chillies, to name but a few. All of these come dried as well as fresh and are crushed and ground. In addition to sauces, chillies are made into powders, pickled, smoked, roasted, and canned whole as well as chopped. Chillies are very high in vitamin C and also provide a good measure of vitamin A.

Common names and synonyms: Capsicum (pepper), *chile* (pepper), chili (pepper), chilli(es), Japanese mustard (Korean), pepper, pepper of Calicut (archaic), *pimiento,* red pepper.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4; "Spices and Flavorings," Part II, Section F, Chapter 1.

Chilli pequeño – *see* **TEPÍN CHILLIES AND RELATIVES**

Chilli pequín – *see* **TEPÍN CHILLIES AND RELATIVES**

Chilli rocoto – *see* **MANZANA**

Chilli seco – *see* **SERRANO**

CHIMAJA (*see also* **CHERRY**) – Also called the "holly-leaved cherry," this wild cherry plant (*Prunus ilicifolia*) has roots and leaves that are dried, ground, and added to the dishes of Mexico (where it originated) and those of the southwestern United States. The sweet fruit is also eaten, and in the past Native Americans processed the kernel of the stone to make a kind of meal.

Common names and synonyms: Holly-leaved cherry.

China bean – *see* **COWPEA**

CHINABERRY (*see also* **BERRIES**) – An Asiatic tree, the chinaberry (*Melia azedarach*) has smooth, yellow, edible berries. The tree has become naturalized in the southern United States. A soapberry (*Sapindus saponaria*) of the desert Southwest and Mexico is also called "chinaberry."

China orange – *see* **CALAMONDIN**

China sweet orange – *see* **ORANGE**

Chinchayote – *see* **CHAYOTE**

Chinchilla – *see* **ANISILLO**

CHINESE AMARANTH (*see also* **AMARANTH**) – There are several species of *Amaranthus* cultivated in southwestern Asia, with Chinese amaranth (*A. tricolor*) probably the most important. It is an ancient food that is mentioned in early Chinese records, but despite its scientific name, the plant seems to sport only two colors. The green kind resembles spinach and is used in much the same way in vegetable dishes, salads, and the like. The other is known as "red-in-snow" in China, because it grows early in the spring when the ground still has something of a snow cover. This type is eaten fresh and also pickled. Chinese amaranth is grown to a limited extent for the Chinese market in the United States.

Common names and synonyms: Chinese spinach, red-in-snow, *tampala.*

See in addition: "Amaranth," Part II, Section A, Chapter 1.

Chinese anise – *see* **STAR-ANISE**

Chinese apple – *see* **POMEGRANATE**

CHINESE ARTICHOKE – The Chinese artichoke (*Stachys sieboldii* = *S. affinis*) has nothing to do with the globe artichoke. Rather, it is a crisp, edible tuber, which resembles the Jerusalem artichoke in taste and is native to and grown in China and Japan. Also called the Japanese artichoke, in Europe it goes by the name of *crosne,* which – according to legend – was also the name of a small town in France where the Chinese artichoke was introduced in 1822. Chinese artichokes are usually boiled for a few minutes and then eaten as a cooked vegetable; they may also serve as an ingredient in other dishes, especially soups.

Common names and synonyms: Crosne, Japanese artichoke, Japanese potato.

CHINESE BROCCOLI (*see also* **CABBAGE**) – Also known as *gai-larn,* "Chinese kale," and *kailan,* Chinese broccoli (*Brassica alboglabra*) resembles Chinese flowering cabbage but has a flavor similar to kale. As in the case of the flowering cabbage, the tender green stems are of more interest to consumers than the leaves. The stems are steamed or braised and often served with oyster sauce. They are also used in soups and noodle dishes.

Common names and synonyms: Chinese kale, *gai-larn, kailan.*

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

CHINESE CABBAGE (*see also* **CABBAGE**) – Also called napa, nappa, celery cabbage, and *pe-tsai*, this vegetable (*Brassica pekinensis*) is often confused with bok choy (*Brassica chinensis*), which is also sometimes called "Chinese cabbage." They resemble one another in their oblong or pointed (as opposed to round) form. The leaves of the Chinese cabbage, which look something like those of pale romaine lettuce, are crisp, tender, mild tasting, and certainly more delicate than those of round cabbages. Chinese cabbage has been an important dietary item in China since ancient times and is also consumed in other parts of Asia – especially in Japan and Korea, where it is stir-fried, boiled, pickled, or braised for use in a number of different dishes (the well known Korean pickle, *kimchee,* is made with Chinese cabbage). Chinese cabbages were virtually unknown in the West until the Israelis began to grow them, after which growers in California followed suit (hence napa or nappa cabbage, after the Napa Valley). Chinese cabbage is high in folic acid, vitamin A, and potassium.

Common names and synonyms: Celery cabbage, *chihli* cabbage, Chinese broccoli, Chinese leaf, *chou de chine, gay lon, hakusai,* Michihli, Napa, napa cabbage, nappa cabbage, Peking cabbage, *pe-tsai,* pointed cabbage, Shantung cabbage, Tientsin, *wong bok.*

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Chinese chard – *see* **PAKCHOI AND KAI CHOY**

Chinese chestnut – *see* **CHESTNUT**

CHINESE CHIVE(S) – Other names for Chinese chives (*Allium tuberosum*) – such as "Oriental garlic," "Chinese leeks," "garlic chives," and "flowering chives" – indicate that not only are the leaves employed as chives but the bulbs are also used much like garlic. Flowering chives are Chinese chives that are allowed to mature and grow an edible pointed flower. The Chinese also grow these chives without exposure to sunlight, whereupon they become "yellow chives."

Common names and synonyms: Chinese leeks, flowering chives, garlic chives, Oriental garlic, yellow chives.

See also: "The *Allium* Species," Part II, Section C, Chapter 2.

Chinese cinnamon – *see* **CINNAMON AND CASSIA**

Chinese date – *see* **JUJUBE**

Chinese eddoe – *see* **COCOYAM**

Chinese fig – *see* **PERSIMMON**

CHINESE FLOWERING CABBAGE (*see also* **CABBAGE**) – Also called *choy sum* and "mock *pak choy,*" Chinese flowering cabbage (*Brassica parachinensis*) has long, white-to-green stems, with rounded green leaves. *Choy sum* means "vegetable hearts," and it is the stems rather than the leaves that are sought after. They are generally cooked without peeling and served with an oyster sauce.

Common names and synonyms: Choy sum, mock *pak choy.*

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Chinese garlic – *see* **CHIVE(S)**

Chinese gooseberry – *see* **KIWI FRUIT**

Chinese kale – *see* **CHINESE BROCCOLI, KALE**

Chinese lantern – *see* **TOMATILLO**

Chinese laurel – *see* **BIGNAY**

Chinese snow pea – *see* **SUGAR PEA**

Chinese spinach – *see* **CALLALOO, CHINESE AMARANTH**

Chinese squash – *see* **FUZZY MELON**

Chinese star fruit – *see* **CARAMBOLA**

CHINESE TALLOW TREE – Known also as "Chinese vegetable tallow" or simply "vegetable tallow," the Chinese tallow tree (*Sapium sebiferum*) is a native of China and Japan but is now grown in other countries of East and South Asia and the southern United States. Also called the "white wax-berry," the tree is cultivated for these fruits about the size of peas, the seeds of which yield an oil with numerous industrial applications. However, the oil is used for cooking in Asia.

Common names and synonyms: Chinese vegetable tallow, tallow tree, vegetable tallow, white wax-berry.

Chinese taro – *see* **ALOCASIA**

Chinese vegetable marrow – *see* **FUZZY MELON**

Chinese vegetable tallow – *see* **CHINESE TALLOW TREE**

CHINESE WHITE OLIVE – Often mistakenly called the "Java almond," the Chinese white olive (*Canarium album*) is a large tree of South and Southeast Asia that belongs to a large genus of tropical trees. Many of these bear nuts sometimes called pilai nuts. In the case of the Chinese white olive, it bears a fruit with pulp that is preserved for use as a condiment.

Common names and synonyms: Chinese olive.

Chinese winter melon – *see* **FUZZY MELON, MELONS**

CHINESE YAM (*see also* **LESSER YAM, YAMS**) – A yam that is a native of China and widely cultivated there, the Chinese yam (*Dioscorea batatas*) is also called "Chinese potato" and, sometimes, "cinnamon vine" because the flowers smell of cinnamon. The tubers, which are also grown in Japan and other parts of East Asia, are mainly employed in sliced and grated form to add substance to various dishes, but they can also be fried, baked, or boiled like potatoes. This yam, along with others, has served as food for the peoples of China since the days of the hunter-gatherers.

Common names and synonyms: Chinese potato, cinnamon vine.

See in addition: "Sweet Potatoes and Yams," Part II, Section B, Chapter 5.

Chipiles – *see* **QUELITES**

Chipotle (chilli) – *see* **JALAPEÑO**

Chipotle grande – *see* **JALAPEÑO**

Chiquilla – *see* **ANISILLO**

Chirauli nut – *see* **CUDDAPAH ALMOND**

Chirimen – *see* **KABOCHA (SQUASH)**

Chirimoya – *see* **CHERIMOYA, POSHTE**

CHIVE(S) – The chive (*Allium schoenoprasum*) is of the lily family, is related to the onion, leek, and garlic, and has the most delicate taste of all of its close relatives. Chives are grown for their long, thin, grasslike, hollow stalks, which are used in salads, cheeses, soups, omelettes, and other dishes. Chives are also among the fines herbes – a traditional French blend of chervil, chives, parsley, and tarragon used for seasoning soups, salads, omelettes, and cottage and cream cheeses. The chive is an ancient herb. It is said to be native to the Mediterranean, but it was known by the Chinese some 5,000 years ago (varieties are called "Chinese onion" and "Oriental garlic") and grew wild in North America as well. Chives were enjoyed by the ancient Greeks but only reached the gardens of much of the rest of Europe in the sixteenth century. Chives are rich in vitamins A and C.

Common names and synonyms: Chinese garlic, Chinese onion, Oriental garlic.

See also: "The *Allium* Species," Part II, Section C, Chapter 2; "Spices and Flavorings," Part II, Section F, Chapter 1.

Chocho – *see* **ANDEAN LUPIN, CHAYOTE**

Chocolate – *see* **CACAO, MUTAMBA**

Chocolate-pudding fruit – *see* **BLACK SAPOTE**

Choctaw-root – *see* **HEMP DOGBANE**

CHOKEBERRY (*see also* **BERRIES**) – The chokeberry (*Aronia melanocarpa* or *A. arbutifolia*), like its fellow family (Rosaceae) member, the chokecherry (*Prunus virginiana*), is a very astringent fruit. Nonetheless, in eastern North America, the red, purple, or black fruits were gathered by Native Americans, who dried them for winter use. Around 1700, the plant was imported into Europe, where it was desired more for the ornamental appeal of the shrub than for its bitter fruit. However, the berries also make a useful substitute for black currants in areas where these cannot be grown. Chokeberries are very rich in vitamin C.

CHOKECHERRY (*see also* **CHERRIES**) – A member of the Rosaceae family, the chokecherry (*Prunus virginiana*), also called the wild black cherry, is a wild North American cherry and should not be confused with another family member, the chokeberry. With a name like chokecherry, one can be certain that the dark red or blackish fruit is very astringent. Nonetheless, chokecherries were gathered by Native Americans, who dried them and combined them with other fruits for winter storage. Later foragers have used them for jams and jellies, and they were even cultivated for a time in the southern provinces of Canada. Chokecherries were also employed for decades in cough remedies and were the principal ingredient in "Smith Brothers'" cough drops. Like other sour cherries, chokecherries are high in vitamin C and beta-carotene.

Common names and synonyms: Black chokecherry, capulin, western chokecherry, wild black cherry, wild cherry.

Choko – *see* **CHAYOTE**

Chopsuey greens – *see* **CHRYSANTHEMUM**

Chou de chine – *see* **CHINESE CABBAGE**

Chou-rave – *see* **KOHLRABI**

Choy sum – *see* **CHINESE FLOWERING CABBAGE, FLOWERING WHITE CABBAGE**

Christmas Rose (grape) – *see* **GRAPES**

Christmas tea-bush – *see* **YAUPON**

Christophene – *see* **CHAYOTE**

Christophine – *see* **CHAYOTE**

CHRIST'S-THORN FRUIT – Several prickly or thorny bushes of Palestine and the Near East are called "Christ's-thorn," especially *Ziziphus* (= *Zizyphus*) *spina-christi* and *Paliurus spina-christi.* They bear a small, red, edible fruit (a jujube), which is dried and eaten locally. Also called "Jerusalem thorn," this bush is popularly believed to have been used to fashion Christ's crown of thorns.

Common names and synonyms: Christ-thorn berry, Jerusalem thorn.

Christ-thorn berry – *see* **CHRIST'S-THORN FRUIT**

CHRYSANTHEMUM – "Japanese greens" (*Chrysanthemum coronarium*), also called "chopsuey greens," and the crown daisy or garland chrysanthemum (*C. spatiosum*) both have aromatic leaves that are cooked much like spinach in East Asia and are also used raw as garnishes.

Common names and synonyms: Chopsuey greens, crown daisy, edible-leaved chrysanthemum, garland chrysanthemum, Japanese greens.

Chu chi – *see* **MATRIMONY VINE**

Chuchu – *see* **CHAYOTE**

CHUFA – The edible roots of the weed "chufa" (*Cyperus esculentus*) are tubers that look somewhat like peanuts and, in the past, have been called "earth almonds" and "rush nuts." They can be eaten raw or cooked by boiling or roasting. They are also dried for later use and made into a flour, and chufa seeds can substitute for coffee. In Europe and the Middle East, desserts and drinks are made from the tubers. The plant, which is widespread geographically, is also of some antiquity. It was used by native North Americans on one side of the world and by the ancient Egyptians on the other side. Another common (and confusing) name for chufa is galingale, which is actually *Alpinia galanga.*

Common names and synonyms: Earth almond, galingale, nut(-)grass, purple nutgrass, rush nut, sedge, tigernut, yellow nutsedge, zula nut.

CICELY – Also known as "sweet cicely" – and sometimes as "sweet chervil" and even "myrrh" and "garden myrrh" – cicely (*Myrrhis odorata*) is an herb native to the Savoy region of France. Its pale green leaves and especially its ripe, glossy brown seeds have a licorice-like flavor that goes well with fruits and in salads and desserts. Cicely is so sweet that it can be added to stewed fruit dishes (such as rhubarb) and thereby considerably reduce the amount of sugar that is normally called for. In the past, cicely roots were boiled and eaten as a vegetable, but the plant is much less popular than it once was.

Common names and synonyms: Anise root, candy plant, European sweet chervil, garden myrrh, myrrh, Spanish chervil, sweet chervil, sweet cicely.

Cilantrillo – *see* **CILANTRO**

CILANTRO (*see also* **CORIANDER**) – Cilantro is a term that indicates the fresh green leaves of coriander (*Coriandrum sativum*), a plant whose seeds are also used as a spice (treated separately – along with the history of the plant – under the entry **Coriander**). Also called Chinese parsley, the pungent leaves of cilantro were long ago thought by some to smell delightfully peppery and by others to carry the odor of bedbugs. Nonetheless, cilantro has been acclaimed today as the most common flavoring herb in the world. The word cilantro comes from Spanish, but in Caribbean Spanish the term is *cilantrillo,* which can lead to confusion. Cilantro is available in bunches in produce departments and looks much like flat-leafed parsley. But there is also "culantro," which tastes like cilantro (although stronger) but looks like blades of grass. Cilantro is most important to the cuisines of Iberia, the Middle East, China, India, and many of the South American countries, and it is absolutely crucial to Mexican cookery, in which it appears as a green in many dishes, especially in salsas, guacamole, and with fish. Until recently, however, when Mexican food became more popular and widespread, cilantro was little known in the United States. The leaves deliver some vitamin A as well as vitamin C.

Common names and synonyms: Chinese parsley, *cilantrillo,* coriander, culantro, Mexican parsley, *yuen sai*.

Cimaru – *see* **TONKA BEAN**

Cinderella pumpkin – *see* **ROUGE VIF D'ÉTAMPES (PUMPKIN)**

Cinnamon – *see* **CINNAMON AND CASSIA, INDIAN BARK, SAIGON CINNAMON, WHITE CINNAMON**

CINNAMON AND CASSIA (*see also* **SAIGON CINNAMON**) – These ancient spices – cinnamon (*Cinnamomum zeylanicum = C. verum*) and cassia (*Cinnamomum cassia*) – are both derived from the dried inner bark of two related evergreen trees that belong to the laurel family. The trees are native to different parts of Asia (Sri Lanka and Burma, respectively), and, thus, cinnamon was an early – as well as vital – item in the spice trade that moved from the East to the West. Evidence exists to suggest that cinnamon was valued by the ancient Egyptians for witchcraft and embalming and, perhaps, for culinary purposes as well. It is mentioned in the Old Testament (along with cassia) and in Sanskrit manuscripts. In the East, cassia was cultivated by the Chinese as early as 2500 B.C., and may have been in use well before that. Cinnamon has been credited with magical ("love potions") as well as medicinal properties, and a drink prescribed for colds by a Roman physician – hot liquor and stick cinnamon – is still in use today. At one time cinnamon was viewed as more precious than gold. Cinnamon has long been an essential ingredient in Moroccan and Greek chicken and beef dishes, and in the Middle East it is commonly used with meats, especially lamb. Europeans and North Americans tend to employ cinnamon mostly in sweets. Much of the cinnamon used in Europe is true cinnamon, whereas most of that reaching the United States is actually cassia. The difference is easy to spot: Cinnamon is tan, whereas cassia is reddish brown in color.

Common names and synonyms: Chinese cinnamon (cassia), cinnamon bark (both), false cinnamon (cassia), *kayu manis* (both), Seychelles cinnamon (cinnamon), sweet wood (both), true cinnamon (cinnamon).

See in addition: "Spices and Flavorings," Part II, Section F, Chapter 1.

Cinnamon bark – *see* **CINNAMON AND CASSIA**

Cinnamon vine – *see* **CHINESE YAM**

CINSAULT (*see also* **GRAPES**) – One of the important grapes of the southern Rhône Valley of France, the Cinsault (*Vitis vinifera*) is large, black, and used mostly to blend wines. A small amount is also produced in California.

See in addition: "Wine," Part III, Chapter 13.

Ciruela – *see* **BUNCHOSIA**

Citrange – *see* **CITRANGEQUAT**

CITRANGEQUAT (*see also* **CITRUS FRUITS, KUMQUAT, ORANGE**) – A cross between the orange relative *Poncirus trifoliata* and varieties of the sweet orange produced the hybrid known as a "citrange." Crossing the citrange with the kumquat has resulted in yet another hybrid, the "citrangequat" (involving three genera: *Citrus, Poncirus,* and *Fortunella*), which has a very sour fruit. Like the limequat and the orangequat, the citrangequat is the result of a breeding program – sponsored by the U.S. Department of Agriculture (USDA) – that is attempting to breed the cold-resistance of the kumquat into other plants.

CITRON (*see also* **CITRUS FRUITS, LEMON**) – A native of Southeast Asia, the citron (*Citrus medica*) was cultivated by the Chinese and Sumerians in very ancient times and in southern Italy, Corsica, and Sicily by around the fourth century B.C. It reached the Americas with the Europeans, and a small crop was finally grown in California at the beginning of the twentieth century. The citron is cultivated mostly for its thick, spongy rind, in appearance like the rind of a large lemon, which is candied and often chopped into fruitcakes. It is also used to make fruit syrups, liqueurs, and perfume. In the past, the citron was used medicinally, and it has enjoyed considerable religious significance. The unripe fruit is the "citron of the law" used by Jewish communities in ceremonies celebrating the harvest festival Succoth. The citron's principal areas of cultivation are Italy, Corsica, and Greece, and a variety came to be known as the "Leghorn citron" when the islands of Corsica and Sardinia shipped their crops to Leghorn, Italy, for processing.

Another fruit (*Citrullus lanatus* var. *citroides* – of the same species as the watermelon) is also called "citron" and, except for its bitter taste, resembles a small watermelon. That it is used somewhat in the same way as *C. medica* is suggested by another of its common names, "preserving melon." It is also called the "stock melon" because it is sometimes fed to hogs.

Common names and synonyms: Citron melon, Corsican citron, Diamante citron, esrog, ethrog, etrog, Leghorn citron, preserving melon, stock melon.

See in addition: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

CITRUS FRUITS (*see also* the various citrus entries) – Save for recent hybrids (uglis, ortaniques, or tangelos, for example) and the grapefruit, all members of the citrus family (Rutaceae) originated in Southeast Asia (or – in the case of the sweet orange – China) and were first cultivated in China and India. Gradually they moved westward to Arabia and then to the countries surrounding the Mediterranean. The ancient Greeks apparently knew nothing of citrus fruits, and the Romans had only the citron. Oranges were recorded in Sicily at the beginning of the eleventh century and were reported as growing around Seville in Spain a couple of centuries later. The lemon was in the Near East by the tenth century or so and was being cultivated in Italy by the fifteenth century. Christopher Columbus and those explorers who followed in his wake scattered citrus seeds over much of the rest of the globe, discovering in the process the loose-skinned mandarin (tangerine) species that had long been cultivated in China and Japan. Grapefruits seem to have been born in the eighteenth century in the West Indies as a cross between the pomelo and the orange. The kumquat, a native of China and Japan, is not a citrus fruit but belongs to a similar genus.

Civet-cat fruit – *see* **DURIAN**

Ckoito – *see* **AMARANTH**

CLARY – An herb, clary (*Salvia sclarea*) is also called "clary sage." The taste of its flowering tops combines the flavors of sage and mint. In the past, clary was much employed in Europe as a seasoning for various foods and for wine. It is still used to enhance egg dishes and is one of the herbs that is used in making Italian vermouths.

Common names and synonyms: Clary sage.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Clear-up cactus – *see* **PITAHAYA**

Cleavers – *see* **GOOSEGRASS**

Clevner – *see* **PINOT BLANC**

Climbing bittersweet – *see* **AMERICAN BITTERSWEET**

Clotbur – *see* **BURDOCK**

CLOUDBERRY (*see also* **BERRIES**) – A creeping plant of northern climates, the cloudberry (*Rubus chamaemorus*) does best close to or even within the Arctic Circle, flourishing in the nearly 24-hour-long days of summer sunshine. The reddish orange to yellow fruit and white flowers of the cloudberry plant are found throughout the Scandinavian countries and Alaska. The Eskimos and Lapps collect the juicy, sweet berries in the fall and freeze them for winter consumption – the berries have doubtless done much over the centuries to provide vitamin C to peoples in a part of the world that is decidedly lacking in the usual fruits and vegetables. Cloudberries are also sold in northern Scandinavia for making preserves and baking pastries, and they are fermented to make vinegar. Like other berries, cloudberries are high in vitamin C.

Common names and synonyms: Bakeberry, baked-apple berry, *malka, Moltebeere,* salmonberry, *Torfbeere,* yellowberry.

CLOUD EAR (*see also* **MUSHROOMS AND FUNGI**) – The Tremellales, or the jelly fungi, are a group of gelatinous, edible wood fungi of which the cloud ears *Auricularia polytrica* and *A. auricula* are the species commonly eaten. They are brown to black gelatinous lobes that resemble human ears, are widely distributed in the world, and are found in the wild in clusters on logs. In China *A. polytrica* has been used in cooking for some 2,000 years. In the Pacific Northwest and Rocky Mountain regions of the United States they are often encountered near melting snow. Often consumed after being dried, cloud ears are most appreciated for their delicate flavor. In the Far East and in China, they are cultivated.

Common names and synonyms: Black (tree) fungus, Chinese mushroom, Jew's-ear, Judas('s) ear, *kikurage, mo-ehr, mook yee,* silver ear, tree ear, wood ear, *yun er.*

See in addition: "Fungi," Part II, Section C, Chapter 7.

CLOVE(S) – A pungent flavoring agent, the clove (*Syzygium aromaticum*) is another of those ancient spices that have an exotic past. Cloves are the dried buds of trees native to the Moluccas and provided one of the reasons those islands have long been called the Spice Islands. Centuries before the Christian era, cloves were used by the Chinese and became an important item in the spice trade with the West. The Egyptians, Greeks, and Romans were all familiar with cloves. Indeed, the name "clove" comes from the Latin word *clavus,* which means "nail" and aptly describes their appearance. The Portuguese were the first from the West to reach the Spice Islands and create a monopoly on the clove trade. At the beginning of the seventeenth century, they were succeeded by the Dutch, who established their own monopoly and limited production to just one of the islands. This monopoly was only broken at about the time of the American

Revolution, when a French diplomat managed to smuggle out some seedlings. Today, cloves are grown in Tanzania (which accounts for about half the world's production), Madagascar, Sri Lanka, and – in the New World – Grenada. Perhaps the first use of cloves was to freshen the breath, but it doubtless required little time to discover that their strong aroma and flavor went well with foods. Any meat dish, especially ham, can be enhanced with cloves. They are also called for in a multitude of recipes for spiced cakes, mincemeat, gingerbread, marinades, stewed-fruit dishes, any apple dish, and mulled-wine drinks. Cloves can be purchased dried, either whole or ground.

Common names and synonyms: Mother-of-clove(s).

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

CLOVER (*see also* **PRAIRIE CLOVER, SWEET CLOVER**) – Rarely used for human consumption except in times of famine, clover (genus *Trifolium*) is typically employed as fodder. Some exceptions are *T. repens, T. pratense,* and *T. campestre.* Icelanders boil *T. repens* (white Dutch clover, white clover) as a vegetable. In Europe, the young leaves of *T. pratense* (wild red clover) are eaten in salads and sandwiches, and the flowers are used to make a tea. A bitter variety, *T. campestre* (the "large hop clover") was used to flavor beer before the discovery of hops.

Common names and synonyms: Ladino clover, large hop clover, red clover, sweet clover, white clover, white Dutch clover, wild red clover.

Clusterbean – *see* **GUAR**

Cluster yam – *see* **BITTER YAM**

Cob – *see* **HAZELNUT AND FILBERT**

Cobnut – *see* **HAZELNUT AND FILBERT**

COCA – This shrub (*Erythroxylum coca*) is native to the Andean region of South America. The dried leaves yield a crystalline alkaloid substance known as cocaine. Taken internally, cocaine is a stimulant, whereas external use has the effect of a local anesthetic. The Indians of Peru and Bolivia chew the leaves to help them work long hours and ward off hunger, fatigue, and cold temperatures. This practice is comparable to the chewing of betel nut in Southeast Asia or kola nut in Africa. Some people make a coca "wine" from the leaves as well. Coca is also grown in Sri Lanka, Java, and Taiwan.

Common names and synonyms: Cocaine plant, spadic.

Cochineal plant – *see* **NOPALES**

COCKLEBUR – The seeds of the cocklebur (*Xanthium commune*) were used by Native Americans, who ground them into a meal. They may also have employed the shoots and leaves of *X. strumarium,* which others have reportedly boiled and eaten as a vegetable.

COCKSPUR (*see also* **BERRIES**) – A small tree of Colombia and Central America, *Celtis iguanaea* produces edible, berry-like fruits that are green when immature and yellowish when ripe. They are generally eaten raw and have an excellent taste.

Cockspur thorn – *see* **HAWTHORN BERRY**

Coco – *see* **COCONUT**

Cocoa – *see* **CACAO**

Cocoaplum – *see* **COCOPLUM**

COCONA (*see also* **BERRIES**) – A berry native to northern South America, cocona (*Solanum topiro* = *S. sessiliflorum*) is edible, although many other species of the genus *Solanum* are poisonous. The berry is cultivated today from Trinidad to Costa Rica and, although not known in the wild, also "voluntarily" plants itself in abandoned plots and clearings. The berries are yellowish to red when ripe and are covered with a kind of fuzz that can be brushed off.

Common names and synonyms: Topiro.

COCONUT – Hunter-gatherers doubtless learned hundreds of thousands of years ago to crack open these fruit seeds of the coconut palm (*Cocos nucifera*) for the "milk" and "meat" contained therein, not to mention the usefulness of the shell as a drinking and eating vessel and as a scraping utensil. Truly, the coconut is one of the oldest of food plants. It originated in the Malayan Archipelago but long ago distributed itself throughout the world's tropics because it easily floats and, hence, can cross oceans. The coconut is mentioned in Sanskrit manuscripts, but it is said that Marco Polo (in his narratives of his travels in Asia) was the first European to describe it. During the Portuguese expansion of the fifteenth and sixteenth centuries, coconuts were carried back to Europe, and the Portuguese gave us the name we know the fruit by today. They called it *coco,* which meant "head" or "noggin." The hairy shell that encloses the fruit is itself enclosed by a greenish, fibrous husk. As the fruit ripens within this double seal – full ripening requires a year – more and more of the thin white liquid within (coconut "water") is converted to meat (called copra when dried), which is pressed for oil and made into various coconut foods and cosmetic products. Coconut cream is a blending of the coconut water and flesh. For the moment, at least, the coconut – especially its oil – is somewhat in disrepute because of its heavy concentration of saturated fat.

Common names and synonyms: Coco, cokernut.

See also: "Coconut," Part II, Section E, Chapter 2; "An Overview of Oils and Fats," Part II, Section E, Chapter 1.

COCOPLUM – Also known as cocoaplum, hicaco, and icaco, the cocoplum (*Chrysobalanus icaco*) is the fruit of a small tree native to tropical America. The fruit's color can be either white, black, or a combination of the two, and cocoplums are generally used for preserves.

Common names and synonyms: Cocoaplum, hicaco, icaco, icaco plum.

COCOYAM (*see also* **TARO**) – Often – and understandably – confused with taro and with malanga, from both of which it is practically indistinguishable, the cocoyam (*Colocasia esculenta*) is a variety of taro that is probably native to India but also possibly to parts of Southeast Asia. The problem is that the taxonomy of the cultivars of *Colocasia* remains a subject of investigation. These plants have clearly traveled, moving from India to Egypt some 2,000 years ago and from there to southern Europe. From Iberia, the cocoyam was carried to the Americas and then probably introduced into West Africa from the New World. It was successfully established in East Africa as well and moved eastward out of India to the Pacific. In these travels, the cocoyam picked up many names. Like taro and malanga, the cocoyam is also called "dasheen," "eddoe," and a dozen other names, including "taro." Moreover, in West Africa malanga is also called cocoyam. The plant was especially important in the West Indies for feeding slaves, and it continues to be a common part of the diet in many islands. Its young shoots and leaves serve as a cooked vegetable (callaloo), and the tubers are fried, roasted, or boiled. The leaves are a good source of vitamin A, calcium, and potassium; the corms brim with starch and, thus, energy.

Common names and synonyms: Abalong, arvi, Barbados eddoe, Chinese eddoe, curcas, dagmay, dalo, dasheen, eddo, eddoe, *keladi,* koko, kolkas, malangay, malangu, taioba, taro, *taro de chine, ya, ya bené, yu-tao.*

See in addition: "Taro," Part II, Section B, Chapter 6.

Cocozelle – *see* **ZUCCHINI**

COFFEE – Also called *kaffe, kahve,* and *kahwa,* coffee (*Coffea arabica*) is surrounded by myths and legends, especially those dealing with the discovery of the plant, which seems to have originated in both Yemen and southern Ethiopia (in the province of Caffa). One of the most pervasive legends has an Arab goatherd around A.D. 850 becoming curious about the lively behavior of his goats and subsequently discovering that the animals were nibbling the coffee berries of nearby evergreen trees. Apparently, the first human use of coffee was to emulate the goats by also chewing the "beans" to get a lift, but by around A.D. 1000 (or even earlier) coffee beans were being roasted and crushed to make a beverage. From this point to the cultivation of coffee trees was a short step, and the beans came to be monopolized by Arab merchants, who shipped them from the Yemeni port of Mocha. Coffee quickly became an important beverage for the Muslims, who were prohibited alcohol (although many fanatically condemned the new drink), and coffeehouses of a sort were established in cities and towns throughout the Islamic world. Constantinople (Istanbul) has been put forward as the location of the world's first real coffeehouse, established at about the end of the fifteenth century (the dates given vary from 1474 to 1554), and at about the same time coffeehouses were also opened in Medina, Mecca, Cairo, Damascus, and Baghdad – all of the capitals of the Islamic world. The new social centers were viewed with suspicion by various sultans worried about sedition, and coffeehouses were closed from time to time, but never for long. Coffee drinking had become an entrenched part of Arab life.

Europe soon had a similar experience. Venice, heavily involved in the spice trade, was exposed to coffee as early as the fifteenth century, and its first coffeehouse was established around the middle of the sixteenth century – about the same time that Vienna got its first one. Another century elapsed, however, before the new beverage moved northward and westward. Coffeehouses were opened at Oxford in 1650, at Marseilles in 1671, and at Paris the following year, but it was only in 1686 that the Café Procope, the first true café in Paris, opened its doors (it still exists although at a different location). It may be doubted that the first of the coffeehouses in England were inundated with patrons because – as late as 1657 in London – coffee was advertised as a medicine for ills such as gout and scurvy. But the coffeehouses clearly were doing a brisk business by 1675 when, like the Islamic sultans, King Charles II issued a proclamation to suppress them on the grounds that they were hotbeds of sedition. The proclamation, however, was rescinded the following year, and over time coffeehouses in England developed into gentlemen's clubs, whereas in France they continued to be cafés (albeit also clubs at times).

Both the British and the Dutch East India Companies bought coffee at Mocha for import into Europe, but as decades passed and overseas empires developed, the Arab monopoly on coffee became a major irritant. As the eighteenth century got under way, the Dutch began growing their own coffee in Java and later introduced it into Sri Lanka, whereas the English planted coffee in their West Indian colonies – especially Jamaica and Guiana. The Portuguese in Brazil were also in the coffee business (after the plant was introduced there from Guiana in 1727), and the French planted coffee, first in their colony of Martinique and a bit later in San Domingue – which, by the end of the eighteenth century (when the revolution began that would lead to the new nation of Haiti), was producing almost two-thirds of the world's supply. Later, coffee would also be a Cuban crop, and throughout the Americas coffee production became inextricably linked with slave labor, until abolition finally came to Brazil and Cuba in the last decades of the nineteenth century. Sugar was also cultivated with slave labor, and increasing sugar production, in turn, was inextricably linked with the soaring consumption of coffee – along with tea and chocolate – in Europe.

In 1774, in the soon-to-be United States, colonists were increasing their consumption of coffee as a protest against British taxes on tea, and this trend continued as a tea-drinking people were converted to coffee drinking. By 1850 or so, average per capita consumption exceeded 6 pounds annually. Americans were accustomed to buying their coffee beans green and doing their own roasting and grinding, but after the Civil War, Folger's Coffee (established in San Francisco) began to give people a choice. The Folger's brand was soon followed by Chase and Sanborn (which in 1878 became the first company to pack roasted coffee in sealed cans), Hills Brothers, and Maxwell House (named for a Nashville hotel). In 1901, the first "instant" coffee was invented in Chicago, and in 1964, General Foods introduced "Maxim" freeze-dried instant coffee.

Coffee is ground in different ways for different purposes: "Coarse" and "medium" for use in percolators, urns, and the like; "drip" (which is finer than medium) for use in electric drip coffee makers; and "fine" for cone filters and drip pots. There is also the very fine espresso, for espresso machines, and the even more finely ground Turkish, for use in Turkish brewers. Almost 90 percent of the world's coffee is *C. arabica,* but another species, *C. canephora* = *C. robusta* and generally known as *Robusta,* is cultivated in Africa and India and – because it is cheaper and contains substantially more caffeine – is often a component of supermarket blends. Brazil produces about half of the world's coffee and has been the major U.S. supplier since the early days of the republic. Jamaican Blue Mountain, Hawaiian Kona, Java, and Mocha coffees are relatively rare and highly prized, followed by the Andean-grown Colombian coffee (the top grade is *supremo*).

Common names and synonyms: Colombian coffee, espresso, Hawaiian Kona, Jamaican Blue Mountain, Java, joe, *kaffe, kahve, kahwa,* Mocha, *Robusta, supremo* coffee, Turkish coffee.

See also: "Coffee," Part III, Chapter 4.

Coffee weed – *see* **SESBAN**

COHUNE PALM – A native of Central America and Mexico, the cohune nut palm (*Orbignya cohune* and *Attalea cohune*) produces nuts that yield an oil that can substitute for coconut oil. In addition, the tree's young leaf buds are cooked and eaten as a vegetable.

Coimi – *see* **AMARANTH**

Coines – *see* **QUINCE**

Coing – *see* **QUINCE**

Coinworth – *see* **PENNYWORT**

Cokernut – *see* **COCONUT**

Cola nut – *see* **KOLA NUT**

Cole cabbage – *see* **CABBAGE**

Colewort – *see* **CABBAGE**

Colicroot – *see* **WILD YAM**

Colirrambano – *see* **KOHLRABI**

COLLARDS (*see also* **CABBAGE, KALE**) – Called *couve* in Brazil and often regarded as a form of kale (which they are, differing mostly in the smoothness of their leaves), collards (*Brassica oleracea* var. *acephala*) constitute one of the oldest members of the cabbage family and probably originated in the Mediterranean region. However, collard greens subsequently spread over much of the tropical and subtropical world and are cultivated today in Southeast Asia (including southern China), East and West Africa, the West Indies, South America, and the southern United States. Collards probably reached the Americas from Africa via the slave trade and are mostly consumed in those regions that formerly harbored slave societies. The flavor of the vegetable is milder than that of kale, and the large, dark green leaves, which are a component of southern "soul food," are traditionally boiled with pork or fatback. Collards supply folic acid and vitamin A and are a rich source of calcium, potassium, and iron. In addition, as a cruciferous vegetable, collards are said to act as a preventive against certain cancers.

Common names and synonyms: Borecole, collard greens, *couve,* kale.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Colocynth – *see* **EGUSI**

Colombian coffee – *see* **COFFEE**

COLTSFOOT – The wide leaves of this plant (*Tussilago farfara*) resemble horses' hooves, hence the name "coltsfoot," along with a variety of similar names such as "assfoot," "foalfoot," "horsefoot," "sowfoot," and just plain "hoofs." Coltsfoot is a European plant with roots that have been used medicinally since the days of the ancient Greeks. The plant is now naturalized in eastern North America. When young, the leaves can be eaten raw, whereas older ones are cooked as greens, and ashes from the leaves have been used as a salt substitute. The plant also has a yellow flower head that opens only in sunny weather, and this, along with its stalk, is also edible when raw. Coltsfoot is grown and widely used in Japan, where the celery-like flavor of its green stalks is especially appreciated.

Common names and synonyms: Assfoot, bog rhubarb, bullsfoot, coughwort, foalfoot, hoofs, horsefoot, sowfoot.

Colza – *see* **RAPE**

COMFREY – A somewhat hairy herb that is native to Eurasia, comfrey (*Symphytum officinale,* among some 25 other comfrey species) has long been employed by humans, but more for healing than for sustenance. Its roots and leaves were used historically to treat wounds, and in fact, the name comes from ancient Greek and means to grow together – which in this case refers to the edges of wounds and broken bones (accounting for one of the plant's old names, "knit-bones"). But comfrey is also edible. It is frequently used to make a tisane, can be added to salads, and is cooked like spinach as a vegetable.

Common names and synonyms: Knit-bones.

Comice – *see* **PEAR**

Comino – *see* **CUMIN**

Commas – *see* **CAMAS**

Common red ribes – *see* **CURRANT(S)**

COMMON REED – A plant widespread throughout the world, the common reed (*Phragmites communis* or *P. australis*) has rhizomes and roots that in Russia are harvested for their starch content. Native Americans also procured starch from the rootstock of the common reed and ate its young shoots. The stems – rich in sugar – have been ground into a sweet powder for use in baking. They also exude a gumlike substance that was highly regarded as a sweet by Native Americans.

Compass plant – *see* **SILPHIUM**

Concombre des Antilles – *see* **GHERKIN**

CONCORD GRAPE (*see also* **GRAPES**) – A variety of the fox grape, the North American Concord grape (*Vitis labrusca*) lacks sugar, which limits its use in wine making. But these grapes are much used for the production of grape juice and jellies. They come from a wild grape named after Concord, Massachusetts, by Ephraim Bull, who planted the vines there in 1843.

CONEFLOWER – Several plants are called coneflower. Those that are subsumed under the genus *Echinacea* are tall weeds with purple blossoms and grow throughout the prairie region of the United States. They have edible roots, leaves, and seeds that were used mostly for medicinal purposes by Native Americans. Another coneflower, *Ratibida columnifera,* is also a prairie plant, bearing leaves that Native Americans made into a tea. A final coneflower is *Rudbeckia laciniata,* of eastern North America, with leaves that were cooked as a vegetable.

Congo goober – *see* **BAMBARA GROUNDNUT**

Congo pea – *see* **PIGEON PEA**

Cook's-truffle – *see* **TRUFFLE(S)**

COOLWORT – An American plant also called false miterwort, toothwort, and foam flower, coolwort (*Tiarella cordifolia*) is a white-flowered herb of the woodlands and was reportedly used by Native Americans as a spice. The true miterwort (genus *Mitella*) is also called fairywort.

Common names and synonyms: Fairywort, false miterwort, foam flower, miterwort, toothwort.

Coontie – *see* **ZAMIA**

Coptis – *see* **GOLDTHREAD**

CORAL BEAN – Cultivated in Central America and Mexico, the coral bean trees – *Erythrina berteroana* (called *pito*) and *E. rubinervia* (called *gallito*) – all have young shoots, leaves, and buds that have long been consumed in salads, stews, and various other dishes. Another species, *E. fusca,* is used in like fashion in India and the East Indies, whereas still another relative, *E. poeppigiana* (called *poro*), which serves as a shade tree for coffee bushes in Central and South America and the West Indies, has flowers that are used in salads and soups. The pretty (but poisonous) seeds of *pito* and *gallito* are used medicinally, as a toxin for rats and fish, and as beads that are strung together to make necklaces, bracelets, and the like.

Common names and synonyms: Gallito, macrette, pito, poro.

Corazon – *see* **CUSTARD APPLE**

CORDIA – A flowering shrub or small tree of Asia and Australia, cordia (*Cordia myxa*) belongs to a large genus of mostly tropical plants that bear fleshy, often edible fruits. In the case of cordia, it produces yellowish, nutlike fruits that helped to sustain aboriginal populations.

CORIANDER (*see also* **CILANTRO**) – Also known as cilantro, culantro, and Chinese parsley, coriander (*Coriandrum sativum*) is an herb that is cultivated for its aromatic seeds and leaves. It is a member of the parsley family and closely related to caraway. Coriander is apparently a native of the Mediterranean region, and its dried seeds have been in use for some 7,000 years. They have been found in the tombs of ancient Egypt and were widely used by the Hebrews, Greeks, and Romans (who flavored their bread with coriander) of antiquity. The seeds contain an aromatic oil and are used to flavor liquors (such as gin), to season soups and pastries, and to spice up marinades in Scandinavia and Greece. Dried coriander seeds are generally more appreciated in northern than in southern Europe, and coriander is vital to the cuisine of India because of its crucial role as an ingredient in curry powder.

Common names and synonyms: Chinese parsley, cilantro, culantro, *yuen sai.*

See in addition: "Spices and Flavorings," Part II, Section F, Chapter 1.

Corkwood tree – *see* **SESBAN**

Corn – *see* **MAIZE**

Cornel – *see* **CORNUS**

Cornelian cherry – *see* **CORNUS**

CORNFLOWER – A garden plant native to Eurasia, the cornflower (*Centaurea cyanus*) – like cornsalad – is so called because it is found in fields of corn. It is also known as "bachelor's-button" and "bluebottle" because of its bold blue blossoms. These flowers were used in the past by pastry chefs to provide a blue color for creamy desserts.

Common names and synonyms: Bachelor's-button, bluebottle.

CORN MINT – Found in temperate regions, this herb (*Mentha arvensis*) is cultivated commercially in China, Japan, and Brazil. The leaves yield an oil that is 60 percent menthol and is used to flavor pharmaceuticals, toothpaste, food products, cigarettes, and alcoholic beverages. The leaves can also be boiled and eaten or used as a condiment.

Common names and synonyms: Field mint, Japanese mint.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

CORNSALAD – "Cornsalad," so named because these plants with small, bluish flowers grow in cornfields, actually refers to any of several plants of the genus *Valerianella,* especially *V. olitoria* and *V. locusta.* Also called "lamb's-lettuce," "field salad," "fat-hen," "lamb's-quarter," "marsh salad," "hog salad," and a variety of other names, these European natives – found throughout North America as well – provide slightly bitter-tasting leaves that are much appreciated in salads. The various types of cornsalad were considered weeds until the seventeenth century, when they began to be cultivated, and cultivation doubtless accounts for the different varieties now identified.

Common names and synonyms: European cornsalad, fat-hen, field salad, hog salad, lamb's-lettuce, lamb's-quarter, mache, *mâche,* marsh salad.

CORNUS – The genus *Cornus,* native to Europe, eastern Asia, and North America, includes a number of shrubs and trees that bear what is actually not a berry but a drupe. Among those in North America is *C. florida,* often called the "flowering dogwood," which is native to the eastern United States. This has edible fruits that (like the leaves) become scarlet-colored in the autumn. The "bunchberry" (*C. canadensis*) is a close relative, and Native Americans used this fruit for both food and medicine. The cornelian cherry (*C. mas*) is a European species, the fruit of which is eaten fresh and made into preserves and wine (*vin de corneulle*); at one time, it was widely cultivated.

Common names and synonyms: Bunchberry, cornel, cornelian cherry, dogberry, dog cherry, dogwood berry, dogwood cherry, dogwood tree, flowering dogwood, Siberian cherry, Tartar cherry.

Corsican citron – *see* **CITRON**

Cos – *see* **LETTUCE**

Coscushaw – *see* **CUSHAW (SQUASH)**

Costa Rican guava – *see* **WILD GUAVA**

Costeño – *see* **GUAJILLO AND PULLA CHILLIES**

COSTMARY – A plant that is native to Asia, was a popular herb in ancient Greece, and has seen both past and present use in England, costmary (*Chrysanthemum balsamita*) – with its leaves' hint of lemon and mint flavorings – is employed to season poultry as well as stuffings, soups, salads, and sauces. It was naturalized, and now grows wild, in North America, where it is known as "Bible leaf" because its long, narrow leaves were used in former times as page markers in Bibles. Costmary has also been known in the past as "alecost" because it was used in the production of home-brewed ale.

Common names and synonyms: Alecost, balsam herb, Bible leaf, Bible-leaf mace, mace, mint geranium.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

COTTONSEED OIL – In 1887, Wesson Oil began as the Southern Cotton Oil Company in Philadelphia. The firm had cottonseed-crushing mills throughout the southern United States and quickly became the largest producer of cottonseed oil as well as the first U.S. manufacturer of vegetable shortening. Cottonseed oil (from cotton – genus *Gossypium*) was employed as an inexpensive substitute for olive oil in cooking and in salads prior to the advent of other oils, such as that from soybeans. Cottonseed oil has found continued use in the food-packing industry, as, for example, in the packing of sardines.

See also: "An Overview of Oils and Fats," Part II, Section E, Chapter 1.

Couch-couch – *see* **CUSH-CUSH YAM**

COUCH GRASS – Also known as "wheat grass" and a host of other names including "quack grass," couch grass (*Agropyron repens = Elytrigia repens*) is a Eurasian grass now naturalized in North America. It is generally used for grazing and hay production, but in medieval Europe the tender tips of its rhizomes were gathered in the spring to be eaten raw as a vegetable and the whole rhizome later dried to make a flour. Today, in England, the rhizomes are still gathered and dried (and sometimes exported to France and Italy) for making a tea and, when roasted, are used in Central Europe as a coffee substitute.

Common names and synonyms: Dogtooth, quack grass, quick grass, scutch, twitch grass, wheat grass.

Coughwort – *see* **COLTSFOOT**

Country almond – *see* **MALABAR ALMOND**

Courge – *see* **SQUASH AND PUMPKIN**

Courgette – *see* **SQUASH AND PUMPKIN, ZUCCHINI**

Cousee-cousee – *see* **CUSH-CUSH YAM**

COUVE (*see also* **CABBAGE, COLLARDS**) – Couve is a tall, dark green Portuguese cabbage that (like the 400-odd other cabbage varieties) is a member of the species *Brassica oleracea.* Couve has a taste that is something of a cross between turnip greens and kale, and it is the primary ingredient in *caldo verde,* the well-known soup of Portugal. Many Portuguese grow the cabbage in their yards; in Minho, it is often grown under trellised grape vines.

See in addition: Collards and "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Cowberry – *see* **LINGONBERRY**

Cow bitter(s) – *see* **TANSY**

COW PARSNIP – With a taste somewhat like that of asparagus, the leaves and stems of the European cow parsnip (*Heracleum sphondylium*), found in temperate areas of Europe and Asia, are cooked and consumed as a green vegetable, and its roots have been used as a condiment. In Lithuania and Poland, a home-brewed beer is made from the stems and seeds, and elsewhere in eastern Europe the cow parsnip was also employed to make borscht. The American cow parsnip (*H. lanatum*) has a much stronger taste and served Native Americans as a food. The roots were cooked, and the shoots and leaves were eaten both cooked and raw.

Common names and synonyms: American cow parsnip, European cow parsnip, Meadow parsnip.

COWPEA (*see also* **BEANS, LEGUMES**) – Also called "long bean," "asparagus bean," and "yard long bean" because of the length of its pods, the cowpea (*Vigna unguiculata* or *V. sesquipedalis* or *V. sinensis*) is, in fact, a bean. It has been cultivated since prehistoric times in tropical Asia (especially India) and is a relative of the mung bean and other Asian legumes, suggesting a South Asian origin for the plant. However, China has been proposed as another center of origin, and because the plant occurs in the wild in many parts of Africa, that continent may have been yet another cradle of the cowpea. It reached the New World via the slave trade and today is cultivated throughout the tropical and subtropical world.

The cowpea comes in a number of varieties. Black-eyed peas are perhaps the best known of these in the United States, where they are available fresh, dried, canned, and frozen. Crowder peas and field peas are other favorites, especially in the U.S. South. Prior to the Civil War, cowpeas were sometimes given to slaves but were used mostly for animal fodder. Today, they are one of the major constituents of "soul food."

Common names and synonyms: Asparagus bean, black-eyed bean, black-eyed pea, China bean, Crowder pea, field pea, long bean, red pea, southern pea, yard-long bean.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

COWSLIP – Two plants are known by this name. The first is a European wildflower (*Primula veris*). Its sweet-smelling flowers are added to salads or used to make wine, vinegar, mead, and tea. The flower may also be candied. In the United States, however, "cowslip" refers to the marsh marigold, whose Latin name is *Caltha palustris.* This plant is found in the temperate regions of North America, Asia, and Europe. A hardy perennial herb, the entire plant is eaten as a vegetable. The leaves may also be used as a potherb, and the pickled flower buds can be substituted for capers.

Common names and synonyms: Kingcup, marsh marigold, may-bob, meadow-bright.

Cowtree – *see* **MIMUSOPS**

Cow vetch – *see* **TUFTED VETCH**

Coyo – *see* **AMARANTH**

Coyote melon – *see* **SQUASH AND PUMPKIN**

CRAB APPLE (*see also* **APPLE**) – There are several species of wild fruit trees of the genus *Malus* (especially *M. coronaria*) that produce small, brightly colored crab apples. The crab apple is the ancestor of cultivated apples and has been used as a food since prehistory, although the harsh, acidic taste of these fruits doubtless precluded eating them raw. Crab apples make excellent jellies and preserves.

Common names and synonyms: Sweet crabapple, wild apple.

Cramp bark – *see* **BERRIES, HIGHBUSH CRANBERRY**

CRANBERRY (*see also* **BERRIES, HIGHBUSH CRANBERRY, LINGONBERRY**) – Of the same genus as the blueberry, the cranberry (*Vaccinium macrocarpon*) is a North American shrub that is so named because its flower stamens resemble a beak – hence "crane berry," a name (which subsequently became "cranberry") assigned to it by the early European settlers in New England. The berries, which grew wild in New England, had long been used by Native Americans for pemmican (dried meats pounded into a paste and mixed with berries and fat). The early European settlers found cranberries too tart to eat by themselves but made them into pies, puddings, tarts, relishes, preserves, and cranberry sauce. Perhaps appropriately, it was in Massachusetts that commercial cranberry production was begun in the 1840s, and that state still supplies about half of the U.S. crop.

Cranberries are planted in sandy bogs that are irrigated, and harvesting entails loosening the berries so that they fall into the water, then sweeping the floating berries into processing machinery. Before being crushed, however, cranberries (also known as "bounce berries") are "bounced" to determine ripeness, meaning that they must clear a hurdle or are discarded.

Another, smaller cranberry (*V. oxycoccos*) is also native to North America as well as to northern Europe and Asia. It is seldom cultivated commercially, but the wild berries are picked for home consumption. The so-called lowbush cranberries are actually lingonberries. In addition, "highbush cranberries" are erroneously called cranberries. North American commercial cranberries have been introduced in the Scandinavian countries and Great Britain. Almost all of the commercial crop is made into juice or canned cranberry sauce. Cranberry juice is a recent (since 1959) development, representing a successful effort to diversify an industry that once did most of its business around the holidays, producing the indispensable accompaniment to turkey. Cranberries are very high in vitamin C and in the past have proven an effective cure for scurvy.

Common names and synonyms: Airelle de myrtille, American cranberry, bounce berry, crane berry, fen berry, large cranberry, small cranberry.

Cranberry bush – *see* **HIGHBUSH CRANBERRY**

Crane berry – *see* **CRANBERRY**

Crapaudback – *see* **CALABAZA (SQUASH)**
Cream nut – *see* **BRAZIL NUT**
Creeping myrtle – *see* **PERIWINKLE**
Creole mustard – *see* **HORSERADISH**

CREOSOTE BUSH – Also called the "little stinker" because of the resinous odor it gives off, the creosote bush (*Larrea tridentata = L. mexicana*) is a native of the desert Southwest of the United States and Mexico. It was used by Native Americans for medicinal purposes and as a wood for smoking foods. In addition, its flower buds have been consumed.

Common names and synonyms: Little stinker.

CRESS – "Cress" is a name applied to a number of greens belonging to the mustard family, especially garden cress (*Lepidium sativum*). The British are especially fond of cresses, which are grown in enormous quantities in market gardens around London. Young sprouts of garden cress are often mixed with mustard greens in salads. Another name for cress is "pepper-grass."

Common names and synonyms: Garden cress, pepper-grass.

See also: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Crinkleroot – *see* **TOOTHWORT**
Crosne – *see* **CHINESE ARTICHOKE**
Cross-leaf heath – *see* **BOG HEATHER**
Crowberry – *see* **BEARBERRY**
Crowder pea – *see* **COWPEA**
Crown daisy – *see* **CHRYSANTHEMUM**
Cuachilote – *see* **CUAJILOTE**

CUAJILOTE – A tree native to Mexico and Central America, the cuajilote (*Parmentiera edulis = P. aculeata*) produces pointed, yellowish green fruits. They have a sweet taste and are eaten raw, cooked, and preserved (often as pickles).

Common names and synonyms: Cuachilote, guajilote.

Cubanelle pepper – *see* **SWEET PEPPERS**
Cuban spinach – *see* **PURSLANE**
Cuban squash – *see* **CALABAZA (SQUASH)**
Cuban sweet potato – *see* **BONIATO**
Cubeb – *see* **TAILED PEPPER**
Cuckoo flower – *see* **LADY'S SMOCK**

CUCUMBER (*see also* **GHERKIN, INDIAN CUCUMBER, SQUASH AND PUMPKIN**) – A native of southwestern Asia, the cucumber (*Cucumis sativus*) is a member of the squash family and has been cultivated since prehistoric times for its fruit. It is related to melons and, like melons, has a high water content, which means that it is always cool. The ancient Egyptians enjoyed cucumbers (and reputedly fed them to their Hebrew slaves), as did the Greeks and the Romans. The latter probably spread the cucumber about their empire (as was the case with so many foods), although at least one source states that the cucumber first reached France as late as the ninth century, and England only in the fourteenth century.

We know that the vegetable came to the Americas with the Spaniards, but a problem with keeping track of cucumbers historically is that there are so many related species. They range, for example, from the West Indian gherkin (*C. anguria*), a tropical American vine originally from Africa that reached the West Indies via the slave trade, to the snake or serpent cucumber (*C. melo* var. *flexuosus*), which is botanically a melon, to the African horned cucumber (*C. metuliferus*). Cucumbers are divided into three groups: the standard field-grown slicing cucumber, the new hothouse varieties (some of which are seedless), and the smaller pickling kinds.

The West Indian gherkin is perhaps the most widely used for this latter purpose, although, of course, all lend themselves well to pickling and to the relishes that are so prominent in Indian cookery. Cucumbers suffered a decline in popularity in Europe from the Middle Ages to the eighteenth century, as they fell under medical suspicion of being hard on the digestive system. They are low in calories but contain little in the way of important nutrients. Cucumbers can be baked, boiled, steamed, and braised as well as added to salads, and because of their high water content, they can also be used to make warm teas and cool drinks.

Common names and synonyms: American gherkin, cassabanana, cuke, gherkin, hothouse cucumber, lemon cucumber, Mandera cucumber, pickling cucumber, serpent cucumber, slicing cucumber, snake cucumber, West Indian gherkin.

See in addition: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

Cucumber tree – *see* **BELIMBING**
Cucurutz – *see* **MAIZE**

CUDDAPAH ALMOND – Also called the "chirauli nut," the cuddapah almond (*Buchanania latifolia*) is a tree that provides food for the peoples of South and Southeast Asia and has also helped to feed the Aborigines of Australia. Moreover, the seeds, which are eaten, yield an edible oil used in cooking.

Common names and synonyms: Chirauli nut.

Cudrang – *see* **CHE**
Cuime – *see* **AMARANTH**
Cuke – *see* **CUCUMBER**
Culantro – *see* **CILANTRO, CORIANDER**

CUMIN – Known as *comino* in Spanish, cumin (*Cuminum cyminum*) seems to be a Mediterranean plant – as are most other members of the carrot family – although some think it originated in Asia, and it apparently has been cultivated in India, Egypt, and the Mediterranean region since time immemorial. Certainly cumin was prescribed in early Hindu medicine for a variety of ailments; it was also a popular spice in ancient Rome and is mentioned in both the Old and New Testaments of the Bible. Cumin seeds are aromatic and yield an oil used in the perfume industry. Whole or ground, they season many Mexican dishes and are a vital ingredient in *chile* powders. Similarly, cumin is also crucial to curry powder and many dishes of India. In addition, North African recipes call for cumin in marinades, couscous, and lamb dishes. Finally, cumin is used in baking – especially in rye breads.

Common names and synonyms: Comino, cummin, *jintan.*

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Cummin – *see* **CUMIN**

Cumquat – *see* **KUMQUAT**

Cup plant – *see* **SILPHIUM**

CUPUASSU – A relative of cacao, *cupuassu* (*Theobroma grandiflorum*) is a fruit of the Amazon Basin that is generally available in local markets. It is used for making sweetened juice and frozen desserts.

Curcas – *see* **COCOYAM**

Curcas oil – *see* **PHYSIC NUT**

Curcuma – *see* **TURMERIC**

CURLED DOCK – A European plant that has become naturalized as a weed in North America, curled dock (*Rumex crispus*) has long provided food for gatherers. Its leaves and seeds are edible, as is its large and fleshy root, which is dug up in the fall and dried.

Common names and synonyms: Curly dock, narrow dock, sour dock, yellow dock.

CURRANT(S) (*see also* **BERRIES, BLACK CURRANT**) – There are three kinds of European currants that come in the colors red, white, and black. These berries of the genus *Ribes* were cultivated in northern Europe prior to the seventeenth century and subsequently brought to North America. In addition, there is a native North American red currant – *Ribes sanguineum.* The European red currant (*R. rubrum*), a small, tart, red- or scarlet-colored berry, is much used in northern Europe for making juice, jellies, cakes and other desserts, compotes, and mixed drinks. The black currant (*R. nigrum*), which is of greater commercial importance, is the basis for jelly, juice, sweet must, and the liquor crème de cassis, as well as a clear, biting alcoholic beverage that is much like schnapps. White currants (*R. sativum*) are made into a white wine but are generally less used than red or black currants, which are very rich in vitamins A and C. Currants were extremely important in the diet of Native Americans, who cooked them, ate them raw, and made them into pemmican. In recent years, currants have been utilized less in the United States.

Common names and synonyms: Aka-suguri, black currant, common red ribes, European black currant, European red currant, garden currant, North American red currant, northern red currant, red currant, white currant.

Currant bush – *see* **BUSH CURRANT**

Curri – *see* **HAZELNUT AND FILBERT**

CURRY LEAF – The small, shiny, pungent leaves of this Asiatic shrub (*Murraya koenigii*) are used for flavoring. The curry leaf tree is best associated with Sri Lankan cuisine, but it grows in most tropical Southeast Asian countries. The leaves are employed fresh, dried, and powdered.

CUSHAW (SQUASH) (*see also* **SQUASH AND PUMPKIN**) – The designation of various squashes as cushaws has led to some semantic confusion. "Cushaw" is sometimes intended to be synonymous with "calabaza" squash. But one of the crooknecks of *Cucurbita moschata* that is widely grown in the United States received its name from the Algonquian *coscushaw.* In general, however, the cushaw squashes are understood to be of the species *C. mixta,* which grows in an area ranging from Costa Rica north to the southern United States. This "mixed" squash type was originally included in *C. moschata* but later came to be regarded as a separate species.

Common names and synonyms: Cashaw, *coscushaw,* crookneck.

See in addition: "Squash," Part II, Section C, Chapter 8.

CUSH-CUSH YAM (*see also* **YAMS**) – A native of northern South America and the Caribbean, the cush-cush yam (*Dioscorea trifida*) was an important food for resident Native Americans and is still widely cultivated in this region today; it is also now cultivated to a limited extent in the tropics of Asia and West Africa. The cush-cush is a climbing vine that produces subterranean, yellow-skinned tubers. These yams are small but have an excellent flavor and are frequently baked or boiled. The vegetable is called a *ñame* (e.g., *ñame vino, ñame de la India*) as well as *mapuey* in the Spanish-speaking Caribbean, whereas English speakers name it "couch-couch."

Common names and synonyms: Couch-couch, couche-couche, cousee-cousee, *ñame, ñame mapuey,* yampi.

See in addition: "Sweet Potatoes and Yams," Part II, Section B, Chapter 5.

CUSTARD APPLE (*see also* **CHERIMOYA, PAPAW, SWEETSOP, WHITE SAPOTE, WILD CUSTARD APPLE**) – The term "custard apple" is a nickname for the cherimoya but also refers to its close relative, the fruit known around the world as custard apple (*Annona reticulata*). Also called "bullock's-heart," it is a native of the American tropics, grows on a small tree with yellow flowers, is almost round and up to 4 or 5 inches in diameter, and has a tough skin, which protects a creamy white flesh of thick custard-like consistency. Its flavor is not especially appreciated by many (some find it insipidly sweet), but it is nonetheless widely cultivated in the West Indies, tropical Africa, and Southeast Asia. The custard apple, although generally eaten raw, is also used as a flavoring for milk shakes and the like.

Common names and synonyms: Anona, bullock's-heart, *corazon,* nona, pawpaw, sugar apple.

Custard marrow – *see* **CHAYOTE**
Cut-eye bean – *see* **JACKBEAN**
Cycad – *see* **ZAMIA**
Cydonian apple – *see* **QUINCE**
Cymling – *see* **SQUASH AND PUMPKIN**

D

Dagmay – *see* **COCOYAM**

DAHOON HOLLY – A native of southeastern North America, dahoon holly (*Ilex cassine*) has leaves that – like those of its close relatives, yaupon holly and yerba maté – contain a substantial amount of caffeine. Native Americans used them to brew an emetic tea, which was consumed in purification rituals.

Common names and synonyms: Cassine, dahoon.

DAIKON – A native of Asia and also called the "Oriental radish," the daikon (*Raphanus sativus* spp.) bears little resemblance to round, red-skinned radishes. It is a very long root that averages about a foot in length (although in Japan there are more oblate varieties) and is white in color. Daikon is the Japanese name for this type of radish, which is called *mooli* in India and the West Indies. The daikon is an ancient vegetable that is grown throughout Asia but is probably most appreciated in Japan, China, and Korea. It has a pungent flavor, which the Koreans utilize in a type of *kimchee.* In Japan, daikon is often grated and used as a condiment in numerous dishes including sushi, and in China it is worked into a pudding and served raw at dim sum restaurants.

Two relatives (also *R. sativus*) of the daikon are of interest as well. One is the red-fleshed radish called *sing li mei,* which means "the heart is beautiful." These are eaten as a snack food and add color to salads. Another is the "green Oriental radish," which can grow to a size approaching that of its giant cousin and which is generally used in soups and dishes that are simmered. In addition, spicy sprouts, called *kaiware,* can be grown from daikon seeds. *Kaiware* are most commonly used in salads or for garnish.

Common names and synonyms: Chinese radish, giant white radish, green Oriental radish, Japanese radish, Japanese white radish, *kaiware, mooli,* Oriental radish, red-fleshed radish, *sing li mei, tsumamina.*

See also: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Dalima – *see* **POMEGRANATE**

Dalo – *see* **COCOYAM**

DAMIANA – The dried leaf of damiana (*Turnera diffusa = T. aphrodisiaca*) was consumed in the past for its alleged aphrodisiacal properties and as a tonic. It is a plant found in the American tropics and in Texas and California.

DAMSON PLUM (*see also* **PLUM**) – The Damson plum (*Prunus insititia*) is the classic small, dark blue plum that ripens in August and has been virtually unaltered for thousands of years. It is named for the city of Damascus, from which the fruit traveled to reach Italy and then spread out across the rest of Europe, where it grows today both in the wild and in home orchards. The Damson plum is notable for its ability to resist disease and cold and to thrive with little or no care. It is tart and used mostly in preserves and in the production of liqueurs such as slivovitz.

Common names and synonyms: Bullace plum, tart Damson plum.

Dancy tangerine – *see* **MANDARIN ORANGE**

DANDELION – Although regarded as a nuisance by many whose lawns become infested with these "weeds," dandelions (*Taraxacum officinale*) have served as a versatile wild food in the Old World since the days of the hunter-gatherers. This bright spring flower was reported in seventeenth-century Massachussetts, and dandelions had entrenched themselves in Australia by the mid-nineteenth century. Today the plants are cultivated commercially – by the French and the Italians in particular – for their bitter, chicory-like flavor. Dandelion leaves are eaten raw in salads or cooked as greens, whereas the roots are also edible and can be boiled or ground and used as a coffee substitute. The white crowns are cooked as a vegetable, the flower buds are frequently pickled, and the flower heads have been used to make wine. The leaves are very high in vitamin A and, like most other greens, provide an abundance of calcium and iron, some thiamine and riboflavin, and, if not cooked too thoroughly, vitamin C as well.

Darjeeling – *see* **TEA**

Darnel – *see* **RYEGRASS**

Dasheen – *see* **CALLALOO, COCOYAM, MALANGA, TARO**

DATE – Arabs say that there are as many culinary and pharmaceutical ways of using dates (*Phoenix dactylifera*) as there are days in the year, which serves to underscore the importance of dates to desert peoples. The date tree grows in hot and arid regions where most plants cannot, and at its top are clusters of dates packing a high-energy-giving sugar content of 54 percent. The date palm is thought to be native to North Africa and Arabia – three-quarters of the world's date crop is still produced in the Middle East – and its cultivation stretches back in time some 7,000 years, beyond even the time of the Sumerians and Babylonians, who made it their sacred tree. The name is from the Greek *daktulos* (meaning "finger," from the shape of the fruit). Dates were also known to Mediterranean peoples from early times, and the Spaniards introduced them into the New World. Spanish missionaries carried dates to California, which today – along with Arizona – produces most of the U.S. crop.

There are soft, semisoft, and dry dates, depending on moisture content. The semisoft Deglet Noor variety dominates U.S. production. Elsewhere the semisoft Zahidi and Medjool are popular, along with the Bahri, a soft date. Dates are eaten fresh, naturally preserved, or dried, and they are ground into meal to make cakes. In addition, dates are pressed for juice to make *shekar* and alcoholic beverages. They are an ingredient in many dishes of the Middle East and wherever else they have been cultivated for a long time. Most dates available outside of their growing areas are soft, partly dried ones. The sap of the date palm is also employed as a beverage. Aside from the Middle East and the United States, dates are grown in India, Pakistan, northern Africa, and the Canary Islands. Dates are high in calories but supply much potassium and a fair amount of vitamin B_6, niacin, iron, and magnesium.

Common names and synonyms: Bahri date, date palm, Deglet Noor date, dry date, Medjool date, red date, semisoft date, soft date, Zahidi date.

Date palm – *see* **DATE**

Date plum – *see* **PERSIMMON**

Datura – *see* **MOONFLOWER**

DAYLILY – Any of the plants of the genus *Hemerocallis* are called daylilies. These natives of Eurasia reached North America as garden plants but subsequently "went native" there as well. In China, the buds of *H. fulva* in particular are cooked in slow-simmering dishes. But any daylily buds are good boiled or stir-fried as a vegetable. Plants of the genus *Hosta* – called plantain lilies – are also referred to as "daylilies" but do not appear to be consumed as a food.

Common names and synonyms: Plantain lily.

DE AGUA (*see also* **CHILLI PEPPERS**) – A chilli pepper of the genus *Capsicum,* this medium-hot variety looks a lot like a larger but more slender version of the jalapeño. It is much used in parts of Mexico for stuffing and in salsas, but is seldom found north of the border.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

De árbol – *see* **CAYENNE PEPPER**

Deer's-ears – *see* **GENTIAN**

Deertongue – *see* **CAROLINA VANILLA**

Deglet Noor date – *see* **DATE**

Delica – *see* **KABOCHA (SQUASH)**

DELICATA (SQUASH) (*see also* **SQUASH AND PUMPKIN**) – A small squash, generally about 7 or 8 inches long with a diameter of 2 to 3 inches, the delicata (*Cucurbita pepo*) has a taste and smell of, alternatively, butternut squash, corn, or sweet potato – the latter the reason for another of its names, "sweet-potato squash." Of American parents, this is a delicious squash, "human-made" by squash breeding. It is a great source of vitamins A and C along with iron and potassium.

Common names and synonyms: Bohemian squash, Jack-Be-Little, Munchkin, sweet-potato squash.

See in addition: "Squash," Part II, Section C, Chapter 8.

Demon walnut – *see* **WALNUT**

Dent maize – *see* **MAIZE**

DESERT APPLE – Also known as "Indian jujube" and "ber" as well as "desert apple," the small thorny tree this fruit grows on (*Ziziphus mauritiana*) may be of either African or Indian origin. The fruits, which smell like carob, are round or oblong, about the size of plums, and have a taste that is sweet to slightly acidic and suggests that of an apple. They are eaten raw, preserved, or dried. The desert apple is cultivated as a desert crop in India but has spread throughout tropical Southeast Asia as well. It does best, however, where the climate is not continually moist. The name "jujube" comes from the French for a lozenge, which the fruit was supposedly reminiscent of.

Common names and synonyms: Ber, Indian jujube.

Desert blazing star – *see* **MOONFLOWER**

Desert holly – *see* **SALTBUSH**

Desert jointfir – *see* **MORMON TEA**

Devilwood – *see* **OSMANTHUS**

DEWBERRY (*see also* **BERRIES, BLACKBERRY**) – Blackberries grow upright, whereas the several forms of the dewberry (such as *Rubus hispidus* and *R. caesius*) trail on the ground. Otherwise, dewberries (although sometimes a little smaller) are practically identical to blackberries, are used for the same purposes, and are rich in vitamin C.

Diamante citron – *see* **CITRON**

Dihé – *see* **TECUITLATL**

Dijon mustard(s) – *see* **MUSTARD SEED**

DILL – This herb (*Anethum graveolens*), a member of the parsley family and more aromatic than fennel (a relative), has been pronounced native to central Asia and to southeastern Europe. The name, however, comes from the Norse word *dilla,* meaning "lull," apparently because the seeds were believed to be good for insomnia. Confusion over the plant's origin is probably inevitable because it grows wild in most temperate regions. The ancient Greeks used dill as a remedy for hiccups as well as for culinary purposes, and it has been a part of Mediterranean cuisines ever since. The Romans credited the plant with fortifying qualities and made certain that gladiators were well fortified with it. As their empire receded, dill remained behind to become seminaturalized in much of northern Europe, although it has to be cultivated in the Scandinavian countries. Today, both dill seed and dill weed are used as seasonings. The aromatic seed heads flavor pickles (their best-known use for most Americans is in dill pickles), sauces, and other foods such as fish, cheeses, and yoghurt. The feathery green leaves (dill weed) have a wonderful aroma when fresh and taste milder than the seeds. The fresh leaves go well in potato and tuna salads. Dried, the leaves lose all their aroma and most of their taste.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Dilly – *see* **SAPODILLA**

DITTANY – There are three herbs with the name dittany. One is an aromatic Old World plant called Crete dittany (*Origanum dictamnus*), a relative of marjoram and once believed to have the power to expel arrows from the body. The second is the so-called gas plant (*Dictamnus albus*), native to Eurasia and also named "burning bush" because it emits a vapor that can be ignited. The third is "stone mint" (*Cunila origanoides* – also known as Maryland dittany), an eastern North American plant that is a member of the mint family. True to its name, it grows in rocky places and was harvested by Native Americans to make a tea. Stone mint can also substitute for other herbs such as marjoram and thyme.

Common names and synonyms: Burning bush, Cretan dittany, Crete dittany, gas plant, Maryland dittany, stone mint.

Dock – *see* **SORREL**

Dogbane – *see* **HEMP DOGBANE**

Dogberry – *see* **CORNUS, WINTERBERRY**

Dog rose – *see* **ROSE HIP(S)**

Dogtooth – *see* **COUCH GRASS**

Dogwood berry – *see* **CORNUS**

Dogwood cherry – *see* **CORNUS**

Dogwood tree – *see* **CORNUS**

DOM PALM – Grown in Florida and the Nile region of Africa, the leaves of the plant *Hyphaene thebaica* are used for cordage, mats, and paper. The unripe seeds are eaten raw or made into sweetmeats or molasses. The outer husk or pulp is said to taste like gingerbread, thus encouraging its common names, "gingerbread palm" and "gingerbread tree."

Common names and synonyms: Doom palm, doum palm, Egyptian doum, gingerbread palm, gingerbread tree.

Doodhi – *see* **BOTTLE GOURD**

Doom palm – *see* **DOM PALM**

Douhé – *see* **TECUITLATL**

Doum palm – *see* **DOM PALM**

Downy groundcherry – *see* **CAPULIN**

Downy haw – *see* **HAWTHORN BERRY**

Dragon's-eye – *see* **LONGAN**

Dragon's-tongue – *see* **PIPSISSEWA**

Drumstick tree – *see* **BENOIL TREE**

Drumstick vegetable – *see* **BENOIL TREE**

DUAN SALAM – Also called "Indonesian bay" and "laurel leaf," duan salam (*Eugenia polyantha* or *Syzygium polyantha*) is a tall tree that seems to be a native of South Asia. Its aromatic leaves can be dried and used like bay leaves. When young, they are frequently cooked like greens, often with a bit of meat for flavoring.

Common names and synonyms: Indonesian bay, laurel leaf.

Duck potato – *see* **ARROWHEAD**

DUIKA – Called a wild mango – which it is not – the duika (*Irvingia gabonensis*) is a fruit that grows on trees of Central Africa. Its flavor is something like that of a mango but not very tasty. The seed, however, which is oily, provides cooking oil and is used to make Gabon chocolate.

Common names and synonyms: Wild mango.

Du jour – *see* **KALE**

Duku – *see* **LANGSAT**

DULSE (*see also* **SEAWEED**) – A coarse, reddish brown seaweed, dulse (especially *Rhodymenia palmata*) is found on North Atlantic coasts and is plentiful in New England waters and those of the British Isles. It is first dried in the sun, then used as a vegetable in salads and – in Scotland – as a condiment. Dulse is generally available in health-food stores.

Common names and synonyms: Dulce, sea moss.

See in addition: "Algae," Part II, Section C, Chapter 1.

DURIAN – A foul-smelling fruit with a spiked skin like that of a pineapple, the durian (*Durio zibethinus*) grows on a tall tree native to the Malaysian region but is now cultivated throughout Southeast Asia. When mature, the fruit is normally the size of a football and weighs about 5 pounds, although there have been reports of weights up to 100 pounds. The edible, cream-colored pulp has a delicious "figs-and-bananas" flavor – despite its obnoxious odor (some have likened it to that of Limburger cheese) – and is generally eaten raw, although unripe fruits can be boiled and eaten as a vegetable. The large seeds are roasted.

The fruit is also grown in East Africa, but, although introduced in the American tropics, did not become popular there. Because of their odor, durians are seldom available in fresh form. They are exported to Europe and the United States but few airlines will accept them for shipment. The fruit is also sold in cans and bottles, packed in sugar syrup. Durian is a fine source of potassium and fairly high in vitamin C.

Common names and synonyms: Civet-cat fruit, Lahong, Tutong.

Dutch durian – *see* **SOURSOP**

DUTCH RED PEPPER (*see also* **CHILLI PEPPERS**) – Understandably also known as the "Holland chilli," this member of the genus *Capsicum* is a fairly recently developed hybrid chilli pepper for the Dutch export trade in produce. It is red and hot and used in all the many ways – from stuffing to salsas to pickles – that other peppers have long been used.

Common names and synonyms: Holland chilli.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

E

Early Red – *see* **LOQUAT**

Earth almond – *see* **CHUFA**

EARTH NUT – In addition to serving as another synonym for peanut, the term "earth nut" can mean an Old World plant (*Conopodium denudatum* – also called "pignut") with small tubers that – in England at least – are often eaten raw. Another "earth nut," *Lathyrus tuberosus* (known as well as the "heath pea"), is also European in origin but is now naturalized in the United States. These tubers have been used as food and to flavor whiskey in Scotland and are now cultivated commercially in Holland. Both earth nuts reportedly have the flavor of chestnuts, and both have been mistakenly called chufa.

Common names and synonyms: Heath pea, pignut.

Ebisu – *see* **KABOCHA (SQUASH)**

Eboe yam – *see* **WHITE YAM**

Eddo – *see* **COCOYAM, TARO**

Eddoe – *see* **COCOYAM, TARO**

Eddy root – *see* **TARO**

Edible-pod pea – *see* **PEA(S), SUGAR PEA**

Eggfruit – *see* **CANESTEL, LUCUMA**

Eggfruit (tree) – *see* **CANISTEL**

EGGNUT – A little-known nut of the Amazon region, the eggnut (*Couepia longipendula*) has an extraordinarily hard shell that protects its oil-rich kernels. The nut is said to have an excellent flavor.

EGGPLANT – The size and color of the eggplant (*Solanum melongena*) range from the white, egg-shaped types of India (from whence the name derives) to a large, green or white variety of melon size, although the most common (in North America) remains the familiar dark purple, ovoid form sometimes called the "Japanese eggplant." In West Africa, eggplants – there called "garden eggs" – are small and round, with colors that run from white to yellow, whereas in the West Indies eggplants are often streaked with green and have a variety of names including "gully bean," "susumber," and "pea aubergine."

Known in much of the world as "aubergine" and in the Middle East as "poor-man's-caviar," the vegetable (technically a fruit) is native to southern and eastern Asia and was only introduced into Europe (by the Arabs via Spain) during the Middle Ages. It is a member of the nightshade family, which includes the potato, and has a reputation for bitterness, but is so versatile – it can be fried, grilled, boiled, baked, deep-fried, stuffed, or stewed – that its flavor changes with different methods of preparation, and in some cuisines (and diets) the eggplant, with its fleshy texture, takes the place of meat.

Eggplant is the star in many famous dishes, such as the moussaka of Greece and the eggplant parmigiana of Italy. Although not especially nutritious, the eggplant is a good source of folic acid.

Common names and synonyms: Apple-of-love, Asiatic aubergine, aubergine, baby eggplant, *brinjal,* garden egg, Guinea squash, gully bean, Italian eggplant, Japanese eggplant, melanzana, melongene, Oriental eggplant, pea apple, pea aubergine, poor-man's-caviar, susumber, *terong,* white eggplant.

EGUSI – The egusi (*Citrullus colocynthis*) is of the same genus as the watermelon and, like it, a native of tropical Africa. But the similarities end abruptly with taste, because the egusi is an extremely bitter fruit. Instead of the pulp, it is the seeds of the egusi that are utilized. Oil is extracted from them, and they are ground into powder for cooking purposes. They are also roasted for consumption.

Common names and synonyms: Colocynth.

Egyptian onion – *see* **ONION TREE**

Egyptian taro – *see* **TARO**

Egyptian thorn – *see* **ACACIA**

Egyptian tree onion – *see* **ONION TREE**

EINKORN (*see also* **WHEAT**) – This grain (*Triticum monococcum*) – a one-seeded wheat – is one (along with emmer) of the ancestral species of modern wheat and one of the founder grain crops of the Neolithic Revolution. Primitive varieties of einkorn such as *T. monococcum* spp. *boeoticum* originated in the Balkans, western Asia, and the eastern Mediterranean, and the transition to the cultivated variety (*T. monococcum*) probably took place in Anatolia. About 7,000 years ago, einkorn came to Europe, where it was grown until the nineteenth century, especially in barren regions where other crops were not successful. Primitive varieties still grow wild in the Balkans and West Asia. Although it is seldom cultivated as a cereal, einkorn is used as livestock feed and in the manufacture of beers and vinegars.

Common names and synonyms: One-grained wheat, wild einkorn, wild einkorn wheat.

See in addition: "Wheat," Part II, Section A, Chapter 10.

ELAEAGNUS (*see also* **BERRIES**) – There are a number of shrubs of the genus *Elaeagnus* that produce edible berries. *Elaeagnus umbellata,* the "autumn olive" of Asia, has small orange or red berries that are used like red currants or dried like raisins. *Elaeagnus angustifolia,* called the "Russian olive," "wild olive," or "oleaster," originated in Asia but is now a popular berry in southeastern Europe, its sweetness enjoyed raw or cooked. In the Philippines, the "lingaro" (*E. philippinenis*) – a large shrub – yields red berries that taste like cherries. Also in the East Asian neighborhood is the "silverthorn" (*E. pungens*), a spiny shrub or tree that has sweet red fruits. Finally, *E. commutata* – the "silverberry" – is a native of northwestern North

America with berries that helped to sustain Native Americans such as the Inuits.

Common names and synonyms: Autumn olive, lingaro, oleaster, Russian olive, silverberry, silverthorn, wild olive.

ELDERBERRY (*see also* **BERRIES**) – There are a number of shrubs and trees of the genus *Sambucus* (elder) that produce elderberries – some of the trees growing to upwards of 50 feet in height. A native of both the Americas (*S. canadensis* and *S. caerulea*) and the Old World (*S. nigra*), the elderberry has been gathered, dried, and cooked for millennia and its fragrant flowers added to salads and made into fritters. The berries vary considerably in color – ranging from blue to red to black – and also in taste. Popular wisdom holds that they should not be eaten raw in any quantity, and it is the case that the foliage and stems are slightly toxic. Native Americans employed elderberries as food and used the tree's vertical hollow stems for arrows and whistles and as taps for gathering maple sap. The ancient Greeks employed the stems for musical instruments called "sambuke." Elderberries are generally employed in tarts and pies and can be made into syrup, jelly, and wine. Although usually found in the wild, in Portugal elderberries are cultivated in large quantities and used to add a deep red color to port wine. Like all berries, elderberries are rich in vitamin C.

Common names and synonyms: American elder, American elderberry, blueberry elder, blue elderberry, eastern elderberry, red elderberry, western elderberry.

ELECAMPANE – A large herb of Eurasia, elecampane (*Inula helenium*) has been naturalized in North America. It has yellow flowers that are edible – as are its young leaves – but the major reason for the cultivation of elecampane, which has been going on since ancient times, is for its aromatic root, employed both medicinally and as a flavoring. The roots can be grated into a spice and added to any number of dishes. In the past they were candied; today their essential oil continues to flavor vermouth.

Elephant(-)apple – *see* **INDIAN WOOD-APPLE, QUINCE**

Elephant's-ear – *see* **MALANGA, TARO**

Elk-weed – *see* **GENTIAN**

Emblic – *see* **AMALAKA**

EMMER (*see also* **WHEAT**) – A Eurasian wheat, and (along with einkorn) one of the ancestral species of modern wheat and a founder grain crop of the Neolithic Revolution, emmer (*Triticum dicoccum* = *T. dicoccon*) originated in the Middle East and western Asia at the dawn of the Neolithic Age. It is a winter or spring wheat and was used by the Babylonians and the Egyptians before it spread across Europe beginning about 5000 B.C., making it one of the earliest grains to be cultivated there. But emmer, although hardy, was not suitable for bread making, and, slowly, crossbreeding with varieties of einkorn developed softer (and more productive) wheats that were suitable. Gradually, emmer gave way to these softer "bread wheats," although it is still grown in the United States for use as livestock feed and in breakfast cereals. Its starchy white flour is also favored for making fine pastries and cakes.

Common names and synonyms: Emmer wheat, German wheat, rice wheat, starch wheat, two-grained spelt, two-grained wheat, wild emmer wheat.

See in addition: "Wheat," Part II, Section A, Chapter 10.

Emu apple – *see* **SOUR PLUM**

ENDIVE AND ESCAROLE (*see also* **CHICKORY**) – This plant (*Cichorium endivia*) is a member of the daisy family and is cultivated for its crisp, succulent (if somewhat bitter) leaves that are used in salads and are also braised. It should not be confused with a relative – Belgian endive, called chickory in Europe. Its ancestor was wild chicory (probably native to India), but endive was domesticated early and grown in ancient Egypt, Greece, and Rome. It was introduced (or reintroduced) in Europe by the Dutch during the sixteenth century. The two principal types under cultivation are curly endive and broad-leafed or Batavian endive. The latter is also known as escarole (from the Old French *scariole* and Late Latin *escariola*) and has a bushy head with large, open, green and white leaves. The roots of this plant are ground, roasted, and added to coffee. Another variety, not bushy at all but rather blanched and spidery in appearance, is called *frisée.* Endive and escarole are fairly high in vitamin A and provide some vitamin C.

Common names and synonyms: Batavian endive, broad-leafed endive, *chicorée,* curly endive, *escariola, frisée, scariole.*

English tomato – *see* **KIWANO**

Enoki – *see* **ENOKITAKE, MUSHROOMS AND FUNGI**

ENOKITAKE (*see also* **MUSHROOMS AND FUNGI**) – Enokitake (*Flammulina velutipes* = *Collybia velutipes*) is a long-stemmed, tight-capped mushroom that is much appreciated in Japan, where it is cultivated. It grows wild in North America (where it is called the "winter mushroom"), but only the cultivated varieties are available in (usually Asian) markets. It is very white, has a somewhat sweet taste, and supplies a small quantity of the B-complex vitamins.

Common names and synonyms: Enoki, enok mushroom, golden mushroom, velvet stem, winter mushroom.

See in addition: "Fungi," Part II, Section C, Chapter 7.

Enok mushroom – *see* **ENOKITAKE**

ENSETE (*see also* **BANANA**) – Alternately called the "jungle banana," the "Abyssinian banana," and the "little red banana," this plant (*Musa ensete*) is now grown mostly as an ornamental because of its erect and bright green, broad leaves. Another fruit called "ensete" and closely related to the banana is *Ensete ventricosum,* which is grown as a staple in some of the higher altitudes of Ethiopia. The pulp is made into bread.

Common names and synonyms: Abyssinian banana, jungle banana, little red banana.

See in addition: "Bananas and Plantains," Part II, Section B, Chapter 1.

EPAZOTE (*see also* **CHENOPODIUM**) – Called *paiku* in Peru, this semicultivated green, epazote (*Chenopodium ambrosioides*) is traditional and necessary in Mexican and Central American cooking. The aromatic leaves (some would say the odor is foul, others find it pleasant) of this sweet and mild-flavored herb are found in markets on large green stalks as well as in chopped and dried forms. When added to dishes containing beans, epazote is believed to reduce gassiness, and it is also used to make "Mexican tea," which is another name for the plant. Epazote has a reputation for combating helminthic boarders in the body, and the leaves and tops of one variety (*C. ambrosioides* var. *anthelminticum*) are considered especially powerful in this regard. An essential oil is extracted from this plant for medicinal uses.

Common names and synonyms: American wormseed, Jerusalem oak, Mexican tea, wormseed.

EVENING PRIMROSE – Native to North America, the various species of the genus *Oenothera* grow southward from British Columbia and Newfoundland and are found across most of the continental United States. The young shoots and leaves provided food for Native Americans, as did the boiled seeds and roots of some species. The evening primrose was one of the first American plants introduced as a food in Europe, where it was cultivated for both young shoots and roots. In France, *O. biennis* came to be known as *jambon du jardinier* or "gardener's ham."

Common names and synonyms: Gardener's ham, *jambon du jardinier.*

Evening star – *see* **MOONFLOWER**

EVERLASTING PEA – Any of several species of the genus *Lathyrus* – and especially *Lathyrus latifolius* – are called "everlasting pea." It is a native of southern Europe that is now consumed mostly in Asia, where the pods and shoots are boiled as a vegetable and the seeds are roasted.

Common names and synonyms: Perennial pea.

See also: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

FAVA BEAN (*see also* **BEANS, LEGUMES**) – Known to the English as the "broadbean" or the "horse bean," the fava (*Vicia faba* – from *faba,* which means "bean" in many of the Romance languages) has a very long history, figuring in Chinese cuisine at least 5,000 years ago. Today, favas are very prominent in the cuisines of Mediterranean countries, the Middle East, Africa, South America, and China, but not, for some reason, in that of North America – perhaps because of the need to skin them, which is time-consuming. A remote potential difficulty with ingesting the beans, or even inhaling the pollen from the flowers, is hemolytic anemia, brought on by a type of enzyme deficiency – glucose-6-phosphate-dehydrogenase (G6PD) deficiency – that has developed among some of the people of the world as a protection against malaria. Like most beans, favas deliver protein and iron and, in addition, are a good source of vitamin A and a good provider of the B-vitamin complex.

Common names and synonyms: Broadbean, horse bean, tickbean, Windsor bean.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

Fecula – *see* **ARRACACHA**

Feijão-prêto – *see* **TURTLE BEAN**

FEIJOA – The feijoa, a fruit (*Feijoa sellowiana*), is a native of Brazil with a Portuguese name suggestive of a bean (in Portuguese, *feijão*). But although it is unlikely that the kiwi fruit–sized berry of this evergreen shrub would ever be confused with a bean, its common names – "pineapple guava" or even just "guava" – do tend to promote confusion. The feijoa has a green, bumpy skin and a jelly-like pulp surrounded by a whitish flesh with a delicious, tart taste that is something of a cross between the flavors of pineapple and strawberry and goes well in fresh fruit salads. Beginning at the end of the nineteenth century, the feijoa traveled from Brazil to be grown in and exported from southern Europe (1890) and California (1900) on one side of the in world and, more recently, New Zealand and Australia on the other. It is frequently eaten fresh or made into a jelly. When fresh, in particular, the feijoa is a good source of vitamin C.

Common names and synonyms: Guava, pineapple guava.

Felon herb – *see* **MUGWORT**

Fen berry – *see* **CRANBERRY**

FENNEL – Fennel (*Foeniculum vulgare*), a native of southern Europe, is often wrongly called "anise" or "sweet anise" because of its licorice flavor. However, that flavor is less pronounced in fennel than in anise, and the seeds (as well as the roots, leaves, and stalks) of fennel have been employed since ancient times as an ingredient in sauces, sausages, stews, and salads, as well as in breads and various meat, egg, and fruit dishes.

The herb was cultivated by the Egyptians and was popular with the ancient Greeks and Romans. According to Greek mythology, when humans received knowledge from Olympus, the gift came in the form of a fiery-hot coal within a fennel stalk. The name "fennel" derives from a Latin word that indicates a kind of sweet-smelling hay – a hay that was discovered to keep insects at bay. The use, as a vegetable, of the celery-like stalks and leaves of one variety, called "Florence fennel," is mostly seen in Italian cuisine (the root is especially vital in Sicilian cuisine), although fennel is also cultivated for its vegetable (in contrast to herbal) qualities in Greece, France, and the United States – in the latter case, largely because of an Italian-American demand.

Like the seed, the vegetable is licorice-like in taste and has long been associated in Europe with fish recipes. It is also employed raw in salads and appetizers and cooked in any number of dishes. The vegetable provides some vitamin A and niacin, and a little iron. The seed was called the "meetin' seed" by the early New England Puritans, who were accustomed to nibble them during church services. Fennel seeds are especially important in flavoring fish, shellfish, and fish sauces. They are also added to meat dishes, spaghetti sauces, and breads and pastries.

Common names and synonyms: Finocchio, Florence fennel, meetin' seed, Roman fennel, sweet anise, sweet fennel, wild fennel.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Fennel-flower – *see* **NIGELLA**

FENUGREEK – The leguminous seeds of fenugreek (*Trigonella foenum-graecum*), a Eurasian plant, are employed as a spice throughout the Mediterranean region, South Asia, and North Africa. Fenugreek was mentioned in the Ebers papyrus and was used by the ancient Egyptians to make a paste that, when applied to the body, was supposed to combat fevers. In Latin, the name means "Greek hay," presumably because the clover-like plant made good fodder for animals.

Fenugreek seeds have a bitter taste (which is removed by dry-roasting) and a yellow coloring, that they impart to other foods. Ground, they are an important ingredient in curry powders. In parts of Africa, the dried seeds are soaked and prepared like the legumes, which means they are rich in protein. The dried leaves (called *methi*) are mixed into vegetable dishes in Indian, Middle Eastern, and Asian cuisines. Other uses for fenugreek are as the most important flavoring in artificial maple syrup and in halvah, as well as an ingredient in some oral contraceptives. In addition to protein, fenugreek, like most other legumes, is high in the B-vitamins.

Common names and synonyms: Foenugreek, *methi.*

Fernbush – *see* **SWEET FERN**

Ferngale – *see* **SWEET FERN**

Fever bush – *see* **WINTERBERRY**

Feverwort – *see* **BONESET**

FIDDLEHEAD FERN – All ferns are "fiddleheads" when their new, tightly coiled, green shoots emerge from the earth – usually in the spring. After they uncoil into fronds, they are no longer edible, and as with certain mushrooms, there are questions about the edibility of some of the so-called fiddleheads which are suspected of being carcinogenic. However, the one usually marketed – the ostrich fern (*Matteuccia struthiopteris*) – is supposed to be safe. Fiddleheads grow in damp places and in North America are sought mostly in forests along the eastern seaboard, especially in New Brunswick, Maine, and Vermont. For some, their taste is akin to that of artichokes; for others, it is more like the flavor of asparagus. Although they are often added raw to salads, fiddleheads are best when (as with asparagus or artichoke hearts) they are lightly boiled and served with melted butter or some other appropriate dressing. The nutrients provided are vitamins A and C.

Common names and synonyms: Fiddlehead(s), fiddlehead greens, ostrich fern.

Fiddlehead greens – *see* **FIDDLEHEAD FERN**

Field pennycress – *see* **PENNYCRESS**

Field salad – *see* **CORNSALAD**

Field vetch – *see* **VETCH**

FIG – The common fig tree (*Ficus carica*) is a member of the mulberry family. Although a native of Southwest Asia, it long ago was growing wild around the Mediterranean basin, and its sweet, pear-shaped, and many-seeded fruit was picked up by hunter-gatherers. Figs have been cultivated for over 6,000 years, and nowadays practically every Mediterranean garden has its fig tree. When the fruits are ripe, the ground around becomes slippery with their pulp.

The fig was known to the Egyptians, the Greeks, and the Romans, who fed them to their gladiators for quick energy. The Greek word "sycophant," meaning "one who shows the fig," was first applied to the priests who declared that a fig crop was ripe and could be gathered. Later, it meant those who informed on individuals in the illegal fig trade from Greece. The common fig was brought to the Americas by the Spaniards around 1600 and was first planted in California by Franciscan friars around 1770. Commercial production there, however, only dates from about 1900. Today, California produces almost all of the U.S. crop. Other commercial producers are Italy, Turkey, Algeria, Greece, Spain, and Portugal.

In all, there are about 100 kinds of figs, such as the Smyrna fig; even the rubber and banyan trees are species of figs. Major varieties of the fruit are the Black Mission, with a black or purple skin; the Kadotta, with a yellow-green skin; a large fig, the Calimyrna, with a yellow-green skin; and the Brown Turkey, which has a somewhat purplish skin. The fruit is eaten fresh but is also stewed, canned, preserved, and dried. The latter form is the most nutritious, and for millennia dried figs have been a staple food in many parts of the world, where they were known as "poor-man's-food." Fig leaves are also eaten. Figs are a good source of carbohydrates, vitamin A, fiber, and potassium, as well as calcium, iron, and copper.

Common names and synonyms: Adriatic fig, Black Mission fig, Brown Turkey fig, Calimyrna fig, common fig, Kadotta fig, poor-man's-food, Smyrna fig, sycamore fig.

FIG-LEAFED GOURD (*see also* **SQUASH AND PUMPKIN**) – Unknown in the United States, although of American origin, the fig-leafed gourd (*Cucurbita ficifolia*) was cultivated at least 5,000 years ago in Peru. It is so called because the plant has leaves similar to those of the fig tree. Immature fruits are prepared and eaten like summer squashes, whereas the black seeds are roasted for consumption and are turned into a kind of gravy. In addition, the fruit of this versatile vegetable is candied for special occasions in Central American and Andean countries, and the flesh is also fermented to make beer.

Common names and synonyms: Malabar gourd.

See in addition: "Squash," Part II, Section C, Chapter 8.

Filbert – *see* **HAZELNUT AND FILBERT**

Filé – *see* **SASSAFRAS**

FINGER MILLET (*see also* **MILLET**) – Known as *ragi* in the dry areas of India and Sri Lanka, where it is a major grain, finger millet (*Eleusine coracana*) is generally made into flour, porridges, and flatbreads. It is also used for making beer. Higher in protein and fat than most other grains, finger millet is a very wholesome food.

Common names and synonyms: African millet, *ragi.*

See in addition: "Millets," Part II, Section A, Chapter 5.

Finocchio – *see* **FENNEL**

Fish-hook cactus – *see* **BARREL CACTUS**

Fitweed – *see* **LONG CORIANDER**

Five-angled fruit – *see* **CARAMBOLA**

Flag – *see* **IRIS**

Flageolet – *see* **BEANS**

Flag root – *see* **SWEET FLAG**

FLAX SEED – The fibers from a number of plants of the genus *Linum,* and especially the cultivated *L. usitatissimum,* have long been used to make fine linen, and for just as long the seeds of these plants have been crushed to make linseed oil. Indeed, flax is one of the oldest cultivated crops, dating back at least 7,000 years. The Egyptians raised it, and it was among the first crops in Syria and Turkey. Flax cultivation spread to Europe about 3,000 years ago. Although the oil is generally thought of as a drying oil – used in such products as paints and varnishes – one occasionally reads of it being employed as a cooking oil in the past. Flax seed has also been employed to make teas.

Common names and synonyms: Linseed (oil).

Florida arrowroot – *see* **ZAMIA**

Florida sago – *see* **ZAMIA**

Florist's fern – *see* **ASPARAGUS**

Flowering bean – *see* **MALOGA BEAN**

Flowering chives – *see* **CHINESE CHIVE(S)**

Flowering dogwood – *see* **CORNUS**

FLOWERING WHITE CABBAGE (*see also* **CABBAGE**) – A type of Chinese cabbage grown near Canton, the flowering white cabbage (*Brassica campestris*) is similar to broccoli and to bok choy, which seems to be a close relative. It is also called *choy sum* (which translates as "vegetable hearts"), and nearly all its parts are edible and highly nutritious.

Common names and synonyms: Choy sum.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Flowery Orange Pekoe – *see* **TEA**

Fluted cucumber – *see* **OYSTERNUT**

FLUTED GOURD – Practically unknown in the United States, the fluted gourd (*Telfairia occidentalis*) is cultivated in West Africa, often on trellises. The fruit is not eaten, but the seeds are protein-rich and are roasted, boiled, and made into a powder for soups.

Common names and synonyms: Fluted pumpkin, oysternut.

Fluted pumpkin – *see* **FLUTED GOURD**

Foalfoot – *see* **COLTSFOOT**

Foam flower – *see* **COOLWORT**

Foenugreek – *see* **FENUGREEK**

FONIO – Fonio is perhaps the oldest of Africa's cereal crops. For thousands of years, fields of its barely knee-high stalks have stretched across the uplands of West Africa. White fonio (*Digitaria exilis*) is cultivated in an area that extends from the Atlantic coast to Chad. People on the central plateau in Nigeria call it *acha.* Black fonio (*Digitaria iburua*) is more likely found on the Jos-Bauchi Plateau of Nigeria and in northern Togo and Benin.

The history of the crop is little known, as scholars have yet to give it much attention. The seeds of both species are white, but black fonio (despite its lesser popularity) is nutritionally equal to its cousin. Their protein and fat contents are similar to those of wheat and fonio is very rich in several important amino acids.

Unlike some other ancient African cereals, fonio is still widely cultivated and serves as an important food for as many as 4 million people. No doubt one of the reasons for this is its excellent taste. Perhaps another reason is that the crop is particularly well suited to West Africa's semiarid savanna regions; it tolerates poor soil and often grows well where few other cultigens do. Moreover, a number of varieties mature very quickly, and hence provide food during normally lean times when other cereals are still far from being ready for harvest, giving rise to one of its many names – "hungry rice."

In many West African societies, fonio was (and still is) held in high esteem. At times, it was reserved for chiefs and royalty or saved for special festivities. In some cultures, it denoted part of the bride-price, and many feel that it is the best-tasting cereal of all. The kernels can be cooked as a porridge; they serve as a delicious base for couscous; and they are brewed into beer. Heated over a hot fire, they can be popped. Ground into flour, they are baked into breads or used as a substitute for semolina.

Common names and synonyms: Acha, black fonio, hungry rice, white fonio.

Food-of-the-gods – *see* **ASAFETIDA**

FOREST MILKBERRY – A tree of southern Africa, the forest milkberry (*Manilkara discolor*) ranges from 15 to over 50 feet in height and grows at many different altitudes. It bears flowers that are followed by tiny (less than a half inch in diameter) fruits that are fleshy and yellow to red in color.

Forest mushroom – *see* **CHANTERELLE, MUSHROOMS AND FUNGI**

Four-angled bean – *see* **WINGED BEAN**

Four-wing saltbush – *see* **SALTBUSH**

Foxberry – *see* **LINGONBERRY**

FOX GRAPE (*see also* **GRAPES**) – Originating in the New World, the fox grape (*Vitis labrusca*) was gathered by native peoples of eastern North America. Later, with the arrival of the Europeans, this purplish black fruit became the source of many cultivated grape varieties that were made into wine. These varieties are hardier and more disease resistant than grapes native to the Old World. Because the skin separates readily from the pulp, labrusca grapes are also called "slip-skin" grapes. The taste of these grapes made into wine has been defined as "foxy."

Common names and synonyms: Labrusca grape, slip-skin grape, wild grape.

See in addition: "Wine," Part III, Chapter 13.

Foxtail barley – *see* **WILD BARLEY**

Fremont screwbean – *see* **MESQUITE**

FRENCH COLOMBARD (*see also* **GRAPES**) – A high-yielding white grape, French Colombard (*Vitis vinifera*) is used in France mostly for making cognac. In California, it generally goes into bulk wines and is often marketed as chablis.

See in addition: "Wine," Part III, Chapter 13.

French endive – *see* **BELGIAN ENDIVE**

French peanut – *see* **MALABAR NUT**

French weed – *see* **PENNYCRESS**

Fresadilla – *see* **TOMATILLO**

FRESNO (*see also* **CHILLI PEPPERS**) – Another member of the genus *Capsicum,* the Fresno is a red pepper that resembles the jalapeño but is a bit wider (and hotter). It is grown in California and other places in the U.S. Southwest as well as in Mexico. In addition to their use in salsa, Fresnos are excellent when roasted.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Frutillo – *see* **MATRIMONY VINE**

Fumé Blanc – *see* **SAUVIGNON BLANC**

Fuyu – *see* **PERSIMMON**

FUZZY MELON (*see also* **MELONS**) – Also called "hairy melon," "Chinese squash," "Chinese vegetable marrow," and "Chinese winter melon," the fuzzy melon (*Benincasa hispida = B. cerifera*) is a huge cucurbit that grows on a vine that spreads out over the ground like a pumpkin vine. Apparently native to southern China (and an ancient food of the Chinese), the fuzzy melon comes in two varieties; one is cylindrical in shape, whereas the other narrows at the middle like a dumbbell. Both have a splotchy green skin that is waxy (they are also called "wax gourds") and both are covered with white, fuzzy hairs. The flavor of their pale green flesh is reportedly delicious, and in addition to peeling them and eating them raw, fuzzy melons are braised, boiled, and used in stir-fries.

Common names and synonyms: Chinese squash, Chinese vegetable marrow, Chinese winter melon, hairy melon, *moqua,* wax gourd.

See in addition: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

Gai choy – *see* **PAKCHOI AND KAI CHOY**

Gai-larn – *see* **CHINESE BROCCOLI**

Galanga – *see* **GALANGAL**

GALANGAL – Also called galingale, greater galangal (*Alpinia galanga*) is an aromatic root, native to Indonesia, that resembles ginger and is a close relative of the gingerroot family. It is joined in this relationship by both the lesser galangal (*A. officinarum*) and by galanga – *Kaempferia galanga.* In fact, greater galangal (also called laos) almost replaces gingerroot in much of the cooking of Southeast Asia. Lesser galangal and galanga are also eaten, but more as a cooked vegetable than a spice. At one time, galangal was widely used in Europe (for example, in England during the Middle Ages), where the root was sliced in both fresh and dried forms and added to dishes; it was also dried and ground. Now, however, galangal's principal use in the West is in making liqueurs and bitters.

Common names and synonyms: Galanga, galangale, galingale, greater galanga(l), laos, lesser galanga(l).

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Galangale – *see* **GALANGAL**

Galega – *see* **GOAT'S-RUE**

Galingale – *see* **CHUFA, GALANGAL**

Gallberry – *see* **WINTERBERRY**

Gallito – *see* **CORAL BEAN**

GAMAY (*see also* **GRAPES**) – Grown in France, California, and elsewhere, Gamay grapes (*Vitis vinifera*) are used to produce the dry red table wines of the Beaujolais district of Burgundy. In California, two distinct types are grown: Napa Valley Gamay and Gamay Beaujolais. These names actually give a false impression. It seems that the Napa variety is the true Beaujolais grape, and the California Gamay Beaujolais is actually a variant of Pinot Noir – a famous grape of Burgundy.

Common names and synonyms: Gamay Beaujolais, Gamay Noir, Napa Valley Gamay.

See in addition: "Wine," Part III, Chapter 13.

Gamay Beaujolais – *see* **GAMAY**

Gamay Noir – *see* **GAMAY**

Gandul – *see* **PIGEON PEA**

Garden egg – *see* **EGGPLANT, LOCAL GARDEN EGG**

Gardener's ham – *see* **EVENING PRIMROSE**

Garden huckleberry – *see* **WONDERBERRY**

Garden myrrh – *see* **CICELY**

GARLIC – A close relative of the onion, garlic (*Allium sativum*) is the common name for several small bulbous herbs of the lily family – among them British wild garlic (*A. oleraceum*), American wild garlic (*A. canadense*), and British and American field garlic (*A. vineale* – also known as "wild garlic"). *Allium sativum* is said by some to be a native of southern Europe; most, however, say central Asia.

Garlic was much appreciated by Egyptians, Hebrews, Greeks, and Romans, and by the time of the Middle Ages, was well entrenched in the cookery of southern Europe, where it remains to this day. Garlic may have somehow reached the Americas before the voyages of Christopher Columbus: The expedition of Hernando Cortés reportedly encountered it on its march into Mexico.

The term "garlic" comes from an old Anglo-Saxon word for "spear," after its spear-shaped leaves. Garlic is controversial – and not only because of "garlic breath." Throughout the ages, it has been regarded as a powerful medicine (even today it is viewed by some as protective against heart disease and cancer), an aphrodisiac, and a talisman for warding off demons and vampires. The bulb itself consists of bulblets or "cloves" grouped together between membranous scales and enclosed within a whitish or reddish skin. Recently, "elephant garlic," a hybrid of garlic and onion, has appeared in supermarkets – with its popularity the result of the current practice of garlic roasting. It is much larger than normal garlic bulbs (hence the name "elephant") and has a considerably milder flavor.

Common names and synonyms: American field garlic, American wild garlic, British field garlic, British wild garlic, elephant garlic, field garlic, *rocambole,* sand leek, wild garlic.

See also: "The *Allium* Species," Part II, Section C, Chapter 2; "Spices and Flavorings," Part II, Section F, Chapter 1.

Garlic chives – *see* **CHINESE CHIVE(S)**

GARLIC-MUSTARD – A tall weed that is native to Europe, garlic-mustard (*Alliaria officinalis = Sisymbrium alliarin*) has the odor of garlic (hence the scientific name, derived from "Allium"), tastes something like mustard seed, and can be used in salads. Also called "hedge garlic," the plant was much used in the past by Europeans as an herb. It is now naturalized in North America.

Common names and synonyms: Hedge garlic.

Garnacha – *see* **GRENACHE**

Garnacha Blanc – *see* **GRENACHE**

Gas plant – *see* **DITTANY**

Gbanja kola – *see* **KOLA NUT**

Gean – *see* **CHERRY**

Genip – *see* **GENIPAP, SPANISH LIME**

GENIPAP – The greenish or russet-brown fruit of *Genipa americana* is the size of a small orange and grows in clusters. Its acidic taste militates against its consumption raw, and its common use is in marmalade-like preserves. However, a cool drink known as *genipapado* is also made from the fruits, and the plant yields an indelible blue dye used as body paint. Genipap is found in Mexico, the West Indies, and South America, where it is also known as the "marmalade box."

Common names and synonyms: Genip, genipe, genipop, jagua, marmalade box.

Genipe – *see* **GENIPAP, SPANISH LIME**

Genipop – *see* **GENIPAP**

GENTIAN – There are numerous plants of the type genus *Gentiana*, some with large blue flowers. The dried rhizome and roots of a yellow-flowered European variety, yellow gentian (*G. lutea*), are sometimes used to make a tonic. Another plant of the Gentianaceae family is called deer's-ears, elk-weed, or green gentian (*Frasera speciosa* or *Swertia radiata*). Its roots were consumed by Native Americans in the American West.

Common names and synonyms: Deer's-ears, elk-weed, gentian root, green gentian, yellow gentian.

Gentle balm – *see* **LEMON BALM**

Gerasole – *see* **JERUSALEM ARTICHOKE**

German mustard – *see* **HORSERADISH**

German wheat – *see* **EMMER**

Gerrard vetch – *see* **TUFTED VETCH**

GEWÜRZTRAMINER (*see also* **GRAPES**) – In German, Gewürz means "spice" or "herb," which serves to indicate the aroma of the wine made from these grapes (*Vitis vinifera*) of the Rhine valley type. The region of Alsace produces most of the dry white wine made from Gewürz (also called Traminer, which is actually a cousin) grapes in Europe. In the United States, the grapes are also employed to make very creditable California "Rhine" wines.

Common names and synonyms: Traminer.

See in addition: "Wine," Part III, Chapter 13.

GHERKIN (*see also* **CUCUMBER**) – There are several varieties of small, rough-skinned cucumbers called gherkins (an English name for cucumber), and there exists some confusion about their origin. It was long believed in the West that the original gherkin was the so-called Jamaican gherkin or West Indian gherkin (*Cucumis anguria*) – a trailing herb also common in Brazil. But a kind of cucumber, which the English called "gherkin," has been eaten in India (where cucumbers are thought to have originated) for over 3,000 years and has been enjoyed in Europe since classical times. This was probably *C. melo* var. *conomon,* a native of India, commonly called the "Oriental pickling melon." The West Indian gherkin, by contrast, is a native of tropical Africa and thus must have reached the tropical New World from there, probably with the early-sixteenth-century slave trade. Soon afterward, it was carried back across the Atlantic and mentioned for the first time in Europe in a French publication of 1549. Immature gherkins are both cooked and eaten raw, but their general use is as pickles.

Common names and synonyms: Concombre des Antilles, Jamaican cucumber, Jamaican gherkin, Oriental pickling melon, *pepinito, pepino,* West Indian gherkin, West Indian gourd.

See in addition: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

Ghia – *see* **CHIA**

Giant bladder weed – *see* **SEAWEED**

Giant cane – *see* **LARGE CANE**

GIANT GRANADILLA – A robust climbing vine that is a native of tropical South America, the giant granadilla (*Passiflora quadrangularis*) now grows throughout the tropical world. It has roundish, medium to dark green leaves that are 6 to 9 inches across, and pleasantly scented white flowers sometimes edged with pink. Its greenish yellow fruits can reach from 5 to 10 inches in length. Their shape is oblong, and their light-colored, firm flesh surrounds a cavity that is filled with numerous dark seeds embedded in a pink pulp. The juice is fragrant and slightly acidic and lends itself well to flavoring ice creams and other desserts and to making refreshing drinks. One such drink, known as a *marquesa* (or *markeesa*), is very popular in Indonesia. Unripe, the fruit may also be cooked and eaten as a vegetable. It contains considerable amounts of phosphorus and vitamin A.

GIANT HOLLY FERN – Known also as a "sword fern," which is the name given to several ferns of both the Old and the New Worlds, the giant holly fern (*Polystichum munitum*) is a plant of western North America. Native Americans ate the rhizome of this species, and those of other species are still consumed in Asia.

Common names and synonyms: Sword fern.

Giant sea kelp – *see* **KELP, SEAWEED**

Giant sunflower – *see* **INDIAN POTATO, SUNFLOWER OIL AND SEED**

Giant taro – *see* **ALOCASIA**

Giant white radish – *see* **DAIKON**

Gilliflower – *see* **GILLYFLOWER**

Gill-over-the-ground – *see* **GROUND IVY**

GILLYFLOWER – The term "gillyflower" (also spelled gilliflower) refers to any of several plants with fragrant flowers, generally of the genus *Dianthus,* an important Old World genus of herbs. Gillyflowers were used as herbs for flavoring food and especially beverages.

Common names and synonyms: Gilliflower.

Ginep – *see* **SPANISH LIME**

Gingelly – *see* **SESAME**

GINGER – The underground rhizome of a tropical flowering plant, gingerroot (*Zingiber officinale*) can be purchased fresh, dried, grated, ground, preserved in vinegar or syrup, and crystallized. If fresh, its tan skin must be removed before grating or slicing. The word *zingiber* means "horn-shaped" in Sanskrit and was applied to ginger because of the shape of its rhizomes. Ginger was used in China and India 7,000 years ago and was an important item in the spice trade that stretched overland and by sea from India to the ports of the eastern Mediterranean, and to Egypt via the Red Sea.

Although known to the Greeks and the Romans, ginger apparently only became popular in Europe during the Middle Ages. The Portuguese took it to Africa as they explored the western coast of that continent in the fifteenth century, and the Spaniards carried it to the New World in the following century. In fact, the latter encouraged the cultivation of ginger in the Americas as part of an effort to grow those exotic (and expensive) spices that usually were only available from the East.

Ginger requires fertile soil and a warm climate to grow properly, and Haiti and especially Jamaica became, and remain, major New World producers. In fact, it is said that the highest-quality ginger comes from the central mountain region of Jamaica. The sharp but sweet flavor of ginger goes well in Asian dishes, and the ground root is used extensively in baking – in gingerbread, spice cakes, and the like. It is also employed in making various alcoholic beverages.

Common names and synonyms: Gingerroot, Jamaica ginger.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Gingerbread palm – *see* **DOM PALM**

Gingerbread tree – *see* **DOM PALM**

Ginger bud – *see* **MYOGA GINGER, TORCH GINGER**

Ginip – *see* **SPANISH LIME**

GINKGO NUT – Also called the "maidenhair tree," the ginkgo nut (*Ginkgo biloba*) appears to be native to China. One says "appears" because the *Ginkgo* genus, with some of its representatives long extinct, includes members that are among the oldest plants on the planet. Their fanlike leaves basked in the same sunlight as the dinosaurs, and their fleshy, inedible, odoriferous, yellow fruit contains a plumlike, hard-shelled, cream-colored nut that must have provided food for humans since the beginning of their time on earth. Grown in China for thousands of years, the tree reached Japan about 1,000 years ago (presumably after first being introduced in Korea) and found its way to Europe during the early part of the eighteenth century. The tree is said to have first been planted in North America in 1784 in a garden outside of Philadelphia. The nuts are still widely used – after being roasted, grilled, steamed, or boiled – in Asian soups, appetizers, and desserts. Boiled and canned ginkgo kernels are imported from the Orient and are available in ethnic food stores.

Common names and synonyms: Ginkgo (tree), ginko nut (tree), maidenhair tree.

Ginnie pepper – *see* **CAYENNE PEPPER**

GINSENG (*see also* **BLUE COHOSH**) – There are a few plants of the genus *Panax* that are called ginseng (especially *P. quinquefolius* and *P. schinseng*) and are strongly associated with the Chinese, who credit their forked roots (which resemble the lower part of the human body) with health-giving and especially aphrodisiacal properties. Actually, however, *P. quinquefolius* is North American in origin, and its leaves were used by Native Americans to brew a kind of tea. They also consumed the roots of dwarf ginseng (*P. trifolius*) both raw and boiled. American ginseng is now cultivated in North America for export to China and for the health-food industry at home.

Common names and synonyms: American ginseng, dwarf ginseng.

Girasole – *see* **JERUSALEM ARTICHOKE**

Giraumon – *see* **CALABAZA (SQUASH)**

Girolle – *see* **CHANTERELLE, MUSHROOMS AND FUNGI**

Girsole – *see* **JERUSALEM ARTICHOKE**

GLASSWORT (*see also* **SAMPHIRE**) – Glasswort actually comprises a number of species, among them *Salicornia europaea* and *S. herbacea*, which are both edible and often called "samphire." A cousin, *S. stricta,* employed in the making of glass, may have provided the official name, although the crunching sound glasswort makes when stepped upon also sounds like glass being broken. The roots of these small plants grow wild along rocky seacoasts (even right through rocks) and have historically been much appreciated by the French and English, who pickled them. And today *S. europaea* is gathered commercially in France to be served raw with fish and pickled. Because the plant seems to flourish in the presence of salt, however, it also grows around salt marshes far away from the sea. The plant is crisp and salty tasting when young and can be used in salads as well as pickled. Glasswort is high in iron and vitamin C. In the United States, glasswort is generally but wrongly called samphire.

Common names and synonyms: Marsh samphire, *pousse-pied,* samphire, sea bean, seagrass, sea pickle.

Goa bean – *see* **WINGED BEAN**

GOAT CHILLI (*see also* **CHILLI PEPPERS**) – A cold-tolerant *Capsicum* variety, the goat pepper is said to belong to the species *C. pubescens* but cannot be crossed with any of its other members. It is grown in the high Andes, where its leaves as well as its dried fruit are used for seasoning.

Common names and synonyms: Goat pepper.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Goat-nut – *see* **JOJOBA NUT**

Goat pepper – *see* **GOAT CHILLI**

GOAT'S-RUE – Also called "galega," goat's-rue (*Galega officinalis*) is a tall, bushy, blue-flowered European herb now cultivated as an ornamental but used in the past as a potherb.

Common names and synonyms: Galega.

Gobo – *see* **BURDOCK**

Golden alexanders – *see* **ALEXANDER**

GOLDEN APPLE – Not to be confused with the Golden Delicious apple, the golden apple (*Spondias cytherea = S. dulcis*) is not an apple at all, but rather a yellow fruit with a single large stone (something like the avocado) surrounded by flesh with a taste ranging from tart to sweet. It is a native of Polynesia but is widely grown in the West Indies. Golden apples are used for tall, sweet drinks and made into jam and chutneys. They are now available in many tropical markets.

Common names and synonyms: Ambarella, Jew plum, Otaheita-apple, vi-apple.

Goldenberry – *see* **CAPE GOOSEBERRY**

Golden button(s) – *see* **TANSY**

Golden chanterelle – *see* **CHANTERELLE, MUSHROOMS AND FUNGI**

GOLDEN CLUB – An aquatic plant native to the eastern United States, golden club (*Orontium aquaticum*) was exploited by Native Americans for food in a number of different ways. The roots were dried and made into flour, the seeds were also dried, and even the flowers were eaten.

Golden gram – *see* **MUNG BEAN**

Golden husk – *see* **CAPE GOOSEBERRY**

Golden mushroom – *see* **ENOKITAKE**

GOLDEN NUGGET (SQUASH) (*see also* **SQUASH AND PUMPKIN**) – The Golden Nugget (*Cucurbita maxima*) is a winter squash that – with its orange skin – looks like a miniature pumpkin. It is a product of plant breeding and has a pleasant squash taste. Generally baked or roasted, one Golden Nugget provides a single serving and delivers much in the way of vitamin A and iron.

Common names and synonyms: Gold Nugget.

See in addition: "Squash," Part II, Section C, Chapter 8.

Golden orange – *see* **KUMQUAT**

GOLDENROD – Native to central and eastern North America, one species of goldenrod (*Solidago odora*) is also known as "blue mountain tea" and "sweet goldenrod" because its fragrant leaves are made into a licorice- or anise-scented tea. The leaves of another species (*S. missouriensis*) were used as food by Native Americans, who ate them raw when young and cooked them as a vegetable.

Common names and synonyms: Blue mountain tea, sweet goldenrod.

Golden timothy (grass) – *see* **MILLET**

Gold Nugget – *see* **GOLDEN NUGGET (SQUASH)**

GOLDTHREAD – A small plant with shiny green leaves, native to both North America and northern Asia, goldthread (*Coptis trifolia*) is named for its long, slender, golden-colored roots. They are bitter but were apparently eaten by natives of the Northern Hemisphere. The roots have also been employed to flavor beer.

Common names and synonyms: Cankerroot, coptis, yellowroot.

Gombaut – *see* **OKRA**

Gombo – *see* **OKRA**

Goober (pea) – *see* **PEANUT**

GOOD-KING-HENRY (*see also* **CHENOPODIUM**) – A member of the goosefoot family, "Good-King-Henry" (*Chenopodium bonus-henricus*) is a Eurasian plant naturalized in North America and was said to be named for King Henry VII of England (reigned 1485–1509). But the truth seems to be that it was first named "Good-Henry" to distinguish it from a weed called "Bad-Henry," and "King" was added later. In England, the plant was also called "fat-hen" because chickens seemed to like it. Remains of the plant (a leafy green vegetable) have been found in Neolithic sites, but it was doubtless gathered by our Paleolithic forebears long before the dawn of agriculture. Good-King-Henry was cultivated as a potherb during the Middle Ages and the beginning of the modern period but afterward returned to the wild state in which it can be found (and gathered) today.

Common names and synonyms: Fat-hen, perennial goosefoot.

Goongoo pea – *see* **PIGEON PEA**

GOOSEBERRY (*see also* **BERRIES**) – The origin of the gooseberry (*Ribes grossularia = R. uva-crispa* – of the same genus as currants), and that of its name, is something of a mystery. The one that is cultivated is a Eurasian native that was apparently brought to France by the Normans in the tenth century. There – because it was made into a sauce to go with mackerel – the berry came to be known as *groseille à maquereau* ("currant for mackerel"). The English name is thought to have been the result of using the berry to stuff roasted goose and accompanying the dish with a relish of gooseberries as well. In Scandinavia, Hungary, and Russia, a soup is made with gooseberries. Over the past few centuries, the berry has been tinkered with by European farmers, so that now over 2,000 varieties exist that come in several shapes and sizes, almost all bigger and sweeter than the generally wild gooseberries that grow in the United States.

American gooseberries are apt to be rough and prickly. Although mostly greenish, they also come in shades of white and purple, and they vary in taste from sweet to sour, indicating the wide variety of species that provided Native Americans with food. Among the wild North American gooseberry species consumed by Native Americans were the "orange gooseberry" (*R. pinetorum*) and the "wolf currant" (*R. wolfii*); the latter is still in use in baking and making tart jellies. Where the gooseberry is cultivated in Europe – and now in New Zealand – the tree is often placed against brick or stone walls. In several areas of the United States and Canada, however, growing the fruit is prohibited because it is host to a disease called "white-pine blister-rust," which is deadly to white pine trees.

Common names and synonyms: English gooseberry, European gooseberry, *groseille à maquereau,* old gooseberry, orange gooseberry, wolf currant.

Gooseberry tree – *see* **OTAHEITE GOOSEBERRY**

GOOSEFOOT (*see also* **CHENOPODIUM, GOOD-KING-HENRY, QUINOA**) – The term "goosefoot" actually refers to a number of closely related plants of the genus *Chenopodium* that are also called "lamb's-quarter" and "pigweed." Some of these have arrived in the New World during the past few centuries from Europe, Asia, and elsewhere, but most are native to the Americas. Moreover, because "pigweed" is also a name for some members of genus *Amaranthus,* and "lamb's-quarter" another name for some members of genus *Valerianella,* we quickly sink into semantic quicksand. Goosefoot today is a weed with leaves that are sometimes gathered and eaten as a vegetable. In the pre-Columbian New World, goosefoot leaves were similarly gathered and used, but in Mesoamerica and the Andean region, the grains of another close relative, quinoa, were consumed as a cereal.

Common names and synonyms: Lamb's-quarter, pigweed.

GOOSEGRASS – A number of different grasses are named goosegrass, including several plants of the genus *Galium* (especially *G. aparine* – also called "cleavers" and "catchweed"), along with *Eleusine indica* and *Potentilla anserina,* among many others. The seeds of some were reportedly used for food by Native Americans.

Common names and synonyms: Catchweed, cleavers.

Gorget – *see* **POKEWEED**

Gota kola – *see* **PENNYWORT**

Gourd – *see* **PUMPKIN, SQUASH AND PUMPKIN**

GOVERNOR'S PLUM (*see also* **PLUM**) – Also called the "botoko plum" and "ramontochi," the governor's plum (*Flacourtia indica*) originated in South Asia and grows in tropical Africa but enjoys its greatest popularity in the West Indies. The plum is a small, purple fruit about the size of a large grape. High in vitamin C, governor's plums are regularly cooked and eaten with fish and make an excellent jelly.

Common names and synonyms: Botoko plum, ramontochi.

Gow kee – *see* **MATRIMONY VINE**

Goyave – *see* **GUAVA**

Grains-of-paradise – *see* **MELEGUETA PEPPER**

Gram – *see* **CHICKPEA**

Gram pea – *see* **CHICKPEA**

Granada – *see* **POMEGRANATE**

Granadilla – *see* **GIANT GRANADILLA, MAYPOP, PASSION FRUIT**

Granny's-bonnet – *see* **HABANERO AND SCOTCH BONNET PEPPERS**

Grão do bico – *see* **CHICKPEA**

GRAPEFRUIT (*see also* **CITRUS FRUITS**) – A large and tart member of the citrus family, the grapefruit (*Citrus* × *paradisi*) is so named because it grows in clusters like grapes. Its origins, however, are something of a mystery. All members of the citrus family (lemons, oranges, limes, etc.), save for the grapefruit, are native to Southeast Asia. The grapefruit, it seems, although of Southeast Asian parents, was born in the Americas. It is believed that one of its progenitors – the pomelo (*C. maxima*) – somehow crossed the Indian Ocean and moved about the Middle East, eventually reaching Europe and then sailing off to the West Indies. There, perhaps in the eighteenth century, it may be that either a mutation occurred or the pomelo was crossed with an orange, with the modern grapefruit the result.

But further confusing the picture was the arrival in the Americas around 1800 of a ship commanded by Captain James Shaddock, who brought a cargo of pomelos (or grapefruit), claiming that he had discovered them in the Fiji Islands. Consequently, the grapefruit was subsequently called "shaddock" in America. A variation on the story would have the captain taking the fruits to England, whereupon they were carried by the British to the Caribbean. A third version would have the pomelo reaching Florida, where it was hybridized with orange pollen for sweetness, and the grapefruit came into being. The Ruby Red grapefruit variety was definitely the result of a seed mutation in McAllen, Texas, in 1929. Certainly, the grapefruit has long been one of the most popular citrus fruits in North America, but it was only following World War II that it became a breakfast food in Europe – the result of American influence. Like all citrus fruits, the grapefruit is high in vitamin C.

Common names and synonyms: Marsh grapefruit, Ruby Red, shaddock, Thompson grapefruit, Webb grapefruit.

GRAPE LEAF – Greek and Middle Eastern recipes frequently call for young grape leaves (genus *Vitis*) to be wrapped around meat, rice, and other fillings, making little packages for poaching or steaming. The fresh leaves are generally first steamed or blanched. Grape leaves can also be purchased in cans.

GRAPES (*see also* **RAISIN**) – Botanically, the grape is a berry of any species of *Vitis,* the genus of the vine family that was growing wild over much of the earth long before there were humans about. In North America, the vines evolved toward the species *V. labrusca* – the fox grape, one variety of which is the Concord grape. But practically all of the world's wine comes from varieties of a single Old World species, *V. vinifera* – the vine that bears wine. It is thought to have originated in Asia Minor and, as people early discovered (to their delight) that grapes and their juice ferment, has been cultivated for some 6,000 years.

Perhaps the Egyptians initially exploited the grape on a large scale. New varieties were developed by the Greeks and, later, by the Romans, who first practiced grafting and who introduced the vines into the cooler regions of Europe, including what is now France. Over the centuries, human intervention has given rise to a great number of varieties, such as the Chardonnay, the Pinot Noir, and the Riesling, along with the many different grapes of Bordeaux, Burgundy, and the Rhineland, to name but a very few regions.

Although it is largely because of wine that the grape is one of the most heavily cultivated of all fruit crops, grapes are also eaten as fresh fruit. Until the beginning of the twentieth century, however, table grapes were not marketed but rather were consumed by those who grew them. (The grapes that make the best wine do not necessarily make the best dessert grapes.) Today, California table grapes include the Calmeria, the Christmas Rose, the Emperor, the Exotic, the Flame Seedless, the Perlette, the Red Globe (about the size of a small plum), the Ribier, the Ruby Seedless, the Superior, and the Thompson Seedless.

Table grapes that do not "measure up" to table-grape standards are made into juice and other nonalcoholic beverages. In 1869, "Welch's Grape Juice" was born in Vineland, New Jersey (but later moved to Watkin's Glen, New York), when prohibitionist Thomas Bramwell Welch developed a substitute for the wine used in his church's communion services. Grapes also become jellies and especially raisins, which have doubtless been eaten since humans discovered grapes. California is now the biggest producer of these wrinkly, sun-dried sweetmeats. In some cultures, the seeds of grapes have been consumed as well.

Common names and synonyms: Black grape, California grape, Calmeria, catawba, Christmas Rose, Concord grape, dessert grape, Emperor, European grape, Exotic, Flame Seedless, fox grape, green grape, muscadine, Perlette, Red Globe, Ribier, Ruby Seedless, scuppernong, southern fox grape, Superior grape, table grape, Thompson Seedless, wine grape.

See in addition: "Wine," Part III, Chapter 13.

Grass pea – *see* **CHICKLING VETCH**

Gravek-plant – *see* **TRAILING ARBUTUS**

Gray pea – *see* **PIGEON PEA**

Great angelica – *see* **PURPLESTEM ANGELICA**

Greater yam – *see* **WATER YAM**

Great green plum – *see* **BIG GREEN PLUM**

Grecian laurel – *see* **BAY LEAF**

Green bell pepper – *see* **SWEET PEPPERS**

Greenbriar – *see* **GREENBRIER**

GREENBRIER – A number of plants of the genus *Smilax* are called greenbrier, especially the prickly vine *S. rotundifolia*, found in the eastern United States. Its roots were used by Native Americans for starch, and the shoots were eaten both raw and cooked as a vegetable. Other species in Asia are still in use as food, including their berries. The roots of some American species, such as *S. aristolochiifolia,* provide sarsaparilla.

Common names and synonyms: Bullbrier, catbrier, greenbriar.

Greengage – *see* **PLUM**

Green gram – *see* **MUNG BEAN**

Green haricot – *see* **BEANS**

Green leaf – *see* **AMARANTH**

Green lemon – *see* **LIME**

Green mung bean – *see* **LENTIL(S)**

Green Oriental radish – *see* **DAIKON**

Green pepper – *see* **SWEET PEPPERS**

GREEN SAPOTE – Another of the sapotes, the green sapote (*Calocarpum viride = Pouteria viridis*) grows on a large, tropical, American evergreen tree. The fruits, each containing a single big seed, are ovoid and up to 6 inches long. The inner pulp of the fruit has a rich, sweet, creamy flavor.

Common names and synonyms: Injerto.

Green sloke – *see* **SEAWEED**

Green snap bean – *see* **BEANS**

Green Swiss chard – *see* **SWISS CHARD**

Green tea – *see* **TEA**

Green tomato – *see* **TOMATILLO**

GRENACHE (*see also* **GRAPES**) – There are both red and white Grenache grapes (*Vitis vinifera*), but unless white (Grenache Blanc or Garnacha Blanc) is specified, "Grenache" refers to the red version, Grenache Noir. The grape – the second most important in the world – is grown in Spain (there, it is called Garnacha) and California and is especially popular in the Rhône Valley of France. Grenache grapes have a high level of sugar and consequently can produce wines with a high percentage of alcohol.

Common names and synonyms: Garnacha, Garnacha Blanc, Grenache Blanc, Grenache Noir.

See in addition: "Wine," Part III, Chapter 13.

Grenache Blanc – *see* **GRENACHE**

Grenache Noir – *see* **GRENACHE**

Grenade – *see* **POMEGRANATE**

Grenadine – *see* **POMEGRANATE**

Groseille à maquereau – *see* **GOOSEBERRY**

Grosella – *see* **OTAHEITE GOOSEBERRY**

Ground bean – *see* **HAUSA GROUNDNUT**

Groundcherry – *see* **CAPE GOOSEBERRY**

GROUND IVY – Also called "gill-over-the-ground," ground ivy (*Glechoma hederacea*) is a Eurasian native. A creeping or trailing aromatic plant with small purple flowers, it has been used as a potherb and for making tisanes.

Common names and synonyms: Gill-over-the-ground.

Groundnut – *see* **APIOS, BAMBARA GROUNDNUT, HAUSA GROUNDNUT, PEANUT**

Ground pea – *see* **BAMBARA GROUNDNUT**

GRUMICHAMA – A Brazilian shrub, now grown in the West Indies and South Florida, the grumichama (*Eugenia dombeyi = E. brasiliensis*) has a very pleasant-tasting, purple-black fruit about the size and flavor of a cherry.

Gruya – *see* **ACHIRA**

Guaba – *see* **ICE-CREAM BEAN**

Guacimo – *see* **MUTAMBA**

Guaje – *see* **LEUCAENA**

GUAJILLO AND PULLA CHILLIES (*see also* **CHLLI PEPPERS**) – These two closely related chillies (*Capsicum annuum*) are very common in Mexico. Both grow to upward of 6 inches in length, are orange red in color, are tapered like an Anaheim, and are generally dried. The difference is mostly in the heat they produce. The *guajillo* is a relatively mild chilli that goes well in salsas and makes a fine chilli sauce. The *pulla* is used in the same ways but adds substantially more "fire" to dishes. Another relative, the *costeño,* is roughly the same color and also dried but is only about half as long and is even hotter than the *pulla*.

Common names and synonyms: Costeño.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Guajilote – *see* **CUAJILOTE**

Guama – *see* **ICE-CREAM BEAN**

Guamochil – *see* **PITHECELLOBIUM**

Guanabana – *see* **SOURSOP**

GUAR (*see also* **LEGUMES**) – Also called "clusterbean" because of the way its pods cluster together, the guar (*Cyamopsis tetragonolobus*) is a native of India. This drought-tolerant legume has long been cultivated there for use in vegetarian cooking. Its small, hairy pods, which resemble soybeans, are picked when very young for human consumption. The rest are employed for fodder or for their seeds, which contain a gum used as a thickening agent.

Common names and synonyms: Clusterbean, *Gwaar ki phalli.*

GUARANÁ – A Brazilian climbing shrub that yields seeds from which a dried paste is made, guaraná (*Paullinia cupana*) contains much caffeine and tannin. The paste is employed medicinally, but the most important use of guaraná is as a base for the guaraná beverage, which is an enormously popular soft drink in Brazil.

Guasima – *see* **MUTAMBA**

GUAVA (*see also* **FEIJOA, ICE-CREAM BEAN, STRAWBERRY GUAVA, WILD GUAVA**) – Easily identified by an intense tropical aroma, the guava (*Psidium guajava*) is native to Brazil and possibly the Caribbean region. Today, however, its many varieties are commercially produced in Hawaii, Australia, India, Colombia, Venezuela, Mexico, South Africa, and Southeast Asia. There are also guava groves in Florida and California. The guava is highly vulnerable to fruit-fly infestation and therefore is rarely a welcome import. The fruit is usually pear shaped but sometimes round, ranges in size from that of a small egg to that of a large orange, and can taste either sweet or sour. The skin is almost always yellow green or pale yellow, and the meaty flesh runs from white to yellow or from pinkish to red. Guavas are eaten whole, sliced into salads, and made into guava paste or jelly for spreading on bread and crackers; they are also employed to make syrup and vinegar and are even boiled down to become "guava cheese." Guavas are rich in vitamin A, the B complex, and vitamin C.

Common names and synonyms: Brazilian guava, common guava, goyave, *guayaba,* Guinea guava, guyaba, lemon guava, montain guava, purple guava, *waiawi-'ula'ula.*

Guava machete – *see* **ICE-CREAM BEAN**

Guavo-bejuco – *see* **ICE-CREAM BEAN**

Guayaba – *see* **GUAVA**

Gucil – *see* **BUSH CURRANT**

Güero – *see* **WAX PEPPERS**

Guiana chestnut – *see* **MALABAR NUT**

Guigne – *see* **CHERRY**

GUINEA ARROWROOT – This perennial (*Calathea allouia*) has been cultivated by indigenous farmers in its tropical American habitat for more than a millennium. In Brazilian Amazonia, the plant held an important place in the diet and culture of native peoples until as recently as the 1950s. Increasingly, however, it has been abandoned by its traditional growers in favor of other crops or food products from industrialized regions. The Guinea arrowroot, also known as "sweet-cornroot" or "leren" (and *lerenes* in Puerto Rico), has several relatively large leaves (2 to 4 feet long) and white flowers aboveground, but it is cultivated for its tubers, which (like the potatoes they resemble) grow underground.

These roots are a rich source of many essential amino acids and are valued for their texture (which remains crisp even after cooking) and for their flavor (said to resemble that of green maize). Now grown throughout many parts of the world, including various countries in South America, Africa, and Asia, and particularly in Puerto Rico and other Caribbean islands, the Guinea arrowroot enhances numerous salads, stews, and fish dishes.

Common names and synonyms: Allouya, leren, *lerenes, llerén, llerenes,* sweet-corm-root, *topee-tambu.*

Guinea corn – *see* **MAIZE, SORGHUM**
Guinea grains – *see* **MELEGUETA PEPPER**
Guinea squash – *see* **EGGPLANT**
Guinea yam – *see* **WHITE YAM, YELLOW YAM**
Guine pepper – *see* **CAYENNE PEPPER**
Güiro – *see* **XICALLI**
Guispui – *see* **CHAYOTE**
Gulfweed – *see* **SEAWEED**
Gully bean – *see* **EGGPLANT**
Gum arabic – *see* **ACACIA**
Gumbo – *see* **OKRA**

GUM PLANT (*see also* **YERBA SANTA**) – Also known as "gumweed," the gum plant (*Grindelia robusta* or *G. squarrosa*) is found in western North America. It grows to about 18 inches in height, and its name derives from a resinous substance that covers the entire plant. Native Americans made tea from its leaves, which they also chewed.

Common names and synonyms: Gumweed.

Gum tree – *see* **MANNA GUM**
Gumweed – *see* **GUM PLANT**
Gungo pea – *see* **PIGEON PEA**
Gunpowder – *see* **TEA**
Guyaba – *see* **GUAVA**
Guyana chestnut – *see* **MALABAR NUT**
Gwaar ki phalli – *see* **GUAR**

H

HABANERO AND SCOTCH BONNET PEPPERS (*see also* **CHILLI PEPPERS**) – The name habanero implies that the first of these small, lantern-shaped chillies (they look like miniature, collapsed bell peppers) is a native of Havana, which seems to be contradicted both by its scientific name *Capsicum chinense* (most chilli peppers are *C. annuum*) and by the fact that it is most extensively cultivated and consumed in Central America and the Yucatán. It is slightly larger than its very close relative the Scotch Bonnet (it does look a bit like one), which is grown mostly on Jamaica and other Caribbean islands, and with which it is regularly confused. The confusion is eminently understandable because they do resemble each other, in their colors (red, green, orange, and yellow) and because they hold the distinction of being the hottest domesticated peppers in the world.

In a very close second place, however, are two other relatives. One is the Jamaican hot pepper, which is always a bright red but is similar in shape to both the habanero and the Scotch Bonnet. The other is the Rocotillo (sometimes called rocoto or squash pepper because of a resemblance to pattypan squash), a South American chilli that ranges from red to pale yellow in color and is a frequent addition to ceviches.

A major use of these peppers (save for the Rocotillo) is in commercially prepared hot sauces (now available in astounding variety), with the Scotch Bonnet prevailing in Jamaican jerk sauces and the Jamaican hot pepper foremost in Caribbean chutneys and curries. Habaneros and Scotch Bonnets are also much used in the preparation of numerous dishes as well as sauces in Central and South America and in West Africa, where, as in the Caribbean, they are greatly appreciated.

Common names and synonyms: Bonnet pepper, Granny's-bonnet, Jamaican hot pepper, Jamaican Red, Rocotillo, rocoto, squash pepper.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Habichuela – *see* **HYACINTH BEAN**
Hachiya – *see* **PERSIMMON**

HACKBERRY (*see also* **BERRIES**) – The genus *Celtis* encompasses a number of trees and shrubs that have a berry-like, often edible fruit that is sometimes called a "sugarberry." The hackberry was an important food gathered in late fall and early winter by Native Americans for thousands of years. As with the American persimmon, the berries are best after the first frost. Hackberry seeds have also served as a food.

Common names and synonyms: Sugarberry.

Hakusai – *see* **CHINESE CABBAGE**

HAMBURG PARSLEY (*see also* **PARSLEY**) – Popular in central Europe, Hamburg parsley (*Petroselinum crispum* var. *tuberosum*) is a variety of parsley cultivated not for its leaves but for its edible root, which resembles a small parsnip. It has a strong taste that is appreciated in stews.

HANOVER KALE (*see also* **CABBAGE, KALE**) – Another member of the cabbage family, Hanover kale (*Brassica napus*) has leaves similar to those of spinach. They are used in salads and cooked as a vegetable.

Common names and synonyms: Hanover salad, spring kale.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Harebell – *see* **CAMPANULA**
Haricot – *see* **BEANS**
Haricot riz – *see* **RICE BEAN**
Harlock – *see* **BURDOCK**
Haselnuss – *see* **HAZELNUT AND FILBERT**
Hass – *see* **AVOCADO**

HAUSA GROUNDNUT – Also called "ground bean" and "Kersting's groundnut," the Hausa groundnut (*Kerstingiella geocarpa* = *Macrotyloma geocarpa*) is an herb cultivated in the drier portions of western Africa from Senegal to Nigeria. It produces pods that contain from 1 to 3 kidney-shaped seeds. The seeds are high in protein, and the leaves are also cooked as a vegetable. The Hausa groundnut is very similar to the more wide-ranging bambara groundnut.

Common names and synonyms: Ground bean, groundnut, Kersting's groundnut.

Hausa potato – *see* **KAFFIR POTATO, SUDAN POTATO**

Hautbois – *see* **WILD STRAWBERRY**

HAW (*see also* **BERRIES, BLACK HAW, HAWTHORN BERRY, SLOE**) – The reddish fruit of the hawthorn (genus *Crataegus*) is known as a haw. But in the United States the term has signified the bluish black, plumlike fruit of the blackthorn (*Prunus spinosa,* a Eurasian shrub) as well; this fruit is also called "sloe" and is used to flavor sloe gin. And the semantic confusion goes even further because the fruit of one of the hawthorns of southeastern North America (*C. uniflora*) is called both a "pear haw" and a "blackthorn." Haws were well utilized by Native Americans, who ate them raw and also dried them to make pemmican. The leaves of some species were eaten as well.

Common names and synonyms: Blackthorn, pear haw, sloe, stagbush.

Hawaiian Kona coffee – *see* **COFFEE**

HAWAIIAN PLANTAIN (*see also* **PLANTAIN**) – Perhaps better known as *hua moa,* the Hawaiian plantain (*Musa* × *sapientum*) is a common plantain of many Pacific Islands. In 1960, William F. Whitman brought the plant to the United States from Tahiti, and it has since found a comfortable niche in southern Florida and special favor with Cuban-Americans. The fruit is shorter but much thicker than the usual plantains and often looks as if two bananas were enveloped by the same skin. It is used like other plantains for frying and cooking in the unripe state but is also eaten out of hand when ripe.

Common names and synonyms: Hua moa.

See in addition: "Bananas and Plantains," Part II, Section B, Chapter 1.

Hawthorn – *see* **BLACK HAW, HAWTHORN BERRY**

HAWTHORN BERRY (*see also* **BERRIES**) – The genus *Crataegus* is comprised of a great number of thorny shrubs and trees that bear a reddish fruit called a haw. In England, the white to pink blossoms of the hawthorn, which appear in May, inspired the name of the ship *Mayflower.* The berry is actually a small pome fruit with a high sugar content. In the United States, those hawthorns that still have fruit in the winter help to sustain wildlife until spring. This "winter fruit" did the same for Native Americans.

Common names and synonyms: Cockspur thorn, downy haw, haw, hawthorn, haw tree (archaic), mayhaw, red haw, scarlet haw.

Haw tree – *see* **HAWTHORN BERRY**

HAZELNUT AND FILBERT – The term "hazelnut" has been used so interchangeably with "filbert" that the two are sometimes listed as synonymous in dictionaries – and no wonder, because they appear as practically identical, have the same sweet taste, and grow on shrubs or trees that are members of the birch family. But despite the German word *Haselnuss,* filberts come from Eurasian plants (*Corylus avellana,* the European filbert, and *C. maxima,* the giant filbert), whereas the hazelnut comes from an American shrub (*C. americana*). To add to the confusion, "hazelnut" (instead of "filbert") was apparently the name first given to this acorn-like nut in Europe because of its medium brown color (for example, the French word *noisette* means both the nut and the color). The name was later changed to filbert because St. Philbert's day falls on August 22, the day the nuts are supposedly finally ripe in France. The American hazelnut is found mostly in the eastern United States. In the Pacific states, imported filbert trees are cultivated. But, most of North America's hazelnuts are actually filberts imported from Turkey. For those who would dwell on the differences between hazelnuts and filberts, another has to do with the outer husks – those of hazelnuts are shorter, whereas the filbert husk extends beyond the nut. Like all nuts, hazelnuts and filberts alike provide some selenium, calcium, and iron, are rich in folacin, and supply vitamin E and the B complex.

Common names and synonyms: American hazelnut, beaked hazel, Chinese filbert, Chinese hazel, Chinese hazelnut, cob, cobnut, curri, European filbert, European hazel, giant filbert, *Haselnuss,* Himalayan hazel, Lambert's filbert, *noisette,* Siberian hazel, Tibetan filbert, Tibetan hazelnut, Turkish filbert, Turkish hazel.

Heartnut – *see* **WALNUT**

HEART(S) OF PALM – There are thousands of palm species in the world's tropics, all with edible "hearts," of which perhaps 100 have hearts large enough to be commercially valuable. In the United States the hearts have in the past often meant the terminal buds of the palmetto, a small palm (*Sabal palmetto* – called the "cabbage palm") that grows in Florida. More recently, the hearts have been the buds of South American (and especially Brazilian) members of the families Palmae and Arecaceae. The whole heart can weigh some 2 to 3 pounds and may be cut up and fried or boiled, as was the case in old Florida, where the vegetable was called "swamp cabbage." Most palm hearts today, however, are stripped of their tough husk, cut into small cylinders, and canned for use in salads or as a snack or appetizer served with a sauce. They have a delicate, asparagus-like flavor. Fortunately, the palms grow prolifically, because removing the heart kills the tree.

Common names and synonyms: Cabbage palm, palmetto, palm heart(s), swamp cabbage.

Heart snakeroot – *see* **WILD GINGER**

Heath – *see* **HEATHER**

HEATHER – Eurasian heather consists of *Calluna vulgaris* and several related plants of the genus *Erica.* Also called ling, heather grows in dense masses, with clusters of pink and purplish flowers. Heather ale – a traditional Scottish beverage – is made from the blossoms. In the southwest of North America, Native Americans have used the berries of the heather "manzanita" (*Arctostaphylos uva-ursi* – also called bearberry) for food and for making a beverage.

Common names and synonyms: Bearberry, heath, ling, pointleaf manzanita.

Heath pea – *see* **EARTH NUT**

Hedged gourd – *see* **KIWANO**

Hedge garlic – *see* **GARLIC-MUSTARD**

HEMLOCK – The soft inner bark of a few species of the evergreen trees of the genus *Tsuga* was used as food by Native Americans. That of western hemlock (*T. heterophylla*) and mountain hemlock (*T. mertensiana*) was shaped into loaves for baking. The bark of the eastern hemlock (*T. canadensis*) was also eaten, and its leaves were used to make a tea.

Common names and synonyms: Eastern hemlock, mountain hemlock, western hemlock.

HEMP DOGBANE – An American native that grows as a weed throughout the United States, hemp dogbane (*Apocynum cannabinum* – also known as Indian hemp) – has a rootstock that has long been used for medicinal purposes. The plant's leaves are poisonous, but its seeds were employed as food by Native Americans.

Common names and synonyms: Black hemp, black Indian hemp, Choctaw-root, dogbane, Indian hemp.

HEMP SEED – The seeds of hemp (*Cannabis sativa*), an Asiatic herb, yield a fatty oil that is used in cooking, mostly in Asia. The seeds have been cultivated for thousands of years and were often roasted for consumption. This plant that we know as marijuana has also long been a source of fiber for rope making.

Hemp tree – *see* **CHASTE TREE**

HERB BENNET – Also called the "blessed herb" and "avens," the herb bennet (*Geum urbanum*) is a European plant with yellow flowers and an odor of cloves. It has been grown or gathered as a potherb and has long been used to make a tea.

Common names and synonyms: Avens, blessed herb.

Herb-of-grace – *see* **RUE**

Hicaco – *see* **COCOPLUM**

HICKORY (*see also* **PECAN**) – Hickories (of the genus *Carya*) are American members of the walnut family that produce edible nuts. The only commercially important one of these nuts is the pecan (treated in a separate entry). Hickories are widespread throughout eastern and central North America and yield an incredible variety of nuts, the most abundant and popular of which come from the shagbark hickory (*C. ovata*).

Historically, these have been divided into thick-shell shagbarks and thin-shell shagbarks, with the latter nuts considered the most desirable because their meat is more easily obtainable. Native Americans of central and eastern North America made hickory nuts a regular part of their diet. Hickory nuts have a sweet flavor and are much used in baking. Chunks and chips of hickory wood are used to flavor barbecued and smoked meats. Hickory nuts provide calcium, potassium, iron, vitamin E, and the vitamins of the B complex.

Common names and synonyms: Shagbark, thick-shell shagbark, thin-shell shagbark.

HIGHBUSH CRANBERRY – A North American shrub, the highbush cranberry (*Viburnum trilobum*) has scarlet berries that are often mistakenly called "cranberries" and are used as a cranberry substitute in sauces. They were employed by Native Americans as a medicine and in stews, as well as for making teas and pemmican. The berries are low in calories and high in vitamin C and potassium.

Common names and synonyms: Cramp bark, cranberry bush, squaw bush, viburnum.

Higüero – *see* **XICALLI**

Hijiki – *see* **SEAWEED**

HINAU BERRY – The hinau (*Elaeocarpus dentatus*) is a New Zealand timber tree that produces an edible berry. The latter was one of the many gathered foods that sustained the Maori – the aboriginal people of New Zealand.

Hing – *see* **ASAFETIDA**

Hoarhound – *see* **HOREHOUND**

HOG PEANUT – Also called the wild peanut, the hog peanut (*Amphicarpaea bracteata*), a native of central North America, is a brown, edible seed. It comes in an underground pod, resembles a peanut, and is much appreciated by hogs. However, long before hogs arrived to root for these subterranean fruits, hog peanuts were being dug by Native Americans, for whom they were an important dietary item.

Common names and synonyms: Wild peanut.

HOG PLUM (*see also* **PLUM**) – Quite a few fruits go by the name of "hog plum." One is *Spondias pinnata,* a Malayan fruit also called *amra.* It is not much appreciated as it is said to smell of rotting apples. More popular in that part of the world is the "great hog plum" (*S. cytherea*), also known as *kĕdondong,* which has an oblong fruit that is yellow with whitish flesh when ripe. These fruits are eaten raw and stewed and also made into a jam or chutney. Other *Spondias* plants, such as *S. mombin* (the "yellow mombin") and *S. purpurea* (variously named "Spanish plum," "Jamaican plum," and "red mombin"), have edible fruits that resemble plum-sized mangoes and are called "hog plum" by some. In the United States, *Prunus americana* grows wild in its native Florida and South Carolina. Sometimes called a hog plum, it, too, is a small, oval-shaped fruit, which is generally made into jams and jellies.

Common names and synonyms: Amra, great hog plum, Jamaican plum, *ke̱dondong,* red mombin, Spanish plum, yellow mombin.

Hog salad – *see* **CORNSALAD**

Hogweed – *see* **HORSEWEED**

Hoka – *see* **KABOCHA (SQUASH)**

Hokkaido – *see* **BUTTERCUP SQUASH**

Holland chilli – *see* **DUTCH RED PEPPER**

HOLLAND GREENS (*see also* **CABBAGE**) – Also known as "tyfon," Holland greens (*Brassica rapa* 'tyfon') are the greens of a new plant – a cross between the Chinese cabbage and the turnip. The new plant is tolerant of cold, grows vigorously, and is reluctant to bolt. Holland greens are used in the same fashion as turnip greens or mustard greens or collards – in salads and as a cooked vegetable.

Common names and synonyms: Tyfon.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Holland pepper – *see* **SWEET PEPPERS**

Holly – *see* **DAHOON HOLLY, HOLLYBERRY, YAUPON, YERBA MATÉ**

HOLLYBERRY (*see also* **BERRIES**) – There are numerous trees and shrubs that we call holly, have bright red berries, and belong to the genus *Ilex.* Two are especially worthy of culinary comment. One is the American holly (*I. opaca*), native to the eastern United States, the berries of which yield an edible pulp that helped Native Americans with their vitamin C intake. The other is *I. paraguariensis,* native to Paraguay and Brazil in South America; its berries and leaves are employed to make yerba maté tea.

Common names and synonyms: American holly.

Holly-leaved barberry – *see* **BARBERRY**

Holly-leaved cherry – *see* **CHIMAJA**

Ho loan – *see* **SUGAR PEA**

HONEWORT – There are two related plants called honewort. One is *Cryptotaenia canadensis,* a native of North America; the other is a native of Japan – Japanese honewort (*C. japonica*), which is also called *mitsuba.* They are members of the carrot family, and the roots are often boiled and served with oil. The greens (which resemble flat Italian parsley) and stems have a distinctive flavor and are used as garnishes, eaten raw in salads, added to soups, and cooked as a vegetable. The Japanese variety is grown commercially in California for Japanese-Americans.

Common names and synonyms: Japanese honewort, Japanese parsley, *mitsuba.*

Honeyberry – *see* **SPANISH LIME**

HONEYDEW (MELON) (*see also* **MELONS**) – A winter melon (*Cucumis melo*), the honeydew has the advantage of keeping well for up to a month. As a consequence, these melons – about the size of large muskmelons, with a whitish rind and pale green flesh – are ubiquitous in produce markets.

Common names and synonyms: Winter melon.

See in addition: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

HONEY LOCUST – A tall, usually spiny tree of eastern North America, the honey locust (*Gleditsia triacanthos*) bears long, twisted pods that resemble beans. These were cooked and eaten by Native Americans, even though they are reported to be mildly toxic. Because the pods have a sweetish pulp surrounding the seeds, the tree is also known as sweet bean, sweet locust, and honeyshuck.

Common names and synonyms: Honeyshuck, sweet bean, sweet locust.

Honey mushroom – *see* **MUSHROOMS AND FUNGI**

Honeyshuck – *see* **HONEY LOCUST**

HONEYSUCKLE – There are a number of species of the genus *Lonicera* – called honeysuckle – spread about the globe, and some are or have been used as food. Others, however, are toxic and can even cause death. Probably the edible ones have been consumed since the early days of the hunter-gatherers because they are sweet, whereas many (but not all) of the poisonous species are bitter. Native Americans enjoyed the sweetness of a few species, and in Japan, the young leaves of *L. japonica* (the Japanese honeysuckle) are still used as a vegetable.

Common names and synonyms: Japanese honeysuckle.

Honey tree – *see* **JAPANESE RAISIN TREE**

Hoofs – *see* **COLTSFOOT**

Hoogly – *see* **UGLI FRUIT**

HOP(S) – There are several twining vines of the genus *Humulus* – especially *H. lupulus,* a Eurasian-American vine – that have green, cone-like flowers. When dried, the flowers yield a bitter, aromatic oil used in brewing beer. Hop plants have been cultivated in Germany for about 1,000 years and were once used to prevent beer from spoiling. Hops also put out shoots in the spring that can be gathered and cooked and eaten like asparagus. Doubtless they were consumed by hunter-gatherers in Eurasia, as well as by Native Americans in the Western Hemisphere.

Common names and synonyms: Hop plant.

See also: "Beer and Ale," Part III, Chapter 1.

Hop plant – *see* **HOP(S)**

HOPTREE – A tall shrub of eastern North America, the hoptree (*Ptelea trifoliata*) is so called because its bitter fruits have been used as a substitute for hops in flavoring beer. Native Americans also ground them for use as a condiment, and after malaria was imported from Europe and Africa, the bark of the hoptree's roots was sometimes used like quinine against the disease.

Common names and synonyms: Ague bark, waferash.

HOREHOUND – The bitter extract of horehound (*Marrubium vulgare*) comes from an aromatic plant of the mint family. It is an Old World native now naturalized in North America. Horehound is used in candies, cordials, and cough medicines and has been cultivated since antiquity for other medicinal uses. It is also said to have been employed as a condiment.

Common names and synonyms: Hoarhound.

Horned melon – *see* **KIWANO**

Horse balm – *see* **HORSEWEED**

Horsebean – *see* **FAVA BEAN, JACKBEAN**

Horse chestnut – *see* **BUCKEYE**

Horsefoot – *see* **COLTSFOOT**

Horse grain – *see* **HORSE GRAM**

HORSE GRAM – Also called "horse grain" and "bonavist bean," the horse gram (*Dolichos biflorus*) is a native of the Old World tropics (probably India) that grows on a twining herb. The plant is generally cultivated for fodder in Asia, but its immature seeds are also used as food for humans.

Common names and synonyms: Bonavist bean, horse grain.

See also: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

HORSE MANGO – Growing on a tree native to southern Asia that is some 70 feet in height, the horse mango (*Mangifera foetida*), reaches about 5 inches in length and about 3 inches in diameter. It is yellowish green when ripe and has a bright orange to yellow flesh. Unripe, the fruit contains a sap that irritates the skin and is not safe to eat. Even ripe the horse mango has a bad smell and consequently is seldom eaten raw. Instead, it is used in curries and made into chutney.

Common names and synonyms: Bachang.

Horsemint – *see* **BEE BALM, BERGAMOT**

HORSERADISH (*see also* **CABBAGE**) – A member of the cabbage family and a relative of the radish, horseradish (*Armoracia rusticana = A. lapathifolia*) is sometimes called "German mustard," perhaps because its strong, biting flavor derives from mustard oils that are released when the tissue of the root is cut. The latter is thick, white, and cylindrical, with a thin, brown skin, and is safe to eat even though the leaves and stems of the plant are said to contain a toxic substance.

Horseradish is native to southeastern Europe and western Asia (where it continues to grow wild) but is cultivated in most other parts of the world and has been naturalized in the northeastern United States and southern Canada. Traditionally, the root was peeled and grated in the home and served on the side with meats such as boiled beef. But grated horseradish became a commercial product in the first part of the nineteenth century. It was preserved in vinegar and bottled initially in brown bottles to disguise the turnip filler that was often included. In 1869, however, H. J. Heinz began his business at Sharpsburg, Pennsylvania, by packing processed horseradish in clear bottles.

Today, horseradish is generally bottled in combination with vinegar and salt, blended into a cream sauce, or mixed with mustard to become Creole mustard. Horseradish vinegar and horseradish powder are also horseradish products, as is red horseradish, which has had beet juice added to it. Horseradish is a good source of vitamin C.

Common names and synonyms: Creole mustard, German mustard, horse-reddish root (archaic), red horseradish.

See in addition: "Spices and Flavorings," Part II, Section F, Chapter 1.

Horseradish tree – *see* **BENOIL TREE**

HORSETAIL PLANT – Any of the various plants of the genus *Equisetum* are called horsetail. The field horsetail (*E. arvense*) of the United States and Canada produces brownish shoots that have been used medicinally, eaten as a vegetable, and made into tea. The plant also grows in Eurasia, where it long ago provided food for hunter-gatherers.

Common names and synonyms: Field horsetail.

HORSEWEED – Also called horse balm, butterweed, hogweed, mare's-tail, erigeron, and a host of other names, horseweed (*Erigeron canadensis = Conyza canadensis*) is a common herb found throughout North America. The boiled young seedlings served as food for Native Americans, and the plants were introduced in Japan, where they are still reportedly consumed. In addition, erigeron oil, which is used medicinally, is distilled from the plants.

Common names and synonyms: Butterweed, erigeron, hogweed, horse balm, mare's-tail.

Hot red pepper – *see* **CAYENNE PEPPER**

Huachinango – *see* **JALAPEÑO**

Hua moa – *see* **HAWAIIAN PLANTAIN**

Huautli – *see* **AMARANTH**

Huauzontle – *see* **QUINOA**

HUBBARD SQUASH (*see also* **SQUASH AND PUMPKIN**) – As old – as well as old-fashioned – squashes, the large Hubbards (*Cucurbita maxima*) are less popular today than in the past because they are indeed large, reaching 30 pounds or more, which frequently makes it necessary to sell them in pieces. The big Hubbards come in blue, orange, and green hues and generally have a wart-covered skin that can resist anything short of an axe in an attempt to carve them. Fortunately, there are now smaller Hubbards, such as the Baby Blue and Golden varieties, that come in a 5- to 15-pound range and are much easier to manage. Their flesh is a brilliant orange and has a superior taste.

Common names and synonyms: Baby Blue Hubbard, Golden Hubbard.

See in addition: "Squash," Part II, Section C, Chapter 8.

HUCKLEBERRY (*see also* **BERRIES**) – Any of a number of shrubs of the genus *Gaylussacia* bear huckleberries. They are American natives that traveled early to Europe. These blackish berries are often confused with blueberries (to which they are related) and are a great favorite of wildlife as well as humans, although they are not as sweet as blueberries. One of the many berries that were regular items in the diet of Native Americans, this berry also lent its name to the famous lad of literature, Huckleberry Finn. At one time, huckleberries were a staple food for Scottish Highlanders, who made them into – among other things – a wine. Huckleberries have become increasingly less popular with the commercial success of blueberries.

Common names and synonyms: Black huckleberry, common huckleberry, hurtleberry, whortleberry.

Hue – *see* **BOTTLE GOURD**

Huesito – *see* **ACEROLA**

HUITLACOCHE (*see also* **MUSHROOMS AND FUNGI**) – A maize-smut fungus, huitlacoche (*Ustilago maydis*) grows on cornstalks. It is a favorite in Mexico, where it can be found in restaurants and grocery stores, if only briefly during the summer. Huitlacoche is used in the same ways that mushrooms are used.

Common names and synonyms: Mexican corn fungus.

See in addition: "Fungi," Part II, Section C, Chapter 7.

HUNGARIAN CHERRY PEPPER (*see also* **CHILLI PEPPERS**) – A red and round pepper often encountered at salad bars, the Hungarian cherry pepper (*Capsicum annuum* L.) has numerous seeds and is generally sweet, although some can have a bit of a bite. The original area of domestication was probably Mexico, but these chillies are now distributed across the globe and are grown chiefly in California and eastern Europe, especially Hungary. Cherry peppers are often pickled and sold in jars. They are also dried to a mahogany color and used to flavor simmered dishes and to make sauces.

Common names and synonyms: Cherry pepper.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Hungarian grass – *see* **MILLET**

Hungarian sweet chilli – *see* **SWEET PEPPERS**

Hungarian wax pepper – *see* **WAX PEPPERS**

Hungarian yellow wax pepper – *see* **WAX PEPPERS**

Hungry rice – *see* **FONIO**

Hurtleberry – *see* **HUCKLEBERRY**

Husk tomato – *see* **TOMATILLO**

HYACINTH BEAN (*see also* **BEANS**) – Also known as the "lablab bean," "Egyptian bean," and *habichuela,* the hyacinth bean (*Lablab niger = L. purpureus*) probably originated in tropical Asia but was introduced in tropical Africa about a thousand years ago and spread with the slave trade to the West Indies and Central and South America. The seeds are generally available in cans as well as fresh and dried forms. The immature pods, along with the young leaves, are cooked as a vegetable and contain much in the way of vitamin C.

Common names and synonyms: Egyptian bean, *habichuela,* lablab bean.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

HYPTIS – There are several species of the genus *Hyptis,* the seeds of which were used as food by Native Americans and in some instances are still in use. One (*H. suaveolens*), a native of southern Mexico and Central America, is called "chan" or "wild spikenard"; its seeds, rich in linoleic acid, fed pre-Columbian peoples of the region. Two others, both called "desert lavender," are *H. albida* and *H. emoryi.* The former is a Mexican plant with leaves that are still used for flavoring foods. The latter, of the desert Southwest, provided seeds that were eaten whole, roasted, and ground into a meal. In addition, its minty leaves were used to make a tea.

Common names and synonyms: Chan, desert lavender.

Hyson – *see* **TEA**

HYSSOP – A venerable herb, native to the Mediterranean region and a member of the mint family, hyssop (*Hyssopus officinalis*) was employed by the ancient Greeks for medicinal purposes and is mentioned several times in the Bible (although some scholars believe that the "hyssop" of the Bible was not *H. officinalis*). The Arabs used it, and in the European Middle Ages hyssop was employed as a potherb. Its fresh leaves are aromatic, with a somewhat bitter taste, and are added to salads and pasta dishes. The dried leaves go well in soups and stews and are used in tisanes ("hyssop tea"). The purple hyssop flowers are also added to green salads, and hyssop oil flavors liqueurs such as the chartreuse and absinthe of France.

Common names and synonyms: Hyssop tea.

Hyssop tea – *see* **HYSSOP**

Hyuga – *see* **KABOCHA (SQUASH)**

I

Ibope – *see* **ALGARROBO**

Icaco – *see* **COCOPLUM**

Icaco plum – *see* **COCOPLUM**

ICE-CREAM BEAN – The ice-cream bean (*Inga vera*) apparently originated in Hispaniola, Jamaica, and Puerto Rico but has since joined *I. edulis* and other *Inga* species in Central and South America. The "beans" grow on evergreen trees that reach up to 60 feet in height and are widely used to shade coffee and cacao trees. The fruit is a hairy brown pod between 4 and 6 inches long that embraces a whitish pulp and several brown seeds. The pulp is eaten out of hand and used to flavor various desserts. In addition, Colombian Indians use the fruit to make *cachiri,* an alcoholic beverage. The blossoms are exceptionally rich in nectar and serve as a magnet for bees, thereby lending themselves to honey production.

Common names and synonyms: Cachira, guaba, guama, guava machete, guavo-bejuco.

Iceland lichen – *see* **ICELAND MOSS**

ICELAND MOSS – An edible lichen, Iceland moss (*Cetraria islandica*) is, as the name implies, found in northerly regions, frequently on heather moors. Its somewhat erect, reddish brown thallus lobes are boiled and dried before being ground into powder for use in baking.

Common names and synonyms: Iceland lichen, Island moss.

ICE PLANT – With a name like ice plant, it seems incongruous that this vegetable (*Mesembryanthemum crystallinum*) is a native of southern Africa and member of a family of some 600 species that are also mostly centered in that region. The name, however, has to do with its edible leaves, which are fleshy and seem to glint like ice crystals in the sunlight. They are cooked and eaten much like spinach.

Igope – *see* **ALGARROBO**

ILAMA – Another member of the family Annonaceae, the ilama (*Annona diversifolia*) is a fruit tree that grows on the Pacific slopes from Mexico to El Salvador but is most common in southwestern Guatemala. The fruit has a thin skin, which encloses flesh of a white to reddish color, and has the characteristically delicious, sweet flavor of the other "custard apples." Some find it better than the cherimoya; others think it inferior. The ilama is not, however, cultivated commercially on a large scale and is grown mostly by local peoples for their own consumption. Ilamas are eaten fresh and used as an ingredient in ice cream.

Common names and synonyms: Anona blanca.

IMBÉ – The trees of the imbé (*Garcinia livingstonei*) are grown mostly as ornamentals outside of their native habitat in East Africa. They are cultivated for fruit in Florida, but not commercially. The leaves are up to 6 inches in length and a glossy dark green; the fruits, which are yellow to orange in hue, are shaped somewhat like miniature apples and measure approximately 2 inches in diameter. They have a large seed covered by a small amount of juicy flesh and a thin, tender skin. The taste is pleasant but relatively tart, and imbé juice is noted for creating lasting stains. Most are eaten fresh, although some are employed in beverages.

Imbu – *see* **UMBÚ**

Imperial – *see* **TEA**

Inca wheat – *see* **QUINOA**

Indian almond – *see* **MALABAR ALMOND**

Indian bael – *see* **BAEL FRUIT**

Indian balm – *see* **TRILLIUM**

INDIAN BARK – Also known as "Indian cassia," Indian bark (*Cinnamomum tamala*) is a native of the Indian subcontinent and is grown extensively in northern India. Like its relatives, cassia and cinnamon, it is a tree cultivated for its bark, which is processed into a spice. In addition, its leaves are used as a flavoring in curries.

Common names and synonyms: Indian cassia.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

INDIAN BORAGE – Probably a native of Indonesia (it grows wild in Malaysia), Indian borage (*Coleus amboinicus*) is grown in Southeast Asia and the West Indies for its aromatic leaves, which can substitute for sage. Indeed, the herb is used exactly like sage for seasoning stuffings, poultry, and other dishes.

Indian breadroot – *see* **BREADROOT**

Indian buchu – *see* **MYRTLE**

Indian cassia – *see* **INDIAN BARK**

Indian corn – *see* **MAIZE**

Indian cress – *see* **NASTURTIUM**

INDIAN CUCUMBER – Also known as "Indian cucumber root," this member of the lily family is a small herb (*Medeola virginica*) native to eastern North America. Native Americans enjoyed the plant's crisp and succulent white rhizomes, which have a texture and taste similar to that of cucumbers.

Common names and synonyms: Indian cucumber root.

Indian cucumber root – *see* **INDIAN CUCUMBER**

Indian date – *see* **TAMARIND**

Indian fig – *see* **PRICKLY PEAR**

Indian gooseberry – *see* **AMALAKA, OTAHEITE GOOSEBERRY**

Indian hemp – *see* **HEMP DOGBANE**

Indian jujube – *see* **DESERT APPLE, JUJUBE**

INDIAN LONG PEPPER – A native of South Asia, the Indian long pepper (*Piper longum*) is a member of the genus that includes the common black and white peppercorns. It is grown mostly in India and Indonesia for its berries, which are dried and used as a spice – generally by adding them whole to curries, pickles, and the like.

Indian mulberry – *see* **MORINDA**

Indian mustard – *see* **MUSTARD GREENS**

Indian nut – *see* **PINE NUT**

Indian pea – *see* **PIGEON PEA**

Indian pear – *see* **PRICKLY PEAR**

Indian posy – *see* **BUTTERFLY WEED**

INDIAN POTATO (*see also* **APIOS, BREADROOT**) – Any of several native American plants with edible tubers are called "Indian potatoes." One is the groundnut (apios; another is the breadroot; still another is the giant sunflower (*Helianthus giganteus*), which is a tall North American plant with edible tuberous roots. Finally, there is the "yamp" (or "yampa," or "yampah" – *Carum gairdneri* or *C. kelloggii*); also called the "squawroot," this plant, too, has fleshy, edible roots. Another "yampah" is "Parish's yampah" (*Perideridia parishii*), of the parsley or carrot family. Native to the southwestern United States, this plant provided roots that were an important food for Native Americans and pioneers, who frequently ground them into a flour.

Common names and synonyms: Giant sunflower, Parish's yampah, squawroot, yamp, yampa, yampah.

INDIAN PRUNE – Known as *rukam manis* in its native Malaysia, the Indian prune (*Flacourtia rukam*) belongs to a large family of mostly tropical trees. It produces a dark purplish red, plumlike fruit that is juicy and sweet when ripe. These fruits are generally eaten raw but are also used for jams and chutneys.

Common names and synonyms: Rukam, rukam manis.

Indian rice – *see* **WILD RICE**

Indian ricegrass – *see* **RICEGRASS**

Indian saffron – *see* **TURMERIC**

Indian soap – *see* **SOAPBERRY**

Indian sorrel – *see* **ROSELLE**

Indian spice – *see* **CHASTE TREE**

Indian spinach – *see* **AMARANTH, MALABAR SPINACH**

INDIAN TURNIP (*see also* **BREADROOT**) – There are quite a few plants with the name "Indian turnip." One, also called "jack-in-the-pulpit" (*Arisaema triphyllum*), has an acrid but edible tuber. Another is *Eriogonum longifolium,* the roots of which were consumed by Native Americans in the western United States. The tuberous roots of several species of the genus *Psoralea* (known collectively as "breadroots" as well as "Indian turnips") were also consumed, often after being dried and later ground into flour, but they could also be eaten raw. The leaves of some species were cooked and eaten as a vegetable.

Common names and synonyms: Breadroot, jack-in-the-pulpit.

Indian walnut – *see* **CANDLENUT**

INDIAN WOOD-APPLE – Also known as the "elephant-apple," the Indian wood-apple (*Feronia limonia = Limonia acidissima*) is probably a native of India but now grows throughout Southeast Asia. The fruit – borne on a medium-sized tree – has a woody shell, making it difficult to get at its pulp, which consists of many seeds surrounded by a red, gummy substance. The fruit can be eaten raw but is used mostly to make jelly, chutney, and a refreshing drink.

Common names and synonyms: Elephant-apple.

Indonesian bay – *see* **DUAN SALAM**

Injerto – *see* **GREEN SAPOTE**

Inkberry – *see* **POKEWEED, WINTERBERRY**

Intermediate wheatgrass – *see* **WILD TRIGA**

IRIS – Any of the various members of the *Iridaceae* genus are called "iris," which includes colorful, herbaceous plants that develop from rhizomes or bulbs. It is the rhizomes that serve as a food for humans, especially in East Asia. The roots of *I. germanica,* known as "orris root," are pulverized and used in perfumery, medicines, and as a flavoring in certain gins.

Common names and synonyms: Flag, orris root.

Irish moss – *see* **CARRAGEEN AND CARRAGEENIN, SEAWEED**

Irish potato – *see* **WHITE POTATO**

Irish shamrock – *see* **WOOD SORREL**

Island moss – *see* **ICELAND MOSS**

Italian asparagus – *see* **BROCCOLI**

Italian brown mushroom – *see* **MUSHROOMS AND FUNGI**

Italian parsley – *see* **LOVAGE, PARSLEY**

Italian squash – *see* **ZUCCHINI**

Italian turnip – *see* **BROCCOLI RAAB**

IVY GOURD (*see also* **TANDOORI**) – Not to be confused with the tandoori, which is also called "ivy gourd," this ivy gourd (*Coccinea cordifolia = C. grandis*) is a native of tropical Asia and Africa. Also called the "small gourd," the plant is cultivated today in India, Indonesia, and Sudan. Its leaves, roots, and immature fruits are cooked as vegetables.

Common names and synonyms: Small gourd.

J

JABOTICABA – A member of the Myrtaceae family, the jaboticaba (*Myrciaria cauliflora*) is a very popular fruit in Brazil. It is also an unusual tree, because the fruit and flowers are borne on the trunk and on older branches. In color, it is a dark purple or nearly black fruit and its size – about a half inch in diameter – is that of a grape. Indeed, its pulp has the taste of a sweet grape, but the skin is tough and generally not eaten. The jaboticaba is consumed raw, used in salads, and made into jellies and wine.

Common names and synonyms: Brazilian grape, Brazilian grape tree.

Jaca – *see* **JACKFRUIT**

Jack – *see* **JACKFRUIT**

JACKBEAN (*see also* **BEANS**) – Also called the "horsebean" and the "cut-eye bean" and sometimes confused with the sword bean (a close relative), the jackbean (*Canavalia ensiformis*) originated in Central America and the Caribbean area but now is grown throughout much of the tropical and subtropical world. The young pods and seeds are employed as a cooked vegetable, and the seeds can be dried for later use.

Common names and synonyms: Cut-eye bean, horsebean, sword bean.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

Jack-Be-Little – *see* **DELICATA (SQUASH)**

JACKFRUIT – Also called "jakfruit," "jak," "nangka," and a half dozen other names mostly derived from the Portuguese *jaca,* the jackfruit (*Artocarpus heterophyllus = A. integrifolius*) is a tropical fruit closely related to the breadfruit. The consensus is that it is likely a native of India, but because it is of ancient cultivation and has spread so widely throughout tropical Asia, its original home will probably never be known with certainty. In more recent times, the jackfruit has also been grown in Africa and in tropical America, including Florida.

Like the breadfruit, the jackfruit can be large, with a length of up to 2 feet and a weight of up to 20 and, on occasion, even as much as 60 pounds. Layers of flesh around the seeds are sweet and can be eaten raw, but other parts of the fruit contain latex and must be cooked before eating. Often the seeds are roasted and eaten as well, either on their own or as an added seasoning in other dishes, especially curries. The jackfruit is rich in carbohydrates but offers little in the way of other nutrients.

Common names and synonyms: Jaca, jack, jack hirsutus Lam, jak, jakfruit, nangka.

Jack hirsutus Lam – *see* **JACKFRUIT**

Jack-in-the-pulpit – *see* **INDIAN TURNIP**

Jagua – *see* **GENIPAP**

Jak – *see* **JACKFRUIT**

Jakfruit – *see* **JACKFRUIT**

Jalapa hybrid – *see* **JALAPEÑO**

JALAPEÑO (*see also* **CHILLI PEPPERS**) – Named for the Mexican town of Jalapa, the jalapeño pepper (*Capsicum annuum*) is probably the best known of the hot chilli peppers and is believed to have been domesticated in Mexico long before the Spaniards arrived. Generally, jalapeños are purchased to be consumed while still green, but mature red fruits (with a sweeter flavor) are also readily available in most produce markets. The jalapeño is a fairly hot pepper and stars in many salsa preparations as well as in cooked dishes. Additionally, jalapeños are pickled and canned, stuffed as a snack, and roasted. Moreover, the ripe (red) form is dried and smoked (which imparts a chocolate-like flavor), after which it becomes a chipotle chilli, and the *huachinango,* a large and highly prized jalapeño, is similarly treated to become a chipotle grande.

The dried fruits are dark brown to black in color, are much gentler on the palate (with less heat) than the fresh peppers, and are available in cans in a red adobo sauce. Chipotles are vital to Mexican cuisine – as well as to that of the southwestern United States – and are used in stews, soups, and salsas. Other types of jalapeños that are smoked and dried include the *mora* or *mora rojo,* the *morita,* and the *mora grande* – the names indicating the relative sizes of these chillies, which range from about 3 inches to about 1 inch in length. And finally there is a new jalapeño – the Jalapa hybrid – which is more productive than its predecessors. Jalapeños are grown chiefly in Mexico (especially the *mora*), Texas, and New Mexico.

Common names and synonyms: Chipotle (chilli), chipotle grande, *huachinango,* Jalapa hybrid, *mora* chilli, *mora grande, mora rojo, morita.*

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Jamaica pepper – *see* **ALLSPICE**

Jamba oil – *see* **ARUGULA**

Jamberry – *see* **TOMATILLO**

JAMBOLAN (*see also* **JAMBOLAN PLUM, PLUM**) – A native of India and Java, the jambolan tree (*Eugenia cumini* or *Syzygium cumini*) has now spread throughout much of the world's tropics. Its fruits, green at first, turn purple as they ripen. They are about the size of a Damson plum and are mostly eaten raw, although in India a wine is made from the ripe ones and a vinegar from those that are still green.

Jambolana – *see* **JAMBOLAN PLUM**

JAMBOLAN PLUM (*see also* **PLUM**) – Also called the jambolan, the jambolana, and the Java plum, the jambolan plum (*Eugenia jambolana*) is the fruit of a large tree found mostly in the East Indies and Australia. The fruits are disappointing when eaten raw, and the seeds are very astringent. The bark of the tree is used medicinally.

Common names and synonyms: Jambolan, jambolana, Java plum.

Jambon du jardinier – *see* **EVENING PRIMROSE**

Jambos – *see* **JAVA APPLE, ROSE APPLE**

Jambu – *see* **JAVA APPLE, ROSE APPLE**

Jambu merah (tree) – *see* **MALAY APPLE**

Japanese greens – *see* **CHRYSANTHEMUM**

Japanese horseradish – *see* **WASABI**

Japanese medlar – *see* **LOQUAT**

JAPANESE MILLET (*see also* **MILLET**) – A quick-growing cereal, Japanese millet (*Echinochloa frumentacea*) can be ready for harvesting in about six weeks. It is also called "billion-dollar grass," and its light brown to purplish grains are used as a food in India and the Far East and serve as a quickly grown substitute if the rice crop fails.

Common names and synonyms: Billion-dollar grass.

See in addition: "Millets," Part II, Section A, Chapter 5.

Japanese mint – *see* **CORN MINT**

Japanese parsley – *see* **HONEWORT**

Japanese pear – *see* **ASIAN PEAR**

JAPANESE PLUM (*see also* **LOQUAT, PLUM**) – Thought to have originated in China – but domesticated in Japan – the Japanese plum (*Prunus salicina*) reached the United States around 1870 to become a popular fruit. It is relatively large for a plum (from 1.5 to 2 inches in diameter), reddish in color, and juicy when ripe. U.S. production is mostly in California.

Japanese potato – *see* **CHINESE ARTICHOKE**

Japanese pumpkin – *see* **KABOCHA (SQUASH)**

JAPANESE QUINCE – A native of China, the Japanese quince (*Chaenomeles speciosa*) is a small tree or shrub with scarlet flowers and widely grown as an ornamental. It produces a small fruit with a quince-like odor, which is generally made into jellies and jams.

Common names and synonyms: Japonica.

Japanese radish – *see* **DAIKON**

JAPANESE RAISIN TREE – Also called the "Chinese raisin tree," the Japanese raisin tree (*Hovenia dulcis*) is from both of these countries. A member of an Asiatic genus of trees and shrubs, it is a spicy-smelling plant that is grown for its sweet, swollen, reddish, edible flower stalks, which have a fruity taste.

Common names and synonyms: Chinese raisin tree, honey tree.

Japanese white celery mustard – *see* **PAKCHOI AND KAI CHOY**

Japanese white radish – *see* **DAIKON**

JAPANESE WINEBERRY (*see also* **BERRIES**) – Although the Japanese wineberry (*Rubus phoenicolasius*) is a native of Southeast Asia, it now grows wild in the southern Appalachian region of the United States. There it is called the "strawberry-raspberry" and resembles the latter of the two in appearance. Despite its designation as a "wineberry," the fruit is not, as a rule, made into wine, but it does yield a good-tasting juice.

Common names and synonyms: Strawberry-raspberry, wineberry.

Japonés – *see* **ASIAN CHILLIES, CHILLIES**

Japonica – *see* **JAPANESE QUINCE**

JASMINE – Any of a number of plants with extremely sweet-smelling flowers are called "jasmine" (genus *Jasminum*). The flowers are mostly prized for their essential oils that are used in perfumery, but they are also combined with black tea to make jasmine tea.

Java – *see* **COFFEE**

JAVA ALMOND – A member of an extensive genus of tropical plants, the Java almond (*Canarium commune*) is a large tree of the East Indies that produces rich, oily nuts of the same name. These are pressed for oil and used as food.

Common names and synonyms: Kanari.

JAVA APPLE – A native of Indonesia, the Java apple (*Eugenia javanica*) is one of the jambu fruits and, because of a similarity in both scientific and common names, often is confused with the rose apple. The Java apple, which is also known by the names "wax-apple" and "jambos," has fruits that are usually green, although some are pink or red, and they appear a little like miniature bell peppers. Called the wax-apple because of a skin that feels waxlike, the fruit is usually eaten raw but is also made into a sauce.

Common names and synonyms: Jambos, jambu, wax-apple.

Java jute – *see* **ROSELLE**

JAVANESE LONG PEPPER – Another member of the genus *Piper,* which includes common black and white peppercorns, the Javanese long pepper (*P. retrofractum = P. officinarum*) yields berries that are dried and added whole to curries and pickles. The Javanese long pepper is very much like its close relative, the Indian long pepper.

Java pepper – *see* **TAILED PEPPER**

Java plum – *see* **JAMBOLAN PLUM**

Jelly melon – *see* **KIWANO**

JELLY PALM – Also known as the pindo palm, the jelly palm (*Butia capitata*) is a native of South America and is now found throughout the West Indies and the U.S. South as far north as Georgia. It has white flowers that bloom in the spring, and the tree produces large bunches of yellow, orange, or pinkish fruits that are used to make jelly – hence the name. It might also have been called the "wine tree" after yet another use of the fruit.

Common names and synonyms: Pindo palm.

Jenny-stonecrop – *see* **STONECROP**

JERING – A native of tropical Asia, *Pithecellobium jiringa* has seeds that are boiled or roasted for food. The tree's young shoots and seed pods are also eaten.

JERUSALEM ARTICHOKE (*see also* **SUNFLOWER**) – Although widely cultivated around the world, Jerusalem artichokes (*Helianthus tuberosus*), which are the tubers of the American sunflower, are nowhere a major crop. In many places, however, these tubers serve as a minor source of food for humans and livestock. This vegetable is rather unusual among root and tuber crops in that the reserve food is inulin rather than starch. The plant is a hexaploid. Some have thought that *Helianthus annuus* (the wild sunflower) is involved as one of the parents in its origin, but it seems more likely that only perennial species figured in its ancestry.

The wild Jerusalem artichoke is widespread in eastern North America, and Native Americans adopted it as a cultivated plant in prehistoric times. The first written notice of the plant was provided in 1605 by Samuel de Champlain in his observations on the area that is now Massachusetts. Shortly after, the plant appeared in France and then spread throughout Europe. Its early reception as a food was favorable, one writer of the time stating that the tubers were "dainties for a Queene." Yet another was soon to state that they "caused the belly to be pained and [are] a meat more fit for swine, than man." But despite their flatulent properties, Jerusalem artichokes continue to be consumed, and in the United States in recent years they have enjoyed a renewed popularity. The tubers are generally eaten cooked, but they can be used raw in salads.

The name "Jerusalem artichoke" has generally been thought to be a corruption of the Italian *girasole articiocco.* The artichoke part is easily explained, for early writers found the taste to be similar to that of the more familiar globe (or French) artichoke. R. N. Salaman (1940), however, has suggested that Jerusalem is a corruption of Ter Neusen, a place in Holland from whence the tubers were imported into England.

Common names and synonyms: Gerasole, girasole, girsole, sunchoke.

See in addition: "Sunflower," Part II, Section E, Chapter 6.

Jerusalem oak – *see* **EPAZOTE**

JERUSALEM PEA (*see also* **BEANS, LEGUMES**) – A native of the East Indies but now cultivated mostly in West Africa, the Jerusalem pea (*Phaseolus trinervius*) is sometimes regarded as a variety of the mung bean. It grows wild in India, where it is considered a famine food. Each of the small pods of the Jerusalem pea contains about nine edible seeds.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

Jerusalem thorn – *see* **CHRIST'S-THORN FRUIT**

Jesuit nut – *see* **WATER CHESTNUT**

JEWELWEED – Several American and Eurasian species of the genus *Impatiens* are known as jewelweed or "touch-me-not." Their leaves and stems are used as food in Asia, and the same parts of *I. capensis* were boiled and eaten by Native Americans in eastern and central North America.

Common names and synonyms: Touch-me-not.

Jew plum – *see* **GOLDEN APPLE**

Jew's-ear – *see* **CLOUD EAR, MUSHROOMS AND FUNGI**

JEW'S-MALLOW – Also known as "jute mallow," Jew's-mallow (*Corchorus olitorus*) is a native of India that now grows in most of the world's tropical and subtropical regions. This stout herb is cultivated in Egypt, Syria, South America, and the Caribbean as a potherb and in India for its jute fiber. The young, tender, green leaves of Jew's-mallow – which are edible (and palatable) raw as well as cooked – have been used for food since the days of the hunter-gatherers. In Egypt, they are used to make the country's national dish – a thick soup called *molokhia.* The greens are high in beta-carotene, calcium, and vitamin C.

Common names and synonyms: Bush okra, jute, jute mallow, long-fruited jute, Nalta jute, Spanish okra, tossa jute, tussa jute, West African sorrel.

JÍCAMA – A plant that provides both a root vegetable and beans, the jícama (*Pachyrhizus erosus* = *Dolichos erosus*) is also called "Mexican potato," "yam bean," and "potato bean." The jícama is an American native that – along with a closely related species, *P. tuberosus* (also called "yam bean" and ajipo) – was cultivated long ago by the Aztecs and the Maya. The young pods are eaten as a cooked vegetable. The root is cylindrical and has a rough, sandy-colored skin, the removal of which reveals a white interior. In the past, the roots were normally eaten raw and enjoyed for their cool crispness rather than their bland flavor. Today, jícama remains a popular snack food eaten with lime juice in Mexico as well as California, where it is also grown. It can be baked like a potato but is mostly pickled and included in salads and casseroles. Until recently, jícama was practically unknown in North America, but now it can be found in most produce departments. Asian-American cooks occasionally employ it as a substitute for water chestnuts.

Common names and synonyms: Erosus yam bean, *jícama de agua, jícama de leche,* Mexican potato, potato bean, yam bean.

Jícama de agua – *see* **JÍCAMA**

Jícama de leche – *see* **JÍCAMA**

Jicara – *see* **XICALLI**

Jimsonweed – *see* **MOONFLOWER**

Jintan – *see* **ANISE, CARAWAY, CUMIN**

JOB'S-TEARS (*see also* **MILLET**) – A grass probably native to Southeast Asia, "Job's-tears" (*Coix lacryma-jobi*) now grows throughout the world's tropics, where it is sometimes cultivated and sometimes regarded as a weed. At one time, it was a major cereal in India, where people pounded its large, nut-flavored grains into flour, cooked them in gruels and soups, ate them whole, and used them to make teas and fermented beverages. The grain remains a minor cereal in India and elsewhere, and the pearly white seeds of some ornamental varieties are often sold as beads and strung to make necklaces.

Common names and synonyms: Adlay, adlay millet, tear-grass.

See in addition: "Millets," Part II, Section A, Chapter 5.

Johannisberg Riesling – *see* **RIESLING**

Johnson grass – *see* **SORGHUM**

JOJOBA NUT – About the size of an acorn, the jojoba nut (*Simmondsia chinensis*) is – despite its scientific name – native to the North American Southwest and the Baja peninsula. The nuts grow on a bush, usually in a wild state, although today they are also cultivated for their oil, which is used in lubricants and medicines. In the past, however, Native Americans made a coffee-like beverage from the nuts.

Common names and synonyms: Goat-nut.

Joseph's-coat – *see* **AMARANTH**

Judas('s) ear – *see* **CLOUD EAR**

Juglans – *see* **WALNUT**

JUJUBE (*see also* **DESERT APPLE**) – A native of China with a French name meaning "lozenge," the jujube (*Ziziphus jujuba*) resembles a large, dark red cherry. The spiny tree that bears jujubes has been cultivated by the Chinese for more than 4,000 years and has been growing in the Mediterranean region for some 2,500 years. It has spread throughout East Asia and is also grown in parts of Africa. The jujube was introduced in the United States in 1837; better varieties were obtained from China in 1906, and they continue to thrive in the hot, dry climate of the U.S. Southwest, although they are not grown on a large commercial scale.

Also called "Chinese dates" and "Chinese red dates," jujubes were often cooked in traditional Chinese households with millet or rice to make a kind of sweet porridge, and the dried fruit has always been especially popular. There are other very similar and related fruits. One, called the Indian jujube (*Z. mauritiana*), produces a fruit with a color ranging from yellowish to orange and brown and is now grown in Florida. Another – a Mediterranean variety, *Z. lotus* – yields a fruit that is like a sweet olive. This is said to be the fruit of the lotus-eaters described by Homer in the *Odyssey.* The "Christ-thorn" berry (*Z. spina-christi*) is yet one more relative. Jujubes are eaten fresh but are also baked, boiled, stewed, and made into syrup. The juice of the fruit is employed in making the small candies that are called "jujubes." Jujubes (the fruit) are rich in vitamin C.

Common names and synonyms: Chinese date, Chinese jujube, Chinese red date, common jujube, cottony jujube, Indian jujube.

Jumbie bean – *see* **LEUCAENA**

Juneberry – *see* **SERVICEBERRY**

Jungle banana – *see* **ENSETE**

Jungle plum – *see* **LITTLE GOOSEBERRY TREE**

JUNIPER BERRY – The fruits of a small evergreen tree or shrub, juniper berries (*Juniperus communis*) are legendary in folklore for their supposed medicinal and magical properties. Their most important application, however, lies in the oil derived from the dried berries, which is added to the final distillation of gin for flavoring. The spicy taste of juniper is also added to other liquors and foods. In cooking, the dried and crushed (to release their full powerful flavor) berries work well with wild game and are added to sauerkraut, sausages, stuffings, and marinades as well. In Europe during the Middle Ages, juniper berries were used to flavor beef, pork, mutton, and especially venison. A bit later on, they were one of the ingredients employed to adulterate pepper.

Juniper berries grow wild in most of the world's temperate regions. In North America, they were used as food by some Native American groups, who ate them fresh and also dried and ground them to make a mush. Others have roasted juniper berries as a coffee substitute. But their flavor and especially their potency varies considerably. The best are said to come from southern Europe in general and the mountainous regions of Italy in particular.

Common names and synonyms: Common juniper.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

JUNIPER MISTLETOE – A yellow-green mistletoe, juniper mistletoe (*Phoradendron juniperinum*) is parasitic to several species of juniper. It has translucent, globular berries that birds feed on, after which they carry the sticky seeds to other trees, thus spreading the parasite. At one time, the Navaho reportedly employed the berries for food, but today the juniper mistletoe is used only medicinally (by the Hopi Indians).

Common names and synonyms: Mistletoe.

Jute – *see* **JEW'S-MALLOW**

Jute mallow – *see* **JEW'S-MALLOW**

K

KABOCHA (SQUASH) (*see also* **SQUASH AND PUMPKIN**) – The name "kabocha" designates a group of squashes (*Cucurbita maxima* or *C. moschata*) that were developed in Japan and are exceptionally sweet and flavorful. Weighing an average of 3 to 4 pounds, they generally have thick, green skins with pale stripes and a yellow-orange flesh. The Japanese – who consume large amounts of squash on a per capita basis – are big importers of kabocha during the off-season, when they cannot grow it themselves. New Zealand and Mexico are major producers. Like other winter squashes, the kabocha contains much in the way of vitamins A and C.

Common names and synonyms: Chirimen, Delica, ebisu, hoka, Home Delite, hyuga, Japanese pumpkin, Sweet Mama.

See in addition: "Squash," Part II, Section C, Chapter 8.

Kachun – *see* **PEPINO**

Kaffir corn – *see* **SORGHUM**

Kaffir date – *see* **KAFFIR PLUM**

KAFFIR LIME (*see also* **CITRUS FRUITS**) – A species of *Citrus* grown in Southeast Asia, the Kaffir lime (*C. hystrix*) is cultivated more for its leaves than for its fruit, although its juice is used as a flavoring. The leaves are employed both fresh and dried (like bay leaves) in soups, curries, sauces, and gravies. Powdered leaves of the Kaffir lime can be found in Asian markets, but these are not totally satisfactory as a substitute for the whole leaves.

Common names and synonyms: Papeda, wild lime.

Kaffir orange – *see* **MONKEY ORANGE**

KAFFIR PLUM – A tree of South Africa, the Kaffir plum (*Harpephyllum caffrum*) produces a sweet, red fruit a bit smaller than a plum – in fact about the size of a date (and the fruit is also called a "Kaffir date"). The tree is now grown in California and Florida as an ornamental.

Common names and synonyms: Kaffir date.

KAFFIR POTATO – An apparently close relative of the Sudan potato, with which it shares the common name "Hausa potato," the Kaffir potato (*Plectranthus esculentus*) is a native of tropical West Africa that today is cultivated in an area extending throughout Central Africa and into East Africa. The tubers, which have been food for Africans since prehistoric times, are generally boiled and frequently added to the many vegetables in the always-simmering family soup.

Common names and synonyms: Hausa potato, Livingstone potato.

KAI APPLE – Also known as "kau apple" and "kei apple," the kai apple (*Aberia caffra = Dovyalis caffra*) is a South African native. The "apple" grows on a thorny tree or bush and is a very acidic, yellowish fruit with the general shape of an apple. It is usually employed to make preserves.

Common names and synonyms: Kau apple, kei apple.

Kai choy – *see* **PAKCHOI AND KAI CHOY**

Kail – *see* **KALE**

Kailan – *see* **CHINESE BROCCOLI**

Kaiware – *see* **DAIKON**

Kaki – *see* **PERSIMMON**

KALE (*see also* **CABBAGE, COLLARDS, HANOVER KALE**) – A variety of cabbage with ruffled, crinkled leaves that form no head, kale (*Brassica oleracea* var. *acephala*) is an ancient vegetable. It is descended from the wild cabbage, which was native to the Mediterranean region, doubtless was enjoyed by Stone Age hunter-gatherers, and may have been the first form of cultivated cabbage. It was one of the many plants consumed by the Romans, who spread its cultivation throughout their empire. Kale is a hardy plant that can be left in the ground over the winter and thus has been especially appreciated when other greens are scarce.

Curly kale is the variety most frequently consumed, although local forms have been developed in specific areas. Of these, Scotch kale (which is very curly and somewhat prickly) and blue kale (which is less curly and a blue-green in color) are probably the most common types. Kale has coarse leaves, which can become very wide, and grows best in cool weather.

It is used in several different ways, most typically in soups and salads or as a steamed vegetable. In Portugal, a special kind of kale – called *couve* – is grown to make the country's famed *caldo verde.* Colored varieties of kale – sometimes called "salad savory" – are grown as ornamentals; in Japan, for example, they are often employed to enhance flower gardens. Kale is rich in vitamins A and C and fairly high in calcium and iron.

Common names and synonyms: Blue kale, borecole, cail, Chinese kale, *couve,* curly greens, curly kale, du jour, green cabbage, kail, marrow stem, Nagoya kale, ornamental kale, peacock kale, red flowering kale, red-on-green flowering kale, red Russian kale, salad savory, Scotch kale, thousand-headed, white flowering kale.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Kalonji – *see* **NIGELLA**

Kampyo – *see* **BOTTLE GOURD**

KAMUT (*see also* **WHEAT**) – Kamut (*Triticum turgidum*) is regarded by some to be the ancestor of grains and, at the very least, the oldest relative of modern durum wheats. This is reflected in the name "kamut," which was the ancient Egyptian word for wheat. There is disagreement over the plant's biological classification, and a number of different subspecies have been proposed.

About a half century ago, kamut reached America, and it is now produced commercially on a small scale in both the United States and Canada, mostly for the health-food market. It has never been hybridized, and its kernels are about three times the size of most wheat. They have a pleasant, nutlike flavor and are used – in conjunction with wheat flour – mostly for making pastas, puffed cereals, crackers, and bread. Kamut is high in dietary fiber and rich in the B-vitamin complex; it also delivers good quantities of folic acid and iron.

See in addition: "Wheat," Part II, Section A, Chapter 10.

Kana – *see* **MAIZE**

Kanari – *see* **JAVA ALMOND**

KANGAROO APPLE – A yellow, mealy fruit with the shape of an egg, the kangaroo apple (*Solanum aviculare*) grows on shrublike trees in New Zealand and Australia. It contributed to the diets of the aboriginal peoples of both countries.

Kang kong – *see* **SWAMP CABBAGE**

Kang(-)kung – *see* **SWAMP CABBAGE**

Kanten – *see* **AGAR**

Kápari – *see* **CAPER(S)**

KAPOK TREE – Also called the "silk-cotton tree" because of the cotton-like substance surrounding its seeds (which is used in life preservers), the kapok tree (*Ceiba pentandra*) is an East Indian native (now grown in Florida) and a close relative of Africa's famous baobab tree. The young leaves of the kapok tree are often cooked as a vegetable.

Common names and synonyms: Ceiba, silk-cotton tree.

KARAKA – *Karaka,* a Maori word, refers to an orange-colored fruit (*Corynocarpus laevigata*) of New Zealand, and the same word also means the tree on which the fruit grows. The fruit has an edible pulp and poisonous seeds, but – interestingly – the seeds are the most valuable part of this plant. When cooked and dried, they become edible, and they have long been an important item in the Maori diet.

Keemun – *see* **TEA**

Kei apple – *see* **KAI APPLE**

Keladi – *see* **COCOYAM**

KELP (*see also* **SEAWEED**) – Any of the brown and olive-green seaweeds of the orders Laminariales and Fucales are called "kelp," including several large Pacific plants known as "giant kelp," such as *Macrocystis pyrifera* and *Laminaria japonica.* The Japanese, in particular, are skilled in preparing kelp (called *kombu*) as a food product by drying and shredding it. Kelp is used in soups, is boiled as a vegetable, and is especially important in making stocks for savory dishes. It is also burned to produce iodine.

Common names and synonyms: Bladder weed, giant kelp, *kombu,* sea kelp, tangle kelp.

See in addition: "Algae," Part II, Section C, Chapter 1.

Kerela – *see* **BITTER MELON**

Kersting's groundnut – *see* **HAUSA GROUNDNUT**

Ketembilla – *see* **CEYLON GOOSEBERRY**

Key lime – *see* **LIME**

KHAT – Also called kat, cat, qat, qhat, and African or Arabian tea, khat (*Catha edulis*) is a shrub cultivated by the Arabs for its leaves. These are either chewed or made into a tea for the narcotic effect they produce.

Common names and synonyms: African tea, Arabian tea, cat, kat, qat, qhat.

See also: "Khat," Part III, Chapter 7.

Kinnikinnick – *see* **BEARBERRY**

KIWANO – A member of the cucumber family, the kiwano (*Cucumis metuliferus*) was long known as the "African horned melon," but New Zealand growers had so much success marketing the Chinese gooseberry after they changed its name to "kiwifruit" that they have pursued a similar course with this fruit. It is a colorful one, about the size and shape of a small cucumber, with a bright orange (and inedible) skin covered with little horns, and bright green flesh. The kiwano is eaten raw and makes a fine ingredient in salads. It is, however, very expensive, and although now beginning to appear in produce markets, it has in the past been available only through mail-order businesses specializing in exotic fruits.

Common names and synonyms: African horned cucumber, African horned melon, English tomato, hedged gourd, horned melon, jelly melon, melano, *metulon.*

See also: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

Kiwicha – *see* **AMARANTH**

KIWIFRUIT – The kiwifruit (*Actinidia chinensis*) was a small, hard berry growing wild in China at the beginning of the twentieth century. It was subsequently cultivated in New Zealand, where it was known as the "Chinese gooseberry." But later, when China became Communist China, the name "kiwifruit" was applied, thus disassociating it from its homeland. In part, this was to facilitate marketing in the West, and in part, it was because of the fruit's supposed resemblance to New Zealand's kiwi, a small, flightless bird with brown, hairlike plumage. The new name provoked a remarkable marketing success, and during the 1950s, New Zealand acreage devoted to the fruit increased rapidly to meet the sudden demand. The kiwifruit – about the size of a large egg – is very juicy and usually sweet, although sometimes it has a tart flavor. The thin skin is hairy and brown, and the flesh is a bright green with very small black seeds that surround a creamy white core. In addition to appearing in salads as a fresh fruit, the kiwifruit is also processed into juice, jams, and jellies and is canned and frozen. The fruit is grown on trellises and provides much in the way of vitamins A and C.

Common names and synonyms: Chinese gooseberry, *yang tao.*

Klarbar – *see* **CHERRY**

Knit-bones – *see* **COMFREY**

Knol-kohl – *see* **KOHLRABI**

KNOTTED WRACK (*see also* **SEAWEED**) – A perennial brown algae, knotted wrack of the genus *Ascophyllum* attaches itself to rocks in sheltered areas of temperate seas. In the United States, it is used mostly for fertilizers, soil conditioners, and fodder as well as packing material for shipping live lobsters and clams. However, this "sea vegetable" is also ground into a meal that is consumed by humans.

Common names and synonyms: Rockweed.

See in addition: "Algae," Part II, Section C, Chapter 1.

KNOTWEED AND SMARTWEED – A number of plants of the genus *Polygonum* are called "knotweed" or "smartweed." Many species, such as the Japanese knotweed (*P. cuspidatum* – also known as "Mexican bamboo"), have been introduced into the New World from Eurasia. Others, like *P. coccineum,* are natives of North America, and still others, like *P. viviparum,* are native to both North America and Eurasia.

In some cases, such as that of the "bistort" or "smokeweed" (*P. bistorta* or *P. bistortoides*), it was the rhizomes of the plant that were eaten by gatherers in the northern portions of the continents. But the young shoots and leaves of most knotweeds are also edible, and Japanese knotweed is cultivated for its immature stems, which are employed in salads and as a potherb. *Polygonum persicaria* may have been employed as food in the past; it was certainly used for medicinal purposes by Native Americans. The seeds of some species are edible as well. Native Americans, for example, ground the seeds of *P. douglasii* into a meal, whereas the seeds of *P. convolvulus* have long been made into a kind of porridge. And finally, the smartweed, "water pepper" (*P. hydropiper*), yields an acrid, peppery juice that has been used medicinally and as a condiment.

Common names and synonyms: Bistort, Japanese knotweed, lady's-thumb, Mexican bamboo, smokeweed, water pepper.

KOHLRABI (*see also* **CABBAGE**) – Native to northern Europe, kohlrabi (*Brassica oleracea* Gongylodes Group) is of the mustard family. It is a relative newcomer to *Brassica,* the cabbage genus, having been developed from marrow cabbages some 400 to 500 years ago. It was first described in the sixteenth century and by the end of that century was known in Germany, England, Italy, and Spain. But it was only cultivated in the United States at the beginning of the nineteenth century.

The name comes from the German words *Kohl* (meaning cabbage) and *Rabi* (meaning turnip), and in fact, it is a type of cabbage with stems that swell into turnip-like bulbs – hence, "turnip cabbage" is another of its names. Kohlrabi grows best in cool climates. It is sweet and crisp when the bulbs are small but tough and bitter when they grow large. This vegetable can be eaten raw but is usually cooked and is commonly used in soups. Some kohlrabi varieties are "Prague Special," "Purple Vienna," "Triumph of Prague," and "White Vienna."

Common names and synonyms: Cabbage turnip, caulorapa, chou-rave, colirrambano, knol-kohl, koolrabi, Prague Special, Purple Vienna, Triumph of Prague, turnip cabbage, White Vienna.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Koko – *see* **COCOYAM**

KOLA NUT – Native to West Africa, the kola nuts – *abata kola* (*Cola acuminata*) and *gbanja kola* (*C. nitida*) – have been an important trade commodity in sub-Saharan Africa for thousands of years. *Cola nitida* is indigenous to Ashanti, the Ivory Coast, and Sierra Leone but is now cultivated extensively in Nigeria as well. *Cola acuminata* is native to Nigeria, Gabon, and the Congo Basin but is less cultivated.

The kola nut is a brownish, bitter seed about the size of a chestnut. The nuts grow on small trees and are enclosed – beanlike – in green, wrinkled pods. Because they contain caffeine, kolatine, and theobromine, kola nuts have a stimulating effect when chewed or otherwise utilized, as, for example, in flavoring cola soft drinks. Kola nuts are also credited with allaying thirst and promoting energy. In addition to Africa, kola nuts are cultivated in the West Indies, South America, and Indonesia.

Common names and synonyms: Abata kola, cola, cola nut, *gbanja kola, owe kola.*

See also: "Kola Nut," Part III, Chapter 8.

Kolkas – *see* **COCOYAM**

Kombu – *see* **KELP, SEAWEED**

Kong(-)kong taro – *see* **MALANGA**

Koolrabi – *see* **KOHLRABI**

Korean chilli (pepper) – *see* **ASIAN CHILLIES**

KORILA (*see also* **CUCUMBER**) – A cucurbit that may have originated in the Caribbean region (but more likely South America or Mesoamerica), korila (*Cyclanthera pedata* – also known as the "wild cucumber") is now cultivated in all of these regions and in parts of Southeast Asia as well. The Incas ate the young fruits raw and stuffed the mature ones – often with meat – after which they were dried and stored in warehouses for future use. Today, the pale green fruits are still eaten raw and are frequently stuffed with meat or fish and baked. The shoots are also consumed, but the seeds generally are not.

Common names and synonyms: Achokcha, caihua, caygua, cayua, wild cucumber.

KUDZU – A vine native to Japan, kudzu (*Pueraria thunbergiana* = *P. lobata*) has starchy roots that can be boiled and eaten or are processed into a thickener for sauces. The plant has also been appreciated since ancient times for its medicinal properties, which supposedly become active when the roots are dried and ground into a powder. Kudzu has joined the group of Asian plants now growing in the southern United States.

KUINI – The kuini (*Mangifera odorata*) is a tall tree, probably native to Malaysia. It bears green, oval-shaped fruits about the size of large oranges. Their flesh is orange in color, quite juicy, and very sweet. The fruits have a strong smell when ripe, which tells their consumers they are safe. Immature fruits with little odor contain a poisonous sap. The kuini is eaten raw and used to make chutney.

Common names and synonyms: Kuwini.

Kumara – *see* **SWEET POTATO**

Kümmel – *see* **CARAWAY**

KUMQUAT (*see also* **LIMEQUAT**) – Native to East Asia, the several varieties of the kumquat tree (genus *Fortunella*) belong to the family Rutaceae – the same family as citrus fruits. Kumquats are cultivated throughout the subtropics, including places like California and Florida in the United States. The most common varieties are Nagami (*F. margarita*), Meiwa (*F. crassifolia*), and Marumi (*F. japonica*). The edible skin resembles that of an orange, and in fact, the kumquat was thought to be a citrus fruit until early in the twentieth century, when it was decided that it belongs to a different – but related – genus. The bright-colored, orange-yellow fruit is about the size of a large olive or a small plum, varies in shape between round and oval, and ranges in taste from sweet to mildly acidic. Availability is best during the winter. Kumquats are cooked, candied, canned, made into preserves, and used in salads, but most are popped into the mouth whole and eaten raw. Kumquats are an excellent source of vitamin C.

Common names and synonyms: Cumquat, golden orange, *kin-kan, limau pagar,* Marumi, Meiwa, Nagami.

KUNDANGAN – An Indochina native, the kundangan (*Bouea macrophylla*) is yellow, about the size of a small orange, and soft when ripe. The mature fruits are made into chutneys and jams, and the young green fruits are pickled for curries. This tree-growing fruit is also known as Setar and star.

Common names and synonyms: Setar, star.

Kusaie – *see* **RANGPUR AND KUSAIE**

Kuwini – *see* **KUINI**

L

Lablab bean – *see* **HYACINTH BEAN**

Labrusca grape – *see* **FOX GRAPE**

LADY APPLE –Also known as the "red wild-apple," the lady apple (*Syzygium suborbiculare*) is a relative of the clove. A wild, reddish fruit of Australia, it is mentioned as one of the gathered foods of the Australian Aborigines.

Common names and synonyms: Red wild-apple.

Lady('s)-finger(s) – *see* **OKRA**

LADY'S BEDSTRAW – Also known as "yellow bedstraw" and "yellow cleavers" (because the barbed stems cleave to fur and clothing), lady's bedstraw (*Galium verum*) shares the common name "bedstraw" with a few other species of the genus *Calium*. The name came about because the plants were used as mattress stuffing, but they also have some food value; the seeds, for example, have served as a coffee substitute.

Common names and synonyms: Yellow bedstraw, yellow cleavers.

LADY'S SMOCK – Also called "cuckoo flower," lady's smock (*Cardamine pratensis*) is a bitter cress of North America and Europe. It finds use mostly as a condiment.

Common names and synonyms: Cuckoo flower.

Lady's-thumb – *see* **KNOTWEED AND SMARTWEED**

Lahong – *see* **DURIAN**

Lambert's filbert – *see* **HAZELNUT AND FILBERT**

LAMBRUSCO (*see also* **GRAPES**) – The vines that produce the Lambrusco variety, an Italian wine grape (*Vitis vinifera*) that originated in the Emilia-Romagna wine region, are still heavily planted in the clay soils of the Po Valley. The Lambrusco grape makes a sweet, light- to medium-bodied, sparkling red wine that has been popular in the United States. Lambrusco grapes are also used to make dry red and white wines.

See in addition: "Wine," Part III, Chapter 13.

Lamb's lettuce – *see* **CORNSALAD**

LAMB'S-QUARTER (*see also* **CHENOPODIUM, CORNSALAD, GOOSEFOOT**) – The leaves of lamb's-quarter (*Chenopodium album*) – also known as pigweed – a wild plant common in Europe and now naturalized in North America, taste something like spinach when they are cooked. When young, they are delicious raw. The seeds are also edible after the saponin they contain is leached out.

Common names and synonyms: Goosefoot, pigweed.

Lampong (pepper) – *see* **PEPPER(CORNS)**

LANGSAT – Natives of western Malaysia, both the langsat and the duku are classified under the same botanical name – *Lansium domesticum.* Their pale yellowish, berry-like fruits have been grown since ancient times. In the fifteenth century, Chinese voyagers saw these fruit trees in Java and attempted without success to grow them in China. The trees will not tolerate even the slightest cold, nor will they endure long dry spells, all of which means that they have remained typically Malaysian. Aside from a milky juice present in the langsat, the major difference between the duku and the langsat seems to be that the duku is somewhat larger (about 2 inches long in contrast to about 1.5 inches for the langsat) but has fewer fruits in a bunch. The fruits, which are generally eaten raw, are not very sweet, and some are slightly bitter (the seeds are extremely bitter). Both fruits are difficult to find, even in Asian markets.

Common names and synonyms: Duku, lanzone.

Lanzone – *see* **LANGSAT**

Laos – *see* **GALANGAL**

Lapsung Souchong – *see* **TEA**

LARGE CANE – Also called "giant cane," large cane (*Arundinaria gigantea*) is the tall grass that constitutes the canebrakes of the southern United States. Its succulent young shoots were gathered by Native Americans to cook as a vegetable.

Common names and synonyms: Giant cane.

Laurel – *see* **BAY LEAF**

Laurel leaf – *see* **DUAN SALAM**

LAVENDER – An Old World plant now grown for its scent – from the essential oil of its flowers – lavender (*Lavandula officinalis = L. angustifolia*) was popular in the past as a potherb and was used for flavoring jellies as well. Its sole remaining culinary use is to make a tisane.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

LAVER (*see also* **AGAR, SEAWEED**) – Any of several seaweeds – mostly of the genus *Porphyra* – are called laver, including such species as *P. laciniata* or *P. vulgaris* (red laver) and *P. tenera* or *P. umbilicalis* (green, purple, and sea laver). In Japan, laver is called *nori* and is employed principally to obtain a gelatin to make agar-agar, which are sheets of dried and compressed laver used as sushi wrappers. But laver is also shredded into soups and other dishes. In Scotland and Ireland, where this "sea vegetable" has been named *sloak* or *slook,* laver is boiled and served with butter, or perhaps fried in bacon fat after boiling. Laver is also pickled.

Common names and synonyms: Agar-agar, green laver, *nori,* purple laver, red laver, sea laver, *sloak, slook.*

See in addition: "Algae," Part II, Section C, Chapter 1.

Lead tree – *see* **LEUCAENA**

Leaf beet – *see* **SWISS CHARD**

Leafcup – *see* **YACÓN**

Leaf mustard – *see* **MUSTARD GREENS**

Leaf pekoe – *see* **TEA**

Leafy cactus – *see* **BARBADOS GOOSEBERRY**

LEAFY SPURGE – A tall perennial Eurasian herb that has been naturalized in the northern United States and Canada, leafy spurge (*Euphorbia esula*) has stems that contain a milky juice. Formerly, this plant and other species of the genus *Euphorbia* were used as purgatives – hence the name spurge – although some also have served as food.

LECHEGUILLA – With a name that is the diminutive of the Spanish *lechuga* (meaning "lettuce"), lecheguilla (*Agave lecheguilla*) is a wild lettuce that can be toxic to sheep and goats that feed on it. Nonetheless, it was reportedly consumed by humans in the past.

Common names and synonyms: Lechuguilla.

Lechuguilla – *see* **LECHEGUILLA**

Leechee – *see* **LITCHI**

LEEK(S) – A plant related to the onion, the leek (*Allium porrum*) looks like a giant scallion. It is native to the Mediterranean region, where it was apparently cultivated in prehistory and later enjoyed by the ancient Greeks. The Roman emperor Nero ate leeks regularly, and the Romans carried leeks to much of the rest of Europe, where the vegetable was especially popular during the Middle Ages. In Wales, leeks are the national emblem and regarded as the national vegetable. Legend has it that seventh-century Welsh troops – in battle with the Saxons – wore leeks in their hats to distinguish themselves from the enemy.

Leeks are most appreciated in Europe, where they are a favorite; France, Belgium, and the Netherlands are the leading producers. California, New Jersey, and Florida satisfy much of the U.S. market. The vegetable – known as "poor-man's-asparagus" in France – is used to make soups, and is a vital ingredient in many of the French *potage* standards, including vichyssoise (which was actually invented in New York City). The Welsh and the Scots both have famous leek soups as well.

Leeks are also boiled, blanched, or braised, and served perhaps with cheese or a dressing. Despite its warm-climate origin, the leek is a hardy plant that can survive the ice and snow of the cold months in temperate climates and thus is a winter vegetable. Leeks are a rich source of folacin and a good source of vitamin C and vitamin B_6.

Common names and synonyms: Poor-man's-asparagus.

See also: "The *Allium* Species," Part II, Section C, Chapter 2.

Leghorn citron – *see* **CITRON**

LEGUMES (*see also* **BEANS, PEAS**) – The legumes (peas, beans, and lentils), also called pulses, are members of the second most important family of plants in the human diet (after the grasses that have given us our grains). It was the Romans who decided that a legume is the edible seed in a pod that splits into two valves with seeds attached to the lower edge of one of the valves, all of which means that peas as well as beans belong to the family Leguminosae (Fabaceae). The family name derives from the Latin verb *legendus* or *legere* and the Greek *legein,* meaning to gather or collect, and doubtless wild legumes were gathered by humans long before they got around to domesticating them. The first wave of the latter activity probably took place in the Near East, with the lentil, pea, chickpea, and broadbean all domesticated between 7000 and 3000 B.C.

Bean domestication in the Americas took place at about this same time, which saw four species of beans brought under human control beginning around 6000 B.C. These, all of the genus *Phaseolus* and called *haricots* by the French, added considerably to the world's stock of beans. The tepary bean developed in the area that became Mexico and the southeastern United States. The scarlet runner was domesticated farther south in Mexico, and the lima bean even farther south in the Andean region (a smaller sieva bean of the same species was developed in Mexico). However, by far the most familiar and most widespread of the American beans was the common bean (*P. vulgaris*), several varieties of which were cultivated from the Great Lakes to Argentina. These have since been further developed, so that today there are hundreds of varieties of the common bean, including the black bean, navy bean, kidney bean, pinto bean, white bean, and great northern bean.

Somewhat later in Asia, perhaps around 1000 B.C., the mung bean, the azuki bean, and the winged bean were domesticated, although all were apparently preceded a bit in China by the soybean. More complicated and less certain are the dates for the domestication of African legumes. The cowpea may have been cultivated as early as 3000 B.C. Domestication of the pigeon pea and the yam pea were presumably somewhat later, although too little is known with certainty about the development of legumes in Africa. In fact, in many instances, it is difficult if not impossible to determine which ones may have been Asian transients.

Without doubt, there are many species of legumes that have disappeared, and others may still await discovery. Some legumes, such as the peanut (which is eaten as a nut), the carob bean (made into a cocoa substitute), and alfalfa and jackbeans (used for animal fodder), are treated in separate entries.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3; "Peanuts," Part II, Section D, Chapter 2; "Soybean," Part II, Section E, Chapter 5.

LEMON (*see also* **CITRUS FRUITS**) – A native of Southeast Asia, the lemon (*Citrus limon*) was slow to leave that region. Although it reached China about 1900 B.C., it was not until the Middle Ages that the fruit entered Europe via trade with the Arabs, who spread it around the Mediterranean basin from Greece to Spain. The word *citron* (or some variation of it) became the name given to the lemon by many of the various European peoples, although not by the Iberians. The Spaniards called it *limón,* and the Portuguese named it *limão* and carried both the fruit and the name to the New World. Indeed, lemons were reported growing in the Azores as early as 1494, and the men of Christopher Columbus and those who followed in their wake must have been quick to scatter lemon seeds around the West Indies, because lemon trees were recorded in the Greater Antilles in 1557; 30 years later, lemon orchards were seen in South America.

The most common lemons are the "Lisbon" and the "Eureka" – both yellow ovoids with a blunt nipple at the flower end and a characteristic acid taste. The Eureka is distinguished by a short neck at the stem end and may have a few seeds, whereas the Lisbon is seedless. In the United States, Florida-grown lemons (of the Lisbon variety) are called "bearss." The Meyer lemon – a cross between a lemon and a tangerine – is golden in color and sweet. Yet another lemon, the bergamot, is grown largely for its aromatic leaves and skin. In terms of food use, lemons are employed in a number of ways. The taste of seafoods is frequently enhanced with a squeeze of lemon juice, and lemons are also used to flavor salads, vegetable and meat dishes, drinks (especially lemonade), sauces, and desserts. In addition, lemon peel yields an essential oil with a number of culinary and industrial applications. Lemons brim with vitamin C and, like limes, have long had a reputation as a scurvy preventive as well as a cure. During the California gold rush, scurvy was so prevalent that miners would pay up to a dollar for a lemon.

Common names and synonyms: Bearss, bergamot lemon, *citron* (archaic), Eureka lemon, *limão, limón, limou amarillo,* Lisbon lemon, Meyer lemon.

LEMON BALM – Probably a native of the Middle East and Asia, lemon balm (*Melissa officinalis*) has been cultivated in the Mediterranean at least since the time of the ancient Greeks. In fact, the name comes from the Greek *melissa,* meaning honeybee, which this lemon-scented plant attracts in abundance. The aromatic leaves with a distinct lemon odor are used fresh and dried to flavor fish and poultry dishes. They are also employed in stuffings, salads, and soups, and they go well in egg dishes. In addition, lemon balm is used as a flavoring in many liqueurs.

Common names and synonyms: Balm, balm mint, bee herb, garden balm, gentle balm, melissa, sweet balm.

Lemon cucumber – *see* **CUCUMBER, MANGO MELON**

LEMONGRASS – There are two grasses of the genus *Cymbopogon* that are cultivated for lemongrass oil. One is West Indian lemongrass (*Cymbopogon citratus*), which has long, spear-shaped leaves and is now grown in many tropical and subtropical parts of the world. The other is *C. flexuosus,* or East Indian lemongrass. In both instances, in addition to providing lemongrass oil for making perfumes, the whole stalk, with a strong, lemon-like flavor, is used in many dishes. Indeed, this herb is a most important ingredient in Asian cuisines, especially those of Vietnam and Thailand, where it provides both the base and added flavorings for numerous soups, including its namesake, "lemongrass soup." Lemongrass also goes well in curries, stews, and casseroles.

LEMON VERBENA – A plant originally native to Chile and Argentina, lemon verbena (*Lippia citriodora*) gives off a lemon-like scent when cut. It was long ago carried by the Spaniards to Europe, where an essential oil distilled from its leaves was employed in making soaps and cosmetics. The leaves of lemon verbena are used both fresh and dried in tisanes, salads, soups, stews, fruit drinks, and as a substitute for lemongrass in Asian recipes.

Common names and synonyms: Verbena.

Lemon vine – *see* **BARBADOS GOOSEBERRY**

LENTIL(S) (*see also* **BEANS, LEGUMES**) – Probably the oldest of the cultivated legumes (which also includes peas and beans), the lentil (*Lens esculenta*) – a native of Southwest Asia that had grown wild in the Middle East and central Asia – was brought under cultivation by the first Neolithic peoples of India, Egypt, and the Middle East some 9,000 years ago. They were heavily consumed by the ancient Greeks and Romans. The Egyptians were and remained the chief lentil exporter of those (and later) times and the Romans the chief importer. Since then, Europeans have continued to consume these little, flat, disk-shaped, dried seeds – mostly in soups, stews, and the like. The European variety is greenish or brownish in color, but others are often bright red, yellow, black, or green, and in South Asia they can be narrow in shape like rice grains. In India, lentils are usually served as *dahl* – a side dish that accompanies almost every meal – and they continue as a staple in the Middle East and Eastern Europe. Beans, peas, and lentils become intertwined in the Indian subcontinent. The black lentil (*Phaseolus mungo*) – used for *dahl* – is considered to have the best flavor. The red mung bean and the green mung bean or green lentil (*Phaseolus aureus*) are also used to make *dahl* in India and are sprouted throughout much of the rest of Asia. Yellow lentils (*Pisum sativum*) are closely related to the garden pea and, in addition to being used for *dahl,* are dry-roasted and seasoned to make a snack. Lentils are an important source of protein, are rich in folacin, iron, and phosphorus, and are a fair source of thiamine and vitamin B_6.

Common names and synonyms: Black lentil, brown lentil, green lentil, green mung bean, large-seeded lentil, red mung bean, small-seeded lentil, wild lentil, yellow lentil.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

Lentisk – *see* **MASTIC TREE**

Leren – *see* **GUINEA ARROWROOT**

Lerenes – *see* **GUINEA ARROWROOT**

Lesser burnet – *see* **BURNET**

Lesser galanga(l) – *see* **GALANGAL**

LESSER YAM (*see also* **YAMS**) – An ancient cultivar that, although native to Southeast Asia, has been cultivated in China for some 2,000 years, the lesser yam (*Dioscorea esculenta*) now grows throughout the world's tropics. These yams are used in soups and stews, are boiled as a vegetable, and are also roasted and fried.

Common names and synonyms: Asiatic yam, Chinese yam, potato yam.

See in addition: "Sweet Potatoes and Yams," Part II, Section B, Chapter 5.

LETTUCE – The various lettuces are plants of the genus *Lactuca* and – along with endive and dandelions – members of the daisy family. Wild lettuce was gathered for millennia by hunter-gatherers and was still being gathered by humans at the time of the ancient Greeks. The latter probably began its cultivation, which was continued by the Romans. The first cultivated lettuce was *L. serriola,* which is native to the Mediterranean region.

There are four major lettuce varieties. One, *L. sativa* var. *crispa,* consists of the red and green loose-leafed lettuces (also called garden lettuce), easily grown by gardeners and generally used in salads. A second, which is essentially confined to romaine (also called "cos" by the English after that once-Greek island), is *L. sativa* var. *longifolia* – the latter referring to the elongated head, the leaves of which are featured in Caesar salads. Butterhead lettuces (*L. sativa* var. *capitata*) include the Boston and Bibb lettuces with their "buttery" flavors. Boston lettuce is loosely headed and larger than the more compact Bibb lettuce (also called "limestone"), a recent (nineteenth-century) development. A fourth group consists of the iceberg lettuce (*L. sativa* var. *capitata*), more properly called "crisphead," which is actually classified with the butterheads but is a relatively new variety that emerged at the hands of growers in just the last century or so.

In addition to use in salads, lettuces are sometimes braised and creamed; in some cultures, lettuce seeds have been eaten as well as the leaves. Romaine and loose-leaf lettuces contain far more vitamin C and beta-carotene than iceberg, which provides relatively little in the way of nutrients. All, however, deliver some magnesium – perhaps the reason lettuce has been credited by some with soothing properties.

Common names and synonyms: Asparagus lettuce, Bibb lettuce, Boston lettuce, butterhead lettuce, celtuce, cos, crisphead lettuce, curled lettuce, garden lettuce, green oak-leaf lettuce, green romaine lettuce, head lettuce, iceberg lettuce, limestone lettuce, lolla rossa, loose-leaf lettuce, Perella Red, red oak-leaf lettuce, red romaine lettuce, romaine lettuce, Tango lettuce.

LEUCAENA – Known also as the "wild tamarind," "jumbie bean," and (in Spanish) *guaje,* the leucaena (*Leucaena leucocephala*) probably originated in Mexico and Central America but now grows throughout the world's tropics. It is a tree that produces flower buds, foliage, young pods, and seeds, all of which have been foods for humans since prehistoric times.

Common names and synonyms: Guaje, jumbie bean, lead tree, wild tamarind.

Libyan lotus – *see* **LOTUS**

Lichee – *see* **LITCHI**

Lichen(s) – *see* **ICELAND MOSS, MANNA**

Lichi – *see* **LITCHI**

LICORICE – The Greek word *glykyrrhiza,* meaning "sweet root," gave rise to the Latin name (*Glycyrrhiza glabra*) for licorice, which is the condensed juice from the roots of this Old World plant. A native of the Middle East, licorice was employed by the ancient Egyptians in medicinal preparations. Today, it is used in candy, to flavor liquors, and in the manufacture of tobacco. In addition, there is American licorice, *G. lepidota*, a wild licorice of North America with roots that were cooked by Native Americans, who also nibbled on the raw roots as a treat.

Common names and synonyms: American licorice, licorice root, liquorice, wild licorice.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Lily – *see* **DAYLILY, TIGER LILY**

Limão – *see* **LEMON**

Limau pagar – *see* **KUMQUAT**

LIME (*see also* **CITRUS FRUITS, LIMEQUAT**) – Like most of the other members of the citrus family, the lime (*Citrus aurantiifolia*) is native to Southeast Asia. It was first cultivated in China and India, then introduced in southern Europe (probably during the Crusades), and carried much later by the Spaniards to the West Indies. The original lime – small, round, and quite tart – is today called the "Mexican," "West Indian," or "Key" lime, with its juice deemed essential to Key lime pies. The limes generally encountered in the produce departments of U.S. supermarkets, however, are "Persian" (sometimes called "Tahiti") limes. These are larger and – save for the green skin – quite lemon-like in appearance. Persian limes are a fairly recent development, apparently the result of a cross between the Key lime and the citron early in the twentieth century. The lime and lemon industry of Florida (which provides close to 90 percent of the limes grown in North America) got its start in the 1880s, declined after freezes in the 1890s, and revived after World War I. Limes are very high in vitamin C and figured prominently in warding off scurvy, the dread disease of seamen from the sixteenth through the nineteenth centuries. In the eighteenth century, the British navy issued lime juice to all seamen to keep the disease at bay – hence the nickname "limeys."

Common names and synonyms: Green lemon, Key lime, Mexican lime, Persian lime, sour lemon, Tahiti lime, West Indian lime.

LIMEBERRY (*see also* **BERRIES**) – A spiny shrub of Southeast Asia, the limeberry (*Triphasia trifolia*) is now naturalized in Florida and Mexico, where it is often used for hedges. Its fruit is a small, red berry, called the "miracle fruit" because, after it is eaten, all subsequent foods eaten for hours to come will seem to have a sweet, lime-like taste.

Common names and synonyms: Miracle fruit.

LIMEQUAT (*see also* **KUMQUAT, LIME**) – A hybrid resulting from a cross between the Key lime and the kumquat, the limequat (genera *Citrus* and *Fortunella*) has a limelike flavor, and some varieties have an edible rind like the kumquat. Along with the orangequat and citrangequat, the limequat is the result of a U.S. Department of Agriculture breeding program to introduce the cold-hardiness of the kumquat into other plants.

LIMETTA (*see also* **CITRUS FRUITS**) – Also known as "sweet lemon" and "sweet lime" (with good reason), the limetta (*Citrus limetta*) looks like a lemon but is sufficiently lacking in citric acid that it is not sour. In fact, when eaten raw, the limetta tastes like lemonade, although it can be insipidly sweet when ripe. The best known of the limetta varieties is the Millsweet, which is grown in Italy and in California. Egypt and other tropical countries also cultivate limettas. Because they do not travel well, limettas are seldom seen in produce markets.

Common names and synonyms: Millsweet limetta, sweet lemon, sweet lime.

Limón – *see* **LEMON**

Limu – *see* **SEAWEED**

Ling – *see* **HEATHER**

Lingaro – *see* **ELAEAGNUS**

Lingen – *see* **LINGONBERRY**

LINGONBERRY (*see also* **BERRIES**) – The lingonberry (*Vaccinium vitis-idaea*) is the red and somewhat acidic fruit of a creeping evergreen shrub native to the northern regions of the world. Related to the cranberry, lingonberries are very popular in the Scandinavian countries, where they are made into preserves and pastries and served to accompany meat dishes. They are also mentioned with frequency as one of the foods of native North Americans.

Common names and synonyms: Cowberry, foxberry, lingen, mountain cranberry, rock cranberry.

Linseed (oil) – *see* **FLAX SEED**

Lipstick tree – *see* **ANNATTO**

Liquorice – *see* **LICORICE**

LITCHI – Also called lichee, lichi, and lychee, the litchi nut (*Litchi chinensis*) is actually a white, sweet berry with a rough, red or pink outer shell. A relative of the longan, litchis grow on tropical and subtropical evergreen trees that are members of the soapberry family and native to southern China, where they have been cultivated for at least 2,000 years. Only the pulp of the ripe fruit is eaten; the skin and seeds are inedible. Peeled, litchis look like large white grapes and have a sweet fragrance and flavor. Their appearance in the Western world began in 1775, when they were introduced in Jamaica, and now litchis are cultivated in Hawaii, California, and Florida (Florida's first crop was in 1916), as well as other tropical and subtropical areas of the world. Litchis are eaten raw, are also preserved and canned, and are high in vitamin C. In addition, dried litchis are consumed for their smoky flavor. Often called litchi nuts or litchis, these are not the central seeds – which are never eaten – but rather the raisinlike pulp.

Common names and synonyms: Leechee, lichee, lichi, litchi nut, lychee, lychi.

Litchi nut – *see* **LITCHI**

Little barley – *see* **WILD BARLEY**

LITTLE GOOSEBERRY TREE – Also called the "jungle plum," the little gooseberry tree (*Buchanania arborescens*) produces a wild, plumlike fruit that has served as food in the Australian bush for millennia.

Common names and synonyms: Jungle plum.

Little red banana – *see* **ENSETE**

Little stinker – *see* **CREOSOTE BUSH**

Liver fistulina – *see* **MUSHROOMS AND FUNGI**

Livingstone potato – *see* **KAFFIR POTATO**

Llerén – *see* **GUINEA ARROWROOT**

Llerenes – *see* **GUINEA ARROWROOT**

LOCAL GARDEN EGG – A close relative of the eggplant, the "local garden egg" (*Solanum incanum* and *S. macrocarpon*) comes in two forms. These are both cultivated in West Africa, even though the plants are generally regarded as wild forms of the eggplant. *Solanum incanum* is also known as the "bitter tomato" and is used in soups and stews to add flavor. *Solanum macrocarpon* is utilized more like the eggplant in that it is sliced and fried or cooked as a vegetable.

Common names and synonyms: Bitter tomato.

LOCUST (*see also* **AFRICAN LOCUST, AFRICAN LOCUST BEAN, CAROB, HONEY LOCUST, MESQUITE**) – A tall tree of eastern North America, also known as the "black locust," the locust tree (*Robinia pseudoacacia*) provided much in the way of food for Native Americans. Its edible flowers were sweet treats that were also used to make a tea; the young pods were cooked as a vegetable; and the seeds were boiled and eaten.

Common names and synonyms: Black locust, honey locust.

Locust bean – *see* **AFRICAN LOCUST BEAN, CAROB**

LOGANBERRY (*see also* **BERRIES, BLACKBERRY**) – The loganberry (*Rubus loganobaccus*) was produced in 1881 (it is a hybrid) by Judge James H. Logan (1841–1928) in Santa Cruz, California, and was introduced commercially in 1882. The red berry (similar to a blackberry) grows on a prickly bramble shrub, and although its parentage has been a matter of some debate, it would seem that it is a hybrid of the blackberry and the red raspberry. At one time it was grown commercially in California and the Pacific Northwest but proved overly susceptible to disease. Now loganberries generally are grown only in home gardens.

LONGAN – Sometimes called "dragon's-eyes," longans (*Euphoria longan* = *Dimocarpus longan*) are related to litchis. They are native to Southeast Asia and popular in southern China but are not a major crop outside of Asia, although a small one is raised in Florida. The fruit grows in clusters in the depths of thick evergreen trees that can reach up to 36 feet in height and 40 or more feet in circumference. This sweet fruit ranges in size from that of a grape to that of a plum. It is covered by a brown shell and has a whitish, jelly-like fruit with a single dark seed in the middle. Longans are usually eaten raw and are very high in vitamin C. They are also available canned.

Common names and synonyms: Cat's-eye, dragon's-eye, long an, longyen, lungan.

Long an – *see* **LONGAN**

Long bean – *see* **COWPEA, WINGED BEAN**

LONG CORIANDER – Also called "false coriander" and "fitweed," long coriander (*Eryngium foetidum*) is an herb with long, stiff, green leaves that have serrated edges and give off a strong smell when crushed. The plant is probably a native of China, where it has been used for thousands of years as a medicine as well as a substitute for coriander – both as a garnish and in cooking. The Chinese carried the long coriander throughout Asia, and it is now cultivated in Malaysia and India. It reached Europe in the seventeenth century and is also grown there.

Common names and synonyms: False coriander, fitweed.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Long-podded cowpea – *see* **WINGED BEAN**

Long red chilli – *see* **ANAHEIM**

Longyen – *see* **LONGAN**

Lontar palm – *see* **WINE PALM**

Loose-leaf lettuce – *see* **LETTUCE**

LOQUAT – A native of eastern Asia, the loquat (*Eriobotrya japonica*) is a small tree of the rose family (Rosaceae), with fragrant white flowers and is often grown as an ornamental. It bears a popular Asian fruit – sometimes called the Japanese medlar or plum – that resembles an apricot in its yellow coloring, shape (like a pear), and tart flavor. The loquat originated in China and, after its introduction in Japan, was expanded into 10 or more species. Many uses have been found for this fruit in pies, jams, and salads, and in the production of liquors. It is also eaten fresh, stewed, candied, and preserved. Today, the fruit is grown in California, Florida, Hawaii, southern Europe, and Israel as well as East Asia. Loquats, however, are delicate fruits that are difficult to ship because they bruise easily. Canned loquats preserved in syrup are probably more widely available. Loquats are a fine source of beta-carotene.

Common names and synonyms: Advance, Champagne, Early Red, Japanese medlar, Japanese plum, nispero, Premier, tanaka, thales.

LOTUS – There are about 90 species of the water-lily family (Nymphaeaceae), many of which have served as food. The "sacred lotus" (*Nelumbo nucifera*), for example, is a perennial aquatic plant of India that was carried to China and to Egypt, where it was consumed at least 4,000 years ago. The poor in Egypt frequently have eaten the seeds and rhizome of the Egyptian lotus (*Nymphaea lotus*), boiled, dried, and ground into flour. Native Americans employed the yellow American marsh lotus (*Nelumbo lutea*) in much the same fashion, and the women would gather the roots of plants of the genus *Nuphar* from the lairs of beavers and muskrats that had collected them for their own use. The Chinese have eaten the rhizome of their pink lotus (*Nelumbo nucifera*) since ancient times and have used lotus leaves for wrapping food. In India, lotus is employed in curries, and all Asians appreciate its crunchy texture and its appearance. The tuberous roots have air tunnels, so that, when sliced, the crisp round looks like a piece of Swiss cheese or – perhaps a better description – a lacy-patterned snowflake. Lotus roots are sliced, chopped, and grated for soups, salads, and stir-frying.

Common names and synonyms: American marsh lotus, blue lotus, blue water lily, Chinese pink lotus, Egyptian lotus flower, Hindu sacred lotus, Libyan lotus, lotus root, water lily, water-lily tuber.

Lotus root – *see* **LOTUS**

LOVAGE – As is the case with numerous herbs employed at least since the time of the ancient Greeks and Romans, many uses for the seeds, leaves, and roots of lovage (*Levisticum officinale*) have been long forgotten. The plant, a native of Europe, looks like angelica, and in fact, its stems are candied like those of angelica. The leaves, however, are parsley-like, which has given rise to other names such as "Italian parsley," "love parsley," and "wild parsley." Yet lovage tastes very much like celery, and in parts of Italy the roots are peeled and cooked like celery root. Most uses, however, involve the leaves, which can be obtained fresh or dried (those that are dried retain their strong flavor), and sometimes the dried seeds, which are added to soups, salads, stuffings, and stews.

Common names and synonyms: Common lovage, garden lovage, Italian lovage, Italian parsley, love parsley, smallage, wild parsley.

Lovegrass – *see* **TEF**

Lucerne – *see* **ALFALFA**

LUCUMA – A native of South America that is partial to the coolness of highlands, the lucuma (*Pouteria obovata*) is, as its species name suggests, an egg-shaped fruit, also called eggfruit. It is yellow when mature and has a yellow flesh that is sometimes eaten raw but more often made into a drink. In Chile and Peru, where the lucuma is a commercial crop of some importance, the fruits are normally dried and ground into a powder that is stirred into milk.

Common names and synonyms: Eggfruit.

Lychee nut – *see* **LITCHI**

Lychi – *see* **LITCHI**

M

MABOLO – A relative of the persimmon and native to the Philippines but uncommon elsewhere, this fruit (*Diospyros discolor*) is also called the "velvet apple" from the reddish brown, peachlike hair that covers its thin skin. In fact, its shape is much like that of a peach. The skin may be pink or brown and turn a brilliant red in late summer when the fruit is ripe. Then it is eaten mostly fresh, skin and all, after the hairy covering has been rubbed off. But the mabolo is also made into desserts. Its flesh is creamy, its taste is sweet and slightly acidic, and its aroma is said to be reminiscent of cheese. For some, the taste may have to be an acquired one.

Common names and synonyms: Mabulo, velvet apple.

Mabulo – *see* **MABOLO**

MACA – A turnip-like plant of the mustard family, maca (*Lepidium meyenii*) was one of the root crops of the ancient Incas and has been cultivated for at least 2,000 years. Its small leaves are edible, and the small roots can be roasted or made into a gruel. Today, the plant is cultivated only on small plots at high altitudes in Peru, where strong winds and cold temperatures limit other crops. Peasants there believe that eating maca will help infertile couples to have children.

MACADAMIA NUT – Always in demand even though they contain more fat and calories than any of their counterparts, macadamia nuts are actually divided into two species, *Macadamia integrifolia* and *M. tetraphylla.* They represent one of Australia's few contributions to the food plants of the world (they were first called "Queensland nuts" by early white settlers). The nuts of *M. integrifolia* come from an evergreen tree native to the rain forests of southeastern Queensland, whereas *M. tetraphylla* is found farther south – in the rain forests of New South Wales.

Until 1858, they were enjoyed almost exclusively by the Aborigines, who had gathered them every autumn for millennia. But in that year a German botanist engaged in collecting Australian botanical specimens encountered and described a new genus of trees, which he named *Macadamia* in honor of an Australian friend, Dr. John Macadam (d. 1865).

Macadamia trees were introduced into Hawaii in 1881 and after 1930 became the basis of a major industry there. Indeed, at one time Hawaii produced some 90 percent of the world's supply, and macadamias remain one of that state's most important crops. However, Australian efforts over the past 30 years have begun to threaten the Hawaiian dominance of world production, and the nuts are grown in California as well. Impossible to open without some kind of nutcracker, macadamias have a superb crunch and taste has recommend them to the rarefied world of the gourmet – with a corresponding price. The nuts are a good source of protein and carbohydrates and are fairly high in magnesium and thiamine as well as iron.

Common names and synonyms: Australian nut, Queensland nut.

MACAW PALM – The macaw palm is also called "macaw tree" and *macaúba,* and these names are used for several species of the genus *Acrocomia,* which provide fruits that yield both pulp and kernel oil. Macaw palms grow throughout Central and South America in dry regions, where African oil palms do not do well. In some instances, the violet-scented oil is used only in perfumery, but in others the oils produced are edible and used in cooking.

Common names and synonyms: Macaúba, macaw tree.

MACE (*see also* **NUTMEG**) – This spice tastes like strong nutmeg, which is understandable, as mace is the lacy covering (aril) of the nutmeg berry. The berry fruits on an evergreen (*Myristica fragrans* = *M. officinalis*) that is a native of the Moluccas in the Spice Islands. After harvesting (several times a year), the berries are put in the sun to dry, and the mace is removed by hand and flattened into "blades" to dry separately from the nutmeg. Mace and nutmeg moved slowly westward, apparently reaching the Byzantine court in the sixth century. In the eleventh century, the famous Arab physician Avicenna described the two spices, and, in the following century, they seem to have reached Europe via Arab traders. Initially, however, they were used for perfumes or in medicines and only gradually found culinary applications.

After the Portuguese moved into the Spice Islands, they established a monopoly on mace and nutmeg as well as on cloves. The Dutch succeeded them as monopolists and worked zealously to prevent the export of any nutmeg trees. But during the wars of the eighteenth and nineteenth centuries, the islands were shuttled back and forth between Dutch and English domination, and – to be on the safe side – the latter took the opportunity to remove some of the trees to Singapore and to the West Indies. Today, the island of Grenada produces about 40 percent of the world's mace and nutmeg, although the trees are also grown in Brazil, Colombia, Central America, and Madagascar. Mace is available whole in "blades" and in ground form. It is used mostly in puddings, cakes, and sauces, and in poultry and fish dishes.

See in addition: "Spices and Flavorings," Part II, Section F, Chapter 1.

MAHAWASOO – A South American tree, the mahawasoo (*Vaupesia cataractarum*) produces toxic oilseeds that are rendered edible by boiling. In the past, the seeds served as a famine food for Native Indians in the northwestern Amazon Basin, who also consumed them in connection with various ceremonial rites.

MAHUA – Native to the Indian subcontinent, mahua (*Madhuca longifolia*) is an evergreen tree, the seeds of which yield an oil that substitutes for butter and is used in cooking. The tree's flowers are also eaten and employed in the production of liqueurs. India is the major producer of mahua.

Maidenhair tree – *see* **GINKGO NUT**

MAIZE – Maize (*Zea mays*), native to the Americas and now the second-largest cereal crop in the world, has been one of the most versatile cultivated food plants in human history. Hundreds of varieties of maize (or "corn," as it is generally called in the United States) thrive in an astonishing assortment of geographic regions and environmental conditions, and the crop is employed in a number of ways, ranging from its increasing role as a staple food for humans in certain developing areas, to its principal present use as a feed for livestock animals (largely but not solely in industrialized countries), to its growing importance as a raw material in food processing and nonfood manufacturing.

It is usually accepted that maize was growing in Mesoamerica by between 8000 and 5000 B.C. Reliable archaeological evidence of domesticated maize dates from as long ago as 3600 B.C. in what is now central Mexico, and it is thought that domestication of the crop first took place – doubtless at a much earlier date – in this general area. To the south, a separate domestication of maize may have been accomplished at about the same time by South American Indians in the central Andes, or the crop may simply have traveled to that area from its point of origin. To the north, however, there seems to be no doubt that domesticated maize arrived much later, with locally adapted varieties appearing in the Eastern Woodlands of North America around A.D. 200 and in the central portion of the continent by about A.D. 600.

Indigenous American societies intensively cultivated maize, and it became a principal staple of the Aztecs, the Inca, the Maya, and many groups of North American Indians – especially those in what is now the southeastern United States – for several centuries before the arrival of Europeans. All parts of the plant were used for food and other purposes; the Inca even made maize "beers," known collectively as *chicha.* It is interesting that New World natives and their forebears – the original cultivators and consumers of maize – did not suffer from pellagra, the dangerous nutritional deficiency disease (caused by a lack of niacin, one of the B-vitamins) that has plagued most of the world's maize-eating peoples for centuries. This apparent immunity caused much puzzlement among medical researchers until it was realized that the Native American customs of preparing maize grain in alkali solutions and frequently consuming the grain in combination with leguminous vegetables tended to increase both the niacin availability and the protein quality of maize, thus greatly improving its nutritional value. But when maize was adopted as a staple food by Old World populations, and by non-natives (blacks and whites) in North America, these customs failed to accompany it, with pellagra the result.

Christopher Columbus carried maize to Spain, where by 1500 or so it was under cultivation. Before many years had passed, maize was being grown throughout the Iberian and Italian peninsulas and had appeared as a garden vegetable in England and central Europe; it had also entered eastern Europe via the Balkans and areas along the Danube River. By the seventeenth century, maize had become an important European field crop and staple food, especially in those areas that now comprise northern Italy, Romania, Slovenia, Serbia, and Bulgaria, in addition to Spain; perhaps a century later, it was a principal dietary item in Austria-Hungary and southern France as well.

As the new crop spread across Europe, its New World origins were largely forgotten, but in each locality people at least knew that it came from somewhere else, and it was called "Barbary corn," "Egyptian corn," "Guinea corn," and a host of other names. "Corn" was a generic word meaning simply "grain" in a number of European languages, so that its many aliases actually identified maize as "foreign grain," and the American usage of "corn" for maize grows out of such terminology – in this case, "corn" is the shortened version of the English term "Indian corn," by which the colonists meant, of course, "Indian grain," or maize.

During the sixteenth century, Portuguese traders carried the plant to East Africa and Asia, whereas Arab merchants were probably responsible for its introduction into North Africa. Somewhat later, maize reached West Africa from the Caribbean and was used on both sides of the Atlantic as an inexpensive means of provisioning the human cargoes of the slave trade. The crop spread rapidly throughout the African continent, greatly augmenting the food supply, had become a major staple by the end of the nineteenth century, and even increased in importance by the late twentieth century. In Asia, maize spread along trade routes from the Indian subcontinent, reaching points in China and Southeast Asia by the mid-sixteenth century. It was established in the Philippines and Indonesia during the seventeenth century, and during the eighteenth was much expanded as a crop in China. From there, it spread to Korea and Japan.

Meanwhile, in North America, the early English colonists as well as later immigrants (unlike their Spanish predecessors) had adopted maize as a staple food, and the grain later became the foundation of the U.S. diet and the country's agricultural economy. Countless American dishes and recipes testify to the early pervasiveness of "corn" in direct human consumption, and beginning about the turn of the nineteenth century, U.S. farmers and gardeners began to develop a number of varieties of sweet corn for use as a vegetable (sweet varieties had, however, existed long before this in South America). Moreover, from the mid-nineteenth century onward, U.S. agricultural scientists took the lead in creating hybrid maize varieties with greatly increased grain yields and other desirable characteristics, and with the growth of American livestock industries, the value of "corn" for feeding animals destined to become food themselves surpassed even its importance as a human staple.

Today, maize provides the basis for a number of commercial and industrial products as well as human foods, including starches, sweeteners, corn "flakes" and other packaged breakfast cereals, corn "chips," corn oil, corn syrup, whiskeys, beers, ethanol, plastics, and – most important – animal feed.

Maize is a good source of carbohydrates, and thus of calories and energy, and is high in protein and certain essential fatty acids. But its protein quality is marginal, with low levels of the essential amino acids tryptophan and lysine. It is also low in calcium, and white maize is low in vitamin A.

Common names and synonyms: Bactrian typha, Barbary corn, *blé de Turquie,* corn, cornmeal, *cucurutz,* dent maize, Egyptian corn, flint maize, floury maize, Guinea corn, Indian corn, Indian meal, *kana,* mealies, *milho,* popcorn, Roman corn, *sara chulpi,* Sicilian corn, Spanish corn, sweet corn, Syrian dourra, Turkie corne, Turkish wheat, Virginia wheat, waxy maize, Welsch corn, yellow maize.

See also: "Maize," Part II, Section A, Chapter 4.

Maja pahit – *see* **QUINCE**

MALABAR ALMOND – Also called the "Indian almond," the "country almond," and the "tropical almond," the Malabar almond (*Terminalia catappa*) is an evergreen tree of tropical Asia – probably a native of the Malay Peninsula, although it is now planted in North America and elsewhere as an ornamental. The fruit is about 2 inches long and red to green in color, and its pulp is eaten for its sweet flavor. The almond-shaped kernel inside the fruit is also eaten both raw and roasted, but first it is necessary to break its very tough shell.

Common names and synonyms: Country almond, Indian almond, tropical almond.

Malabar chestnut – *see* **MALABAR NUT**

Malabar gourd – *see* **FIG-LEAFED GOURD, SQUASH AND PUMPKIN**

MALABAR NUT – A nut known by a number of common names such as "Guyana chestnut" and "French peanut," the malabar nut also has two scientific names – *Bombax glabra* and *Pachira aquatica.* A native of the tropical estuaries in a region that stretches from southern Mexico to Guyana and northern Brazil, the malabar nut grows on an attractive evergreen tree. The fruit is a relatively large green pod (4 to 12 inches long and 2 to 2.5 inches in diameter), which contains the nuts until it finally bursts to spill them on the ground. Consumed fresh, the nuts have a flavor reportedly like that of peanuts; when roasted or fried, the taste resembles that of chestnuts. The nuts are also ground into flour for bread, and the young leaves and flowers of the tree are cooked as a vegetable. Another Malabar nut, *Adhatoda vasica,* comes from an East Indian shrub and is used medicinally.

Common names and synonyms: French peanut, Guiana chestnut, Guyana chestnut, Malabar chestnut, provision tree, saba nut.

MALABAR SPINACH – Also called "red vine spinach," malabar spinach (*Basella rubra = B. alba*) is a plant of the Asian tropics that has now spread around the world to be cultivated in most tropical and temperate regions. In the Western Hemisphere, malabar spinach is grown in Mexico and parts of North America for its succulent leaves that are used in the same ways as spinach – as a potherb and raw in salads.

Common names and synonyms: Ceylon spinach, Indian spinach, red vine spinach, vine spinach.

Malacca tree – *see* **AMALAKA**

Malagueta (pepper) – *see* **BRAZILIAN MALAGUETA, MELEGUETA PEPPER**

MALANGA – When the Spaniards arrived in the West Indies, one of the first native American plants they described was *yautía* – still the Puerto Rican name for malanga. However, this leads us straight into a semantic jungle, because the plant is also called "tania," "elephant's-ear," and a score of other names, including "cocoyam" (which it is not) in Africa. Contributing to the confusion are some 40 species of malanga, many of which are mixed up with taro (*Colocasia esculenta*).

Perhaps the most important distinction to be made is that between white malanga (*Xanthosoma sagittifolium = X. violaceum*) and yellow (*X. atrovirens*). White malanga is tania and *yautía* and was also called "dasheen" historically in the West Indies – a name that also is used to refer to taro. However, white malanga is not cultivated for its tuber (as taro is) but rather for its stem and heart leaves, known in the West Indies as callaloo.

Yellow malanga, in contrast, is cultivated for a corm that is shaped like a big yam and is cooked in much the same ways, by boiling, steaming, baking, frying, or roasting. In Africa, the corms are sometimes ground to make "foo-foo." Malanga most probably originated in South America and was brought to the Caribbean Islands by migrating Taino and Carib Indians. It made another leap when it was introduced into West Africa – to feed slaves bound for the Americas – and took root there as one kind of cocoyam. Today, malanga is also cultivated in Central America, the Pacific Islands, and tropical Asia. Malanga provides mostly energy in the form of carbohydrates, although the yellow variety does contain a little vitamin A.

Common names and synonyms: American taro, callaloo, cocoyam, dasheen, elephant's-ear, kong(-)kong taro, spoonflower, tania, tannia, white malanga, *yautía,* yellow malanga.

See also: "Taro," Part II, Section B, Chapter 6.

Malangay – *see* **COCOYAM**

Malangu – *see* **COCOYAM**

MALAY APPLE – A native of Indonesia, the jambu merah tree has been cultivated for millennia. In the past few centuries, the Portuguese spread its fruit, the Malay apple (*Eugenia malaccensis = Syzygium malaccense*), throughout the tropical Old World, and the English brought it to the West Indies in the New World. Malay apples are oblong, about the size of a large orange, and red or crimson when ripe. They are generally eaten raw.

Common names and synonyms: Jambu merah (tree), Tahiti apple.

Malay gooseberry – *see* **OTAHEITE GOOSEBERRY**

Malka – *see* **CLOUDBERRY**

MALLOW – Native to Europe, several herbs of the Malvaceae family are called mallows and are employed to flavor cheese. In the United States, the best known of the mallows is the marsh mallow (*Althaea officinalis*). The plant was so called because it was found in and around marshes near the sea, and it has been naturalized in the marshes of eastern North America. In past centuries, the roots of the marsh mallow were used to flavor candy "marshmallows," which are now made with sugar, corn syrup, gelatin, and starch, then dusted with a little powdered sugar.

Common names and synonyms: Marsh mallow.

Malmsey – *see* **MALVASIA**

MALOGA BEAN – Also called the "flowering bean," the maloga bean (*Vigna lancelota*) is an Australian tree whose roots served as food for the Aborigines.

Common names and synonyms: Flowering bean.

Malt – *see* **BARLEY**

Maltaise orange – *see* **BLOOD ORANGE**

Maltese Blood (orange) – *see* **BLOOD ORANGE**

Maltese orange – *see* **BLOOD ORANGE**

MALVASIA (*see also* **GRAPES**) – An ancient fruit of Greece, Malvasia grapes (*Vitis vinifera*) were used during the Middle Ages to make sweet dessert wines that were frequently shipped from the Greek port of Monemvasia. The name Malvasia is an Italian corruption of that city's name, just as *malvoisie* is a French corruption and "malmsey" an English one. Actually, the name "Malvasia" refers today to a complex of varieties; these are among Italy's most widely planted grapes and constitute an important part of the grape crop of Spain as well. Those planted are mostly white, but there are also red grapes, and both sweet and dry wines are made from them. In addition, the Malvasia lives on in Madeira wine, which has traditionally been based on this grape.

Common names and synonyms: Madeira, malmsey, *malvoisie*.

See in addition: "Wine," Part III, Chapter 13.

Malvoisie – *see* **MALVASIA**

MAMEY SAPOTE – Little known outside the American tropics, the mamey (also mammey) sapote (*Calocarpum sapota* = *Pouteria sapota*) is related to the sapodilla and is found chiefly in Central America, Mexico, northern South America, Cuba, Hispaniola, and the state of Florida. The light, coffee-colored fruit grows on medium-sized trees. It is a large fruit, weighing up to a pound, with a rough, brown skin. The flesh is salmon colored and surrounds a large avocado-like pit. It has a rich and distinctive flavor, not appreciated by everyone. The mamey sapote is a good source of vitamins A and C.

Common names and synonyms: Mammey sapote, sapota.

MAMMEE – The tropical American mammee (*Mammea americana*) is native to the West Indies (and its fruits are common in markets there) but is now grown in the tropics and subtropics around the world, including Florida. Also known as the mammee apple and the San Domingo apricot, the fruit grows on trees that can reach 60 feet in height. It is about the size of a small grapefruit and tastes something like a tart apple while still green and something like an apricot when it is ripe and stewed. The fruit is sometimes eaten raw and in salads but is generally cooked. Mammee flowers are used to make an aromatic liqueur called *eau de Créole.* The mammee is not related to the mamey sapote.

Common names and synonyms: Mammee apple, mammy apple, San Domingo apricot, South American apricot.

Mammee apple – *see* **MAMMEE**

Mammee sapota – *see* **SAPODILLA**

Mammey sapote – *see* **MAMEY SAPOTE**

Mammy apple – *see* **MAMMEE**

Mamoncilla – *see* **SPANISH LIME**

Mamoncillo – *see* **SPANISH LIME**

Manchurian wild rice – *see* **WATER BAMBOO**

Mandarin melon-berry – *see* **CHE**

MANDARIN ORANGE (*see also* **CITRUS FRUITS**) – Other citrus fruits that are very similar (or identical) to the Mandarin orange include the tangerine, the *satsuma,* and the "Clementine," all of which are identified as members of *Citrus reticulata* and orange varieties. The Mandarin – developed in China, or possibly Cochin China (southern Vietnam) – probably took its name from the yellow robes of the Chinese civil servants called Mandarins. It worked its way toward the Near East at a leisurely pace and reached Europe directly from China only at the beginning of the nineteenth century. By midcentury, Mandarin oranges were being grown around the Mediterranean, and they entered the United States at about the same time. Believed to have originated in Tangier, they came to be known as tangerines in North America.

The Clementine – a cross between the Mandarin and the bitter orange – originated in Algiers, whereas the *satsuma* is a seedless Japanese Mandarin. In the early 1870s, Florida orange grower Col. George L. Dancy pioneered commercial tangerine cultivation, and the Dancy tangerine became the most popular of the Mandarin oranges. Florida remains the largest tangerine producer, although the fruits are also grown in California, Texas, and Louisiana. In 1898, U.S. Department of Agriculture botanist Walter Tennyson Swingle developed the tangelo, a cross between a tangerine and a grapefruit. All fruits belonging to *C. reticulata* are small, sweet, easily peeled, and segmented.

Common names and synonyms: Clementine, Dancy tangerine, *satsuma,* tangelo, tangerine.

Mandioc – *see* **MANIOC**

Mandioca – *see* **MANIOC**

MANDRAKE (*see also* **MAYAPPLE**) – An herb of southern Europe and North Africa, the mandrake (*Mandragora officinarum*) has spherical yellow fruits that in the past were believed to have aphrodisiacal properties. This was doubtless because the plant has a long forked root that was believed to resemble the human body from the waist down and was the subject of much sexual superstition. It was also a narcotic. The root was ground and used to encourage a sense of well-being, and possibly of enhanced sexuality.

Manga - *see* **MANGO**

MANGABA – An interesting vine (*Hancornia speciosa*) of Brazil called *mangabeira* produces the mangaba fruits, which are plum-sized and red and have a sweet taste. The same plant also produces a latex that yields a rubber.

Common names and synonyms: Mangabeira.

Mangabeira – *see* **MANGABA**

Man-gay – *see* **MANGO**

Mangel – *see* **BEET**

MANGELWURZEL (*see also* **BEET**) – From the German *Mangold-Wurzel,* meaning "beet root," the mangelwurzel is a variety of the common beet (*Beta vulgaris*) that is chiefly produced for cattle feed, although the young beets are sometimes consumed by humans.

Common names and synonyms: Mangle, mangold, mangold-wurzel.

Mangetout – *see* **PEAS, SUGAR PEA**

Mangga – *see* **MANGO**

Manggis – *see* **MANGOSTEEN**

Manggusta – *see* **MANGOSTEEN**

Mangle – *see* **MANGELWURZEL**

MANGO (*see also* **DUIKA, HORSE MANGO**) – The mango tree (*Mangifera indica*) is an Asian evergreen that can attain a height of 100 feet or more. It is cultivated throughout the tropics of the world, most abundantly in India (where it may have originated and where the mango is connected with both folklore and religious ceremonies) for its greenish yellow fruit, much of which is made into chutney. Mango flesh surrounds a flat but rounded seed or stone and is sweet and golden, even though the skin is tough and inedible. Mangoes are eaten ripe and pickled when green.

All of the 40-some species of *Mangifera* are Southeast Asian in origin, and some may have been domesticated as early as 4,000 to 6,000 years ago. Exactly how they were subsequently dispersed around the world is a matter of conjecture. The Portuguese (who named the fruit *manga*) doubtless had a hand in this in the sixteenth century, taking the mango to islands of the Pacific, throughout the Indian Ocean, and to the east and west coasts of Africa. Mangoes were planted in Brazil around 1700, were carried to the West Indies (where they remain extremely popular) at about the middle of the eighteenth century, and reached Florida (which now produces about 20 percent of the world's mangoes) in North America in the early nineteenth century.

Mangoes belong to the Anacardiaceae family, which includes poison ivy, and for those who are allergic, touching mango juice can cause the skin to swell and blister. For some reason, Midwesterners in the United States call sweet bell peppers "mangoes"; both are good sources of vitamin A and a great source of vitamin C and potassium, not to mention fiber. The mango kernel is also eaten after it is boiled or roasted.

Common names and synonyms: Manga, man-gay, mangga, man-kay.

Mangold – *see* **MANGELWURZEL**

Mangold-Wurzel – *see* **MANGELWURZEL**

MANGO MELON (*see also* **MELONS**) – The genus *Cucumis* embraces the different species of melons and cucumbers. The mango melon (*C. melo* var. *chito*) is a muskmelon that is mistakenly called a mango, and the fact that it is also known as a "lemon cucumber" further indicates a considerable popular ambivalence about this fruit's identity. It is a small melon – about the size of an orange, with a yellow skin and white flesh – and is cultivated primarily for making preserves and "mango pickles."

Common names and synonyms: Lemon cucumber.

See in addition: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

Mango squash – *see* **CHAYOTE**

Mangostan – *see* **MANGOSTEEN**

MANGOSTEEN – This fruit, native to Malaya, enjoys a reputation among those who should know as the world's most delicious fruit. Actually a berry (and unrelated to the mango), the mangosteen (*Garcinia mangostana*) is the size of a small- to medium-sized orange, and at first glance with its purplish leathery skin looks something like a pomegranate. Its flesh is juicy, pink- or cream-colored, and somewhat tart; its taste blends the flavors of grape and strawberry by some accounts and those of peach and pineapple according to others.

The Portuguese called the fruit *manggusta* and later mangistão and *maggistan,* but by the seventeenth century it had become "mangostan" and eventually "mangosteen." It was described by Captain James Cook in 1770, was introduced in Ceylon (Sri Lanka) around 1800, and spread out from there. Today, the fruit is grown in parts of the southern United States, the West Indies, and Central America, as well as Southeast Asia, but nowhere on a commercial scale because it bruises too easily to ship well. A mangosteen is almost always eaten raw.

Common names and synonyms: King-of-fruits, *maggistan,* manggis, *manggusta,* mangostan, men-gu.

MANGROVE (*see also* **BURMA MANGROVE, TAGAL MANGROVE, NIPA PALM**) – The fruits and leaves of mangroves have long been used as food by indigenous peoples – especially during hard times. On the coasts of tropical America, West Africa, and the islands of Polynesia, the mangrove in question is the red mangrove (*Rhizophora mangle*), the fruit of which, with its starchy interior, can be eaten both fresh and preserved. Moreover, a light wine has been made from its fermented juice. In the Old World tropics (from South and East Africa to southern China, Australia, Melanesia, and Micronesia), the plant is the Asiatic mangrove (*R. mucronata*). This fruit would seem to be sweeter than its New World counterpart and, again, can be made into a light wine. Both plants have also long been a part of the pharmacopoeia of folk medicines.

Common names and synonyms: American mangrove, Asiatic mangrove, red mangrove.

Mani – *see* **PEANUT**

Manihot – *see* **MANIOC**

Manila bean – *see* **WINGED BEAN**

Manila tamarind – *see* **PITHECELLOBIUM**

Manilla bean – *see* **WINGED BEAN**

MANIOC – The name "manioc" (*Manihot esculenta*) comes from the Brazilian Indian word *mandioca,* but the plant is also known as cassava, yuca, and the tapioca-plant. A Brazilian native, it is a perennial shrub with long, narrow, starchy tubers. Manioc traveled in canoes with South American Indians migrating northward into the Caribbean and, later, in Portuguese ships from Brazil to Africa. Its advantages are that it requires little labor to cultivate yet produces more calories per acre than any other food plant, and it keeps in the ground until needed.

A disadvantage is that save for carbohydrates, it has little to offer in the way of nutrients. Another is that although sweet manioc varieties pose no threat, the roots of most varieties are bitter and can contain enough cyanide to be toxic. The poison must first be removed by pounding, scraping, and cooking. The vegetable is then boiled or baked like a potato, made into a flour for breads, and employed to thicken soup. The meal or flour is sprinkled onto most any dish. Tapioca is a kind of manioc flour.

Common names and synonyms: Cassava, mandioc, *mandioca,* manihot, tapioca-plant, yuca.

See also: "Manioc," Part II, Section B, Chapter 2.

Man-kay – *see* **MANGO**

MANNA – Some of the lichens of the genus *Lecanora* are called manna, presumably because one of them, *L. esculenta,* (a kind of moss containing a fungus that grows on trees, rocks, and stones and is blown about the desert), is reputed to be the manna that dropped out of heaven in ancient times to sustain the Israelites in their flight from Egypt. In the Middle East, lichen bread and manna jelly are made from it. Another "manna lichen" is *Gyrophora esculenta,* which is widely eaten in Japan.

Common names and synonyms: Manna lichen.

MANNA GUM – Also known as "manna eucalyptus" and "gum tree," the manna gum (*Eucalyptus viminalis*) is an Australian native (as are all eucalypts) that exudes a red gum or "manna" from punctures or cracks in the bark. This gum, along with the tree's aromatic leaves, was eaten by Australian Aborigines.

Common names and synonyms: Gum tree, manna eucalyptus.

Manna lichen – *see* **MANNA**

MANZANA (*see also* **CHILLI PEPPERS**) – Appearing very much like a small sweet bell pepper, the manzana, with black seeds that distinguish it as a member of *Capsicum pubescens,* has nothing sweet about it. Barely known to consumers in the United States, this pepper (like the other members of *C. pubescens*) originated in South America and migrated north, reaching Mexico and Central America, where it is now cultivated, perhaps as late as a century ago. This hot, deep yellow–colored pepper is frequently stuffed or used in salsas.

Common names and synonyms: Chile caballo, chilli rocoto, manzano.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Manzanillo (olive) – *see* **OLIVE**

MAPLE SYRUP AND MAPLE SUGAR – Both maple syrup and maple sugar are made from the sap of several varieties of maple trees (*Acer* spp.) and especially from that of the sugar maple (*A. saccharum*). All of these trees are natives of the northern United States and Canada. The sap is collected by boring a tap-hole into the tree, then inserting a spout upon which a sap-bucket is hung. The collected sap is subsequently boiled down into syrup, and the granular residue left when all the liquid is gone is the sugar. Maple sugar (and syrup) was the only sweetener for Native Americans and continued to be the only one used in much of Canada and by some of those in the northeastern United States until fairly recently. The gathering season is in the early spring and ends when the trees begin to bud.

Common names and synonyms: Sugar maple (tree).

Mapuey – *see* **CUSH-CUSH YAM**

Maracuja – *see* **PASSION FRUIT**

Mare's-tail – *see* **HORSEWEED**

MARIGOLD – Although marigolds generally are thought of as members of the genus *Tagetes* and natives of tropical America, this familiar daisy-like flower (*Calendula officinalis*) – the "pot marigold" – is said to have originated in Europe. Its orange petals were used as one of the first coloring agents for cheeses and are sometimes employed as a substitute for saffron in rice dishes. Nowadays, the pot marigold is used much less frequently for seasoning foods than it was in the past, especially in the Middle Ages, when its cultivation began.

Common names and synonyms: Pot marigold, Scotch marigold.

MARJORAM AND OREGANO – Native to the Mediterranean region, oregano (*Origanum vulgare*) is actually a variety of wild marjoram. The name "oregano" comes from a Greek term meaning "joy of the mountains"; indeed, oregano thrives in mountainous terrain, and strongly flavored varieties of this herb – called *rigani* – grow in the mountains of Greece. Marjoram comes as pot marjoram (*O. onites*) and sweet marjoram (*O. majorana*). Both varieties have a flavor similar to, but more delicate than, that of oregano. Although marjoram and oregano have long played an important role in French, Greek, and especially Italian cuisines, it was only with the return of American GIs from Italy after World War II that the two spices became well known in the United States. They are available both fresh and dried and go well in tomato-based dishes. Oregano is the quintessential herb for pizza and is also an important ingredient in chilli powders.

Common names and synonyms: Knotted marjoram, pot marjoram, *rigani,* Spanish oregano, sweet marjoram, wild marjoram.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Marmalade box – *see* **GENIPAP**

Marmalade plum – *see* **SAPODILLA**

Marmelo – *see* **BAEL FRUIT**

MARROW – In the case of plant foods, the term "marrow" in its broadest sense can mean the pulp of any fruit. For the British in particular, "vegetable marrow" or "marrow squash" generally connotes summer squashes with white to green skins like the zucchini (*Cucurbita pepo*). In the eastern United States, however, "marrow" often indicates a huge orange winter squash (*C. maxima*) used in cooking.

Common names and synonyms: Marrow squash, vegetable marrow.

See also: "Squash," Part II, Section C, Chapter 8.

Marrow stem – *see* **KALE**

Marsh-elder – *see* **SUMPWEED**

Marsh mallow – *see* **MALLOW**

Marsh marigold – *see* **COWSLIP**

Marsh salad – *see* **CORNSALAD**

Marsh samphire – *see* **GLASSWORT**

Marsh trefoil – *see* **BOG MYRTLE**

Martynia – *see* **UNICORN PLANT**

MARULA PLUM – A large wild tree of southern Africa, the marula (*Sclerocarya caffra*) has plumlike fruits with a thick yellow peel and white, sweet-sour flesh. They are eaten raw, used to flavor alcoholic beverages, and made into juices and jams. In addition, the seeds of the fruits are eaten like nuts by aficionados, who are clearly enthusiastic about what they call the "king's-nut."

Common names and synonyms: King's-nut.

Marumi – *see* **KUMQUAT**

MASHUA – Also called *anu* (among other common names) and related to the ornamental nasturtium, the carrot- and potato-shaped tubers of mashua (*Tropaeolum tuberosum*) are an important staple in the Andean region, esprcially at altitudes where potatoes and other tubers cannot be grown successfully. The tubers of mashua are not eaten raw, but rather are cured in the sun, then freeze-dried and used like potatoes. The plant is also said to have medicinal properties.

Common names and synonyms: Anu, capucine, *ysaño.*

Mast – *see* **BEECHNUT**

Masterwort – *see* **PURPLESTEM ANGELICA**

MASTIC BULLY – *Sideroxylon mastichodendron* is a tree of South Florida and the West Indies with "ironlike" wood that in the past was useful for shipbuilding. The fruits of this and related species such as *S. foetidissimum* are edible although quite acidic.

MASTIC TREE – Also called "mastic shrub," the mastic tree (*Pistacia lentiscus*) is a small tree grown in southern Europe for mastic (also "lentisk") – a resin obtained by cutting into the tree. Mastic is used mostly for varnishes, paints, and the like, but the word "mastic" also designates an alcoholic beverage flavored with mastic. Another group of trees called mastic trees are South American "pepper trees" (genus *Schinus*), especially *S. molle,* a Peruvian evergreen that has small red drupes – the pink peppercorns that have recently been discovered to be potentially harmful. In the past, a good *chicha* (a beerlike drink) was made from the seeds of the tree they call *molle* in Peru.

Common names and synonyms: Lentisk, mastic shrub, *molle,* pepper tree.

Mat bean – *see* **MOTH BEAN**

Maté – *see* **YERBA MATÉ**

MATRIMONY VINE – Also called "box thorn," *gow kee,* and *chu chi,* the matrimony vine (of the genus *Lycium*) comprises *L. chinense* (originally from East Asia) and a number of species native to the southwestern United States and Mexico, such as *L. andersonii* – the "desert thorn." The tender leaves and shoots were eaten in the past by Native Americans and are still consumed in Asia. In addition, the plants produce red, juicy, oblong berries (known as *frutillos* in Mexico) that are edible but do not seem to excite much enthusiasm. They were put to use as a famine food by Native Americans.

Common names and synonyms: Box thorn, *chu chi,* desert thorn, *frutillo, gow kee.*

Matsutake (mushroom) – *see* **MUSHROOMS AND FUNGI**

Ma-tum – *see* **QUINCE**

MAUKA – Called *mauka* in Bolivia and *chago* (among other terms) in Peru, this plant (*Mirabilis expansa*) constitutes a seeming contradiction: It is a virtually unknown crop with a wide geographic distribution. Grown in the Andes region from Venezuela to Chile in small vegetable gardens, the cultivation of *mauka* was described for the first time only a quarter of a century ago. Both the tuberous roots and the leaves are consumed – the latter in salads and chilli sauces. The roots are used like manioc and are an ingredient in soups and stews.

Common names and synonyms: Chago.

MAVRODAPHNE (*see also* **GRAPES**) – Mavrodaphne is an eastern Mediterranean wine grape (*Vitis vinifera*), which the Greeks in particular have used to make sweet, portlike, dessert wines for many centuries. The name means "black laurel," and the grape is aromatic and powerful.

See in addition: "Wine," Part III, Chapter 13.

Maw seed – *see* **POPPY SEED**

Maya – *see* **PINGUIN**

MAYAPPLE (*see also* **MAYPOP**) – Because it was commonly known as the "American mandrake" or just plain "mandrake," many refrained from eating the mayapple (*Podophyllum peltatum*), fearing that like the mandrake of Europe, it too was poisonous. In fact, the roots, leaves, and seeds of this woodland plant of eastern North America *are* poisonous, but its lemon-shaped fruit is not and is often made into a marmalade. This wild-growing plant with its distinctive white flowers was surely also a food of Native Americans, who probably learned the hard way that only its fruit was edible.

Common names and synonyms: American mandrake, mandrake.

May-bob – *see* **COWSLIP**

Maycock – *see* **MAYPOP**

Mayflower – *see* **TRAILING ARBUTUS**

MAYGRASS – In North America, there are native species of maygrass (*Phalaris caroliniana*) as well as other species of the genus *Phalaris* that have been introduced from the Mediterranean region, from West Africa, and from the Canary Islands (the latter, *P. canariensis,* is called "canary grass"). Their seeds have been used as a grain and the young shoots eaten raw or cooked like a vegetable.

Common names and synonyms: Canary grass.

Mayhaw – *see* **HAWTHORN BERRY**

MAYPOP – A North American cousin to the South American passion fruit, the maypop (*Passiflora incarnata*) grows wild in the southeastern United States. Originally, the plant was called "maycock" after the Powhatan *machawq,* suggesting that Native Americans were familiar with it. The fruit is about the size of a small lemon, has a hint of a lemon taste, and has also been called "mayapple." In addition to the use of the fruit as a food, the leaves, stems, and yellow flowers of maypops have long been used medicinally.

Common names and synonyms: Apricot vine, granadilla, mayapple, maycock, wild passion-flower.

Mazzard – *see* **CHERRY**

Meadow-bright – *see* **COWSLIP**

Meadow fern – *see* **SWEET FERN**

Meadow mushroom – *see* **MUSHROOMS AND FUNGI**

Meadow parsnip – *see* **COW PARSNIP**

Meadow salsify – *see* **MOONFLOWER**

Mediterranean rocket – *see* **ARUGULA**

Medjool date – *see* **DATE**

MEDLAR – Originating in Persia (and possibly also in Europe), the medlar (*Mespilus germanica*) belongs to the apple family but is a small, round, brown fruit that looks like a plum. Medlars were known to the ancient Greeks, and Pliny wrote of the Romans having three kinds. Like so many fruits and vegetables, medlars were carried throughout the Roman Empire and afterward remained very popular in Europe. The fruit traveled with Europeans to North America, where medlar trees now grow from the southern United States to southern Canada. The medlar is interesting in that it is not edible until well after it has achieved ripeness – in fact when it has begun to decay. Its juice makes a fine cold drink, and although the pulp was once consumed raw, most medlars that are used nowadays go into jelly. Medlars are, in fact, becoming a forgotten fruit. This medlar should not be confused with the loquat, which is also called the Japanese medlar.

Meetin' seed – *see* **FENNEL**

Meiwa – *see* **KUMQUAT**

Melano – *see* **KIWANO**

Melanzana – *see* **EGGPLANT**

MELEGUETA PEPPER – Also known as "malagueta pepper" and "grains-of-paradise," melegueta pepper (*Aframomum melegueta*) is the pungent seed of a West African plant. Related to cardamom – and with a similar odor – the tiny grains have a hot and peppery taste and are used as a spice.

Common names and synonyms: Grains-of-paradise, Guinea grains, malagueta pepper.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Melilot – *see* **SWEET CLOVER**

Melissa – *see* **BEE BALM, LEMON BALM**

Melist – *see* **SWEET CLOVER**

Mellarosa – *see* **BERGAMOT**

Melloco – *see* **ULLUCO**

MELON CACTUS – Called "melon-thistle," "Turk's-cap," "Turk's-head," and *melon,* as well as melon cactus, about 35 species in the genus *Melocactus* in one form or another resemble melons and have a bristly crown filled with woolly fibrous matter. Many of these natives of the West Indies, Central America, and tropical South America (especially *M. communis* of Jamaica) bear small, pinkish, edible fruits.

Common names and synonyms: Melon, melon-thistle, Turk's-cap, Turk's-head.

Melon fruit – *see* **PAPAYA**

Melongene – *see* **EGGPLANT**

Melon pawpaw – *see* **PAPAYA**

Melon(-)pear – *see* **PEPINO**

MELONS (*see also* **PUMPKIN, SQUASH AND PUMPKIN,** and various melon entries) – Most melons are members of the extensive Cucurbitaceae or gourd family, along with such diverse relatives as the pumpkins and squashes of the New World and the cucumber of the Old World. Plant expert Charles B. Heiser, Jr., has pointed out that the Latin word *cucurbitare* means (or at least meant) "to commit adultery," and it is the case that melons have interbred so promiscuously that classification is difficult. What follows is a discussion of a few basic melon types.

Save for the watermelon, melons are like winter squashes in structure – with a thick rind and a seed-filled center. The watermelon, by contrast, resembles the cucumber in that its seeds are more evenly dispersed. Watermelons (*Citrullus lanatus* = *C. vulgaris*) are the first melons to show up in the historical record – about 6,000 years ago in Egyptian tomb art. However, it would appear from archaeological remains that they were in India much earlier – during prehistoric times – and unidentified melons were being cultivated in the Indus Valley about 4,000 years ago. This gives India a claim to be the cradle of melons, but Persia and tropical Africa have also been put forward as likely candidates. Most probably, tropical Africa was the home of the watermelon, and the other melons arose elsewhere – perhaps in both India and the Middle East. Certainly it was Africa that sent watermelons to the Americas via the slave trade, and now they are grown all around the globe.

The past of the other melons, all (along with the cucumber) closely related members of the genus *Cucumis,* is even more obscure. They seem to have been unknown to the ancients, and although Pliny in the first century A.D. apparently mentioned melons, it was not with much enthusiasm. Melons were still thought of as green vegetables – and not particularly good ones at that, unless they were cooked and eaten with plenty of spices. Nonetheless, melons were spread by the Romans throughout their empire; the Moors encouraged melon cultivation in Spain after their invasion in 711; and real enthusiasm for the fruits was expressed for the first time during the fifteenth century, when they became popular at the French court. Sweet melons seem finally to have been developed at this point – perhaps through the patience of Mediterranean gardeners in southern Europe, or perhaps in the Arab world – and were introduced into Europe via the Moors still holding Granada in Spain at the time.

And such development continued. The word for the melon known as cantaloupe (*Cucumis melo* var. *cantalupensis*) comes from Cantalupo, a papal garden near Rome where that variety of melon was born during the Renaissance. Christopher Columbus reached the West Indies with melon seeds, and melons were reported growing in New Mexico by 1540. Later, the Spaniards began cultivating muskmelons in California. In fact, what North Americans call cantaloupes are actually descendants of these muskmelons – the difference basically being that the muskmelon (*Cucumis melo* var. *reticulatus*) has a netted skin, whereas the true cantaloupe of Europe has a scaly or warty rind. Both have flesh ranging in color from orange to green, and both are aromatic. The Persian melon – also aromatic – is a variety of the muskmelon. The winter melons (*Cucumis melo* var. *inodorus*), by contrast, are not aromatic. These include the honeydew (the sweetest of the melons) and the casaba – a melon that has been crossed with the Persian melon to produce the Crenshaw.

Chief among the Asian melons is the bitter melon (*Momordica charantia*) – bitter, among other reasons, because it contains quinine, which has doubtless helped many to live with malaria in the Asian tropics. The bitter melon is braised or steamed and sometimes cut up and stir-fried. The Chinese winter melon or "fuzzy melon" (*Benincasa hispida*) – one of the largest vegetables grown – is also cooked as a vegetable.

All melons are rich in vitamin C and potassium. Those with orange flesh are also a good source of beta-carotene.

Common names and synonyms: Bitter melon, cantaloupe, casaba, Chinese winter melon, Crenshaw (melon), fuzzy melon, honeydew, muskmelon, Ogen melon, Oriental melon, Persian melon, sweet melon, watermelon, winter melon.

See in addition: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

Melonshrub – *see* **PEPINO**

Melon-thistle – *see* **MELON CACTUS**

Men-gu – *see* **MANGOSTEEN**

Merkel – *see* **MOREL**

MERLOT (*see also* **GRAPES**) – A red grape, the Merlot (*Vitis vinifera*) produces a wine that has been used mostly to blend with other wines but is now achieving an identity of its own. Until 1970 or so, Merlot grapes were grown almost exclusively in Europe. Since that time, however, they have become increasingly popular in California, where initially they were used to blend with Cabernets. In the process it was discovered that Merlot grapes yield a wine that can stand on its own.

See in addition: "Wine," Part III, Chapter 13.

MERTAJAM – A tree native to Indonesia, the mertajam (*Erioglossum rubiginosum*) has small, purple fruits about the size of large grapes. They grow in clusters and have a somewhat astringent taste. Not a commercial fruit, the mertajam is made into jams and syrups.

MESQUITE – Also called "algarroba" and "honey locust," mesquite comprises several members of the genus *Prosopis* (especially *P. juliflora* var. *juliflora*), all of which are members of the pea family, Fabaceae. Mesquite plants are small trees or shrubs, native to the Americas and especially abundant throughout the southwestern United States and Mexico. The pods of *P. juliflora* var. *juliflora* are among the oldest known foods of humans in the New World and have long constituted a staple for Indians of the desert Southwest.

While still immature, the pods were eaten raw or cooked like a vegetable, and when ripe they yielded a sweetish pulp that was either eaten or fermented to make a mesquite wine. Generally, however, they were ground to make a meal called *pinole,* which was used to make a gruel, and today mesquite flour products are still popular. The branches also exude a sweet gum that can be eaten for dessert. The screwbean mesquite (*P. pubescens*), the western honey mesquite (*P. juniflora* var. *glandulosa*), and the velvet mesquite (*P. velutina*) were used in much the same fashion, with the latter also employed for medicinal purposes.

Common names and synonyms: Algarroba, Fremont screwbean, honey locust, screwbean, screwbean mesquite, screwpod mesquite, tornillo, velvet mesquite, western honey mesquite.

Milfoil – *see* **YARROW**

Milho – *see* **MAIZE**

Milkmaid – *see* **YAM DAISY**

MILKWEED – Most plants of the genus *Asclepias* have milky juice, especially *A. syriaca,* the "common milkweed" of eastern North America, which is also called "silkweed." It has clusters of purple blossoms and pointed pods that Native Americans dried and used to flavor foods.

Common names and synonyms: Common milkweed, silkweed.

MILLET (*see also* **FINGER MILLET, JAPANESE MILLET, JOB'S-TEARS, SORGHUM**) – Millet is a name applied to a variety of cultivated grasses (*Panicum* spp. and *Setaria* spp.) that are native to Asia and Africa. Millet was cultivated for food some 9,000 years ago at Thessaly in Greece (making it one of the oldest grains known to humans) and around 8,000 years ago in China (where it was considered one of the sacred plants). By the second century B.C. (and probably long before), millet was the most important cereal in Japan, and it was one of the first plants cultivated in Africa. It was an important crop in Europe during the Middle Ages and, much more recently, has been grown in the New World for hay.

Among the most important varieties are the "pearl," "finger," and "foxtail" millets. Despite the tiny size of millet grains (the smallest of all the grains), they have sustained huge numbers of people for millennia, and it is interesting to note that it was millet – not rice – that was first predominant in China. Early on, the significant centers of Chinese agriculture were in the north, where millet was an important staple. Because millets lack gluten, they are a particularly important food for those who must avoid that protein. However, the absence of gluten also means that millets cannot be used for making raised breads but only flatbreads. Pearl millet, the most important of the varieties grown for human consumption, is used for couscous and makes a fine hot cereal as well. Millet (available in health-food stores) provides the consumer with significant amounts of folacin, thiamine, and magnesium.

Common names and synonyms: Bajra, Bengal grass, bristle grass, bulrush millet, finger millet, foxtail millet, German millet, golden timothy (grass), guinea millet, Hungarian grass, Italian millet, *milho,* panic(oid) grass(es), pearl millet, *ragi,* Siberian millet.

See in addition: "Millets," Part II, Section A, Chapter 5.

Millmi – *see* **AMARANTH**

Millsweet limetta – *see* **LIMETTA**

Miltomate – *see* **TOMATILLO**

Mimosa – *see* **ACACIA**

MIMUSOPS – The *Mimusops* – within the family Sapotaceae – constitute a large genus (also called *Manilkara*) of tropical trees that are primarily used for timber but also yield a gum and bear edible fruits. Perhaps the best-known representative of the genus is the sapodilla (*Manilkara zapota*), but there are many others. One of these is *Mimusops parvifolia* of the Philippines and the southwestern Pacific area. Another is *Mimusops elengi,* a large East Asian tree called the "tanjong tree" (also the "Spanish cherry"), which has yellow berries that are eaten despite a floury consistency and also yield an oil from their seeds. The Brazilian cowtree (*Mimusops elata*) has fruits about the size of an apple, which yield a milky latex that is used in coffee. The naseberry (*Mimusops sieberii*) that grows in the southern United States and Mexico is eaten raw for its fine flavor. *Manilkara bidentata* (called "balata"), that grows in Trinidad and northern

South America, bears an oily, sweet fruit that is much appreciated by children. In addition, the young shoots of many of these trees are cooked and eaten with other vegetables, and the latex is chewed like gum.

Common names and synonyms: Balata, cowtree, naseberry, Spanish cherry, tanjong tree.

Miner's-lettuce – *see* **PURSLANE**

Miner's-salad – *see* **PURSLANE**

MINT (*see also* **CORN MINT**) – Some 600 perennial herbs of the genus *Mentha*, which are widely distributed throughout the world, fall under the rubric of mint – a name derived from the nymph Minthe, who was reputed to have turned into this plant. All apparently originated in the Mediterranean area and North Africa and have been used since ancient times for the flavor provide by the essential oils contained in their leaves. Perhaps the most ubiquitous of the mint plants is spearmint (*M. spicata*), which flavors a favorite tea in North Africa, mint juleps in the U.S. South (said to have been invented in 1809), and mint sauces or jellies to accompany lamb. A pungent offspring of spearmint is peppermint (*M.* × *piperita*), with its menthol-containing essential oil that adds flavor to many things from toothpaste to the liqueur crème de menthe and has dozens of pharmaceutical uses. Still another commonly grown variety is apple mint (*M.* × *rotundifolia*) – also called Bowles mint – which has the flavor of apples and is sweeter than other varieties. Mint is sold fresh or dried and goes well in herbal teas, salads, stews, and candies, and with fruit, poultry, meat, and fish dishes.

Common names and synonyms: Apple mint, Bowles mint, corn mint, field mint, pennyroyal, peppermint, red mint, Scotch spearmint, spearmint.

See in addition: "Spices and Flavorings," Part II, Section F, Chapter 1.

Mint geranium – *see* **COSTMARY**

MINTHOSTACHYS – The family Lamiaceae (Labiatae) comprises a great number of aromatic plants, many of which contain essential oils that are used for flavoring foods and teas. Among these are a dozen or so species of the genus *Minthostachys,* which are mintlike herbs native to a range in the Andean region stretching from Venezuela to Argentina. Piperina (*M. verticillata*), which grows in the latter country, is employed to make a popular tea called "Peperina." Tipo or poleo (*M. mollis*) and other species are also used to make beverages, and their minty flavor is employed as a condiment. Some of these herbs are added to potatoes in storage to inhibit sprouting.

Common names and synonyms: Piperina, poleo, tipo.

Mioga ginger – *see* **MYOGA GINGER**

Miracle berry – *see* **MIRACLE FRUIT**

MIRACLE FRUIT (*see also* **LIMEBERRY**) – Native to hot, tropical lowlands in West Africa, this fruit (*Synsepalum dulcificum*) is about the size and shape of an olive and has a single seed surrounded by white flesh and a deep red skin. The fruit is eaten fresh but did not derive its name from an exceptional sweetness. Rather, "miracle fruit" comes from its ability to affect the palate in a way that makes subsequently consumed sour or acidic foods appear sweet. This "miraculous berry" grows on bushes or trees reaching up to 18 feet in height in their native habitat, but in other areas they rarely achieve 5 feet. The leaves are elongated and a lush green (in some varieties the leaves are hairy); the flowers are small and white.

Common names and synonyms: Miracle berry, miraculous berry.

Miraculous berry – *see* **MIRACLE FRUIT**

Mirliton – *see* **CHAYOTE**

Mississippi chicken corn – *see* **SORGHUM**

Missouri gourd – *see* **BUFFALO GOURD**

Mistletoe – *see* **JUNIPER MISTLETOE**

Miterwort – *see* **COOLWORT**

Mitsuba – *see* **HONEWORT**

Mizuna – *see* **MUSTARD GREENS**

MOCAMBO – Of the same genus as cacao (from which chocolate is made), the mocambo (*Theobroma bicolor*) is a tree that is native to Central and South America and reaches some 30 feet in height. Its fruit is cone shaped, with a chocolate-colored interior, and is used mostly for making a beverage.

Mocha – *see* **COFFEE**

Mock pak choy – *see* **CHINESE FLOWERING CABBAGE**

Mo-ehr – *see* **CLOUD EAR**

Molle – *see* **MASTIC TREE**

Moltebeere – *see* **CLOUDBERRY**

Mombin – *see* **HOG PLUM, YELLOW MOMBIN**

MONGONGO – This large, deciduous tree (*Ricinodendron rautanenii*), growing wild in the arid soils of southern Africa, belongs to the Euphorbiaceae, a generally poisonous family of plants. However, the fruit from this particular tree is not only edible but is said to provide over half of the daily calories consumed by the !Kung San, a hunting-and-gathering people of the Kalahari Desert. The fruit's flesh is edible, as is its kernel, which is protected by a hard-shelled stone. This nut is high in both fat and protein. Mongongo nuts do not mature on the tree but fall when still green. Only then do they start the ripening process, with the skin changing to brown, the flesh softening, and the flavor developing.

Monkey-bread – *see* **BAOBAB**

Monkey nut – *see* **PEANUT**

MONKEY ORANGE – This small, thorny shrub (*Strychnos spinosa*) can be found throughout tropical and subtropical eastern and southern Africa, particularly on arid savannas and the lower ranges of mountain slopes. The skin of its brilliantly green fruit changes to yellow when ripening. The gelatin-like flesh, too, is yellow, but of a darker shade. Sweet yet acidic in taste, the fruits are frequently mixed with milk. They are also used to make an alcoholic beverage. Unripe fruits and the roots of the shrub serve as the basis of a snakebite antidote for some native African peoples. The seeds of *Strychnos spinosa* are poisonous.

Common names and synonyms: Kaffir orange, Natal orange.

Monkey-puzzle (tree) – *see* **CHILEAN PINE**

Monk's pepper tree – *see* **CHASTE TREE**

MONSTERA – A peculiar-looking fruit, the monstera (*Monstera deliciosa*) is native to Mexico and Guatemala, where it is called *ceriman.* Also called the "Swiss-cheese plant" and "Mexican breadfruit," it is in fact the fruit of the split-leaf philodendron, which is (in smaller size), a familiar houseplant. The fruit grows on large vines with leaves up to 3 feet wide. In shape, it resembles an elongated pinecone, covered as it is with many small kernels. When ripe, these kernels split apart to reveal a pale yellow, sweet pulp with a delicious taste seemingly a cross between the flavors of banana and pineapple. If the fruit is not allowed to ripen fully, however, it can irritate the mouth and the throat. In the United States, the monstera is grown in Florida and California, and some gourmet shops carry the fruit.

Common names and synonyms: Ananas de Mexico, balazo, banana de brejo, ceriman, ceriman de Mexico, fruta de Mexico, fruit-salad fruit, Mexican breadfruit, *pina anona,* Swiss-cheese plant.

Montmorency – *see* **CHERRY**

Mook yee – *see* **CLOUD EAR**

Mooli – *see* **DAIKON**

MOONFLOWER – A number of plants are called "moonflower." One is *Mentzelia pumila,* the "desert blazing star" (also "evening star"), which, in addition to bright yellow, star-shaped flowers, has a bullet-shaped seed capsule. Native Americans ground these seeds for meal. Another moonflower is the yellow salsify (*Tragopogon dubius*), which is also called meadow salsify. It is a perennial herb that was introduced from Europe and is now naturalized in the Americas. Native Americans used this plant for both food and medicine. Two more moonflowers are comprised of South American plants of the genus *Datura* – called "angel's-trumpets" – that are cultivated for their large, trumpet-like flowers. In the United States, "sacred datura" (*Datura meteloides*), also called jimsonweed and moon lily, is a dangerous plant: All its parts are extremely poisonous if ingested. However, sacred datura was one of the most important medicinal plants for Native Americans.

Common names and synonyms: Angel's-trumpet, *datura,* desert blazing star, evening star, jimsonweed, meadow salsify, moon lily, sacred datura, yellow salsify.

Moon lily – *see* **MOONFLOWER**

Moqua – *see* **FUZZY MELON**

Mora – *see* **JALAPEÑO**

MOREL (*see also* **MUSHROOMS AND FUNGI**) – Perhaps the best-known and most sought-after type of fungus, morel mushrooms (genus *Morchella*) come in many varieties – all edible – and are distinguished by their hollow stems and the irregular pits and ridges in their cone-shaped caps. Of all the various morels, probably the two most common are the true or yellow morel (*M. esculenta*), which is 2 to 6 inches tall (3 to 4 inches making up the length of the cap), and the white morel (*M. deliciosa*), which is slightly longer and is thought to be the best-tasting morel. Morels grow wild, often in wooded areas that have been burned-over, but they cannot (at least to this point) be cultivated. They are used in several different dishes. Morels were doubtless viewed as a springtime delicacy by countless generations of Native Americans; moreover, there are European species of morels that have also been consumed for millennia.

Common names and synonyms: Black morel, golden morel, merkel, morille, narrow-capped morel, pinecone mushroom, sponge mushroom, true morel, white morel, yellow morel.

See in addition: "Fungi," Part II, Section C, Chapter 7; "Mushrooms and Fungi," Part VIII.

Morella – *see* **WONDERBERRY**

Moreton Bay chestnut – *see* **AUSTRALIAN CHESTNUT**

Morille – *see* **MOREL**

MORINDA – Members of a large genus of East Indian tropical trees and shrubs, many *Morinda* plants produce an edible, pulpy fruit that is eaten raw and often used in chutneys and curries. One of these, called the "Indian mulberry" (*M. citrifolia*), now grows in the Florida Keys.

Common names and synonyms: Indian mulberry.

Moringa nut (tree) – *see* **BENOIL TREE**

Morita – *see* **JALAPEÑO**

MORMON TEA – Also called the "desert jointfir" and "teposote" among other appellations, "Mormon tea" was sometimes the longleaf ephedra shrub (*Ephedra trifurca*), sometimes *E. nevadensis,* and sometimes *E. viridis.* It received the name "Mormon tea" after Mormon settlers in Utah made tea from the dried twigs and stems of these plants. However, Native Americans preceded the Mormons in using the various species of *Ephedra* for tea making and also for treating illnesses.

Common names and synonyms: Desert jointfir, longleaf ephedra, teposote.

Moro (orange) – *see* **BLOOD ORANGE**

Mostarda – *see* **MUSTARD SEED**

Mostaza – *see* **MUSTARD SEED**

MOTH BEAN – Native to tropical Asia and also called the "mat bean," the moth bean (*Phaseolus aconitifolius = Vigna aconitifolia*) is a small, yellowish brown seed in a cylindrical pod that grows on vines which provide a matlike cover for the soil. The bean is used, especially in India, for human food. It is made into dhal and bean paste, and the immature pods are cooked as a vegetable.

Common names and synonyms: Mat bean.

See also: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

Mother-of-clove(s) – *see* **CLOVE(S)**

MOUNTAIN ASH – A native of northeastern North America and the Appalachian region, the mountain ash (*Sorbus americana*) produces clusters of orange red berries. Although these are much too bitter to eat out of hand, Native Americans in the past dried them and ground them into a meal. The berries are also made into syrup, jams, and the like.

Mountain balm – *see* **YERBA SANTA**

Mountain cranberry – *see* **LINGONBERRY**

Mountain hemlock – *see* **HEMLOCK**

Mountain hollyhock – *see* **WASABI**

MOUNTAIN PAPAYA – A hardy member of the papaya family, the mountain papaya (*Carica candamarcensis = C. pubescens*) constitutes an exception to the tropical nature of its relatives by growing at elevations of 8,000 to 9,000 feet in Ecuador and Colombia. The price of such cold-resistance, however, is a small, tart fruit. Too acidic to eat raw, it is always cooked, and then only eaten when better fruits are unavailable.

Mountain plum – *see* **TALLOW WOOD PLUM**

MOUNTAIN SORREL – Mountain sorrel (*Oxyria digyna*), with its long-stemmed leaves, grows in an area ranging from Alaska and Greenland through British Columbia to the mountains of New Hampshire. Eskimos gather mountain sorrel and ferment it like sauerkraut. Mountain sorrel is also eaten raw in salads when the plants are young, whereas mature plants are used as a potherb. The plant is a valuable source of vitamin C in the far north, accounting for its nickname "scurvy grass."

Common names and synonyms: Scurvy grass.

Mountain spinach – *see* **ORACH**

Mountain sumac – *see* **SMOOTH SUMAC**

Mousseron – *see* **MUSHROOMS AND FUNGI**

Mousseron d'automne – *see* **MUSHROOMS AND FUNGI**

Moutarde – *see* **MUSTARD SEED**

Moxa – *see* **MUGWORT**

MUGWORT – The dried leaves of the perennial Eurasian plants of the genus *Artemisia* – and particularly *A. vulgaris* – are called mugwort and have long been used as an herb to flavor various dishes, especially those containing fatty foods such as goose or pork. Mugwort's aromatic, slightly bitter taste is also good for seasoning stews, stuffings, sweets, and ale. Some make a tea from mugwort that is believed to relieve the symptoms of rheumatism, and it is employed to flavor absinthe. A related plant – *A. verlotorum,* called Chinese mugwort – is used in the Far East to flavor rice and as a tobacco substitute, and its young leaves are boiled and eaten in Japan.

Common names and synonyms: Chinese mugwort, felon herb, *moxa.*

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Mulato – *see* **POBLANO**

MULBERRY (*see also* **BERRIES**) – Several trees of the genus *Morus* have edible mulberries. The red mulberry (*M. rubra*), which is native to eastern and central North America, has fruits that resemble blackberries. The white – or "Chinese" – mulberry (*M. alba*) is the one that the Chinese use to feed silkworms. It has whitish or purplish fruit. The Russian mulberry (*M. nigra*), also called the black mulberry, was introduced in the United States during the last quarter of the nineteenth century. All mulberries are quite sweet, with the white mulberry being the sweetest. More popular in Europe than in the United States, mulberries are quite perishable and thus are not grown for market. They are eaten fresh and made into pies and jellies.

Common names and synonyms: Black mulberry, Chinese mulberry, red mulberry, Russian mulberry, white mulberry.

Munchkin – *see* **DELICATA (SQUASH)**

MUNG BEAN (*see also* **BEANS, LEGUMES**) – Small and frequently green, mung beans (*Phaseolus aureus*) are generally used for bean sprouts and are especially important in the cooking of both China and Japan, where they are frequently stir-fried. Also known as "black grams" and in India as "green grams," mung beans are also boiled and eaten as a vegetable, used in curries, and made into flour. The bean also finds its way into soups and is the base for cellophane noodles. In the past, consumers had to sprout mung beans themselves, but bean sprouts have been sold commercially on an ever-increasing scale since the 1950s.

Common names and synonyms: Black dhal, black gram, black mung, golden gram, gram bean, green gram, red mung bean, urd.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

Muntok (pepper) – *see* **PEPPER(CORNS)**

Murnong – *see* **YAM DAISY**

MUSCADINE (*see also* **GRAPES**) – A purple grape of the southeastern United States, the muscadine (*Vitis rotundifolia* – also called the "bullace grape" and the "scuppernong") serves mostly as a grape for the table and for making jellies, jams, and juices. But some wine is made from muscadine grapes, especially dessert wines that taste something like muscat wines. There are several dozen cultivars of muscadines, grown mostly for use in the home and for local markets.

Common names and synonyms: Bullace grape, scuppernong, southern fox grape.

See in addition: "Wine," Part III, Chapter 13.

MUSCAT (*see also* **GRAPES**) – Several varieties of sweet white grapes are called muscats (*Vitis vinifera*) and are used for making wines such as muscatels and sauternes. They are also used as raisins and as table grapes.

See in addition: "Wine," Part III, Chapter 13.

MUSHROOMS AND FUNGI – Mushrooms are found in almost all temperate parts of the world. Although often viewed as the plant itself, they are actually the fruit of a network of stems that remain underground. The mushroom aboveground is there to propagate the organism by diffusing spores to extend the underground network. As plants that have neither leaves nor roots, mushrooms cannot photosynthesize sugars and instead live on the rotting remains of other organisms. That they are successful in such parasitic activity seems clear enough when one learns that (depending on the authority consulted) mushrooms and fungi comprise between 40,000 and 120,000 species around the world, of which some 1,800 are recognized as edible.

One cannot imagine our hunter–gatherer ancestors not eating mushrooms, which have been described as "vegetable meat." However, it is downright painful to imagine the trial-and-error process that eventually separated those that were edible from those that were poisonous. Perhaps early foragers concentrated on a few species that were fairly easy to identify, such as puffballs (of the family Lycoperdaceae) with their ball-shaped fruiting bodies. In fact, puffball remains have been found in Paleolithic settlements. Yet it may be that our Stone Age forebears had a substantially more sophisticated knowledge of fungi than this. Observation of contemporary hunter-gatherers indicates that they know a great deal about mushrooms both edible and poisonous, and they consume the former while employing the latter to bring down game and bring up fish.

Mushrooms of the *Agaricus* genus are among the relatively few fungi that can be grown commercially, and some of these have been propagated since classical times. The *Champignon d'Paris,* or Paris mushroom (*Agaricus bisporus* and *A. campestris*), is the most common mushroom in produce markets today. It is also called the common white mushroom, and if small, a "button" mushroom, or in France a *mousseron,* from which the English "mushroom" was derived. This mushroom has been cultivated since the seventeenth century in France. During Napoleonic times, they were grown on so-called farms located in caves in the many stone quarries close to Paris. There, the mushrooms were nurtured in the dark coolness, where humidity and temperature were both controlled, on beds of horse manure mixed with straw and soil – a method that is continued today both commercially and in the corners of family basements, with the important difference that the horse manure is now sterilized and pasteurized. Most mushrooms that come sliced or whole in cans, or marinating in jars, are "button" mushrooms.

By the late 1800s, mushrooms were being grown commercially in other countries. Italian growers also cultivated the common mushroom but preferring the brown-capped variety, which are often called cremini mushrooms (or Italian brown) and have an earthy flavor that is fine for soups and stews and for stuffing. The large and beefy Portabello (also Roma) is actually a fully grown cremini, with dense and meaty flesh that lends itself nicely to grilling or roasting. Originally, cremini mushrooms were imported from Italy, but now they are cultivated in the United States.

Although many swear by the hearty flavor of the cultivated Portabello, wild mushrooms are generally regarded as significantly more flavorful than their domesticated counterparts, and wild varieties are becoming increasingly available in produce markets, in both fresh and dried forms. One of these is the chanterelle (*Cantharellus cibarius*) – the golden chanterelle (*girolle*) of France, and the *Pfifferling* of Germany – which has long been highly regarded as a "forest" mushroom in Europe but is now becoming increasingly popular in the United States, where it grows in forests from coast to coast. It is orange in color, funnel shaped, and has firm, light, yellowish flesh. There are numerous other chanterelles that come in colors ranging from red, brown, and gray to orange-and-yellow, and almost all are also ranked as delicious, although they are much more difficult to locate.

Also in the delicious category is *Boletus edulis,* which goes by the name of *Steinpilz* in Germany, *porcini* in Italy, and *cèpe* (also cep) in France and the United States, where it grows as well. Indeed, many consider these stout-stemmed fungi with their large brown, dry caps to be the finest tasting of all the wild mushrooms. Their rich flavor and firm texture make them ideal for soups, sauces, and stuffings.

Morel (*Morchella esculenta*) fanciers, however, would give the "best-tasting" ranking to their favorite fungus. Nicknamed the "pinecone mushroom" because of the elongated, dome-like shape of its whitish to light brown head, which is composed of chambers that make it appear a network of ridges and pits, the true morel appears only in the spring and thus commands a very high price throughout the year.

Many mushrooms that are originally from the Far East are not only available dried and canned but can also be found fresh in produce markets the world over. Perhaps the best known of these – and certainly the most available – is the Japanese brown mushroom or shiitake (*Cortinellus shiitake*). Once grown only in Japan by introducing spores to a local type of oak tree, this mushroom is now cultivated in the United States – on artificial logs. The shiitake is umbrella-like in shape, brown to black in color, and firmly textured; it has an assertive flavor that goes well in sautés. Its cousin, the Chinese black mushroom (*Lentinus edodes*), is actually brown to pale buff in color. Known as the "winter mushroom" in China (as is the shiitake, which is also grown there), it is like most other mushrooms in that its flavor intensifies with drying.

The enokitake (*Flammulina velutipes*), or sometimes just *enoki* (their home is on the stumps of the Chinese hackberry tree called *enoki*), are slender mushroom stalks with small bulbs at the top, which grow in clumps and reach upwards of 5 inches in length. Their delicate flavor is called for in many Asian dishes, but they are best appreciated when eaten raw in salads. Enokitake mushrooms are now cultivated in California. Another cultivated mushroom is the straw mushroom (*Volvariella volvacea*) that is small, globe-shaped, and grown on straw, from which it develops its distinctive earthy taste. These are only occasionally found fresh, and never dried, but are universally available in cans.

Rarely found outside of Japan is the matsutake (*Armillaria edodes*), a thick, meaty, and delicious mushroom that is very popular there and also very expensive. A final Asian fungus is the cloud-ear fungus (*Auricularia auricula* and *A. polytrica*), better known in the United States as "wood ear" but also as "tree ear," "Jew's-ear," and "black tree fungus." The cloud-ear fungus is highly regarded for supposed medicinal properties (it does seem to thin the blood) by the Chinese, who have also incorporated it into their cuisine for at least 1,500 years. It is found mostly in Asian markets in the United States.

Oyster mushrooms (*Pleurotus ostreatus*) are also called "tree mushrooms" because they grow (in clusters) on rotting trees in parts of every continent except Antarctica. Although a wild variety, they are easily cultivated and thus widely available. Of the same family is the most famous of the tree fungi, the beefsteak fungus (*Fistulina hepatica*). It is also known by a variety of other names, such as "liver fistulina," "oak tongue," "vegetable beefsteak," and "beef tongue" because of its rough, reddish surface – which suggests a beef tongue or steak or liver – and its reddish juice, not to mention a meaty taste when cooked. A final mushroom that lives on dead as well as living trees (in clusters) is the honey mushroom (*Armillariella mellea*) – the name describing the color of its cap rather than its taste, which is delicious nonetheless.

The field mushroom (*Agaricus campestris* – also "meadow mushroom" and "pink-bottom") is more or less the same as the "common" mushroom (discussed first in this entry) except that it is a wild version. Rodman's mushroom (*Agaricus rodmani*) with its white to yellowish cap is another that is very similar (and closely related) to the common mushroom. Fairy-ring mushrooms (*Marasmius oreades*) are so called because of their tendency to grow in rings or circles. They appear mostly in the autumn and in France are called the *mousseron d'automne* or the false *mousseron* because of the resemblance of their caps to those of the button mushroom.

Mushrooms are far more nutritious than many people believe. In addition to a good deal of protein, they deliver essential minerals and substantial amounts of the B complex. Moreover, they contain various medicinal substances and some (such as the common mushroom) may provide a cancer preventive. Cooked fresh, mushrooms are considerably more nutritious than those that are available marinated and canned. As a rule, dried mushrooms have an intensely concentrated flavor (especially after they are reconstituted by soaking in hot water) and consequently are used more as a seasoning than as a vegetable. In the United States, Pennsylvania is the leading mushroom-producing state (accounting for about half the domestic crop), and most of this activity is accomplished in and around the little Pennsylvania town of Kennett Square. Michigan, California, and Florida are also important producers, and the countries of Italy, France, China, Japan, and Thailand all export mushrooms in large quantities.

Common names and synonyms: Beefsteak fungus, beef tongue, black tree fungus, brown-capped mushroom, button mushroom, cep, *cèpe, champignon d'Paris,* chanterelle, Chinese black mushroom, cloud-ear fungus, common mushroom, common white mushroom, cremini mushroom, English mushroom, *enoki,* enokitake, fairy-ring mushroom, false *mousseron,* field mushroom, forest mushroom, *girolle,* golden chanterelle, honey mushroom, Italian brown mushroom, Japanese brown mushroom, Jew's-ear, liver fistulina, matsutake, meadow mushroom, morel, *mousseron, mousseron d'automne,* oak tongue, oyster mushroom, Paris mushroom, *Pfifferling,* pinecone mushroom, pink-bottom, *porcini,* Portabello, puffball, Rodman's mushroom, Roma, shiitake, *Steinpilz,* straw mushroom, tree ear, tree mushroom, vegetable beefsteak, vegetable meat, wild mushroom, winter mushroom, wood ear.

Musk lime – *see* **CALAMONDIN**

Muskmelon – *see* **CANTALOUPE AND MUSKMELON, MELONS**

Musk seed – *see* **AMBERSEED**

Mustard cabbage – *see* **PAKCHOI AND KAI CHOY**

MUSTARD GREENS (*see also* **CABBAGE, MUSTARD SEED**) – A vegetable belonging to the cabbage family (and also called "leaf mustard" and "leaf mustard cabbage"), mustard greens (*Brassica juncea*) have a more delicate flavor than kale, but one that is, at the same time, more piquant. Most plants of the genus *Brassica,* are of Eurasian origin. *Brassica* *juncea,* however, is probably a native of Africa that spread into Asia, although the plant may have originated in China and spread outward from there. Mustard greens have an arching stalk and large green leaves, which grow in clusters. The leaves are generally eaten when young, because they become coarse with age. They can be cooked and eaten as a vegetable or used in salads. Mustard greens are fairly high in beta-carotene, vitamin C, and calcium.

Common names and synonyms: Brown mustard, Chinese mustard, curled mustard, Indian mustard, leaf mustard, leaf mustard cabbage, *mizuna,* Oriental mustard, rape(seed), red Asian mustard, southern curled mustard.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

MUSTARD SEED (*see also* **MUSTARD GREENS**) – There are three basic types of mustard that are all members of the cabbage family: black mustard (*Brassica nigra*); white mustard (*B. alba*); and brown mustard (*B. juncea*). The mustard plants were originally weeds, and some evidence suggests that our prehistoric ancestors may have utilized their seeds to chew with meat.

Mustard plants have been cultivated since ancient times and were highly valued for their oil content. The Greeks and Romans used mustard as a medicine and plaster for rheumatism and arthritis; it was also a part of the cuisine of the ancient Egyptians, Greeks, and Romans as a condiment; and mustard seed is mentioned several times in the New Testament.

Each country and region has subsequently developed mustards to accompany their own cuisines. Ground mustard seeds are mixed with a liquid medium (at which point a reaction of enzymes causes the seeds to become pungent), such as vinegar, wine, beer, or mayonnaise. One such medium was grape "must," hence the French *moutarde,* the Italian *mostarda,* the Spanish *mostaza,* and the English "mustard" – all from the Latin *mustum ardens,* meaning "burning must."

In China, white mustard seeds from the West (*B. alba* is a Mediterranean native) were being grown by the tenth century, but the hot Chinese mustard and the even hotter Japanese mustard (*karaschi*) are made from brown mustard seed. The English also have a preference for hot mustard, which goes well with sausages and rare roast beef. French mustards, such as those from Dijon, seem to go with French sausages, just as German mustards, such as Düsseldorf, are suited to the sausages of Germany. And what is a hot dog without the yellow (because of the turmeric added) mustard of the United States? In addition, mustard seeds and powder are used in cooking meats and vegetables, in pickling, and in the preparation of sauces, relishes, and salad dressings, and mustard seeds and oil are frequently added to dishes. Black mustard seeds, for example, are vital to the cuisines (especially curries) of India, and many meats are dusted with mustard powder before cooking.

Common names and synonyms: Black mustard (seed), brown mustard (seed), Dijon mustard(s), Düsseldorf mustard, hot Chinese mustard, hot mustard, Japanese mustard, *karaschi, mostarda, mostaza, moutarde, mustum ardens,* white mustard (seed), yellow mustard.

See in addition: "Spices and Flavorings," Part II, Section F, Chapter 1.

Mustum ardens – *see* **MUSTARD SEED**

MUTAMBA – This native of both North and South America is a tall tree (*Guazuma ulmifolia*) with some 25 to 30 aliases ranging from "West Indian elm" and "mutambo" to "chocolate" and "guasima." The reason for the plethora of names is because it is known in many languages in a region stretching from Brazil to Peru to Mexico. The mutamba produces an edible fruit, but its major contribution has been to the herbal medicine practiced in all of the countries in which it is grown. The teas made from its bark, roots, and leaves have been used against everything from asthma to leprosy, often with such effectiveness that it has attracted the attention of medical science, and a number of studies have appeared on its usefulness against heart-related diseases and cancer.

Common names and synonyms: Chocolate, guacimo, guasima, mutambo, West Indian elm.

Mutambo – *see* **MUTAMBA**

MYOGA GINGER – A native of Japan, myoga (*Zingiber mioga*) is a member of the ginger family that is grown for its young shoots and buds. These are mostly used raw in salads and shredded as a garnish but are also added to soups and simmered dishes.

Common names and synonyms: Ginger bud, mioga ginger.

Myrobalan – *see* **AMALAKA**

Myrobalan plum – *see* **CHERRY PLUM**

Myrrh – *see* **CICELY**

Myrtille – *see* **BILBERRY**

MYRTLE (*see also* **CHILEAN GUAVA MYRTLE, PERIWINKLE**) – An evergreen aromatic shrub, native to the Mediterranean region and western Asia, myrtle (*Myrtus communis*) has blue-black berries that are sweet and pulpy and are dried for use as a condiment as well as eaten raw. Myrtle was enjoyed by the ancient Greeks, who also accorded it a role in their mythology (it was sacred to Aphrodite). Other myrtles are native to South America or New Zealand save for the North American native (*M. verrucosa*) called "stopper," which also has edible fruit.

Common names and synonyms: Indian buchu, "stopper."

MYRTLE APPLE – A wild shrub native to southern Africa, the myrtle apple (*Eugenia capensis*) provides both nourishment as a fruit and medicinal relief from diarrhea. It ranges in color from orange to red and looks like a tiny apple; on average, it reaches not quite 2 inches in diameter. Like the strawberries that they are said to resemble in taste, myrtle apples grow close to the ground and are ready for picking in summer. Their pulp is consumed as food, whereas the roots are used medicinally.

Myrtle flag – *see* **SWEET FLAG**

Myrtle-leafed orange – *see* **ORANGE**

Myrtle pepper – *see* **ALLSPICE**

N

Nagami – *see* **KUMQUAT**

Nalta jute – *see* **JEW'S-MALLOW**

Ñame – *see* **CUSH-CUSH YAM**

Ñame mapuey – *see* **CUSH-CUSH YAM**

Nana – *see* **PINEAPPLE**

NANCE – A relative of the acerola and native to the West Indies, Central America, and much of South America, the nance (*Byrsonima crassifolia*) is a small tree with yellow fruits ranging from the size of a walnut to that of a lemon. The fruit is sweet and generally eaten raw but is also turned into a juice that is sometimes fermented to make an alcoholic beverage.

Nangka – *see* **JACKFRUIT**

Nannyberry – *see* **BLACK HAW**

Napa – *see* **CHINESE CABBAGE**

Napa Valley Gamay – *see* **GAMAY**

Nappa – *see* **CHINESE CABBAGE**

NARANJILLA – Found in Ecuador, Peru, Colombia, and Costa Rica, this small shrub (*Solanum quitoense*) bears bright orange, tomato-shaped, edible fruit at altitudes of 3,000 to 5,800 feet. Also called *lulo,* it has a juicy pulp that is used to make drinks, sherbet, preserves, and pies. The juice is rich in proteins and mineral salts. It does not travel well, but the fruit's popularity in sherbets has led to its commercial cultivation in Ecuador.

Common names and synonyms: Lulo.

Narrow-capped morel – *see* **MOREL**

Narrow dock – *see* **CURLED DOCK**

Naseberry – *see* **MIMUSOPS, SAPODILLA**

Nashi – *see* **ASIAN PEAR**

NASTURTIUM – The west coast of South America is the homeland of this creeping or climbing plant (*Tropaeolum majus*) also known as "Indian cress," which has a surprising number of culinary uses. Its leaves and young shoots have a hot, peppery flavor that goes well in salads and with eggs. The buds are pickled and can substitute as capers, and the flowers are chopped and added to rice and pasta dishes. From time to time, the nasturtium has been cultivated in Europe for its culinary properties, and it is used as a food in Peru today, as it has been for thousands of years. The plant is rich in vitamin C.

Common names and synonyms: Garden nasturtium, Indian cress.

Natal orange – *see* **MONKEY ORANGE**

NATAL PLUM (*see also* **SOUR PLUM**) – This large, thorny, South African shrub (*Carissa grandiflora = C. macrocarpa*), which is used for hedges in Natal, bears a fruit called the Natal plum. It is purple and plumlike and has a taste of gooseberry that goes well in pies and preserves. The Natal plum now also grows in frost-free areas of the United States, including Hawaii.

NATIVE CHERRY – A shrubby tree of Australia, the "native cherry" (*Exocarpos cuppressiformis*) produces a fruit that is a drupe, with a bright red, cherry-like appearance.

Native cucumber – *see* **PEPINO**

Native gooseberry – *see* **WILD GOOSEBERRY**

NATIVE GUAVA – The small tree or shrub of Australia called the "native guava" (*Rhodomyrtus psidioides*) bears an edible fruit that is remarkably similar to the tropical American guava (*Psidium guajava*). The former has been used as food for millennia by the Aborigines.

NATIVE LIME – Australia has two citrus trees that bear fruits called "native limes." One is designated *Citrus australis,* and the other is *Microcitrus australasica.* In both cases, the fruit is very acidic and quite high in vitamin C.

Native myrtle – *see* **BRUSH CHERRY**

Native peach – *see* **QUANDONG**

Native potato – *see* **WILD YAM**

NAVY BEAN (*see also* **BEANS**) – Also called the "pea bean," the navy bean is any of several varieties of the kidney bean (*Phaseolus vulgaris*) that are cultivated for their nutritious white seeds. The name "navy bean" recalls former times when the beans were among the standard provisions of warships of the U.S. Navy.

Common names and synonyms: Kidney bean, pea bean.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3; "Legumes," Part VIII.

Neapolitan medlar – *see* **AZAROLE**

NEBBIOLO (*see also* **GRAPES**) – The best of the red wine grapes of the Italian Piedmont, Nebbiolo grapes (*Vitis vinifera*) were named from the Italian *nebbia,* meaning "fog," because they are harvested during a time when the Langhe hills of the Piedmont are covered with mist. The Nebbiolo is used to produce the famed Barolo and Barbaresco wines and also to blend with other grapes. Nebbiolo grapes are expensive because, like the Pinot Noir variety, they are very difficult to grow.

See in addition: "Wine," Part III, Chapter 13.

Nebraska currant – *see* **BUFFALO BERRY**

NECTARINE (*see also* **PEACH**) – There are over 150 varieties of nectarines, with the name apparently derived from the Greek *nektar,* meaning "drink-of-the-gods." The nectarine is itself a variety of peach (*Prunus persica*), which it resembles in every way save that it is smaller, sweeter, and fuzzless – meaning that it looks more like a plum than a peach. The peach is an ancient fruit, but nectarines are hardly a newcomer to the dining table, having been known for more than 2,000 years. It is interesting, however, that little mention of nectarines can be found in the writings of the ancients.

In London in 1673, they were being grown for medicinal use by the Worshipful Society of Apothecaries, and by 1720, they were being cultivated among the peaches of Virginia. Like peaches, nectarines are either clingstone or freestone. They constitute one of the world's major fruit crops, with the United States and Italy the principal areas of cultivation. The fruit is grown in California, South America, and the Middle East for the American market, which makes them available year-round. Nectarines are eaten whole, made into juice, poached, baked, and grilled to accompany barbecued meats. Most are orange or yellow fleshed, but some are white fleshed. The orange-fleshed kinds in particular are an excellent source of vitamin A, and all are rich in vitamin C.

NEROLI (*see also* **CITRUS FRUITS**) – Also called "orange-flower water," neroli is the essential oil of bitter orange blossoms (*Citrus aurantium*), which is obtained by distillation. The oil is used in perfumery, and the perfumed essence is employed in making syrups and flavoring liqueurs. The process was introduced in France during the late seventeenth century by Anna Maria de la Trémoille, Princess of Neroli.

Common names and synonyms: Neroli oil, orange-flower oil, orange-flower water.

See in addition: "Spices and Flavorings," Part II, Section F, Chapter 1.

NETTLE(S) – Everyone knows these perennial herbs of the genus *Urtica* (especially *U. dioica*), which are naturalized worldwide. They bear "toothed" leaves that are covered with tiny, hollow hairs containing a number of irritating substances, which inflict a sting and a rash on those who accidentally touch them. But the young tips, picked as they broke through the ground in the spring, were frequently cooked and eaten as a vegetable by our foraging forebears, who may well have been on the lookout for greens to rid themselves of the first symptoms of scurvy after a winter of vitamin-C deprivation. The young leaves of nettles are often prepared much like spinach, are included in other dishes, and have been brewed into tea and even beer. Nettle seeds have been gathered for food as well. Indeed, many people still gather nettles today; the medicinal uses of the plant are as well known as its nutritional capacity. Nettles are rich in vitamins and minerals, particularly vitamin C, iron, sulfur, potassium, and sodium.

Common names and synonyms: Burning nettle(s), stinging nettle(s).

NEW MEXICO CHILLIES (*see also* **CHILLI PEPPERS**) – There are quite a number of chillies called New Mexico – all of the *Capsicum annuum* species, including the Anaheim, which is one of many New Mexico varieties. The major ones are the New Mexico Green (also called the "long green chilli") and the New Mexico Red (the mature form). Between 6 and 10 inches in length, and close to 2 inches in diameter, these peppers are only moderately hot and are favorites for roasting and stuffing. The red form is also used in a number of sauces, including barbecue sauces. When peeled and dried, New Mexico green and red chillies are sometimes called dried California chillies, and the red is also called *chilli colorado.* The latter is used to make chilli sauces and ground chilli powders. Other New Mexico chillies – the "NuMex" Eclipse, Sunrise, and Sunset – are, respectively, purple, goldish, and bright orange in color and are used mostly for decorative purposes, as are the newly developed New Mexico "Miniatures."

Common names and synonyms: Chilli colorado, dried California chilli, long green chilli, New Mexico Green, New Mexico Miniature, New Mexico Red, NuMex Eclipse, NuMex Sunrise, NuMex Sunset.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

NEW ZEALAND SPINACH – Although not actually a spinach (indeed, it is a member of a different botanical family), "New Zealand spinach" (*Tetragonia expansa*) has a spinach-like appearance and flavor, goes well in salads, and is also cooked like spinach. Native to New Zealand and Australia, this vegetable has diffused around the world and grows well in those warmer places where real spinach does not. Like spinach, New Zealand spinach is rich in beta-carotene, folacin, and other vitamins and minerals.

NIGELLA – A member of the buttercup family and native to the northern Himalayan mountains, the Middle East, and eastern Europe, nigella (*Nigella sativa*) consists of tiny dried black seeds, quite similar to black caraway seeds, with which they are sometimes confused. Today, the plant that yields them in swollen pods is most extensively cultivated in India, where nigella is used in numerous dishes. In the United States, it is carried in gourmet shops under the Indian name *kalonji* and, as in the Middle East, is sprinkled on breads. In fact, black nigella seeds are often encountered atop Jewish rye bread, pumpernickel, and the like.

Common names and synonyms: Black caraway, black cumin, black nigella, *charnushka,* devil-in-the-bush, fennel-flower, *kalonji,* love-in-a-mist, Russian caraway.

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Niger – *see* **NIGER SEED**

NIGER SEED – Originating in West Africa and now grown extensively in Ethiopia and India, niger seed (*Guizotia abyssinica*) is cultivated as an oil crop, although the seeds are also used by humans as a condiment and as a food for birds. The oil has a number of industrial applications, but it is edible as well and is employed in the usual culinary ways – for cooking and in salads – especially in Ethiopia, where the seed is called "noog," and its oil is the most important edible oil in the country. In addition, niger-seed oil serves as an adulterant in other oils.

Common names and synonyms: Niger, nog, noog, nug, ramtil.

NIPA PALM – Palms of the genus *Nypa* (or *Nipa*) have leaves that are used locally for thatching, basket weaving, and making hats, whereas the stems are employed to fashion arrows. The Chinese eat the raw fruits of this tree for their sweetness or candy them as preserves. Sugar extracted from the fruit is used to make alcohol and vinegar, and the alcoholic beverage is also called "nipa."

Common names and synonyms: Mangrove, nypa palm.

Nispero – *see* **LOQUAT, SAPODILLA**
Nitta tree – *see* **PARKIA**
Noblecane – *see* **SUGARCANE**
No-eye pea – *see* **PIGEON PEA**

Noisette – *see* **HAZELNUT AND FILBERT**
Nona – *see* **CUSTARD APPLE**
Noog – *see* **NIGER SEED**
Nopal – *see* **NOPALES, PRICKLY PEAR**

NOPALES (*see also* **PRICKLY PEAR**) – Also named *nopalitos* and "cactus pads," nopales are the leaves (called "paddles") of certain varieties of Mexican cacti (genus *Opuntia*). (In addition, the cochineal plant [*Nopalea cochenillifera* = *N. coccinellifera*] is called nopal, and its young joints are often sold as nopales.) These vegetables are fleshy yet slippery (they exude a mucilaginous substance similar to that in okra), have a crunchy texture, and when fresh have a delicate taste somewhere between that of green pepper and asparagus. Nopales can be eaten raw (once the spines are removed) but more often are cooked in boiling water until tender. They are frequently cooked with eggs, are often steamed for a vegetable dish, and (after cooling) can be added to salads. Nopales that are purchased in jars have a tart and pickle-like taste; they are called for in many "Tex-Mex" dishes. Nopales have been consumed by Native Americans of Mesoamerica and the southwestern portion of North America for millennia and have often served as a famine food. They are a fine source of beta-carotene, vitamin C, and some of the B-vitamins as well.

Common names and synonyms: Cactus pad, cactus paddle, cochineal plant, nopal, *nopalitos.*

Nopalitos – *see* **NOPALES**
Nori – *see* **LAVER, SEAWEED**
Northern pine – *see* **WHITE PINE**
Nug – *see* **NIGER SEED**
NuMex Eclipse – *see* **NEW MEXICO CHILLIES**
NuMex Sunrise – *see* **NEW MEXICO CHILLIES**
NuMex Sunset – *see* **NEW MEXICO CHILLIES**
Nut(-)grass – *see* **CHUFA**

NUTMEG (*see also* **MACE**) – A kernel of the fruit of a tropical tree (*Myristica fragrans*), the dried nutmeg berry is called "nutmeg" because of its nutlike appearance. Nutmeg and mace are the only spices that come from the same fruit, with mace the aril of the dried seed. The nutmeg berry can be as small as an apricot or as large as a peach. An ancient spice, nutmeg is native to the Moluccas (the "Spice Islands") and was employed in South Asian cuisines for many centuries before it found its way to Rome, where Pliny wrote of a tree that bore a nut with two different tastes. Its subsequent history is that of mace. Like mace, nutmeg has been used in the West primarily in sweet beverages and desserts. Many grate it at home, as needed, with a small grater. But nutmeg can also be purchased already ground. A sprinkle works well in stews and numerous sauces. The oil derived from nutmeg has medicinal applications and is also a component of nutmeg butter. Today, nutmeg is grown primarily in Grenada and Indonesia.

See in addition: "Spices and Flavorings," Part II, Section F, Chapter 1.

Nut pine – *see* **PINE NUT**
Nux gallia – *see* **WALNUT**
Nypa palm – *see* **NIPA PALM**

O

Oak tongue – *see* **MUSHROOMS AND FUNGI**

OAT(S) – One of the last of the wild grasses to be domesticated and cultivated, oats (*Avena sativa*) have served humans principally as a feed for domestic animals. Historically, oats achieved only a relatively minor status as a food for humans – perhaps because the crop was a latecomer among the domesticated grains – and today only about 5 percent of the world's crop is consumed in this way. Developed from wild grasses of eastern Europe and Asia, oats were despised by the Egyptians and others of the Middle East and were viewed as animal fodder by the Greeks and Romans. Indeed, it may be the case that the plant, which existed mostly as a weed in wheatfields, was not domesticated until after the Christian era had begun.

Some time after this, oats became a staple food in Scotland (mostly in the form of porridge) and by 1600 the grain was adapted as an important crop to the wet climate of northern Europe. By 1650, oats had crossed the Atlantic to be planted in Massachusetts, and in 1877 the Quaker Mill Company was founded in Ravenna, Ohio. Beginning in 1884, "Quaker Oats" – one of the first packaged foods to be marketed – were sold in the now-famous cardboard canisters. "Steel-cut" oats are cracked-oat kernels, whereas "rolled" oats have been put through a roller to flatten them into thin flakes. Oats are a good source of manganese, folacin, iron, zinc, and vitamin E and an excellent source of dietary fiber. Oat bran is said to be an effective cholesterol reducer and thus was the focus of a health-food craze for a period in the latter part of the twentieth century. Today, we know that oats can help to lower LDL (the "bad" cholesterol), but not by enough to justify the claims of the faddists.

Common names and synonyms: Rolled oat(s), steel-cut oat(s).

See also: "Oat," Part II, Section A, Chapter 6.

OCA – An important crop in the Andean highlands, oca (*Oxalis tuberosa*) has edible leaves and young shoots, but its tubers are the most important parts nutritionally. They are wrinkled and come in a variety of sizes and shapes, not to mention colors, which range from red and orange to yellow and white. There are two kinds, sweet and bitter. The sweet variety is eaten raw, cooked, and dried (by the sun). More intensive drying produces a product that tastes like dried figs and has been used as a sweetener by native populations.

Bitter oca is freeze-dried and stored for later use. After the potato, it was oca that sustained Native American highland populations for millennia, and it remains a staple of Peruvian and Bolivian Indians living at high altitudes. Around 1830, oca reached the British Isles, where it served as a food, especially in Wales. In France, the plant grows wild and is gathered to make a dish called Peruvian soup. In the 1860s, oca was carried to New Zealand by an English immigrant who acquired some of the tubers in Chile, and the plant has recently become popular there as a misnamed "yam" that is boiled, baked, and fried.

Common names and synonyms: Bitter oca, occa, oka, sweet oca, ulluco.

Occa – *see* **OCA**

Ochro – *see* **OKRA**

OGEN MELON (*see also* **MELON**) – This cultivar of the green-fleshed muskmelon was developed in Israel. Smaller than most melons, the Ogen melon (*Cucumis melo*) averages from 3 to 4 pounds and has a golden yellow skin with attractive vertical green stripes. When ripe, its creamy flesh has an appealing aroma and is deliciously sweet, which may explain why the chefs of many acclaimed restaurants offer the melon on their menus. The Ogen melon is featured in appetizers, salads, and desserts, often in tandem with other fruits or sorbets. An enticing combination is Ogen melon, raspberries, and port.

See in addition: "Cucumbers, Melons, and Watermelons," Part II, Section C, Chapter 6.

OIL-BEAN TREE – A tropical West African native, the oil-bean tree (*Pentaclethra macrophylla*) has seeds that are rich in an oil (owala oil) used locally for cooking purposes. The seeds, high in protein, are also employed as a condiment.

Common names and synonyms: Owala-oil tree.

Oil nut – *see* **WALNUT**

Oil palm – *see* "An Overview of Oils and Fats," Part II, Section E, Chapter 1; "Palm Oil," Part II, Section E, Chapter 3

Oka – *see* **OCA**

OKARI NUT – This nut (*Terminalia okari*) belongs to the family Combretaceae. Native to Papua New Guinea, it is now grown in Southeast Asia as well as in Hawaii and Florida. The nut has a shiny dark outer skin but is white inside. It is eaten raw or roasted and is pressed into oil.

OKRA – A member of the mallow family, and called "gumbo" and "lady-fingers" along with a host of other common names, okra (*Abelmoschus esculentus = Hibiscus esculentus*) is often thought of as a vegetable but is actually a fruit. A native of Africa (most likely tropical Africa), okra was used by the Egyptians, was known to the Spanish Moors in the twelfth century A.D., and in the late seventeenth century was carried by slaves to the Americas. According to legend, okra was introduced in southeastern North America by the "Cassette Girls" – 25 young Frenchwomen who landed at Mobile in 1704 in search of husbands. They had with them okra that had been obtained from slaves in the West Indies, and which they used to invent "gumbo," which is a soup or stew thickened with okra. Okra has played a major role in the cuisines of ex-slave societies in the Americas, where it continues to be especially popular. It is also cultivated in Africa and East and South Asia. Okra has been commonly used in gumbo, but the pods are also cooked (especially fried) as a vegetable. The plant is often found in home gardens and produces seeds that can be saved and used the following year. Much of the okra crop is frozen and canned, and in Asia a dried okra powder is also used. Okra is a good source of calcium, magnesium, and potassium as well as vitamin C, folacin, and some of the other B-vitamins.

Common names and synonyms: Bamia, *bendi,* bhindee, bhindi, bindi, cantarela, gombaut, gombo, gumbo, lady('s)-finger(s), mesta, ochro, okro, quiabo, quimbambo, quingombo, rosenapfel, vendakai.

Okro – *see* **OKRA**

Olallieberry – *see* **BLACKBERRY**

Old-man – *see* **SOUTHERNWOOD**

Oleaster – *see* **ELAEAGNUS**

OLIVE (*see also* **ELAEAGNUS, OSMANTHUS**) – A very old fruit – actually a berry – the olive grows on gnarled and twisted evergreen trees (*Olea europaea*) that are apparently eastern Mediterranean in origin and were under cultivation by Semitic peoples some 5,000 years ago. Phoenician colonists, who carried olive trees to the Iberian Peninsula about 800 B.C., may have introduced them throughout much of Mediterranean Europe and Africa as well. Ancient Hebrew texts mention olives, and they were known in Greece by about 900 B.C. The olive tree – called the "king of trees" in the Bible – was further spread by the Romans about those regions of Europe that could grow it. In the first century A.D., Pliny recorded a number of varieties under cultivation as far away as Gaul (France) and Iberia, and any areas in the Mediterranean basin that the Romans may have missed were later filled in with olive trees by the conquering Arabs. Olives reached the New World with the Spaniards in the first decades of the sixteenth century and were later carried to California by the Franciscans, who planted the trees in San Diego. And just prior to the American Revolution, Thomas Jefferson tried unsuccessfully to grow olives at Monticello.

Olives have been cultivated mostly for their oil. Those that are consumed are too bitter to be eaten fresh and are first pickled – cured in lye, brine, or dry salt, with the majority brine-cured. Olives come in all shapes and sizes but are sometimes misleadingly categorized as "green" and "ripe." In fact, the green ones are actually the ripest, whereas the black, so-called ripe olives from California are really unripe green olives that have been processed with lye and oxidized to turn them brownish black. Black olives that have been picked when truly ripe will appear shriveled. Among the best-known olive varieties that are pickled are the Queen (especially the Sevillano of Spain), the Mission (California's most important variety), and the Manzanillo (an Old World variety), which is the largest of the pickling olives. In the United States, olives have long been stuffed with pimento and more recently with tiny onions, almonds, hot peppers, and anchovies. In Europe, olives have an important place in cooking, especially in the Mediterranean cuisines of Greece, Italy, and Provence in France. They are also frequently permitted to ferment a bit, then served as an appetizer. Spain, Italy, Greece, and Portugal are the world's leading olive producers. California accounts for about 5 percent of the world's crop. Delicious as olives can be, the reason they are pressed for oil is because they are loaded with fat. After processing, they are also loaded with sodium.

Common names and synonyms: Black olive, green olive, king-of-trees, Manzanillo, Mission, pickling olive, Queen, ripe olive, Sevillano.

See in addition: "An Overview of Oils and Fats," Part II, Section E, Chapter 1.

Olivo – *see* **ACEITUNA**

Olluco – *see* **ULLUCO**

Omam – *see* **AJOWAN**

Omum – *see* **AJOWAN**

ONION (*see also* **ONION TREE, RAKKYO, WELSH ONION, WILD LEEK(S)**) – Cultivated since prehistoric times, the onion (*Allium cepa*) is a native of central or western Asia that has become indispensable to cuisines the world over. This plant was used by the ancient Egyptians, Babylonians, Romans, and Greeks, who believed it to have curative powers. In addition, onions – along with garlic and chickpeas – reportedly made up the bulk of the food rations for the 100,000 or so laborers who built the Great Pyramid of Cheops around 2900 B.C. The ancients interpreted the layered internal structure of the onion as a symbol of eternity, and later the onion-shaped towers which became part of the architecture of Russia and Eastern Europe were so constructed to (hopefully) ensure that the buildings would stand forever. During the Middle Ages in Europe, physicians prescribed onions for people's ills, and even today they are a part of many home remedies.

The most common of the onions is the yellow onion, which accounts for more than 75 percent of the world's production. Sweet onions include the Spanish, the Bermuda, the California Italian Red, the Vidalia (from the area around Vidalia, Georgia), the Walla Walla (from Washington State), and the Maui (from Hawaii). "Scallions," used in salads and vegetable trays, are also called salad or green onions. Red onions (known to some as Italian red onions), purple onions, and tiny "pearl onions" (used for pickling and added whole to soups and stews) round out the list of the cultivated varieties.

In addition, there are many wild varieties around the world, including those of North America. Onions are common in salads, and both raw and fried onions are used in sandwiches and a great variety of other dishes. They are made into soups and are baked, boiled, and sautéed. Onions can be purchased frozen and canned, and they are also dehydrated to become onion flakes, onion powders, and onion salt. Onions are high in vitamin C and were long important to sea and desert travelers as a means of preventing scurvy.

Common names and synonyms: Bermuda onion, California Italian Red onion, common onion, green onion, Italian red onion, Maui onion, pearl onion, purple onion, red onion, salad onion, scallion, Spanish onion, spring onion, sweet onion, Vidalia onion, Walla Walla onion, white onion, wild onion, yellow onion.

See in addition: "The *Allium* Species," Part II, Section C, Chapter 2; "Spices and Flavorings," Part II, Section F, Chapter 1.

ONION TREE (*see also* **ONIONS**) – An unusual plant, the onion tree (*Allium cepa*) has no bulb at the base of the stem. Rather, the bulb, bulbils, or bulblets are located at the top of the plant, and as the top becomes too heavy for the stem, the latter bends – so that the bulbils may root several inches away from the main plant. Because of this, the onion tree is sometimes called a "walking onion." The top bulblets are generally pickled, but the stems and tops are also used as scallions.

Common names and synonyms: Egyptian onion, Egyptian tree onion, perennial onion, walking onion.

See in addition: "The *Allium* Species," Part II, Section C, Chapter 2.

ONZA (*see also* **CHILLI PEPPERS**) – Although called for in many soup and sauce recipes, the onza pepper (*Capsicum annuum*) is difficult to find even in its native Mexico. It is a small chilli that looks like a bright red jalapeño and delivers a medium amount of heat.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Oolong – *see* **TEA**

ORACH – The various plants of the genus *Atriplex,* especially *A. hortensis,* are called orach. Orach has edible green leaves that resemble those of spinach and are used in the same ways. Although naturalized in America, orach is a Eurasian native that has doubtless been a quarry of foragers for millennia. It is also an ancient cultivar that continued to be widely grown until the eighteenth century. Today, however, like other plants such as "Good-King-Henry," orach has returned to the wild.

Common names and synonyms: Garden orach, green orach, mountain spinach, orache, red orach.

Orache – *see* **ORACH**

ORANGE (*see also* **BLOOD ORANGE, CITRUS FRUITS, MANDARIN ORANGE, TANGOR**) – One way to categorize this fruit of the genus *Citrus* is to distinguish bitter oranges (*C. aurantium*) from sweet oranges (*C. sinensis*). The bitter orange (also known as Sevilla, sour orange, and Bigarade) is a native of Southeast Asia and was cultivated in the Indus Valley some 6,000 years ago. The sweet orange (also known as the China sweet orange and – in India – the Malta orange) may also have originated in Southeast Asia, although many believe it to be a native of southern China, as is evidenced by its scientific name. Both fruits were slow to find their way to the Mediterranean basin; the bitter orange eventually arrived with the Arabs around A.D. 1000, but the Western advent of the sweet orange came more than 400 years later, perhaps with the help of Genoese traders or Portuguese explorers.

Sweet-orange trees were planted at Versailles in 1421, and later (1548) in Lisbon. Meanwhile, in 1493, the second voyage of Christopher Columbus is said to have carried sweet-orange seeds (along with lemon seeds) to Hispaniola, and Spaniards stationed in Florida were reportedly growing oranges there in 1565, the year St. Augustine was founded. A couple of centuries later, the Franciscans began planting orange groves at their mission of San Diego in California. In western North America, however, California trailed behind Arizona, which saw its first groves at the beginning of the eighteenth century. By the end of the Civil War, Florida was already shipping large quantities of oranges to the rest of the country, and today that state produces about 70 percent of the U.S. crop, practically all of which (some 90 percent) is made into juice.

Sweet oranges can be further divided into the varieties that have been developed. In the United States, only sweet oranges are grown commercially. The Valencia – a major representative of the sweet orange, sometimes called the "common orange" – accounts for about half of the oranges produced annually. The popular "navel oranges" constitute another variety that is easily identified by thick skins and navel-like scars. Most of California's orange crop is from Washington navel orange trees (which were developed in Bahia, Brazil, and ripen for Christmas holiday sales) or from those of the Valencia variety. Still other varieties are the virtually seedless Hamlins (grown mostly in Florida), "Pineapple oranges" (good for juicing but with many seeds), and Jaffa oranges (developed in Israel), which are sweeter than Valencias. Still other sweet oranges, such as the blood oranges and the Mandarin oranges (Clementine, Tangelo, Tangerine, Temple) are treated in separate entries in this work.

There is less to say about sour-orange trees, which are grown mostly as rootstock for other *Citrus* species, and produce fruits that are too sour to be eaten raw. Their major use is for marmalades and preserves, although the bergamot orange is grown for its oil, and others, such as the myrtle-leafed orange, have small fruits that are candied. Oranges contain much in the way of vitamin C, and in fact, orange juice is the most important supplier of this vitamin for many Americans.

Common names and synonyms: Bergamot orange, Bigarade, bitter orange, China sweet orange, Chinese orange, Clementine, common orange, Hamlin, Jaffa orange, Malta orange, Mandarin orange, myrtle-leafed orange, navel orange, Pineapple orange, Sevilla, sour orange, sweet orange, tangelo, tangerine, Valencia, Washington navel orange.

Orange pekoe – *see* **TEA**

ORANGEQUAT (*see also* **CITRUS FRUITS**) – A cross between the kumquat and the Mandarin orange, the orangequat (genera *Citrus* and *Fortunella*) is another hybrid resulting from a program of research, sponsored by the U.S. Department of Agriculture, designed to breed the resistance to cold of the kumquat into plants of other genera that have desirable qualities. The orangequat has a good, kumquat-like flavor.

OSMANTHUS – Also called "devilwood" and "wild olive," *Osmanthus* is a widely distributed genus of evergreen shrubs or trees with small, olive-like fruits that are softened in brine and used like green olives. In addition, the flowers of *O. americanus* are employed to add aroma to black teas.

Common names and synonyms: Devilwood, wild olive.

Ostrich fern – *see* **FIDDLEHEAD FERN**
Oswego tea – *see* **BEE BALM**
Otaheita-apple – *see* **GOLDEN APPLE**

OTAHEITE GOOSEBERRY – Also known as the "gooseberry tree," the Otaheite gooseberry (*Phyllanthus acidus*) is a small tropical tree, native to Africa and South Asia, that is now naturalized in the Caribbean and southern Florida. It produces a small, round, acidic fruit that is edible but is too sour to be eaten raw. Rather, it is pickled, made into chutney, and used to produce a syrup and jams.

Common names and synonyms: Chermai, gooseberry tree, grosella, Indian gooseberry, Malay gooseberry.

OTAHEITE ORANGE (*see also* **CITRUS FRUITS**) – Otaheite was the former name of Tahiti, and the Otaheite orange (*Citrus taitensis*) has retained the old name while also going by the name "Tahiti orange." The fruit is the size of an apple, has the shape of a lemon, and is colored like an orange. The pulp tastes something like pineapple.

Common names and synonyms: Tahiti orange.

Oudo – *see* **UDO**
Oval-leaf – *see* **PEPEROMIA**
Owala-oil tree – *see* **OIL-BEAN TREE**
Owe kola – *see* **KOLA NUT**

OYSTER MUSHROOM (*see also* **MUSHROOMS AND FUNGI**) – Raised mostly in California, Canada, and the southeastern United States, the oyster mushroom (*Pleurotus ostreatus*) grows in wooded areas and forms clusters on the stumps of dead trees. The 2- to 6-inch cap resembles a seashell and is moist and spongy; the color is usually brown to gray and fades with age. The gills run down the stem and are widely separated; they have a creamy beige or white color. The stem, which may be absent, is white, short, and firm (not as soft as the cap). The oyster mushroom is very much in demand but is only good as long as it is immature.

Common names and synonyms: Oyster fungus, pleurotte, shimeji, tree mushroom, tree oyster.

See in addition: "Fungi," Part II, Section C, Chapter 7.

OYSTERNUT – A native of tropical Africa and cultivated in East and Central Africa, the oysternut (*Telfairia pedata*), also called the "Zanzibar oil vine," is cultivated mostly for its large, edible, nutlike seeds, which are very high in protein. They are generally roasted before consumption and are also pressed to yield an oil similar to that from olives.

Common names and synonyms: African pumpkin, fluted cucumber, Zanzibar oil-vine.

Oyster-plant – *see* **SALSIFY**

P

Pacura – *see* **BAKUPARI**
Pai – *see* **ALOCASIA**
Paiko – *see* **CHENOPODIUM, EPAZOTE**

PAKCHOI AND KAI CHOY (*see also* **CHINESE CABBAGE**) – Both pakchoi (*Brassica chinensis*) and kai choy (*B. campestris*) are variations of Chinese cabbage with many synonyms. Pakchoi looks like tiny Swiss chard, whereas the leaves of kai choy are cupped.

Common names and synonyms: Celery mustard, Chinese chard, gaai chow, gaai choy, gai chow, gai choy, Japanese white celery mustard, mustard cabbage, pak choy, pak choy sum, pak toy, spoon cabbage.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Pak choy – *see* **PAKCHOI AND KAI CHOY**
Pak choy sum – *see* **PAKCHOI AND KAI CHOY**
Pak toy – *see* **PAKCHOI AND KAI CHOY**
Palmetto – *see* **HEART(S) OF PALM**
Palm heart(s) – *see* **HEART(S) OF PALM**

Palm oil – *see* "An Overview of Oils and Fats," Part II, Section E, Chapter 1; "Palm Oil," Part II, Section E, Chapter 3
Palmyra – *see* **WINE PALM**

PALOMINO (*see also* **GRAPES**) – A grape grown mostly in Spain, the Palomino (*Vitis vinifera*) accounts for 90 percent of the grapes planted to make sherry (*jerez*), the renowned fortified wine of that country.

See in addition: "Wine," Part III, Chapter 13.

Palta – *see* **AVOCADO**
Pana de pepita – *see* **BREADFRUIT**
Panama berry – *see* **CAPULIN**
Panama orange – *see* **CALAMONDIN**

PANDANUS – There are a number of species of palmlike trees and shrubs of the genus *Pandanus* (also called "screw-pines") that are found in southeastern Asia and the Pacific region. Most are utilized for fiber to weave mats and other such articles. Some, however, are used as a food source by Pacific Islanders in places like Papua New Guinea. The terminal bud of the branch, or "heart," is eaten along with the tips of roots, the young leaves, and the seeds and fleshy part of the fruit, which in cultivated varieties can weigh upwards of 30 pounds. In addition, the heart can be made into a flour that is high in carbohydrates. Eaten raw, pandanus is a good source of vitamins A and C.

Common names and synonyms: Fruited pandanus, pandanus fruit, pandanus heart(s), pandanus key(s), pandanus nut, screw(-)pine.

Panic(oid) grass(es) – *see* **MILLET**

Papa – *see* **WHITE POTATO**

PAPAW – Also called "pawpaw" and "custard apple," the papaw is a small, fleshy, edible fruit from the tree designated *Asimina triloba.* These trees reach from 30 to 40 feet in height and grow wild in North America along the East Coast of the United States and from New York State through the Midwest. The fruit, which is shaped like a thick, short banana, turns black as it ripens, at which point the yellowish pulp has the taste of an overripe cantaloupe. Papaws can be eaten raw, but many people find the taste more agreeable when the fruit is cooked. Generally mentioned as one of the many foods that sustained Native Americans, the papaw is central to a muddle of nomenclature because its names, "papaw" and "pawpaw," probably came from "papaya," a fruit to which it is not related. Nor is "custard apple" an appropriate nickname, because it is generally one of the names given to the cherimoya – also not a relative.

Common names and synonyms: Custard apple, paw(-)paw.

PAPAYA (*see also* **BABACO, CHAMBURO, MOUNTAIN PAPAYA**) – The papaya tree (*Carica papaya*) is an evergreen with a palmlike appearance. It is native to tropical Mesoamerica, is related to the gourd, melon, and pumpkin family, and may represent an ancient fusion of two or more species of the genus *Carica,* native to Mexico and Central America. The first Spaniards to reach Yucatán were welcomed by Mayans bearing gifts of fruit, among them papayas. At that time, the papaya was known only from Mexico to Panama, but shortly afterward, the Spaniards began moving the fruit via their Manila galleons westward across the Pacific to the Philippines and beyond, and the Portuguese carried it around the globe in the other direction.

The result is that the papaya is now cultivated throughout the tropical world – especially in Hawaii, Africa, and South Asia – for its fruit and for its milky latex. The latex contains the proteolytic enzyme papain, which is used as a meat tenderizer, to clear beer, and also for medical purposes. The yellow, orange, or pinkish somewhat sweet fruit is usually eaten raw (often for breakfast) but is also candied, converted into juice, put into pies and salads, and used to make sherbets. The unripe fruit is cooked like squash.

The papaya is sometimes wrongly called "pawpaw" or "papaw." Although papayas are grown throughout the world's tropical regions, most of those reaching U.S. consumers are the pear-shaped Solo varieties from Hawaii (introduced there from Barbados). These are about 6 inches in length and have either pink or yellow flesh. Papayas are a fine source of vitamin C.

Common names and synonyms: Green papaya, melon fruit, melon pawpaw, papaw, paw(-)paw, Solo (papaya).

Papdi – *see* **SUGAR PEA**

PAPER MULBERRY – This tree (*Broussonetia papyrifera*) is called "paper mulberry" because its bark is used to make paper in China and Japan. The tree also produces a sweet, red fruit, which is eaten raw, and leaves that are also edible. The paper mulberry is a native of East Asia that is now naturalized in southeastern North America.

Paper-reed – *see* **PAPYRUS**

Paper-rush – *see* **PAPYRUS**

Papoose root – *see* **BLUE COHOSH**

PAPRIKA (*see also* **CHILLI PEPPERS, SWEET PEPPERS**) – Because paprika, like cayenne, is made from dried American red peppers (*Capsicum annuum* and *C. frutescens*), it is a relative newcomer to the world's spice rack. As a rule, the chillies made into paprika are less potent than those used for cayenne. Chilli peppers were carried by the conquistadors from Mexico to Spain. The peppers subsequently found their way to Poland (the name "paprika" comes from the Polish *pierprzyca*) and then to Hungary, where they became a vital ingredient in Hungarian goulash – and, in due course, as the Hungarians perfected it, paprika became the national spice.

Paprika comes as sweet, mild, and hot (only the seeds are used for the mild type; the hot version is made from the whole fruit), and the best is made in Hungary; paprika made elsewhere is without much flavor and used mostly for the color it imparts. Paprika both flavors and adorns many Hungarian dishes, and it also spices and colors the sausages of Spain – another country that produces large quantities of paprika for its own national dishes.

Common names and synonyms: Paprika pepper, paprika plant.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

PAPYRUS – A tall sedge of the Nile Valley, papyrus (*Cyperus papyrus*) has also been called "paper-rush" and "paper-reed" because it was used by the ancient Egyptians, Greeks, and Romans to make a sheet or roll of material to write on. Practically forgotten is the food value of the plant, which provided tender shoots and rhizomes for the cooking pot.

Common names and synonyms: Paper-reed, paper-rush.

Paradise nut – *see* **SAPUCAIA NUT**

Paradise tree – *see* **ACEITUNA**

Paraguay(an) tea – *see* **YERBA MATÉ**

Para nut – *see* **BRAZIL NUT**

Paris mushroom – *see* **MUSHROOMS AND FUNGI**

Parish's yampah – *see* **INDIAN POTATO**

PARKIA – Named for the eighteenth-century Scottish explorer and surgeon Mungo Park, *Parkia* is a genus of leguminous, Old World tropical trees with pods that contain edible seeds and pulp. Among the species are the nitta tree (*P. biglobosa*) and the petai tree (*P. speciosa*). The latter has large, edible beans that hang down on the outside of the tree.

Common names and synonyms: Nitta tree, petai tree.

Parry pinyon pine – *see* **PINE NUT**

PARSLEY (*see also* **HAMBURG PARSLEY, LOVAGE**) – The aromatic leaves of parsley (*Petroselinum crispum*), a native of southern Europe, are employed for flavoring, although some parsley varieties are boiled and their roots consumed as a vegetable. The use of parsley dates from at least the time of the ancient Greeks, and because the plant has been introduced into most areas of the globe, it is one of the world's best-known herbs. According to the Sardinians, it is native to their island, although other regions also claim parsley as their own; regardless, it has been used in the Mediterranean region for thousands of years. The Greeks, who made crowns of it to honor athletes at ceremonies and themselves at banquets, also had medical uses for the herb. The Romans utilized parsley as an herb and introduced the plant throughout Europe.

There are three basic kinds of parsley. One is the familiar, bright-green curly parsley; another, sometimes called Italian parsley, has flat leaves and a stronger flavor than the curly type. The third is Hamburg parsley, also called turnip-rooted parsley, which is grown for its long white root, that when cooked tastes something like celeriac. Both curly and Italian parsley lend taste and eye appeal to salads and other dishes. Parsley also comes in dried flakes, but these have virtually no taste. The fresh kinds are rich in vitamins A and C, calcium, and iron.

Common names and synonyms: Curly parsley, Italian parsley.

See in addition: "Spices and Flavorings," Part II, Section F, Chapter 1.

PARSNIP – The parsnip (*Pastinaca sativa*), a native of Europe and western Asia, has been cultivated for its long, yellowish brown, carrot-shaped edible taproot since at least the time of the ancient Greeks. In the Middle Ages, physicians credited parsnips with medicinal properties, and in parts of England and Ireland (where parsnips have long enjoyed considerable popularity), many different ways of preparing the vegetable have evolved, and even a kind of wine has been made from its fermented roots.

Parsnips were introduced into the West Indies during the sixteenth century and North America at the beginning of the seventeenth century, whereupon their use spread rapidly among Native Americans. The vegetable also served as an important staple in the diet of the European colonists until the potato finally replaced it in the nineteenth century. Parsnips are usually boiled, then sometimes mashed or pureed, but they can also be fried and baked and go well in stews. The taste of parsnips is best only after the first frost; indeed, it was long customary to leave much of a crop in the ground over the winter to let the action of frost improve the flavor even more.

Such a practice, however, was not without controversy; some people insisted that parsnips became poisonous when left in the ground, whereas others held that the vegetable was not safe to eat until after it had weathered the first frost. Both sides have been pronounced wrong for various reasons, but very recently, medical science has suggested that parsnips may be toxic after all – because they contain psoralens, which have been linked to the development of cancer and mutations in laboratory animals. Unlike their relative the carrot, parsnips contain little beta-carotene, but they are rich in vitamin C.

Common names and synonyms: Wild parsnip.

Pasado – *see* **ANAHEIM**

PASILLA (*see also* **CHILLI PEPPERS**) – In Spanish, *pasa* means raisin, and thus *pasilla* translates as "little raisin." However, there is nothing raisin-like about the size of this chilli pepper (*Capsicum annuum*), which when fresh is called *chilaca* and averages about 6 inches in length. And even though it does have a wrinkled skin when dried, its other name, chilli negro, inspired by its dark color, seems more appropriate. Fresh *chilacas* are seldom available – in part, one suspects, because of the considerable demand for the dried fruit, which is regarded as crucial to many Mexican mole sauces. Other pasilla relatives that are smoked and dried are the *Pasilla de Oaxaca* (so called because it is grown only in Oaxaca) and the *Pátzcuaro,* both of which are relatively hot. *Pasillas* are also employed in salsas and are available in both dried and powdered forms. They are moderately hot.

Common names and synonyms: Chilaca, chilli negro, *Pasilla de Oaxaca, Pátzcuaro.*

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

PASSION FRUIT – Native to southern Brazil, the passion fruit (*Passiflora edulis* or *P. quadrangularis*) is so named because early Spaniards in the New World thought that they saw in its flowers the symbols of the passion of Christ. However, they also called it a *granadilla,* representing the more mundane observation that the fruit resembled a small pomegranate. The fruits are yellow or purple berries, which can be either sour or sweet. They are eaten raw (including the edible seeds), the pulp is used to make cold drinks, and immature fruits are sometimes boiled as a vegetable.

Most passion fruits, however, become passion-fruit juice, which is used in numerous beverages and sauces. Passion fruits are grown commercially in California, Australia, South Africa, New Zealand, Hawaii, Kenya, and especially Colombia. There are some 350 other types of passion fruits, among them the "yellow granadilla" and the "wild water lemon" of Brazil and the "sweet granadilla" of Central America. Passion fruits are an excellent source of vitamins C and A and iron.

Common names and synonyms: Granadilla, maracuja, purple granadilla, purple passionfruit, sweet granadilla, wild passion-flower, wild water lemon, yellow granadilla, yellow passionfruit.

Patate aquatique – *see* **SWAMP CABBAGE**

PATAUÁ – A palm tree (*Jessinia bataua*) that is native to the Americas and is, indeed, the most common palm in the Amazon region, patauá has a huge fruit that provides both an edible oil (patauá oil) and a beverage. The oil, similar to olive oil, is used in cooking. The beverage, *chicha de seje,* tastes like chocolate.

Common names and synonyms: Seje ungurahuay.

Pátzcuaro – *see* **PASILLA**

Paw(-)paw – *see* **PAPAW, PAPAYA**

PEA(S) (*see also* **BEACH PEA, CHICKLING VETCH, LEGUMES, PEA LEAF, SUGAR PEA**) – Technically legumes, "peas" are the edible seeds enclosed in the elongated green pods of the vine *Pisum sativum.* Peas comprise a large group that can be divided into those that are "edible-podded" and those that are "tough-podded." Foremost among the latter are "green peas," also known as "garden peas" and "English peas" – the large, bulging sweet peas, fresh from gardens or found in produce markets. Other varieties – often canned or frozen – include baby green peas (*petits pois*) and the larger "early" or "June" peas. The edible-podded peas include "sugar" or "snow" peas, the sugar snap pea (*mange-tout*), and the Chinese pea pod. Historically, however, by far the most important peas in a nutrition sense were those that were preserved and consumed throughout the year.

Like so many of our foods, there is confusion over the origin of the pea, which may have occurred in central or southern Asia or in the Middle East. In any event, the wild forms must have been tasty seasonal items on the menus of hunter-gatherers, and peas were among the first plants to be domesticated – about 8,000 years ago (following the beginning of agriculture), after which they spread quickly to the Mediterranean region and to India and China.

Peas were an important food of the Egyptians, Greeks, and Romans – indeed, the word "pea" is from the Latin *pisum,* which was in turn derived from the Greek *pison.* The ancient Greeks mostly ate peas dried, as did the Europeans of the Middle Ages. The Old English *pise* became *pease* to remind us that "pease porridge" hot, cold, or nine days old was a bulwark of the English diet. In the sixteenth century, tender varieties of green peas (designed to be eaten fresh) entered the diet as the *mange-tout* or sugar pea was developed in Dutch gardens, and *petits pois* became a part of French cuisine.

Meanwhile, peas had made their way with the earliest settlers to the New World, becoming part of the diet of North America, and in 1870 the vegetable was among the first to be canned by what would become the Campbell Soup Company. And while dwelling on the subject of peas and their history, we should mention the famous experiments during the 1860s in which the Austrian monk Gregor Mendel employed peas to deduce two fundamental laws of genetic inheritance.

Chickpeas, black-eyed peas ("cowpeas"), and pigeon peas are not true peas and are treated in other entries.

Common names and synonyms: Baby green pea, chickling vetch, Chinese pea pod, early pea, edible-podded pea, English pea, field pea, garden pea, green pea, June pea, *mange-tout, petits pois,* snow pea, sugar pea, sugar snap pea, sweet pea, tough-podded pea.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

Pea apple – *see* **EGGPLANT**

Pea aubergine – *see* **EGGPLANT**

PEACH – Apparently a native of China despite its scientific name, *Prunus persica,* the peach spread to the Middle East and then to Greece. The Romans introduced the fruit in Europe, and the Spaniards carried it to the New World. In fact, peaches were growing so widely in eastern North America by the time of the American Revolution that many assumed the fruit to be an American native. Peaches are one of the stone fruits (drupes) and are classified as freestone or clingstone, depending on how easily the flesh separates from the pit. Modern peaches, the result of centuries of selective breeding, have either white or yellow flesh. Yellow-fleshed freestone types are the most preferable, and the "Bonanza" is the most popular of these. Peaches that are sold fresh or frozen are almost always freestone (as, for example, the Rio Oso Gem); clingstones (like the Red Haven) are generally used for canning. Peaches are a fine source of vitamins A and C.

Common names and synonyms: Bonanza peach, clingstone peach, freestone peach, Red Haven peach, Rio Oso Gem peach.

Peach palm – *see* **PEJEBAYE**

PEA LEAF (*see also* **PEA**) – In China, the tender leaves of the garden pea (*Pisum sativum*) are prevented from flowering or fruiting, which allows them to grow. Sold fresh, they are stir-fried and used in soups, generally on special occasions.

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

PEANUT (*see also* **HOG PEANUT**) – Native to South America, the peanut (*Arachis hypogaea*) is actually not a nut but a legume that develops belowground (hence the name "groundnut") and is very soft before it is dried. Peanuts dating from around 800 B.C. have been found in archaeological excavations in Peru. Native Americans ate the nuts fresh as a vegetable but also roasted them and crushed them into a nutritious, oily paste. Peanuts were being grown by the Tainos on Hispaniola when the Spaniards first arrived in the West Indies, and were later carried to the Philippines and the East on the Spanish Manila galleons.

The Portuguese accomplished the same thing, heading in the other direction. From Brazil, they introduced peanuts into Africa, where the crop became an important staple almost immediately. They also carried them to India, which today is the largest producer of peanuts, followed by China and the United States (with Nigeria the biggest exporter). In fact, the peanut is now a crop of tremendous commercial importance the world over.

Until World War II, peanuts were used mostly as livestock feed, but since then their importance in the human diet has increased enormously, although peanut meal continues to be used for animal feed. Peanuts are salted in the shell by soaking in a brine solution. They are dry-roasted, boiled, and made into peanut butter (which accounts for about half of the U.S. crop) and peanut brittle. Peanuts are also pressed to yield an oil for cooking, preserving, and use at the table and are made into flour for bread baking. Indonesians, Indians, Africans, and the Chinese prepare wonderful dishes that include peanuts, but this is generally not the case in the plant's home hemisphere, save for the West African cookery of the Brazilian northeast. Peanuts are higher in protein than any other nut and are a fine source of the B-vitamins, magnesium, and iron.

Common names and synonyms: Earth nut, goober (pea), groundnut, *mani,* monkey nut, runner peanut, Spanish peanut, Valencia peanut, Virginia peanut.

See in addition: "Peanuts," Part II, Section D, Chapter 2; "An Overview of Oils and Fats," Part II, Section E, Chapter 1.

Peanut-butter fruit – *see* **BUNCHOSIA**

PEAR – Indicative not so much of the millennia over which the pear (*Pyrus communis*) has been cultivated but rather of grafting done over the past few centuries, there are now some 5,000 varieties of the fruit. Native to the Middle East, pears today also grow wild across much of Europe and Asia. They do not seem to have been known to the ancient Greeks or Egyptians, but were to the Romans, who spread pear cultivation throughout their empire.

Pear trees were brought by early European visitors to North America, where the bell-shaped, yellow-skinned Bartlett, a summer pear, has emerged as the most widely grown and a pear much used in canning. The Anjou is the most abundant winter pear. Other varieties that can be found in markets include the Bosc, which is firm and thus is good for cooking and baking; the Comice, perhaps the sweetest of pears; the tiny Seckel; the juicy, sweet Clapp; and the Nellis, a late-winter pear. A pome fruit, the pear is related to the apple, and like apples, pears are frequently baked or otherwise cooked as well as eaten raw, especially as dessert pears. In addition, they are turned into cider ("perry"), although not so often today as in the past. Pears are also canned and made into pear nectar. Most of the vitamin C and fiber that raw pears supply in good quantity is contained in the skins.

Common names and synonyms: Anjou, Bartlett, Bosc, Clapp, Comice, common pear, Nellis, perry, pome(-fruit), Seckel, summer pear, Winter Nellis, winter pear.

Pear haw – *see* **HAW**

Pearl moss – *see* **CARRAGEEN AND CARRAGEENIN**

Pear(-)melon – *see* **PEPINO**

Pearson bean – *see* **SWORD BEAN**

PECAN – A North American nut (actually a kind of hickory nut) sometimes said to be a native of Oklahoma, the pecan (*Carya illinoinensis*) is really indigenous to an area extending from the U.S. Midwest throughout the South and Southwest into Mexico – a region where it still grows wild today. Pecans are commercially cultivated in the band of states running from Georgia west to New Mexico, as well as in Mexico, Brazil, and, outside of the Western Hemisphere, in Israel, South Africa, and Australia.

The first recorded instance of pecan cultivation is said to have been when Thomas Jefferson carried the trees from the Mississippi Valley back to Virginia and gave them to George Washington. But long before this – eons before the Europeans arrived – pecans were an important item in the diet of Native Americans living in the south-central region of North America. The name "pecan" comes from the Algonquian *paccan,* which is similar to the Ojibwa *pagân,* meaning "hard-shelled nut."

The shells of wild pecans are indeed hard, but those that are cultivated have been bred for thinner shells that are easier to crack. The nuts are eaten raw, roasted, dry-roasted, and fried. They flavor stuffings for poultry as well as numerous desserts, including pecan pie. Unfortunately, as a nut, the pecan is high in fat and low in protein, but it does deliver a respectable amount of the B-vitamins, vitamin E, and numerous minerals.

Common names and synonyms: Carya pecan.

PEDRO XIMÉNEZ (*see also* **GRAPES**) – The best of the grapes planted to make sherry, the Pedro Ximénez (*Vitis vinifera*) is named for Peter Siemons, who carried the grape from Germany to Spain. Pedro Ximénez grapes are also employed to make white wines.

See in addition: "Wine," Part III, Chapter 13.

PEJEBAYE – Also known as the "peach palm," the pejebaye (*Bactris gasipaës = Guilielma utilis = G. gasipaës*) is a palm tree of the western Amazon region that was domesticated by Native Americans. It bears a fruit (largely unknown outside of Brazil) that somewhat resembles an apricot, although it is triangular in form. It is cooked before eating – usually by roasting. In addition, the fruit is dried and ground into flour and is also pressed for vegetable oil. But the tree's main culinary function (at least recently) has been to provide fresh palm hearts for Latin American and North American markets.

Common names and synonyms: Peach palm.

Peking cabbage – *see* **CHINESE CABBAGE**

Pekoe souchong – *see* **TEA**

PENNYCRESS – Plants of the genus *Thlaspi* are called "pennycress" along with a host of other names. Their leaves are edible, and the seeds can be employed as a condiment, like mustard seed. There are native species in North America that were a part of the diet of Native Americans. In Asia, Eurasian pennycress species have also long been cultivated.

Common names and synonyms: Fanweed, field pennycress, French weed, penny grass, thoroughwort pennycress.

Penny grass – *see* **PENNYCRESS**

Pennyroyal – *see* **MINT**

PENNYWORT – Any of several plants of the genus *Centella* (and the closely related *Hydrocotyle*) are called "pennywort," including Indian pennywort (*C. asiatica*). Also known as "coinworth" and *gota kola,* Indian pennywort has round green leaves that historically have been considered a stimulant to brain activity in India. They are eaten raw, cooked as a vegetable, and made into tea. Sometime in the past, the plant reached the eastern United States, where it grows as a weed.

Common names and synonyms: Asiatic pennywort, coinworth, *gota kola,* Indian pennywort.

PEPEROMIA – A large genus of tropical herbs, *Peperomia* belongs to the family Piperaceae – the same family as *Piper nigrum,* which provides the white and black peppercorns used at the table. Today, species of *Peperomia* are grown as ornamentals, but in the past some, like "oval-leaf" (*Peperomia obtusifolia*), were cultivated for their leaves, which were eaten as a vegetable.

Common names and synonyms: Oval-leaf.

Pepinella – *see* **CHAYOTE**

Pepinito – *see* **GHERKIN**

PEPINO – Also called "melon-shrub," "melon-pear," and "pear-melon," and often mistaken for a melon because of its taste and shape, the pepino (*Solanum muricatum*) is a native of the Andean region of South America and, like peppers and tomatoes, a member of the nightshade family. It was domesticated in pre-Columbian times and was widely cultivated when the Spaniards first arrived. For reasons that remain obscure, they named it *pepino de la tierra,* or "native cucumber." Although the pepino comes in many varieties, none of them resemble a cucumber. The most common are reddish, with stripes of varying color. The fruit is quite sweet and watery, like the cantaloupe. Outside of the American tropics, pepinos are cultivated in California and New Zealand, which together meet most North American demand.

Common names and synonyms: Kachun, melon (-)pear, melon(-)shrub, native cucumber, pear (-)melon, *pepino de la tierra, pepino dulce.*

Pepino de la tierra – *see* **PEPINO**

Pepino dulce – *see* **PEPINO**

Pepitas – *see* **PUMPKIN**

Pepo – *see* **SQUASH AND PUMPKIN**

Pepper – *see* **CHILLI PEPPERS, INDIAN LONG PEPPER, JAVANESE LONG PEPPER, MELEGUETA PEPPER, PEPPER(CORNS), SICHUAN PEPPERCORN, SWEET PEPPERS**

PEPPERCORN – *Piper nigrum* is a vine – native to the East Indies – that has a small berry-like fruit called a peppercorn. Peppercorns, from which pepper is ground, come in colors. Underripe berries are green. When the full-grown but unripe fruit is dried, it is black. If the berries are allowed to mature further, they turn red or pink. White pepper – which commands a higher market price – is the result of drying the ripe fruit, then removing the outer shell. Lampong and Tellicherry are black peppercorns; Muntok and Sarawak are white. These pungent condiments are among the most important of the East Indian spices that have been eagerly sought since ancient times.

The Greeks and Romans accepted peppercorns as tribute, and the spice was certainly the basis for much of the "lure of the East" that impelled first the Portuguese and then other European explorers around Africa toward the fabled Spice Islands. Although both are called "pepper," *Piper nigrum* should not be confused with the American chilli peppers of the *Capsicum* genus. Major producers of pepper(corns) today include Indonesia, India, Malaysia, and China; white pepper is preferred by the majority of people in the latter country. In addition, white pepper yields an oil that is used in perfumes and medicines.

Common names and synonyms: Black pepper(corn), green pepper(corn), Lampong, long pepper, mignonette pepper, Muntok, pepper, pink pepper(corn), *pippah,* red pepper(corn), Sarawak, Sichuan pepper(corn), Tellicherry, white pepper(corn).

See also: "Spices and Flavorings," Part II, Section F, Chapter 1.

Pepper(-)grass – *see* **CRESS**

Pepperidge – *see* **BARBERRY, BLACK GUM**

Peppermint – *see* **MINT**

Pepper of Calicut – *see* **CHILLI PEPPERS**

PEPPERONCINI (*see also* **CHILLI PEPPERS**) – An orange-red chilli that is also known as "pepperoncino," the pepperoncini (*Capsicum annuum*) is a favorite in Italy, Sicily, and Sardinia. When dried, it is wrinkled, curved, and about 2 to 3 inches in length. A moderately hot pepper, the pepperoncini is used in sauces and cooked dishes and is often bottled in olive oil. It is also grown in Louisiana for the production of hot sauces.

Common names and synonyms: Pepperoncino.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Pepper-root – *see* **TOOTHWORT**

Pepper tree – *see* **MASTIC TREE**

Pequín – *see* **TEPÍN CHILLIES AND RELATIVES**

Perennial goosefoot – *see* **GOOD-KING-HENRY**

Perennial onion – *see* **ONION TREE**

Perennial pea – *see* **EVERLASTING PEA**

Périgord (truffle) – *see* **TRUFFLE(S)**

PERILLA – Native to the Himalayan mountains between India and China, perilla (*Perilla frutescens* and *P. ocimoides*) is a plant grown for its fruit and leaves. The fruit seeds contain an oil that is employed in cooking and has industrial applications as well. The leaves are dried and used as an herb in cooking.

PERIWINKLE – Periwinkle is comprised of several Old World vetchlike herbs of the genus *Vinca. Vinca major,* a trailing foliage plant, is called "large periwinkle," whereas *V. minor,* a trailing evergreen herb, is known as "common periwinkle," "myrtle," "running myrtle," and "creeping myrtle." A third plant – this of the Old World tropics – is *V. rosea* (= *Catharanthus roseus*), which is called "cape periwinkle," "red periwinkle," and "Madagascar periwinkle." These plants are cultivated mostly for fodder, but their seeds have also served humans as food, especially during times of hardship.

Common names and synonyms: Cape periwinkle, common periwinkle, creeping myrtle, large periwinkle, Madagascar periwinkle, myrtle, red periwinkle, running myrtle.

Perry – *see* **PEAR**

Persian lime – *see* **LIME**

Persian walnut – *see* **WALNUT**

PERSIMMON – Although there are persimmon trees that are native to North America, the orange-red persimmon (*Diospyros kaki*) that North Americans usually consume originated in Asia. This persimmon is native to China but is known as the Japanese persimmon because it has been cultivated mostly in Japan. Today, however, the fruit is also cultivated in the south of France and some of the Mediterranean countries, where it was introduced in the early nineteenth century, and in the southern United States and California, where it arrived in 1870.

The American persimmon (*Diospyros virginiana*) is native to the eastern and southern United States, and the name "persimmon" – deriving from the Algonquian *pessemin* – is American, too. The Algonquians ate persimmons raw and also dried the fruits for winter consumption. American persimmons are smaller than those from Japan, which are about the size of a tomato. Both varieties may be yellow, orange, or red, although the American persimmon can be a darker red, almost purple. The trees of the *D. kaki* species grow to between 20 and 30 feet in height, whereas *D. virginiana* reaches 30 to 60 feet. A mature tree will yield 75 to 100 pounds of persimmons annually.

The Hachiya variety, which accounts for the overwhelming bulk of the commercial crop in the United States (grown mostly in California), is an astringent variety, meaning that it is bitter until it is ripe. Another variety, Fuyu (crisper and lighter in color), is more common in Japan and Israel. When ripe, persimmons are soft, and their brown or orange pulp has a sweet taste. They are a good source of beta-carotene and potassium as well as vitamin C.

Common names and synonyms: American persimmon, Chinese fig, common persimmon, date plum, Fuyu, Hachiya, Japanese persimmon, *kaki,* Oriental persimmon.

Peruvian carrot – *see* **ARRACACHA**

Peruvian groundcherry – *see* **CAPE GOOSEBERRY**

Peruvian parsnip – *see* **ARRACACHA**

Petai tree – *see* **PARKIA**

Petanga – *see* **PITANGA**

PETITE SIRAH (*see also* **GRAPES**) – Not the true Syrah (also Shiraz) grape, the Petite Sirah (*Vitis vinifera*) makes a wine that is dark red to almost purple, with a peppery taste. Although in California the Petite Sirah grape was at one time believed to be the Syrah, it is now generally thought that it is the Durif Rhône grape, which is no longer grown in France. Once used to make a blending wine, the Petite Sirah has become an important varietal in the California wine industry.

See in addition: "Wine," Part III, Chapter 13.

Petits pois – *see* **PEA(S)**

Pe-tsai – *see* **CHINESE CABBAGE**

Pfifferling – *see* **CHANTERELLE, MUSHROOMS AND FUNGI**

PHALSA – Also known as "pharsa," phalsa (*Grewia asiatica*) is a shrubby tree of India and the East Indies. It produces a small red berry that is used to make sorbets and syrups but is too tart to eat out of hand.

Common names and synonyms: Pharsa.

Pharsa – *see* **PHALSA**

Philippine orange – *see* **CALAMONDIN**

Philippine spinach – *see* **TALINUM**

PHYSIC NUT – A small tree, originally of the American tropics, *Jatropha curcas* produces the "physic nut," which yields curcas oil. The oil has medicinal uses, especially as a purgative, but is toxic in high doses. When roasted, however, the nuts are said to be relatively harmless and are apparently consumed by many in India as well as the Americas. The young leaves of the tree are cooked like greens, and ashes of the burned root are used as a substitute for salt.

Common names and synonyms: Curcas oil, purging nut.

Piasa – *see* **SUDAN POTATO**
Pico de Pajaro – *see* **CAYENNE PEPPER**
Piedmont truffle – *see* **TRUFFLE(S)**
Pie-plant – *see* **RHUBARB**
Pigeon berry – *see* **POKEWEED**

PIGEON PEA (*see also* **BEANS, LEGUMES**) – Called by literally scores of names including "Congo pea," "no-eye pea," "red gram," and "gandul," the pigeon pea (*Cajanus cajan* or *C. indicus*) is probably native to South Asia and perhaps tropical Africa. Actually a bean that grows on a perennial shrub, it is one of the oldest cultivated plants and now is widespread throughout the tropical world, with India a center of diversity. In the Americas, it is a very important crop in Jamaica and is naturalized in South Florida and Mexico.

The fresh leaves are often used as a vegetable, as are the immature pods. The seeds are dried and used in the same ways as lentils or split peas in soups, stews, and so forth. Like other dried beans, pigeon peas are rich in nutrients. They are high in calcium, iron, protein, the vitamin-B complex, and folacin.

Common names and synonyms: Alverja, Bengal bean, Congo pea, dhal(l), gandul, goongoo pea, gray pea, Gungo pea, Indian dhal, Indian pea, no-eye pea, pois cajun, pois d'Angole, red gram, yellow dhal(l).

See in addition: "Beans, Peas, and Lentils," Part II, Section C, Chapter 3.

PIGEON PLUM (*see also* **PLUM**) – An American plant that (like its close relative the sea grape) grows on the seacoasts of the southern United States, Mexico, and the Caribbean, the pigeon plum (*Coccoloba diversifolia* = *C. floridana*) is a drupaceous fruit that is quite astringent until ripe, after which it has a pleasant sweet-and-sour taste. Additionally, there is the edible fruit of an African tree (*Chrysobalanus ellipticus*) that is also called "pigeon plum."

Common names and synonyms: Snailseed.

Pignoli – *see* **PINE NUT**
Pignolia – *see* **PINE NUT**
Pignon – *see* **PINE NUT**
Pignut – *see* **EARTH NUT**
Pigweed – *see* **AMARANTH, CHENOPODIUM, GOOSEFOOT, LAMB'S-QUARTER, PURSLANE, QUELITES, QUINOA**

PILI NUT – A tropical evergreen tree of the Philippines, the pili nut (*Canarium ovatum*) has a number of uses. Its nuts are eaten both raw and roasted and in either case are said to have a very pleasant flavor. Additionally, pili nuts are used in baked goods and ice cream, and the kernel is pressed for an edible oil of high quality. The pulp of its fruit is also pressed for oil but can be eaten, as can the young shoots, which frequently appear in salads. Most of the nuts are harvested from trees growing in the wild, which means that the crop has remained a relatively minor one.

Pimenta – *see* **ALLSPICE**
Pimento – *see* **ALLSPICE, SWEET PEPPERS**
Pimiento – *see* **SWEET PEPPERS**

Piña – *see* **PINEAPPLE**
Pina anona – *see* **MONSTERA**
Pinang – *see* **BETEL NUT**
Pindo palm – *see* **JELLY PALM**

PINEAPPLE – A native of the New World, the pineapple (*Ananas comosus*) is now cultivated in frost-free areas around the world. The Tupi-Guarani Indians of South America have been credited with its domestication, although this is in some dispute. It would seem, however, that the origins of the pineapple are definitely in lowland South America. The earliest written references to the fruit were made by Spanish chroniclers, including Christopher Columbus, who is alleged to have named the fruit, calling it the "pine of the Indies" because of its resemblance to a pinecone. It is still called *piña* in Spanish today, whereas the Portuguese word for "pineapple," *ananás* (also part of the scientific name), derives from an Indian term for the fruit.

After their discovery, pineapples were used to provision ships and spread from the Americas by two routes: One was across the Pacific in Spain's Manila galleons to the Philippines and from there to China; the second was in Portuguese ships from Brazil to Africa and beyond to India. Before the end of the sixteenth century, pineapple cultivation had spread across much of the tropical world, and the plant had found its way to some of the Pacific Islands. In the late eighteenth century, pineapples were introduced in Hawaii, where they have since become that state's most important fruit crop. Pineapples are mostly canned and made into juice, although some are eaten fresh. They are an excellent source of vitamins A and C and potassium.

Common names and synonyms: Anana, *ananás,* Cayenne pineapple, Hawaiian pineapple, nana, *piña.*

Pineapple guava – *see* **FEIJOA**
Pineapple orange – *see* **ORANGE**
Pineapple quince – *see* **QUINCE**
Pinecone mushroom – *see* **MOREL, MUSHROOMS AND FUNGI**

PINE NUT – Also called pignoli, pignolia, pignons, piñon nuts, and Indian nuts, these ivory-toned seeds come from the pinecones of several trees of the genus *Pinus* and rank alongside macadamias and pistachios as the most expensive nuts on the market. The European term for pine nuts is pignolia, indicating that they come from the Italian stone pine, which grows in Italy, Iberia, and North Africa. They are especially used in Mediterranean cooking, and Italian pignolia (from the Italian term for Pinocchio) are a vital ingredient in making pesto. But although the European pine nut has a higher oil content and is the one most widely available in the United States, there are American varieties – and some from South America are much larger than their European counterparts. In the American Southwest, the piñon or Indian nut from the Colorado piñon tree has been consumed for thousands of years and was assiduously gathered and stored by many Native American tribes. Pine nuts go well in soups, salads, and desserts, in addition to pesto sauce, and they are also eaten roasted, salted, and raw. Like other nuts, pine nuts are a good source of thiamine, magnesium, and iron.

Common names and synonyms: Indian nut, Mexican nut pine, nut pine, Parry pinyon pine, pignoli, pignolia, pignon, pinolia, piñon (pine) (nut), pinyon (pine) (tree), silver pine, stone nut.

PINGUIN – A plant of the American tropics, and a relative of the pineapple, the pinguin (*Bromelia pinguin*) is used for hedges but also has a crowded head of berries that are plumlike and edible. Another of its names is "wild pineapple," and the fruit is employed mostly for juice. Similar fruits – such as *B. balansae* and *B. karatas* – also grow in South America. These, too, are used mostly for juice, although the yellow fruit of *B. karatas* is good to eat out of hand when ripe.

Common names and synonyms: Maya, piñuela, wild pineapple.

Pink-bottom (mushroom) – *see* **MUSHROOMS AND FUNGI**

Pink ginger-bud – *see* **TORCH GINGER**

Piñon (pine) (nut) – *see* **PINE NUT**

Pinot Bianco – *see* **PINOT BLANC**

PINOT BLANC (*see also* **GRAPES**) – A white wine grape grown mostly in the Alsace region of France, the Pinot Blanc (*Vitis vinifera*) yields an affordable, all-purpose, dry wine. It has been confused with the Chardonnay grape (which also makes a dry, white wine) to the extent that a number of Australian wines that are called Pinot Blanc are actually Chardonnay. Pinot Blanc grapes are also used in the production of sparkling wines and are grown in California.

Common names and synonyms: Beli Pinot, Clevner, Pinot Bianco, Weissburgunder, Weisserburgunder, Weisser Klevner.

See in addition: "Wine," Part III, Chapter 13.

PINOT MEUNIER (*see also* **GRAPES**) – A black wine grape that yields a white juice and is heavily planted in the Champagne region of France, Pinot Meunier (*Vitis vinifera*) is one of the three wine grapes (along with Chardonnay and Pinot Noir) used to make champagne. In the Australian state of Tasmania, Pinot Meunier grapes are now grown to fuel an ever-increasing production of sparkling wine "down under."

See in addition: "Wine," Part III, Chapter 13.

PINOT NOIR (*see also* **GRAPES**) – A black grape that yields a white juice and is sometimes regarded as the "headache" grape by growers because of the difficulties (fragility and genetic changeability) in working with it, the Pinot Noir grape (*Vitis vinifera*) is nonetheless the grape responsible for the revered red wines of Burgundy. Indeed, Appellation Contrôlée laws prescribe that all red burgundies (save for Beaujolais) be made from Pinot Noir grapes, which are also one of the three principal grapes used to fashion French champagne. Pinot Noir grapes have also been adapted for growing in California. Needless to say, because of the difficulties in growing them, wines made from these grapes are generally on the expensive side.

See in addition: "Wine," Part III, Chapter 13.

Piñuela – *see* **PINGUIN**

Pinyon (pine) (tree) – *see* **PINE NUT**

Piperina – *see* **MINTHOSTACHYS**

Pippah – *see* **PEPPER(CORNS)**

PIPSISSEWA – Plants with many more common names than uses, pipsissewa are two species of weeds, *Chimaphila umbellata* and *C. maculata,* that grow in northern and eastern North America, respectively. Found in wooded areas, they are small herbs with bitter leaves that have long been employed in folk remedies and to make teas. More recently, pipsissewa has been used as one of the ingredients in root beer. *Chimaphila maculata* is known, among other things, as the striped or spotted pipsissewa, ratsbane, and dragon's-tongue. *Chimaphila umbellata* is called common pipsissewa and, more colorfully, king's-cure and love-in-winter.

Common names and synonyms: Common pipsissewa, dragon's-tongue, king's-cure, love-in-winter, ratsbane, spotted pipsissewa, striped pipsissewa.

Pisong jacki – *see* **BANANA**

Pistache – *see* **PISTACHIO NUT**

PISTACHIO NUT – A native of central Asia and member of the cashew family, the pistachio nut (*Pistacia vera*) has been cultivated for some 3,000 years and has a long history of popularity in the Mediterranean world. But it was not until the 1930s, with the advent of vending machines, that pistachio nuts (also called pistache) imported from Italy became something of a rage in the United States as a snack food. Their red-dyed, bony shells split naturally, making them easy to crack by hand or with the teeth. Following World War II, the evergreen trees that bear pistachios were imported to California, and although the imported nuts are still dyed, most American-grown pistachios are sold without dye, in naturally tan shells. The name "pistachio" is the Italian version of the Persian word *pistah,* meaning "nut." In the Middle East, pistachio nuts are an accompaniment for roast lamb, and many Mediterranean dishes also call for them. The characteristically green kernels are a good source of thiamine and iron.

Common names and synonyms: Pistache.

PITAHAYA (*see also* **SAGUARO**) – The cerus type of cacti is divided into *pitayos* – tall columnar cacti (like the saguaro [*Carnegia gigantea*]) with large fruits called *pitayas* – and *pitahayos,* which are smaller cacti with smaller fruits (*pitahayas*). Pitahayas were a staple of Native Americans, have been cultivated commercially in Mexico and Central America since colonial times, and are today grown in Texas, Florida, and the desert Southwest of the United States.

The flavorful, generally red to purple fruits are eaten fresh, made into drinks, preserves, jams, ice cream, and other desserts, and frozen and dried for later reconstitution. Some of the fruits also contain a natural oil, which is thought to improve the functioning of the digestive tract. Pitahayas are regularly shipped to Europe, but the United States – for health reasons – prohibits entry to those grown in certain countries, save in the form of a frozen puree. Among the fruit-bearing cacti are the "tree cactus" (genus *Cephalocereus*) and, in the genus *Echinocereus,* the *pitahaya de Agosto* (*E. conglomeratus*), the "Mexican strawberry" "(*E. stramineus*), and the "clear-up cactus" (*E. triglochidiatus*). The pitahayo or *pitahayas de agua* (genus *Heliocereus*) is another, as are the *pitahaya* (*Hylocereus undatas*) and the *pitayo dulce* (*Lemaireocereus queretaroensis*), also called the "organ-pipe cactus."

Common names and synonyms: Clear-up cactus, Mexican strawberry, organ-pipe cactus, *pitahaya de Agosto, pitahayas de agua, pitahayo, pitayo dulce,* tree cactus.

Pitahaya de Agosto – *see* **PITAHAYA**
Pitahayas de agua – *see* **PITAHAYA**
Pitahayo – *see* **PITAHAYA**

PITANGA – Also known as the "Surinam cherry," pitanga (*Eugenia uniflora*) is native to Brazil but now can be found throughout the world's tropics and subtropics. Given room, the tree will reach 20 feet or so in height, but generally it is grown as a bush or shrub. The fruits vary in size, color, and flavor but are usually oblate and, when ripe, maroon or nearly black. The taste is tart, very much like that of a sour cherry. In addition to being simply popped in the mouth, the fruits are used in salads, jellies, and pies.

Common names and synonyms: Brazilian cherry, Cayenne cherry, petanga, pitanga cherry, Surinam cherry.

Pitanga cherry – *see* **PITANGA**
Pitaya – *see* **SAGUARO**
Pitaya – *see* **CACTUS APPLE**
Pitayo – *see* **SAGUARO**
Pitayo dulce – *see* **PITAHAYA**
Pitchiri – *see* **PITURI**

PITHECELLOBIUM – Some species of the genus *Pithecellobium,* such as *P. dulce* (otherwise known as the "Manila tamarind" and guamochil), are native to the Americas in general, whereas a few New World species (like *P. flexicaule*) are native to North America (Texas, South Florida, and Mexico). Other species are native to tropical Asia. The young pods and shoots are edible and are cooked as a vegetable. The seeds are also eaten, after roasting, and the pulp that surrounds the seeds of *P. dulce* is made into a beverage.

Common names and synonyms: Guamochil, Manila tamarind.

Pito – *see* **CORAL BEAN**

PITOMBA – A relative of the guava, the pitomba (*Eugenia luschnathiana*) is a small yellow or orange fruit that grows on a small tree or bush. The fruit, a native of Brazil and grown almost exclusively there, is sometimes eaten raw but more often is made into juice and preserves.

PITURI – Of the family Solanaceae, pituri (*Duboisia hopwoodii*) is a perennial shrub of Australia. It produces a black berry, but its main use involves the leaves, which traditionally were dried, powdered, and mixed with other "power plants" by the Aborigines, then made into a quid and chewed. This preparation – called *pituri* or *pitchiri* – was commonly thought to be a narcotic by the first European visitors. A high nicotine content, however, seems to have been the reason for its use.

Common names and synonyms: Pitchiri.

PLANTAIN (*see also* **HAWAIIAN PLANTAIN**) – A herbaceous plant of the tropics, the plantain (*Musa × paradisiaca*) is a fruit similar to the banana (and a close relative), but it is larger, is green (although some varieties undergo the same changes of color as bananas), has more starch, and is not eaten raw. Plantains are believed to have originated in Southeast Asia but are now grown throughout the tropics of Asia, the New World, Africa, and the Pacific. They are fried, roasted, baked, boiled, and also dried and ground into a flour. In addition, in Africa plantains are used to make beer. Plantains (*plátanos*) are a favorite in the diets of many West Indian and Latin American populations, in which they replace potatoes or yams as the most important starch. Like bananas, plantains are a good source of potassium and vitamin C, and they are a better source of betacarotene than bananas.

Another group of plants with the name "plantain" belongs to the genus *Plantago.* These are weeds with broad leaves that, when young, serve as a potherb. The plants were used by Native Americans for food and for medicine, and the leaves can also be boiled to make a tisane.

Common names and synonyms: Plátano.

See in addition: "Bananas and Plantains," Part II, Section B, Chapter 1.

Plantain lily – *see* **DAYLILY**
Plátano – *see* **PLANTAIN**
Pleurisy root – *see* **BUTTERFLY WEED**
Pleurotte – *see* **OYSTER MUSHROOM**

PLUM (*see also* **BEACH PLUM, CHERRY PLUM, DAMSON PLUM, JAPANESE PLUM, SLOE**) – A pitted fruit, or drupe, and related to peaches and apricots, the plum is the most widely distributed of all the stone fruits, growing on every continent save Antarctica. Certainly wild plums would have been a favorite of our hunting-and-gathering ancestors. Plums appear to have been cultivated by the ancient Egyptians and definitely were raised by the Romans, who encouraged the establishment of orchards throughout their empire.

Europeans brought their own plum (*Prunus domestica*) to the New World, with the result that American plum varieties have not been produced commercially. The plums of *P. domestica* are frequently dried (thus becoming prunes) and are also stewed and made into preserves. Then there is *P. salicina* – often called the "salicina" plum or the Japanese plum – which found its way from China to Japan about 300 years ago and subsequently reached North America. Salicina plums, with juicy, reddish to yellow flesh, are not turned into prunes but rather are eaten fresh, and a few varieties can be used in cooking. European plums, especially the California French variety with its high sugar content and firm flesh, make the best prunes. Plums that become prunes are generally freestone, and the drying process consolidates the nutrients, making the dried fruits a good source of vitamins A and E and a fair source of the vitamin-B complex. Prune juice is naturally very sweet, and pitted prunes are frequently cooked with poultry and lamb. Prunes, of course, are well known for their laxative properties, as is prune juice. Plums are a good source of vitamin C.

Common names and synonyms: California French, common plum, garden plum, greengage, Japanese plum, prune, prune plum, Red Beauty, red plum, Reine Claude, salicina plum, Santa Rosa, wild plum.

POBLANO (*see also* **CHILLI PEPPERS**) – Appearing something like a dark-green or almost black (or red in the mature form) bell pepper with a point, this member of the genus *Capsicum* is said to be one of the most popular peppers in Mexico, doubtless in no small part because of its versatility. Fresh, the poblano – a usually mild pepper – is often roasted, and its relatively large size makes it a favorite for stuffing (*chiles rellenos*). In addition, fresh poblanos are used in a number of cooked dishes. Dried, the poblano is called an ancho or a mulato. Ancho means "broad" or "wide" in Spanish and refers to the dried pepper's appearance, which is flat and wrinkled with a color ranging from oxblood to nearly black. The mulato is chocolate brown in color, and both impart a smoky flavor vital to mole sauces, with that of the mulato said to be superior.

Common names and synonyms: Ancho, mulato.

See in addition: "Chilli Peppers," Part II, Section C, Chapter 4.

Pocan – *see* **POKEWEED**

POHOLE – A fiddlehead fern native to Hawaii, the pohole (genus *Athyrium*) grows on the volcanic slopes of Maui, and its tender shoots have been a part of the Hawaiian diet for centuries. Their taste has been described as a blend of the flavors of asparagus and artichoke. Pohole shoots are steamed, sautéed, and added to salads.

Poi – *see* **TARO**

Pointed gourd – *see* **TANDOORI**

Pointleaf manzanita – *see* **HEATHER**

Pois cajun – *see* **PIGEON PEA**

Pois d'Angole – *see* **PIGEON PEA**

Poke – *see* **POKEWEED**

Pokeberry – *see* **POKEWEED**

Pokeroot – *see* **POKEWEED**

Poke salad – *see* **POKEWEED**

POKEWEED – Its blackish red berries are just one of the products of pokeweed (*Phytolacca americana*), a tall North American plant. In the U.S. South, the young shoots and tender tops of the plant are boiled to make "poke salad" in the early spring, and for many in the past – especially slaves – this dish was (despite the boiling) an important source of vitamin C after a winter of meat and meal. The root is poisonous but, with processing, has medicinal uses. The seeds of the berries are also toxic, but the flesh is not, and it is often pressed into a juice. The word "poke" comes from the Algonquian *pocan,* and doubtless the shoots, leaves, and berries of pokeweed were consumed by red men long before white and black men ever reached North America.

Common names and synonyms: Gorget, inkberry, pigeon berry, *pocan,* poke, pokeberry, pokeroot, poke salad, scoke, skoke, Virginian poke.

Polecat weed – *see* **SKUNK CABBAGE**

Poleo – *see* **MINTHOSTACHYS**

POLYNESIAN CHESTNUT – This edible kidney-shaped nut of the Polynesian chestnut tree (*Inocarpus edulis*) is called the Polynesian chestnut by everyone except the Maori of New Zealand (who call it *rata*) and others who prefer the name "Tahitian chestnut." The taste of the nuts is similar to that of chestnuts. They are boiled, roasted, and baked; in addition, some puree the seeds and flavor them with coconut cream.

Common names and synonyms: Rata, Tahitian chestnut.

POMEGRANATE – The pomegranate tree (*Punica granatum*), which reaches a height of 15 to 20 feet, is an ancient tree native to the Middle East (probably Iran). Along with olives, figs, dates, and grapes, the pomegranate was (some 5,000 to 6,000 or more years ago) among the first fruits to be cultivated. Because pomegranates are hardy and easily transported, they were widely known in early times, even in regions where they could not be grown. From Mesopotamia, the pomegranate spread out to be cultivated in ancient Egypt, India, Afghanistan, and China, and it reached Europe at a very early date. The fruit became important in ancient Greek mythology and was mentioned in early literature, including the Bible. It is now grown in all of the drier subtropical areas of Europe and Asia, and in the Americas from the warmer parts of North America (especially California) to Chile.

The name "pomegranate" translates literally as "apple with many seeds." The fruit is round and about the size of a large orange, with a smooth, leathery skin that varies in color from brownish yellow to red. Inside, the fruit is filled with edible, juicy pulp and hundreds of small seeds that are also edible. The rind is tough, which has permitted the pomegranate to serve as a kind of natural canteen for those navigating desert areas. The fruit is eaten fresh, made (including the seeds) into sauces, and is a part of various desserts. Pomegranate juice is highly regarded and is also used commercially to make grenadine syrup, which is employed around the world to flavor milk drinks, desserts, sodas, lemonades, and cocktails. The seeds (which some use as a meat tenderizer) figure prominently in the making of chutneys.

Common names and synonyms: Chinese apple, dalima, granada, grenade, grenadine.

POMELIT (*see also* **CITRUS FRUITS, GRAPEFRUIT**) – A cross between the pomelo and the grapefruit, the pomelit (genus *Citrus*) was developed in Israel for export. Its fruit is sweeter than the grapefruit and juicier than the pomelo.

POMELO (*see also* **CITRUS FRUITS, GRAPEFRUIT**) – The progenitor of the grapefruit, the pomelo (also pummelo) (*Citrus maxima* or *C. grandis*) probably originated in southeastern Asia, where it grew wild in the Indochinese peninsula and Indonesia (although the West Indies has also been proposed as a place of origin). The pomelo is the largest of the citrus fruits and is also known as "pumelo" and "shaddock" because it (or the grapefruit) was brought to the Caribbean by Captain James Shaddock. The aromatic fruit is very large and oval shaped with a thick skin. The pulp is sweet and a light-colored pink or red, the outside ranging from green to yellow to pink. Usually the pomelo is eaten raw, but in Asia the peel is candied, and an alcoholic beverage is made from the fruit. Today, pomelos are grown in California, China, and Japan. They differ from other kinds of citrus fruits in that the white pith is not edible. Pomelos have a high content of vitamin A and are a fine source of vitamin C.

Common names and synonyms: Chinese grapefruit, pumelo, shaddock, sweet pomelo.

Popcorn – *see* **MAIZE**

POPLAR – Mostly native to North America, poplar trees (genus *Populus*) grow from Alaska to the mountains of Kentucky and westward through the Rockies to California and Mexico. The inner bark of most species can be eaten raw, and the bark was also boiled or dried and ground into meal by Native Americans. In addition, the bark was used to make a tea and cut into strips to be cooked like noodles. Whites on the frontier learned to rely on the poplar for sustenance – even the sugary sap was collected and drunk. Because the use of the poplar provided much in the way of vitamin C, it was a scurvy preventive during the winter months.

POPPY SEED – The opium poppy (*Papaver somniferum*), which yields a latex that provides the drug opium (and the opiate derivatives morphine and codeine), has a botanical name that means "sleep-bearing." Fortunately for poppy-seed consumers, the latex comes from unripe seedpods, whereas the tiny, kidney-shaped, edible seeds form in ripe pods and thus have no narcotic effect. Asia Minor seems to be the plant's native region, and doubtless its "magical" effects attracted the attention of hunter-gatherers early on. Its medicinal properties have been put to work for humans at least since the time of the ancient Egyptians. Despite the minuscule size of the seeds – it takes close to a million of them to make a pound of weight on the scales – at some time in the distant past it was discovered that oil could be pressed from them. Their nutty taste was also appreciated, so that today poppy seeds are widely grown (the Netherlands is a major producer) and widely used in baked goods, from India through the Middle East to Europe and North America.

Common names and synonyms: Maw seed.

Porcini – *see* **BOLETE, MUSHROOMS AND FUNGI**

Porcino – *see* **BOLETE**

Poro – *see* **CORAL BEAN**

Portabello (mushroom) – *see* **MUSHROOMS AND FUNGI**

POSHTE – Perhaps the least known of the Annonaceae, the poshte (*Annona scleroderma*) is mostly cultivated in southwestern Guatemala and is prominent in the markets of that part of the world. Unlike its relatives – the cherimoya, the soursop, and the sugar apple – the poshte has a very tough skin, which means that it is less likely to be damaged in handling and transportation. But like the others it has a delicious pulp that is easily removed with a spoon.

Common names and synonyms: Anana del monte, cawesh, chirimoya.

Potato bean – *see* **APIOS, JÍCAMA**

Potato(es), sweet – *see* **SWEET POTATO**

Potato(es), white – *see* **WHITE POTATO**

Prague Special – *see* **KOHLRABI**

PRAIRIE CLOVER – A number of species of the genus *Petalostemon* are called prairie clover, among them *P. candidum* (the white-tassel-flower) and *P. oligophyllum.* Native Americans ate the roots and young leaves as well as the flowers.

Common names and synonyms: White-tassel-flower.

Prairie potato – *see* **BREADROOT**

Prairie sunflower – *see* **SUNFLOWER OIL AND SEED**

Prairie turnip – *see* **BREADROOT**

Premier – *see* **LOQUAT**

Preserving melon – *see* **CITRON**

Prickly ash tree – *see* **SICHUAN PEPPERCORN**

PRICKLY LETTUCE – A wild Eurasian lettuce naturalized in North America, prickly lettuce (*Lactuca scariola = L. serriola*) reaches as many as 7 feet in height, with large lower leaves that can approach a foot in length. The upper ones are much smaller, but they, along with the bigger leaves, are eaten in salads and cooked as a vegetable.

Common names and synonyms: Wild lettuce, wild opium.

PRICKLY PEAR – The prickly pear is the edible fruit of various cacti of the genus *Opuntia.* Native to the Americas, where varieties can be found from South America to Canada, prickly pear cacti produce fruits that are pear shaped and bristle with sharp spines that require careful removal before eating or cooking. Also called cactus pears or Indian pears, the fruits (actually large berries) come in an estimated 300 species – often incredibly colored (inside and out) – with some sweet, some sour, some that can be eaten raw, and others that need cooking. About the size of large eggs, the berries contain a multitude of hard, black seeds.

The Aztecs used the berry juice to make an alcoholic beverage, and also boiled the juice down for its sugar. Indeed, the prickly pear was an important dietary item in Mexico long before the Spaniards arrived and until well into the twentieth century constituted the bulk of the diet of entire communities. When the Spaniards were adapting to their newly conquered Mexico, they called the pears *tunas* and delighted in encouraging new arrivals to eat one particular *tuna* that caused the urine of the consumer to turn bright red. Today, prickly pears are greatly appreciated for their sweet taste, and not just in Mexico and Central and South America but throughout much of the world, including all of the countries ringing the Mediterranean, southwestern Asia, Australia, and South Africa.

In the latter two areas, where the cacti were introduced by early European explorers, they had no natural parasites or competitors and have prospered to the point of becoming more nuisance than food. In Israel, the word *sabra* (meaning prickly pear) has given rise to the nickname "sabras" for the Israelis themselves – prickly on the outside, sweet on the inside! Prickly pears are crushed to make punches and cocktails, sliced into salads as well as eaten raw, and preserved or pickled with other fruits, such as lemons. The juice is sometimes used as a drink mixed with vodka or rum. In addition, prickly pears have served as a handy cattle feed in times of shortage. The prickly pear is a fine source of vitamin C, potassium, and fiber.

Common names and synonyms: Barbary fig, Burbank's spineless, cactus fig, cactus pear, Indian fig, Indian pear, *nopal, sabra,* spineless cactus, *tuna.*

PULASAN – A tree native to the Malay Archipelago, pulasan (*Nephelium mutabile*) is related to the litchi. Pulasan trees grow wild. Those that are cultivated are grown mostly for their fruits, which are oblong, about 2 inches in length, and dark red when ripe. The skin is thin and leathery but not attached to the tart flesh, which comes out easily. The fruits are eaten raw and stewed, and made into jams and preserves.

Pulla chilli – *see* **GUAJILLO AND PULLA CHILLIES**

Pulse – *see* **CHICKPEA**

Pumelo – *see* **POMELO**

Pummelo – *see* **POMELO**

Pumpion – *see* **PUMPKIN**

PUMPKIN (*see also* **PUMPKIN SEED, ROUGE VIF D'ÉTAMPES [PUMPKIN], SQUASH AND PUMPKIN) –** Known in Old English as "pumpions" or "pompions," pumpkins (or calabazas) make up several species of the genus *Cucurbita,* and considerable confusion exists about the differences between them and winter squashes. From the standpoint of the consumer, pumpkins generally have orange-colored skins (although there are both black and white pumpkins as well) and are the more strongly flavored of the two. Pumpkins, which were domesticated in Mexico some 6,000 years ago, were probably initially cultivated for their edible seeds. Called *pepitos,* these were dried for consumption as a snack and also became vital ingredients in sauces, moles, and enchilada-type dishes.

Pumpkins spread northward and across North America long before the Europeans arrived to become one of the most important foods of the Native Americans of eastern North America. Later on, they were a chief factor in saving the Pilgrims of Plymouth Plantation from starvation during the winter of 1622–3. Today, pumpkins are far less important as a food than they were during colonial times, and in the United States the bulk of the pumpkin crop is grown for use at Halloween.

Most of the Halloween pumpkins belong to *C. pepo,* but *C. moschata* and *C. mixta* are also represented, as well as very large specimens of *C. maxima.* As a rule, those pumpkins used for decoration are too big and stringy to eat. How big? In 1900, a 400-pound pumpkin earned first prize at the World's Fair, but since then 800-pound pumpkins have been raised, which makes them the largest fruits of the plant kingdom. Such a behemoth would make quite a pie if used in this fashion, but it is generally the smaller and sweeter pumpkins (usually *C. pepo*) that are made into pie fillings and soups and used for other cooking purposes.

Perhaps the world's best pumpkin for use in this regard escaped from the Americas to be developed by the French. This is their famous *Rouge Vif d'Étampes* – also known as the "Cinderella pumpkin" – the flesh of which is very thick and is traditionally used for soups.

Pumpkin for cooking is available in canned (and frozen) form, which most people prefer to fresh. The taste is no different but there is considerably less mess. Pumpkin seeds are still eaten as a snack, and pumpkins themselves are cultivated worldwide.

Common names and synonyms: Calabaza, New England pie pumpkin, pepitas, pompion, pumpion, sugar pumpkin.

See in addition: "Squash," Part II, Section C, Chapter 8.

PUMPKIN SEED (*see also* **PUMPKIN, SQUASH AND PUMPKIN**) – The roasted and boiled seeds of other winter squashes as well as those of pumpkins (*Cucurbita pepo*) were a staple in the diets of Native American peoples for many millennia. In fact, pumpkins may well have started out as gourds raised for their edible seeds. Even today, pumpkin seeds are regarded as a tasty snack after they are dried, salted, and toasted – with a little oil – until golden brown. Indeed, on the street corners of Mexico City, *pepita* vendors are ubiquitous, as they are in many other cities of the world. Pumpkin seeds also yield an edible oil and are made into a paste used for thickening soups and other culinary purposes. In addition to their fine flavor, pumpkin seeds are low in fat, high in protein, and a good source of iron.

See also: "Squash," Part II, Section C, Chapter 8.

PUNCTURE VINE – Called the puncture vine because its prickly fruits can pierce tires, the feet of humans, and the hooves of livestock, this annual weed (*Tribulus terrestris*) is a Mediterranean native now naturalized in southwestern North America. The fruit separates into five nutlets that have been pounded into a meal for consumption during hard times. In addition, the leaves have been cooked as a vegetable.

Common names and synonyms: Punctureweed.

Punctureweed – *see* **PUNCTURE VINE**

Punk tree – *see* **CAJEPUT**

PUNTARELLE – A member of the genus *Cichorium* and a close relative of chicory, puntarelle (*C. intybus*) is an Italian vegetable with a name meaning "little points" – presumably because of the tiny points on its feathery leaves. Also known as "Roman chicory" or "wild Roman chicory," it is available only in the winter months. The typical head of puntarelle has bitter green leaves borne on less bitter, hollow, white stalks – the whole appearing much like endive. There is also a variety called "puntarelle red-rib," with bright red stalks and dark green leaves. Puntarelle stalks are used in salads (often with anchovy dressing), braised and eaten with fava beans, sautéed with garlic, and wilted in soups.

Common names and synonyms: Puntarelle red-rib, Roman chicory, wild Roman chicory.

Puntarelle red-rib – *see* **PUNTARELLE**

Purple granadilla – *see* **PASSION FRUIT**

Purple nutgrass – *see* **CHUFA**

PURPLESTEM ANGELICA – Also called "American angelica," "great angelica," and "masterwort," purplestem angelica (*Angelica atropurpurea*) is a North American native, found in the eastern half of that continent (as far west as Minnesota). It reaches from 4 to 6 feet in height and has an aromatic odor. Its roots (said to be poisonous when fresh) have been candied, and its stems and leaves were eaten by Native Americans and by early European settlers.

Common names and synonyms: American angelica, great angelica, masterwort.

Purple Vienna – *see* **KOHLRABI**

PURSLANE – Also called "pussley," purslane (*Portulaca oleracea*) is a trailing weed that has small yellow flowers, reddish stems, and leaves that are sometimes used in salads and stews and are also cooked like spinach as a side dish. Like okra, purslane has the ability to thicken dishes in which it is cooked. A relative – winter purslane (*Montia perfoliata*), also known as "miner's-lettuce" – is used in much the same manner.

Common names and synonyms: Cuban spinach, miner's-lettuce, miner's-salad, pigweed, pussley, winter purslane.

Pussley – *see* **PURSLANE**

Quandang – *see* **QUANDONG**

QUANDONG – Also known as quondong, quandang, and native peach, the quandong tree (*Fusanus acuminatus* or *Elaeocarpus grandis*), of the family Santalaceae, is a native of Australia. It produces round and red edible drupes, called "native peaches." The stone also contains an edible seed called the quandong nut. Both drupes and nuts were food for the Aborigines.

Common names and synonyms: Native peach, quandang, quandong nut, quondong.

Quañiwa – *see* **CAÑIHUA**

Queen-Anne's-lace – *see* **CARROT**

Queensland arrowroot – *see* **ACHIRA**

Queensland nut – *see* **MACADAMIA NUT**

QUELITES – The generic Spanish term *quelites* refers to a wide variety of edible greens gathered by the indigenous inhabitants of Mexico and Central America. Some prominent examples of the more than 2,000 species that have been identified are pigweed (genus *Amaranthus*), shrubby wound-wort (*Liabum glabrum*), *violeta* (*Anoda cristata*), *chipiles* (*Crotalaria pumila*), *yerba de conejo* (*Tridax coronopifolium*), and *beldobes* (*Galinsoga parviflora*). Native cultivators allowed these plants to grow freely in their *milpa* fields and harvested them young to eat raw, to boil in soups, or to spice mole sauces and tamales. Mature specimens were fed to animals along with maize leaves. Although many of these varieties are considered famine foods, used to extend maize after crop failures, they also provide an important source of vitamin A in the diets of many peasants. However, their consumption has declined in recent years in favor of European vegetables, which are considered more prestigious. The spread of modern agricultural methods, particularly the use of herbicides, has also decreased the importance of these herbs in Mexican diets.

Common names and synonyms: Beldobes, chipiles, pigweed (amaranth), shrubby wound-wort, *violeta, yerba de conejo.*

Quetembilla – *see* **CEYLON GOOSEBERRY**

Quiabo – *see* **OKRA**

Quick grass – *see* **COUCH GRASS**

Quihuicha – *see* **QUINOA**

Quimbambo – *see* **OKRA**

QUINCE – An aromatic fruit, quince (*Cydonia oblonga*) is yellow, small, and pear shaped, with very tough flesh. It is not eaten raw, but when cooked, its orange pulp turns a deep pink and becomes very sweet. The quince – a native of western Asia (Iraq and Iran) – grows on a small, twisted tree that rarely reaches a height of more than 12 to 15 feet. It is an old fruit that was very popular among the ancient Greeks and Romans (it was reportedly introduced in Rome in 65 B.C. by Pompey), and both Pliny and Columella were well acquainted with it.

Because of its sweetness, the quince became very popular around the Mediterranean during the Middle Ages. The Portuguese called the fruit *marmelo,* and the preserve they made from it *marmelada.* In fact, because of the great amount of pectin the quince yields, it is ideal for marmalade, jelly, jam, and candies and shares with the guava, the apple, and a few others the distinction of being among the best jelly fruits. However, beginning with the advent of cane sugar (and continuing through the fairly recent loss of interest in preserving), the quince has been reduced from a near-essential item in Western kitchens to a specialty fruit. Quince production is now principally located in the United States and a few European countries. The quince is a good source of vitamin C and fiber.

Common names and synonyms: Coines, coing, Cydonian apple, elephant apple, maja pahit, ma-tum, pineapple quince, quitte, vilvam.

Quingombo – *see* **OKRA**

QUINOA (*see also* **CHENOPODIUM**) – Pronounced "keen-wah," quinoa (*Chenopodium quinoa*) is an annual herb of the tropical American highlands and a native of Chile and Peru. Also known as quinua and sometimes as "goosefoot," quinoa is and historically has been the most important of the cultivated chenopods. Like amaranth, it is technically not a grain, meaning that it is not one of the cultivated grasses. Also like amaranth, quinoa helped sustain a great American civilization – in this case the Incas. After maize, it was the most utilized grain in the Andes region at the time of the Spanish conquest. It was used to make beer (*chicha*) as well as soups, stews, and porridges, and its leaves were employed as a potherb.

Quinoa does well in poor soils at high altitudes; indeed, it flourishes at 13,000 feet above sea level. One reason for this is its content of saponin, a bitter, soaplike coating that discourages birds and insects and protects the seeds from the greater radiation of sunlight at high altitudes. A closely allied species called *huauzontle* (*C. nuttalliae = C. berlandieri*) was developed in pre-Columbian Mexico, and a third, less important chenopod – *cañihua* (*C. pallidicaule*) – was also cultivated in the Altiplano regions of Peru and Bolivia.

Quinoa is cultivated today throughout the Andes from Ecuador to Bolivia and at one time was grown in England, where the leaves were consumed as greens and the seeds given to poultry. It is superior to the true grains in nutritional quality, with a better yield of riboflavin, folacin, magnesium, and zinc. Quinoa is employed in soups and gruels and is also toasted and ground into flour for breads, cakes, and biscuits. Quinoa can be found in health-food stores and even supermarkets. The bitter – and perhaps toxic – saponin must be washed away before consumption.

Common names and synonyms: Goosefoot, *huauzontle,* Inca wheat, pigweed, *quihuicha,* quinua.

Radicchio – *see* **CHICORY**

RADISH (*see also* **DAIKON**) – Technically referring to any of a number of plants belonging to the genus *Raphanus* and the mustard family, the term "radish" is usually taken to mean the thickened edible ends of *R. sativus,* which are used in salads and eaten as snacks and appetizers. Radishes come in innumerable varieties, colors (especially red, white, purple, and black), and shapes (ranging from round, to oblong, to long and finger-like). The most common in U.S. produce markets are red and round and are eaten raw, often in salads. Black radishes, common in Eastern Europe and found in a number of Russian dishes, have a very strong flavor and consequently are usually mixed with other foods. The white varieties are sometimes cooked and eaten like the turnips they resemble in taste. Additionally, in East Asia there is a giant white radish called a daikon, which is grated and cooked and used in salads and stir-fries.

Common names and synonyms: Clover radish.

See in addition: "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Ragi – *see* **FINGER MILLET, MILLET**

RAGWEED – A group of mostly North American plants, viewed as chief culprits in emitting a profuse pollen that provokes allergenic symptoms among hay-fever and asthma sufferers, ragweeds nonetheless belong to a genus called *Ambrosia* – a term from ancient Greek mythology meaning "food for the gods." The weeds' more appropriate common name derives from the ragged shape of their leaves, although the plants are also called "tansy ragwort," "bitterweed," and just plain "ragwort." The plants do have a food use, however, because an edible oil (oil of ragweed) can be obtained from their achenes, and the leaves of some species have reportedly been used as a flavoring.

Common names and synonyms: Bitterweed, ragwort, tansy ragwort.

Ragwort – *see* **RAGWEED**

RAIN TREE – So called because of a belief that it somehow exudes water from its leaflets, the rain tree (*Pithecellobium saman*) is a native of the American tropics that now also grows in the Old World tropics. It is widely used as a shade tree for crops such as coffee, cacao, and nutmeg, but it also produces sweet-pulp pods that serve as cattle fodder as well as a snack food for humans, especially children. A beverage is also made from the pulp.

RAISIN (*see also* **GRAPES**) – Doubtless, wild grapes that had dried on the vine were consumed by our hunting-and-gathering ancestors for hundreds of thousands of years. These were the first raisins (genus *Vitis*). With vine cultivation came the more conscious process of picking grapes and spreading them out to be sun-dried. Raisins were an important item of trade in the Near East and were highly prized by the Romans, who introduced grapes and the knowledge of raisin making to the rest of Europe. The Spaniards brought grapes and raisin-making techniques to the New World, and Spanish missionaries introduced them in California, where today, in the San Joaquin valley, about half of the world's raisins are produced. Like prunes, raisins have concentrated nutrients and are a good source of the B-vitamins – thiamine and B_6 – along with iron.

RAKKYO (*see also* **ONION**) – A relative of the onion, rakkyo (*Allium chinense*) is a small onion bulb that resembles garlic. Rakkyo is cultivated in China, Japan, and Thailand (and by Asian-Americans in the United States) and is used mostly for pickling, although it is also occasionally employed in cooking.

See in addition: "The *Allium* Species," Part II, Section C, Chapter 2.

RAMBAI – A widely cultivated native of Indonesia, the rambai tree (*Baccaurea motleyana*) is adorned with strings of rambai fruits that hang from its branches. The fruits are about the size of a hen's egg, brownish yellow, and soft to the touch when ripe. They are eaten fresh, stewed and made into jam.

Ramboutan – *see* **RAMBUTAN**

RAMBUTAN – A native of the Malay Archipelago, rambutan (*Nephelium lappaceum*) is a member of the soapberry family, a relative of the litchi and the longan, and one of the most common fruits of Southeast Asia. The fruit is bright red and oval, is about the size of a small egg, is covered with long, soft spines, and has a sweet, acid flesh that combines the tastes of pineapple and apricot. It grows on trees that can reach 60 feet in height and generally fruit twice a year. Rambutan has been cultivated in the Southeast Asian region since prehistoric times and figured prominently in early trade with the Arabs, who took the fruit to Zanzibar, where it is still cultivated. Rambutan is normally eaten raw but is also stewed and made into jams. Rambutans are high in vitamin C.

Common names and synonyms: Ramboetan, rambotan, ramboutan, rambustan, ramtum.

Ramtil – *see* **NIGER SEED**

Ramtum – *see* **RAMBUTAN**

RANGPUR AND KUSAIE (*see also* **LIME**) – Both of these fruits are called "limes," but neither wholly deserves the name. Rather, both are probably hybrids of the Mandarin orange (*Citrus reticulata*) and the true lime (*C. aurantiifolia*). The rangpur develops a deep orange color that the kusaie does not. Both are acid in taste, although not so much as the lime, and the ease with which the segments separate is suggestive of the Mandarin orange. In the Western Hemisphere, the fruits are grown in the West Indies and California.

RAPE – An annual herb of European origin, rape (*Brassica napus*) looks like a cabbage but is cultivated mostly for its seeds, which yield an edible oil (rapeseed oil, called "canola oil" in the United States). The oil (also called "colza") is used for cooking and in salads, and the leaves of the young plants serve as a vegetable, in much the same way as spinach.

Common names and synonyms: Canola oil, colza, rapeseed oil.

See in addition: "An Overview of Oils and Fats," Part II, Section E, Chapter 1; "Cruciferous and Green Leafy Vegetables," Part II, Section C, Chapter 5.

Rapini – *see* **BROCCOLI RAAB**

RASPBERRY (*see also* **BERRIES**) – A number of shrublike, prickly plants of the genus *Rubus* have fruits that we call raspberries. Among them are *R. strigosus* (= *R. leucodermis*), which is a purple and black berry (the "black-cap") native to eastern North America, and *R. idaeus,* which is native to Europe. The latter species bears red raspberries, and most varieties cultivated today are a cross between the two. Pliny the Elder mentioned raspberries as a wild fruit, and they were probably not cultivated much before the seventeenth century. The apothecary and botanist John Parkinson – in his 1629 *Paradisi in sole paradisus terrestris* – wrote of red, white, and thornless varieties, indicating that some were under cultivation at that point.

The raspberry has a range that extends from the polar regions down through temperate North America, Asia, and Europe. One berry appears like a group of tiny berries lumped together. In addition to flavoring desserts and ice cream, raspberries are turned into wine, jams, and jellies, and the fruit is also used to flavor certain liqueurs. In the past, raspberries were among the berries gathered regularly and ritually by the Native Americans. Raspberries provide a good amount of vitamin C.

Common names and synonyms: American red raspberry, black-cap, black raspberry, purple raspberry, thimbleberry.

Rata – *see* **POLYNESIAN CHESTNUT, RATA VINE**

RATA VINE – A Maori word, *rata* indicates New Zealand trees of the genus *Metrosideros.* Some are hardwood trees that the Maori employed to make paddles and weapons such as war clubs. One (*M. fulgens*) has a vine that the Maori exploited as a sweetener. *Rata* can also mean the Polynesian chestnut.

RHUBARB – Chinese rhubarb (*Rheum officinale*) is used mostly for medical purposes. Garden rhubarb (*R. rhabarbarum*) is grown for its edible stalks. The plant is native to southwestern Russia, southern Siberia, and China, where it was grown in ancient times for the alleged medicinal value of its roots. Rhubarb was cultivated in Europe from at least the seventeenth century and reached North America shortly after the American Revolution. The leaves are highly toxic, and only the reddish pink and celery-like stalk is consumed as a "fruit" in pies and sauces. Rhubarb, which has a bitter taste, contains much oxalic acid, which can adversely affect the absorption of calcium and iron.

Common names and synonyms: Chinese rhubarb, garden rhubarb, pie-plant, wild rhubarb.

Ribier – *see* **GRAPES**

RICE (*see also* **AFRICAN RICE, WILD RICE**) – Rice (*Oryza sativa*) is the most "super" of all the "superfoods" in that it helps to sustain more than half of the world's population. It is an ancient grain that has been cultivated for around 5,000 years and now comes in some 2,500 varieties. Most rice species are native to the Indian subcontinent – save for a minor species with red grains that is native to Africa. (The wild rice of North America is not actually a rice but rather an aquatic oat.) A plant of hot climates, rice only became important in China when agriculture developed in the southern provinces. Some have credited Alexander the Great with introducing the grain in Europe, but it was not until the eighth century that the Muslims grew large quantities of it in Spain. "Carolina rice" came into being in 1685, when rice was introduced into South Carolina.

Today, rice is divided into long-, medium-, and short-grained varieties, and various cultures prize one or another of these over the rest. Long-grained rice is preferred in most Western kitchens and in India. Medium-grained rice is more appreciated in some Asian countries, whereas short-grained rice, with its starch that makes the grains stick together, is the favorite of those who use chopsticks, such as the Japanese and Chinese.

In most industrialized countries, white rice is enriched to replace the nutrients stripped from the grain by milling. Brown rice is far more nutritious because it has only had the husk removed during milling and retains the bran on its outer coating. Parboiled or converted rice is soaked and steamed before milling to drive nutrients into the grain. Instant rice has been fully cooked and then dehydrated. In addition, there are special rices, such as Arborio, which absorbs much water as it cooks and plumps up well for dishes like Italy's specialty, risotto, and Spain's paella. *Basmati* rice, grown in India and Pakistan, elongates rather than plumps and is commonly featured in Indian cooking, whereas Jasmine rice is a traditional rice of Thailand.

Common names and synonyms: Arborio, *Basmati,* brown rice, Carolina rice, dry rice, *gohan,* hill rice, instant rice, Jasmine rice, long-grained rice, medium-grained rice, *meshi,* polished rice, short-grained rice, white rice.

See in addition: "Rice," Part II, Section A, Chapter 7.
