Introduction 1

Part I Determining What Our Ancestors Ate 11

I.1. Dietary Reconstruction and Nutritional Assessment of Past Peoples: The Bioanthropological Record 13
Clark Spencer Larsen

I.2. Paleopathological Evidence of Malnutrition 34
Donald J. Ortner and Gretchen Theobald

I.3. Dietary Reconstruction As Seen in Coprolites 44
Kristin D. Sobolik

I.4. Animals Used for Food in the Past: As Seen by Their Remains Excavated from Archaeological Sites 51
Elizabeth S. Wing

I.5. Chemical Approaches to Dietary Representation 58
Ted A. Rathbun

I.6. History, Diet, and Hunter-Gatherers 63
Mark Nathan Cohen

Part II Staple Foods: Domesticated Plants and Animals

II.A. Grains **75**

II.A.1. Amaranth 75
Mary Karasch

II.A.2. Barley 81
Joy McCorriston

II.A.3. Buckwheat 90
G. Mazza

II.A.4. Maize 97
Ellen Messer

II.A.5. Millets 112
J. M. J. de Wet

II.A.6. Oat 121
David M. Peterson and J. Paul Murphy

II.A.7. Rice 132
Te-Tzu Chang

II.A.8. Rye 149
Hansjörg Küster

II.A.9. Sorghum 152
J. M. J. de Wet

II.A.10. Wheat 158
Joy McCorriston

II.B. Roots, Tubers, and Other Starchy Staples

II.B.1. Bananas and Plantains 175
Will C. McClatchey

II.B.2. Manioc 181
Mary Karasch

II.B.3. Potatoes (White) 187
Ellen Messer

II.B.4. Sago 201
H. Micheal Tarver and Allan W. Austin

II.B.5. Sweet Potatoes and Yams 207
Patricia J. O'Brien

II.B.6. Taro 218
Nancy J. Pollock

II.C. Important Vegetable Supplements

II.C.1. Algae 231
Sheldon Aaronson

II.C.2. The *Allium* Species (Onions, Garlic, Leeks, Chives, and Shallots) 249
Julia Peterson

II.C.3. Beans, Peas, and Lentils 271
Lawrence Kaplan

II.C.4. Chilli Peppers 281
Jean Andrews

II.C.5. Cruciferous and Green Leafy Vegetables 288
Robert C. Field

II.C.6. Cucumbers, Melons, and Watermelons 298
David Maynard and Donald N. Maynard

II.C.7. Fungi 313
Sheldon Aaronson

II.C.8. Squash 335
Deena S. Decker-Walters and Terrence W. Walters

II.C.9. Tomatoes 351
Janet Long

II.D. Staple Nuts

II.D.1. Chestnuts 359
Antoinette Fauve-Chamoux

II.D.2. Peanuts 364
Johanna T. Dwyer and Ritu Sandhu

II.E. Animal, Marine, and Vegetable Oils

II.E.1. An Overview of Oils and Fats, with a Special Emphasis on Olive Oil 375
Sean Francis O'Keefe

II.E.2. Coconut 388
Hugh C. Harries

II.E.3. Palm Oil 397
K. G. Berger and S. M. Martin

II.E.4. Sesame 411
Dorothea Bedigian

II.E.5. Soybean 442
Thomas Sorosiak

II.E.6. Sunflower 427
Charles B. Heiser, Jr.

II.F. Trading in Tastes

II.F.1. Spices and Flavorings 431
Hansjörg Küster

II.F.2. Sugar 437
J. H. Galloway

II.G. Important Foods from Animal Sources

II.G.1. American Bison 450
J. Allen Barksdale

II.G.2. Aquatic Animals 456
Colin E. Nash

II.G.3. Camels 467
Elizabeth A. Stephens

II.G.4. Caribou and Reindeer 480
David R. Yesner

II.G.5. Cattle 489
Daniel W. Gade

II.G.6. Chickens 496
Roger Blench and Kevin C. MacDonald

II.G.7. Chicken Eggs 499
William J. Stadelman

II.G.8. Dogs 508
Stanley J. Olsen

II.G.9. Ducks 517
Rosemary Luff

II.G.10. Game 524
Stephen Beckerman

II.G.11. Geese 529
Kevin C. MacDonald and Roger Blench

II.G.12. Goats 531
Daniel W. Gade

II.G.13. Hogs (Pigs) 536
Daniel W. Gade

II.G.14. Horses 542
Daniel W. Gade

II.G.15. Insects 546
Darna L. Dufour and Joy B. Sander

II.G.16. Llamas and Alpacas 555
Daniel W. Gade

II.G.17. Muscovy Ducks 559
Daniel W. Gade

II.G.18. Pigeons 561
Richard F. Johnston

II.G.19. Rabbits 565
Peter R. Cheeke

II.G.20. Sea Turtles and Their Eggs 567
James J. Parsons

II.G.21. Sheep 574
Daniel W. Gade

II.G.22. Turkeys 578
Stanley J. Olsen

II.G.23. Water Buffalo 583
Robert Hoffpauir

II.G.24. Yak 607
Richard P. Palmieri

Part III Dietary Liquids

III.1. Beer and Ale 619
Phillip A. Cantrell II

III.2. Breast Milk and Artificial Infant Feeding 626
Antoinette Fauve-Chamoux

III.3. Cacao 635
Murdo J. MacLeod

III.4. Coffee 641
Steven C. Topik

III.5. Distilled Beverages 653
James Comer

III.6. Kava 664
Nancy J. Pollock

III.7. Khat 671
Clarke Brooke

III.8. Kola Nut 684
Edmund Abaka

III.9. Milk and Dairy Products 692
Keith Vernon

III.10. Soft Drinks 702
Colin Emmins

III.11. Tea 712
John H. Weisburger and James Comer

III.12. Water 720
Christopher Hamlin

III.13. Wine 730
James L. Newman

Part IV The Nutrients – Deficiencies, Surfeits, and Food-Related Disorders

IV.A. Vitamins

IV.A.1. Vitamin A 741
George Wolf

IV.A.2. Vitamin B Complex: Thiamine, Riboflavin, Niacin, Pantothenic Acid, Pyridoxine, Cobalamin, Folic Acid 750
Daphne A. Roe

IV.A.3. Vitamin C 754
R. E. Hughes

IV.A.4. Vitamin D 763
Glenville Jones

IV.A.5. Vitamin E 769
Glenville Jones

IV.A.6. Vitamin K and Vitamin K–Dependent Proteins 774
Myrtle Thierry-Palmer

IV.B. Minerals

IV.B.1. Calcium 785
Herta Spencer

IV.B.2. Iodine and Iodine-Deficiency Disorders 797
Basil S. Hetzel

IV.B.3. Iron 811
Susan Kent and Patricia Stuart-Macadam

IV.B.4. Magnesium 824
Theodore D. Mountokalakis

IV.B.5. Phosphorus 834
John J. B. Anderson

IV.B.6. Potassium 843
David S. Newman

IV.B.7. Sodium and Hypertension 848
Thomas W. Wilson and Clarence E. Grim

IV.B.8. Other Trace Elements 856
Forrest H. Nielsen

IV.B.9. Zinc 868
Ananda S. Prasad

IV.C. Proteins, Fats, and Essential Fatty Acids

IV.C.1. Essential Fatty Acids 876
Jacqueline L. Dupont

IV.C.2. Proteins 882
Kenneth J. Carpenter

IV.C.3. Energy and Protein Metabolism 888
Peter L. Pellett

IV.D. Deficiency Diseases

IV.D.1. Beriberi 914
Frederick L. Dunn

IV.D.2. Iron Deficiency and Anemia of Chronic Disease 919
Susan Kent

IV.D.3. Keshan Disease 939
Yiming Xia

IV.D.4. Osteoporosis 947
Robert P. Heaney

IV.D.5. Pellagra 960
Daphne A. Roe and Stephen V. Beck

IV.D.6. Pica 967
Margaret J. Weinberger

IV.D.7. Protein–Energy Malnutrition 977
J. D. L. Hansen

IV.D.8. Scurvy 988
R. E. Hughes

IV.E. Food-Related Disorders

IV.E.1. Anorexia Nervosa 1001
Heather Munro Prescott

IV.E.2. Celiac Disease 1008
Donald D. Kasarda

IV.E.3. Food Allergies 1022
Susan L. Hefle

IV.E.4. Food-Borne Infection 1031
Sujatha Panikker

IV.E.5. Food Sensitivities: Allergies and Intolerances 1048
Judy Perkin

IV.E.6. Lactose Intolerance 1057
K. David Patterson

IV.E.7. Obesity 1062
Leslie Sue Lieberman

IV.F. Diet and Chronic Disease

IV.F.1. Diabetes 1078
Leslie Sue Lieberman

IV.F.2. Nutrition and Cancer 1086
Robert Kroes and J. H. Weisburger

IV.F.3. Nutrition and Heart-Related Diseases 1097
Melissa H. Olken and Joel D. Howell

IV.F.4. The Cardiovascular System, Coronary Artery Disease, and Calcium: A Hypothesis 1109
Stephen Seely

VOLUME TWO

Part V Food and Drink around the World

V.A. The Beginnings of Agriculture: The Ancient Near East and North Africa 1123
Naomi F. Miller and Wilma Wetterstrom

V.B. The History and Culture of Food and Drink in Asia

V.B.1. The Middle East and South Asia 1140
Delphine Roger

V.B.2. Southeast Asia 1151
Christine S. Wilson

V.B.3. China 1165
Françoise Sabban (translated by Elborg Forster)

V.B.4. Japan 1175
Naomichi Ishige

V.B.5. Korea 1183
Lois N. Magner

V.C. The History and Culture of Food and Drink in Europe

V.C.1. The Mediterranean (Diets and Disease Prevention) 1193
Marion Nestle

V.C.2. Southern Europe 1203
Kenneth Albala

V.C.3. France 1210
Eva Barlösius

V.C.4. The British Isles 1217
Colin Spencer

V.C.5. Northern Europe – Germany and Surrounding Regions 1226
Hansjörg Küster

V.C.6. The Low Countries 1232
Anneke H. van Otterloo

V.C.7. Russia 1240
K. David Patterson

V.D. The History and Culture of Food and Drink in the Americas

V.D.1. Mexico and Highland Central America 1248
John C. Super and Luis Alberto Vargas

V.D.2. South America 1254
Daniel W. Gade

V.D.3. The Caribbean, Including Northern South America and Lowland Central America: Early History 1260
William F. Keegan

V.D.4. The Caribbean from 1492 to the Present 1278
Jeffrey M. Pilcher

V.D.5. Temperate and Arctic North America to 1492 1288
Elizabeth J. Reitz

V.D.6. North America from 1492 to the Present 1304
James Comer

V.D.7. The Arctic and Subarctic Regions 1323
Linda J. Reed

V.E. The History and Culture of Food and Drink in Sub-Saharan Africa and Oceania

V.E.1. Africa South from the Sahara 1330
James L. Newman

V.E.2. Australia and New Zealand 1339
Brian Murton

V.E.3. The Pacific Islands 1351
Nancy Davis Lewis

V.F. Culinary History 1367
Ellen Messer, Barbara Haber, Joyce Toomre, and Barbara Wheaton

Part VI History, Nutrition, and Health

VI.1. Nutrition and the Decline of Mortality 1381
John M. Kim

VI.2. Nutrition and Mortality Decline: Another View 1389
William Muraskin

VI.3. Infection and Nutrition: Synergistic Interactions 1397
Nevin S. Scrimshaw

VI.4. Famine 1411
Brian Murton

VI.5. Height and Nutrition 1427
Bernard Harris

VI.6. The Nutrition of Women in the Developing World 1439
Eileen Kennedy and Lawrence Haddad

VI.7. Infant and Child Nutrition 1444
Sara A. Quandt

VI.8. Adolescent Nutrition and Fertility 1453
Heather Munro Prescott

VI.9. Nutrition and Mental Development 1457
Donald T. Simeon and Sally M. Grantham-McGregor

VI.10. Human Nutritional Adaptation: Biological and Cultural Aspects 1466
H. H. Draper

VI.11. The Psychology of Food and Food Choice 1476
Paul Rozin

VI.12. Food Fads 1486
Jeffrey M. Pilcher

VI.13. Food Prejudices and Taboos 1495
Louis E. Grivetti

VI.14. The Social and Cultural Uses of Food 1513
Carole M. Counihan

VI.15. Food as Aphrodisiacs and Anaphrodisiacs? 1523
Thomas G. Benedek

VI.16. Food as Medicine 1534
J. Worth Estes

VI.17. Vegetarianism 1553
James C. Whorton

VI.18. Vegetarianism: Another View 1564
H. Leon Abrams, Jr.

Part VII Contemporary Food-Related Policy Issues

VII.1. The State, Health, and Nutrition 1577
Carol F. Helstosky

VII.2. Food Entitlements 1585
William H. Whitaker

VII.3. Food Subsidies and Interventions for Infant and Child Nutrition 1593
Penelope Nestel

VII.4. Recommended Dietary Allowances and Dietary Guidance 1606
Alfred E. Harper

VII.5. Food Labeling 1621
Eliza M. Mojduszka

VII.6. Food Lobbies and U.S. Dietary Guidance Policy 1628
Marion Nestle

VII.7. Food Biotechnology: Politics and Policy Implications 1643
Marion Nestle

VII.8. Food Safety and Biotechnology 1662
Michael W. Pariza

VII.9. Food Additives 1667
K. T. H. Farrer

VII.10. Substitute Foods and Ingredients 1677
Beatrice Trum Hunter

VII.11. Nonfoods as Dietary Supplements 1685
R. E. Hughes

VII.12. Food Toxins and Poisons from Microorganisms 1694
Gordon L. Klein and Wayne R. Snodgrass

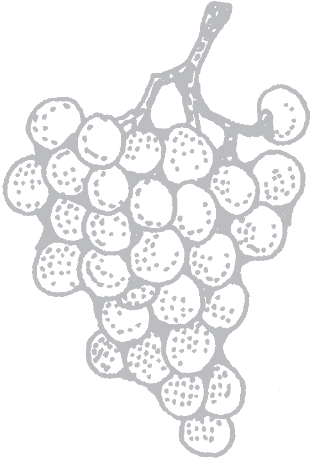
VII.13. The Question of Paleolithic Nutrition and Modern Health: From the End to the Beginning 1704
Kenneth F. Kiple

Part VIII A Dictionary of the World's Plant Foods 1711

Sources Consulted 1887
Index of Latin Names 1890

Name Index 1901
Subject Index 1917

TABLES, FIGURES, AND MAPS



Tables

II.A.3.1. Percent composition of buckwheat seed and its milling *page* 91
II.A.3.2. Average mineral and vitamin contents of buckwheat whole grain 92
II.A.3.3. Chemical composition of buckwheat, barley, and corn starch granules smaller than 315 µ 92
II.A.3.4. Quality of buckwheat and wheat protein 93
II.A.3.5. Primary grade determinants of buckwheat (Canada) 93
II.A.3.6. Absorbance of extracted color and tristimulus values of buckwheat samples stored at 25° C and 5 water activities for 19 months 94
II.A.3.7. Influence of cultivar and moisture content on dehulling characteristics and color of buckwheat seeds stored at 25° C and water activities of 0.23–0.97 for 45 days 95
II.A.6.1. World oat production, area harvested, and yield by continent and country, 1965 through 1994 126
II.A.7.1. Contrast in diversification: *Oryza sativa* vs. *glaberrima* 136
II.A.10.1. Prehistoric cultures of the Near East 162
II.A.10.2. Principal wheat types 164
II.B.6.1. Nutritional value of the four types of taro 228
II.C.1.1. Algae and blue-green bacteria eaten in contemporary Chile and Peru 232
II.C.1.2. Algae eaten by humans now and in the past 233
II.C.1.3. The gross chemical composition of edible algae 239
II.C.1.4. Amino acid content of edible algae 240
II.C.1.5. Vitamin content of edible algae 242
II.C.1.6. The range of fatty acids found in edible algae 244
II.C.3.1. Beans, peas, and lentils 272
II.C.6.1. World cucumber and gherkin production, 1995 309
II.C.6.2. World cantaloupe and other melon production, 1995 309
II.C.6.3. World watermelon production, 1995 310
II.C.6.4. Per capita consumption of cucumbers, melons, and watermelons in the United States, 1996 311
II.C.6.5. Nutritional composition of some cucurbits 311
II.C.7.1. Fungi eaten by humans around the world now and in the past 317
II.C.7.2. Gross chemical composition of fungi as a percentage of fungal dry weight 325

II.C.7.3. Variations in the gross chemistry of different stages in the development of the *Volvariella volvacea* sporophore 326
II.C.7.4. Vitamin content of edible fungi 326
II.C.7.5. Foods and beverages that require fungal processing 328
II.C.8.1. Domesticated varieties of *Cucurbita argyrosperma* ssp. *argyrosperma* 338
II.C.8.2. Horticultural groups of *Cucurbita moschata* 339
II.C.8.3. Horticultural groups of *Cucurbita pepo* 341
II.C.8.4. Horticultural groups of *Cucurbita maxima* 342
II.C.8.5. Mineral and vitamin content of young fruits, mature fruits, leaves, and growing tips and ground seed meal 349
II.D.2.1. Characteristics of peanut varieties 365
II.D.2.2. Comparison of various indexes of protein quality for peanuts and other protein-rich foods 368
II.D.2.3. Comparison of the amino acids in peanuts compared to high-quality proteins 368
II.D.2.4. Comparison of nutritive value of peanuts with other common cereals and legumes 369
II.D.2.5. Nutritional value of *Arachis hypogaea* I. 369
II.D.2.6. Nutritive value of common peanut foods 372
II.E.1.1. Average oil contents of plant sources of oil 377
II.E.1.2. Fatty acid composition ranges of natural populations of vegetable oils 379
II.E.1.3. Levels of minor components in olive oil 379
II.E.1.4. Fatty acid compositions of modified fatty acid vegetable oils 380
II.E.1.5. Tocopherol isomer distribution in dietary fats and oils 381
II.E.1.6. Approximate biological activity relationships of Vitamin E compounds 381
II.E.1.7. Nontriacylglycerol materials in crude palm oil 382
II.E.1.8. Fatty acid compositions in palm olein and stearin 382
II.E.1.9. Common names for rapeseed species 383
II.E.1.10. Fatty acid composition of butterfat 385
II.E.1.11. Fat-soluble vitamin levels in fish liver oils 387
II.E.3.1. Indonesia: Oil palm area 399
II.E.3.2. Malaysia: Oil palm area 400
II.E.3.3. Latin America: Earliest oil palm plantings 400
II.E.3.4. Latin America: Oil palm area, 1992 400
II.E.3.5. Comparison of village palm oil processes 401
II.E.3.6. Palm oil exports from selected countries 406
II.E.3.7. Specifications of special grades of crude palm oil 406
II.E.3.8. Palm oil imports to selected regions 407
II.E.3.9. Composition of palm oil 407
II.E.3.10. Tocopherol content of typical refined palm oil 408
II.E.6.1. Sunflower production 429
II.F.1.1. The origin of spices used historically and today 432
II.G.4.1. Weights and edible weights for caribou *(Rangifer tarandus)* 484
II.G.4.2. Age distribution of caribou from an Alaskan archaeological site 487
II.G.7.1. Egg production of several countries of the world 502
II.G.15.1. Numbers of species of insects used as food by stage of life cycle and geographic region 547
II.G.15.2. Number of species of the insects most commonly consumed throughout the world by geographic region 552
II.G.19.1. Nutrient composition of rabbit meat 566
II.G.22.1. Southwestern chronology 579
II.G.23.1. Population of water buffalo 586
III.2.1. Typical analyses of milk from various species 627
III.2.2. Daily quantities of milk a healthy child should ordinarily absorb during the first six months of life 627
III.2.3. Number of babies, aged less than 1, abandoned in Paris Foundling Hospital, 1773–7, with infant mortality for each group, according to their origin 630
III.2.4. General infant and child mortality in four European

countries during the second half of the eighteenth century 631
III.2.5. Number of children abandoned in Paris Foundling Hospital, 1773–7, according to their age and origin 631
III.7.1. Nutritional components of khat *(Catha edulis)* 680
III.8.1. Chemical composition of the pod husk, testa, and nut of kola 685
IV.A.1.1. Association of vitamin A potency with yellow color in food 744
IV.A.1.2. Countries categorized by degree of health; importance of vitamin A deficiency by WHO region 748
IV.A.3.1. Ascorbic acid content of some plants 759
IV.A.6.1. Vitamin K analogues 775
IV.A.6.2. Phylloquinone content of common foods 775
IV.B.1.1. Calcium balances of males and females during a low calcium intake 788
IV.B.1.2. Studies of the calcium requirement 789
IV.B.1.3. Effect of aluminum-containing antacids on the calcium and phosphorus balance 790
IV.B.1.4. Effect of a high-protein diet on calcium metabolism 793
IV.B.1.5. Patients with chronic alcoholism and osteoporosis 793
IV.B.1.6. Effect of corticosteroids on the calcium balance 793
IV.B.2.1. The spectrum of iodine-deficiency disorders 803
IV.B.2.2. Estimated prevalence of iodine-deficiency disorders in developing countries, by region and numbers of persons at risk 806
IV.B.3.1. Normal hematological values for the more common iron indexes 814
IV.B.3.2. Comparison of laboratory values of anemia of dietary iron deficiency and anemia of chronic disease 815
IV.B.3.3. Types of disorders associated with iron overload 818
IV.B.3.4. Morphological classification of anemia 820
IV.B.4.1. Some important dates with reference to magnesium 826
IV.B.4.2. Year of first application of different procedures for measuring magnesium in biological materials 826
IV.B.4.3. Causes of human magnesium deficiency and year of their first description 827
IV.B.4.4. Generally accepted symptoms and signs of magnesium deficiency 829
IV.B.4.5. Additional symptoms and signs attributed to magnesium deficiency by some authors 829
IV.B.4.6. Magnesium intake in the modern-day world 832
IV.B.5.1. Content of phosphorus and calcium in commonly consumed foods in mg per serving 836
IV.C.1.1. Unsaturated fatty acids 879
IV.C.2.1. Reproduction of the final summary of the rat's requirements for amino acids, as determined by Rose and colleagues in 1948 885
IV.C.2.2. The World Health Organization (1985) estimates of human requirements for protein and selected amino acids, by age 886
IV.C.2.3. The typical protein concentrations of a variety of foods (edible portions only) expressed as "protein calories as a percentage of total calories" 887
IV.C.3.1. Energy exchange in humans: An example from Atwater and Benedict 891
IV.C.3.2. Food availability data for industrialized and developing countries. Data for 1994 893
IV.C.3.3. The principal dietary carbohydrates 893
IV.C.3.4. Equations for predicting basal metabolic rate from body weight and age 895
IV.C.3.5. Physical activity levels suggested to estimate total daily energy expenditure from the mean basal metabolic rate of children, adolescents, and adults 897
IV.C.3.6. Early protein and energy intakes from Europe and America with requirement estimates 898
IV.C.3.7. International food energy requirements (1950–96) 898
IV.C.3.8. Distribution of food energy, fat, and protein in the various world regions 899
IV.C.3.9. Summary of nonessential amino acid biosynthesis in mammals 903
IV.C.3.10. Other functions of some amino acids 903

IV.C.3.11. Fate of the nitrogen and the carbon atoms in the degradation of the amino acids for energy 904
IV.C.3.12. Recommended scoring patterns, 1950–91 905
IV.C.3.13. International protein recommendation (1936–96) 906
IV.C.3.14. Summary of some recent committee recommendations for practical protein allowances in various age groups 906
IV.C.3.15. FAO/WHO/UNU (1985) safe levels of protein intake 907
IV.C.3.16. Factorial approach for human protein requirements: Adapted from FAO/WHO (1973) 907
IV.C.3.17. Amino acid composition of major food groups from the Massachusetts Nutrient Data Bank 908
IV.C.3.18. Mean values per capita for the availability of specific indispensable amino acids in developed and developing regions. Data for 1994 908
IV.C.3.19. A proposed classification using BMI (WT/HT^2) 909
IV.D.3.1. Keshan disease incidence and prognosis of selenium-supplemented and control children (1–9 years old) in Mianning County during 1974–7 942
IV.D.3.2. Keshan disease incidence in selenium-supplemented and control children (1–12 years old) in five counties of Sichuan Province during 1976–80 942
IV.D.3.3. Selenium levels in human blood and hair from residents in Keshan disease–affected and nonaffected areas in 1972–3 943
IV.D.3.4. Blood glutathione peroxidase (GPX) activities of children from Keshan disease–affected and nonaffected areas in 1975 943
IV.D.3.5. Selenium contents of blood, hair, and grains in Keshan disease–affected and nonaffected areas 943
IV.D.3.6. Selenium contents and glutathione peroxidase (GPX) activities in tissues from patients with subacute Keshan disease and controls in affected or nonaffected areas 944
IV.D.3.7. Indexes for oxidant defense capability in blood of children from Dechang and Mianning Counties in 1987 945
IV.D.3.8. Comparison of selenium content in cereals and human hair between the 1970s and 1980s 946
IV.D.4.1. Threshold calcium intakes during growth 957
IV.D.7.1. The Wellcome classification of PEM 978

V.D.3.1. Comparison of house-garden cultigens in native Amazonian and prehistoric West Indian gardens 1264
V.D.3.2. Fishes identified in Lucayan sites 1265
V.D.3.3. Return rates and resource rankings of Lucayan foods 1267
V.D.3.4. Garifuna ceremonial foods and the probable time of their introduction 1273
V.D.5.1. General chronological sequence 1288
V.D.5.2. List of scientific and common names for plants 1289
V.D.5.3. List of scientific and common names for animals 1290
VI.3.1. 108 acute infections among 32 children ages 2 to 9 years observed in a "model" convalescent home in Guatemala City for 90 days 1398
VI.3.2. Antimicrobial systems in the neutrophil 1399
VI.3.3. Intake of calories in acute state, and 2 weeks and 8 weeks after recovery 1404
VI.5.1. Changes in the heights of European army recruits circa 1900–1975 1429
VI.5.2. Median menarcheal age of girls in various European countries, 1950s–60s and 1970s–80s 1430
VI.5.3. Average heights of selected groups of Indo-Mediterranean children at different periods 1434
VI.7.1. Percentage of first-born infants ever breast-fed between 1951 and 1970 in the United States, by ethnic group and education 1449
VI.11.1. Psychological categorization of acceptance and rejection 1478
VI.13.1. Selected forbidden foods: Leviticus (Hebrew source with English translations) 1499
VI.13.2. BaTlokwa ba Moshaweng: Foods restricted by gender and age 1505
VI.15.1. Ancient sexual stimulants and depressants 1523
VI.15.2. Most commonly cited aphrodisiacs, 1546–1710 1527
VI.16.1. Past and present medicinal uses of flavorings and spices 1540
VI.16.2. Past and present medicinal uses of fruits and nuts 1540
VI.16.3. Past and present medicinal uses of vegetables 1541
VI.16.4. Past and present medicinal uses of beverages 1541
VI.16.5. Past and present medicinal uses of grains 1541
VI.16.6. Past and present medicinal uses of gums and roots 1541
VI.16.7. Past and present medicinal uses of miscellaneous foodstuffs 1541
VII.6.1. Selected landmarks in the history of U.S. lobbying 1631
VII.6.2. Selected examples of food lobbying groups 1633
VII.6.3. A partial list of food and agriculture Political Action Committees (PACs) contributing to the 1989–90 election campaign of Senator Tom Harkin (D–IA), a member of the Appropriations and Agriculture, Nutrition and Forestry Committees 1634
VII.6.4. Evolution of federal recommendations to reduce dietary fat through changes in meat consumption 1637
VII.7.1. Theoretical and current applications of food biotechnology 1644
VII.7.2. Key events in the history of the commercialization of food products of biotechnology in the United States 1647
VII.7.3. Safety issues raised by food biotechnology 1648
VII.7.4. The principal arguments for and against the patenting of transgenic animals 1651

VII.7.5. Public perceptions of food biotechnology 1653
VII.7.6. Analytical framework for predicting public acceptance of a food product of biotechnology 1654
VII.8.1. Ranking food safety risks 1663
VII.8.2. Summary of reported food-borne disease outbreaks in the United States, 1983–7 1663
VII.8.3. Some natural pesticidal carcinogens in food 1665
VII.9.1. Food additives and their functions 1671
VII.11.1. Publications during 1930–90 relating to the nutritional significance of bioflavonoids and carnitine 1687

Figures

I.1.1. Temporal changes in mean values of δ13C of prehistoric eastern North American Indians 17
I.1.2. Scanning electron micrographs of prehistoric hunter–gatherer molar and historic agriculturalist molar from the southeastern U.S. Atlantic coast 18
I.1.3. Views of mandibular dentitions showing agriculturalist and hunter–gatherer wear planes 19
I.1.4. Lingual wear on anterior teeth of prehistoric Brazilian Indian 19
I.1.5. Dental carious lesion in maxillary molar from historic Florida Indian 20
I.1.6. Growth curves from Dickson Mounds, Illinois, Indian population 21
I.1.7. Micrograph showing hypermineralized rings within an osteon from prehistoric Nubian 22
I.1.8. Radiograph and section of prehistoric California Indian femur with Harris lines 23
I.1.9. Juvenile anterior dentition showing hypoplasias on incompletely erupted incisors 24
I.1.10. Micrograph of canine tooth showing Wilson band from Native American Libben site 25
I.1.11. Femora and tibiae of nineteenth-century black American showing limb bone deformation due to rickets 26
I.1.12. Porotic hyperostosis on prehistoric Peruvian Indian posterior cranium 27
I.1.13. Cribra orbitalia in historic Florida Indian 27
I.2.1. External view of the maxilla of a child about 6 years of age at the time of death 37
I.2.2. Right sphenoid and adjacent bone surfaces of case seen in Figure I.2.1 38
I.2.3. Orbital roof of case seen in Figure I.2.1 38
I.2.4. Inner table of the frontal bone of case seen in Figure I.2.1 38
I.2.5. Right lateral view of the ninth through the twelfth thoracic vertebrae from the skeleton of a male about 45 years of age at the time of death 40
I.2.6a. Photomicrograph of a bone section from the femur of the burial seen in Figure I.2.5 41
I.2.6b. Photomicrograph of a microradiograph of the bone section seen in Figure I.2.6a 41
II.A.3.1. Flow diagram of two buckwheat mills: (A) roller mill; (B) stone-roller mill 96
II.A.6.1. Flow diagram of typical oat-milling sequence 128
II.A.10.1. Related wheats and goat-faced grasses 166
II.A.10.2. Photograph of the Nahal Hemar sickle 167
II.B.6.1. Different types of taros 220
II.C.4.1. Cross-section of a pepper 286
II.C.6.1. Netted cantaloupe fruit 299
II.C.6.2. Casaba melon 300
II.C.6.3. Juan Canary melon 301
II.C.6.4. Santa Claus melon 301
II.C.6.5. Pistillate and staminate cucumber flowers 302
II.C.6.6. Cucumbers 302
II.C.6.7. Gynoecious, parthenocarpic greenhouse cucumbers 303
II.C.6.8. Variation in watermelon fruit size, shape, and color and flesh color 303
II.C.6.9. Seedless watermelon with seeded watermelon 304
II.C.6.10. ‘Jubilee’ watermelon developed by J. M. Crall, University of Florida, in 1963 308
II.C.6.11. Watermelon seedlings grafted by machine onto Fusarium-resistant rootstocks in Japan 309

II.C.6.12. Melons for sale as special gifts in Kyoto, Japan 310
II.C.6.13. Low, supported row covers for watermelon production in Daiei, Japan 310
II.C.6.14. NMR watermelon quality determination in Japan 312
II.C.6.15. Watermelon for sale in Japan at U.S. $50 312
II.C.8.1. *Cucurbita moschata* 338
II.C.8.2. Seeds of *Cucurbita pepo, C. moschata, C. argyrosperma,* and 'Silverseed Gourd' 339
II.C.8.3. 'Butternut', a "bell squash" cultivar of *Cucurbita moschata* 340
II.C.8.4. An unusual "acorn squash" of *Cucurbita pepo* 340
II.C.8.5. 'Delicata' *(Cucurbita pepo)* 341
II.C.8.6. Various small-fruited cultivars of *Cucurbita pepo* 341
II.C.8.7. 'Turk's Turban' *(Cucurbita maxima)* 342
II.C.8.8. 'Buttercup', a "turban squash" of *Cucurbita maxima* 343
II.C.8.9. A "hubbard squash" of *Cucurbita maxima* 343
II.C.8.10. Mature fruit of *Cucurbita argyrosperma* ssp. *sororia* 344
II.C.8.11. 'Seminole Pumpkin' *(Cucurbita moschata)* 345
II.C.8.12. Wild *Cucurbita pepo* ssp. *ovifera* var. *ozarkana* from a riparian site in the Mississippi Valley 346
II.C.8.13. Wild spp. *ovifera* var. *texana,* 'Mandan' and wild ssp. *fraterna* 346

PREFACE

This work together with its predecessor, *The Cambridge World History of Human Disease,* represents an effort to encapsulate much of what is known about human health as a new millennium begins. As such the volumes should prove important to researchers of the future just as today many investigators find important August Hirsch's three-volume *Handbook of Geographical and Historical Pathology* that was translated and published in London during the years 1883 to 1886. We hope, however, that in light of the accelerating academic and public interest in the things we eat and drink and what they do for us (or to us) the present work will also find an appreciative audience here and now. It is, to our knowledge, the first effort to draw together on a global scale the work of scholars on both nutritional and food-related subjects and to endow the whole with a strong interdisciplinary foundation that utilizes a great number of approaches to food questions ranging from the anthropological to the zoological.

Many of these questions are policy-related and look at real and pressing problems such as poor nutrition among the young of the developing world, food additives and biotechnology in the developed world, and food entitlements in both worlds. Many others, however, are dedicated to determining what our ancestors ate in Paleolithic times; the changes – both dietary and physiological – brought on by the various Neolithic Revolutions and the domesticated plants and animals they nurtured; and what products of those Revolutions have been consumed in the various corners of the globe ever since.

Another broad set of questions employs nutritional science to evaluate the quality of diets, both past and present, and to indicate the diseases, defects, and disorders that can and have developed when that quality is low. A final focus is on the numerous psychological, cultural, and genetic reasons individual humans as well as societies embrace some foods and beverages yet reject others that counterparts find eminently satisfactory.

More implicit than explicit are two threads that loosely stitch together the essays that follow. One is the thread of food globalization, although by globalization we do not mean the current concern about world "burgerization" or even the process of menu homogenization – the latter which began in the aftermath of World War II and has been accelerating ever since. Rather, we mean the inexorable process of food globalization that started some eight to ten thousand or more years ago with the domestication of plants and animals. Although this first occurred in places such as Mesopotamia, the Indus Valley, Egypt, and China in the Old World and Peru and MesoAmerica in the New World, and the fruits of domestication were at first shared mostly by propinquous peoples, those fruits sooner or later spread out over the entire globe. They were carried by restless folk – initially by explorers, pioneers, and the like and then by merchants, missionaries, marauders, and mariners who followed on their heels.

The second thread has to do with the taxes that technological advances generally levy on human nutrition. Many believe that this process began in the distant past as hunter-gatherers devised tools which enabled them to become so efficient in hunting large animals that their growth in numbers and a decline in the amount of prey seriously jeopardized their food supply. This forced another technological advance – the greatest of all – which was the invention of agriculture. But with sedentism came even more population growth, circumscribed diets, and pathogenic prosperity. Such problems continue to curse many in the developing world today where the response to any technologically driven increase in the food supply has generally been an increase in the number who share that food. Meanwhile, in the developed world the response to ever more abundance – much of it in the form of new calorie-dense foods – has been a different kind of population growth as its citizens individually grow ever larger in an outward direction.

ACKNOWLEDGMENTS

This work is the offspring of the Cambridge History and Culture of Food and Nutrition project which, in turn, was the progeny of the Cambridge History of Human Disease project. As the latter effort neared completion in 1990, the former was launched. We are enormously grateful to the National Library of Medicine for providing one grant (1 RO1 LMO5320-01) to begin the effort and another (1RO1 LMOC574-01) to see it completed. In between, funding was provided by a Bowling Green State University History Department challenge grant from the State of Ohio, by grants from Cambridge University Press, and by various university budgets. In addition, Department of History chairpersons Gary Hess, Fujiya Kawashima, and Donald Nieman each ensured that the project was always staffed by graduate students who checked sources, entered manuscripts into the computer, and performed countless other duties. That some four generations of students worked on the project can be seen in the list of assistant editors whose names appear opposite the title page. We are indebted to all of them. In addition, we wish to thank the History Department secretaries Connie Willis and Judy Gilbert for the countless hours of their labor given cheerfully and generously.

Frank Smith, our editor at Cambridge University Press, was instrumental in launching this project. He collaborated in its conceptualization, worked with us in assembling the Board Members, encouraged us at every stage of the effort for a full decade, procured last-minute permissions, and took over the task of securing the decorative art. He has been a true partner in the project.

Rachael Graham, who served as executive editor of the disease project, retired with husband Jim shortly after the food and nutrition project began. She was succeeded by Mike Tarver (also a veteran of the earlier effort) – a computer whiz who propelled all of us in the direction of computer literacy while overseeing the daily office procedures of entering manuscripts into the computer and checking sources. But then he, too, left us (for “a real job” as we heard one of our assistant editors mutter under his breath), and Stephen Beck took over.

Steve was born for the job, and many of our authors, including myself, are in his debt for sentences that are now clearer and sharper (and in some instances far more coherent) than they were before. His grasp of the English language is also matched by a fine eye for details and a much appreciated ability to keep track of those details over months and even years. This is particularly apparent in Part VIII where he maintained an ever-growing list of the names of plant foods, both common and scientific, which prevented much repetition, not to mention duplication. In addition he and Coneè supervised the activities of the assistant editors on the project and finally, on numerous occasions (such as the pellagra essay, and some of the Part VIII entries), Steve also took on the tasks of researcher and author.

None of this is to imply that others had no hand in the editorial and production process. Kathi Unger and Steve Shimer compiled the very large indexes on the other end of this work both swiftly and competently. Kathie Kounouklos produced the handsome page layouts, and Mary Jo Rhodes steadfastly checked the manuscript and proof from beginning to end. Claire McKean and Phyllis Berk under the direction of Françoise Bartlett at G&H SOHO did a wonderful job of imposing order on a manuscript whose very size doubtlessly made it intimidating. In so doing they untangled and straightened out much that we thought we had untangled and straightened out. We are very grateful to them and to Cathy Felgar of Cambridge University Press who was ultimately in charge of the work's production.

However, despite the editorial exertions here and in New York, in the final analysis these volumes belong to its authors – in this case around 160 of them – of which fully a quarter represent some 15 countries in addition to the United States. We thank each one for what has become a magnificent collective achievement and apologize for the "extra" years that it took to get the work into print. As we have explained (or confessed) to the many who have inquired, the project just became so large that every one of its stages required considerably more time than estimates based on the earlier disease project allowed for.

The nearly 40 members of our Board of Editors have been a vital part of the project. Most of the suggestions for authors came from them, and every essay was read by them for scientific and historical accuracy. Especially active in this latter capacity were Thomas G. Benedek, Kenneth J. Carpenter, Alfred W. Crosby, Frederick L. Dunn, Daniel W. Gade, Jerome S. Handler, Clark Spencer Larsen, Leslie Sue Lieberman, Ellen Messer, Marion Nestle, James L. Newman, K. David Patterson, and Jeffrey M. Pilcher. In addition, Frederick J. Simoons not only read a number of essays with his characteristically painstaking care but made numerous and invariably sterling suggestions for authors that lightened our load considerably.

It should be noted, however, that we did not always take the suggestions of Board Members. In some cases this was because reports disagreed. In others it was because authors made good cases against proposed revisions. And at times it was because, rightly or wrongly, we decided that suggested revisions were not necessary. But this means only we and the authors bear final responsibility for the essays embraced by these volumes. In no way does it detract from the great wisdom (not to mention the great amount of time) so graciously donated by the members of our Board of Editors.

One of these individuals, K. David Patterson, died suddenly and prematurely during the latter stages of the project. Dave was a good friend as well as colleague who served both of our Cambridge projects as an energetic board member and enthusiastic author. He did everything from collaborating in their conceptualization to accepting huge writing assignments for each to the researching and writing of essays whose authors failed to deliver them. Yet, despite taking on so much, everything that he did reflected scholarship of the highest possible quality. Dave truly was a scholar in the best sense of the word, and we greatly miss him.

This work is dedicated to Dave and to four other individuals who died during this project. We did not personally know Norman Kretchmer, one of the board members, or authors Richard P. Palmieri, James J. Parsons, and Daphne A. Roe, but we knew them by their work and reputations. We know that they will be sorely missed in, among other fields, those of the Nutritional Sciences and Geography.

KENNETH F. KIPLE
KRIEMHILD CONEÈ ORNELAS

ABOUT THESE VOLUMES AND HOW TO USE THEM

The history of the world's major staple foods – both animal and vegetable – along with supplementary foods that loom large in such diets – are dealt with at length in Part II. Shorter entries of these same staple plant foods also appear in Part VIII along with some 1,000 of the world's other fruits and vegetables.

These volumes were never intended to comprise an encyclopedia but rather to be a collection of original essays. Therefore, the chapters are far from uniform, and at times there is overlap between them, which was encouraged so that each essay could stand alone without cross-referencing. Bibliographies range from gargantuan to gaunt; most (but not all) authors employ in-text citations, and a few use end notes as well. Such disproportion was not considered a problem. Our authors represent many disciplines, each with his or her own manner of delivering scholarship, and, consequently, they were given considerably latitude in their style of presentation.

The table of contents, of course, is one way of navigating this work, and to help in its use the entries have been arranged in alphabetical order wherever it made sense to do so. But although the table of contents will direct readers to a major entry such as "Wheat," it is in the index where every mention of wheat in both volumes is indicated and the grain's geographic spread and historical uses can be discerned.

The capability for tracing foods longitudinally came with the preparation of a special subject index that was also geographically focused; hence, a food like manioc can be found both by subject and under the various areas of the world where it is, or has been, important, such as Brazil, the Caribbean, and West Africa. In addition, there is an index of all names mentioned in the text.

The entries in Part VIII are also represented in the subject index. This is the only part of the work that is cross-referenced, and it contains numerous synonyms that should prove useful to researchers and intriguing to linguists, including those no longer in use such as "colewort" (cabbage) or "pompion" (pumpkin). The synonyms appear twice: once in alphabetical order to direct readers to (in the case of the examples just used) "Cabbage" or "Pumpkin" and then again in a synonyms list at the end of these entries. Moreover, the Part VIII articles send the reader to related entries in that section and also to chapters in Parts II and III (in the case of cabbage or pumpkin to "Cruciferous and Green Leafy Vegetables" and "Squash," respectively).

We should note for the record that any discussion in these volumes of a foodstuff (or a nonfood for that matter) which might be consumed should not be taken as a recommendation that it be consumed, or that it is safe to consume. The new (and sometimes unfamiliar) foods that our authors state are edible doubtlessly are. But as many of the chapters that follow indicate, foods, especially plant foods, are generally toxic to some degree to help protect against predators.

A good example is bitter manioc whose tubers contain prussic acid – a poison that must be removed before consumption. But toxicity can vary with plant parts. Thus, the celery-like stalks of rhubarb are edible after cooking, but the rhizomes and leaves of the plant are so loaded with oxalic acid as to be deadly. Even the common white potatoes that many of us eat may contain solanine in their skins that can make a person sick.

Some plant foods – kava, khat, and coca, for example – are frequently illegal to possess; and still other potential foods, such as the numerous fungi and myriad other wild plants, require specialized knowledge to sort out the edible from the fatal.

Finally, the chapters on vitamins and minerals discuss the importance of these nutrients to human health both historically and today. In Part VIII "ballpark" nutrient values are provided for many of the foods listed there. But our authors on the nutrients warn against too much of a good thing, just as our ancient ancestors would have done. Caution and moderation in matters of food were vital to their survival and, by extension, to our presence.

Introduction

We began work on the Cambridge History and Culture of Food and Nutrition Project even as we were still reading the page proofs for *The Cambridge World History of Human Disease,* published in 1993. At some point in that effort we had begun to conceive of continuing our history of human health by moving into food and nutrition – an area that did more than simply focus on the breakdown of that health. For the history of disease we had something of a model provided by August Hirsch in his three-volume *Handbook of Geographical and Historical Pathology* (London, 1883–6). Yet there was no "Handbook of Geographical and Historical Food and Nutrition" to light the way for the present volumes, and thus they would be unique.

Fortunately, there was no lack of expertise available; it came from some 200 authors and board members, representing a score of disciplines ranging from agronomy to zoology. This undertaking, then, like its predecessor, represents a collective interdisciplinary and international effort, aimed in this case at encapsulating what is known of the history of food and nutrition throughout humankind's stay on the planet. We hope that, together, these volumes on nutrition and the earlier one on disease will provide scholars of the future – as well as those of the present – a glimpse of what is known (and not known) about human health as the twentieth century comes to a close.

Two of our major themes are embedded in the title. *Food,* of course, is central to history; without it, there would be no life and thus no history, and we devote considerable space to providing a history of the most important foodstuffs across the globe. To some extent, these treatments are quantitative, whereas by contrast, *Nutrition* – the body's need for foods and the uses it makes of them – has had much to do with shaping the quality of human life. Accordingly, we have placed a considerable array of nutritional topics in longitudinal contexts to illustrate their importance to our past and present and to suggest something of our nutritional future.

The word "Culture," although not in the book title, was a part of the working title of the project, and certainly the concept of culture permeates the entire work, from the prehistoric culture of our hunting-and-gathering ancestors, through the many different food cultures of the historical era, to modern "food policies," the prescription and implementation of which are frequently generated by cultural norms. Finally, there is "health," which appears in none of our titles but is – either explicitly or implicitly – the subject of every chapter that follows and the raison d'être for the entire work.

An Overview

Functionally, it seems appropriate to begin this overview of the work with an explanation of the last part first, because we hope that the entries in Part VIII, which identify and sketch out brief histories of vegetable foods mentioned in the text, will constitute an important tool for readers, especially for those interested in the chapters on geographic regions. Moreover, because fruits have seldom been more than seasonal items in the diet, all of these save for a few rare staples are treated in Part VIII. Most readers will need little explanation of foods such as potatoes (also treated in a full chapter) or asparagus but may want to learn more about lesser-known or strictly regional foods such as ackee or zamia (mentioned in the chapters that deal with the Caribbean area). On the one hand, Part VIII has spared our authors the annoyance of writing textual digressions or footnotes to explain such unfamiliar foods, and on the other, it has provided us with a splendid opportunity to provide more extensive information on the origins and uses of the foods listed. In addition, Part VIII has become the place in the work where synonyms are dealt with, and readers can discover (if they do not already know) that an aubergine is an eggplant, that "swedes" are rutabagas, and that "Bulgar" comes from *bulghur,* which means "bruised grain."

We now move from the end to the beginning of the work, where the chapters of Part I collectively constitute a bioanthropological investigation into the kinds and quantities of foods consumed by early humans, as well as by present-day hunter-gatherers. Humans (in one form or another) have been around for millions of years, but they only invented agriculture and domesticated animals in the past 10,000 years or so, which represents just a tiny fraction of 1 percent of the time humankind has been present on earth. Thus, modern humans must to some extent be a product of what our ancient ancestors ate during their evolutionary journey from scavengers to skilled hunters and from food gatherers to food growers.

The methods for discovering the diet (the foods consumed) and the nutritional status (how the body employed those foods) of our hunting-and-gathering forebears are varied. Archaeological sites have yielded the remains of plants and animals, as well as human coprolites (dried feces), that shed light on the issue of diet, whereas analysis of human remains – bones, teeth, and (on occasion) soft tissue – has helped to illuminate questions of nutrition. In addition, the study of both diet and nutrition among present-day hunter-gatherers has aided in the interpretation of data generated by such archaeological discoveries. The sum of the findings to date seems to suggest that at least in matters of diet and nutrition, our Paleolithic ancestors did quite well for themselves and considerably better than the sedentary folk who followed. In fact, some experts contend that the hunter-gatherers did better than any of their descendants until the late nineteenth and early twentieth centuries.

Part II shifts the focus from foraging to farming and the domestication of plants and animals. The transition from a diet of hunted and collected foods to one based on food production was gradual, yet because its beginnings coincided with the time that many large game animals were disappearing, there is suspicion that necessity, born of an increasing food scarcity, may have been the mother of agricultural invention. But however the development of sedentary agriculture came about, much of the blame for the nutritional deterioration that appears to have accompanied it falls on the production of the so-called superfoods – rice, maize, manioc, and wheat – staples that have sustained great numbers of people but only at a considerable cost in human health, in no small part because diets that centered too closely on such foods could not provide the range of vitamins, minerals, and whole protein so vital to human health.

Part II is divided into sections, or groups of chapters, most of which consider the history of our most important plant foods under a number of rubrics ranging from "Grains," "Roots, Tubers, and Other Starchy Staples," through "Important Vegetable Supplements," to plants that are used to produce oils and those employed for flavorings. All of the chapters dealing with plants treat questions of where, how, and by whom they were first domesticated, along with their subsequent diffusion around the globe and their present geographic distribution. With domestication, of course, came the dependence of plants on humans along with the reverse, and this phenomenon of "mutualism" is explored in some detail, as are present-day breeding problems and techniques.

The historical importance of the migration of plant foods, although yet to be fully weighed for demographic impact, was vital – although frequently disruptive – for humankind. Wheat, a wild grass that flourished in the wake of retreating glaciers some 12,000 years ago, was (apparently) deliberately planted for the first time in the Middle East about 2,000 years later. By the first century B.C., Rome required some 14 million bushels per year just to feed the people of that city, leading to a program of expansion that turned much of the cultivable land of North Africa into wheatfields for the Romans. Surely, then, Italians had their pastas long before Marco Polo (1254?–1324?), who has been credited with bringing notions of noodles back with him from China. But it was only the arrival of the vitamin C–loaded American tomato that allowed the Italians to concoct the great culinary union of pasta and tomato sauce – one that rendered pasta not only more satisfactory but also more healthy. And, speaking of China, the New World's tomato and its maize, potatoes, sweet potatoes, and peanuts were also finding their respective ways to that ancient land, where in the aftermath of their introduction, truly phenomenal population increases took place.

Migrating American plants, in other words, did much more than just dress up Old World dishes, as tomatoes did pasta. Maize, manioc, sweet potatoes, a new kind of yam, peanuts, and chilli peppers reached the western shores of Africa with the ships of slave traders, who introduced them into that continent to provide food for their human cargoes. Their success exceeded the wildest of expectations, because the new foods not only fed slaves bound for the Americas but helped create future generations of slaves. The American crops triggered an agricultural revolution in Africa, which in greatly expanding both the quantity and quality of its food supply, also produced swelling populations that were drained off to the Americas in order to grow (among other things) sugar and coffee – both migrating plants from the Old World.

In Europe, white potatoes and maize caught on more slowly, but the effect was remarkably similar. Old

World wheat gave back only 5 grains for every 1 planted, whereas maize returned 25 to 100 (a single ear of modern maize yields about 1,000 grains) and, by the middle of the seventeenth century, had become a staple of the peasants of northern Spain, Italy, and to a lesser extent, southern France. From there maize moved into much of the rest of Europe, and by the end of the eighteenth century, such cornmeal mushes (*polenta* in Italy) had spread via the Ottoman Empire into the Balkans and southern Russia.

Meanwhile, over the centuries, the growth of cities and the development of long-distance trade – especially the spice trade – had accelerated the process of exploring the world and globalizing its foods. So, too, had the quest for oils (to be used in cooking, food preservation, and medicines), which had been advanced as coconuts washed up on tropical shores, olive trees spread across the Mediterranean from the Levant to the rim of the Atlantic in Iberia, and sesame became an integral part of the burgeoning civilizations of North Africa and much of Asia.

In the seventeenth century, invasion, famine, and evictions forced Irish peasants to adopt the potato as a means of getting the most nourishment from the least amount of cultivated land, and during the eighteenth century, it was introduced in Germany and France because of the frequent failures of other crops. From there, the plant spread toward the Ural Mountains, where rye had long been the only staple that would ripen during the short, often rainy summers. Potatoes not only did well under such conditions, they provided some four times as many calories per acre as rye and, by the first decades of the nineteenth century, were a crucial dietary element in the survival of large numbers of northern Europeans, just as maize had become indispensable to humans in some of the more southerly regions.

Maize nourished humans indirectly as well. Indeed, with maize available to help feed livestock, it became increasingly possible to carry more animals through the winters and to derive a steady supply of whole protein in the forms of milk, cheese, and eggs, in addition to year-round meat – now available for the many rather than the few. Thus, it has been argued that it is scarcely coincidence that beginning in the eighteenth century, European populations began to grow and, by the nineteenth century, had swollen to the point where, like the unwilling African slaves before them, Europeans began migrating by the millions to the lands whose plants had created the surplus that they themselves represented.

The last section of Part II treats foods from animal sources ranging from game, bison, and fish to the domesticated animals. Its relatively fewer chapters make clear the dependence of all animals, including humans, on the plant world. In fact, to some unmeasurable extent, the plant foods of the world made still another important contribution to the human diet by assisting in the domestication of those animals that – like the dog that preceded them – let themselves be tamed.

The dog seems to have been the first domesticated animal and the only one during the Paleolithic age. The wolf, its progenitor, was a meat eater and a hunter (like humans), and somewhere along the way, humans and dogs seem to have joined forces, even though dogs were sometimes dinner and probably vice versa. But it was during the early days of the Neolithic, as the glaciers receded and the climate softened, that herbivorous animals began to multiply, and in the case of sheep and goats, their growing numbers found easy meals in the grains that humans were raising (or at least had staked out for their own use). Doubtless, it did not take the new farmers long to cease trying to chase the animals away and to begin capturing them instead – at first to use as a source of meat to go with the grain and then, perhaps a bit later, to experiment with the fleece of sheep and the waterproof hair of goats.

There was, however, another motive for capturing animals, which was for use in religious ceremonies involving animal sacrifice. Indeed, it has been argued that wild water buffalo, cattle, camels, and even goats and sheep were initially captured for sacrifice rather than for food.

Either way, a move from capturing animals to domestication and animal husbandry was the next step in the case of those animals that could be domesticated. In southeastern Europe and the Near East (the sites of so much of this early activity), wild goats and sheep may have been the first to experience a radical change of lifestyle – their talent for clearing land of anything edible having been discovered and put to good use by their new masters. Soon, sheep were being herded, with the herdsmen and their flocks spreading out far and wide to introduce still more humans to the mysteries and rewards of domestication.

Wild swine, by contrast, were not ruminant animals and thus were not so readily attracted to the plants in the fields, meaning that as they did not come to humans, humans had to go to them. Wild boars had long been hunted for sacrifice as well as for meat and would certainly have impressed their hunters with their formidable and ferocious nature. Tricky, indeed, must have been the process that brought the domesticated pig to the barnyard by about 7000 to 6000 B.C.

Wild cattle were doubtless drawn to farmers' fields, but in light of what we know about the now-extinct aurochs (the wild ancestor of our modern cattle), the domestication of bovines around 6000 B.C. may have required even more heroic efforts than that of swine. Yet those efforts were certainly worth it, for in addition to the meat and milk and hides cattle provided, the ox was put to work along with sheep and goats as still another hand in the agricultural process – stomping seeds into the soil, threshing grain, and pulling carts, wagons, and (later on) the plow.

The last of today's most important animals to be domesticated was the chicken, first used for sacrifice and then for fighting before it and its eggs became food. The domesticated variety of this jungle bird was present in North China around 3000 B.C.; however, because the modern chicken is descended from both Southeast Asian and Indian wildfowl, the question of the original site of domestication has yet to be resolved. The wildfowl were attracted to human-grown grain and captured, as was the pigeon (which, until recently, played a far more important role in the human diet than the chicken). Ducks, geese, and other fowl were also most likely captivated by – and captured because of – the burgeoning plant-food products of the Neolithic. In other parts of the world, aquatic animals, along with the camel, the yak, and the llama and alpaca, were pressed into service by *Homo sapiens,* the "wise man" who had not only scrambled to the top of the food chain but was determinedly extending it.

The chapters of Part III focus on the most important beverages humans have consumed as accompaniment to those foods that have preoccupied us to this point. One of these, water, is crucial to life itself; another, human breast milk, has – until recently, at least – been vital for the survival of newborns, and thus vital for the continuation of the species. Yet both have also been sources of infection for humans, sometimes fatally so.

Hunter-gatherers, in general, did not stay in one place long enough to foul springs, ponds, rivers, and lakes. But sedentary agriculturalists did, and their own excreta was joined by that of their animals. Wherever settlements arose (in some cases as kernels of cities to come), the danger of waterborne disease multiplied, and water – essential to life – also became life-threatening. One solution that was sensible as well as pleasurable lay in the invention of beverages whose water content was sterilized by the process of fermentation. Indeed, the earliest written records of humankind mention ales made from barley, millet, rice, and other grains, along with toddies concocted from date palms and figs – all of which makes it apparent that the production of alcohol was a serious business from the very beginning of the Old World Neolithic.

It was around 3000 B.C. that grape wine made its appearance, and where there was honey there was also mead. The discovery of spirit distillation to make whiskeys and brandies began some seven to eight hundred years ago, and true beer, the "hopped" successor of ales, was being brewed toward the end of the Middle Ages (about 600 years ago). Clearly, humans long ago were investing much ingenuity in what can only be described as a magnificent effort to avoid waterborne illness.

Milk, one of the bonuses of animal domestication, was also fermented, although not always with desired outcomes. Yet over time, the production of yoghurts, cheeses, and butter became routine, and these foods – with their reduced lactose – were acceptable even among the lactose-intolerant, who constituted most of the world's population. Where available, milk (especially bovine milk) was a food for the young after weaning, and during the past few centuries, it has also served as a substitute for human milk for infants, although sometimes with disastrous results. One problem was (and is) that the concentrated nutrient content of bovine milk, as well as human antibodies developed against cow's-milk protein, make it less than the perfect food, especially for infants. But another was that bovine tuberculosis (scrofula), along with ordinary tuberculosis, raged throughout Europe from the sixteenth to the nineteenth centuries. Wet nurses were another solution for infant feeding, but this practice could be fraught with danger, and artificial feeding, especially in an age with no notions of sterile procedure, caused infants to die in staggering numbers before the days of Joseph Lister and Louis Pasteur.

Boiling water was another method of avoiding the pathogens it contained, and one that, like fermentation, could also produce pleasant beverages in the process. The Chinese, who had used tea since the Han period, embraced that beverage enthusiastically during the Tang dynasty (618–907) and have been avid tea drinkers ever since. The nomads of central Asia also adopted the drink and later introduced it into Russia. Tea use spread to Japan about the sixth century, but it became popular there only about 700 years ago. From Japan, the concoction was introduced into Indonesia, where much later (around 1610) the Dutch discovered it and carried it to Europe. A few decades later, the English were playing a major role in popularizing the beverage, not to mention merchandising it.

Coffee, although it found its way into Europe at about the same time as tea, has a more recent history, which, coffee-lore would have it, began in Ethiopia in the ninth century. By 1500, coffee drinking was widespread throughout the Arab world (where alcohol was forbidden), and with the passing of another couple of centuries, the beverage was enjoying a considerable popularity in Europe. Legend has it that Europeans began to embrace coffee after the Ottoman Turks left some bags of coffee beans behind as they gave up the siege of Vienna in 1683.

These Asian and African contributions to the world's beverages were joined by cacao from America. Because the Spaniards and the Portuguese were the proprietors of the lands where cacao was grown, they became the first Europeans to enjoy drinking chocolate (which had long been popular among pre-Columbian Mesoamericans). In the early decades of the sixteenth century, the beverage spread through Spain's empire to Italy and the Netherlands and, around midcentury, reached England and France.

Thus, after millennia of consuming alcoholic beverages to dodge fouled water, people now had (after a century or so of "catching on") an opportunity for relative sobriety thanks to these three new drinks, which all arrived in Europe at about the same time. But an important ingredient in their acceptance was the sugar that sweetened them. And no wonder that as these beverages gained in popularity, the slave trade quickened, plantation societies in the Americas flourished, and France in 1763 ceded all of Canada to Britain in order to regain its sugar-rich islands of Martinique and Guadeloupe.

Sugar cultivation and processing, however, added still another alcoholic beverage – rum – to a growing list, and later in the nineteenth century, sugar became the foundation of a burgeoning soft-drink industry. Caffeine was a frequent ingredient in these concoctions, presumably because, in part at least, people had become accustomed to the stimulation that coffee and tea provided. The first manufacturers of Coca-Cola in the United States went even further in the pursuit of stimulation by adding coca – from the cocaine-containing leaves that are chewed in the Andean region of South America. The coca was soon removed from the soft drink and now remains only in the name Coca-Cola, but "cola" continued as an ingredient. In the same way that coca is chewed in South America, in West Africa the wrapping around the kola nut is chewed for its stimulative effect, in this case caused by caffeine. But the extract of the kola nut not only bristles with caffeine, it also packs a heart stimulant, and the combination has proven to be an invigorating ingredient in the carbonated beverage industry.

In East Africa, the leaves of an evergreen shrub called khat are chewed for their stimulating effect and are made into a tealike beverage as well. And finally, there is kava, widely used in the Pacific region and among the most controversial, as well as the most exotic, of the world's lesser-known drinks – controversial because of alleged narcotic properties and exotic because of its ceremonial use and cultural importance.

In addition to the beverages that humans have invented and imbibed throughout the ages as alternatives to water, many have also clung to their "waters." Early on, special waters may have come from a spring or some other body of water, perhaps with supposed magical powers, or a good flavor, or simply known to be safe. In more recent centuries, the affluent have journeyed to mineral springs to "take the waters" both inside and outside of their bodies, and mineral water was (and is) also bottled and sold for its allegedly healthy properties. Today, despite (or perhaps because of) the water available to most households in the developed world, people have once more staked out their favorite waters, and for some, bottled waters have replaced those alcoholic beverages that were previously employed to avoid water.

Part IV focuses on the history of the discovery and importance of the chief nutrients, the nutritional deficiency diseases that occur when those nutrients are not forthcoming in adequate amounts, the relationship between modern diets and major chronic diseases, and food-related disorders. Paradoxically, many such illnesses (the nutritional deficiency diseases in particular), although always a potential hazard, may have become prevalent among humans only as a result of the development of sedentary agriculture.

Because such an apparently wide variety of domesticated plant and animal foods emerged from the various Neolithic revolutions, the phenomenon of sedentary agriculture was, at least until recently, commonly regarded as perhaps humankind's most important step up the ladder of progress. But the findings of bioanthropologists (discussed in Part I) suggest rather that our inclination to think of history teleologically had much to do with such a view and that progress imposes its own penalties (indeed, merely to glance at a newspaper is to appreciate why many have begun to feel that technological advances should carry health-hazard warnings).

As we have already noted, with agriculture and sedentism came diets too closely centered on a single crop, such as wheat in the Old World and maize in the New, and although sedentism (unlike hunting and gathering) encouraged population growth, such growth seems to have been that of a "forced" population with a considerably diminished nutritional status.

And more progress seems inevitably to have created more nutritional difficulties. The navigational and shipbuilding skills that made it possible for the Iberians to seek empires across oceans also created the conditions that kept sailors on a diet almost perfectly devoid of vitamin C, and scurvy began its reign as the scourge of seamen. As maize took root in Europe and Africa as well as in the U.S. South, its new consumers failed to treat it with lime before eating – as the Native Americans, presumably through long experience, had learned to do. The result of maize in inexperienced hands, especially when there was little in the diet to supplement it, was niacin deficiency and the four Ds of pellagra: dermatitis, diarrhea, dementia, and death. With the advent of mechanical rice mills in the latter nineteenth century came widespread thiamine deficiency and beriberi among peoples of rice-eating cultures, because those mills scraped away the thiamine-rich hulls of rice grains with energetic efficiency.

The discovery of vitamins during the first few decades of the twentieth century led to the food "fortification" that put an end to the classic deficiency diseases, at least in the developed world, where they were already in decline. But other health threats quickly took their place. Beginning in the 1950s, surging rates of cancer and heart-related diseases focused suspicion on the environment, not to mention food additives such as monosodium glutamate (MSG), cyclamates, nitrates and nitrites, and saccharin. Also coming under suspicion were plants "engineered" to make them more pest-resistant – which might make them more carcinogenic as well – along with the pesticides and herbicides, regularly applied to farm fields, that can find their way into the human body via plants as well as drinking water.

Domesticated animals, it has turned out, are loaded with antibiotics and potentially artery-clogging fat, along with hormones and steroids that stimulate the growth of that fat. Eggs have been found to be packed with cholesterol, which has become a terrifying word, and the fats in whole milk and most cheeses are now subjects of considerable concern for those seeking a "heart-healthy" diet. Salt has been implicated in the etiology of hypertension, sugar in that of heart disease, saturated fats in both cancer and heart disease, and a lack of calcium in osteoporosis. No wonder that despite their increasing longevity, many people in the developed world have become abruptly and acutely anxious about what they do and do not put in their mouths.

Ironically, however, the majority of the world's people would probably be willing to live with some of these perils if they could share in such bounty. Obesity, anorexia, and chronic disease might be considered tolerable (and preferable) risks in the face of infection stalking their infants (as mothers often must mix formulas with foul water); protein-energy malnutrition attacking the newly weaned; iodine deficiency (along with other mineral and vitamin deficiencies) affecting hundreds of millions of children and adults wherever foods are not fortified; and undernutrition and starvation. All are, too frequently, commonplace phenomena.

Nor are developing-world peoples so likely as those in the developed world to survive the nutritional disorders that seem to be legacies of our hunter-gatherer past. Diabetes (which may be the result of a "thrifty" gene for carbohydrate metabolism) is one of these diseases, and hypertension may be another; still others are doubtless concealed among a group of food allergies, sensitivities, and intolerances that have only recently begun to receive the attention they deserve.

On a more pleasant note, the chapters of Part V sketch out the history and culture of food and drink around the world, starting with the beginnings of agriculture in the ancient Near East and North Africa and continuing through those areas of Asia that saw early activity in plant and animal domestication. This discussion is followed by sections on the regions of Europe, the Americas, and sub-Saharan Africa and Oceania.

Section B of Part V takes up the history of food and drink in South Asia and the Middle East, Southeast Asia, and East Asia in five chapters. One of these treats the Middle East and South Asia together because of the powerful culinary influence of Islam in the latter region, although this is not to say that Greek, Persian, Aryan, and central Asian influences had not found their way into South Asia for millennia prior to the Arab arrival.

Nor is it to say that South Asia was without its own venerable food traditions. After all, many of the world's food plants sprang from the Indus Valley, and it was in the vastness of the Asian tropics and subtropics that most of the world's fruits originated, and most of its spices. The area is also home to one of our "superfoods," rice, which ties together the cuisines of much of the southern part of the continent, whereas millet and (later) wheat were the staples of the northern tier. Asia was also the mother of two more plants that had much to do with transforming human history. From Southeast Asia came the sugarcane that would later so traumatize Africa, Europe, and the Americas; from eastern Asia came the evergreen shrub whose leaves are brewed to make tea.

Rice may have been cultivated as many as 7,000 years ago in China, in India, and in Southeast Asia; the wild plant is still found in these areas today. But it was likely from the Yangtze Delta in China that the techniques of rice cultivation radiated outward toward Korea and then, some 2,500 years ago, to Japan. The soybean and tea also diffused from China to these Asian outposts, all of which stamped some similarities on the cuisines of southern China, Japan, and Korea. Northern China, however, also made the contribution of noodles, and all these cuisines were enriched considerably by the arrival of American plants such as sweet potatoes, tomatoes, chillies, and peanuts – initially brought by Portuguese ships between the sixteenth century (China) and the eighteenth century (Japan).

Also characteristic of the diets of East Asians was the lack of dairy products as sources of calcium. Interestingly, the central Asian nomads (who harassed the northern Chinese for millennia and ruled them when they were not harassing them) used milk; they even made a fermented beverage called *kumiss* from the milk of their mares. But milk did not catch on in China and thus was not diffused elsewhere in East Asia. In India, however, other wanderers – the Aryan pastoralists – introduced dairy products close to 4,000 years ago. There, dairy foods did catch on, although mostly in forms that were physically acceptable to those who were lactose-intolerant – a condition widespread among most Asian populations.

Given the greater sizes of Sections C (Europe) and D (the Americas) in Part V, readers may object to what clearly seems to be something of a Western bias in a work that purports to be global in scope. But it is the case that foods and foodways of the West have been more systematically studied than those of other parts of the world, and thus there are considerably more scholars to make their expertise available. In most instances, the authors of the regional essays in both these sections begin with the prehistoric period, take the reader through the Neolithic Revolution in the specific geographic area, and focus on subsequent changes in foodways wrought by climate and cultural contacts, along with the introduction of new foods. At first, the latter involved a flow of fruits and vegetables from the Middle and Near East into Europe, and an early spice trade that brought all sorts of Asian, African, and Near Eastern goods to the western end of the Mediterranean. The expansion of Rome continued the dispersal of these foods and spices throughout Europe.

Needless to say, the plant and animal exchanges between the various countries of the Old World and the lands of the New World following 1492 are dealt with in considerable detail because those exchanges so profoundly affected the food (and demographic) history of all the areas concerned. Of course, maize, manioc, sweet potatoes and white potatoes, peanuts, tomatoes, chillies, and a variety of beans sustained the American populations that had domesticated and diffused them for a few thousand years in their own Neolithic Revolution before the Europeans arrived. But the American diets were lacking in animal protein. What was available came (depending on location) from game, guinea pigs, seafoods, insects, dogs, and turkeys. That the American Indians did not domesticate more animals – or milk those animals (such as the llama) that they did domesticate – remains something of a mystery. Less of a mystery is the fate of the Native Americans, many of whom died in a holocaust of disease inadvertently unleashed on them by the Europeans. And as the new land became depopulated of humans, it began to fill up again with horses, cattle, sheep, hogs, and other Old World animals.

Certainly, the addition of Old World animal foods to the plants of the New World made for a happy union, and as the authors of the various regional entries approach the present – as they reach the 1960s, in fact – an important theme that emerges in their chapters is the fading of distinctive regional cuisines in the face of considerable food globalization. The cuisine of the developed world, in particular, is becoming homogenized, with even natives of the Pacific, Arctic, and Subarctic regions consuming more in the way of the kinds of prepared foods that are eaten by everybody else in the West, unfortunately to their detriment.

Section E treats the foodways of Africa south of the Sahara, the Pacific Islands, and Australia and New Zealand in three chapters that conclude a global tour of the history and culture of food and drink. Although at first glance it might seem that these last three disparate areas of the planet historically have had nothing in common from a nutritional viewpoint, they do, in fact, share one feature, which has been something of a poverty of food plants and animals.

In Africa, much of this poverty has been the result of rainfall, which depending on location, has generally been too little or too much. Famine results from the former, whereas leached and consequently nitrogen- and calcium-poor soils are products of the latter, with the plants these areas do sustain also deficient in important nutrients. Moreover, 40 inches or more of rainfall favors proliferation of the tsetse fly, and the deadly trypanosomes carried by this insect have made it impossible to keep livestock animals in many parts of the continent. But even where such animals can be raised, the impoverished plants they graze on render them inferior in size, as well as inferior in the quality of their meat and milk, to counterparts elsewhere in the world. As in the Americas, then, animal protein was not prominent in most African diets after the advent of sedentism.

But unlike the Americas, Africa was not blessed with vegetable foods, either. Millets, yams, and a kind of African rice were the staple crops that emerged from the Neolithic to sustain populations, and people became more numerous in the wake of the arrival of better-yielding yams from across the Indian Ocean. But it was only with the appearance of the maize, peanuts, sweet potatoes, American yams, manioc, and chillies brought by the slave traders that African populations began to experience the substantial growth that we still witness today.

Starting some 30,000 to 40,000 years ago, waves of Pacific pioneers spread out from Southeast Asia to occupy the islands of Polynesia, Melanesia, and Micronesia. They lived a kind of fisher–hunter–gatherer existence based on a variety of fish, birds, and reptiles, along with the roots of ferns and other wild vegetable foods. But a late wave of immigrants, who sailed out from Southeast Asia to the Pacific Basin Islands about 6,000 years ago, thoughtfully brought with them some of the products of the Old World Neolithic in the form of pigs, dogs, chickens, and root crops like the yam and taro. And somehow, an American plant – the sweet potato – much later also found its way to many of these islands.

In a very real sense, then, the Neolithic Revolution was imported to the islands. Doubtless it spread slowly, but by the time the ships of Captain James Cook sailed into the Pacific, all islands populated by humans were also home to hogs, dogs, and fowl – and this included even the extraordinarily isolated Hawaiian Islands. Yet, as with the indigenous populations of the Americas, those of the Pacific had little time to enjoy any plant and animal gifts the Europeans brought to them. Instead, they began to die from imported diseases, which greatly thinned their numbers.

The story of Australia and New Zealand differs substantially from that of Africa and the Pacific Islands in that both the Australian Aborigines and (to a lesser extent) the New Zealand Maori were still hunter-gatherers when the Europeans first reached them. They had no pigs or fowl nor planted yams or taro, although they did have a medium-sized domesticated dog and sweet potatoes.

In New Zealand, there were no land mammals prior to human occupation, but there were giant flightless birds and numerous reptiles. The Maori arrived after pigs and taro had reached Polynesia, but at some point (either along the way to New Zealand or after their arrival) they lost their pigs, and the soil and climate of New Zealand did not lend themselves to growing much in the way of taro. Like their Australian counterparts, they had retained their dogs, which they used on occasion for food, and the sweet potato was their most important crop.

Thus, despite their dogs and some farming efforts, the Aborigines and the Maori depended heavily on hunting-and-gathering activities until the Europeans arrived to introduce new plant and animal species.

Unfortunately, as in the Americas and elsewhere in the Pacific, they also introduced new pathogens and, consequently, demographic disaster.

Following this global excursion, Part V closes with a discussion of the growing field of culinary history, which is now especially vigorous in the United States and Europe but promises in the near future to be a feast that scholars the world over will partake of and participate in.

Part VI is devoted to food- and nutrition-related subjects that are of both contemporary and historical interest. Among these are some examples of the startling ability of humans to adapt to unique nutritional environments, including the singular regimen of the Inuit, whose fat-laden traditional diet would seem to have been so perfectly calculated to plug up arteries that one might wonder why these people are still around to study. Other chapters take up questions regarding the nutritional needs (and entitlements) of special age, economic, and ethnic groups. They show how these needs frequently go unmet because of cultural and economic circumstances and point out some of the costs of maternal and child undernutrition that are now undergoing close scrutiny, such as mental decrement. In this vein, food prejudices and taboos are also discussed; many such attitudes can bring about serious nutritional problems for women and children, even though childbearing is fundamentally a nutritional task and growing from infancy to adulthood a nutritional feat.

A discussion of the political, economic, and biological causes and ramifications of famine leads naturally to another very large question treated in the first two chapters of Part VI. The importance of nutrition in humankind's demographic history has been a matter of some considerable debate since Thomas McKeown published *The Modern Rise of Population* in 1976. In that work, McKeown attempted to explain how it happened that sometime in the eighteenth century if not before, the English (and by extension the Europeans) managed to begin extricating themselves from seemingly endless cycles of population growth followed by plunges into demographic stagnation. He eliminated possibilities such as advances in medicine and sanitation, along with epidemiological factors such as disease abatement or mutation, and settled on improved nutrition as the single most important cause. Needless to say, many have bristled at such a high-handed dismissal of these other possibilities, and our chapters continue the debate with somewhat opposing views.

Not entirely unrelated is a discussion of height and nutrition, with the former serving as proxy for the latter. Clearly, whether or not improving nutrition was the root cause of population growth, it most certainly seems to have played an important role in human growth and, not incidentally, in helping at least those living in the West to once again approach the stature of their Paleolithic ancestors. Moreover, it is the case that no matter what position one holds with respect to the demographic impact of nutrition, there is agreement that nutrition and disease cannot be neatly separated, and indeed, our chapter on synergy describes how the two interact.

Cultural and psychological aspects of food are the focus of a group of chapters that examines why people eat some foods but not others and how such food choices have considerable social and cultural resonance. Food choices of the moment frequently enter the arena of food fads, and one of our chapters explores the myriad reasons why foods can suddenly become trends, but generally trends with little staying power.

The controversial nature of vegetarianism – a nutritional issue always able to trigger a crossfire of debate – is acknowledged in our pages by two chapters with differing views on the subject. For some, the practice falls under the rubric of food as medicine. Then there are those convinced of the aphrodisiacal benefits of vegetarianism – that the avoidance of animal foods positively influences their sexual drive and performance. For many, vegetarianism stems from religious conviction; others simply feel it is wrong to consume the flesh of living creatures, whereas still others think it downright dangerous. Clearly, the phrase "we are what we eat" must be taken in a number of different ways.

The closing chapters of Part VI address the various ways that humans and the societies they construct have embraced particular foods or groups of foods in an effort to manipulate their own health and well-being as well as that of others. Certain foods, for example, have been regarded by individuals as aphrodisiacs and anaphrodisiacs and consumed in frequently heroic efforts to regulate sexual desires. Or again, some – mostly plant – foods have been employed for medicinal reasons, with many, such as garlic, viewed as medical panaceas.

Part VII scrutinizes mostly contemporary food-related policy questions that promise to be with us for some time to come, although it begins with a chapter on nutrition and the state showing how European governments came to regard well-nourished populations as important to national security and military might. Other discussions that follow treat the myriad methodological (not to mention biological) problems associated with determining the individual's optimal daily need for each of the chief nutrients; food labeling, which when done fairly and honestly can aid the individual in selecting the appropriate mix of these nutrients; and the dubious ability of nonfoods to supplement the diet.

As one might expect, food safety, food biotechnology, and the politics of such issues are of considerable concern, and – it almost goes without saying – politics and safety have the potential at any given time for being at odds with one another. The juxtaposition is hardly a new one, with monopoly and competitive capital on the one hand and the public interest on the other. The two may or may not be in opposition, but the stakes are enormous, as will readily be seen.

First there is the problem of safety, created by a loss of genetic diversity. Because all crops evolved from wild species, this means that in Darwinian terms, that the latter possessed sufficient adaptability to survive over considerable periods of time. But with domestication and breeding has come genetic erosion and a loss of this adaptability – even the loss of wild progenitors – so that if today many crops were suddenly not planted, they would simply disappear. And although this possibility is not so alarming – after all, everyone is not going to cease planting wheat, or rice, or maize – the genetic sameness of the wheat or the maize or the rice that is planted (the result of a loss of genetic material) has been of some considerable concern because of the essentially incalculable risk that some newly mutated plant plague might arise to inflict serious damage on a sizable fraction of the world's food supply.

There is another problem connected with the loss of genetic material. It is less potentially calamitous but is one that observers nevertheless find disturbing, especially in the long term. The problem is that many crops have been rendered less able to fend off their traditional parasites (in part because of breeding that reduces a plant's ability to produce the naturally occurring toxicants that defend against predators) and thus have become increasingly dependent on pesticides that can and do find their way into our food and water supplies.

Genetic engineering, however, promises to at least reduce the problem of chemical pollution by revitalizing the ability of crops to defend themselves – as, for example, in the crossing of potatoes with carnivorous plants so that insects landing on them will die immediately. But the encouragement of such defense mechanisms in plants has prompted the worry that because humans are, after all, parasites as far as the plant is concerned, resistance genes might transform crops into less healthy or even unhealthy food, perhaps (as mentioned before) even carcinogenic at some unacceptable level. And, of course, genetic engineering has also raised the specter of scientists accidentally (or deliberately) engineering and then unleashing self-propagating microorganisms into the biosphere, with disastrous epidemiological and ecological effect.

Clearly, biotechnology, plant breeding, plant molecular and cellular biology, and the pesticide industry all have their perils as well as their promise, and some of these dangers are spelled out in a chapter on toxins in foods. But in addition, as a chapter on substitute foods shows, although these substitutes may have been developed to help us escape the tyranny of sugars and fats, they are not without their own risks. Nor, for that matter, are some food additives. Although most seem safe, preservatives such as nitrates and nitrites, flavor enhancers like MSG, and coloring agents such as tartrazine are worrisome to many.

As our authors make clear, however, we may have more to fear from the naturally occurring toxins that the so-called natural foods employ to defend themselves against predators than from the benefits of science and technology. Celery, for example, produces psoralins (which are mutagenic carcinogens); spinach contains oxalic acid that builds kidney stones and interferes with the body's absorption of calcium; lima beans have cyanide; and the solanine in the skins of greenish-appearing potatoes is a poisonous alkaloid.

From biological and chemical questions, we move to other problems of a political and economic nature concerning what foods are produced, what quantities are produced, what the quality is of these foods, and what their allocation is. In the United States (and practically everywhere else) many of the answers to such questions are shaped and mediated by lobbying groups, whose interests are special and not necessarily those of the public. Yet if Americans sometimes have difficulty in getting the truth about the foods they eat, at least they get the foods. There is some general if uneasy agreement in America and most of the developed world that everyone is entitled to food as a basic right and that government programs – subsidies, food stamps, and the like – ought to ensure that right. But such is not the situation in much of the developing world, where food too frequently bypasses the poor and the powerless. And as the author of the chapter on food subsidies and interventions makes evident, too often women and children are among the poor and the powerless.

To end on a lighter note, the last chapter in Part VII takes us full circle by examining the current and fascinating issue of the importance of Paleolithic nutrition to humans entering the twenty-first century.

We close this introduction on a mixed note of optimism and pessimism. The incorporation of dwarfing genes into modern plant varieties was responsible for the sensationally high-yielding wheat and rice varieties that took hold in developing countries in the 1960s, giving rise to what we call the "Green Revolution," which was supposed to end world hunger and help most of the countries of the world produce food surpluses. But the Green Revolution also supported a tremendous explosion of populations in those countries it revolutionized, bringing them face to face with the Malthusian poles of food supply and population.

Moreover, the new plants were heavily dependent on the petrochemical industry for fertilizers, so that in the 1970s, when oil prices soared, so did the price of fertilizers, with the result that poorer farmers, who previously had at least eked out a living from the land, were now driven from it. Moreover, the new dwarfed and semidwarfed rice and wheat plants carried the same genes, meaning that much of the world's food supply was now at the mercy of new, or newly mutated, plant pathogens. To make matters worse, the plants seemed even less able to defend themselves against existing pathogens. Here, the answer seemed to be a still more lavish use of pesticides (against which bitter assaults were launched by environmentalists) even as more developing-world farmers were being driven out of business by increasing costs, and thousands upon thousands of people were starving to death each year. Indeed, by the 1980s, every country revolutionized by the Green Revolution was once again an importer of those staple foods they had expected to produce in abundance.

Obviously, from both a social and political-economic as well as a biological viewpoint, ecologies had not only failed to mesh, they had seriously unraveled. However, as our earlier chapters on rice and wheat point out, new varieties from plant breeders contain variations in genes that make them less susceptible to widespread disease damage, and genetic engineering efforts are under way to produce other varieties that will be less dependent on fertilizers and pesticides.

Meanwhile, as others of our authors point out, foods such as amaranth, sweet potatoes, manioc, and taro, if given just some of the attention that rice and wheat have received, could help considerably to expand the world's food supply. But here again, we teeter on the edge of matters that are as much cultural, social, economic, and political in nature as they are ecological and biological. And such matters will doubtless affect the acceptance of new crops of nutritional importance.

As we begin a sorely needed second phase of the Green Revolution, observers have expressed the hope that we have learned from the mistakes of the first phase. But of course, we could call the first flowering of the Neolithic Revolution (some 10,000 years ago) the first phase and ponder what has been learned since then, which – in a nutshell – is that every important agricultural breakthrough thus far has, at least temporarily, produced unhappy health consequences for those caught up in it, and overall agricultural advancement has resulted in growing populations and severe stress on the biosphere. As we enter the twenty-first century, we might hope to finally learn from our mistakes.

The Editors

PART I

Determining What Our Ancestors Ate

About 10,000 years ago, humans started changing the way they made a living as they began what would be a lengthy transition from foraging to farming. This transformation, known as the Neolithic Revolution, was actually comprised of many revolutions, taking place in different times and places, that are often viewed collectively as the greatest of all human strides taken in the direction of progress. But such progress did not mean better health. On the contrary, as the following chapters indicate, hunter-gatherers were, on the whole, considerably better nourished and much less troubled with illnesses than their farmer descendants. Because hunter-gatherers were mobile by necessity, living in bands of no more than 100 individuals they were not capable of supporting the kinds of ailments that flourished as crowd diseases later on. Nor, as a rule, did they pause in one spot long enough to foul their water supply or let their wastes accumulate to attract disease vectors – insects, rodents, and the like. In addition, they possessed no domesticated animals (save the dog late in the Paleolithic) who would have added to the pollution process and shared their own pathogens.

In short, hunter-gatherers most likely had few pathogenic boarders to purloin a portion of their nutritional intake and few illnesses to fight, with the latter also sapping that intake. Moreover, although no one questions that hunter-gatherers endured hungry times, their diets in good times featured such a wide variety of nutriments that a healthy mix of nutrients in adequate amounts was ensured.

Sedentism turned this salubrious world upside down. Because their livelihood depended on mobility – on following the food supply – hunter-gatherers produced relatively few children. By contrast, their sedentary successors, who needed hands for the fields and security in old age, reproduced without restraint, and populations began to swell. Squalid villages became even more squalid towns, where people lived cheek to jowl with their growing stock of animals and where diseases began to thrive, along with swarms of insects and rodents that moved in to share in the bounty generated by closely packed humans and their animals.

But even as pathogens were laying an ever-increasing claim to people's nutritional intake, the quality of that intake was sharply declining. The varied diet of hunter-gatherers bore little resemblance to the monotonous diet of their farmer successors, which was most likely to center too closely on a single crop such as wheat, millet, rice, or maize and to feature too little in the way of good-quality protein.

The chapters in Part I focus on this transition, the Neolithic revolutions, which although separated in both time and space, had remarkably similar negative effects on human health.

I.1. ∾ Dietary Reconstruction and Nutritional Assessment of Past Peoples: The Bioanthropological Record

The topics of diet (the foods that are eaten) and nutrition (the way that these foods are used by the body) are central to an understanding of the evolutionary journey of humankind. Virtually every major anatomical change wrought by that journey can be related in one way or another to how foods are acquired and processed by the human body. Indeed, the very fact that our humanlike ancestors had acquired a bipedal manner of walking by some five to eight million years ago is almost certainly related to how they acquired food. Although the role of diet and nutrition in human evolution has generally come under the purview of anthropology, the subject has also been of great interest to scholars in many other disciplines, including the medical and biological sciences, chemistry, economics, history, sociology, psychology, primatology, paleontology, and numerous applied fields (e.g., public health, food technology, government services). Consideration of nutriture, defined as "the state resulting from the balance between supply of nutrition on the one hand and the expenditure of the organism on the other," can be traced back to the writings of Hippocrates and Celsus and represents an important heritage of earlier human cultures in both the Old and New Worlds (McLaren 1976, quoted in Himes 1987: 86).

The purpose of this chapter is threefold: (1) to present a brief overview of the basic characteristics of human nutriture and the history of human diet; (2) to examine specific means for reconstructing diet from analysis of human skeletal remains; and (3) to review how the quality of nutrition has been assessed in past populations using evidence garnered by many researchers from paleopathological and skeletal studies and from observations of living human beings. (See also Wing and Brown 1979; Huss-Ashmore, Goodman, and Armelagos 1982; Goodman, Martin, et al. 1984; Martin, Goodman, and Armelagos 1985; Ortner and Putschar 1985; Larsen 1987; Cohen 1989; Stuart-Macadam 1989. For a review of experimental evidence and its implications for humans, see Stewart 1975.) Important developments regarding nutrition in living humans are presented in a number of monographic series, including *World Review of Nutrition and Dietetics, Annual Review of Nutrition, Nutrition Reviews,* and *Current Topics in Nutrition and Disease.*

Human Nutriture and Dietary History

Although as living organisms we consume foods, we must keep in mind that it is the *nutrients* contained in these foods that are necessary for all of our bodily functions, including support of normal growth and maturation, repair and replacement of body tissues, and the conduct of physical activities (Malina 1987). Estimations indicate that modern humans require some 40 to 50 nutrients for proper health and well-being (Mann 1981). These nutrients are typically divided into six classes – carbohydrates, proteins, fats, vitamins, minerals, and water. Carbohydrates and fats are the primary energy sources available to the body. Fats are a highly concentrated source of energy and are stored in the body to a far greater degree than carbohydrates. Fats are stored in the range between about 15 and 30 percent of body weight (Malina 1987), whereas carbohydrates represent only about 0.4 to 0.5 percent of body weight in childhood and young adulthood (Fomon et al. 1982). Proteins, too, act as energy sources, but they have two primary functions: tissue growth, maintenance, and repair; and physiological roles.

The building blocks of proteins are chains of nitrogen-containing organic compounds called amino acids. Most of the 22 amino acids can be produced by the body at a rate that is necessary for the synthesis of proteins, and for this reason they are called nonessential amino acids. Eight, however, are not produced in sufficient amounts and therefore must be supplied to the body as food (essential amino acids). Moreover, all essential amino acids have to be present simultaneously in correct amounts and consumed in the same meal in order to be absorbed properly. As noted by W. A. Stini (1971: 1021), "a reliance on any one or combination of foods which lacks even one of the essential amino acids will preclude the utilization of the rest, resulting in continued and increased excretion of nitrogen without compensatory intake."

Vitamins, a group of 16 compounds, are required in very small amounts only. Save for vitamin D, none of these substances can be synthesized by the body, and if even one is missing or is poorly absorbed, a deficiency disease will arise. Vitamins are mostly regulatory in their overall function. Minerals are inorganic elements that occur in the human body either in large amounts (e.g., calcium and phosphorus) or in trace amounts (called trace elements: e.g., strontium, zinc, fluorine). They serve two important types of functions, namely structural, as in bone and blood production, and regulatory, such as proper balance of electrolytes and fluids. Water, perhaps the most important of the nutrients, functions as a major structural component of the body in temperature regulation and as a transport medium, including elimination of body wastes. About two-thirds of body weight in humans is water (Malina 1987).

Throughout the course of evolution, humans, by adaptation, have acquired a tremendous range of means for securing foods and maintaining proper nutriture. These adaptations can be ordered into a temporal sequence of three phases in the evolution of the human diet (following Gordon 1987). The first phase involved the shift from a diet comprised primarily of unprocessed plant foods to one that incorporated deliberate food-processing techniques and included significant amounts of meat. These changes likely occurred between the late Miocene epoch and early Pleistocene (or by about 1.5 million years ago). Archaeological and taphonomic evidence indicates that the meat component of diet was likely acquired through a strategy involving scavenging rather than deliberate hunting. Pat Shipman (1986a, 1986b) has examined patterns of cut marks produced by stone tools and tooth marks produced by carnivores in a sample of faunal remains recovered from Olduvai Bed I dating from 2.0 to 1.7 million years ago. In instances where cut marks and tooth marks overlapped on a single bone, her analysis revealed that carnivore tooth marks were *followed* in sequence by hominid-produced cut marks. This pattern of bone modification indicates that hominids scavenged an animal carcass killed by another animal.

The second phase in the history of human diet began in the Middle Pleistocene epoch, perhaps as long ago as 700,000 years before the present. This phase is characterized by deliberate hunting of animal food sources. In East Africa, at the site of Olorgesailie (700,000 to 400,000 years ago), an extinct species of giant gelada baboon (*Theropithecus oswaldi*) was hunted. Analysis of the remains of these animals by Shipman and co-workers (1981) indicates that although the deaths of many were not due to human activity, young individuals were selectively killed and butchered by hominids for consumption.

Some of the most frequently cited evidence for early hominid food acquisition is from the Torralba and Ambrona sites, located in the province of Soria, Spain (Howell 1966; Freeman 1981). Based on an abundance of remains of large mammals such as elephants, along with stone artifacts, fire, and other evidence of human activity, F. Clark Howell and Leslie G. Freeman concluded that the bone accumulations resulted from "deliberate game drives and the killing of large herbivores by Acheulian hunting peoples" (1982: 13). Richard G. Klein (1987, 1989), however, subsequently argued on the basis of his more detailed observations of animal remains from these sites that despite a human presence as evidenced by stone tools, it is not possible to distinguish between human or carnivore activity in explaining the extensive bone accumulations. First, the relatively greater frequency of axial skeletal elements (e.g., crania, pelves, vertebrae) could be the result of the removal of meatier portions of animal carcasses by either humans or the large carnivores who frequented the site. Second, the overabundance of older elephants could represent human hunting, but it also could represent carnivore activity or natural mortality. Thus, although hominids in Spain were quite likely acquiring protein from animal sources, the evidence based on these Paleolithic sites is equivocal. We know that early hominids acquired meat through hunting activity, but their degree of success in this regard is still unclear.

By later Pleistocene times (20,000 to 11,000 years ago), evidence for specialized hunting strategies clearly indicates that human populations had developed means by which larger species of animals were successfully hunted. For example, at the Upper Paleolithic site of Solutré, France, Howell (1970) noted that some 100,000 individuals of horse were found at the base of the cliff, and at Predmosti, Czechoslovakia, about 1,000 individuals of mammoth were found. Presumably, the deaths of these animals resulted from purposeful game drives undertaken by local communities of hominids. Virtually all faunal assemblages studied by archaeologists show that large, gregarious herbivores, such as the woolly mammoth, reindeer, bison, and horse, were emphasized, particularly in the middle latitudes of Eurasia (Klein 1989). But some of the best evidence for advances in resource exploitation by humans is from the southern tip of Africa. In this region, Late Stone Age peoples fished extensively, and they hunted dangerous animals like wild pigs and buffalo with considerable success (Klein 1989).

Because of the relatively poor preservation of plant remains as compared to animal remains in Pleistocene sites, our knowledge of the role of plant foods in human Paleolithic nutriture is virtually nonexistent. There is, however, limited evidence from a number of localities. For example, at the *Homo erectus* site of Zhoukoudian in the People's Republic of China (430,000 to 230,000 years before the present), hackberry seeds may have been roasted and consumed. Similarly, in Late Stone Age sites in South Africa, abundant evidence exists for the gathering of plant staples by early modern *Homo sapiens.* Based on what is known about meat and plant consumption by living hunter-gatherers, it is likely that plant foods contributed substantially to the diets of earlier, premodern hominids (Gordon 1987). Today, with the exception of Eskimos, all-meat diets are extremely rare in human populations (Speth 1990), and this almost certainly was the case in antiquity.

The third and final phase in the history of human diet began at the interface between the Pleistocene and Holocene epochs about 10,000 years ago. This period of time is marked by the beginning of essentially modern patterns of climate, vegetation, and fauna. The disappearance of megafauna, such as the mastodon and the mammoth, in many parts of the world at about this time may have been an impetus for human populations to develop new means of food acquisition in order to meet protein and fat requirements. The most important change, however, was the shift from diets based exclusively on food collection to those based to varying degrees on food production.

The transition involved the acquisition by human populations of an intimate knowledge of the life cycles of plants and animals so as to control such cycles and thereby ensure the availability of these nutriments for dietary purposes. By about 7,000 years ago, a transition to a plant-based economy was well established in some areas of the Middle East. From this region, agriculture spread into Europe, and other independent centers of plant domestication appeared in Africa, Asia, and the New World, all within the next several millennia.

It has been both the popular and scientific consensus that the shift from lifeways based exclusively on hunting and gathering to those that incorporated food production – and especially agriculture – represented a positive change for humankind. However, Mark N. Cohen (1989) has remarked that in game-rich environments, regardless of the strategy employed, hunters may obtain between 10,000 and 15,000 kilocalories per hour. Subsistence cultivators, in contrast, average between 3,000 and 5,000 kilocalories per hour.

More important, anthropologists have come to recognize in recent years that the shift from hunting and gathering to agriculture was characterized by a shift from generally high-quality foods to low-quality foods. For example, animal sources of protein contain all essential amino acids in the correct proportions. They are a primary source of vitamin B_{12}, are high in vitamins A and D, and contain important minerals. Moreover, animal fat is a critical source of essential fatty acids and fat-soluble vitamins (Speth 1990). Thus, relative to plant foods, meat is a highly nutritional food resource. Plant foods used alone generally cannot sustain human life, primarily because of deficiency in essential amino acids (see discussion in Ross 1976). Moreover, in circumstances where plant foods are emphasized, a wide variety of them must be consumed in order to fulfill basic nutritional requirements. Further limiting the nutritional value of many plants is their high fiber content, especially cellulose, which is not digestible by humans.

Periodic food shortages resulting from variation in a number of factors – especially rainfall and temperature, along with the relative prevalence of insects and other pests – have been observed in contemporary human populations depending on subsistence agriculture. Some of the effects of such shortages include weight loss in adults, slowing of growth in children, and an increase in prevalence of malaria and other diseases such as gastroenteritis, and parasitic infection (Bogin 1988).

Archaeological evidence from prehistoric agriculturalists, along with observation of living peasant agriculturalists, indicates that their diets tend to be dominated by a single cereal staple: rice in Asia, wheat in temperate Asia and Europe, millet or sorghum in Africa, and maize in the New World. These foods are oftentimes referred to as *superfoods,* not because of nutritional value but rather because of the pervasive focus by human populations on one or another of them (McElroy and Townsend 1979).

Rice, a food staple domesticated in Southeast Asia and eventually extending in use from Japan and Korea southward to Indonesia and eastward into parts of India, has formed the basis of numerous complex cultures and civilizations (Bray 1989). Yet it is remarkably deficient in protein, even in its brown or unmilled form. Moreover, the low availability of protein in rice inhibits the activity of vitamin A, even if the vitamin is available through other food sources (Wolf 1980). Vitamin A deficiency can trigger xerophthalmia, one of the principal causes of blindness. White rice – the form preferred by most human populations – results from processing, or the removal of the outer bran coat, and consequently, the removal of thiamine (vitamin B_1). This deficiency leads to beriberi, a disease alternately involving inflammation of the nerves, or the heart, or both.

Wheat was domesticated in the Middle East very early in the Holocene and has been widely used since that time. Wheat is deficient in two essential amino acids – lysine and isoleucine. Most human populations dependent on wheat, however, have dairy animals that provide products (e.g., cheese) that make up for these missing amino acids. Yet in some areas of the Middle East and North Africa where wheat is grown, zinc-deficient soils have been implicated in retarding growth in children (Harrison et al. 1988). Moreover, the phytic acid present in wheat bran chemically binds with zinc, thus inhibiting its absorption (Mottram 1979).

Maize (known as corn in the United States) was first domesticated in Mesoamerica. Like the other superfoods, it formed the economic basis for the rise of civilizations and complex societies, and its continued domestication greatly increased its productivity (Galinat 1985). In eastern North America, maize was central in the evolution of a diversity of chiefdoms (Smith 1989), and its importance in the Americas was underscored by Walton C. Galinat, who noted:

> [By] the time of Columbus, maize had already become the staff of life in the New World. It was distributed throughout both hemispheres from Argentina and Chile northward to Canada and from sea level to high in the Andes, from swampland to arid conditions and from short to long day lengths. In becoming so widespread, it evolved hundreds of races, each with special adaptations for the environment including special utilities for man. (Galinat 1985: 245)

Like the other superfoods, maize is deficient in a number of important nutrients. Zein – the protein in maize – is deficient in lysine, isoleucine, and tryptophan (FAO 1970), and if maize consumers do not supplement their diets with foods containing these amino acids, such as beans, significant growth retardation is an outcome. Moreover, maize, although not deficient in niacin (vitamin B_3), contains it in a chemically bound form that, untreated, will withhold the vitamin from the consumer. Consequently, human populations consuming untreated maize frequently develop pellagra, a deficiency disease characterized by a number of symptoms, including rough and irritated skin, mental symptoms, and diarrhea (Roe 1973). Solomon H. Katz and co-workers (1974, 1975;

see also Katz 1987) have shown that many Native American groups treat maize with alkali (e.g., lye, lime, or wood ashes) prior to consumption, thereby liberating niacin. Moreover, the amino acid quality in alkali-treated maize is significantly improved. Most human populations who later acquired maize as a dietary staple did not, however, adopt the alkali-treatment method (see Roe 1973). Maize also contains phytate and sucrose, whose negative impact on human health is considered later in this chapter.

Dietary Reconstruction: Human Remains

Chemistry and Isotopy

Skeletal remains from archaeological sites play a very special role in dietary reconstruction because they provide the only *direct* evidence of food consumption practices in past societies. In the last decade, several trace elements and stable isotopes have been measured and analyzed in human remains for the reconstruction of diets. Stanley H. Ambrose (1987) has reviewed these approaches, and the following is drawn from his discussion (see also van der Merwe 1982; Klepinger 1984; Sealy 1986; Aufderheide 1989; Keegan 1989; Schoeninger 1989; Sandford 1993).

Some elements have been identified as potentially useful in dietary reconstruction. These include manganese (Mn), strontium (Sr), and barium (Br), which are concentrated in plant foods, and zinc (Zn) and copper (Cu), which are concentrated in animal foods. Nuts, which are low in vanadium (V), contrast with other plant foods in that they typically contain high amounts of Cu and Zn. Like plants, marine resources (e.g., shellfish) are usually enriched in Sr, and thus the dietary signatures resulting from consumption of plants and marine foods or freshwater shellfish should be similar (Schoeninger and Peebles 1981; Price 1985). In contrast, Br is deficient in bones of marine animals, thereby distinguishing these organisms from terrestrial ones in this chemical signature (Burton and Price 1990).

The greater body of research done on elemental composition has been with Sr. In general, Sr levels decline as one moves up the food chain – from plants to herbivores to primary carnivores – as a result of natural biopurification (a process called fractionation). Simply put, herbivores consume plants that are enriched with Sr contained in soil. Because very little of the Sr that passes through the gut wall in animals is stored in flesh (only about 10 percent), the carnivore consuming the herbivore will have considerably less strontium stored in its skeleton. Humans and other omnivores, therefore, should have Sr concentrations that are intermediate between herbivores and carnivores in their skeletal tissues. Thus, based on the amount of Sr measured in human bones, it is possible (with some qualifications) to determine the relative contributions of plant and meat foods to a diet.

Nonetheless, in addition to the aforementioned problem with shellfish, there are three chief limitations to Sr and other elemental analyses. First, Sr abundance can vary widely from region to region, depending upon the geological context. Therefore, it is critical that the baseline elemental concentrations in local soils – and plants and animals – be known. Second, it must be shown that diagenesis (the process involving alteration of elemental abundance in bone tissue while it is contained in the burial matrix) has not occurred. Some elements appear to resist diagenesis following burial (e.g., Sr, Zn, Pb [lead], Na [sodium]), and other elements show evidence for diagenesis (e.g., Fe [iron], Al [aluminum], K [potassium], Mn, Cu, Ba). Moreover, diagenetic change has been found to vary within even a single bone (e.g., Sillen and Kavanaugh 1982; Bumsted 1985). Margaret J. Schoeninger and co-workers (1989) have evaluated the extent of preservation of histological structures in archaeological bone from the seventeenth-century Georgia coastal Spanish mission Santa Catalina de Guale. This study revealed that bones with the least degree of preservation of structures have the lowest Sr concentrations. Although these low values may result from diet, more likely they result from diagenetic effects following burial in the soil matrix. And finally, pretreatment procedures of archaeological bone samples in the laboratory frequently are ineffective in completely removing the contaminants originating in groundwater, such as calcium carbonate, thus potentially masking important dietary signatures.

Valuable information on specific aspects of dietary composition in past human populations can also be obtained by the analysis of stable isotopes of organic material (collagen) in bone. Isotopes of two elements have proven of value in the analysis of diets: carbon (C) and nitrogen (N). Field and laboratory studies involving controlled feeding experiments have shown that stable isotope ratios of both carbon ($^{13}C/^{12}C$) and nitrogen ($^{15}N/^{14}N$) in an animal's tissues, including bone, reflect similar ratios of diet. Because the variations in isotopic abundances between dietary resources are quite small, the values in tissue samples are expressed in parts per thousand (o/oo) relative to established standards, as per delta (δ) values.

The $\delta^{13}C$ values have been used to identify two major dietary categories. The first category has been used to distinguish consumers of plants with different photosynthetic pathways, including consumers of C4 plants (tropical grasses such as maize) and consumers of C3 plants (most leafy plants). Because these plants differ in their photosynthetic pathways, they also differ in the amount of ^{13}C that they incorporate. Thus, C4 plants and people who consume them have $\delta^{13}C$ values that differ on average by about 14 o/oo from other diets utilizing non-C4 plants. Based on these differences, it has been possible to track the introduction and intensification of maize agriculture in eastern North America with some degree of precision (Figure I.1.1). The second cate-

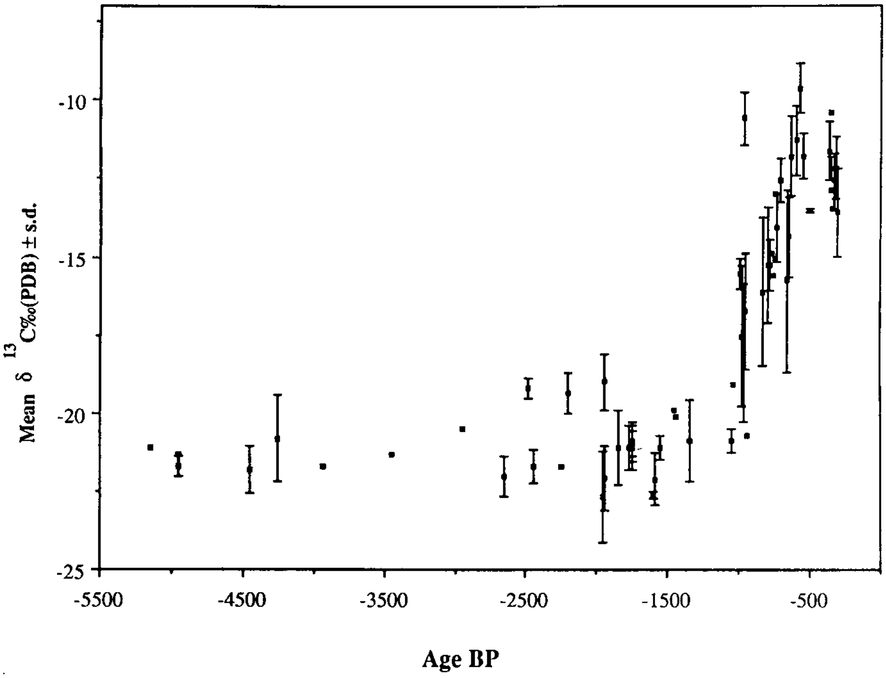

Figure I.1.1. Temporal changes in mean values of δ13C of prehistoric eastern North American Indians. The error bars represent one standard deviation. (From Ambrose 1987, in *Emergent Horticultural Economies of the Eastern Woodlands,* ed. W. F. Keegan; ©1987 the Board of Trustees, Southern Illinois University; reprinted by permission of the author and the Center for Archaeological Investigations.)

gory of dietary identification reflected by $\delta^{13}C$ values includes primarily marine foods. Marine fish and mammals have more positive $\delta^{13}C$ values (by about 6 o/oo) compared to terrestrial animals feeding on C3 foods, and less positive values (by about 7 o/oo) than terrestrial animals feeding on C4 foods (especially maize) (Schoeninger and DeNiro 1984; Schoeninger, van der Merwe, and Moore 1990).

Nitrogen stable isotope ratios in human bone are used to distinguish between consumers of terrestrial and marine foods. Margaret Schoeninger and Michael J. DeNiro (1984; see also Schoeninger et al. 1990) have indicated that in many geographical regions the $\delta^{15}N$ values of marine organisms differ from terrestrial organisms by about 10 parts per thousand on average, with consumers of terrestrial foods being less positive than consumers of marine foods. Recent research on stable isotopes of sulphur (i.e., $^{34}S/^{32}S$) suggests that they may provide an additional means of identifying diets based on marine foods from those based on terrestrial foods because of the relatively greater abundance of ^{34}S in marine organisms (Krouse 1987). A preliminary study of prehistoric populations from coastal Chile has supported this distinction in human remains representative of marine and terrestrial subsistence economies (Kelley, Levesque, and Weidl 1991).

As already indicated, based on carbon stable isotope values alone, the contribution of maize to diets in populations consuming marine resources is difficult to assess from coastal areas of the New World because of the similarity of isotope signatures of marine foods and individuals with partial maize diets (Schoeninger et al. 1990). However, by using both carbon and nitrogen isotope ratios, it is possible to distinguish between the relative contributions to diets of marine and terrestrial (e.g., maize) foods (Schoeninger et al. 1990).

Stable isotopes (C and N) have several advantages over trace elements in dietary documentation. For example, because bone collagen is not subject to isotopic exchange, diagenetic effects are not as important a confounding factor as in trace elemental analysis (Ambrose 1987; Grupe, Piepenbrink, and Schoeninger 1989). Perhaps the greatest advantage, however, is that because of the relative ease of removing the mineral component of bone (as well as fats and humic contaminants) and of confirming the collagen presence through identification of amino acids, the sample purity can be controlled (Ambrose 1987; Stafford, Brendel, and Duhamel 1988). However, collagen abundance declines in the burial matrix, and it is the first substance to degrade in bone decomposition (Grupe et al. 1989). If the decline in collagen value does not exceed 5 percent of the original value, then the isotopic information is suspect (see also Bada, Schoeninger, and Schimmelmann 1989; Schoeninger et al. 1990). Therefore, human fossil specimens, which typically contain little or no collagen, are generally not conducive to dietary reconstruction.

Teeth and Diet: Tooth Wear

Humankind has developed many means of processing foods before they are eaten. Nevertheless, virtually all foods have to be masticated by use of the teeth to one

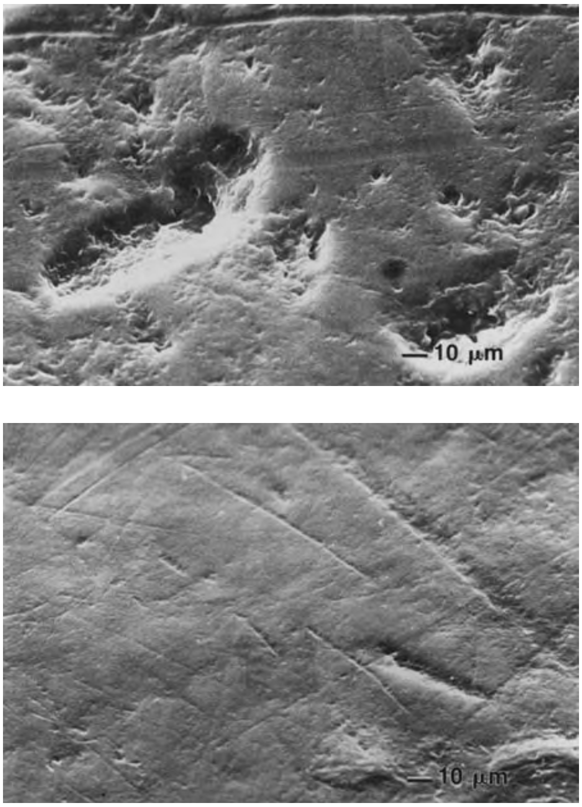

Figure I.1.2. Scanning electron micrographs (×500) of prehistoric hunter–gatherer molar (top) and historic agriculturalist molar (bottom) from the southeastern U.S. Atlantic coast. (From Teaford 1991, in *Advances in Dental Anthropology,* ed. Marc A. Kelley and Clark Spencer Larsen; ©1991; reprinted by permission of the author and Wiley-Liss, a division of John Wiley and Sons, Inc.)

extent or another before they are passed along for other digestive activities. Because food comes into contact with teeth, the chewing surfaces of teeth wear. Defined as "the loss of calcified tissues of a tooth by erosion, abrasion, attrition, or any combination of these" (Wallace 1974: 385), tooth wear – both microscopic and macroscopic – provides information on diets of past populations. The importance of tooth wear in the reconstruction of diet has been underscored by Phillip L. Walker (1978: 101), who stated, "From an archaeological standpoint, dietary information based on the analysis of dental attrition is of considerable value since it offers an independent check against reconstruction of prehistoric subsistence based on the analysis of floral, faunal and artifactual evidence."

Recent work with use of scanning electron microscopy (SEM) in the study of microwear on occlusal surfaces of teeth has begun to produce important data on diet in human populations (reviewed in Teaford 1991) (Figure I.1.2). Field and laboratory studies have shown that microwear features can change rapidly. Therefore, microwear patterns may give information only on food items consumed shortly before death. These features, nevertheless, have been shown to possess remarkable consistency across human populations and various animal species and have, therefore, provided insight into past culinary habits. For example, hard-object feeders, including Miocene apes (e.g., *Sivapithecus*) as well as recent humans, consistently develop large pits on the chewing surfaces of teeth. In contrast, consumers of soft foods, such as certain agriculturalists (Bullington 1988; Teaford 1991), develop smaller and fewer pits as well as narrower and more frequently occurring scratches.

Macroscopic wear can also vary widely, depending upon a host of factors (Molnar 1972; Foley and Cruwys 1986; Hillson 1986; Larsen 1987; Benfer and Edwards 1991; Hartnady and Rose 1991; Walker, Dean, and Shapiro 1991). High on the list of factors affecting wear, however, are the types of foods consumed and manner of their preparation. Because most Western populations consume soft, processed foods with virtually all extraneous grit removed, tooth wear occurs very slowly. But non-Western populations consuming traditional foods (that frequently contain grit contaminants introduced via grinding stones) show rapid rates of dental wear (e.g., Hartnady and Rose 1991). Where there are shifts in food types (e.g., from hunting and gathering to agriculture) involving reduction in food hardness or changes in how these foods are processed (e.g., with stone versus wooden grinding implements), most investigators have found a reduction in gross wear (e.g., Anderson 1965, 1967; Walker 1978; Hinton, Smith, and Smith 1980; Smith, Smith, and Hinton 1980; Patterson 1984; Bennike 1985; Inoue, Ito, and Kamegai 1986; Benfer and Edwards 1991; Rose, Marks, and Tieszen 1991).

Consistent with reductions in tooth wear in the shift to softer diets are reductions in craniofacial robusticity, both in Old World settings (e.g., Carlson and Van Gerven 1977, 1979; Armelagos, Carlson, and Van Gerven 1982; y'Edynak and Fleisch 1983; Smith, Bar-Yosef, and Sillen 1984; Wu and Zhang 1985; Inoue et al. 1986; y'Edynak 1989) and in New World settings (e.g., Anderson 1967; Larsen 1982; Boyd 1988). In prehistoric Tennessee Amerindians, for example, Donna C. Boyd (1988) has documented a clear trend for a reduction in dimensions of the mandible and facial bones that reflects decreasing masticatory stress relating to a shift to soft foods. Although not all studies of this sort examine both craniofacial and dental wear changes, those that do so report reductions in both craniofacial robusticity and dental wear, reflecting a decrease in hardness of foods consumed (Anderson 1967; Inoue et al. 1986). Other changes accompanying shifts from hard-textured to soft-textured foods include an increase in malocclusion and crowding of teeth due to inadequate growth of the jaws (reviewed by Corruccini 1991).

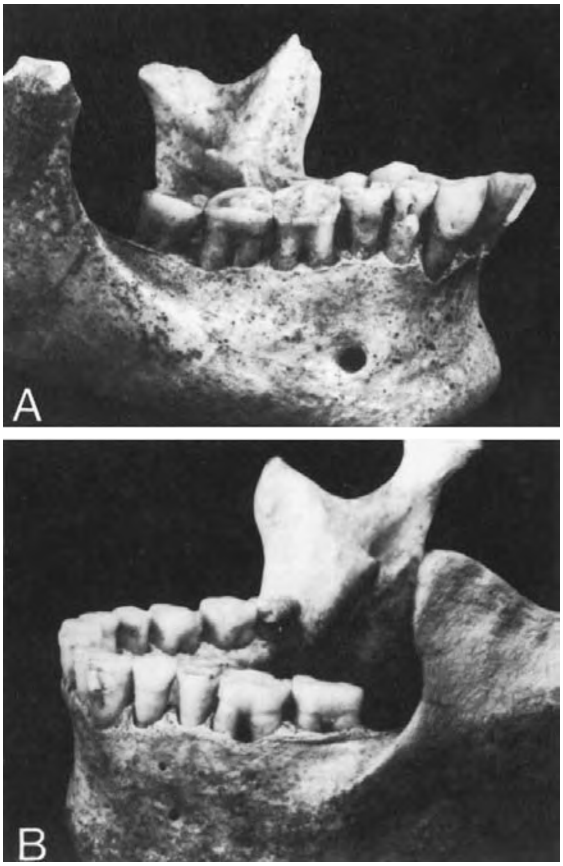

Figure I.1.3. Views of mandibular dentitions showing agriculturalist (A) and hunter–gatherer (B) wear planes. Note the angled wear on the agriculturalist's molars and the flat wear on the hunter-gatherer's molars. (From Smith 1984, in *American Journal of Physical Anthropology;* ©1984; reprinted by permission of the author and Wiley-Liss, a division of John Wiley and Sons, Inc.)

B. Holly Smith (1984, 1985) has found consistent patterns of tooth wear in human populations (Figure I.1.3). In particular, agriculturalists – regardless of regional differences – show highly angled molar wear planes in comparison with those of hunter-gatherers. The latter tend to exhibit more evenly distributed, flat wear. Smith interpreted the differences in tooth wear between agriculturalists and hunter-gatherers as reflecting greater "toughness" of hunter–gatherer foods.

Similarly, Robert J. Hinton (1981) has found in a large series of Native American dentitions representative of hunter-gatherers and agriculturalists that the former wear their anterior teeth (incisors and canines) at a greater rate than the latter. Agriculturalists that he studied show a tendency for cupped wear on the chewing surfaces of the anterior teeth. Because agriculturalists exhibit a relatively greater rate of premortem posterior tooth loss (especially molars), Hinton relates the peculiar wear pattern of the anterior teeth to the use of these teeth in grinding food once the molars are no longer available for this masticatory activity.

Specific macroscopic wear patterns appear to arise as a result of chewing one type of food. In a prehistoric population from coastal Brazil, Christy G. Turner II and Lilia M. Machado (1983) found that in the anterior dentition the tooth surfaces facing the tongue were more heavily worn than the tooth surfaces facing the lips (Figure I.1.4.). They interpreted this wear pattern as reflecting the use of these teeth to peel or shred abrasive plants for dietary or extramasticatory purposes.

Teeth and Diet: Dental Caries

The health of the dental hard tissues and their supporting bony structures are intimately tied to diet. Perhaps the most frequently cited disease that has been linked with diet is dental caries, which is defined as "a disease process characterized by the focal demineralization of dental hard tissues by organic acids produced by bacterial fermentation of dietary carbohydrates, especially sugars" (Larsen 1987: 375). If the decay of tooth crowns is left unchecked, it will lead to cavitation, loss of the tooth, and occasionally, infection and even death (cf. Calcagno and Gibson 1991). Carious lesions can develop on virtually any exposed surface of the tooth crown. However, teeth possessing grooves and fissures (especially posterior teeth) tend to trap food particles and are, therefore, more prone to colonization by indigenous bacteria, and thus to cariogenesis. Moreover, pits and linear depressions arising from poorly formed enamel (hypoplasia or hypocalcification) are also predisposed to caries attack, especially in populations with cariogenic diets (Powell 1985; Cook 1990) (Figure I.1.5).

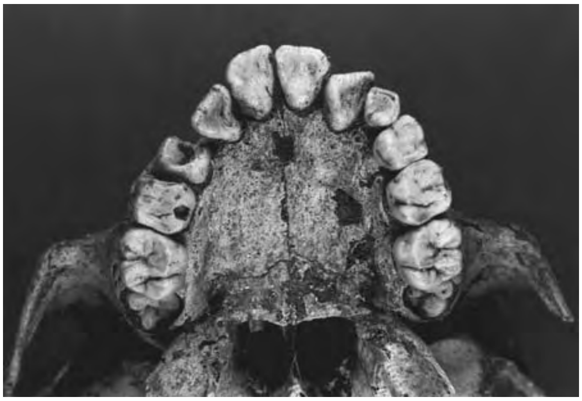

Figure I.1.5. Dental carious lesion in maxillary molar from historic Florida Indian. (Photograph by Mark C. Griffin.)

Dental caries is a disease with considerable antiquity in humans. F. E. Grine, A. J. Gwinnett, and J. H. Oaks (1990) note the occurrence of caries in dental remains of early hominids dating from about 1.5 million years ago (robust australopithecines and *Homo erectus*) from the Swartkrans site (South Africa), albeit at low prevalence levels. Later *Homo erectus* teeth from this site show higher prevalence than australopithecines, which may reflect their consumption of honey, a caries-promoting food (Grine et al. 1990). But with few exceptions (e.g., the Kabwe early archaic *Homo sapiens* from about 130,000 years before the present [Brothwell 1963]), caries prevalence has been found to be very low until the appearance of plant domestication in the early Holocene. David W. Frayer (1988) has documented one of these exceptions – an unusually high prevalence in a Mesolithic population from Portugal, which he relates to the possible consumption of honey and figs.

Turner (1979) has completed a worldwide survey of archaeological and living human populations whereby diet has been documented and the percentage of carious teeth has been tabulated. The samples were subdivided into three subsistence groups: hunting and gathering (*n* = 19 populations), mixed (combination of agriculture with hunting, gathering, or fishing; *n* = 13 populations), and agriculture (*n* = 32 populations). By pooling the populations within each subsistence group, Turner found that hunter-gatherers exhibited 1.7 percent carious teeth, mixed subsistence groups (combining hunting, gathering, and agriculture) exhibited 4.4 percent carious teeth, and agriculturalists exhibited 8.6 percent carious teeth.

Other researchers summarizing large comparative samples have confirmed these findings, especially with regard to a dichotomy in caries prevalence between hunter-gatherers and agriculturalists. Clark Spencer Larsen and co-workers (1991) compared 75 archaeological dental samples from the eastern United States. Only three agriculturalist populations exhibited less than 7 percent carious teeth, and similarly, only three hunter–gatherer populations exhibited greater than 7 percent carious teeth. The greater frequencies of carious teeth in the agricultural populations are largely due to those people's consumption of maize (see also Milner 1984). The cariogenic component of maize is sucrose, a simple sugar that is more readily metabolized by oral bacteria than are more complex carbohydrates (Newbrun 1982). Another factor contributing to high caries prevalence in later agricultural populations may be due to the fact that maize is frequently consumed in the form of soft mushes. These foods have the tendency to become trapped in grooves and fissures of teeth, thereby enhancing the growth of plaque and contributing to tooth decay due to the metabolism of sugar by indigenous bacteria (see also Powell 1985).

High prevalence of dental caries does not necessarily indicate a subsistence regime that included maize agriculture, because other carbohydrates have been strongly implicated in prehistoric nonagricultural contexts. Philip Hartnady and Jerome C. Rose (1991) reported a high frequency of carious lesions – 14 percent – in the Lower Pecos region of southwest Texas. These investigators related elevated levels of caries to the consumption of plants high in carbohydrates, namely sotal, prickly pear, and lecheguilla. The fruit of prickly pear (known locally as tuna) contains a significant sucrose component in a sticky, pectin-based mucilage. The presence of a simple sugar in this plant food, coupled with its gummy nature, is clearly a caries-promoting factor (see also Walker and Erlandson 1986, and Kelley et al. 1991, for different geographical settings involving consumption of nonagricultural plant carbohydrates).

Nutritional Assessment

Growth and Development

One of the most striking characteristics of human physical growth during the period of infancy and childhood is its predictability (Johnston 1986; Bogin 1988). Because of this predictability, anthropometric approaches are one of the most commonly used indices in the assessment of health and well-being, including nutritional status (Yarbrough et al. 1974). In this regard, a number of growth standards based on living subjects have been established (Gracey 1987). Comparisons of individuals of known age with these standards make it possible to identify deviations from the "normal" growth trajectory.

Growth is highly sensitive to nutritional quality, especially during the earlier years of infancy and early childhood (birth to 2 years of age) when the human body undergoes very rapid growth. The relationship between nutrition and growth has been amply demonstrated by the observation of recent human populations experiencing malnutrition. These populations show a secular trend for reduced physical size of children and adults followed by increased physical size with improvements in diet (e.g., for Japanese, see Kimura 1984; Yagi, Takebe, and Itoh 1989; and for additional populations, Eveleth and Tanner 1976).

Based on a large sample of North Americans representative of different socioeconomic groups, Stanley M. Garn and co-workers (Garn, Owen, and Clark 1974; Garn and Clark 1975) reported that children in lower income families were shorter than those in higher income families (see also review in Bogin 1988). Although a variety of factors may be involved, presumably the most important is nutritional status.

One means of assessing nutrition and its influence on growth and development in past populations is by the construction of growth curves based on comparison of length of long bones in different juvenile age groups (e.g., Merchant and Ubelaker 1977; Sundick 1978; Hummert and Van Gerven 1983; Goodman, Lallo, et al. 1984; Jantz and Owsley 1984; Owsley and Jantz 1985; Lovejoy, Russell, and Harrison 1990) (Figure I.1.6). These data provide a reasonable profile of rate or velocity of growth. Della C. Cook (1984), for example, studied the remains of a group ranging in age from birth to 6 years. They were from a time-successive population in the midwestern United States undergoing the intensification of food production and increased reliance on maize agriculture. Her analysis revealed that individuals living during the introduction of maize had shorter femurs for their age than did individuals living before, as hunter-gatherers, or those living after, as maize-intensive agriculturalists (Cook 1984). Analysis of depressed growth among prehistoric hunter-gatherers at the Libben site (Ohio) suggests, however, that infectious disease was a more likely culprit in this context because the hunter–gatherers' nutrition – based on archaeological reconstruction of their diet – was adequate (Lovejoy et al. 1990).

Comparison of skeletal development, a factor responsive to nutritional insult, with dental development, a factor that is relatively less responsive to nutritional insult (see the section "Dental Development"), can provide corroborative information on nutritional status in human populations. In two series of archaeological populations from Nubia, K. P. Moore, S. Thorp, and D. P. Van Gerven (1986) compared skeletal age and dental age and found that most individuals (70.5 percent) had a skeletal age younger than their dental age. These findings were interpreted as reflecting significant retardation of skeletal growth that was probably related to high levels of nutritional stress. Indeed, undernutrition was confirmed by the presence of other indicators of nutritional insult, such as iron-deficiency anemia.

In living populations experiencing generally poor nutrition and health, if environmental insults are removed (e.g., if nutrition is improved), then children may increase in size, thereby more closely approximating their genetic growth potential (Bogin 1988). However, if disadvantageous conditions are sustained, then it is unlikely that the growth potential will be realized. Thus, despite prolonged growth in undernourished populations, adult height is reduced by about 10 percent (Frisancho 1979). Sustained growth depression occurring during the years of growth and development, then, has almost certain negative consequences for final adult stature (Bogin 1988 and references cited therein).

In archaeological populations, reductions in stature have been reported in contexts with evidence for reduced nutritional quality. On the prehistoric Georgia coast, for example, there was a stature reduction of about 4 centimeters in females and 2 centimeters in males during the shift from hunting, gathering, and fishing to a mixed economy involving maize agriculture (Larsen 1982; Angel 1984; Kennedy 1984; Meiklejohn et al. 1984; Rose et al. 1984; and discussions in Cohen and Armelagos 1984; Larsen 1987; Cohen 1989). All workers documenting reductions in stature regard it as reflecting a shift to the relatively poor diets that are oftentimes associated with agricultural food production such as maize in North America.

Cortical Bone Thickness

Bone tissue, like any other tissue of the body, is subject to environmental influences, including nutritional quality. In the early 1960s, Garn and co-workers (1964) showed that undernourished Guatemalan children had reduced thickness of cortical (sometimes called compact) bone compared with better nourished children from the same region. Such changes were related to loss of bone during periods of acute protein energy malnutrition. These findings have been confirmed by a large number of clinical investigations (e.g., Himes et al. 1975; and discussion in Frisancho 1978).

Bone maintenance in archaeological skeletal populations has been studied by a number of investigators.

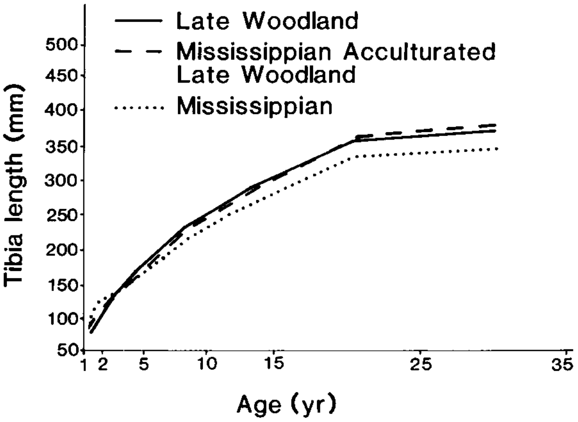

Figure I.1.6. Growth curves from Dickson Mounds, Illinois, Indian population. (Adapted from Lallo 1973; reproduced from Larsen 1987 with permission of Academic Press, Inc.)

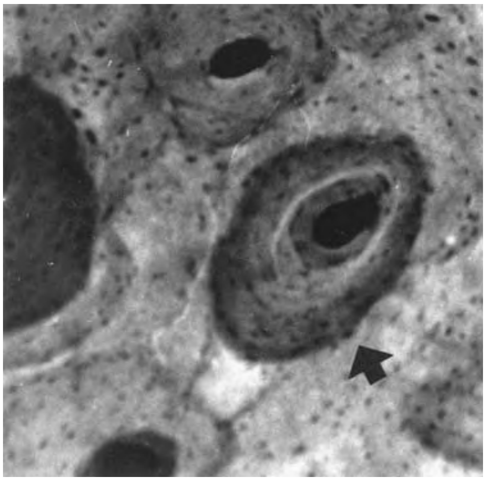

Figure I.1.7. Micrograph (×150) showing hypermineralized rings (dark zones) within an osteon from prehistoric Nubian. (Photograph courtesy of Debra L. Martin.)

Most frequently expressed as a ratio of the amount of cortical bone to subperiosteal area – or percent cortical area (PCCA) or percent cortical thickness (PCCT) – it has been interpreted by most people working with archaeological human remains as reflecting nutritional or health status (e.g., Cassidy 1984; Cook 1984; Brown 1988; Cohen 1989). It is important to note, however, that bone also remodels itself under conditions of mechanical demand, so that bone morphology that might be interpreted as reflecting a reduction in nutritional status may in fact represent an increase in mechanical loading (Ruff and Larsen 1990).

Cortical Bone Remodeling and Microstructure

An important characteristic that bone shares with other body tissues is that it must renew itself. The renewal of bone tissue, however, is unique in that the process involves destruction followed by replacement with new tissue. The characteristic destruction (resorption) and replacement (deposition) occurs mostly during the years of growth and development prior to adulthood, but it continues throughout the years following. Microstructures observable in bone cross sections have been analyzed and have provided important information about bone remodeling and its relationship to nutritional status. These microstructures include osteons (tunnels created by resorption and partially filled in by deposition of bone tissue), Haversian canals (central canals associated with osteons), and surrounding bone.

As with cortical thickness, there is a loss of bone mass that can be observed via measurement of the degree of porosity through either invasive (e.g., histological bone thin sections) or noninvasive (e.g., photon absorptiometry) means. With advancing age, cortical bone becomes both thinner and more porous. Cortical bone that has undergone a reduction in bone mass per volume – a disorder called osteoporosis – should reflect the nutritional history of an individual, especially if age factors have been ruled out (Martin et al. 1985; Schaafsma et al. 1987; Arnaud and Sanchez 1990). If this is the case, then bone loss can affect any individual regardless of age (Stini 1990). Clinical studies have shown that individuals with low calcium intakes are more prone to bone loss in adulthood (Nordin 1973; Arnaud and Sanchez 1990; Stini 1990). It is important to emphasize, however, that osteoporosis is a complex, multifactorial disorder and is influenced by a number of risk factors, including nondietary ones such as body weight, degree of physical exercise, and heredity (Evers, Orchard, and Haddad 1985; Schaafsma et al. 1987; Arnaud and Sanchez 1990; Stini 1990; Ruff 1991; Lindsay and Cosman 1992; Heaney 1993).

Porosity of bone also represents a function of both the number of Haversian canals and their size (Atkinson 1964; Thompson 1980; Burr, Ruff, and Thompson 1990). Therefore, the greater the number and width of Haversian canals, the greater the porosity of bone tissue. The density of individual osteons appears to be related to nutritional quality as well. For example, the presence of osteons containing hypermineralized lines in archaeological human remains likely reflects periods of growth disturbance (e.g., Stout and Simmons 1979; Martin and Armelagos 1985) (Figure I.1.7).

Samuel D. Stout and co-workers (Stout and Teitelbaum 1976; Stout 1978, 1983, 1989) have made comparisons of bone remodeling dynamics between a series of hunter-gatherer and maize-dependent North and South American archaeological populations. Their findings show that the single agricultural population used in the study (Ledders, Illinois) had bone remodeling rates that were higher than the other (nonmaize) populations. They suggested that because maize is low in calcium and high in phosphorus, parathyroid hormone levels could be increased. Bone remodeling is highly stimulated by parathyroid hormone, a disorder known as hyperparathyroidism.

In order to compensate for bone loss in aging adults (particularly after 40 years of age), there are structural adaptations involving more outward distribution of bone tissue in the limb bones. In older adults, such adaptation contributes to maintaining the biomechanical strength despite bone losses (Ruff and Hayes 1982). Similarly, D. B. Burr and R. B. Martin (1983; see also Burr et al. 1990) have suggested that the previously discussed material property changes may supplement structural changes. Thus, different rates of bone turnover in human populations may reflect mechanical adaptations that are not necessarily linked to poor nutrition.

Skeletal (Harris) Lines of Increased Density

Nonspecific markers of physiological stress that appear to have some links with nutrition status are radiographically visible lines of increased bone density, referred to as Harris lines (Figure I.1.8). These lines either partly or completely span the medullary cavities of tubular bones (especially long bones of the arms and legs) and trace the outlines of other bones (Garn et al. 1968; Steinbock 1976). These lines have been found to be associated with malnutrition in modern humans (e.g., Jones and Dean 1959) and in experimental animals (e.g., Stewart and Platt 1958). Because Harris lines develop during bone formation, age estimates can be made for time of occurrence relative to the primary ossification centers (e.g., Goodman and Clark 1981). However, the usefulness of these lines for nutritional assessment is severely limited by the fact that they frequently resorb in adulthood (Garn et al. 1968). Moreover, Harris lines have been documented in cases where an individual has not undergone episodes of nutritional or other stress (Webb 1989), and they appear to correlate negatively with other stress markers (reviewed in Larsen 1987).

Dental Development: Formation and Eruption

Like skeletal tissues, dental tissues are highly sensitive to nutritional perturbations that occur during the years of growth and development. Unlike skeletal tissues, however, teeth – crowns, in particular – do not remodel once formed, and they thereby provide a permanent "memory" of nutritional and health history. Alan H. Goodman and Jerome C. Rose (1991: 279) have underscored the importance of teeth in the anthropological study of nutrition: "Because of the inherent and close relationship between teeth and diet, the dental structures have incorporated a variety of characteristics that reflect what was placed in the mouth and presumably consumed" (see also Scott and Turner 1988).

There are two main factors involved in dental development – *formation* of crowns and roots and *eruption* of teeth. Because formation is more heritable than eruption, it is relatively more resistant to nutritional insult (Smith 1991). Moreover, the resistance of formation to environmental problems arising during the growth years is suggested by low correlations between formation and stature, fatness, body weight, or bone age, and lack of secular trend. Thus, timing of formation of tooth crowns represents a poor indicator for assessing nutritional quality in either living or archaeological populations. Eruption, however, can be affected by a number of factors, including caries, tooth loss, and severe malnutrition (e.g., Alvarez et al. 1988, 1990; Alvarez and Navia 1989). In a large, cross-sectional evaluation of Peruvian children raised in nutritionally deprived settings, J. O. Alvarez and co-workers (1988) found that exfoliation of the deciduous dentition was delayed. Other workers have found that eruption was delayed in populations experiencing nutritional deprivation (e.g., Barrett and Brown 1966; Alvarez et al. 1990). Unlike formation, eruption timing has been shown to be correlated with various measures of body size (Garn, Lewis, and Polacheck 1960; McGregor, Thomson, and Billewicz 1968). To my knowledge, there have been no archaeological populations where delayed eruption timing has been related to nutritional status.

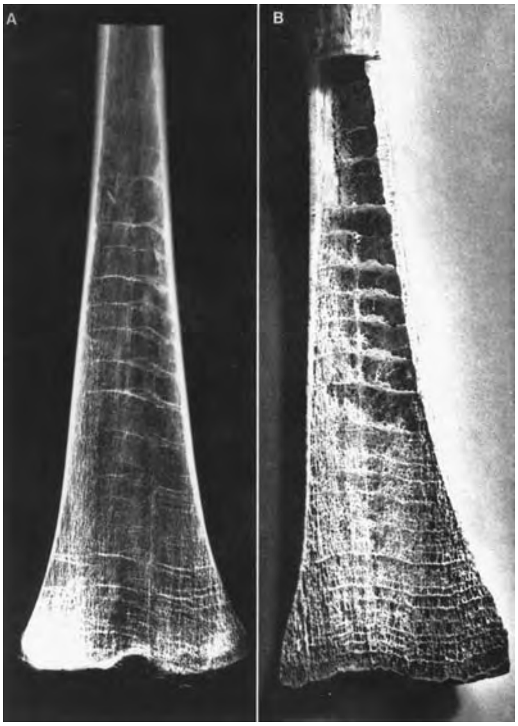

Figure I.1.8. Radiograph (A) and section (B) of prehistoric California Indian femur with Harris lines. (From McHenry 1968, in *American Journal of Physical Anthropology;* ©1968; reprinted by permission of author and Wiley-Liss, a division of John Wiley and Sons, Inc.)

Dental Development: Tooth Size

Unlike formation timing, tooth size appears to be under the influence of nutritional status. Garn and co-workers (Garn and Burdi 1971; Garn, Osborne, and McCabe 1979) have indicated that maternal health status is related to size of deciduous and permanent dentitions. Nutrition and tooth size in living populations has not been examined. However, the role of nutrition as a contributing factor to tooth size reduction has been strongly implicated in archaeological contexts. Mark F. Guagliardo (1982) and Scott W. Simpson, Dale L. Hutchinson, and Clark Spencer Larsen (1990) have inferred that the failure of teeth to reach their maximum genetic size potential occurs in populations experiencing nutritional stress. That is, comparison of tooth size in populations dependent upon maize agriculture revealed that juveniles had consistently smaller teeth than adults. Moreover, a reduction in deciduous tooth size in comparison between hunter-gatherers and maize agriculturalists on the prehistoric southeastern U. S. coast was reported by Larsen (1983). Because

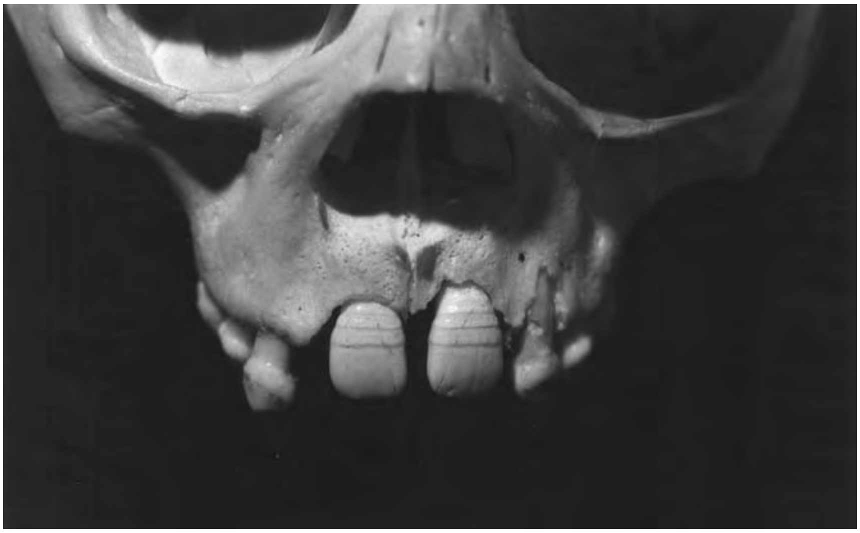

Figure I.1.9. Juvenile anterior dentition showing hypoplasias on incompletely erupted incisors. (Photograph by Barry Stark.)

deciduous tooth crowns are largely formed *in utero,* it was suggested that smaller teeth in the later period resulted from a reduction in maternal health status and placental environment.

Dental Development: Macrodefects

A final approach to assessing the nutritional and health status of contemporary and archaeological populations has to do with the analysis of enamel defects in the teeth, particularly hypoplasias (Figure I.1.9). Hypoplasias are enamel defects that typically occur as circumferential lines, grooves, or pits resulting from the death or cessation of enamel-producing cells (ameloblasts) and the failure to form enamel matrix (Goodman and Rose 1990). Goodman and Rose (1991) have reviewed a wide array of experimental, epidemiological, and bioarchaeological evidence in order to determine whether hypoplasias represent an important means for assessing nutritional status in human populations, either contemporary or archaeological. They indicate that although enamel hypoplasias arising from systemic (e.g., nutrition) versus nonsystemic factors (e.g., localized trauma) are easily identifiable, identification of an exact cause for the defects remains an intractable problem. T. W. Cutress and G. W. Suckling (1982), for example, have listed nearly 100 factors that have a causal relationship with hypoplasias, including nutritional problems. The results of a number of research projects have shown that a high frequency of individuals who have experienced malnutrition have defective enamel, thus suggesting that enamel is relatively sensitive to undernutrition. Moreover, it is a straightforward process to estimate the age at which individual hypoplasias occur based on matching the hypoplasia with dental developmental sequences (e.g., Goodman, Armelagos, and Rose 1980; Rose, Condon, and Goodman 1985; Hutchinson and Larsen 1988).

Studies based on archaeological human remains have examined hypoplasia prevalence and pattern (reviewed in Huss-Ashmore et al. 1982; Larsen 1987). In addition to determining frequency of enamel defects (which tends to be higher in agricultural populations), this research has looked at the location of defects on tooth crowns in order to examine age at the time of defect development. Contrary to earlier assertions that age pattern of defects are universal in humans, with most hypoplasias occurring in the first year of life (e.g., Sarnat and Schour 1941; see discussion in Goodman 1988), these studies have served to show that there is a great deal of variability in age of occurrence of hypoplasias. By and large, however, most reports on age patterning in hypoplasia occurrence indicate a peak in defects at 2 to 4 years of age, regardless of geographic or ecological setting (Hutchinson and Larsen 1988; Goodman and Rose 1991), a factor that most workers have attributed to nutritional stresses of postweaning diets (e.g., Corruccini, Handler, and Jacobi 1985; Webb 1989; Blakely and Mathews 1990; Simpson et al. 1990). Analyses of prevalence and pattern of hypoplasia in past populations have largely focused on recent archaeological populations. In this respect, there is a tendency for agricultural groups to show higher prevalence rates than nonagricultural (hunter-gatherer) populations (e.g., Sciulli 1978; Goodman et al. 1984a, 1984b; Hutchinson and Larsen 1988).

Unlike most other topics discussed in this chapter, this indicator of physiological stress has been investigated in ancient hominids. In the remains of early hominids in Africa, the Plio-Pleistocene australopithecines, P. V. Tobias (1967) and Tim D. White (1978) have noted the presence of hypoplasias and provided some speculation on relative health status. Of more importance, however, are the recent analyses of hypoplasias in European and Near-Eastern Neanderthal (Middle Paleolithic) populations. Marsha D. Ogilvie, Bryan K. Curran, and Erik Trinkaus (1989) have recorded prevalence data and estimates of developmental ages of defects on most of the extant Neanderthal teeth (n = 669 teeth). Their results indicate high prevalence, particularly in the permanent teeth (41.9 percent permanent teeth, 3.9 percent deciduous teeth). Although these prevalences are not as high as those observed in recent archaeological populations (e.g., Hutchinson and Larsen 1990; Van Gerven, Beck, and Hummert 1990), they do indicate elevated levels of stress in these ancient peoples. Unlike other dental series, age of occurrence of hypoplasias on the permanent dentition follows two distinct peaks, including an earlier peak between ages 2 and 5 years and a later peak between ages 11 and 13 years. The earlier peak is consistent with findings of other studies. That is, it may reflect nutritional stresses associated with weaning (Ogilvie et al. 1989). The later peak may simply represent overall high levels of systemic stress in Neanderthals. Because genetic disorders were likely eliminated from the gene pool, Ogilvie and co-workers argue against genetic agents as a likely cause. Moreover, the very low prevalence of infection in Neanderthal populations suggests that infection was an unlikely cause, leaving nutritional deficiencies, especially in the form of periodic food shortages, as the most likely causative agents.

Analysis of dental hypoplasia prevalence from specific Neanderthal sites confirms the findings of Ogilvie and co-workers, particularly with regard to the Krapina Neanderthal sample from eastern Europe (e.g., Molnar and Molnar 1985). With the Krapina dental series, Larsen and co-workers (in preparation) have made observations on the prevalence of an enamel defect known as hypocalcification, which is a disruption of the mineralization process following deposition of enamel matrix by ameloblasts. The presence of these types of enamel defects confirms the unusually high levels of stress in these early hominid populations, which is likely related to undernutrition.

Dental Development: Microdefects

An important complement to the research done on macrodefects has been observations of histological indicators of physiological stress known as Wilson bands or accentuated stria of Retzius (Rose et al. 1985; Goodman and Rose 1990). Wilson bands are features visible in thin section under low magnification (×100 to ×200) as troughs or ridges in the flat enamel surface (Figure I.1.10). Concordance of these defects with hypoplasias is frequent, but certainly not universal in humans (Goodman and Rose 1990), a factor that may be related to differences in histology or etiology or both (Rose et al. 1985; Danforth 1989). K. W. Condon (1981) has concluded that Wilson bands may represent short-term stress episodes (less than one week), and hypoplasias may represent long-term stress episodes (several weeks to two months).

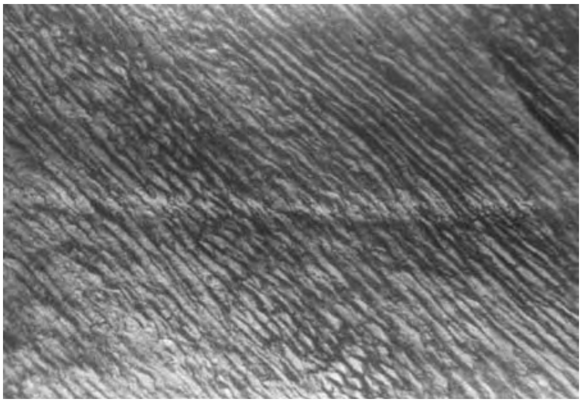

Figure I.1.10. Micrograph (×160) of canine tooth showing Wilson band from Native American Libben site. (Photograph courtesy of Jerome C. Rose.)

Jerome C. Rose, George J. Armelagos, and John W. Lallo (1978) have tested the hypothesis that as maize consumption increased and animal sources of protein consumption decreased in a weaning diet, there should be a concomitant increase in frequency of Wilson bands. Indeed, there was a fourfold increase in rate (per individual) in the full agriculturalists compared with earlier hunter-gatherers. They concluded that the declining quality of nutrition reduced the resistance of the child to infectious disease, thus increasing the individual's susceptibility to infection and likelihood of exhibiting a Wilson band. Most other studies on prehistoric populations from other cultural and geographic contexts have confirmed these findings (references cited in Rose et al. 1985).

Specific Nutritional Deficiency Diseases

Much of what is known about the nutritional quality of diets of past populations is based on the nonspecific indicators just discussed. It is important to emphasize that rarely is it possible to relate a particular hard-tissue pathology with a specific nutritional factor in archaeological human remains, not only because different nutritional problems may exhibit similar pathological signatures, but also because of the synergy between undernutrition and infection (Scrimshaw, Taylor, and Gordon 1968; Gabr 1987). This relationship has been succinctly summarized by Michael Gracey (1987: 201): "Malnourished children characteristically are enmeshed in a 'malnutrition-infection' cycle being more prone to infections which, in turn, tend to worsen the nutritional state." Thus, an episode of infection potentially exacerbates the negative effects of undernutrition as well as the severity of the pathological signature reflecting those effects.

Patricia Stuart-Macadam (1989) has reviewed evidence for the presence in antiquity of three specific nutritional diseases: scurvy, rickets, and iron-deficiency anemia. Scurvy and rickets are produced by respective deficiencies in vitamin C (ascorbic acid) and vitamin D. Vitamin C is unusual in that it is required in the diets of humans and other primates, but only of a few other animals. Among its other functions, it serves in the synthesis of collagen, the structural protein of the connective tissues (skin, cartilage, and bone). Thus, if an individual is lacking in vitamin C, the formation of the premineralized component of bone (osteoid) will be considerably reduced.

Rickets is a disease affecting infants and young children resulting from insufficiencies in either dietary sources of vitamin D (e.g., fish and dairy products) or, of greater importance, lack of exposure to sunlight. The insufficiency reduces the ability of bone tissue to mineralize, resulting in skeletal elements (especially long bones) that are more susceptible to deformation such as abnormal bending (Figure I.1.11).

Both scurvy and rickets have been amply documented through historical accounts and in clinical settings (see Stuart-Macadam 1989). Radiographic documentation shows that bones undergoing rapid growth – namely in infants and young children – have the greatest number of changes. In infants, for example, ends of long bones and ribs are most affected and show "generalized bone atrophy and a thickening and increased density" (Stuart-Macadam 1989: 204). In children, rickets can be expressed as thin and porous bone with wide marrow spaces in general undernourishment. Alternatively, in better nourished individuals, bone tissue is more porous because of excessive bone deposition. Children with rickets can oftentimes show pronounced bowing of long bones with respect to both weight-bearing (leg) and non-weight-bearing (arm) bones.

Both scurvy and rickets, however, have been only marginally documented in the archaeological record, and mostly in historical contexts from the medieval period onward (Moller-Christiansen 1958; Maat 1982). Stuart-Macadam (1989) notes that only in the period of industrialization during the nineteenth century in Europe and North America has rickets shown an increase in prevalence.

Anemia is any condition where hemoglobin or red blood cells are reduced below normal levels. Iron-deficiency anemia is by far the most common form in living peoples, affecting more than a half billion of the current world population (Baynes and Bothwell 1990). Iron is an essential mineral, which must be ingested. It plays an important role in many body functions, especially the transport of oxygen to the body tissues (see Stuart-Macadam 1989). The bioavailability of iron from dietary sources results from several factors (see Hallberg 1981; Baynes and Bothwell 1990). With respect to its absorption, the major determinants are the sources of iron contained within foods consumed depending upon the form, heme or nonheme. Heme sources of iron from animal products are efficiently absorbed (Baynes and Bothwell 1990).

Ortner; from Stuart-Macadam 1989, in *Reconstruction of Life from the Skeleton,* ed. Mehmet Yasar Iscan and Kenneth A. R. Kennedy; ©1989; reprinted by permission of the author and Wiley-Liss, a division of John Wiley and Sons, Inc.)

In contrast, nonheme forms of iron from the various vegetable foods have a great deal of variation in their bioavailability. Moreover, a number of substances found in foods actually inhibit iron absorption. Phytates found in many nuts (e.g., almonds, walnuts), cereals (e.g., maize, rice, whole wheat flour), and legumes inhibit dietary iron bioavailability (summarized in Baynes and Bothwell 1990). Moreover, unlike the sources of protein found in meat, plant proteins, such as soybeans, nuts, and lupines, inhibit iron absorption. Thus, populations depending on plants generally experience reduced levels of iron bioavailability. Tannates found in tea and coffee also significantly reduce iron absorption (Hallberg 1981).

There are, however, a number of foods known to enhance iron bioavailability in combination with nonheme sources of iron. For example, ascorbic acid is a very strong promotor of iron absorption (Hallberg 1981; Baynes and Bothwell 1990). Citric acid from various fruits has also been implicated in promoting iron absorption, as has lactic acid from fermented cereal beers (Baynes and Bothwell 1990). In addition, Miguel Layrisse, Carlos Martinez-Torres, and Marcel Roche

(1968; and see follow-up studies cited in Hallberg 1981) have provided experimental evidence from living human subjects that nonheme iron absorption is enhanced considerably by consumption of meat and fish, although the specific mechanism for this enhancement is not clear (Hallberg 1981).

Iron-deficiency anemia can be caused by a variety of other, nondietary factors, including parasitic infection, hemorrhage, blood loss, and diarrhea; infants can be affected by predisposing factors such as low birth weight, gender, and premature clamping of the umbilical cord (Stuart-Macadam 1989, and references cited therein). The skeletal changes observed in the clinical and laboratory settings are primarily found in the cranium, and include the following: increased width of the space between the inner and outer surfaces of the cranial vault and roof areas of the eye orbits; unusual thinning of the outer surface of the cranial vault; and a "hair-on-end" orientation of the trabecular bone between the inner and outer cranial vault (Huss-Ashmore et al. 1982; Larsen 1987; Stuart-Macadam 1989; Hill and Armelagos 1990). Postcranial changes have also been observed (e.g., Angel 1966) but are generally less severe and in reduced frequency relative to genetic anemias (Stuart-Macadam 1989). The skeletal modifications result from the hypertrophy of the blood-forming tissues in order to increase the output of red blood cells in response to the anemia (Steinbock 1976).

Skeletal changes similar to those documented in living populations have been found in archaeological human remains from virtually every region of the globe. In archaeological materials, the bony changes – pitting and/or expansion of cranial bones – have been identified by various terms, most typically *porotic hyperostosis* (Figure I.1.12) or *cribra orbitalia* (Figure I.1.13). These lesions have rarely been observed prior to the adoption of sedentism and agriculture during the Holocene, but J. Lawrence Angel (1978) has noted occasional instances extending into the Middle Pleistocene. Although the skeletal changes have been observed in individuals of all ages and both sexes, Stuart-Macadam (1985) has concluded that iron-deficiency anemia produces them in young children during the time that most of the growth in cranial bones is occurring. By contrast, the presence of porotic hyperostosis and its variants in adults represents largely anemic episodes relating to the early years of growth and development. Thus, it is not possible to evaluate iron status in adults based on this pathology.

Many workers have offered explanations for the presence of porotic hyperostosis since the pathology was first identified more than a century ago (Hill and Armelagos 1990). Recent discussions, however, have emphasized local circumstances, including nutritional deprivation brought about by focus on intensive maize consumption, or various contributing circumstances such as parasitism, diarrheal infection, or a combination of these factors (e.g., Hengen 1971; Carlson, Armelagos, and Van Gerven 1974; Cybulski 1977; El-Najjar 1977; Mensforth et al. 1978; Kent 1986; Walker 1986; Webb 1989). Angel (1966, 1971) argued that the primary cause for the presence of porotic hyperostosis in the eastern Mediterranean region was the presence of abnormal hemoglobins, especially thalassemia. His hypothesis, however, has remained largely unsubstantiated (Larsen 1987; Hill and Armelagos 1990).

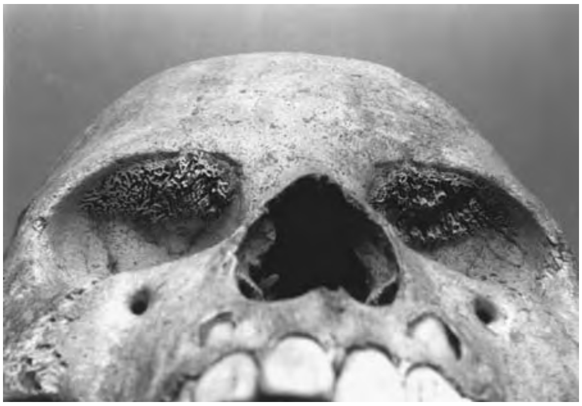

Figure I.1.13. Cribra orbitalia in historic Florida Indian. (Photograph by Mark C. Griffin.)

Several human archaeological populations have been shown to have moderate to high frequencies of porotic hyperostosis after establishing agricultural economies. However, this is certainly not a ubiquitous phenomenon. For example, Larsen and co-workers (1992) and Mary L. Powell (1990) have noted that the late prehistoric populations occupying the southeastern U.S. Atlantic coast have a very low prevalence of porotic hyperostosis. These populations depended in part on maize, a foodstuff that has been implicated in reducing iron bioavailability. But a strong dependence on marine resources (especially fish) may have greatly enhanced iron absorption. In the following historic period, these native populations show marked increase in porotic hyperostosis. This probably came about because after the arrival of Europeans, consumption of maize greatly increased and that of marine resources decreased. Moreover, native populations began to use sources of water that were likely contaminated by parasites, which would have brought on an increase in the prevalence of iron-deficiency anemia (see Larsen et al. 1992).

Conclusions

This chapter has reviewed a range of skeletal and dental indicators that anthropologists have used in the reconstruction of diet and assessment of nutrition in past human populations. As noted throughout, such reconstruction and assessment, where we are dealing only with the hard-tissue remains, is especially difficult because each indicator is so often affected by other factors that are not readily controlled. For this reason, anthropologists attempt to examine as many indicators as possible in order to derive the most complete picture of diet and nutrition.

In dealing with archaeological skeletal samples, there are numerous cultural and archaeological biases that oftentimes affect the sample composition. Jane E. Buikstra and James H. Mielke have suggested:

> Human groups have been remarkably creative in developing customs for disposal of the dead. Bodies have been interred, cremated, eviscerated, mummified, turned into amulets, suspended in trees, and floated down watercourses. Special cemetery areas have been reserved for persons of specific status groups or individuals who died in particular ways; for example, suicides. This variety in burial treatments can provide the archaeologist with important information about social organization in the past. On the other hand, it can also severely limit reliability of demographic parameters estimated from an excavated sample. (Buikstra and Mielke 1985: 364)

Various workers have reported instances of cultural biases affecting cemetery composition. In late prehistoric societies in the eastern United States, young individuals and sometimes others were excluded from burial in primary cemeteries (e.g., Buikstra 1976; Russell, Choi, and Larsen 1990), although poor preservation of thinner bones of these individuals – particularly infants and young children – along with excavation biases of archaeologists, can potentially contribute to misrepresentation (Buikstra, Konigsberg, and Bullington 1986; Larsen 1987; Walker, Johnson, and Lambert 1988; Milner, Humpf, and Harpending 1989). This is not to say that skeletal samples offer a poor choice for assessing diet and nutrition in past populations. Rather, all potential biases – cultural and noncultural – must be evaluated when considering the entire record of morbidity revealed by the study of bones and teeth.

Representation in skeletal samples is made especially problematical when considering the potential for differential access to foods consumed by past human societies. For example, as revealed by analysis of prevalence of dental caries, women ate more cariogenic carbohydrates than men in many agricultural or partially agricultural societies (reviewed in Larsen 1987; Larsen et al. 1991). Even in contemporary foraging groups where food is supposedly equitably distributed among all members regardless of age or gender, various observers have found that women frequently receive less protein and fats than men, and that their diet is often nutritionally inferior to that of males (reviewed in Speth 1990). In these so-called egalitarian societies, women are regularly subject to food taboos, including a taboo on meat (e.g., Hausman and Wilmsen 1985; see discussions by Spielmann 1989 and Speth 1990). Such taboos can be detrimental especially if they are imposed during critical periods such as pregnancy or lactation (Spielmann 1989; Speth 1990). If nutritional deprivation occurs during either pregnancy or lactation, the health of the fetus or infant can be severely compromised, and delays in growth are likely to occur. Thus, when assessing nutrition in past populations, it is important that contributing factors affecting quality of diet in females or other members of societies (e.g., young children, old adults) and potential for variability in health of these individuals be carefully evaluated.

Of equal importance in the study of skeletal remains is the role of other sources of information regarding diet in archaeological settings, especially plant and animal remains. All available sources should be integrated into a larger picture, including plant and animal food remains recovered from archaeological sites, and corroborative information made available from the study of settlement patterns and ethnographic documentation of subsistence economy. The careful consideration of all these sources of information facilitates a better understanding of diet and nutrition in peoples of the past.

I.2. Paleopathological Evidence of Malnutrition

The quantity and nutritional quality of food available to human populations undoubtedly played a major role in the adaptive processes associated with human evolution. This should have been particularly the case in that period of human history from Mesolithic times to the present when epochal changes took place in the subsistence base of many human societies. In the Near East the domestication of plants and animals began toward the end of the Mesolithic period but became fully developed in the Neolithic. This development included agriculture and pastoralism along with cultural changes associated with greater sedentism and urbanism.

Paleopathology, primarily through the study of human skeletal remains, has attempted to interpret the impact such changes have had upon human health. A recent focus has been on the transition from a hunting and gathering way of life to one associated with incipient or fully developed agriculture (e.g., Cohen and Armelagos 1984b; Cohen 1989; Meiklejohn and Zvelebil 1991). One of the questions being asked is whether greater dependence on fewer food sources increased human vulnerability to famine and malnutrition. The later transition into an increasingly sedentary urban existence in the Bronze and Iron Ages has not been as carefully studied. However, analysis of data from skeletal remains in numerous archaeological sites is providing insight into some of the effects upon nutrition that increasing human density and attendant subsistence changes have had.

In the study of prehistoric health, perhaps the least complex nutritional data comes from human remains that have been mummified. Preservation of human soft tissues occurs either naturally, as in the bogs of northern Europe and very arid areas of the world, or through cultural intervention with embalming methods. Some mummies have provided direct evidence of diet from the intestinal contents of their stomachs (e.g., Glob 1971: 42–3; Fischer 1980: 185–9; Brothwell 1986: 92). However, the most ubiquitous source of data comes from human skeletal remains where the impact of dietary factors tends to be indirect, limited, and difficult to interpret.

Generally, only about 10 percent of a typical sample of human archaeological burials will show any significant evidence of skeletal disease. (Clearly the people represented by the normal-appearing burials died of something, but there are no anatomical features that help determine what this might have been.) Of the 10 percent showing pathology, about 90 percent of their disease conditions resulted from trauma, infection, or arthritis – the three predominant pathological skeletal conditions. All other diseases, including those that might be caused by malnutrition, are incorporated in the residual 10 percent, meaning that even in a large sample of archaeological skeletons, one is unlikely to find more than a few examples of conditions that might be attributable to nutritional problems.

Once a pathological condition due to malnutrition is recognized in bone, correct diagnosis is challenging. Identification begins with those nutritional diseases most commonly known today that can affect the skeleton. These are: (1) vitamin D deficiency, (2) vitamin C deficiency, (3) iodine deficiency, (4) iron deficiency, (5) excessive dietary fluorine, (6) protein–calorie deficiency, and (7) trace element deficiencies.

Care needs to be exercised both in establishing a preferred diagnosis for a pathological condition and in interpreting the diagnoses of others. This is particularly the case in interpreting evidence of malnutrition in archaeological remains. Malnutrition is a general state that may cause more than one pathological condition in the same individual, and it may also be accompanied by other disease conditions, making the pathological profile complex and confusing. For example, scurvy and rickets may appear together (Follis, Jackson, and Park 1940), or scurvy may be associated with iron-deficiency anemia (Goldberg 1963).

All of these issues place significant limitations on reconstructing nutritional problems in antiquity. However, emerging research methods, such as stable isotope analysis and bone histology, evidence from related fields, such as dental pathology, and new areas of research concentration, such as infant skeletal studies, may provide additional data. Analysis of stable isotopes of human bone collagen allows us to determine the balance of food sources between terrestrial animal, marine animal, and plant materials (Katzenberg 1992). Isotope analysis of human hair may provide a more refined breakdown of plant materials eaten over a much shorter period than the 25 to 30 years that bone collagen analysis provides (White 1993: 657). C. D. White (1993: 657), working on prehistoric human remains from Nubia, has claimed that isotopic analysis of hair points to a seasonal difference between consumption of plants such as wheat, barley, and most fruits and vegetables and consumption of the less nutritious plants such as sorghum and millet.

Analysis of bone histology by M. Schultz and fellow workers (Schultz 1986, 1990, 1993; Carli-Thiele and Schultz 1994; Schultz and Schmidt-Schultz 1994) has identified features that assist in differential diagnosis in archaeological human skeletal remains. In one study of human remains from an Early Bronze Age (2500 to 2300 B.C.) cemetery in Anatolia, Schultz (1993: 189) detected no anatomical evidence of rickets in an infant sample. However, microscopic examination revealed a rickets prevalence of 4 percent.

Dental paleopathology provides an additional dimension to understanding nutritional problems. For example, caries rate and location may help identify what type of food was eaten (e.g., Littleton and Frohlich 1989, 1993; Meiklejohn and Zvelebil 1991). Enamel hypoplasias, which are observable defects in dental enamel, may provide information about timing and severity of nutritional stress (Goodman, Martin, and Armelagos 1984; Goodman 1991; Meiklejohn and Zvelebil 1991). Patterns of antemortem tooth loss may suggest whether an individual suffered from a nutritional disease, such as scurvy (Maat 1986: 158), or excess calculus or poor dental hygiene (Lukacs 1989).

Thorough analysis of skeletons of infants and children, which until recently has received minimal attention, can also provide valuable information on the health of a population. Indeed, because of a child's rapid growth and consequent need for optimal nutrition, immature skeletons will reflect the nutritional status of a population better than those of adults. This is especially the case with diseases such as scurvy, rickets, and iron-deficiency anemia, whose impact is greatest on children between the ages of 6 months and 2 years (Stuart-Macadam 1989a: 219).

In this chapter, we discuss skeletal abnormalities associated with nutritional diseases for which there is archaeological skeletal evidence in various geographical areas and time periods in the Old World. These diseases are: vitamin D deficiency, vitamin C deficiency, iron deficiency, fluorosis, and protein–calorie deficiency. We will focus on anatomical evidence of nutritional disease but will include other types of evidence as it occurs. For a discussion of the pathogenesis of these diseases we refer the reader to other sources (Ortner and Putschar 1981; Resnick and Niwayama 1988).

Vitamin D Deficiency

Vitamin D deficiency causes rickets in children and osteomalacia in adults. In general, these conditions should be rare in societies where exposure to sunlight is common, as the body can synthesize vitamin D precursors with adequate sunlight. In fact, there has been some speculation that rickets will not occur in areas of abundant sunlight (Angel 1971: 89). Cultural factors, however, may intervene. The use of concealing clothing such as veils, the practice of long-term sequestration of women *(purdah),* or the swaddling of infants (Kuhnke 1993: 461) will hinder the synthesis of vitamin D. Thus, in modern Asia both rickets and osteomalacia have been reported, with the condition attributed to culturally patterned avoidance of sunlight (Fallon 1988: 1994). In the Near East and North Africa cases of rickets have been reported in large towns and sunless slums (Kuhnke 1993: 461).

Vitamin D is critical to the mineralization of bone protein matrix. If the vitamin is not present during bone formation, the protein matrix does not mineralize. Turnover of bone tissue is most rapid during the growth phase, and in rickets much of the newly forming protein matrix may not be mineralized. This compromises biomechanical strength; bone deformity may occur, especially in the weight-bearing limbs, and may be apparent in archaeological human remains.

In the active child, the deformity tends to be in the extremities, and its location may be an indication of when the individual suffered from this disease. Deformities that are restricted to the upper limbs may indicate that the child could not yet walk (Ortner and Putschar 1981: 278), whereas those that show bowing of both the upper and lower limbs may be indicative of chronic or recurring rickets (Stuart-Macadam 1989b: 41). Bowing limited to the long bones of the lower extremities would indicate that rickets had become active only after the child had started walking (Ortner and Putschar 1981: 278).

There is a relatively rare form of rickets that is not caused by a deficiency in dietary vitamin D. Instead, this condition results from the kidneys' failure to retain phosphorus (Fallon 1988: 1994), and as phosphate is the other major component of bone mineral besides calcium, the effect is deficient mineralization as well. This failure may be caused by a congenital defect in the kidneys or by other diseases affecting the kidneys. The importance of nondietary rickets to this chapter is that the anatomical manifestations in the skeleton are indistinguishable from those caused by vitamin D deficiency.

The adult counterpart of rickets in the skeletal record is osteomalacia, whose expression requires an even more severe state of malnutrition (Maat 1986: 157). Women are vulnerable to osteomalacia during pregnancy and lactation because their need for calcium is great. If dietary calcium is deficient, the developing fetus will draw on calcium from the mother's skeleton. If vitamin D is also deficient, replacement of the mineral used during this period will be inhibited even if dietary calcium becomes available. As in rickets, biomechanical strength of bone may be inadequate, leading to deformity. This deformity is commonly expressed in the pelvis as biomechanical forces from the femoral head compress the anteroposterior size of the pelvis and push the acetabula into the pelvic canal.

Undisputed anatomical evidence of rickets or osteomalacia in archaeological remains is uncommon for several reasons. First, criteria for diagnosis of these conditions in dry bone specimens have not been clearly distinguished from some skeletal manifestations of other nutritional diseases such as scurvy or anemia. Second, reports on cases of rickets are often based on fairly subtle changes in the shape of the long bones (Bennike 1985: 210, 213; Grmek 1989: 76), which may not be specific for this condition. Third, cases of rickets that are associated with undernourishment are difficult to recognize because growth may have stopped (Stuart-Macadam 1989b: 41).

A remarkable case from a pre-Dynastic Nubian site illustrates the complexity of diagnosis in archaeological human remains. The case has been described by J. T. Rowling (1967: 277) and by D. J. Ortner and W. G. J. Putschar (1981: 284–7). The specimen exhibits bending of the long bones of the forearm, although the humeri are relatively unaffected. The long bones of the lower extremity also exhibit bending, and the pelvis is flattened in the anteroposterior axis. All these features support a diagnosis of osteomalacia, but the specimen is that of a male, so the problem cannot be associated with nutritional deficiencies that can occur during childbearing. An additional complicating feature is the extensive development of abnormal bone on both femora and in the interosseous areas of the radius/ulna and tibia/fibula. This is not typical of osteomalacia and probably represents a pathological complication in addition to vitamin D deficiency.

Cases of rickets have been reported at several archaeological sites in Europe for the Mesolithic period (Zivanovic 1975: 174; Nemeskéri and Lengyel 1978: 241; Grimm 1984; Meiklejohn and Zvelebil 1991), and the later Bronze Age (Schultz 1990: 178, 1993; Schultz and Schmidt-Schultz 1994). Reports of possible cases have also been recorded in the Middle East as early as the Mesolithic period (Macchiarelli 1989: 587). There may be additional cases in the Neolithic period (Röhrer-Ertl 1981, as cited in Smith, Bar-Yosef, and Sillen 1984: 121) and at two sites in Dynastic Egypt (Ortner and Putschar 1981: 285; Buikstra, Baker, and Cook 1993: 44–5). In South Asia, there have been reports of rickets from the Mesolithic, Chalcolithic, and Iron Age periods (Lovell and Kennedy 1989: 91). Osteomalacia has been reported for Mesolithic sites in Europe (Nemeskéri and Lengyel 1978: 241) and in the Middle East (Macchiarelli 1989: 587).

Vitamin C Deficiency

Vitamin C (ascorbic acid) deficiency causes scurvy, a condition that is seen in both children and adults. Because humans cannot store vitamin C in the body, regular intake is essential. As vitamin C is abundant in fresh fruits and vegetables and occurs in small quantities in uncooked meat, scurvy is unlikely to occur in societies where such foods are common in the diet year-round. Historically, vitamin C deficiency has been endemic in northern and temperate climates toward the end of winter (Maat 1986: 160). In adults, scurvy is expressed only after four or five months of total deprivation of vitamin C (Stuart-Macadam 1989b: 219–20).

Vitamin C is critical in the formation of connective tissue, including bone protein and the structural proteins of blood vessels. In bone, the lack of vitamin C may lead to diminished bone protein (osteoid) formation by osteoblasts. The failure to form osteoid results in the abnormal retention of calcified cartilage, which has less biomechanical strength than normal bone. Fractures, particularly at the growth plate, are a common feature. In blood vessel formation the vessel walls may be weak, particularly in young children. This defect may result in bleeding from even minimal trauma. Bleeding can elevate the periosteum and lead to the formation of abnormal subperiosteal bone. It can also stimulate an inflammatory response resulting in abnormal bone destruction or formation adjacent to the bleeding.

Reports of scurvy in archaeological human remains are not common for several reasons. First, evidence of scurvy is hard to detect. For example, if scurvy is manifested in the long bones of a population, the frequency will probably represent only half of the actual cases (Maat 1986: 159). Second, many of the anatomical features associated with scurvy are as yet poorly understood, as is illustrated by an unusual type and distribution pattern of lesions being studied by Ortner. The pattern occurs in both Old and New World specimens in a variety of stages of severity (e.g., Ortner 1984). Essentially, the lesions are inflammatory and exhibit an initial stage that tends to be destructive, with fine porous holes penetrating the outer table of the skull. In later stages the lesions are proliferative but tend to be porous and resemble lesions seen in the anemias. However, the major distinction from the anemias is that the diploë is not involved in the scorbutic lesions and the anatomical distribution in the skull tends to be limited to those areas that lie beneath the major muscles associated with chewing – the temporalis and masseter muscles.

An interesting Old World case of probable scurvy is from the cemetery for the medieval hospital of St. James and St. Mary Magdalene in Chichester, England. Throughout much of the medieval period the hospital was for lepers. As leprosy declined in prevalence toward the end of the period, patients with other ailments were admitted.

The specimen (Chichester burial 215) consists of the partial skeleton of a child about 6 years old, probably from the latter part of the medieval period. The only evidence of skeletal pathology occurs in the skull, where there are two types of lesion. The first type is one in which fine holes penetrate the compact bone with no more than minimal reactive bone formation. This condition is well demonstrated in bone surrounding the infraorbital foramen, which provides a passageway for the infraorbital nerve, artery, and vein. In the Chichester child there are fine holes penetrating the cortical bone on the margin of the foramen (Figure I.2.1) with minimal reactive bone formation. The lesion is indicative of chronic inflammation that could have been caused by blood passing through the walls of defective blood vessels.

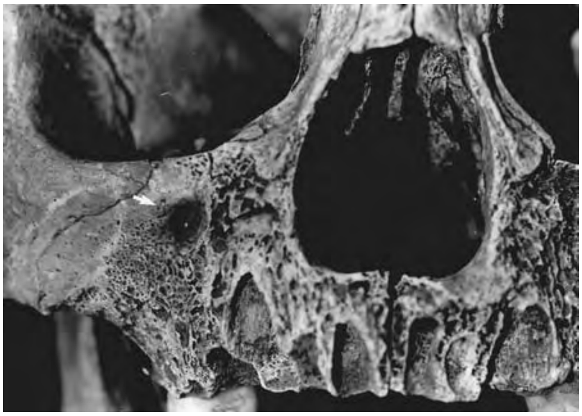

Figure I.2.1. External view of the maxilla of a child about 6 years of age at the time of death. The right infra-orbital foramen exhibits an area of porosity (arrow) with slight evidence of reactive bone formation. Below the foramen is an area of postmortem bone loss that is unrelated to the antemortem porosity. This burial (no. 215) is from the cemetery of the medieval Hospital of St. James and St. Mary Magdalene in Chichester, England.

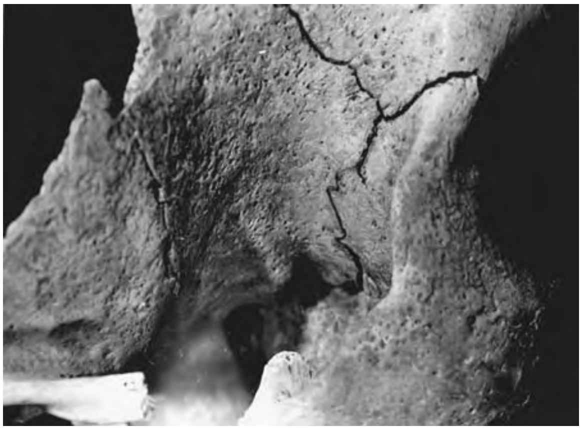

Figure I.2.2. Right sphenoid and adjacent bone surfaces of case seen in Figure I.2.1. Note the abnormal porosity of cortical bone.

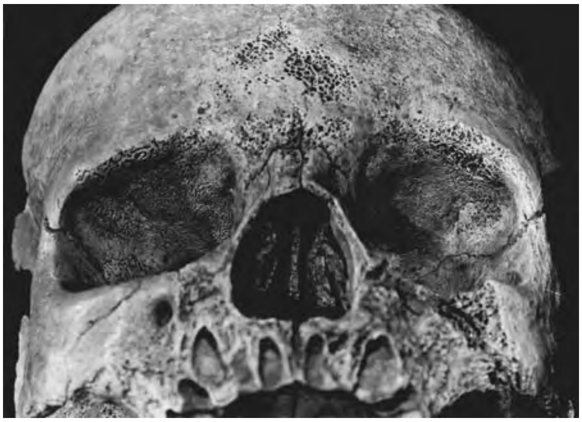

Figure I.2.3. Orbital roof of case seen in Figure I.2.1. Note the enlarged, irregular, and porous surface.

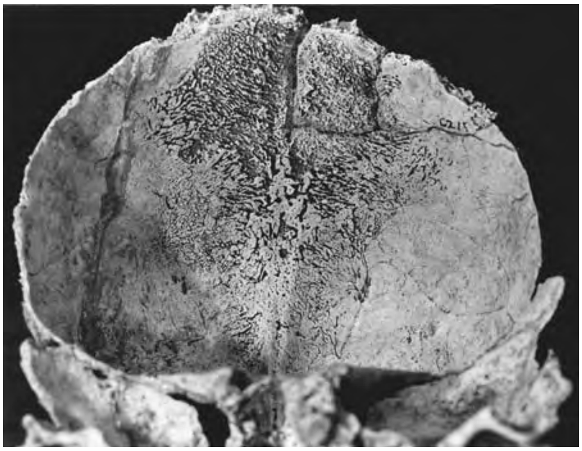

Figure I.2.4. Inner table of the frontal bone of case seen in Figure I.2.1. Note the large area of porous new bone formation.

Another area of porosity is apparent bilaterally on the greater wing of the sphenoid and adjacent bone tissue (Figure I.2.2). This area of porosity underlies the temporalis muscle, which has an unusual vascular supply that is particularly vulnerable to mild trauma and bleeding from defective blood vessels.

The second type of lesion is characterized by porous, proliferative lesions and occurs in two areas. One of these areas is the orbital roof (Figure I.2.3). At this site, bilateral lesions, which are superficial to the normal cortex, are apparent. The surfaces of the pathological bone tissue, particularly in the left orbit, seem to be filling in the porosity, suggesting that recovery from the pathological problem was in progress at the time of death.

The second area of abnormal bone tissue is the internal cortical surface of the skull, with a particular focus in the regions of the sagittal and transverse venous sinuses (Figure I.2.4). Inflammation, perhaps due to chronic bleeding between the dura and the inner table because of trauma to weakened blood vessels, is one possible explanation for this second type of lesion, particularly in the context of lesions apparent in other areas of the skull.

The probable diagnosis for this case is scurvy, which is manifested as a bone reaction to chronic bleeding from defective blood vessels. This diagnosis is particularly likely in view of the anatomical location of the lesions, although there is no evidence of defective bone tissue in the growth plates of the long bones (trümmerfeld zone) as one would expect in active scurvy. However, this may be the result of partial recovery from the disease as indicated by the remodeling in the abnormal bone tissue formed on the orbital roof.

The Chichester case provides probable evidence of scurvy in medieval England. C. A. Roberts (1987) has reported a case of possible scurvy from a late Iron Age or early Roman (100 B.C. to A.D. 43) site in Beckford, Worcestershire, England. She described an infant exhibiting porous proliferative orbital lesions and reactive periostitis of the long bones. Schultz (1990: 178) has discussed the presence of infantile scurvy in Bronze Age sites in Europe (2200 to 1900 B.C.) and in Anatolia (2500 to 2300 B.C.) (Schultz and Schmidt-Schultz 1994: 8). In South Asia pathological cases possibly attributable to infantile scurvy have been reported in Late Chalcolithic/Iron Age material (Lukacs and Walimbe 1984: 123).

Iron Deficiency

Iron deficiency is today a common nutritional problem in many parts of the world. Two-thirds of women and children in developing countries are iron deficient (Scrimshaw 1991: 46). However, physical evidence for this condition in antiquity remains elusive, and detection of trends in space and time remain inconclusive.

There are two general types of anemia that affect the human skeleton. Genetic anemias, such as sickle cell anemia and thalassemia, are caused by defects in red blood cells. Acquired anemias may result from chronic bleeding (such as is caused by internal parasites), or from an infection that will lead to a state of anemia (Stuart-Macadam 1989a; Meiklejohn and Zvelebil 1991: 130), or from an iron-deficient diet. Deficient dietary iron can be the result of either inadequate intake of iron from dietary sources or failure to absorb iron during the digestion of food.

Iron is a critical element in hemoglobin and important in the transfer and storage of oxygen in the red blood cells. Defective formation of hemoglobin may result in an increased turnover of red blood cells; this greatly increases demand for blood-forming marrow. In infants and small children the space available for blood formation is barely adequate for the hematopoietic marrow needed for normal blood formation. Enlargement of hematopoietic marrow space can occur in any of the bones. In long bones, marrow may enlarge at the expense of cortical bone, creating greater marrow volume and thinner cortices. In the skull, anemia produces enlargement of the diploë, which may replace the outer table, creating very porous bone tissue known as porotic hyperostosis. Porotic hyperostosis is a descriptive term first used by J. L. Angel in his research on human remains in the eastern Mediterranean (1966), where it is a well-known condition in archaeological skeletal material. Porotic enlargement of the orbital roof is a specific form of porotic hyperostosis called cribra orbitalia. The presence of both these conditions has been used by paleopathologists to diagnose anemias in archaeological human remains.

Attributing porotic hyperostosis to anemia should be done with caution for several reasons. First, diseases other than anemia (i.e., scurvy, parasitic infection, and rickets) can cause porotic enlargement of the skull. There are differences in pathogenesis that cause somewhat different skeletal manifestations, but overlap in pathological anatomy is considerable. Second, as mentioned previously, some diseases such as scurvy may occur in addition to anemia. Because both diseases cause porotic, hypertrophic lesions of the skull, careful anatomical analysis is critical. Finally, attributing porotic hyperostosis to a specific anemia, such as iron-deficiency anemia, is problematic. On the basis of anatomical features alone, it is very difficult to distinguish the bone changes caused by lack of iron in the diet from bone changes caused by one of the genetic anemias. These cautionary notes are intended to highlight the need for care in interpreting published reports of anemia (and other diseases caused by malnutrition), particularly when a diagnosis of a specific anemia is offered.

Angel (1966, 1972, 1977) was one of the earliest observers to link porotic hyperostosis in archaeological human remains to genetic anemia (thalassemia). He argued that thalassemia was an adaptive mechanism in response to endemic malaria in the eastern Mediterranean. The abnormal hemoglobin of thalassemia, in inhibiting the reproduction of the malarial parasite, protects the individual from severe disease.

As indicated earlier, in malarial regions of the Old World, such as the eastern Mediterranean, it may be difficult to differentiate porotic hyperostosis caused by genetic anemia from dietary anemia. However, in nonmalarial areas of the Old World, such as northern Europe, this condition is more likely to be caused by nongenetic anemia such as iron-deficiency anemia.

Because determining the probable cause of anemia is so complex, few reports have been able to provide a link between porotic hyperostosis and diet. In prehistoric Nubian populations, poor diet may have been one of the factors that led to iron-deficiency anemia (Carlson et al. 1974, as cited in Stuart-Macadam 1989a: 219). At Bronze Age Toppo Daguzzo in Italy (Repetto, Canci, and Borgogni Tarli 1988: 176), the high rate of cribra orbitalia was, possibly, caused by nutritional stress connected with weaning. At Metaponto, a Greek colony (c. 600 to 250 B.C.) in southern Italy noted for its agricultural wealth, the presence of porotic hyperostosis, along with other skeletal stress markers, indicated to researchers that the colony had nutritional problems (Henneberg, Henneberg, and Carter 1992: 452). It has been suggested that specific nutrients may have been lacking in the diet.

Fluorosis

Fluorosis as a pathological condition occurs in geographical regions where excessive fluorine is found in the water supply. It may also occur in hot climates where spring or well water is only marginally high in fluoride, but people tend to drink large amounts of water, thereby increasing their intake of fluoride. In addition, high rates of evaporation may increase the concentration of fluoride in water that has been standing (Littleton and Frohlich 1993: 443). Fluorosis has also been known to occur where water that contains the mineral is used to irrigate crops or to prepare food, thereby increasing the amount ingested (Leverett 1982, as cited in Lukacs, Retief, and Jarrige 1985: 187).

In the Old World, fluorosis has been documented in ancient populations of Hungary (Molnar and Molnar 1985: 55), India (Lukacs et al. 1985: 187), and areas of the Arabian Gulf (Littleton and Frohlich 1993: 443).

Fluorosis is known primarily from abnormalities of the permanent teeth, although the skeleton may also be affected. If excessive fluorine is ingested during dental development, dentition will be affected in several ways, depending upon severity. J. Littleton and B. Frohlich (1989: 64) observed fluorosis in archaeological specimens from Middle Bronze Age and Islamic periods in Bahrain. They categorized their findings into four stages of severity: (1) normal or translucent enamel, (2) white opacities on the enamel, (3) minute pitting with brownish staining, and (4) finally, more severe and marked pitting with widespread brown to black staining of the tooth. They noted that about 50 percent of the individuals in both the Bronze Age and the Islamic periods showed dental fluorosis (1989: 68).

Other cases of dental fluorosis have been reported in the archaeological record. At a site in the Arabian Gulf on the island of Umm an Nar (c. 2500 B.C.), Littleton and Frohlich (1993: 443) found that 21 percent of the teeth excavated showed signs of fluorosis. In Hungary, S. Molnar and I. Molnar (1985) reported that in seven skeletal populations dated from late Neolithic to late Bronze Age (c. 3000 B.C. to c. 1200 B.C.), "mottled" or "chalky" teeth suggestive of fluorosis appeared. The frequencies varied from 30 to 67 percent of individuals (Molnar and Molnar 1985: 60). In South Asia, J. R. Lukacs, D. H. Retief, and J. F. Jarringe (1985: 187) found dental fluorosis at Early Neolithic (c. 7000 to 6000 B.C.) and Chalcolithic (c. 4000 to 3000 B.C.) levels at Mehgarh.

In order for fluoride to affect the skeletal system, the condition must be long-standing and severe (Flemming Møller and Gudjonsson 1932; Sankaran and Gadekar 1964). Skeletal manifestations of fluorosis may involve ossification of ligament and tendon tissue at their origin and insertion (Figure I.2.5). However, other types of connective tissue may also be ossified, such as the tissue at the costal margin of the ribs. Connective tissue within the neural canal is involved in some cases, reducing the space needed for the spinal cord and other neurological pathways. If severe, it can cause nerve damage and paralysis.

Fluorosis may also affect mineralization of osteoid during osteon remodeling in the microscopic structure of bone (Figure I.2.6a). In contrast with the ossification of ligament and tendon tissue, excessive fluorine inhibits mineralization of osteoid at the histological level of tissue organization. It is unclear why, in some situations, fluorosis stimulates abnormal mineralization, yet in other situations, it inhibits mineralization. In microradiographs, inhibited mineralization is seen as a zone of poor mineralization (Figure I.2.6b).

Examples of archaeological fluorosis of bone tissue are rare. However, in Bahrain, excavations from third to second millennium B.C. burial mounds have revealed the full range of this disease (Frohlich, Ortner, and Al-Khalifa 1987/88). In addition to dental problems, skeletons show ossification of ligaments and tendons, and some exhibit ossification of connective tissue within the neural canal. The most severe case is that of a 50-year-old male who had a fused spine in addition to large, bony projections in the ligament attachments of the radius and ulna and tibia and fibula. Chemical analysis indicates almost 10 times the normal levels of fluorine in bone material.

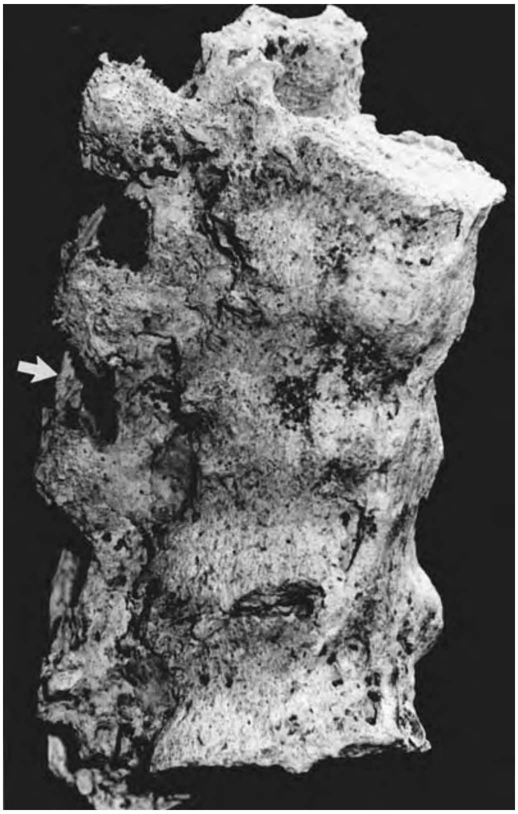

Figure I.2.5. Right lateral view of the ninth through the twelfth thoracic vertebrae from the skeleton of a male about 45 years of age at the time of death. Note the fusion of the vertebral bodies and the ossification of the interspinous ligaments (arrow). Burial (B South 40) is from the Early Bronze Age (c. 2100 B.C.) site of Madinat Hamad in Bahrain.

Protein–Energy Malnutrition

Protein–energy malnutrition (PEM), or protein–calorie deficiency, covers a range of syndromes from malnutrition to starvation. The best-known clinical manifestations are seen in children in the form of kwashiorkor (a chronic form that is caused by lack of protein) and marasmus (an acute form where the child wastes away) (Newman 1993: 950). PEM occurs in areas of poverty, with its highest rates in parts of Asia and Africa (Newman 1993: 954).

PEM has no specific skeletal markers that enable us to identify it in skeletal remains. It affects the human skeleton in different ways, depending on severity and age of occurrence. During growth and development it may affect the size of the individual so that bones and teeth are smaller than normal for that population. There may be other manifestations of PEM during this growth period, such as diminished sexual dimorphism, decreased cortical bone thickness, premature osteoporosis (associated with starvation),

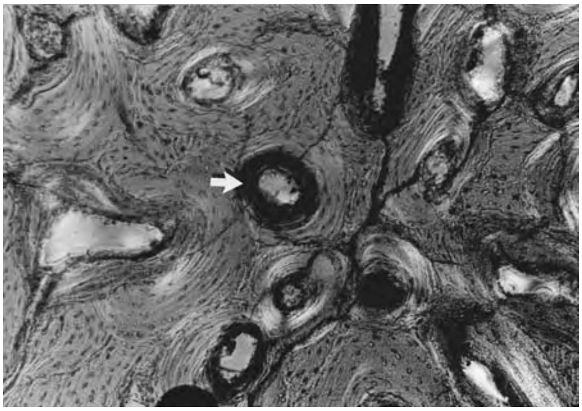

Figure I.2.6a. Photomicrograph of a bone section from the femur of the burial seen in Figure I.2.5. The dark zone (arrow) in several osteons is an area of poor mineralization caused by the toxic effects of excessive fluorine, approximately 125× before reduction.

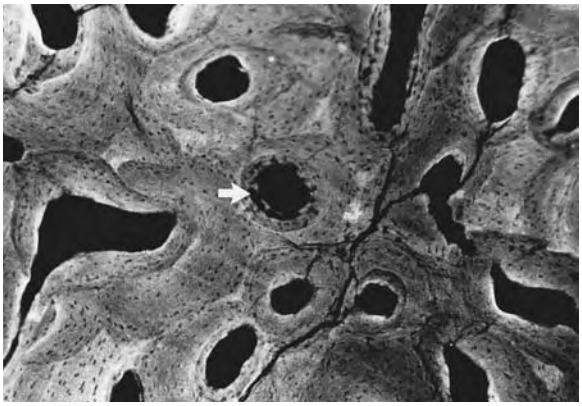

Figure I.2.6b. Photomicrograph of a microradiograph of the bone section seen in Figure I.2.6a. Note the areas of low density (dark to black) that correspond to the dark areas seen in Figure I.2.6a. The arrow indicates one of these areas.

enamel hypoplasias, and Harris lines. Because malnutrition decreases the immune response to infection, a high rate of infection may also indicate nutritional problems. Unfortunately, most of the indicators of growth problems in malnutrition occur in other disease syndromes as well; thus, careful analysis of subtle abnormalities in skeletal samples is needed. Chemical and histological analyses provide supporting evidence of abnormal features apparent anatomically.

PEM is probably as old as humankind (Newman 1993: 953). Written records in the Old World over the past 6,000 years have alluded to frequent famines. Beginning around 4000 B.C. and ending around 500 B.C., the Middle East and northeastern Africa, specifically the Nile and Tigris and Euphrates river valleys, were "extraordinarily famine prone" (Dirks 1993: 162). The skeletal evidence in archaeological remains is based on a number of skeletal abnormalities that, observers have concluded, are the result of nutritional problems.

Several studies suggesting problems with nutrition have been undertaken in northeastern Africa. In reviewing 25 years of work done on prehistoric Nubian skeletal material, G. J. Armelagos and J. O. Mills (1993: 10–11) noted that reduced long bone growth in children and premature bone loss in both children and young women were due to nutritional causes, specifically to impaired calcium metabolism. One of the complications of PEM in modern populations is thought to be interference with the metabolism of calcium (Newman 1993: 953). In Nubia, reliance on cereal grains such as barley, millet, and sorghum, which are poor sources of calcium and iron, may have been a major factor in the dietary deficiency of the population (Armelagos and Mills 1993: 11). In a later Meroitic site (c. 500 B.C. to A.D. 200) in the Sudan, E. Fulcheri and colleagues (1994: 51) found that 90 percent of the children's skeletons (0 to 12 years old) showed signs of growth disturbances or nutritional deficiencies.

There are signs of malnutrition from other areas and time periods as well. In the Arabian Gulf, the Mesolithic necropolis (c. 3700 to 3200 B.C.) of Ra's al Hamra revealed skeletal remains of a population under "strong environmental stress" with numerous pathologies, including rickets, porotic hyperostosis, and cribra orbitalia (Macchiarelli 1989). In addition, indications of growth disturbances in the form of a high rate of enamel hypoplasias and a low rate of sexual dimorphism have led to the conclusion that part of this stress was nutritional (Coppa, Cucina, and Mack 1993: 79). Specifically, the inhabitants may have suffered from protein–calorie malnutrition (Macchiarelli 1989: 587).

At Bronze Age (third millennium B.C.) Jelsovce in Slovakia, M. Schultz and T. H. Schmidt-Schultz (1994: 8) found "strong evidence of malnutrition" for the infant population, but noted that the relatively high frequency of enamel hypoplasia, anemia, rickets, and scurvy, in addition to infection, was not typical for the Bronze Age. Nutritional stress has also been suggested by the presence of premature osteoporosis among the pre-Hispanic inhabitants of the Canary Islands (Reimers et al. 1989; Martin and Mateos 1992) and among the population of Bronze Age Crete (McGeorge and Mavroudis 1987).

Conclusion

A review of the literature combined with our own research and experience leaves no doubt in our minds that humans have had nutritional problems extending at least back into the Mesolithic period. We have seen probable evidence of vitamin C deficiency, vitamin D deficiency, iron-deficiency anemia, fluorosis, and protein–energy malnutrition. However, because the conditions that cause malnutrition may be sporadic or even random, they vary in expression in both time and space. The prevalence of nutritional diseases may be due to food availability that can be affected by local or seasonal environment. For example, crop failure can result from various factors, such as shortage of water or overabundance of pests. Other nutritional problems can be caused by idiosyncratic circumstances such as individual food preferences or specific cultural customs.

Culture affects nutrition in influencing the foods that are hunted, gathered, herded, or cultivated, as well as the ways they are prepared for consumption. Cultural traditions and taboos frequently dictate food choices. All these variables affecting nutrition, combined with differences in observers and the varying methodologies they use in studying ancient human remains, make finding diachronic patterns or trends in human nutrition difficult.

Whether or not humankind benefited from or was harmed by the epochal changes in the quality and quantity of food over the past 10,000 years is, in our opinion, still open to debate. Many studies of skeletal remains conclude that the level of health, as indicated by nutrition, declined with the change from the Mesolithic hunter-gatherer way of life to the later period of developed agriculture. M. N. Cohen and G. J. Armelagos (1984a: 587), in summing up the results of a symposium on the paleopathology of the consequences of agriculture, noted that studies of both the Old and New Worlds provided consistent evidence that farming was accompanied by a decline in the quality of nutrition. Other, more recent studies have indicated agreement with this conclusion. A. Agelarakis and B. Waddell (1994: 9), working in southwestern Asia, stated that skeletal remains from infants and children showed an increase in dietary stress during the agricultural transition. Similarly, N. C. Lovell and K. A. R. Kennedy (1989: 91) observed that signs of nutritional stress increased with farming in South Asia.

By contrast, however, in a thorough review of well-studied skeletal material from Mesolithic and Neolithic Europe, C. Meiklejohn and M. Zvelebil (1991) found unexpected variability in the health status of populations connected with the Mesolithic–Neolithic transition. Part of this variability was related to diet, and they concluded that for Europe, no significant trends in health were visible in the skeletons of those populations that made the transition from hunting and gathering to greater dependence on agriculture, and from mobile to relatively sedentary communities. Although some differences between specific areas (i.e., the western Mediterranean and northern and eastern Europe) seem to exist, deficiencies in sample size mean that neither time- nor space-dependent patterns emerge from their review of the existing data. Clearly, different observers interpret evidence on the history of nutritional diseases in somewhat different ways. This is not surprising given the nature of the data. The questions about the relationship of malnutrition to changes in time and space remain an important scientific problem. Additional studies on skeletal material, particularly those that apply new biochemical and histological methods, offer the promise of a clearer understanding of these issues in the near future.

Donald J. Ortner
Gretchen Theobald

Research support for D. J. Ortner was provided by grants from the Smithsonian Scholarly Studies Program (fund no. 1233S40C). The assistance of Agnes Stix, in preparation of photographic illustrations, and editing, and Janet T. Beck for editing, Department of Anthropology, National Museum of Natural History, is deeply appreciated.

I.3. Dietary Reconstruction As Seen in Coprolites

The question of prehistoric dietary practices has become an important one. Coprolites (desiccated or mineralized feces) are a unique resource for analyzing prehistoric diet because their constituents are mainly the undigested or incompletely digested remains of food items that were actually eaten. Thus they contain direct evidence of dietary intake (Bryant 1974b, 1990; Spaulding 1974; Fry 1985; Scott 1987; Sobolik 1991a, 1994a, 1994b). In addition they can reveal important information on the health, nutrition, possible food preparation methods, and overall food economy and subsistence of a group of people (Sobolik 1991b; Reinhard and Bryant 1992).

Coprolites are mainly preserved in dry, arid environments or in the frozen arctic (Carbone and Keel 1985). Caves and enclosed areas are the best places for preserved samples and there are also samples associated with mummies. Unfortunately, conditions that help provide such samples are not observed in all archaeological sites.

Coprolite analysis is important in the determination of prehistoric diets for two significant reasons. First, the constituents of a coprolite are mainly the remains of intentionally eaten food items. This type of precise sample cannot be replicated as accurately from animal or plant debris recovered from archaeological sites. Second, coprolites tend to preserve small, fragile remains, mainly because of their compact nature, which tends to keep the constituents separated from the site matrix. These remains are typically recovered by normal coprolitic processing techniques, which involve screening with micron mesh screens rather than the larger screens used during archaeological excavations.

The limitations of coprolites are also twofold (Sobolik 1994a). First, even though the analysis of coprolites indicates the ingestion of food items, their constituents do not contain the entire diet of an individual or a population. In fact, because the different food items ingested pass through the digestive system at different rates, coprolite contents do not reflect one specific meal. The problem with coprolites is that they contain the indigestible portion of foods. The actual digested portion has been absorbed by the body. Thus, it has been estimated that meat protein may be completely absorbed during the digestion process, often leaving few traces in the coprolite (Fry 1985). However, recent protein residue analyses conducted on coprolites have indicated that some protein may survive (Newman et al. 1993).

A second limitation is that coprolites can reflect seasonal or short-term dietary intake. Individual coprolites often reflect either items a person ate earlier that day or what may have been eaten up to a month before (Williams-Dean 1978; Sobolik 1988). Thus, determining year-round dietary intake using coprolites, even with a large sample, becomes risky and inconclusive.

The History of Coprolite Research

The first observations of coprolites were those from animals of early geologic age; the Cretaceous in England (Mantell 1822; Agassiz 1833–43) and North America (Dekay 1830); the Lower Jurassic in England (Buckland 1829); and the Eocene in France (Robert 1832–33). Later works in North America include coprolites of the ground sloth (Laudermilk and Munz 1934, 1938; Martin, Sabels, and Shutler 1961; Thompson et al. 1980) and other Pleistocene animals (Davis et al. 1984).

The potential of human coprolites as dietary indicators was realized by J. W. Harshberger in 1896. The first analyses, however, were not conducted until after the beginning of the twentieth century. These initial studies were conducted by G. E. Smith and F. W. Jones (1910), who examined the dried fecal remains from Nubian mummies, and by B. H. Young (1910), L. L. Loud and M. R. Harrington (1929), and Volney H. Jones (1936), who studied materials from North American caves. Early coprolite analyses also included samples from Danger Cave (Jennings 1957), sites in Tamaulipas, Mexico (MacNeish 1958), caves in eastern Kentucky (Webb and Baby 1957), and colon contents from a mummy (Wakefield and Dellinger 1936).

The processing techniques for these early analyses consisted of either cutting open the dry coprolites and observing the large, visible contents, or grinding the samples through screens, in the process breaking much of the material. Improved techniques for analyzing coprolites were later developed by Eric O. Callen and T.W. M. Cameron (1960).

Still used today, these techniques revolutionized the science of coprolite analysis. They involved rehydrating the sample in tri-sodium phosphate, a strong detergent, in order to gently break apart the materials for ease in screening. Processing with tri-sodium phosphate also allowed for the recovery of polleniferous and parasitic materials from the samples, and increased the recovery of smaller, fragile macromaterials. Direct coprolite pollen analyses were soon followed by the first published investigation conducted by Paul S. Martin and F. W. Sharrock (1964) on material from Glen Canyon. Subsequently, there have been other innovative studies (Hill and Hevly 1968; Bryant 1974a; Bryant and Williams-Dean 1975; Hevly et al. 1979).

Coprolite Constituents

Coprolites represent such an unusual data source that their analysis is usually undertaken by specialists, generally by paleoethnobotanists (Ford 1979). A thorough coprolite analysis, however, involves the identification and interpretation of all types of botanical remains (Bryant 1974b, 1986; Fry 1985), such as fiber, seeds, and pollen, as well as nonbotanical remains, such as animal bone and hair, insects, fish and reptile scales, and parasites (to name a few of the many coprolitic constituents). Some recent studies have also identified the presence of wax and lipids through gas chromatography and mass spectrometry analyses and the analysis of phytoliths (Wales, Evans, and Leeds 1991; Danielson 1993). Clearly, then, coprolite analysis covers a myriad of sciences besides paleoethnobotany.

Yet, because coprolite analyses have tended to be conducted by paleoethnobotanists, such studies have tended to focus on the botanical remains. Recently, however, researchers have realized that the botanical portion represents a biased sample of prehistoric diet, and, consequently, studies of the nonbotanical macroremains from coprolites are becoming more prevalent.

A significant early analysis that included the identification and interpretation of a variety of coprolitic constituents was conducted on 50 coprolite samples from Lovelock Cave, Nevada (Napton 1970). As a part of this investigation, Charles L. Douglas (1969) identified eight different animal species through analysis of hair content, and Lewis K. Napton and O. A. Brunetti (1969) identified feathers from a wide variety of birds, most significantly, the mud hen.

A more recent study has focused on small animal remains recovered from coprolites excavated throughout North America (Sobolik 1993). This effort indicates that animals that have been considered noncultural or site-contaminants actually served as human food (Munson, Parmalee, and Yarnell 1971; Parmalee, Paloumpis, and Wilson 1972; Smith 1975; Cordell 1977; Lyman 1982). The large number of coprolites analyzed from North America reveals direct ingestion of small animals, suggesting that small animal remains from sites do, in fact, reflect human dietary patterns, and that reptiles, birds, bats, and a large variety of rodents were an important and prevalent component of the prehistoric diet.

A variety of microremains can be analyzed from coprolites. These constituents include spores and fungi (Reinhard et al. 1989), bacteria (Stiger 1977), viruses (Williams-Dean 1978), and, recently, phytoliths (Bryant 1969; Cummings 1989). The most frequently analyzed microremains from coprolites, however, are pollen and parasites.

Pollen

Pollen is a unique resource in the analysis of coprolites because it can provide information not obtained from the macroremains. If a flower type is frequently ingested, the soft flower parts will most likely be digested. Pollen, depending on size and structure, becomes caught in the intestinal lumen, permitting it to be excreted in fecal samples for up to one month after ingestion. Therefore, the pollen content of coprolites does not reflect one meal, but can reflect numerous meals with a variety of pollen types (Williams-Dean 1978; Sobolik 1988).

Pollen in coprolites can occur through the intentional eating of flowers or seeds, through the unintentional ingestion of pollen in medicinal teas, or by the consumption of plants to which pollen adheres. Pollen, in this context, is considered "economic" because it is actually associated with food or a medicinal item. But it may also become ingested during respiration, with contaminated water supplies, and with food, especially if the food is prepared in an open area (Bryant 1974b, 1987). Such occurrences can be especially prevalent during the pollinating season of a specific plant, such as pine and oak in the spring or ragweed and juniper in the fall. Pollen, in this context, is considered "background" because it was accidentally ingested and was not associated with a particular food or medicinal item.

Pollen types are divided into insect pollinated plants (zoophilous) and wind pollinated plants (anemophilous). Insect pollinated plants produce few pollen grains and are usually insect specific to ensure a high rate of pollination. Indeed, such plants generally produce fewer than 10,000 pollen grains per anther (Faegri and Iversen 1964) and are rarely observed in the pollen record.

Wind pollinated plants, by contrast, produce large amounts of pollen to ensure pollination and are frequently found in the pollen record. The enormous quantity of pollen produced by some plants was highlighted by the study of R. N. Mack and Vaughn M.

Bryant (1974) in which they found over 50 percent *Pinus* pollen in areas where the nearest pine tree is more than 100 miles away. Knut Faegri and J. Iversen (1964) state that an average pine can produce approximately 350 million pollen grains per tree.

In coprolite analyses, this division between pollination types is essential because a high frequency of wind pollinated pollen types in a sample may indicate not diet but rather accidental ingestion from contaminated food or water supplies. A high frequency of insect pollinated pollen types, however, often indicates the intentional ingestion of food containing pollen (economic pollen), since it is unlikely that many grains of this type are accidental contaminants. Bryant (1975) has shown from field experiments that for some of the common insect pollinated types in the lower Pecos region a frequency greater than 2 percent in a coprolite suggests a strong possibility of intentional ingestion of flowers and certain seed types that still have pollen attached, and that a frequency of 10 percent should be interpreted as positive evidence of intentional ingestion.

Parasites and Nutrition

The presence of parasites observed in coprolites can help determine the amount of disease present in populations and indicate much about the subsistence and general quality of life. Examples include studies conducted by Henry J. Hall (1972) and Karl J. Reinhard (1985) in which differences were noted between the prevalence of parasitic disease in hunter-gatherers and in agriculturalists.

Agriculturalists and hunter-gatherers have very different subsistence bases and lifeways, which affect the types of diseases and parasites infecting each group. Hunter-gatherers were (and still are) mobile people who generally lived and moved in small groups and probably had limited contact with outsiders. They lived in temporary dwellings, usually moving in a seasonal pattern, and tended to enjoy a well-balanced diet (Dunn 1968). Subsistence centered on the environment and what it provided, making it the most important aspect of their existence (Nelson 1967; Hayden 1971).

Agriculturalists, by contrast, are generally sedentary and live in larger groups because of the increase in population that an agricultural subsistence base can support. Their dwellings are more permanent structures, and they have extensive contacts with groups because of a more complex society and because of extensive trading networks that link those societies.

Although population increase and sedentary agriculture seem linked, the tendency of sedentary agriculturalists to concentrate their diets largely on a single crop can adversely affect health, even though their numbers increase. Corn, for example, is known to be a poor source of iron and deficient in the essential amino acids lysine and tryptophan. Moreover, the phytic acid present in corn inhibits intestinal absorption of nutrients, all of which can lead to undernourishment and anemia (El-Najjar 1976; Walker 1985). Thus, the adoption of agriculture seems to have been accompanied by a decrease in nutritional status, although such a general proposition demands analysis in local or regional settings (Palkovich 1984; Rose et al. 1984).

Nutritional status, however, can also be affected by parasite infection, which sedentism tends to encourage (Nelson 1967). In the past, as people became more sedentary and population increased, human wastes were increasingly difficult to dispose of, poor sanitation methods increased the chances of food contamination, and water supplies were fouled (Walker 1985). Many parasites thrive in fecal material and create a breeding ground for disease. The problem is exacerbated as feces are used for fertilizer to produce larger crop yields. Irrigation is sometimes used to increase production, which promotes the proliferation of waterborne parasites and also aids the dispersal of bacteria (Cockburn 1967; Dunn 1968; Alland 1969; Fenner 1970; McNeill 1979).

In addition, as animals were domesticated they brought their own suite of parasites to the increasing pool of pathogens (Cockburn 1967; Alland 1969; Fenner 1970; McNeill 1979). And finally, the storage of grains and the disturbance of the local environment, which accompanies agricultural subsistence, can stimulate an increase in rodents and wild animals, respectively, and consequently an increase in their facultative parasites as well (Reinhard 1985).

It seems clear that the quality of the diet declined and parasite load increased as the transition was made to sedentary agriculture. This is not to say that hunter-gatherers were parasite-free. Rather, there was a parallel evolution of some parasites along with humankind's evolution from ancestral nonhuman primates to *Homo sapiens* (Kliks 1983). Then, as human mobility increased, some parasites were lost because of their specific habitat range and because of changes in environment and temperature. But as these latter changes occurred, new parasites were picked up. Probably such changes took place as humans migrated across the cold arctic environment of the Bering Strait into North America. Some parasites would have made the journey with their human hosts, whereas others were left behind (Cockburn 1967; McNeill 1979).

New Approaches to Dietary Reconstruction

Regional Syntheses

As more researchers are analyzing coprolites, regional syntheses of diet are becoming possible. Paul E. Minnis (1989), for example, has condensed a large coprolite data set from Anasazi populations in the Four Corners Region of the southwestern United States, covering a time period from Basketmaker III to Pueblo III (A.D. 500–1300). He observed that for the sample area, local resource structure seemed to be more important for determining diet than chronological differences. For example, domesticated plants, particularly corn, were a consistent dietary item from Basketmaker III to Pueblo III; and there was a "generally stable dietary regime" during the time periods studied, although small-scale changes were also noted (Minnis 1989: 559).

In another example from the Lower Pecos Region of southwestern Texas and northern New Mexico, a total of 359 coprolite samples have been studied (Sobolik 1991a, 1994b). Analysis indicates that the prehistoric populations of the region relied on a wide variety of dietary items for their subsistence. A substantial amount of fiber was provided by the diet, particularly that derived from prickly pear, onion, and the desert succulents (agave, yucca, sotol). A large number of seed and nut types were also ingested, although prickly pear and grass seeds were the most frequent. Animal remains, especially bone and fur, were also observed with a high frequency in the coprolites, indicating that these prehistoric people were eating a variety of animals (e.g., rodents, fish, reptiles, birds, and rabbits). The ingestion of an extremely wide variety of flowers and inflorescences is also indicated by the coprolite pollen data.

Significant differences were also observed in the dietary components of the coprolites. These differences might be attributable to changes in dietary practice, particularly to an increase in the variety of the prehistoric diet. A more plausible explanation, however, is that such differences are a result of the different locations of the archaeological sites from which the coprolite samples were excavated.

These sites are located on a south-north and a west-east gradient. Sites located in the southwestern portion of the region are in a dryer, more desert environment (the Chihuahuan Desert) with little access to water, whereas the sites located in the northeastern portion of the region are closer to the more mesic Edwards Plateau, which contains a diversity of plants and trees and is close to a continuous water supply. Thus, dietary change reflected in the coprolites most likely represents spatial differences rather than temporal fluctuations (Sobolik 1991a).

Nutritional Analyses

Coprolites are extremely useful in providing dietary and nutritional data, although information from botanical, faunal, and human skeletal remains is also needed in any attempt to characterize the nutrition of a prehistoric population (Sobolik 1990, 1994a). A recent study involving the nutritional analysis of 49 coprolites from Nubia was conducted by Linda S. Cummings (1989). This analysis was unique in that the coprolites were taken from skeletal remains buried in cemeteries representing two distinct time periods, including the early Christian period (A.D. 550–750) and the late Christian period (up to A.D. 1450). It is rare that prehistoric coprolites can actually be attributed to specific people, and the health of individuals can be assessed through both the coprolite remains and the human skeletal material, with one method illuminating the other.

In this case, the human skeletal material suggested that cribra orbitalia indicating anemia was the major indicator of nutritional stress. Coprolite analysis by Cummings (1989) revealed that there was probably a synergistic relationship in the diet of the population between iron-deficiency anemia and deficiencies of other nutrients, mainly folacin, vitamin C, vitamin B_6, and vitamin B_{12}. Cummings also noted differences in the diet and health of the two populations, including differences between males and females and older and younger members.

Pollen Concentration Studies

Although the determination of pollen concentration values has not been attempted in many coprolite studies, such values are important in determining which pollen types were most likely ingested. Studies show that after ingestion, pollen can be excreted for many days as the grains become caught in the intestinal folds. Experiments have also demonstrated that the concentration of intentionally ingested pollen can vary considerably in sequentially produced fecal samples (Kelso 1976; Williams-Dean 1978).

Glenna Williams-Dean (1978) conducted a modern fecal study that analyzed Brassicaceae and *Prosopis* pollen as a small component of pollen ingestion. It was revealed that Brassicaceae pollen was retained in the digestive system for much longer periods of time (up to one month after ingestion) than *Prosopis* pollen. Brassicaceae pollen is an extremely small grain with an average size of 12 micrometers (µm) and has a finely defined outer-wall sculpturing pattern. Both traits would most likely increase the retention of this pollen type in the folds of the intestine, allowing for it to be observed in many fecal samples. *Prosopis* pollen is a spherical, medium-sized grain (average size 30 µm), with a smooth exine sculpturing pattern. The larger size of this grain and the decreased resistance provided by the smooth exine would permit this pollen type to pass more quickly through the intestinal folds without retention.

In light of this study, it can be predicted that larger pollen grains, such as corn *(Zea)* and cactus (Cactaceae), and pollen with little exine sculpturing, such as juniper *(Juniperus),* will move quickly through the human digestive system. Thus, these pollen types would be observed in fewer sequential fecal samples than those of other types. By contrast, smaller pollen grains with significant exine sculpturing, such as sunflower pollen (high-spine Asteraceae), can be predicted to move more slowly through the digestive system, become frequently caught in the intestinal lumen, and thus observed in fecal samples many days after initial ingestion.

Such predictions were subsequently applied in an examination of prehistoric coprolites (Sobolik 1988). This investigation revealed that a high pollen concentration value in coprolite samples should indicate that the economic pollen types observed in the samples were ingested recently. Concentration values of over 100,000 pollen grains/gram of material usually contain recently ingested pollen. But samples that contain less than 100,000 pollen grains/gram of material may contain economic pollen types that were intentionally ingested many days before the sample was deposited (Sobolik 1988). Such samples will also contain a wide variety of unintentionally ingested, background pollen types. Therefore, it is more difficult to recognize intentionally ingested pollen types from samples that contain less than 100,000 pollen grains/gram of material.

Modern fecal studies are, thus, invaluable as guides in the interpretation of prehistoric coprolite pollen content and in indicating the limitations of the data. Many more such investigations are needed to determine both pollen percentage and concentration. The diet of the participants will have to be stringently regulated in order to minimize the influence of outside pollen contaminants, particularly those in bread and canned foods (Williams-Dean 1978). Ideally, such studies will include many people and, thus, as diverse a population of digestive systems as possible over a long period of time. An important addition to such a study would be the observance of the effect of a high-fiber and a high-meat diet on pollen output and fecal output in general.

Medicinal Plant Usage

Documenting prehistoric medicinal plant usage is problematic because it is difficult to distinguish between plants that were consumed for dietary purposes and those consumed for medicinal purposes. Indeed, in many instances plants were probably used both dietarily and medicinally.

Nonetheless, the analysis of plant remains from archaeological sites is often employed to suggest dietary and medicinal intake. Such remains can be deposited through a number of channels, most significantly by contamination from outside sources (i.e., water, wind, matrix shifts, and animals). Plants also were used prehistorically as clothing, shelter, baskets, and twining, and these, when deposited into archaeological contexts, can become mistaken for food or medicinal items. Here, then, is a reason why coprolites, which are a direct indication of diet, can provide new insights into prehistoric medicinal usage (Reinhard, Hamilton, and Hevly 1991).

In an analysis of the pollen content of 32 coprolites recovered from Caldwell Cave, Culberson County, Texas, Kristin D. Sobolik and Deborah J. Gerick (1992) revealed a direct correlation between the presence of plants useful for alleviating diarrhea and coprolites that were severely diarrhetic. This correlation suggests that the prehistoric population of Caldwell Cave was ingesting medicinal plants to help alleviate chronic diarrhea. These plants, identified through analysis of the pollen content of the coprolites, included *Ephedra* (Mormon tea) and *Prosopis (mesquite).* Interestingly, this investigation confirmed the study conducted by Richard G. Holloway (1983), which indicated that the Caldwell Cave occupants were possibly using *Ephedra* and *Larrea* (creosote bush) in medicinal teas to help cure chronic diarrhea (Holloway 1983).

Mormon tea pollen, leaves, and stems are widely used as a diarrhetic and have been one of the most prevalent medicinal remedies for diarrhea both prehistorically and historically (Burlage 1968; Niethammer 1974; Moore 1979; Moerman 1986). Mesquite leaves are also useful as a medicinal tea for stomach ailments and to cleanse the digestive system (Niethammer 1974). As part of the process of preparing mesquite leaves for a medicinal tea, pollen could also become incorporated into the sample, either intentionally or unintentionally.

In another study, Reinhard and colleagues (1991) also determined medicinal plant usage through analysis of the pollen content in prehistoric coprolites. They found that willow *(Salix),* Mormon tea *(Ephedra),* and creosote *(Larrea)* were probably used for medicinal purposes prehistorically and that a large variety of other plants may have been used as well.

Protein Residues

It was previously mentioned that analysis of protein residues in coprolites is a relatively new advance in coprolite studies (Newman et al. 1993). This method attempts to link protein residues with the type of plant or animal that was consumed and involves the immunological analysis of tiny amounts of protein through crossover electrophoresis. The unknown protein residue from the coprolites is placed in agarose gel with known antiserum from different plants and animals. The agarose gel is then placed in an electrophoresis tank with a barbital buffer at pH 8.6, and the electrophoretic action causes the protein antigens to move toward the antibody that is not affected by the electrical action. The solution, which contains the unknown protein residue, and the matching plant or animal species antiserum form a precipitate that is easily identifiable when stained with Coomassie Blue R250 solution (Kooyman, Newman, and Ceri 1992). The samples that form a precipitate indicate that the matching plant or animal was eaten by the person who deposited the coprolite sample.

Two sample sets were selected for an analysis of the protein residues found in coprolites – seven from Lovelock Cave, Nevada, and five from an open site in the Coachella Valley of southern California (Newman et al. 1993). Protein analysis of samples from the open site was not successful. But the samples from Lovelock Cave indicated that human protein residues were found in six of the samples and protein residues from pronghorns were found in four samples. Such an initial study suggests that protein residue analysis can be a successful and important component in the determination of prehistoric diet.

Gender Specificity

A new technique that will distinguish the gender of the coprolite depositor is presently being tested on coprolite samples from Mammoth and Salts Caves, Kentucky, by Patricia Whitten of Emory University. In this technique, which has been successful with primate studies, the gonadal (sex) steroids are removed from each coprolite sample and analyzed according to the content of testosterone, the male hormone, and estradiol, the female hormone. Both steroids can be found in each sample, but their frequencies vary depending upon gender. Modern human samples will first be analyzed to determine the frequencies of each gonadal steroid expected in males and females.

DNA analysis is also being attempted from coprolite samples to determine gender (Mark Q. Sutton 1994, personal communication). This type of research should allow archaeologists to determine dietary differences between males and females in a population and should also help in reconstructing the patterns of differential access to resources.

Conclusions

Reconstructing prehistoric human diets is a vast process requiring a variety of assemblages and disciplines to obtain a complete picture. Coprolite analysis provides a diverse and significant insight into the prehistoric diet. When analyzing the entire diet of a population, researchers must take into consideration information gleaned from other archaeological materials. Past coprolite research has focused on developing new and innovative techniques so that recovery of the diverse data inherent in such samples can be achieved. Such development has allowed researchers not only to observe the macrobotanical and macrofaunal remains from coprolites but also to analyze their pollen, parasite, and phytolith content.

Recent advances have seen the discipline progress toward determining medicinal plant ingestion so as to permit inter- and intraregional dietary comparisons; to determine the protein content of the samples; to analyze the nutritional content of the dietary items; and to determine the gender of the depositor of the sample. Coprolite analysis has definitely advanced out of its infancy, and its contributions to the determination of prehistoric diet, health, and nutrition in the future should prove to be significant indeed.

I.4. Animals Used for Food in the Past: As Seen by Their Remains Excavated from Archaeological Sites

Animal remains excavated from archaeological sites are, to a large extent, the remnants of animals that were used for food. These remains include the fragmentary bones and teeth of vertebrates, the shells of mollusks, the tests of echinoderms, and the exoskeletal chitin of crustacea and insects. As with all archaeological remains, they represent discarded fragments of a previous way of life.

Organic remains are particularly subject to losses from the archaeological record, through the destructive nature of food preparation and consumption, the scavenging of refuse by other animals, and the deterioration that results from mechanical and chemical forces over time. Other losses come through excavation with inappropriate sieving strategies in which the remains of smaller individuals or species are lost. Nonetheless, despite all of these opportunities for the loss and destruction of organic material, animal remains constitute a major class of the archaeological remains from most sites and in some sites, such as shell mounds, they are the most obvious of the remains. However, even among those remains that are preserved, care must be taken in evaluating the extent to which they may represent a contribution to the prehistoric diet.

One reason for such caution is that all remains recovered are not necessarily those of animals that were consumed. For example, along the Gulf coast of Mexico, dogs were definitely eaten and probably even raised for food (Wing 1978). Their remains were often burned, disarticulated, and associated with those of other food remains. But in the West Indies, complete or nearly complete skeletons of dogs are found in burials and they are rarely associated with midden refuse, suggesting that dogs were not a regular item in the diet (Wing 1991). Dogs probably have played more roles in human culture than any other animal, ranging from food animal to guardian to hunting companion to faithful friend. But other animals, too, such as chickens, cattle, and horses, have likewise played different roles and thus their archaeological remains cannot automatically be assumed to constitute only the remnants of past meals.

Another problem is that some animals that were consumed left few remains. On the one hand, these were small, soft-bodied animals such as insect larvae, and on the other hand, they were very large animals, such as sea mammals or large land mammals that were too heavy to be brought back to the habitation site. In the case of small animals, mandibles of shrimp have recently been identified in some southeastern sites in the United States through the use of fine-gauge sieves (Quitmyer 1985). This find (which was predicted) gives encouragement that other hard parts of otherwise soft-bodied animals can be found if they are carefully searched for. At the other end of the size scale, many very large animals were butchered at the kill site and only the meat was brought back to the home site, leaving little or no skeletal evidence at the latter site of this hunting enterprise.

Such a phenomenon has been termed the "schlepp effect" (Perkins and Daly 1968), which expresses the commonsense but nonetheless laborious practice of stripping the flesh off the carcass of a large animal and carrying it to the home site but leaving most of the heavy supporting tissue, the skeleton, at the kill site. Kill sites of single large prey species such as mammoths *(Mammuthus)* (Agenbroad 1984) and mass kills of bison *(Bison bison)* (Wheat 1972) have been excavated and the strategy of the kill and processing of the carcasses reconstructed. Good evidence points to the selection of prey based on its fatness and carcass use to maximize caloric intakes of the hunters (Speth 1983).

Human Adaptability

Human technology applied to food procurement and preparation is one of the factors responsible for the broad diet that sets humans apart from other animals and has made their worldwide distribution possible. Prehistoric sites with long sequences of occupation are located on every continent except Antarctica, and almost every island (Woodhouse and Woodhouse 1975). Such a wide distribution encompasses a great range of ecosystems with different potentials and limitations for human subsistence exploitation.

By contrasting the animal resources used in sites located in some of the major landforms, both the similarities and differences in the potentials of these ecosystems can be demonstrated. Some of the differences to be examined are between subsistence exploitation in sites located along rivers and on the marine coast. Other comparisons have to do with sites on continents as compared with those on islands, and subsistence in exploiting the arctic as opposed to the humid tropics.

Levels of Extraction

Different levels of extraction of animal foods from the environment obviously can affect the composition of the diet. The hunting, fishing, and gathering of resources are procurement enterprises that result in diverse food composition and variation throughout the year as different resources become available. During the great majority of human history, beginning several million years ago and extending to the time animals were controlled by domestication, the subsistence economy was based upon hunting, fishing, and gathering. Increased control over animals, whether through the maintenance of captive animals or managed hunting, culminated in animal domestication about 10,000 years ago. A comparison of economies dependent on domestic animals with those relying on wild animals for subsistence reveals a range in diversity and dependability of resources.

The Nature of Animal Remains

Nature of Material

As already noted, the remains of animals used for food consist of the supporting tissue such as bone and teeth of vertebrates, shell of mollusks, and chitin of crustaceans. These tissues are composed of inorganic and organic compounds. The relatively rigid structure of the inorganic portions predominate in bone, constituting 65 percent. In tooth enamel the inorganic portion is 99.5 percent by weight. The inorganic portions of these supporting tissues are composed of compounds of calcium.

By their very nature, skeletal remains are attractive to scavengers: Some meat and other soft tissue may have adhered to them and, in addition, bone itself is sought by many animals as a source of calcium.

Other losses of archaeological remains come about through the influence of forces of nature, termed taphonomic factors. Such natural changes include all types of site disturbances such as erosion or stream washing, land movement, alternating freezing and thawing, and acidic soil conditions. The soil conditions are particularly critical for the preservation of bone, which as a calcium compound can be dissolved in acidic conditions. Destruction of bone under acidic conditions is further complicated by the problem of bone loss being greatest in the least well calcified bones of young individuals. In contrast, losses are the smallest in the enamel portion of teeth (Gordon and Buikstra 1981). Alternating freezing and thawing is the other taphonomic factor that is particularly damaging to organic remains. Bones exposed to the sun develop cracks. When these cracks fill with moisture and then freeze, they enlarge and, ultimately, the bone will fragment into pieces that have lost their diagnostic characteristics.

If losses from the archaeological record can complicate reconstruction of the past, so too can additions to the faunal assemblage. Such additions were often animals that lived and died at the habitation site. These are known as commensal animals, the most well known being the black and the Norway rats *(Rattus rattus* and *Rattus norvegicus)* and the house mouse *(Mus musculus).* Burrowing animals such as moles *(Talpidae)* and pocket gophers *(Geomyidae)* may also dig into a site and become entombed. In addition, middens and habitation sites were occasionally used for burial, and the remains of both people and their animals (i.e., dogs) were thus inserted into earlier deposits.

Other ways in which commensal animals can be incorporated in a midden is by association with the target species. For example, many small creatures, such as mussels, snails, crabs, and barnacles, adhere to clumps of oysters and were often brought to the site on this target species. Occasionally, too, the stomach contents of a target species may contain remains of other animals, which are thus incorporated in the site.

Recovery and Identification

Optimum recovery of faunal material is clearly essential for reconstruction of past diets. In some cases, sieving the archaeological remains with 7-millimeter (mm)-gauge screens will be sufficient to recover the animal remains. But as more and more sieving experiments are conducted and archaeologists gain more and more experience using fine-gauge (2 mm and 4 mm) sieves, it is becoming increasingly obvious that fine-gauge sieves are essential for optimal recovery at most sites. A good example of this importance has to do with what was long thought to be the enigma of the preceramic monumental site of El Paraiso on the Pacific coast of Peru. This site was an enigma because early excavations there uncovered no vertebrate remains, suggesting that the local ancient residents had no animal protein in their diets. It was only when sieving with 2-millimeter-gauge sieves was undertaken that thousands of anchovy *(Engraulidae)* vertebrae were revealed. At last, the part this small schooling fish played in providing fuel for the construction of the monumental architecture was understood (Quilter et al. 1991).

Another methodological problem that needs further consideration at this site and at others is the relative contribution of vertebrates and invertebrates to the prehistoric diet. Mollusk shells are relatively more durable and less likely to be lost to scavengers than are the bones of vertebrates of similar size, which results in a bias favoring mollusks.

In evaluating the potential contribution of vertebrates and mollusks to the prehistoric diet, one must also keep in mind biases in their preservation and recovery. For example, molluskan shells are more massive relative to their edible soft tissues than are the skeletons of vertebrates to their soft tissues. Consequently, shells will be the most visible component of a shell midden even before taking into account the greater durability of shell and the fewer losses to scavengers.

One way some of these problems can be addressed is by making estimations of potential meat weight using allometric relationships between measurable dimensions of the shell or bone and meat weight. Such relationships, of course, can only be developed by using the accurate weights and measurements of modern specimens comparable to the species recovered from archaeological deposits. Knowledge of modern animals and a reference collection are the most important research tools of the faunal analyst.

First, an attempt is made to estimate the minimum weight of the meat represented by the animal remains. Next, this estimate is contrasted with the maximum estimate of the meat weight that could have been provided by the minimum number of individual animals calculated to be represented. If the two estimates are approximately the same, this implies that all of the meat from each animal was consumed at the source of the refuse. Yet if the two estimates differ substantially, it suggests that only portions of some animals were consumed at the site, with other portions distributed within the community.

The Meaning of Animal Remains Assemblages

Animal Exploitation in Different Ecosystems

Riverine versus coastal. Many similarities exist between faunal assemblages from riverine sites and those located along the coast. In each case, both vertebrate and invertebrate aquatic animals were important food sources. Furthermore, these two aquatic situations were subject to influxes of animals, either in breeding congregations or migrations, that augmented the resident fauna. Of course, aquatic species used by riverine fishermen and gatherers were different from those extracted from the sea.

Aquatic organisms, fishes and mollusks, are important in the faunal assemblages of both riverine and coastal sites. Shell mounds are more typically associated with coastal sites, although they do occur along rivers (Weselkov 1987). Riverine shell mounds are accumulations typical of the Archaic time period (about 7000 to 3000 B.P.) in eastern North America, exemplified by those found on the St. Johns River in Florida and the Green River in Kentucky (Claasen 1986). Along coastal shores, shell mounds date from Archaic times to the present.

Gathering mollusks is invariably accompanied by fishing, but the relative contribution of fish and shellfish to the diet follows no pattern. Many shell mounds are visually very impressive and, in fact, are so large that in many places these mounds have been mined for shell material to be used in modern road construction. Less visible components of these archaeological sites are the vertebrate, crustacean, and material cultural remains.

As indicated in the discussion of methods, those for reconstructing the dietary contributions of the two major components of a shell mound are still being perfected. One exciting development has been a greater understanding of the importance (as food) of very small animals in the vertebrate, predominantly fish, components of these mounds.

As already mentioned, the use of fine-gauge screen sieves in the recovery of faunal remains has provided a more accurate understanding of the size range of fishes consumed in the past. Catches of small fishes are being documented in many parts of the world. For example, at four sites in the Darling Region of Australia, otoliths of golden perch *(Maguaria ambigua)* were preserved. These could be used to extrapolate lengths of fishes caught up to 24,000 years ago (Balme 1983). The range in their estimated lengths is

8 to 50 centimeters (cm) and the mean is approximately 20 cm. The range in estimated lengths of sardines *(Sardina pilchardus)* from a fourth-century A.D. Roman amphora is between 11 and 18 cm (Wheeler and Locker 1985). Catfish *(Ariopsis felis)* and pinfish *(Lagodon rhomboides)* from an Archaic site on the southeastern Gulf coast of Florida are estimated to range in length from 4 cm to 25 cm, and the means of the catfish and pinfish are 10 cm and 12 cm, respectively (Russo 1991).

An important question has to do with how these small fishes could be eaten and yet leave skeletal remains behind. Many contemporary diets include small fishes such as sardines and anchovies in which the entire body of the fish is consumed. The answer may lie in the fact that small fishes are used in many parts of the world in the preparation of fish sauces that are made without skeletal tissue. In other words, the well-preserved, intact skeletal remains of small fishes suggest that the fishes might have been employed in sauces.

In addition to mollusks and fishes in the protein portion of a coastal and riverine diet, migratory or breeding congregations would have added significantly to the diet. A well-known example of this phenomenon is the seasonal migration of anadromous fishes such as salmon *(Salmonidae)* and herring *(Clupeidae)* (Rostlund 1952); methods of preserving and storing this seasonal surplus would also have developed.

Other examples of such exploitation include the breeding colonies of sea bird rookeries, sea turtle nesting beaches, and seal and sea lion colonies. Many of these colonies are coastal phenomena and are strictly confined to particular localities. During the breeding cycle, most animals are particularly vulnerable to predation, and people through the ages have taken advantage of this state to capture breeding adults, newborn young, and, in the cases of birds and turtles, eggs.

Unfortunately, only some of the evidence for this exploitation can be demonstrated in the archaeological remains. Egg shells are rarely preserved. Some of the breeding animals in question, like the sea mammals and the sea turtles, are very large and may have been butchered on the beach and the meat distributed throughout the community. Thus, it is difficult to assess the relative importance of these resources within a particular refuse deposit and by extension within the diet of the humans being studied.

Continental versus island. A continental fauna differs from an island fauna in its diversity of species. There is a direct relationship between island size and distance from the mainland and species diversity (MacArthur and Wilson 1967). Human exploitation on a continent can range from catches of very diverse species in regions where different habitats are closely packed, to dependence on one or two species that form herds, typically in open grasslands. On islands other than very large ones, prehistoric colonists found few species and often augmented what they did find with the introduction of domestic species as well as tame captive animals.

This kind of expansion seems to be a pattern in many parts of the world. For example, several marsupials *(Phalanger orientalis, Spilocuscus maculatus,* and *Thylogale brunii),* in addition to pigs *(Sus scrofa)* and dogs *(Canis familiaris),* were deliberately introduced into the Melanesian Islands between 10,000 and 20,000 years ago (Flannery and White 1991). Similarly, sheep (*Ovis* sp.), goats (*Capra* sp.), pigs (*Sus* sp.), and cats (*Felis* sp.) were all introduced into the Mediterranean Islands at a time when the domestication of animals was still in its initial stages. A variety of wild animals, such as hares *(Lepus europaeus),* dormice *(Glis glis),* foxes *(Vulpes vulpes),* and badgers *(Meles meles),* were also introduced into this area (Groves 1989).

Likewise, in the Caribbean Islands, domestic dogs as well as captive agouti *(Dasyprocta leporina),* opossum *(Didelphis marsupialis),* and armadillo *(Dasypus novemcinctus)* were introduced from the South American mainland, whereas the endemic hystricognath rodent locally called "hutia" *(Isolobodon portoricensis)* and an endemic insectivore *(Nesophontes edithae)* were introduced from large to small islands (Wing 1989).

Although tame animals were doubtless kept by people living on the mainland, they are not easily distinguished from their wild counterparts. But this problem is only part of an increasingly complex picture as human modifications of the environment, either overtly through landscape changes resulting from land clearing or more subtly through hunting pressure, have altered the available species on both islands and continental land masses.

Because of the generally lower species diversity on islands, exploitation of terrestrial species was augmented by marine resources. These were primarily fishes and mollusks. In the Caribbean Islands, West Indian top shell *(Cittarium pica)* and conch *(Strombus gigas),* and a whole array of reef fishes including parrotfishes (Scaridae), surgeonfishes *(Acanthuridae),* grouper (Serranidae), and jacks (Carangidae), were of particular importance.

Arctic versus humid tropics. The Arctic has long, cold, dark winters but also short summers, with long spans of daylight that stimulate a brief period of extraordinarily high plant productivity. By contrast, the humid tropics have substantially more even temperatures and lengths of daylight throughout a year that in many cases is punctuated by dry and rainy seasons. Needless to say, these very different environmental parameters have a pronounced effect on the animal populations available for human subsistence within them.

Traditional contemporary subsistence activities as well as evidence from archaeological faunal remains in the Alaskan Arctic indicate that important contributors to the human diet have been caribou *(Rangifer tarandus),* sea mammals – particularly seals *(Callorhinus ursinus* and *Phoca vitulina)* and sea lions *(Eumatopius jubata)* – seabirds, and marine fishes, primarily cod *(Gadus macrocephalus)* (Denniston 1972; Binford 1978; Yesner 1988).

Although the species of animals differ in different parts of the Arctic regions, many characteristics of a northern subsistence pertain. Foremost among these is a marked seasonal aspect to animal exploitation correlated with the migratory and breeding patterns of the Arctic fauna. Moreover, the length of time during which important animal resources, such as the anadromous fishes, are available becomes increasingly circumscribed with increased latitude (Schalk 1977). To take full advantage of this glut of perishable food, people need some means of storage. And fortunately, in a region where temperatures are below freezing for much of the year, nature provides much of the means.

Another characteristic of northern subsistence is the generally low species diversity; but this condition is counteracted by some large aggregations of individuals within the species. Still, the result is that heavy dependence is placed on a few species. At Ashishik Point an analysis of the food contribution of different animals to the prehistoric diet revealed that sea mammals and fishes predominated (Denniston 1972). Of the sea mammals, sea lions are estimated consistently to have provided the greatest number of calories and edible meat. This estimation agrees with the observation by David Yesner (1988) that dietary preference among the prehistoric Aleut hunter-gatherers was for the larger, fattier species.

The fauna of the humid tropics is much more diverse than that of the Arctic, although the tropical animals that people have used for food do not generally form the large aggregations seen in higher latitudes. Exceptions include schools of fishes, some mollusks, bird rookeries, and sea turtle breeding beaches. Many of the animals that have been exploited are relatively small. The largest animals from archaeological sites in the New World tropics are adult sea turtles *(Cheloniidae),* deer *(Mazama americana* and *Odocoileus virginianus),* and peccary *(Tayassu pecari* and *Tayassu tajacu)* (Linares and Ranere 1980). Some of the South American hystricognath rodents, such as the capybara (*Hydrochaeris* sp.), paca *(Agouti paca),* and agouti *(Dasyprocta punctata),* were used and continue to be used widely as food. Fish and shellfish were also very important components of prehistoric diets (Linares and Ranere 1980) and typically augmented those based on terrestrial plants and animals.

The kinds of land mammals that have been most frequently consumed in much of the tropics since the beginning of sedentary agriculture prompted Olga Linares (1976) to hypothesize a strategy for their capture she called "garden hunting." She suggested that many of these animals were attracted to the food available in cultivated fields and gardens and were killed by farmers protecting their crops. Objective ways of evaluating the importance of garden hunting have been proposed, which are based on the composition of the faunal assemblage (Neusius 1996).

Different Levels of Extraction

Hunting, fishing, and gathering. It has been estimated that fully 90 percent of all those who have lived on earth have done so as hunter-gatherers (Davis 1987). The animals that were procured by these individuals varied depending upon the resources available within easy access of the home site or the migratory route. But in addition to these differences in the species that were obtained and consumed, certain constraints governed what was caught, by whom, how the meat was distributed, and how it was prepared. Certainly, technology played an important part in what kinds of animals were caught on a regular basis and how the meat was prepared. Many specialized tools such as water craft, nets, traps, weirs, bows, arrows, and blowguns and darts all permitted the capture of diverse prey.

A limitation imposed on all organisms is that of energy, which meant that food procurement generally took place within what has become known as the "catchment" area (Higgs and Vita-Finzi 1972). This area is considered to be inside the boundaries that would mark a two-hour or so one-way trip to the food source. Theoretically, travel more distant than this would have required more energy than could be procured. Once animal power was harnessed, trips to a food source could be extended. However, another solution to the problem of procurement of distant resources was by adopting a mobile way of life. This might have taken the form of periodic trips from the home site or it might have been a migratory as opposed to a sedentary method of living.

In the past, as today, there was doubtless a division of labor in the food quest. It is generally thought that men did the hunting and fishing (although in many traditional societies today women do the inland, freshwater fishing) whereas the women, children, and older male members of the community did the gathering. Some excellent studies of contemporary hunter-gatherers provide models for these notions about the division of labor. One of the best and most frequently cited is by Betty Meehan (1982) entitled *Shell Bed to Shell Midden,* in which she describes shellfishing practices in detail and the relative importance of shellfish to the diet throughout the year. This is the case at least among the Gidjingali-speaking people of Arnham Land in northern Australia, whose shellfish gathering is a planned enterprise entailing a division of labor for collecting molluscan species.

Food sharing is another phenomenon that probably has great antiquity in the food quest, although admittedly, we know more about the patterns of food sharing from contemporary studies than from archaeological remains. A classic study of sea turtle fishing along the Caribbean coast of Nicaragua (Nietschmann 1973) describes the distribution obligations of meat obtained from the large sea turtle *(Chelonia midas).* Such patterns make certain that meat does not go to waste in the absence of refrigeration and furthermore assure the maintenance of community members who are less able or unable to procure food for themselves.

That a large carcass was shared can sometimes be detected in an archaeological assemblage of animal remains. As we noted earlier, this observation can occur when estimates of meat yield based on the actual remains recovered are compared with estimates of potential meat obtained from the calculated numbers of individual animals represented in the same sample. Disparity between these two estimates could point to the incomplete deposit of the remains of a carcass, which may indicate sharing, either among the households, or through a distribution network, or even through a market system. Plots of the dispersal of parts of deer carcasses throughout a prehistoric community that was entirely excavated provide a demonstration of food distribution (Zeder and Arter 1996). Perhaps sharing also occurred when many small fishes were caught in a cooperative effort. In this case the catch may have been shared equally with an additional share going to the owner of the fishing equipment.

Communal cooperation was probably also involved in the concept of "garden hunting" (Linares 1976), which can be viewed in the broader perspective of deliberately attracting animals. Food growing in gardens or fields, or stored in granaries, was used as bait to entice animals to come close to a settlement.

Clearly this strategy would have been most successful with animals that ate agricultural products. Some of those so trapped were probably tamed and eventually domesticated, suggesting that it is no accident that many of our domestic and tame animals consume crop plants. Today agriculture and animal husbandry are combined to produce the plant and animal foods consumed throughout most of the world. But the cultivation of crops and the husbandry of animals did not arise simultaneously everywhere. In much of the Western Hemisphere crops were grown in the absence of a domestic animal other than the dog. However, the management, control, and domestication of animals eventually led to a different level of exploitation.

Animal domestication. Domestic animals have skeletal elements and teeth that are morphologically distinct from their wild ancestors. The observable changes are the result of human selection, which is why domestic animals are sometimes referred to as man-made animals. Human selection prior to modern animal husbandry may have been unintentional and more a result of isolation and methods of confinement (e.g., whether animals were tethered, or kept in stalls or corrals).

Animals were, of course, tamed first, and paintings on walls and on pottery sometimes provide evidence of domestication. Selection expressed as changes in the morphology of an animal also indicates domestication, but the state of animal "tameness" is difficult to recognize in the fragmentary remains from archaeological sites and consequently rarely possible to document. Moreover, many animals were held captive and tamed but for some reason never became domesticated, meaning that their skeletal remains do not differ morphologically from their wild counterpart. Collared peccaries *(Tayassu tajacu),* for example, were believed to have been tamed and kept by the Maya for food or ritual purposes (Hamblin 1984), and stone pens found on the island of Cozumel are thought to have been used to keep peccaries for human convenience. At the present time, peccaries are trained by some hunters in Central America to fill the role of watchdogs. Clearly, many motives instigated the taming of animals, but the most important of these undoubtedly was ready access to meat.

Some animals were held in captivity with no effort made to tame them. The captivity of these animals was a means of storing fresh meat. An example of animals still kept this way today are sea turtles maintained in corrals along the shore below low tide. Live animals were also maintained on board ships during long ocean voyages. These practices probably were very old, and animals such as domestic pigs were often released on islands to assure a source of food for the next voyage or for other people who followed.

But control over animals, or even their domestication, did not necessarily mean a sole reliance on them for food. Rather, especially in the early stages of domestication, humans continued to depend on hunted and fished resources. But with the introduction of livestock into new regions, traditional subsistence strategies were modified. An interesting example may be seen in sixteenth-century Spanish Florida, where Spanish colonists, suddenly confronted with wilderness and relative isolation, changed their traditional subsistence in a number of ways. They abandoned many accustomed food resources and substituted wild resources used by the aboriginal people of the region. Moreover, their animal husbandry practices shifted from a traditional set of domesticated animals to just those that flourished in the new environment (Reitz and Scarry 1985). These changes required flexibility. Yet presumably, such changes in subsistence behavior documented for Spanish settlers in Florida were repeated in many places throughout the ages (Reitz and Scarry 1985).

Dependence upon livestock became more complete only after peoples and their agricultural systems were well established. It should be noted, however, that even in industrial societies today, reliance upon domestic animals is not complete. Most contemporary Western diets include fish and other seafood, and wild animal food, such as venison, is viewed as a delicacy and is often the food for a feast.

Accompanying a greater human dependence upon domestic animals for food was an increased human use of the animals' energy and other products. Animals, used for draft, greatly increased the efficiency of agricultural enterprises, and utilizing them for transportation extended the catchment area.

The employment of animals for dairy products was of crucial importance and can be detected in archaeological remains by the kill-off pattern that characteristically shows male individuals killed as young animals and females maintained to old age for their milk (Payne 1973). When such provisions as milk (and eggs) came into use, they provided an edible resource without loss of the animal, and the latter came to be viewed as capital.

Conclusion

The human diet is characterized by the great variety of plants and animals that it includes. The animal protein portion of the diet depends most heavily on vertebrates and mollusks but also includes crustaceans, arthropods, and echinoderms. Historically, this flexibility has been instrumental in the worldwide distribution of human beings.

Despite this flexibility, selection for certain resources was clearly practiced. Usually, certain species were targeted even though a great variety of species were used. When selection was exercised, the determining factors seemed to have been those of a dependable resource and one high in body fat. By resource dependability we mean, for example, the annual salmon run, stable oyster beds, perhaps a captive flock of pigeons or a domestic herd of goats. Selection for animals with the highest body fat has been documented specifically in the preference for sea lions by the prehistoric Aleuts and generally by archaeological remains of the bison, which revealed selection of the fattest individuals. In this connection it should be noted that domestic animals tend to store more fatty tissue than do their wild ancestors, which may have been a further incentive for the maintenance of domesticates (Armitage 1986).

Food distribution and sharing is another characteristic of human subsistence that provided everyone with a degree of security even if personal catches were not successful. Methods of food preparation and storage doubtless varied greatly. Most likely these were salting, smoking, or drying, or a combination, but none of these methods is clearly visible in archaeological remains. It is only when animal remains are found far outside of their normal range (e.g., codfish remains in West Indian historic sites) that one can be sure some method of preservation was employed.

Similarly, cooking methods can be interpreted from archaeological remains only in a general way. It is likely that meat was boiled or stewed when bone was not burned and roasted when it was burned. Yet such interpretations must be made cautiously because bone can become burned in many ways.

Even though animal remains from archaeological sites are fragmentary and much is often missing from the whole picture, they do provide an important perspective on past human diets.

I.5. Chemical Approaches to Dietary Representation

Dietary reconstruction for past populations holds significant interest as it relates to biological and cultural adaptation, stability, and change. Although archaeological recovery of floral and faunal remains within a prehistoric or historical context provides some direct evidence of the presence (and sometimes quantity) of potential food resources, indirect evidence for the dietary significance of such foodstuffs frequently must be deduced from other bioarchaeological data.

The types of data with dietary significance range from recovered plant and animal remains through evidence of pathology associated with diet, growth disruption patterns, and coprolite contents. Other traditional approaches involving the people themselves – as represented by skeletal remains – include demographic (Buikstra and Mielke 1985) and metabolic (Gilbert 1985) stress patterns.

In addition to bioanthropological analyses, reconstruction of environmental factors and the availability and limits of food species and their distribution for a population with a particular size, technology, and subsistence base are typical components within an archaeological reconstruction. Although these physical aspects are significant, the distribution, or more likely the restriction, of particular foodstuffs from certain segments of the population (because of sex, age, status, food avoidance, or food taboos) may be important cultural system features. The seasonal availability of food and its procurement, preservation, and preparation may also have influenced group dietary patterns and nutritional status (Wing and Brown 1979).

Analysis of skeletal remains may also provide some direct evidence of diet. Type and adequacy of diet have long been of interest to physical anthropologists, especially osteologists and paleopathologists (Gilbert and Mielke 1985; Larsen 1987). More recently, direct chemical analysis of bones and teeth has been attempted in an effort to assess the body's metabolism and storage of nutritive minerals and other elements. L. L. Klepinger (1984) has reviewed the potential application of this approach for nutritional assessment and summarized the early findings reported in the anthropological literature. (In addition, see Volume 14 of the *Journal of Human Evolution* [1985], which contains significant research surveys to that date.)

General Approaches and Assumptions

The pioneering anthropological work in bone chemical analysis and dietary reconstruction can be attributed to A. B. Brown (1973), who examined strontium concentrations in relation to meat and vegetation, and to R. I. Gilbert (1975), who explored the concentrations of five other elements in relation to prehistoric Native American samples in Illinois. The enthusiastic early promise of a relatively easy, straightforward approach to diet reconstruction from elemental concentrations in bone has more recently been tempered by recognition of the biodynamic complexity, methodological problems, and contextual changes occurring through diagenesis of buried bone. Nonetheless, a number of publications in article, dissertation, and book form have appeared in the anthropological literature from the early 1970s to the current time. Although the emphasis, samples, and time frame have varied considerably, the approaches generally share the assumptions that bone is the vital feature for mineral homeostasis and a reservoir for critical elements, and that variations in bone concentrations by individual and group reflect past intakes of dietary concentrations, which in turn reflect local environmental and cultural milieus. A. C. Aufderheide (1989) and M. K. Sandford (1992, 1993a) have provided excellent reviews of the basic premises, biogenic-diagenetic continuum, diversity of methods, and sampling and analytical protocols. Two recent, extremely important, edited volumes (Price 1989; Sandford 1993b) contain the most comprehensive bibliographies currently available and include syntheses of recent findings, remaining problems, and potential research trajectories and protocols.

Initial anthropological bone chemical research focused primarily on the inorganic mineral phase of bone – which typically makes up 75 to 80 percent of the dry weight – and was concerned with the dietary contrasts and trophic levels of early hominids, hunter-gatherers, and agriculturalists. Analysis of the stable isotopes in the organic collagen component (20 to 25 percent) is now frequently undertaken to investigate the relative importance of C3/C4 plants and reliance on maize in the Americas through a consideration of its carbon content (Bumstead 1984). Such analysis is also focused on the equally troublesome problem of the marine/terrestrial protein components of the diet by investigation of nitrogen isotopes. Other isotopes with possible relevance to aspects of dietary reconstruction include those of oxygen, sulfur, and strontium. W. F. Keegan (1989), M. A. Katzenberg (1992), and S. H. Ambrose (1993) provide excellent introductory reviews of the use of isotopes in the analysis of prehistoric diet. H. P. Schwarcz and M. J. Schoeninger (1991) provide a more esoteric review of the theory and technical details of isotopic analysis for reconstructing human nutritional ecology.

Samples, Instrumentation, and Variables

It is probably unrealistic to expect a finely detailed reconstruction of past diets from skeletal chemical data because of the nature of our evidence. A number of factors influence the survival and recovery of human remains. These include mortuary method, climatic conditions, soil chemistry, decomposition rates, and archaeological methods and goals. Although a single individual, may reflect important aspects of the biocultural past, including diet, we should remember that each individual, and the circumstances and context of the recovery of that individual, is unique.

Moreover, because the bone is analyzed not in life, but after death, bone turnover rates must be viewed in relation to age and health status at the time of that death. For aggregate data, especially for statistical comparisons, the representativeness, comparable size, and composition of the samples are also of concern. Chemical analysis should be done only after thorough and professional osteological analysis is conducted. Useful standardized guides in such analysis are the Paleopathology Association's *Skeletal Database Committee Recommendations* (1991) and the collective recommendations for standard skeletal data collection (Buikstra and Ubelaker 1994).

Accurate demographic profiles are especially important for later considerations of age, sex, health/disease, and perhaps status categories within the population sample. Individual bone samples may be taken for later analysis, especially now that many invaluable skeletal collections are being reburied. Because as little as 1 to 2 grams of bone may be used for chemical analysis, depending upon the instrumentation and method, the removal and laboratory destruction of this amount of bone represents a loss of even less than that of a typical tooth.

Chemical concentrations within bone vary from one bone to another and even in different portions of an individual bone; understandably, earlier comparative studies were difficult before this fact was recognized. Current recommendations are to use cortical bone, preferably from femur midshafts. The particular technique chosen for quantitative elemental analysis will depend upon the number of elements to be analyzed, the cost, and the degree of precision required. Aufderheide (1989) and Sandford (1992) review the theoretical foundations and relative advantage of a number of options. Current laboratory analytical techniques include electroanalysis, light spectrometry, scanning electron microscopy, neutron activation analysis, mass spectrometry, and the widely used inductively coupled plasma (ICP) optical spectrometry for multiple element analysis. Results are typically reported in parts per million of bone or bone ash, the latter preferred (Price et al. 1989).

Although elemental analysis may be conducted directly on bone or in solution, isotopic analysis first requires decalcification, extraction of collagen from bone – approximately 5 milligrams (mg) of collagen is needed – and then analysis through mass spectrometry. Katzenberg (1992) provides a capsular review of the process and cites B. S. Chisholm (1989) and Schoeninger and colleagues (1989) as current basic references. Stringent laboratory conditions and lengthy preparation techniques, frequently with elevated costs, are necessary for isotopic analysis (Ambrose 1990).

Diagenesis appears to be less of a problem with isotopic analysis; however, it must still be considered. Much recent research in elemental analysis has attempted to document and cope with the problems of chemical and physical changes that may occur in buried bone through leaching, contextual contamination, and chemical reactions of bone outside the living body. In addition to the bone, samples of the matrix of soil must be collected and analyzed so that potential contamination may be identified.

Of course, postmortem influences must be detected, but physiological processes may also influence the incorporation and utilization of elements present in a particular diet. Absorption of particular elements ingested may be enhanced or reduced through chemical processes or physiological regulation by competing substances in the diet. Phytates found in some cereals, for example, may bind zinc and iron and reduce the absorption of these elements.

In addition, not all elements are distributed equally through body tissues, and some, such as lead or strontium, may be deposited differentially into bone. Metabolism differences for particular elements may also compound the interpretation. Retention of ingested elements is variable as well in certain tissues as is the rate of bone turnover at different ages and under variable health conditions.

Finally, excretion rates for particular elements depend upon physiological processes and the nature of the element itself. Although there are a great number of variables in the incorporation, retention, and analysis of any particular chemical element in bone, a cautious application of trace element studies with appropriate samples, methods, and situations or research goals continues to hold promise for some aspects of dietary reconstruction. Indeed, despite severe critical evaluation of earlier trace element studies (Radosevich 1993), improved and refined multidisciplinary research and laboratory protocols should prevent the necessity of throwing the baby out with the bathwater.

Anthropological Dietary Chemical Reconstructions

The following sampling of past contributions within anthropological bone chemical research reflects three major thrusts related to diet: trophic level, temporal change in subsistence, and distinctive chemical elements. The general trophic level of past human diets was first investigated by strontium and strontium/calcium ratios. The basic premise was that the relative reliance on meat derived from animals higher on the food chain would be reflected by a lower concentration of strontium in the human bone because of its differential presence and absorption (relative to calcium) along the food chain. For paleoanthropologists concerned with the physical and cultural development of humans and the hunting complex (especially *Australopithecus, Homo habilis,* and *Homo erectus*), it first appeared that the answers could be derived in a relatively straightforward manner (Sillen and Kavanagh 1982). However, the fossilization process itself appears to alter the initial concentration, and other diagenic processes may confound the interpretation (Sillen, Sealy, and van der Merwe 1989).

In the case of more recent human groups, however, an analysis of strontium bone content has proven more fruitful. The anthropological significance of the strontium content of human bone was initially investigated by Brown (1973), and subsequent studies of strontium content suggest that dietary differences may reflect social stratification. Schoeninger (1979), for example, determined that at a prehistoric Mexican site, higher-ranking individuals – as indicated by interment with more grave goods – had lower levels of strontium and, hence, presumably a greater access to animal protein. Other studies, such as that by A. A. Geidel (1982), appear to confirm the value of strontium analysis in this respect, even though diagenetic change must be evaluated.

Temporal dietary changes and the relative amounts of meat and plants in the diet (perhaps related to population size as well as technological complexity) have been documented in a number of regions. Gilbert (1975, 1977), for Late Woodland Mississippian groups in the Midwest, and T. D. Price and M. Kavanagh (1982), for the same area, document an increasing strontium concentration among groups as they experienced an increasing reliance on cereals and a concomitant decrease in meat availability. Katzenberg (1984) determined similar temporal changes among Canadian groups, as did Schoeninger (1981) for areas of the Middle East.

It should be noted, however, that bone strontium concentrations are strongly influenced by ingestion of marine foods – such as shellfish – and some nuts. J. H. Burton and Price (1990) suggest that low barium/strontium ratios distinguish consumption of marine resources. It should also be noted that soil and water concentrations of strontium and, hence, plant absorption of it, also vary geographically. A final caveat is the documentation of the influences of physiological processes such as weaning (Sillen and Smith 1984) and pregnancy and lactation (Blakely 1989), which elevate bone strontium and depress maternal bone calcium concentrations.

A number of other elements found in food and water (Ca, Na, Sr, Cu, Fe, Mn, Mg, Zn, Al, Fe, Ba) have the potential for assisting in dietary reconstruction. These elements have been analyzed in skeletal samples with varying degrees of success in delineating food categories, temporal changes, and subsample variations related to age, gender, or class. Like strontium, these elements are subject to many of the same modifications and processes from ingestion to deposition into bone, and frequently to the same diagenic processes after death, so the same caveats apply to their analysis and interpretation.

In addition, when these various elements are incorporated together in diets (and later deposited in bone), they may be antagonistic to each other, or enhanced when ingested together or as part of the same diet. In anthropological analysis, although the major elements such as calcium or phosphorous may be significant, the majority of research has been concerned with trace elements in either their total concentration for dietary categories, or as deficiencies related to particular diseases, or at toxic levels, such as lead poisoning.

Although there is a relatively abundant literature on individual trace elements and their role in human metabolism and nutrition in the medical and nutrition literature (Underwood 1977; Prasad 1978; Rennert and Chan 1984), these studies tend to focus on Western diets and modern food standards and samples. The major emphasis within anthropological elemental studies has been with meat and vegetable dietary questions and temporal change, especially in the prehistoric American Southeast and Middle West. Research in other world areas has included Europe (Grupe and Herrmann 1988), Southwest Asia (Sillen and Smith 1984), Sicily (Klepinger, Kuhn, and Williams 1986), Tunisia (Sandford, Repke, and Earle 1988), Australia (Kyle 1986), and Peru (Edward and Benfer 1993).

The theoretical premise behind such investigations is based on the different concentration levels of particular elements in dietary resources that then should vary in the human skeletal concentrations. Meat, for example, is typically associated with increased concentrations of iron, zinc, copper, molybdenum, and selenium. Plants, however, generally have greater amounts of strontium, magnesium, manganese, cobalt, and nickel. Unfortunately, a single plant or animal species rarely possesses a unique chemical signature. Besides the problem of mixed dietary resources, many of the prevailing trace elements overlap (Gilbert 1985), and nuts present special problems (Buikstra et al. 1989). Synthetic critical reviews of relevant literature have been provided by Price (1989), Sandford (1992, 1993a, 1993b), Aufderheide (1989), and J. E. Buikstra and colleagues (1989).

The emerging consensus is that elemental and isotopic studies may indeed be significant in circumstantial dietary reconstructions of past populations. But additional research is necessary to cope with the numerous problems and issues connected with such studies. Among these are diagenesis, laboratory analysis and sample preparation, expansion to skeletal samples of more recent origin, wider geographical representations and inclusions, feeding experiments, and more sophisticated statistical and interpretative techniques.

A number of studies have attempted to deal with the question of diagenesis and the need for adjustments before statistical analysis (Lambert, Szpunar, and Buikstra 1979; Katzenberg 1984; Price 1989; Edward and Benfer 1993; Radosevich 1993). Multiple bone analyses, comparisons with nonhuman animals (herbivores, carnivores, and mixed feeders), more multielement surveys, and careful laboratory evaluation are recommended.

Expansion of multielement or single element studies into more recent historical periods should have the advantage of combining available historic information concerning diet and food habits with the chemical analysis of skeletal samples for a more comprehensive understanding. For example, Aufderheide and colleagues (1981, 1985, 1988) have delineated socioeconomic differences, occupational categories, and probably food storage patterns from the analysis of skeletal lead in the United States colonial period. H. A. Waldron (1981, 1983) and T. Waldron (1982, 1987) have addressed similar problems in the United Kingdom. In like fashion, J. S. Handler, Aufderheide, and R. S. Corruccini (1986) combined nineteenth-century descriptions of "dry bellyache" among Barbados slaves with an analysis of slave remains to demonstrate that "dry bellyache" was actually lead poisoning, the result of contaminated rum from stills with lead fittings. T. A. Rathbun and J. D. Scurry (1991) found regional variation in lead burdens in skeletal samples of whites and blacks from the seventeenth- and eighteenth-century eastern United States. Such variations seem to reflect differences in socioeconomic class, food preparation, and drinking patterns. Whites, who made far greater use of drinking and eating utensils, carried considerably higher lead burdens than blacks, with those of the Middle Atlantic states having slightly higher levels than those of other Southeast samples. Among blacks, females had the highest levels, indicating that they also doubtless had greater access to the whites' lead-contaminated food and drink.

Utilizing techniques of chemical analysis, W. D. Wood, K. R. Burns, and S. R. Lee (1985) and Rathbun (1987) were able to document regional and perhaps cultural differences among rural blacks, plantation slaves, and white elites in the nineteenth-century southeastern United States. Among the findings were that whites apparently had more access to meat than did either enslaved or freed African-Americans.

Similarly, Rathbun (1987) and T. A. J. Crist (1991) found dietary variation by gender, age, and perhaps stress level among a nineteenth-century South Carolina plantation slave sample. Males seem to have relied more heavily on meats, grains, and nuts than females, whose diets consisted more of leafy and leguminous vegetables. The remains of older adults reflected diets of grains, vegetables, and seafood, whereas those of younger adults revealed the consumption of more meats and, perhaps, nuts. Analysis of historical documents concerning food allocations on the plantation suggests that much of this differential was because slaves supplemented plantation rations with food items they collected and cooked themselves. Clearly, in many instances, a combining of historical, anthropological, and chemical information has the potential for providing a richer determination of past dietary contents and the consequences of various dietary regimens.

Summary

In addition to the confounding problems of preservation, diagenesis, data collection, and analysis, if elemental and isotopic chemical analysis of skeletal material is to fulfill its potential in dietary reconstruction, insightful and appropriate avenues of interpretation are necessary. Although descriptive statistics of aggregate data drawn from a sample are useful heuristic devices, selection of appropriate analytical techniques appear to be linked to the nature of the concentration distributions.

Parametric and nonparametric – as well as univariate and multivariate – statistics have been applied to bone chemical quantitative data. The multiple problems and considerations involved have recently been discussed by Buikstra and colleagues (1989), who ultimately recommend principal component analysis. Even though mathematical rigor remains extremely important, insightful interpretations of relationships and findings still seem to require evaluation within a biocultural context.

Schoeninger (1989), for example, attempted to match food component elements and isotopes as well as skeletal analysis for prehistoric Pecos Pueblo and historic Dutch whalers to propose reasonable diets for them. Klepinger (1992) also commented on the importance of reevaluating model hypotheses that are frequently invoked in the light of new data and developing technologies.

Chemical approaches to dietary representation, especially of past groups, can be fascinating, frustrating, and fulfilling. But it seems unlikely that we will soon develop a comprehensive picture of past diets through chemical analysis alone. The complexity of the geochemical, biochemical, biological, physiological, cultural, and social systems involved require collaborative research and multidisciplinary sharing of results. Although each discipline and researcher may contribute various pieces of the puzzle, a clearer image can emerge only through integrative interpretations. The goal appears well worth the effort!

I.6. History, Diet, and Hunter-Gatherers

In the years since 1960 there has been a dramatic change in our perception of the diet, nutrition, and health of "hunter-gatherers," who constitute the world's smallest, most "primitive," and presumably oldest-style societies. The Hobbesian perspective (Hobbes 1950, original 1651), which assumes that malnutrition, disease, and hardship characterize primitive life – a view that prevailed among scholars for the nineteenth and the first half of the twentieth centuries – has been challenged during recent decades by a large series of new observations and a new theoretical paradigm.

Contemporary Hunter-Gatherers

Studies of African hunter-gatherers by Richard Lee (1968, see also 1969) and James Woodburn (1968), in the influential anthology *Man the Hunter* (Lee and DeVore 1968), suggested that far from living on the edge of starvation, primitive hunter-gatherers frequently enjoyed not only adequate and well-balanced nutrition but also a relatively light workload.

In his analysis of the diet and workload of the !Kung San hunter-gatherers of the Kalahari Desert in southern Africa, Lee (1968, 1969) noted that the San diet consisted of an eclectic, yet selective, collection of wild foods – mostly (about 80 percent) vegetable, eaten fresh. He found that the San consumed 23 of 85 plant species that they knew to be edible in their environment and 17 of 55 edible animal species.

He calculated that for a relatively small investment of time, San hunter-gatherers obtained an adequate and well-balanced diet. By obtaining chemical analyses of their native foods and estimating the quantity of each food consumed by every individual, he was able to show that theoretically, each individual in the group received sufficient protein, vitamins, and minerals. In contrast to modern diets, what seemed the "limiting" factor – the element in the San diet most likely to be short or lacking – was the number of calories it delivered. Lee estimated the caloric intake at about 2,140 kilocalories (kcal) per person per day during a season of the year that he considered neither the richest nor the poorest.

Similarly, Woodburn (1968), although less precise, was even more sanguine in his description of the diets of the Hadza of Tanzania, who frequented a far richer environment than that of the !Kung San. He described their quest for food as leisurely and richly rewarding.

Medical observations of the San (Truswell and Hansen 1976) confirmed that they showed no signs of qualitative malnutrition, in that they had no visible deficiencies of vitamins, minerals, or protein, although they may have been showing signs of low caloric intake. (Low calorie intake has been cited by various others as responsible for stunting San growth and reducing their fertility.) Also of note was an absence of high blood pressure and elevated serum cholesterol, as well as the scarcity of heart problems. (See also Bronte-Stewart et al. 1960; Wehmeyer, Lee, and Whiting 1969; Metz, Hart, and Harpending 1971). Particularly striking were the observations on both the San and the Hadza suggesting that children did not suffer from the kinds of childhood malnutrition – kwashiorkor, marasmus, and associated weanling diarrhea – that were otherwise so common in African children (Jelliffe et al. 1962; Truswell and Hansen 1976).

At about the same time that these studies were emerging, agricultural economist Ester Boserup (1965) proposed a new model of economic growth in human history. She argued that population growth rather than technological progress had been the main stimulus for economic change. "Primitive" behavior, although usually considered to be a function of ignorance, might, she suggested, be seen as an efficient adjustment to a small population and a small social scale. So-called progress, she argued, might simply be a necessary adjustment to increasing population size, scale, and density and might be associated with declining rather than improving labor efficiency and declining rather than improving individual welfare.

Based on the work of Boserup, Woodburn, and Lee, a number of archaeologists proposed that the initial adoption of farming by prehistoric hunting and gathering groups, which occurred in various parts of the world beginning about 10,000 years ago (the "Neolithic Revolution"), might also have been a grudging response to ecological stress or population "pressure" on resources. In other words, the Neolithic Revolution might not have been the result of technological progress as had previously been assumed (Binford 1968; Flannery 1969; Cohen 1977).

One of these scholars (Cohen 1977) extended the argument by suggesting that much of what had passed for progress in prehistory might, like the adoption of farming, have been a response to the pressure of growing population, rather than the result of new inventions, since the new "progressive" techniques seemed to represent the input of extra effort for relatively little output. These "improvements" would include the adoption of diets based on small seeds and the development of grindstones to process them; the development of small projectiles for hunting small game; and the increase in shellfish consumption and concomitant development of fishing equipment during the Mesolithic or Archaic stages of prehistoric economic development. It is true that an argument could be mounted that such apparent economic trends may be distorted by problems of archaeological preservation. For example, the scarcity of shellfish remains in earlier prehistory might reflect poor preservation. However, it is difficult to defend a similar argument about the late appearance of grindstones and small projectile points.

Questions and Challenges for the New Perspectives

A number of questions remain about these new perspectives and the data upon which they were originally developed. For example, it is not clear whether the !Kung San are as well nourished and as affluent as Lee presented them (see also Sahlins 1968). Nor is it clear that the !Kung San are typical of modern hunter-gatherers in the quality of their nutrition. And finally, it is not clear that they, or *any* contemporary hunter-gatherers, lead lives that are representative of the historic and prehistoric experience of human hunters.

In the matter of the nutritional state of the !Kung San, G. Silberbauer (1981) has suggested that the groups of San he studied were nutritionally depressed and might have been lacking in B vitamins. Similarly, Edwin Wilmsen (1978) estimated that San caloric intake might fall well below 2,000 kcal per person in the poorest season. Others such as Kristen Hawkes and J. F. O'Connell (1985) and N. Blurton-Jones and P. M. Sibley (1978) have also argued that the San are not as well nourished as they have been described, that their caloric intake may be deficient, and that their "leisure" time may actually be an adjustment to the extreme heat and dryness of the Kalahari, which limits activity for significant portions of the year.

Moreover, Carmel Schrire (1980, 1984) and others have questioned the value of the !Kung San and other contemporary hunter-gatherers as models for prehistory, arguing that they are not remnants of an ancient way of life but, rather, modern societies formed by contemporary political and economic conditions in South Africa and elsewhere. As such, according to Schrire, their experience has little meaning for the study of prehistory.

Some New Evidence

Recent work in several fields has suggested that the broad perspectives introduced by Lee, Woodburn, and Boserup are accurate even though some details of their arguments may be open to challenge (Cohen 1989).

Such work rests, at least in part, on the assumption that despite undeniable pressures and inputs from the larger societies that surround them, contemporary hunter–gatherer societies can (with appropriate caution) be viewed as twentieth-century experiments in the hunting and gathering lifestyle. And as such they can tell us important things about patterns in prehistory even if the groups studied are not pristine remnants of that prehistory. For example, they can presumably tell us about a people's ability to extract balanced diets from wild resources with simple technology lacking any source of energy other than human power. They can tell us about the relative efficiency of different foraging techniques and extraction methods connected with hunting big game, hunting smaller animals, fishing, shellfishing, and gathering and processing various vegetable foods. They can also tell us something about the effect of small group size and mobility on the transmission of infectious disease.

A broader collection of comparative data on twentieth-century hunter–gatherer nutrition from around the world (Cohen 1989) suggests that contemporary hunter-gatherers (with the exception of those in the Arctic, where vegetable foods are scarce) seem routinely to enjoy relatively eclectic and thus well-balanced diets of fresh foods. Moreover, their typical practice of exploiting a relatively wide range of soils tends to minimize the impact of specific nutrient deficiencies (such as iodine) that are associated with particular soils. As a result, these groups are, for the most part, well nourished at least by contemporary developing-world standards; and they are conspicuously well nourished in comparison to the modern world's poor.

Where contemporary hunter-gatherers coexist with farming populations, as is now commonly the case, hunter-gatherers typically operate as specialists who trade protein, vitamins, and variety foods to farmers in exchange for calories (Williams 1974; Peterson 1978; Griffin 1984). It would appear, therefore, that hunting and gathering diets are almost always relatively nutritious in terms of variety and quality but potentially lacking in calories.

Nonetheless, caloric intake by hunter-gatherers appears sufficient when compared to modern developing-world populations. For example, San caloric intake, although considered marginal, is estimated at 2,000 to 2,100 kcal per person per day, although it falls somewhat below 2,000 kcal per person per day in poor seasons (Lee 1969; Wilmsen 1978; Tanaka 1980). Yet this compares favorably with estimated caloric intake in developing-world countries such as India and China, which *averages* only 1,800 to 2,200 kcal (Bunting 1970; Clark and Haswell 1970; Pellet 1983). Moreover, it compares very favorably with estimates for modern urban poor, who may take in as few as 1,100 to 1,500 kcal per person per day (Basta 1977).

Contemporary hunter-gatherers also receive a relatively large part of their diet from animal products. This is in the range of 20 to 40 percent of the diet, which is about the same as that estimated for affluent modern Western people but well above the modern world average. Daily animal protein intake among the San, for example, is estimated by various sources at approximately 30 to 50 grams per person per day (Lee 1968; Wilmsen 1978; Tanaka 1980; Silberbauer 1981), which far exceeds an estimated average of 7 to 10 grams of animal protein per person in modern developing-world countries and among the world's poor (Basta 1977; Peterson 1978).

It should also be noted, in response to the observation that contemporary hunter-gatherers may have low caloric intake, that they live in some of the world's poorest environments and consequently those most difficult to exploit for food. In fact, judging from the nutritional experience of other contemporary hunter-gatherers, it would appear that the !Kung San, although typical in the variety of their diets, are actually somewhat below hunter–gatherer average in their calorie and protein intake (Hawkes and O'Connell 1985; O'Connell, Hawkes, and Blurton-Jones 1988; Cohen 1989). Populations such as the Hadza of Tanzania, who live in a richer foraging area, are estimated to get 3,000 kcal and 50 to 250 grams of meat protein per person per day (O'Connell et al. 1988). Indeed, groups like the Hadza appear to be a better model for prehistory than the San because they live in the same kinds of environments as early human beings. Yet even the Hadza frequent an area now partly depleted of big game (Hawkes, O'Connell, and Blurton-Jones 1992).

Infection and Nutrition

Another important but not always apparent factor that must be considered in assessing the diets of hunter-gatherers is their comparative freedom from parasites, which affect the nutritional value of diets in a variety of ways (Scrimshaw, Taylor, and Gordon

1968; Beisel 1982). Parasites can cause diarrhea, speeding up the flow of nutrients through the intestine, and therefore interfere with nutrient absorption from the intestine into the bloodstream. In some diseases, such as malaria or hookworm, the parasites destroy or consume human tissues (in these cases, red blood cells), which must be replaced. Other parasites, such as tapeworms, simply compete with humans for the vitamins and minerals in our digestive tract. And infection may actually cause the body to deny itself nutrients as a means of destroying the invader, as can be the case with the body withholding iron (Weinberg 1974, 1992).

Parasite load is, to a large degree, a function of habitat. Warmth and moisture generally encourage the survival and transmission of parasites, so that tropical forest hunter-gatherers such as the Pygmies of Zaire have higher parasite loads than those in drier or colder climates (Price et al. 1963; cf. Heinz 1961).

But the parasite load also tends to increase with the size and density of the human population and with permanence of human settlement, regardless of climate, since larger accumulations of filth, of people, and of stored food all facilitate parasite transmission. Diarrhea-causing organisms, for example, are typically transmitted by fecal–oral infection, in which feces contaminate food and water supplies, a problem that is relatively rare among small and mobile groups. Hookworm infection also thrives on human crowding. The worms grow from eggs deposited on the ground in human feces. They then penetrate human skin (usually the soles of feet) and find their way "back" to the intestine, where they live by consuming red blood cells while shedding a new generation of eggs. Obviously, people on the move are less likely to contaminate the soil around them.

Tapeworms, whose life cycles commonly include both people and domestic animals, are also rare in societies that keep no animals but obtain their meat by hunting wild game. Tapeworms typically are passed to domestic animals such as cows and pigs by human feces. The proximity of domestic animals as well as the density of both human and animal populations facilitates transmission.

The !Kung San avoid most such parasites (Heinz 1961). They do suffer from hookworm because even their desert habitat, mobile habits, and small groups do not entirely prohibit transmission; but they suffer only a fairly mild infestation that is not generally sufficient to promote anemia, the main danger of hookworm (see Truswell and Hansen 1976).

In short, increased parasite load diminishes the quality of nutrition, but hunter-gatherers suffer less of a nutritional loss to parasites than other societies in the same environments. The consequence is that hunter-gatherers require smaller dietary intakes than people in those other societies.

Hunting and Gathering Populations of Prehistory

Reason to believe that the hunting and gathering populations of prehistory were at least as well nourished as their contemporary counterparts can be gleaned from comparing the environments in which prehistoric hunter-gatherers chose to live and those to which their modern counterparts are confined by the pressures of competition with more powerful neighbors. Prehistoric, but biologically modern, human hunter-gatherers seem to have expanded first through relatively game-rich environments, savannas, steppes, and open forests. Occupation of the deserts and jungles in which most hunting and gathering groups now find themselves is a relatively recent phenomenon.

Hunters also seem initially to have focused on medium- to large-sized animal prey plus a relatively narrow spectrum of plant foods. Small game, seeds to grind, fish and shellfish (at least consistently and in quantity) all appear to be relatively recent additions to the human larder. The additions were made in the Mesolithic period of prehistory (Cohen 1977) and were associated with what K. V. Flannery (1973) has called the "broad spectrum revolution," which took place within, approximately, the last 15,000 years. The use of secondary habitats and the adoption of demonstrably inefficient foraging techniques suggest strongly that the diets of hunter-gatherers began to decline under the pressure of their own populations almost from the time that the efficient hunter, *Homo sapiens,* first emerged to spread out around the world.

Actual tests of the relative efficiency of various foraging techniques indicate that prehistoric hunter-gatherers in environments richer in large game than that occupied by contemporary counterparts would have fared well in comparison to contemporary groups. Indeed, numerous investigations point out that when available, large game animals can be taken and converted to food far more efficiently than most other wild resources. Data provided by Stuart Marks (1976) and recalculated by the author (Cohen 1989) suggest, for example, that big game hunters without modern rifles or shotguns in game-rich environments may obtain an *average* of as much as 7,500 to 15,000 kcal for every hour of hunting. Many other studies also suggest that large game, although relatively scarce in the modern world, can be taken with great efficiency once encountered, even if hunters do not use modern firearms (Jones 1980; Blackburn 1982; Rowly Conway 1984; Hawkes and O'Connell 1985).

By contrast, most of the resources taken by contemporary hunters, including small game, fish, shellfish, and small-seeded vegetables, are far less efficient to gather and convert to food. Estimates of shellfish-gathering efficiency, for example, suggest that it produces about 1,000 kcal per hour of work; hunting small game may average no more than 500 to 800 kcal per hour; small seed processing also produces only about 500 to 1,000 kcal per hour (Jones 1980; Winterhalder and Smith 1981; Rowly Conway 1984; Cohen 1989). Collection of nuts may, however, constitute a partial exception. Brazil nuts, for example, can be harvested at rates that provide kcals comparable to hunting. But the nuts must still be cracked and processed into food, both relatively time-consuming activities. Similarly, anadramous (migratory) fish can be harvested very efficiently but only after large weirs have been constructed (Werner 1983; Rowly Conway 1984).

Interestingly, the relative efficiency of hunting large game (when available) appears to hold whether foragers use iron or stone tools. In fact, metal tools apparently add relatively little to hunting efficiency, although they add significantly to the efficiency of gathering vegetable foods, not to mention growing them. In a Stone Age world, therefore, the advantage of being a big game hunter would have been substantially greater than even these modern comparative tests of various economic activities undertaken with metal tools suggest (Colchester 1984; Harris 1988). Hunting large game with spears is also clearly more efficient than hunting smaller game with bows and arrows and small projectile points or nets or probably even primitive muskets – the point being that "improvements" in hunting technology did not offset the loss of efficiency that occurred as prey size became smaller. In addition, hunting large game would have clearly been more efficient than harvesting wild wheat or farming wheat with stone tools such as the sickles and grindstones that appear in human tool kits relatively late in prehistory (Russell 1988). In short, a decline in available big game was apparently more important than any technological innovation in affecting foraging choices and determining the overall efficiency of the economy. The ultimate adoption of farming seems to have been only one in a long series of strategies adopted to offset diminishing returns.

One further point is worth making. Modern hunter-gatherers, such as the !Kung or even the Hadza, who contend with game-depleted environments or those with legal hunting restrictions must clearly be less efficient in putting food on the table than their (and our) prehistoric forebears.

The data also indicate that prehistoric hunters in game-rich environments would have consumed diets containing a larger proportion of meat than most of their contemporary counterparts. Yet as John Speth (1988) has argued, there are limits to the proportion of meat in the diet that a human being can tolerate since meat, without commensurate carbohydrates or fats, is calorically expensive to process. Moreover, meat is a diuretic, so that people like the San, who live in hot deserts where water and calories are both scarcer than protein, may limit meat consumption to conserve water.

The Evidence of Prehistoric Skeletons

There is also a good deal of direct evidence (most of it gathered since 1960) to support the hypothesis that prehistoric hunter-gatherers were relatively well nourished. Their skeletons, often in large numbers, have been analyzed from various regions of the world. In more than 20 areas of the globe (but mostly in North America) it is possible to use these remains to make comparative analyses of the nutrition and health of two or more prehistoric populations representing different stages in the evolution of food technology (Cohen and Armelagos 1984). For example, in specific cases we can compare hunter-gatherers to the farmers who succeeded them in the same region; or compare early hunters to later foragers; or incipient farmers to intensive farmers, and so forth.

Such analyses generally confirm that infection and associated malnutrition become more common as small groups become larger and more sedentary. The skeleton displays nonspecific infections called periostitis when only the outer surface of the bone is affected and osteomyelitis when the infection penetrates deep into the medullary cavity of the bone. Osteomyelitis is rarely found in prehistoric skeletons, but periostitis is routinely found to have been more common in larger and more sedentary groups and can probably be taken as an index of the prevalence of other infectious diseases. In addition, other types of infection can occasionally be glimpsed. For example, a comparison of mummified populations from Peru (Allison 1984) demonstrates an increase in intestinal parasites with sedentism. A comparison of preserved fecal material from different archaeological layers in the American Southwest also demonstrates an increase in parasites with the adoption of sedentism (Reinhard 1988).

Other such evidence can be found in the characteristic lesions on the skeleton left by diseases such as yaws, syphilis, leprosy, and tuberculosis, all of which increase with density or appear only in relatively civilized populations. Tuberculosis appears to be almost entirely a disease of relatively recent, civilized populations in both the Old World and the New (Buikstra 1981; Cohen and Armelagos 1984). Yaws (a nonvenereal disease caused by a spirochete identical to the one that causes syphilis) has been shown to increase with population density among New World Indians (Cohen and Armelagos 1984).

Skeletons also provide fairly specific signs of anemia, or lack of sufficient red blood cell function. The condition is called porotic hyperostosis and cribra orbitalia and appears as a thickening and porosity of the bones of the cranium and eye orbits in response to the enlargement of marrow cavities where red blood cells are formed.

Anemia can result from inadequate dietary intake of iron associated with diets high in maize and other cereals, since the cereals are poor sources of iron and may actually interfere with iron absorption. However, increasingly, anemia is thought to reflect the secondary loss of iron to parasites such as hookworm, and losses in fighting diseases such as tuberculosis, and even the body's own sequestering of iron to fight infection (Weinberg 1974, 1992; Stuart-Macadam 1992). In one particular archaeological sequence from the American Southwest, in which preserved human feces have been examined, anemia was shown to relate to the frequency of parasitic worms in stools rather than to diet (Reinhard 1988, 1992). But whatever the cause, anemia seems to have been primarily a disease of more civilized or sedentary farmers rather than hunter-gatherers everywhere they have been studied, and it *increases* through time in association with group size and sedentism in almost all reported archaeological sequences (Cohen and Armelagos 1984).

One other dietary deficiency disease, rickets in children and osteomalacia in adults, can be diagnosed in the skeleton. Soft or malformed bones resulting from improper calcification can result from lack of calcium or lack of vitamin D in the diet. Most commonly, however, it occurs from lack of exposure to sunlight, because most vitamin D is produced in the skin as the result of exposure to ultraviolet radiation. The archaeological record suggests that rickets is very rare among prehistoric hunter-gatherers but common, as one might predict, among the inhabitants of smog-bound urban ghettos in the last few centuries (Steinbock 1976; Cohen and Armelagos 1984).

Changes in human growth and stature may also reflect a decline in the quality of human nutrition through time. Many authorities consider average stature to be a fairly reliable indicator of nutritional status (see Fogel et al. 1983), and certainly the increase in European and American stature in the last century has been viewed as evidence of improving nutrition. But for centuries prior to the nineteenth century, decline was the predominant trend in human stature.

The first biologically modern human populations of hunter-gatherers throughout Europe and areas of Asia including India seem to have been relatively tall. Unquestionably these Paleolithic hunters were taller than the Mesolithic foragers and Neolithic farmers that came after them (Angel 1984; Kennedy 1984; Meiklejohn et al. 1984; Smith, Bar-Yosef, and Sillen 1984), and the populations of eighteenth-century Europe to which we compare ourselves with considerable pride were among the shortest human groups that ever lived (Fogel 1984).

Retarded growth may also be identified in the skeletons of children whose bones suggest that they were smaller for their age (as determined by the state of tooth formation and eruption at death) than children living at some other time or place. For example, skeletons of children from the Dickson Mounds archaeological site in Illinois suggest that childhood growth was retarded in a farming population when compared to that of their foraging forebears (Goodman et al. 1984). In addition, malnutrition may show up as premature osteoporosis, the thinning of the outer, solid, cortical portions of bones. This condition seems to be more important in farmers or later populations than in prehistoric hunter-gatherers (e.g., Stout 1978; Smith et al. 1984).

Finally, the adult human skeleton displays scars of biological or nutritional stresses felt in childhood, particularly those associated with weanling malnutrition and weanling diarrhea. Illness while teeth are growing can result in irregularities in tooth enamel that leave a permanent record of stress in the form of visible lines called enamel hypoplasia or microscopic defects called Wilson bands (see Rose, Condon, and Goodman 1985). Prehistoric hunter-gatherers fairly typically show lower rates of these defects than do the farming and civilized populations that followed them, confirming the observation that hunter-gatherer children endured significantly less weanling stress than did farmers or other more "civilized" neighboring populations (Cohen and Armelagos 1984; Cohen 1989).

It is true that some critics object to such conclusions by observing that the use of skeletal indicators of stress in prehistoric populations may be misleading – that, for various reasons and in various ways, skeletons may provide an unrepresentative or biased sample of a once-living population. (For details of the argument see Wood et al. 1992, and Cohen forthcoming). Yet skeletal evidence accords well with ethnographic observations and with predictions of epidemiology. In other words, infection not only increases with sedentism in skeletal populations but also increases in many ethnographic or historically described skeleton groups. Moreover, as already discussed, contemporary hunter-gatherers (and not just prehistoric hunter-gatherers) seem to be well protected against anemia. Put plainly, skeletal data when checked against other results appear to be giving us an accurate and coherent picture of past health and nutrition (Cohen 1989, 1992).

The Texture of the Diet

Although controversies remain about the quality and quantity of food available to both modern and ancient hunter-gatherers, there is little dispute that there have been significant changes in dietary texture throughout history. Contemporary hunter-gatherers as a group (and, presumably, their prehistoric counterparts) eat foods that differ in texture from modern diets in three important ways: Wild foods are comparatively tough to chew; they are high in bulk or fiber; and, with the occasional exception of honey, they lack the high concentrations of calories found in many modern processed foods. These textural differences have several effects on human development and health. First, individuals raised on hunter–gatherer diets develop different occlusion of their teeth in which the upper and lower incisors meet edge to edge. The modern "normal" pattern of slight overbite is actually a consequence of modern soft diets (Brace 1986). Hunter–gatherer diets also generate significantly more tooth wear than do modern diets, so that in contrast to civilized populations, hunter-gatherers are at risk of literally wearing out their teeth.

However, modern diets rich in sweet and sticky substances are far more cariogenic. Significant tooth decay is, for the most part, a relatively recent phenomenon. Historically, rates of caries increased dramatically with the adoption of pottery, grindstones, and farming (which made softer diets possible) and again with the production of refined foods in the last few centuries (Powell 1985). In fact, the difference in caries rates between ancient hunter-gatherers and farmers is so pronounced that many archaeologists use the rate of caries in archaeological skeletons to help distinguish between prehistoric hunters and farmers (see Turner 1979; Rose et al. 1984).

Coarse textured foods have a particularly important effect on two segments of the population, the very old with badly worn teeth and the very young. The problem of feeding the very young may require a mother to delay weaning, and this may help to explain the relatively low fertility of the !Kung – a phenomenon that some, but not all, modern hunter–gatherer populations seem to experience one yet that may have been the experience of hunter-gatherers in prehistory (Cohen 1989; cf. Wood 1990). Without soft foods to wean their children and with "baby food" very difficult to prepare, hunter-gatherers may be forced to nurse both intensively and for a relatively long period. Lactation, especially in combination with low caloric intake and high energy output, is known to exert contraceptive effects (Konner and Worthman 1980; Habicht et al. 1985; Ellison 1990).

But the adoption of cereals and grindstones to prepare gruel by Mesolithic and Neolithic populations would have simplified the problem of feeding the very young whether or not it improved nutrition. And early weaning in turn would help to explain an apparent increase in the growth rate of the human population after the adoption of farming in the Neolithic period, even though no corresponding improvement in health or longevity can be documented (Cohen and Armelagos 1984; Cohen 1989).

The lack of refined foods available to them may also explain the relative immunity of hunting and gathering populations (and many other populations) to diet-related diseases that plague twentieth-century Western populations. For example, the relatively low calorie-for-volume content of hunter–gatherer diets helps to explain the relative scarcity of obesity and obesity-related conditions among such groups. (Even wild animals that must work for a living are relatively lean in comparison to their modern domestic counterparts.) Adult-onset diabetes is very rare in "primitive" societies, although studies in various parts of the world suggest that the same individuals may be diabetes-prone when switched to Western diets (Neel 1962; Cohen 1989). Similarly, high blood pressure is essentially unknown among hunter–gatherer groups who enjoy low sodium (and perhaps also high potassium or calcium) diets, although the same groups develop high blood pressure when "civilized" (Cohen 1989).

High-fiber diets among hunter-gatherers and other "primitive" groups also affect bowel transit time. Members of such groups typically defecate significantly more often than "civilized" people. In consequence, diseases associated with constipation such as appendicitis, diverticulosis, varicose veins, and bowel cancer are all relatively rare among hunter-gatherers (and non-Western populations in general) and are thought to result at least in part from modern, Western low-bulk diets (Burkitt 1982).

In summary, a number of lines of evidence from archaeology, from prehistoric skeletons, and from the study of contemporary populations indicate that small, mobile human groups living on wild foods enjoy relatively well-balanced diets and relatively good health. Indeed, the available evidence suggests that hunter–gatherer diets remain well balanced even when they are low in calories. The data also show that per capita intake of calories and of protein has declined rather than increased in human history for all but the privileged classes. The predominant direction of prehistoric and historic change in human stature has been a decline in size despite the "secular trend" among some Western populations of the last century. Prehistoric remains of more sedentary and larger groups commonly display an increase in general infection and in specific diseases (such as yaws and tuberculosis), combined with an increase in porotic hyperostosis (anemia) and other signs of malnutrition.

PART II

Staple Foods: Domesticated Plants and Animals

Part II, with its almost 60 chapters that concentrate on staple foods (most of the fruits are treated in Part VIII), constitutes the largest portion of this work. Yet the space devoted to it seems more than justified in light of the immensity of the effort that humans have invested in domesticating the plants of the fields and the animals of the barnyard. In the case of plants, the effort began with the harvesting of wild grains and roots, which probably became a seasonal activity for some hunter-gatherers as the last Ice Age receded and the large mammals – mammoths, mastodons, giant sloths, and the like – were embarking on their journey to extinction. The next leap – a giant one – was from locating wild grains for harvest to planting them in permanent places and then tinkering with them and the soil so they would do a better job of growing.

Wolves were domesticated to become dogs toward the end of the Paleolithic. Like their human companions, they were hunters. But with the beginning of farming, a host of other animals followed them into domestication. In the Old World, goats and sheep, which fed on wild grasses but had no objection to domesticated ones, were probably initially perceived by early farmers as competitors – if not outright thieves – to be fenced out or chased away. But with the precedent of dog domestication to guide them, people began to capture these ruminants and eventually raised them in captivity. In many cases, the purpose seems to have been a supply of animals close at hand for ceremonial sacrifice. But even if meat, milk, hides, hair, and wool were secondary products at first, they were, nonetheless, important ones that quickly rose to primacy. Pigs, cattle, water buffalo, horses, even camels and, later on, chickens may have also been initially sought for sacrifice and then, after domestication, exploited for their other products, including labor and transportation.

Such a range of large animals that could be domesticated was, however, restricted to the core of the Old World. On its periphery, in Africa south of the Sahara, trypanosomal infection delivered by the tsetse fly often discouraged livestock keeping, and, in the New World, save for dogs, turkeys, and llamas and llama-like creatures, there was relatively little animal domestication carried out. This meant for many an absence of animal fats in the diet, which nature remedied, to some extent, by making the fat in avocados available to many Americans, and palm oil and coconut palms to most in the tropical world.

In the Americas, a shortage of animal protein also meant a heavy reliance on maize, beans, squashes, and potatoes, along with manioc in tropical and subtropical regions; in Africa, yams, millet, sorghum, and a kind of rice sustained life; and in Oceania, taro served as an important staple, along with the sweet potato – an American plant that somehow had diffused throughout that vast area long before the Europeans arrived.

This mystery, along with another occasioned by Old World onions and garlic noted by the expedition of Hernando Cortes in Mexico, may never be solved, and many other such mysteries probably never had a chance to come to light because of the process of food globalization set in motion after 1492. Animals, grains, and vegetables domesticated in the Old World flourished in the New. Beef, pork, and cheese, for example, fitted so naturally into Mexican cuisine that it is difficult to appreciate that they have not been there forever. In similar fashion, the American plants revolutionized the cuisines of the other lands of the globe. Potatoes spread from Ireland to Russia, fields of maize sprang up as far away as China, and manioc combined with maize to cause a population explosion in Africa. Chilli (we stand by our expert's spelling) peppers raced around the globe to add fire to African soups and Indian curries; the tomato was married to pasta in Italy; and, in the other direction, Africa sent varieties of field peas to enliven regional dishes of the Americas and okra to make gumbos.

The continuation of food globalization since 1492 – especially since the 1960s – has caused increasing concern about the atrophy of regional cuisines on the one hand, and the spread of "fast food" on the other. But, as a 1992 Smithsonian exhibition made clear, the "Seeds of Change" discussed in Part II have been broadcast with increasing intensity around the world since the Columbian voyages, and not always with good effect.

II.A

Grains

II.A.1. Amaranth

A robust annual herb with seeds as small as mustard seeds, amaranth belongs to the genus *Amaranthus* of the family Amaranthaceae, with 50 to 60 species scattered throughout the world in wild and domesticated forms. Most are weeds, such as pigweed *(A. retroflexus),* which commonly invades gardens in the United States, whereas others are raised as ornamentals. The genus derives its name from the Greek meaning "unfading," "immortal," or "not withering" because the flowers remain the same after they are dried. Poets have favored the amaranth, therefore, as a symbol of immortality (Sauer 1976; Berberich 1980; Tucker 1986; Amaranthus 1991).

It is as a food, however, that amaranth was and is most important to human populations, either for its leaves or seeds. Two species of amaranth, *A. tricolor* and *A. dubius,* are popular among Chinese-Americans for soup and salad greens. But the most versatile and nutritious are the grain amaranths, because the genus *Amaranthus,* although a non-grass, is capable of producing great amounts of edible grain (Cramer 1987). Three species of amaranth that were domesticated in the Americas and are commonly utilized as grain are *A. hypochondriacus,* known as "prince's feather" in England, from northwestern and central Mexico; *A. cruentus* of southern Mexico and Central America, whose greens are widely utilized in Africa; and *A. caudatus* of the Andes, known as "love-lies-bleeding" in the United States (Sauer 1976; Cole 1979). The first two species are now cultivated in the United States as seed grains, but *A. caudatus* does not do as well in the United States as in the Andes (Tucker 1986).

The amaranth plant grows from 1 to 10 feet tall in an erect or spreading form. It is a broad-leaved plant that bears up to 500,000 black, red, or white seeds on a single large seedhead, made up of thick fingerlike spikes (Cole 1979; Tucker 1986). The leaves are "often variegated with bronze, red, yellow, or purple blotches" (Wister 1985), and the flowers may be orange, red, gold, or purple. Its beautiful colors have led people throughout the world to raise amaranth species as ornamental plants and to cultivate *A. cruentus,* which is a "deep red" form of the plant, as a dye plant (Sauer 1976).

The principal advantage of amaranth is that both the grain and the leaves are sources of high-quality protein. While most grain foods, such as wheat and corn, have 12 to 14 percent protein and lack the essential amino acid lysine, amaranth seeds have 16 to 18 percent protein and are "lysine-rich" (Barrett 1986; Tucker 1986). In areas of the world where animal protein is lacking, the amaranth plant can stave off protein deficiencies. When amaranth flour is mixed with wheat or corn flour in breads or tortillas, the result is a near-perfect protein (eggs which can supply most of the body's protein requirements). Moreover, amaranth has more dietary fiber than any of the major grains (Tucker 1986). Amaranth seeds also contain calcium and phosphorus, whereas amaranth leaves, which can be eaten like spinach, provide dietary calcium and phosphorus as well as potassium, thiamine, riboflavin, niacin, and vitamins A and C. Amaranth is also richer in iron than spinach (Cole 1979; Tucker 1986).

The amaranth grain (which resembles a miniature flying saucer) is covered with a tough coat that the body cannot digest. Therefore, to obtain nutrition from the seeds it must be processed, and by toasting, boiling, or milling transformed into starch, bran, germ, or oil. Milling the grain yields 28 percent germ-bran and 72 percent white flour. Once processed, the tiny seeds have a "nutty flavor" and are used in breakfast cereals and made into flour for breads (Barrett 1986). Amaranth may also be popped like popcorn or made into candies. The Mexicans mix honey or molasses and popped amaranth into a sweet confection they call "alegría" (happiness) (Marx 1977; Cole 1979). Amaranth may even be brewed into a tea (Barrett 1986).

In addition to its nutritional advantages, amaranth "grows like a weed" in many different environments in the Americas, Africa, and Asia. Although it tends to do best in warm, dry climates with bright sunshine, some species flourish in the wet tropical lowlands, and others do well above 10,000 feet in the Andes. They also tolerate adverse soil conditions, such as high salt, acidity, or alkalinity, in which corn will not survive (Brody 1984; Tucker 1986). Besides growing rapidly under bright sunlight, amaranth has the ability to conserve water by partially closing its leaf pores. It can also tolerate dryness up to a point without wilting (Tucker 1986). Thus, it can be cultivated on marginal soils subject to periodic dry spells, which is an important consideration in semiarid regions.

Two disadvantages of amaranth are that the tiny seeds are awkward to work with and should be harvested by hand. In the United States, machine harvesting is possible after the first severe frost, but yields are lower (Tucker 1986). Yet hand-harvesting is not a major obstacle in countries where agricultural labor is plentiful and its cost is low. Another problem is that the domesticated species easily hybridize via wind pollination with the weedy varieties, yielding low-quality seeds (Marx 1977). Like so many plants, amaranth is also attacked by insects and plant diseases (Tucker 1986). These disadvantages may limit amaranth cultivation to gardeners in the United States and small farmers in the developing world.

Origins

According to J. D. Sauer (1976), wild amaranth seeds were gathered by many Native American peoples. As such, they may have contributed significant protein, as well as essential vitamins, to hunting and gathering populations after the big game animals died out in the Americas. Archaeologists can establish a gradual process of domestication with the appearance of pale, white seeds having improved popping quality and flavor. Notably when seed selection is relaxed, the plants return to producing dark seeds. One of the oldest dates for pale-seeded amaranth is 4000 B.C. from Tehuacan, Puebla, in Mexico, where *A. cruentus* has been found. By 2000 B.C., amaranth was part of the basic Mexican diet (Walsh and Sugiura 1991) (Map II.A.1.1). The Andean species of *A. caudatus* was discovered in 2,000-year-old tombs in northwestern Argentina (Sauer 1976). A more recent date of A.D. 500 marks an additional amaranth species, *A. hypochondriacus.* By the fourteenth century A.D., *A. hypochondriacus* was being cultivated in what is now Arizona.

As Sauer's maps (see also Map II.A.1.2) illustrate, the cores of amaranth cultivation in the pre-Columbian period were in Central Mexico, as well as in the Andes from Peru to northwestern Argentina. Additional pockets were in Ecuador close to the equator, Guatemala, southern and northwestern Mexico, and southwest North America. By the time the Spanish arrived at Vera Cruz in 1519, amaranth had evolved into a major crop staple employed to satisfy tribute obligations to the Aztec Empire. Moctezuma II received tribute from 17 provinces each year in ivory-white seeds known as *huauhtli* (Sauer 1950), which permitted the Aztecs to fill 18 imperial granaries. According to W. E. Safford (1916) and Sauer (1950), each granary had a capacity of 9,000 to 10,000 bushels. That so many seeds were collected each year is certainly impressive testimony to the widespread cultivation of amaranth in central Mexico before the Spanish conquest.

In addition, the Aztecs raised amaranth on *chinampas* (floating gardens) and utilized the plant in many ways: as a toasted grain, as green vegetables, and as a drink that the Spanish found "delicious." They also popped it. Since the Aztecs used both the leaves and the seeds, amaranth must have been an important supplement to their diet, especially in times of drought when corn crops died. Why then did the Spanish not adopt such a useful crop? Indeed, not only did the Spanish not adopt amaranth, they actually prohibited it, leaving us to wonder about the extent to which the abolition of such an important source of protein, minerals, and vitamins may have contributed to widespread malnutrition in the sixteenth century.

The Spaniards objected to amaranth because of its ritual uses as a sacred food associated with human sacrifice and "idolatry." In the early sixteenth century, the Aztecs celebrated a May festival in honor of their patron god, Huitzilopochtli, the god of war, at the great pyramid of Tenochtitlan. The ritual centered on an enormous statue of the god made of amaranth dough and included human sacrifices. Placed on a litter, the statue was carried in procession through the city and then returned to the temple where it was broken up by using other chunks of the same dough. The resulting pieces were subsequently consecrated as the flesh and bones of Huitzilopochtli, then distributed among the people, who ate them with a mixture of reverence and fear. The Spanish missionary and ethnographer Bernardino de Sahagún called the ceremonial paste *zoale* or *tzoalli* and noted that it was also fed to those who were to be sacrificed to Huitzilopochtli (Sauer 1950).

Other deities were also represented by *zoale,* such as the fire god Xiuhtecutli or the goddess Chicomecoatl, but the Tepanecs used it to form bird effigies, and the Tarascans made little figures of animals with the bread of *bledos* (the Spanish term for amaranth). On other occasions, such as the new fire ceremony, this celebration of the new 52-year cycle concluded with everyone present eating the bread of *bledos* and honey (Sauer 1950).

Source: Sauer 1950. Map II.A.1.1. Mexico: Localities and regions where grain amaranth cultivation is indicated.

Despite the Spanish prohibition, however, in the more remote parts of Mexico people continued to cultivate the plant and use it for food and ritual. A half century after the conquest amaranth continued to be an important food throughout much of Mexico (1950). As for ritual in 1629 in Guerrero, the priest Ruiz de Alarcón complained that the Indians were still milling amaranth to make dough for the manufacture of little idols of *zoale* to break up and eat in what appeared to the Spaniards to be a sort of parody of holy communion (Sauer 1950; Early 1992). Even as late as about 1900, a Huichol village of northern Jalisco celebrated one of its major festivals with "cakes" confected to represent animals. Made from amaranth seeds mixed with water, these cakes were usually employed ceremonially (Sauer 1950).

Over time, amaranth was also assimilated into Christian rituals. In the late nineteenth century, a visitor to Mexico described rosaries made of little balls of dough that were called *suale* (Sauer 1950). Sauer himself met a woman near Guadalajara in 1947 who was growing grain amaranths, making dough of them, and fashioning them into little cakes and rosaries (Sauer 1950). On a field trip to Mexico and Guatemala, Sauer discovered amaranth being cultivated in many patches, often unknown to outsiders. He found it to be most important in the Federal District, State of Mexico, and Morelos. Other states where it was grown were Guerrero, Tlaxcala, Puebla, Michoacán, and Sonora, Chihuahua, and Sinaloa. Thirty years after Sauer, Daniel Early (1977) visited Tulyehualco in Mexico where he observed techniques of amaranth planting on *chinampas.* In Guatemala, Sauer found that *A. cruentus* was still being planted by the Maya Indians in association with other crops, as they had done in the pre-Columbian period (Sauer 1950, 1976; Morley and Brainerd 1983).

As in highland Guatemala, Indian farmers in the Andes plant amaranth on "the fringes" of their maize fields. Sauer and others have reported amaranth crops in the highlands of Peru and Bolivia and in northwestern Argentina (Sauer 1950). At that time amaranth plants were known by a variety of names: *Achis, achita, ckoito, coyo,* or *coimi* in Peru; and *coimi, cuime, millmi,* or *quinua millmi* in Bolivia. As Sauer (1950) notes, the term *quinoa* was often used for amaranth as well as quinoa.

Amaranth was apparently widely cultivated in the pre-Columbian Andean highlands (Map II.A.1.2). A funerary urn has been found at Pampa Grande in Salta, Argentina, that was full of maize, beans, chenopod seeds, amaranth flowers, and pale seeds identified as *A. caudatus* (Sauer 1950). In 1971, A. T. Hunziker and A. M. Planchuelo reported finding *A. caudatus* seeds in tombs at least 2,000 years old located in north-western Argentina (Sauer 1976). But in the Inca period, good descriptions of amaranth are lacking, perhaps because it did not play the same ceremonial role as among the Aztecs. The Incas used maize for their sacred bread rather than amaranth. The first Spanish record that Sauer found (1950) is that of the Jesuit chronicler Bernabé Cobo who reported in 1653 that both red and white *bledos* were commonly consumed by Native Americans. Cobo also recognized that *bledos* were different from quinoa (Sauer 1950).

Sometime in the sixteenth century *A. caudatus* was taken from the Andes to Europe. In his *Rariorum Plantarum Historia,* Carl Clusius published the first illustration of the species in Antwerp in 1601 (Sauer 1950). He identified it as *Quinua, sive Blitum majus Peruanum.* Citing Clusius in 1737, Carl von Linné (Linnaeus) named the plant *Amaranthus caudatus* and indicated that it came from South America (Sauer 1950). A pale-seeded variety of *A. hypochondriacus* turned up in a sixteenth-century German collection that was found by P. Hanelt in 1968 (Sauer 1976). According to Sauer (1976), all three domesticated species may have been introduced to the Old World via Europe; henceforth, the American varieties of grain amaranth would be grown as ornamental plants in Europe. Other species of European amaranth now grow wild as weeds.

Asia and North America

The global distribution of amaranth before A.D. 1500 suggests that its cultivation is of "great antiquity," and there is no clear picture of the historical diffusion of American amaranths to Asia, or to Africa, for that matter. Amaranth in Asia probably predates 1492, because it is so widely scattered from Iran to China in remote places, such as Manchuria and eastern Siberia; and it is cultivated by isolated populations in high mountain valleys in the Himalayas. It seems to have been a staple in southern India for centuries (Sauer 1950, 1976), and the Indians argue that it was domesticated in India (Cole 1979).

E. D. Merrill (Cole 1979), however, believed that the Portuguese brought amaranth from Brazil to the Malabar coast of India after 1500, where it was widely cultivated by the nineteenth century. Yet Chinese sources may document its antiquity in Asia. According to Sauer (1950), there apparently is a reference to a grain amaranth in a medical tract of A.D. 950, written for the Prince of Shu in modern Sichuan. It lists six kinds of *hien,* a name that is used for grain amaranths in the same area in modern times.

Most descriptions of cultivated amaranths in Asia are modern, from the nineteenth century on, with a few eighteenth-century references to a European role in diffusing the American plants from Europe to Asia. By the early nineteenth century, amaranth was being cultivated in India, principally in the far south where it was a staple crop in the Nilgiri Hills, and in the north in the foothills of the Himalayas (Sauer 1950, 1976). In the south the people raise it for its seeds, which they convert into flour. Although also grown in the plains regions during the dry winter monsoon, amaranth is especially important in the foothills and mountains of the Himalayas from Afghanistan to Bhutan.

Source: Sauer 1950. Map II.A.1.2. South America: Localities and regions where grain amaranth cultivation is indicated.

Mongoloid nomads on the Tibetan frontier harvest grain at elevations of more than 3,500 meters, while farmers raise *A. caudatus* along with *A. leucocarpus* for grain in Nepal (Sauer 1950). According to Sauer (1950), the Himalayan plants are rich and variable in color with brilliant crimsons and rich yellows (Sauer 1950). Around Tehri in the hills of northern India the grain is popped and made into a dough to form thin cakes. In Nepal the people roast the seeds and eat them in sugar syrup like popcorn balls (Sauer 1950).

Similar popped seeds mixed with a hot sugar syrup are eaten in China, where amaranth seeds are known as *tien-shu-tze,* or millet from heaven. Sauer (1950) received dark-seeded *tien-shu-tze,* grown at elevations of 2,000 to 2,500 meters in northwestern Sichuan and Muping in Sikang. His informant reported that grain amaranths were not grown in Chengtu but in far-off mountain areas. Amaranth was also reportedly grown by the Chinese, who used the seeds to make little cakes (Sauer 1950). In addition, amaranth greens are used for food in China (Zon and Grubben 1976).

In Southeast Asia, amaranth is widely cultivated. In 1747 *A. caudatus* was identified in Indonesia, but the variety widely raised as a vegetable in modern Indonesia and other parts of Asia is *A. tricolor,* as well as species other than *A. caudatus,* such as *A. dubius.* Amaranth is a commercial crop from the Philippines to Taiwan and in Myanmar (Burma), where *A. tricolor* and *A. viridis* are grown (Zon and Grubben 1976).

As A. P. M. van der Zon and G. J. H. Grubben (1976) note, the use of amaranth as a green vegetable is quite extensive in tropical and subtropical regions of Asia and Southeast Asia, where there are many popular names for the plant: *épinard de Chine, amarante de Soudan,* African spinach, Indian spinach, *brède de Malabar,* and Ceylon spinach. Its consumption is nearly always in the form of a cooked spinach.

As of the middle 1970s, pale-seeded *A. hypochondriacus* constituted the bulk of the Asiatic crop; dark-seeded *A. hypochondriacus* and pale-seeded *A. caudatus* were minor components, although their leaves were widely used as a vegetable (Sauer 1976; Zon and Grubben 1976). The third American species, *A. cruentus,* has generally been planted as an ornamental dye plant or herb in Asia. Amaranth cultivation has been spreading in India, and Sauer (1976) believed at that time that India was the one place where amaranth was likely to experience expanded cultivation, perhaps stimulated by plant breeding. This was, of course, before scientists in the United States began extensive research on grain amaranths in the late 1970s and 1980s and American farmers initiated commercial production of amaranth in 1983 (Robinson n.d.).

The Rodale Research Center in Kutztown, Pennsylvania, is one of the leading amaranth research centers in the United States. In part because of amaranth's seed distribution and partly because of promotional efforts, American small farmers are increasingly cultivating the grain. Breads, cereals, cookies, and "Graham" crackers made with amaranth are now available in health-food and grocery stores in the United States.

Africa

How and when amaranth reached Africa is also uncertain. It is widely found as an ornamental plant or weed throughout the continent: from Senegal to Nigeria in West Africa, from Equatorial Africa to Zaire; and to a lesser extent in East Africa. Species have even been identified in Morocco, Ethiopia, and Sudan (Sauer 1950). *A. cruentus* is widespread in Africa, and *A. caudatus* is used as an ornamental and grain amaranth.

According to Zon and Grubben (1976), a variety of *A. cruentus* was introduced "recently" to southern Dahomey (now Benin) from Suriname and has proved to be resistant to drought. Other varieties of *A. cruentus* were widely marketed as a vegetable crop in Dahomey or raised in family gardens. A third American amaranth, *A. hypochondriacus,* was introduced into East Africa in the 1940s as a grain for the Indian population there (Sauer 1976).

That the history of amaranth in Africa remains comparatively unknown may be because of its widespread use in private vegetable gardens. The food preference of many Africans and African-Americans for greens may also mean that amaranth leaves are more important in the diet of Africans than seeds. The problem for the historical record, however, is that the cultivation and consumption of greens usually escapes documentation.

Conclusion

At this stage of research, the historical evolution and diffusion of amaranth remains a research problem for the future. How did amaranth come to be cultivated around the world? Under what conditions and when? As Sauer (1950) notes, amaranth species, cultivation methods, and consumption patterns are remarkably similar in Old and New Worlds. In both areas amaranth tends to be cultivated in the highlands, although the weed species grow well at other altitudes.

Farmers usually cultivate amaranth in conjunction with maize and other crops and consume it themselves in the form of balls of popped seeds, meal, and little cakes, and they use the seeds to make a beverage. It was and is a food crop principally of interest to small farmers and gardeners but one that promises to resolve some problems of world hunger in the twenty-first century. The great advantage of the grain amaranths is that they can be grown on marginal soils where reliable water supplies are problematic and can nourish populations that lack access to animal protein.

Once widely cultivated as a staple crop of the Aztec empire, amaranth has already proven its ability to sustain millions of people in a region lacking in significant sources of animal protein long before the arrival of the

Europeans. If population growth forces small farmers to move to more marginal lands in the next century, amaranth may make an important difference in nutrition levels for people who lack access to good corn or rice lands and cannot afford meat. In short, amaranth may well become an important supplementary food crop in many developing countries in the future.

II.A.2. Barley

That people do not live "by bread alone" is emphatically demonstrated by the domestication of a range of foodstuffs and the cultural diversity of food combinations and preparations. But even though many foods have been brought under human control, it was the domestication of cereals that marked the earliest transition to a food-producing way of life. Barley, one of the cereals to be domesticated, offered a versatile, hardy crop with an (eventual) tolerance for a wide range of climatic and ecological conditions. Once domesticated, barley also offered humans a wide range of valuable products and uses.

The origins of wheat and barley agriculture are to be found some 10,000 years ago in the ancient Near East. Cereal domestication was probably encouraged by significant climatic and environmental changes that occurred at the end of the glaciated Pleistocene period, and intensive harvesting and manipulation of wild cereals resulted in those morphological changes that today identify domesticated plants. Anthropologists and biologists continue to discuss the processes and causes of domestication, as we have done in this book's chapter on wheat, and most of the arguments and issues covered there are not reviewed here. All experts agree, however, on the importance of interdisciplinary research and multiple lines of evidence in reconstructing the story of cereal domestication.

Barley

Readers of this chapter may note some close similarities to the evidence for wheat domestication and an overlap with several important archaeological sites. Nonetheless, barley has a different story to tell. Barley grains and plant fragments are regular components of almost all sites with any plant remains in the Near East, regardless of period or food-producing strategy. Wild barley thrives widely in the Near East today – on slopes, in lightly grazed and fired pastures, in scrub-oak clearings, in fields and field margins, and along roadsides. These circumstances suggest a different set of research questions about barley domestication, such as: What was barley used for? Was its domestication a unique event? And how long did barley domestication take?

In addition, there are subthemes to be considered. Some researchers, for example, have suggested that barley was not domesticated for the same reasons that led to the domestication of other cereals – such as the dwindling of other resources, seasonal shortages, a desire for a sedentary food base, or the need for a surplus for exchange. Instead, barley may have been cultivated for the brewing of ale or beer.

In another view, the very slight differences between the wild and domesticated forms, and the ease with which wild barley can be domesticated, make it difficult to believe that barley domestication did not occur more than once. Geneticists and agricultural historians have generally believed that groups of crops were domesticated in relatively small regions and spread by human migration and trade. If barley was domesticated independently in several different communities, this would indicate that the transition to farming in those areas required little innovation and took place under recurring conditions.

Finally, because of their presence in many excavated sites, ancient barleys provide some of the best archaeological evidence bearing on the general problem of the pace of plant domestication. Whether the process took place over the course of a single human lifetime or evolved over many decades or centuries remains an important issue that may never be resolved with archaeological evidence alone (Hillman and Davies 1990). But the pace of domestication lies at the heart of the debate over the Neolithic – was it revolution or evolution (Childe 1951; Rindos 1984)? Did plant domestication radically transform people's lifestyles, or was it a gradual by-product of long-term behaviors with radical consequences noted only in retrospect? Barley is a crop that may hold answers to such questions.

Archaeological Evidence for the Domestication of Barley

Archaeological evidence points to the domestication of barley in concert with the emergence of Neolithic villages in the Levantine arc of the Fertile Crescent. Pre-Neolithic peoples, notably Natufian foragers (whose cultural remains include relatively large numbers of grinding stones, sickle blades, and storage pits), increasingly depended on plant foods and, perhaps, plant cultivation. Unfortunately, their tools point only to general plant use, and archaeologists continue to discuss which plants were actually processed (e.g., McCorriston 1994; Mason 1995). There is no evidence to suggest that the Natufians domesticated barley or any other plant.

Charred plant remains, the best evidence for domestication of specific plants, have rarely been recovered from pre-Neolithic sites. Preservation is generally poor. In the case of barley, only a few sites prior to the Neolithic contain recognizable fragments, and all examples indicate wild types. A few barley grains from Wadi Kubbaniya, an 18,000-year-old forager site in southern Egypt, were at first thought to be early examples of domesticated barley (Wendorf et al. 1979), but subsequent laboratory tests showed these to be modern grains that had intruded into ancient occupation layers (Stemler and Falk 1980; Wendorf et al. 1984). Other plant remains from Wadi Kubbaniya included relatively high numbers of wild *Cyperus* tubers and wild fruits and seeds (Hillman 1989).

One of the most extraordinary prefarming archaeological sites to be discovered in recent years is Ohalo II, on the shore of the Sea of Galilee, which yielded quantities of charred plant remains, including hundreds of wild barley grains (Kislev, Nadel, and Carmi 1992). About 19,000 years ago, foragers camped there, and the remains of their hearths and refuse pits came to light during a phase of very pronounced shoreline recession several years ago. Excavators believe that the charred plants found in the site were the remains of foods collected by Ohalo II's Epi-Paleolithic foragers. If so, these foragers exploited wild barley (*Hordeum spontaneum* Koch.), which was ancestral to domesticated barley.

Despite the generally poor preservation of plant remains, there are two Natufian sites with evidence suggesting that foraging peoples there collected some wild barley just prior to the beginnings of agriculture. Wadi Hammeh, a 12,000-year-old Early Natufian hamlet overlooking the Jordan Valley (Edwards 1988), contained charred seeds of wild barley *(Hordeum spontaneum),* wild grasses, small legumes, crucifers, and a range of other plants, as yet unidentified (Colledge, in Edwards et al. 1988). The seeds were scattered among deposits in several round houses, somewhat like the scatter of plant remains at another Natufian site, Hayonim Cave, where Early and Late Natufian dwellers had constructed round houses, possibly seasonal dwellings, within the cave (Hopf and Bar Yosef 1987). To be certain that disturbances had not carried later seeds down into Natufian layers (a problem at Wadi Kubbaniya and at another Natufian site, Nahel Oren), excavators had the charred seeds individually dated. Wild lupines found with wild almonds, wild peas, and wild barley *(Hordeum spontaneum)* suggest that the Natufian inhabitants collected plants that could be stored for later consumption.

Although there is little doubt that some foraging groups collected wild barley, evidence for the beginnings of barley domestication is far more controversial. Until recently, archaeologists were convinced that farmers (as opposed to foragers) had occupied any site containing even a few barley grains or rachis fragments with the morphological characteristics of domestic cereals. Thus, the identification of tough-rachis barley in the Pre-Pottery Neolithic A (PPNA) levels at Jericho (Hopf 1983: 609) implied that the earliest Neolithic occupants domesticated barley in addition to wheats and legumes.[1] A tough rachis inhibits seed dispersal, and wild barleys have brittle rachises that shatter when the seeds mature. Each segment of the rachis supports a cluster of three florets (flowers), from which only one grain develops. If a tough rachis fails to shatter, the seeds remain on the intact stalk, vulnerable to predators and unable to root and grow. Yet a tough-rachis crop is more easily and efficiently harvested by humans. Through human manipulation, the tough-rachis trait, which is maladaptive and scarce in the wild (Hillman and Davies 1990: 166–7), dominates and characterizes domesticated barley. At Jericho, the tough-rachis finds suggested to archaeologists that barley domestication had either preceded or accompanied the evident Neolithic practices of plant cultivation using floodwater manipulation in an oasis habitat.

However, at Netiv Hagdud, a contemporary (PPNA) site to the north of Jericho, Neolithic settlers seem to have practiced barley cultivation (Bar-Yosef et al. 1991), and the recovery there of rich archaeobotanical remains has forced archaeobotanists to rethink the significance of a few barley remains of the domesticated type in Early Neolithic sites throughout the Near East. Built on an alluvial fan in a setting not unlike that of Jericho, Netiv Hagdud proved to contain the foundations of almost a dozen large oval and small round structures. Some of these were probably houses with rock platform hearths and grinding equipment (Bar-Yosef et al. 1991: 408–11). The charred plant remains from the site included thousands of barley grains and rachis fragments, and the opportunity to examine these as an assemblage led to a surprising discovery.

Although a number of fragments clearly displayed a domesticated-type tough rachis (Kislev and Bar-Yosef 1986), archaeobotanists realized that as an assemblage, the Netiv Hagdud barley most closely resembles modern *wild* barley. Even among a stand of wild barley, approximately 12 percent of the spikes have a tough rachis (Zohary and Hopf 1993: 62) because this characteristic regularly appears as the result of mutation and self-fertilization to generate a pair of recessive alleles in a gene (Hillman and Davies 1990: 168). At Netiv Hagdud, the thousands of barley remains (including low numbers of tough-rachis examples) were collected, possibly from cultivated stands, by Early Neolithic people who appear from available evidence to have had no domesticated crops, although some scholars suggest that harvesting timing and techniques might still make it difficult to distinguish between wild and semidomesticated barley (Kislev 1992; Zohary 1992; Bar-Yosef and Meadow 1995). That evidence also implies that occasional domesticated-type barley remains at other Neolithic sites, including Tell Aswad (van Zeist and Bakker-Heeres 1982), may actually belong to an assemblage of purely wild barley.

Other Early Neolithic sites with remains of barley include Gilgal I, a PPNA site with cultural remains similar to those at Netiv Hagdud and Jericho. It is still unclear whether the "large amounts of oat and barley seeds" recovered in the mid-1980s from a silo in one of the Neolithic houses were domesticated or wild types (Noy 1989: 13). Tell Aswad, formerly nearer to Mediterranean oak forests and set beside a marshy lakeshore in the Damascus Basin, has also yielded a mix of rachis fragments, predominantly wild-type but with some domesticated-type (van Zeist and Bakker-Heeres 1982: 201–4). This same mix of wild and domesticated types was found in early levels at other early sites, including Ganj Dareh on the eastern margins of the Fertile Crescent (van Zeist et al. 1984: 219).

Over time, the percentages of wild-type and domesticated-type barley remains were inverted at sites in the Damascus Basin (van Zeist et al. 1984: 204). Tell Aswad was the earliest occupied of these sites in a 2,000-year sequence of nearly continuous residence there (Contenson 1985), and when it was abandoned, farmers had already settled nearby, at Tell Ghoraifé. Although the barley remains at Ghoraifé included many domesticated-type specimens, it was from evidence of a later occupation at Tell Aswad (8,500 to 8,900 years ago) and the nearby site of Ramad (occupied from 8,200 years ago) that archaeobotanists could unequivocally distinguish between fully domesticated barley and low numbers of wild barley in the same assemblages. The archaeobotanists suggested that the apparent mix of wild and domesticated types in earlier deposits may indicate an intermediate stage in the domestication process (van Zeist and Bakker-Heeres 1982: 184–5, 201–4).

There has never been much doubt that remains of barley from northern Levantine sites indicate plant collection or incipient stages of cultivation without domestication 10,000 years ago. Wild barley (*Hordeum spontaneum* Koch.) is well represented among the plant remains from Mureybit, an Early Neolithic village on the Euphrates River in the Syrian steppe (van Zeist and Bakker-Heeres 1984a: 171). Contemporary levels at Qeremez Dere, also in the steppe, contain abundant remains of fragmented wild grass grains, some of which "seem most probably to be wild barley" (Nesbitt, in Watkins, Baird, and Betts 1989: 21). Plant remains suggest that cereal cultivation was of little importance as one moved further north and east during the first centuries of Neolithic occupation. Cereals were present only as traces in the northern Iraq site of Nemrik 9 along the Tigris River (Nesbitt, in Kozlowski 1989: 30), at M'lefaat (Nesbitt and Watkins 1995: 11), and not at all at Hallan Çemi (Rosenberg et al. 1995) nor at earliest Çayönü (van Zeist 1972).

Available evidence now seems to suggest that domesticated barley appeared in the second phase of the early Neolithic – Pre-Pottery Neolithic B (PPNB) – several hundred years after wheat farming was established.[2] By the PPNB (beginning around 9,200 years ago), several different forms of domesticated barley, two-row and six-row (see the section "Taxonomy"), appeared among plant remains from Neolithic sites. Jericho and Ramad had both forms from about 9,000 years ago (van Zeist and Bakker-Heeres 1982: 183; Hopf 1983: 609). Barley does not seem to have been among the earliest crops in the Taurus Mountains – at PPNB sites such as Çayönü (van Zeist 1972; Stewart

1976) and Çafar Höyük (Moulins 1993). At Neolithic Damishliyya, in northern Syria (from 8,000 years ago), and Ras Shamra on the Mediterranean coast (from 8,500 years ago), domesticated two-row barley was present (van Zeist and Bakker-Heeres 1984b: 151, 159; Akkermans 1989: 128, 1991: 124). In Anatolia, domesticated barley also characterized the first appearance of farming, for example, at Çatal Hüyük (Helbaek 1964b). This is also the case in the eastern Fertile Crescent, where domesticated plants, barley among them, first showed up around 9,000 years ago – at Jarmo (Helbaek 1960: 108–9) and Ali Kosh (Helbaek 1969).

An excellent review of archaeobotanical remains (Zohary and Hopf 1993: 63–4) tracks the subsequent spread of two-row and six-row barley around the Mediterranean coast, across the Balkans, and into temperate Europe. Barley was one of the fundamental components of the Neolithic economic package introduced (and modified) with the spread of Near Eastern farmers across Anatolia and into various environmental zones of Europe (Bogucki 1996), as well as into northern Egypt (Wetterstrom 1993), Central Asia (Charles and Hillman 1992; Harris et al. 1993), and South Asia. By 8,000 years ago, barley agriculture had reached the foothills of the Indus Valley, where it supported farmers at Mehrgarh, one of the earliest settlements in South Asia (Jarrige and Meadow 1980; Costantini 1984).

During these first several thousand years, domesticated barley also spread into the steppes and desert margins of the Near East, expanding farming practices into an ecological niche where risk was high and barley offered what was probably the best chance for crop survival. At Abu Hureyra, in the Syrian steppe near Mureybit, six-row barley appeared earlier than its two-row barley ancestor (Hillman 1975), suggesting that fully domesticated barley crops were introduced to that site (Hillman and Davies 1990: 206), although recent paleoecological models suggest that wild barley grew nearby (Hillman 1996).

By the end of the PPNB, sites with barley were fairly common in very marginal farming zones – including, for example, El Koum 2 (Moulins, in Stordeur 1989: 108), Bouqras (van Zeist and Waterbolk-van Rooijen 1985), and Beidha (Helbaek 1966). At Nahal Hemar cave, in the dry Judean Hills, a single kernel of domesticated barley recovered was presumably imported to the site some 9,000 years ago (Kislev 1988: 77, 80). The spread of barley not only indicates the success of a farming way of life but also offers important archaeological indicators to complement botanical and ecological evidence of the domestication and significance of this vital crop plant.

Botanical Evidence for the Domestication of Barley

Barley grains and barley rachis internodes recovered from archaeological sites show the telling morphological characteristics of wild and domesticated forms, but botanical studies of modern barleys have also provided critical evidence for an interdisciplinary reconstruction of barley domestication. Archaeologists can examine ancient morphology but not ancient plant behavior. It was changes in both characteristics that established barley as a domesticated plant. Not only did the rachis become tough, but the ripening period of barley narrowed, and a single-season seed dormancy became established. Botanical studies have revealed relationships between species and varieties of barley and the precise nature of the changes that must have occurred under domestication.

Taxonomy

As with wheats, taxonomic classification of barleys has changed with expanding scientific knowledge of genetic relationships. Genetic evidence now indicates much closer relationships among what morphologically once appeared to be distinctive species (Briggs 1978: 77). Yet it is the morphological criteria, easily seen, that offer farmers and archaeologists a ready means by which to classify barleys (but see Hillman and Davies 1990, and Hillman et al. 1993, for alternative experimental approaches). Because archaeologists have had to rely largely on morphological criteria to detect the beginnings of domestication, the old species names remain convenient terms for distinguishing between what are now considered barley varieties (new species names in parentheses follow).

Barleys belong in the grass tribe Triticeae, to which wheats and ryes (barley's closest crop relatives) also belong. There are 31 barley species (almost all wild), and nearly three-fourths of them are perennial grasses (Bothmer and Jacobsen 1985; Nilan and Ullrich 1993). Despite the diversity of wild barleys that can be identified today, most botanists and geneticists concur that all domesticated types most probably have a single wild ancestor, *Hordeum spontaneum* Koch. *(H. vulgare* subsp. *spontaneum)* (Harlan and Zohary 1966; Zohary 1969). This plant crosses easily with all domesticated barleys. The major morphological difference between wild and domesticated barley lies in the development of a tough rachis in the domesticate.

Once farmers had acquired a domesticated two-row form of barley, they selectively favored the propagation of a further morphological variant, the six-row form. Barleys have three flowers (florets) on each rachis segment (node). In the wild and domesticated two-row forms, however, only the central floret develops a grain. Thus, one grain develops on each side of a rachis, giving the spike the appearance of two grains per row when viewed from the side. In the six-row form, *Hordeum hexastichum* L. *(H. vulgare* subsp. *vulgare),* the infertility of the lateral florets is overcome: Nodes now bear three grains each, so the spike has three grains on each side. This gives an appearance of six grains per row in side view. A general evolutionary trend in the grass family has been the reduction of reproductive parts; so, for a long time, it was difficult for botanists to accept that one of the consequences of domestication and manipulation of barley has been to restore fertility in lateral spikelets, thereby increasing the grain production of each plant (Harlan 1968: 10).

A final important morphological change was the appearance of naked-grain barleys. In wild cereals, the modified seed leaves (glumes, lemmas, and paleas) typically tightly enclose the grain and form a protective husk. From a human perspective, one of the most attractive changes in domesticated cereals is the development of grains from which the glumes, lemmas, and paleas easily fall away. Because humans cannot digest the cellulose in the husks, such development considerably reduces processing effort. Naked-grain barleys *(Hordeum vulgare* subsp. *distichum* var. *nudum* and *H. vulgare* subsp. *vulgare* var. *nudum)* appeared shortly after the emergence of six-row forms (Zohary and Hopf 1993: 63). Taxonomists have always recognized these as varieties rather than as distinct species of barley.

Genetics

Genetic relationships remain very close among all barleys, and modern taxonomic schemes collapse all cultivated barleys and the wild *Hordeum spontaneum* ancestor into a single species, *Hordeum vulgare* (Harlan and Zohary 1966: 1075; Briggs 1978: 78; Nilan and Ullrich 1993: 3). *H. vulgare* is a diploid with two sets of seven chromosomes ($2n = 14$) and has proved an excellent subject for genetic and cytogenetic analysis (Nilan and Ullrich 1993: 8). Because the plant is self-fertile (that is, male pollen fertilizes its own or adjacent flowers on the same plant), mutations have a good chance of being copied and expressed in the genes of subsequent generations. This attribute was undoubtedly an important feature of barley domestication, for a very few mutations have caused major morphological changes that were easily favored by humans, both consciously and unconsciously (Harlan 1976; Hillman and Davies 1990).

A brittle rachis, for example, is controlled by a pair of tightly linked genes. A mutant recessive allele in either gene (Bt and Bt_1) will produce a tough rachis in homozygous offspring (Harlan 1976: 94; Briggs 1978: 85). This condition will occur rarely in the wild but may be quickly selected for and fixed in a population under cultivation (Hillman and Davies 1990: 166–8). Experimental trials and computer simulations suggest that under specific selective conditions, the homozygous recessive genotype may become predominant in as few as 20 years (Hillman and Davies 1990: 189). Consequently, barley domestication depends on one mutation!

Furthermore, a single recessive mutation also is responsible for fertility in lateral florets and the conversion from two-row to six-row forms (Harlan 1976: 94). Another gene, also affected by a recessive mutant allele, controls the adherence of lemma and palea to the grain. Jack Harlan (1976: 95–6) has postulated a single domestication of wild barley followed by other recessive mutants for six-row and naked forms.

Objections to this parsimonious reconstruction revolve around the many brittle or semibrittle rachis variants of barley, some of which include six-row forms. Barley is rich in natural variants in the wild (Nevo et al. 1979; Nilan and Ullrich 1993: 9), and geneticists have long tried to incorporate six-row brittle forms (e.g., *Hordeum agriocrithon* Åberg) into an evolutionary taxonomy of the barleys. Most now agree that the minor genetic differences, wide genetic diversity, and ease of hybridization and introgression with domesticated forms account for the great number of varieties encountered in the "wild" (Zohary 1964; Nilan and Ullrich 1993: 3).

Ecological Evidence for Barley Domestication

Geographic Distribution

In the tradition of Nikolay Ivanovich Vavilov, geneticists and botanists have documented the distributions of wild and domesticated varieties of barley. The places where wild races ancestral to domesticated crops grow today may indicate the range within which a crop arose, because the earliest cultivators must have encountered the plant in its natural habitat. Patterns of genetic diversity in different areas may also offer clues about the history of a crop plant. Such patterns may suggest, for example, a long and intensive history of manipulation or an isolated strain. Harlan and Daniel Zohary (1966: 1075–7) have summarized the modern distribution of wild barley, *Hordeum spontaneum,* noting many populations outside the core area of the Fertile Crescent where the earliest agricultural villages lay.

Harlan and Zohary distinguish between truly wild barley *(H. spontaneum)* and weedy races – wild-type barleys derived from domesticated barley crops in areas to which barley farming spread after domestication. Modern distribution of truly wild progenitors is closely associated with the geography of semiarid Mediterranean climates and with an ecological relationship with deciduous oak open woodland that covers the lower slopes of the mountain arc of the Fertile Crescent. This landscape was made famous by Robert J. Braidwood's expedition to the "Hilly Flanks," where he and later archaeologists sought to uncover the first farming villages (Braidwood and Howe 1960: 3). A "small, slender, very grassy type" grows wild in steppic environments with somewhat greater temperature extremes and less annual rainfall. Another distinct truly wild race in the southern Levant has extremely large seeds (Harlan and Zohary 1966: 1078).

In areas outside the semiarid Mediterranean woodlands, wild-type barleys survive in a more continental climate (hotter summers, colder winters, year-round rainfall). Because all the collections in such areas have proved to be weedy races (including brittle-rachis, six-row *Hordeum agriocrithon* Åberg from Tibet), their range provides better information on the spread of barley farming than on the original domestication of the plant.

Ecological Factors

Ecologically, wild barley shares some of the preferences of wheat, but wild barley has not only a much more extensive geographical range but also a wider ecological tolerance. Barleys thrive on nitrogen-poor soils, and their initial cultivation must have excluded dump-heap areas enriched by human and animal fertilizers (Hillman and Davies 1990: 159). But the wild barley progenitors do thrive in a variety of disturbed habitats (Zohary 1964). In prime locales, wild barley flourishes on scree slopes of rolling park-woodlands. It likes disturbed ground – in fields and along roadsides – and is a moderately aggressive fire follower (Naveh 1974, 1984).

Ecological and botanical attributes of wild barley have convinced some that it was the first domesticate (Bar-Yosef and Kislev 1989: 640). Archaeological evidence, however, indicates that despite possible cultivation in the PPNA (Hillman and Davies 1990: 200; Bar-Yosef et al. 1991), barley was not domesticated as early as wheat and some legumes. From the perspective of cultivators, wild wheats have several advantages over wild barley, including greater yield for harvesting time (Ladizinsky 1975) and easy detachment of lemma and palea. Modern wild barleys demonstrate a number of features potentially attractive to foraging peoples, including large grain size, ease of mutant fixation, local abundance, and wide soil and climate tolerance (Bar-Yosef and Kislev 1989: 640). Nevertheless, the archaeological record holds earlier evidence of domesticated wheat than of domesticated barley.

Was wheat domestication fast and that of barley slow? Or were these cereals domesticated at the same rate but at different times? Experimental studies offer significant insights into the archaeological record of cereal domestication, including probable causes of ambiguity where wild forms may or may not have been cultivated (Hillman and Davies 1990; Anderson-Gerfaud, Deraprahamian, and Willcox 1991). Although barley domestication can happen very quickly, the rate of domestication would have varied according to planting and harvesting conditions. It would be nearly impossible to discriminate between collection and cultivation (reseeding) of wild barley in the archaeological record; therefore, it is difficult to know whether barley was cultivated for a long time before becoming a recognizable domesticate. The excellent work of Gordon Hillman and Stuart Davies (1990) with mutation rates, cultivation variables, and harvest strategies suggests little inherent difference between wheat and barley plants for their domesticability. Perhaps the very different archaeological record, with a PPNA emergence of domesticated wheat and a later PPNB emergence of domesticated barley, implies that we should look beyond the genetics and ecology of the plants for other variables in the early history of agriculture.

Uses of Barley and Barley Domestication

Today, barley is primarily important for animal feed, secondarily for brewing beer, and only marginally important as a human food. Although researchers typically assume that cereals were first domesticated as foodstuffs, we do not know what prominence, if any, barley had in early agriculturalists' diets. In its earliest, most primitive, hulled form, barley required extra processing to remove lemma and palea. Once naked barleys appeared, one suspects that they were preferred as human food, but one cannot conclude that hulled barleys were domesticated for animal feed. Although the domestication of barley coincided with the appearance of domesticated animals in the Levant, the Natufian and PPNA evidence clearly indicates harvest and, perhaps, cultivation of wild barley before animal domestication. Some quality of barley attracted cultivators before they needed animal feed.

Solomon Katz and Mary Voigt (1986) have hypothesized that barley domestication was a consequence of early beer brewing. They suspect that epi-Paleolithic peoples intensively cultivated wild barley because they had come to understand its use in fermentation and the production of alcohol, and it was this use that prompted the advent of Neolithic farming. Their theory implies that epi-Paleolithic peoples were sedentary, as Natufians apparently were (Tchernov 1991). Beer brewers must also have possessed pottery or other suitable containers, yet the invention of pottery took place long after cereal domestication in the Near East. And if cereal (barley) domestication was brought about by demand for beer, then domestication probably was impelled by social relationships cemented by alcohol rather than by subsistence values of cereal grains. The social context of drinking has been explored recently by a number of anthropologists (e.g., Moore 1989; Dietler 1990) who have emphasized the important roles that alcohol and other costly perishables play in social relationships, especially in matters of reciprocity and obligation.

Perhaps one of the most significant insights into the theory that a fermented beverage (rather than a nutritive grain) impelled domestication lies in the methods by which early beer was made. Recipes on Mesopotamian clay tablets and iconographic documentation clearly indicate that early beer was made from bread (Katz and Maytag 1991) rather than from malt (sprouted grain), as in modern practice. Both bread making and malting produce a fermentation material in which the cereal-grain endosperm has already been partially broken down mechanically and chemically (Hough 1985: 4–5). Archaeologists have detected residues consistent with beer making on ceramics from as early as the late fourth millennium B.C. (Michel, McGovern, and Badler 1992). If this Sumerian beer-making tradition developed from early antiquity, the most parsimonious theory is that beer-making developed from fermented bread.

But even if barley was first cultivated for its food value (perhaps as grits or gruel), it clearly offered an important array of products to farmers. In addition to grain feed, beer, and bread, barley also yielded straw for fodder, thatch, basketry, mudbrick, and pottery temper. Many of these products must have been essential as barley farming spread to arid regions all but devoid of trees, wood, and lush, wild vegetation.

The Spread of Barley Farming

Perhaps the most significant expansion of domesticated barley was into the truly arid steppes and deserts of the Near East, where irrigation was critical to its survival. Hans Helbaek (1964a: 47) has argued that barley was irrigated by the occupants of Tell es Sawwan in the early fifth millennium B.C. Six-row barley was evident among the site's archaeological plant remains, yet with the available rainfall, plants producing even a third as much seed (such as the two-row forms) would have been hard-pressed to survive; the six-row form could have thrived only under irrigation. Six-row barley was one of the principal crops in ancient southern Mesopotamia, and some have even suggested that barley production lay at the heart of the rise of the earliest truly complex societies in a river-watered desert.

Barley farming has also expanded into temperate regions of China, and into the tropics, where dry and cool highland regions (such as in Ethiopia, Yemen, and Peru) offer appropriate locales for cultivation. Christopher Columbus's voyages first brought the crop to the New World (Wiebe 1968), where it spread most successfully in North America (Harlan 1976: 96).

Conclusion

Domesticated barley was an important crop in human prehistory and provided many products to a wide range of settled peoples. Barley has long been considered one of the initial domesticates in the Southwest Asian Neolithic package of cereals and legumes, and in a broad chronological sweep, this conclusion remains true. But recent archaeological and botanical research indicates that domesticated barley did not appear among the very first domesticated plants. With a growing corpus of plant remains, more attention can be paid to regional variation in the Southwest Asian Neolithic, and archaeologists can now develop a more complex understanding of early plant domestication. Just as there seems to be no barley in PPNA agriculture, barley also seems to be absent from early PPNB farming communities in the Taurus Mountains. Archaeologists have long recognized other late domesticates, such as grapes, olives, and other fruits. The progress of barley domestication, along with its origins, offer potentially interesting insights into the development of domestic lifestyles and the expansion and adoption of farming in new ecological zones.

One explanation for different timing of wheat and barley domestication might be found in the possibility that differences in cultivation practices led to differences in cereal domestication. Modern studies suggest that domestication rates should be similar for wheat and barley, but they also demonstrate that different practices – tending cereals on the same or on new plots each year, for example – can affect domestication rates. An archaeological record implying a long period of cultivation for barley prompts us to wonder if cultivators treated wheats and barleys differently. Did they value one cereal more than another? Can we use such evidence from different regions and different crops to understand the significance of different plants in the diets and lives of the earliest cultivators and farmers?

Increasing botanical and ecological knowledge of cereals will help us address such questions. It may be that differences between wheat and barley domestication are related to the ease with which backcrossing between domesticated and wild cereal plants reintroduces wild traits in generations of barley crops. Ongoing experiments in cereal domestication will provide important information.

Ultimately, our reconstruction of barley domestication, and of its prehistoric importance in human diet and nutrition, depends on interdisciplinary research – the combination of archaeological evidence with botanical, ecological, and experimental evidence. There will always be uncertainties. Archaeological sites have been excavated and analyzed by different researchers practicing different methods and taking plant samples of differing quantity and quality. Modern distributions and plant ecology are the result of historical, environmental, and climatic changes, and ecologists and botanists can only guess in what ways these have affected plant geography. Nevertheless, as more archaeological and botanical evidence emerges, some of these uncertainties may be more conclusively addressed and the process of barley domestication more fully understood.

Joy McCorriston

Endnotes

1. Some of the oldest dates from Jericho can be questioned (Burleigh 1983: 760), and as is the case with wheat remains, domesticated-type barley remains from PPNA Jericho may actually be several hundred years younger than the oldest

Neolithic radiocarbon dates (10,300 to 10,500 years ago) suggest.

2. The earliest unequivocal remains of wheat are the relatively large numbers of domesticated emmer in the lowest levels at Tell Aswad (9,800 years ago), from which no wild wheats were recovered (van Zeist and Bakker-Heeres 1982), and at Jericho, outside the range of wild wheats (Harlan and Zohary 1966).

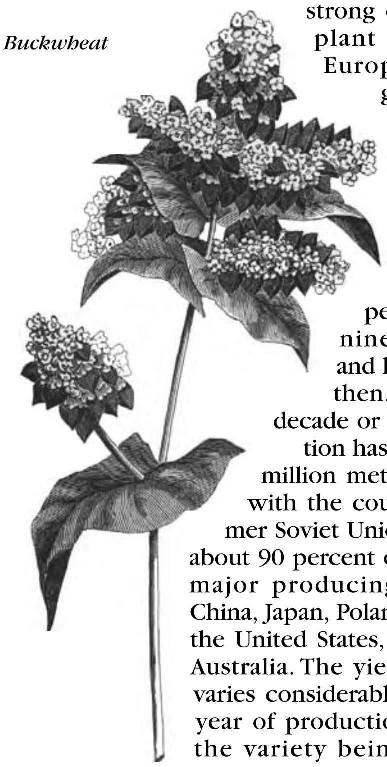
II.A.3. Buckwheat

Buckwheat (*Fagopyrum esculentum* Möench) is a crop commonly grown for its black or gray triangular seeds. It can also be grown as a green manure crop, a companion crop, a cover crop, as a source of buckwheat honey (often for the benefit of bees), and as a pharmaceutical plant yielding rutin, which is used in the treatment of capillary fragility. Buckwheat belongs to the *Polygonaceae* family (as do sorrel and rhubarb). Whereas cereals such as wheat, maize, and rice belong to the grass family, buckwheat is not a true cereal. Its grain is a dry fruit.

Buckwheat is believed to be native to Manchuria and Siberia and, reportedly, was cultivated in China by at least 1000 B.C. However, fragments of the grain have been recovered from Japanese sites dating from between 3500 and 5000 B.C., suggesting a much earlier date for the grain's cultivation. It was an important crop in Japan and reached Europe through Turkey and Russia during the fourteenth and fifteenth centuries A.D., although legend would have it entering Europe much earlier with the returning Crusaders. Buckwheat was introduced into North America in the seventeenth century by the Dutch, and it is said that its name derives from the Dutch word *bochweit* (meaning "beech wheat"), because the plant's triangular fruits resemble beechnuts. In German the name for beech is *Buche,* and for buckwheat, *Buchweizen.* Buckwheat has a nutty flavor and, when roasted *(kasha),* a very strong one. It is a hardy plant that grew in Europe where other grains did not and, thus, supplied peasants in such areas with porridge and pancakes.

Buckwheat



Production of buckwheat peaked in the early nineteenth century and has declined since then. During the past decade or so, world production has averaged about 1 million metric tons annually, with the countries of the former Soviet Union accounting for about 90 percent of the total. Other major producing countries are China, Japan, Poland, Canada, Brazil, the United States, South Africa, and Australia. The yield of buckwheat varies considerably by area and by year of production and also with the variety being cultivated. In Canada, the average yield over the past 10 years has been about 800 kilograms per hectare (kg/ha), although yields of 2,000 kg/ha and higher have been produced.

Types and Cultivars

There are three known species of buckwheat: Common buckwheat *(F. esculentum),* tartary buckwheat *(Fagopyrum tataricum),* and perennial buckwheat *(Fagopyrum cymosum).* Common buckwheat is also known as *Fagopyrum sagigtatum,* and a form of tartary buckwheat may be called *Fagopyrum kashmirianum.* The cytotaxonomy of buckwheat has not been thoroughly studied, but it is generally believed that perennial buckwheat, particularly the diploid type, is the ancestral form of both tartary buckwheat and common buckwheat.

Tartary buckwheat (also known as rye buckwheat, duck wheat, hull-less, broomless, India wheat, Marino, mountain, Siberian, wild goose, and Calcutta buckwheat) is cultivated in the Himalayan regions of India and China, in eastern Canada, and, occasionally, in mountain areas of the eastern United States. Tartary buckwheat is very frost-resistant. Its seeds – and products made from them – are greenish in color and somewhat bitter in taste. Buckwheat is used primarily as an animal feed or in a mixture of wheat and buckwheat flour. It can also be used as a source of rutin.

Common buckwheat is by far the most economically important species of buckwheat, accounting for over 90 percent of world production. Many types, strains, and cultivars of common buckwheat exist – late-maturing and early-maturing types, Japanese and European types, summer and autumn types. Within a given type there may be strains or varieties with tall or short plants, gray or black seeds, and white or pink flowers. In general, however, common buckwheat varieties from different parts of the world may be divided into two major groups. The first group includes tall, vigorous, late-maturing, photoperiod-sensitive varieties, found in Japan, Korea, southern China, Nepal, and India. Members of the second group are generally insensitive to photoperiod and are small and early-maturing. All of the varieties in Europe and northern China belong to this second group.

Prior to 1950, most producers of buckwheat planted unnamed strains that had been harvested from their own fields or obtained from their neighbors or local stores. Named varieties, developed through plant breeding, were first made available in the 1950s. 'Tokyo', the oldest of the named cultivars introduced into North America, was licensed in 1955 by the Agriculture Canada Research Station in Ottawa. Other cultivars licensed for production in Canada are 'Tempest', 'Mancan', and 'Manor', all developed at the Agriculture Canada Research Station in Morden, Manitoba, since 1965. 'Mancan', which has large, dark-brown seeds, thick stems, and large leaves, is the Canadian cultivar preferred in the Japanese market because of its large seeds, desirable flavor and color, and high yield of groats in the milling process.

Cultivars licensed in the United States are 'Pennquad' (released by the Pennsylvania Agricultural Experimental Station and the U.S. Department of Agriculture [USDA] in 1968) and 'Giant American' (a Japanese-type cultivar, apparently developed by a Minnesota farmer). Cultivars developed in the countries of the former Soviet Union since the 1950s include 'Victoria', 'Galleya', 'Eneida', 'Podolyaka', 'Diadema', 'Aelita', and 'Aestoria'. Representative cultivars from other areas of the world include the following: 'Pulawska', 'Emka', and 'Hruszowska' from Poland; 'Bednja 4n' from Yugoslavia; and 'Botan-Soba', 'Shinano No. 1', 'Kyushu-Akisoba Shinshu', and 'Miyazaki Oosoba' from Japan.

Plant and Seed Morphology

Buckwheat is a broad-leaved, erect, herbaceous plant that grows to a height of 0.7 to 1.5 meters. It has a main stem and several branches and can reach full maturity in 60 to 110 days. The stem is usually grooved, succulent, and hollow, except for the nodes. Before maturity, the stems and branches are green to red in color; after maturity, however, they become brown. The plant has a shallow taproot from which branched, lateral roots arise. Its root system is less extensive than those of cereals and constitutes only 3 to 4 percent of the dry weight of the total plant, which – in conjunction with the large leaf surface – may cause wilting during periods of hot and dry weather.

Buckwheat has an indeterminate flowering habit. The flowers of common buckwheat are perfect but incomplete. They have no petals, but the calyx is composed of five petal-like sepals that are usually white, but may also be pink or red. The flowers are arranged in dense clusters at the ends of the branches or on short pedicels arising from the axils of the leaves. Common buckwheat plants bear one of two types of flowers. The pin-type flower has long styles (or female parts) and short stamens (or male parts), and the thrum-type flower has long styles and short pistils. The pistil consists of a one-celled superior ovary and a three-part style with knoblike stigmas and is surrounded by eight stamens. Nectar-secreting glands are located at the base of the ovary. The plants of common buckwheat are generally self-infertile, as self-fertilization is prevented by self-incompatibility of the dimorphic, sporophitic type. Seed production is usually dependent on cross-pollination between the pin and thrum flowers. Honeybees and leaf-cutter bees are effective pollinators that increase seed set and seed yield.

Plants of tartary buckwheat are significantly different from those of common buckwheat. They have only one flower type and are self-fertile. In addition, they tend to be more husky and more branched and to have narrower, arrow-shaped leaves and smaller, greenish-white flowers. Attempts to transfer the self-compatibility of tartary buckwheat to common buckwheat have proved unsuccessful.

The buckwheat kernel is a triangular, dry fruit (achene), 4 to 9 millimeters (mm) in length, consisting of a hull or pericarp, spermoderm, endosperm, and embryo. Large seeds tend to be concave-sided and small seeds are usually convex-sided. The hull may be glossy, gray, brown, or black and may be solid or mottled. It may be either smooth or rough with lateral furrows. The hulls represent 17 to 26 percent (in tartary buckwheat, 30 to 35 percent) of the kernel weight. Diploid varieties usually have less hull than tetraploids.

Structure of the Kernel

Scanning electron microscopy of the buckwheat kernel has revealed that the hull, spermoderm, endosperm, and embryo are each composed of several layers. For the hull, these are (in order from the outside toward the inside) the epicarp, fiber layers, parenchyma cells, and endocarp. The spermoderm is composed of the outer epiderm, the spongy parenchyma, and the inner epiderm. The endosperm includes an aleurone layer and a subaleurone endosperm, containing starch granules surrounded by a proteinaceous matrix. The embryo, with its two cotyledons, extends through the starchy endosperm. The terminal parts of the cotyledons are often parallel under the kernel surface.

Composition

The gross chemical composition of whole buckwheat grain, the groats, and the hulls is shown in Table II.A.3.1. The mineral and vitamin contents of the whole grains are shown in Table II.A.3.2.

Table II.A.3.1. *Percentage composition of buckwheat seed and its milling products*

Seed or products	Moisture	Ash	Fat	Protein	Fiber	Nitrogen-free extracts
Seed	10.0	1.7	2.4	11.2	10.7	64.0
Groats	10.6	1.8	2.9	11.2	0.9	73.7
Dark flour	11.7	1.2	1.8	8.9	1.0	75.3
Light flour	12.0	1.3	1.6	7.8	0.6	76.7
Very light flour	12.7	0.6	0.5	4.7	0.3	81.1
Hulls	8.0	2.2	0.9	4.5	47.6	36.8
Middlings or shorts	10.7	4.6	7.0	27.2	11.4	39.1

Carbohydrates

Starch is quantitatively the major component of buckwheat seed, and concentration varies with the method of extraction and between cultivars. In the whole grain of common buckwheat, the starch content ranges from 59 to 70 percent of the dry matter. The chemical composition of starch isolated from buckwheat grains differs from the composition of cereal starches (Table II.A.3.3). The differences are most pronounced in the case of buckwheat and barley. The amylose content in buckwheat granules varies from 15 to 52 percent, and its degree of polymerization varies from 12 to 45 glucose units. Buckwheat starch granules are irregular, with noticeable flat areas due to compact packing in the endosperm.

Buckwheat grains also contain 0.65 to 0.76 percent reducing sugars, 0.79 to 1.16 percent oligosaccharides, and 0.1 to 0.2 percent nonstarchy polysaccharides. Among the low-molecular-weight sugars, the major component is sucrose. There is also a small amount of arabinose, xylose, glucose, and, probably, the disaccharide melibiose.

Table II.A.3.3. *Chemical composition of buckwheat, barley, and corn starch granules smaller than 315 µ*

	Content (% dry matter)		
Constituent	Buckwheat	Barley	Corn
Total nitrogen	0.23	0.19	0.12
Free lipids	2.88	2.42	1.80
Ash	0.27	1.04	1.25
Dietary fiber	31.82	41.12	32.02
Hemicellulose[a]	15.58	14.03	24.13
Cellulose[a]	2.72	4.07	0.91
Lignin[a]	13.52	24.03	6.99

Proteins

Protein content in buckwheat varies from 7 to 21 percent, depending on variety and environmental factors during growth. Most currently grown cultivars yield seeds with 11 to 15 percent protein. The major protein fractions are globulins, which represent almost half of all proteins and consist of 12 to 13 subunits with molecular weights between 17,800 and 57,000. Other known buckwheat protein fractions include albumins and prolamins. Reports of the presence of gluten or glutelin in buckwheat seed have recently been discredited.

Buckwheat proteins are particularly rich in the amino acid lysine. They contain less glutamic acid and proline and more arginine, aspartic acid, and tryptophan than do cereal proteins. Because of the high lysine content, buckwheat proteins have a higher biological value (BV) than cereal proteins such as those of wheat, barley, rye, and maize (Table II.A.3.4). Digestibility of buckwheat protein, however, is rather low; this is probably caused by the high-fiber content (17.8 percent) of buckwheat, which may, however, be desirable in some parts of the world. Buckwheat fiber is free of phytic acid and is partially soluble.

Lipids

Whole buckwheat seeds contain 1.5 to 3.7 percent total lipids. The highest concentration is in the embryo (7 to 14 percent) and the lowest in the hull (0.4 to 0.9 percent). However, because the embryo constitutes only 15 to 20 percent of the seed, and the hull is removed prior to milling, the lipid content of the groats is most meaningful. Groats (or dehulled seeds) of 'Mancan', 'Tokyo', and 'Manor' buckwheat contain 2.1 to 2.6 percent total lipids, of which 81 to 85 percent are neutral lipids, 8 to 11 percent phospholipids, and 3 to 5 percent glycolipids. Free lipids, extracted in petroleum ether, range from 2.0 to 2.7 percent. The major fatty acids of buckwheat lipids are palmitic (16:0), oleic (18:1), linoleic (18:2), stearic (18:0), linolenic (18:3), arachidic (20:0), behenic (22:0), and lignoceric (24:0). Of these, the first five are commonly found in all cereals, but the latter three, which represent, on average, 8 percent of the total acids in buckwheat, are only minor components or are not present in cereals.

Phenolic Compounds

The content of phenolics in hulls and groats of common buckwheat is 0.73 and 0.79 percent (and that of tartary buckwheat, 1.87 and 1.52 percent). The three major classes of phenolics are flavonoids, phenolic acids, and condensed tannins. There are many types of flavonoids, three of which are found in buckwheat. These are flavonols, anthocyanins, and C-glycosylflavones. Rutin (quercetin 3-rutinoside), a well-known flavonol diglucoside,

Table II.A.3.4. *Quality of buckwheat and wheat protein*

Parameter	Buckwheat (g/16gN)	Barley (g/16gN)	Wheat (g/16gN)	Rye (g/16gN)	Maize (g/16gN)

used as a drug for the treatment of vascular disorders caused by abnormally fragile or permeable capillaries, occurs in the leaves, stems, flowers, and fruit of buckwheat.

Grading, Handling, and Storage

Grading

In most countries, buckwheat grain is priced according to its physical condition in terms of size, soundness, and general appearance. In Canada, buckwheat is marketed according to grades established under the Canada Grain Act: Grades are No. 1, No. 2, and No. 3 Canada, and Sample. Grade determinants are a minimum test weight of 58 and 55 kilograms per hectoliter (kg/hL) (for Nos. 1 and 2 Canada), variety (designated by size, large or small), degree of soundness, and content of foreign material (Table II.A.3.5). Grades No. 1 and 2 Canada must be free from objectionable odors; No. 3 Canada may have a ground or grassy odor but may not be musty or sour. Test weight, seed size, and foreign material content are determined on a dockage-free sample. Seed size is determined with a No. 8 slotted sieve (3.18 × 19.05 mm) and becomes part of the grade name (e.g., "buckwheat, No. 1 Canada, large").

"Foreign material" refers to cereal grains (wheat, rye, barley, oats, and triticale), weed seeds, and other grains that are not readily removable by mechanical cleaners, and may include peas, beans, maize, and other domestic or wild weeds. Buckwheat grain containing more than 5 percent foreign material is graded "buckwheat, Sample Canada, (size), account admixture." Damaged seeds include frosted, moldy, distinctly green or otherwise unsound, and dehulled seeds.

Table II.A.3.5. *Primary grade determinants of buckwheat (Canada)*

			Maximum limits of foreign material (%)				
Grade	kg/hL	Degree of soundness	Stones[a]	Ergot	Sclerotinia	Cereal grains	Total foreign material
No. 1	58.0	Well matured, cool and sweet	3	0.0	0.0	1.0%	1.0%
No. 2	55.0	Reasonably well matured, cool and sweet	3	0.05%	0.05%	2.5%	3.0%
No. 3	No min.	May have a ground or grassy odor, but may not be musty or sour	3	0.25%	0.25%	5.0%	5.0%

[a] Number of kernel-size stones in 500 g.

In the United States, buckwheat is not marketed under federally established grades, but some states (for example, Minnesota) have official grain standards that specify the use of Grades 1, 2, 3, and Sample. The grade determinants are similar to those of the Canadian grading system. In Japan, the Buckwheat Millers Association prefers buckwheat that has large, uniform seeds with black hulls and green-colored groats.

Handling

Marketing of buckwheat can be more seriously affected by handling and storage than by other factors such as nutritional quality or processing. The method of handling varies among production areas; nonetheless, in most cases, losses and grain-quality changes occur at postharvest stages. During harvest, in all countries, losses occur, resulting from shattering, germination, depredation by animals, and infection by molds. Threshing is done with combines or by beating the dried plants against stones or wooden bars or by trampling the plants under bullock feet, carts, or tractor wheels.

Transportation of grain from the field to market also results in losses and quality deterioration. Losses during transportation are mainly due to spillage. However, if the grain is exposed to rain or frost during transit, it can subsequently spoil through infection by microorganisms. An efficient system for transportation and distribution of grain must consist of several components, including: (1) collection of grain from farms into consolidated deposits; (2) facilities for short- and long-term storage; (3) loading, unloading, and conveying systems; (4) methods of packaging or bulk handling; (5) roads, railways, and/or waterways; (6) systems for grading the grain and for servicing and maintaining equipment and facilities; (7) systems for recruiting, training, and managing personnel for operation and administration; and (8) systems for research, education, and extension of information to farmers, merchants, and other personnel involved with the overall handling operation.

Storage

Like other grain crops, buckwheat is stored to ensure an even supply over time, to preserve the surplus grain for sale to deficit areas, and for use as seed in the next planting season. Storage of the seeds may be at the farm, trader, market, government, retail, or consumer levels. Storage containers range from sacks to straw huts to bulk storage bins. In developing countries, traditional storage structures include granaries of gunny, cotton, or jute bags as well as those manufactured from reed, bamboo, or wood and plastered with mud and cow dung. In North America, storage structures include metal, concrete, or wooden bins at the farm level, elevators and annexes at centralized receiving, storage, and shipping points, and concrete silos at grain terminals.

Table II.A.3.6. *Absorbance of extracted color and tristimulus values of buckwheat samples stored at 25° C and 5 different water activities for 19 months*

Bagged buckwheat is highly susceptible to attack by insects and rodents. Hence, bulk storage in bins, elevators, and silos is best. Grain bins made of wood are usually square and, by virtue of their construction, possess a multitude of cracks, crevices, and angles that are havens for insects and their eggs and larvae. Concrete bins are usually round, star-shaped, or hexagonal, and star-shaped bins also have crevices that can harbor grain residues, constituting a source of infestation. Moreover, concrete possesses certain sorptive properties and chemical reactivity, and unless coated with an impervious material such as paint, the walls of concrete bins can interfere with fumigation procedures. Metal bins are usually round, possess few crevices, and do not react significantly with protective chemicals.

Neither concrete nor metal allows interchanges between stored grain and the atmosphere; moisture movement resulting from temperature fluctuations, convection, and condensation can result in deterioration and even internal combustion of the grains. A moisture content of 16 percent or less is required for the safe storage of buckwheat. If the seed requires drying, the temperature of the drying air should not exceed 43° C.

During storage at ambient temperature and relative humidity, the color of the aleurone layer changes from a desirable light green to the undesirable reddish brown. This undesirable quality change can be reduced by storing the seed at a lower temperature and at a relative humidity below 45 percent. Table II.A.3.6 gives the absorbance of the extracted color of buckwheat samples stored at 25° C and 0.11 to 0.67 water activity for 19 months. Maximum browning-pigment production occurs at 0.45 to 0.55 water activity, or 45 to 55 percent relative humidity.

Primary Processing

Primary processing of buckwheat includes cleaning, dehulling, and milling. The aim of seed cleaning is to remove other plant parts, soil, stones, weed seeds, chaff, dust, seeds of other crops, metallic particles, and small and immature buckwheat seeds. The extent and sophistication of the cleaning equipment depends largely on the size of the operation and the requirements for the finished product(s). Milling of buckwheat seed can be carried out by virtually any equipment capable of milling cereal grains. Hammer mills, stone mills, pin mills, disk mills, and roller mills have all been used to mill buckwheat. Of these, stone mills and roller mills are probably the most extensively used today.

The milling process may be of two types. In the first and most common type, the whole seeds are first dehulled and then milled. In the second type, the seeds are milled and then screened to remove the hulls. When dehulling and milling are separate operations, the seeds are segregated according to size and may be steamed and dried prior to dehulling. The latter procedure is carried out by impact or abrasion against emery stones or steel, followed by air- or screen-separation of groats and hulls. A widely used buckwheat dehuller is built on the principle of stone-milling, with emery stones set to crack the hull without breaking the groat. The effectiveness of this type of dehuller depends on the clearance between the seed cracking surfaces, and for any seed size there is an optimal setting. The ease of dehulling and the percentage of recovery of undamaged groats depends on variety and moisture content (Table II.A.3.7). From the dehuller, the groats go over sieves of different mesh for sizing into whole groats and two or more sizes of broken groats. Flour is produced by passing the groats through stone and/or roller grinders.

When buckwheat seed is to be processed into flour only, and production of groats is not a requirement, the seeds are ground on break rolls or stone mills and then screened to separate the coarse flour from the hulls. The coarse flour is further reduced by a series of size reduction rolls, each grinding operation followed by a sifting to fractionate the mixture of particles according to their size (Figure II.A.3.1). The flour yield ranges from 50 to 75 percent depending on the size, shape, and condition of the seeds and the efficiency of the dehulling and milling operations.

End Products

Buckwheat flour is generally dark in color because of the presence of hull fragments. In North America, it is used primarily for making buckwheat pancakes and is commonly marketed in the form of prepared mixes. These mixes generally contain buckwheat flour mixed with wheat, maize, rice, oat, or soybean flours and a leavening agent. Buckwheat is also used with vegetables and spices in kasha and soup mixes, and with wheat, maize, or rice in ready-to-eat breakfast products, porridge, bread, and pasta products.

Figure II.A.3.1. Flow diagram of two buckwheat mills: (A) roller mill; (B) stone-roller mill.

In Japan, buckwheat flour is used primarily for making *soba* or *sobakiri* (buckwheat noodles) and *Teuchi Soba* (handmade buckwheat noodles). These products are prepared at *soba* shops or at home from a mixture of buckwheat and wheat flours. The wheat flour is used because of its binding properties and availability. *Soba* is made by hand or mechanically. In both methods, buckwheat and wheat flours are mixed with each other and then with water to form a stiff dough that is kneaded, rolled into a thin sheet (1.4 mm) with a rolling pin or by passing it between sheeting rolls, and cut into long strips. The product may be cooked immediately, sold fresh, or dried. For consumption, the noodles are boiled in hot water, put into bamboo baskets, and then dipped into cold water.

In Europe, most buckwheat is milled into groats that are used in porridge, in meat products (especially hamburger), or consumed with fresh or sour milk. A mixture of buckwheat groats with cottage cheese, sugar, peppermint, and eggs is employed as stuffing in a variety of dumplings. Buckwheat flour is used with wheat or rye flour and yeast to make fried specialty products such as bread, biscuits, and other confectioneries. An extended ready-to-eat breakfast product of high nutritional value, made from maize and buckwheat, is produced and marketed in Western Europe. This product contains over 14 percent protein and 8 percent soluble fiber. Similar products have also been developed in Poland and the former Soviet Union. In most countries, the quality of buckwheat end products is controlled by law.

The pace of development of new food products from buckwheat is expected to increase. This will likely parallel the increasing consumer demand for foods capable of preventing or alleviating disease and promoting health.

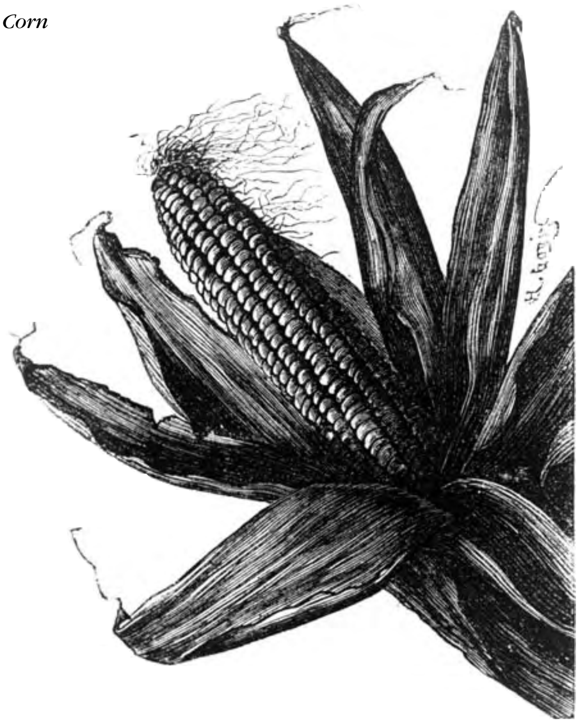
II.A.4. Maize

Maize (*Zea mays* L.), a member of the grass family Poaceae (synonym Gramineae), is the most important human dietary cereal grain in Latin America and Africa and the second most abundant cultivated cereal worldwide. Originating in varying altitudes and climates in the Americas, where it still exhibits its greatest diversity of types, maize was introduced across temperate Europe and in Asia and Africa during the sixteenth and seventeenth centuries.



Corn

It became a staple food of Central Europe, a cheap means of provisioning the African-American slave trade by the end of the eighteenth century, and the usual ration of workers in British mines in Africa by the end of the nineteenth century. In the twentieth century, major increases in maize production, attributed to developments in maize breeding, associated water management, fertilizer response, pest control, and ever-expanding nutritional and industrial uses, have contributed to its advance as an intercrop (and sometimes as a staple) in parts of Asia and to the doubling and tripling of maize harvests throughout North America and Europe. High-yield varieties and government agricultural support and marketing programs, as well as maize's biological advantages of high energy yields, high extraction rate, and greater adaptability relative to wheat or rice, have all led to maize displacing sorghum and other grains over much of Africa.

On all continents, maize has been fitted into a wide variety of environments and culinary preparations; even more significant, however, it has become a component of mixed maize-livestock economies and diets. Of the three major cereal grains (wheat, rice, and maize), maize is the only one not grown primarily for direct human consumption. Approximately one-fifth of all maize grown worldwide is eaten directly by people; two-thirds is eaten by their animals; and approximately one-tenth is used as a raw material in manufactured goods, including many nonfood products.

Maize Literature

Principal sources for understanding the diverse maize cultures and agricultures are P. Weatherwax's (1954) *Indian Corn in Old America,* an account of sixteenth-century maize-based agriculture and household arts; S. Johannessen and C. A. Hastorf's (1994) *Corn and Culture,* essays that capture New World archaeological and ethnographic perspectives; and H. A. Wallace and E. N. Bressman's (1923) *Corn and Corn Growing,* and Wallace and W. L. Brown's (1956) *Corn and Its Early Fathers,* both of which chronicle the early history of maize breeding and agribusiness in the United States. The diffusion of maize in the Old World has been traced in J. Finan's (1950) summary of discussions of maize in fifteenth- and sixteenth-century herbals, in M. Bonafous's (1836) *Natural Agricultural and Economic History of Maize,* in A. de Candolle's (1884) *Origin of Cultivated Plants,* and in D. Roe's (1973) *A Plague of Corn: The Social History of Pellagra.* B. Fussell's (1992) *The Story of Corn* applies the art of storytelling to maize culinary history, with special emphasis on the New World. Quincentenary writings, celebrating America's first cuisines and the cultural and nutritional influence of maize, as well as that of other New World indigenous crops, include works by W. C. Galinat (1992), S. Coe (1994), and J. Long (1996).

More recent regional, cultural, agricultural, and economic perspectives highlight the plight of Mexico's peasant farmers under conditions of technological and economic change (Hewitt de Alcantara 1976, 1992; Montanez and Warman 1985; Austin and Esteva 1987; Barkin, Batt, and DeWalt 1990), the displacement of other crops by maize in Africa (Miracle 1966), and the significance of maize in African "green revolutions" (Eicher 1995; Smale 1995). *The Corn Economy of Indonesia* (Timmer 1987) and C. Dowswell, R. L. Paliwal, and R. P. Cantrell's (1996) *Maize in the Third World* explore maize's growing dietary and economic significance in developing countries. The latter includes detailed country studies of Ghana, Zimbabwe, Thailand, China, Guatemala, and Brazil.

Global developments in maize breeding, agronomy, and extension are chronicled in the publications of Mexico's International Center for the Improvement of Maize and Wheat (CIMMYT), especially in *World Maize Facts and Trends* (CIMMYT 1981, 1984, 1987, 1990, 1992, 1994), and in research reports and proceedings of regional workshops. Maize genetics is summarized by David B. Walden (1978), G. F. Sprague and J. W. Dudley (1988), and the National Corn Growers Association (1992). Molecular biologists who use maize as a model system share techniques in the *Maize Genetics Cooperation Newsletter* and *The Maize Handbook* (Freeling and Walbot 1993). One explanation for the extensive geographic and cultural range of maize lies in its unusually active "promoter," or "jumping," genes and extremely large chromosomes, which have made it a model plant for the study of genetics – the *Drosophila* of the plant world.

Geographic Range

Maize is grown from 50 degrees north latitude in Canada and Russia to almost 50 degrees south latitude in South America, at altitudes from below sea level in the Caspian plain to above 12,000 feet in the Peruvian Andes, in rainfall regions with less than 10 inches in Russia to more than 400 inches on Colombia's Pacific coast, and in growing seasons ranging from 3 to 13 months (FAO 1953). Early-maturing, cold-tolerant varieties allow maize to penetrate the higher latitudes of Europe and China, and aluminum-tolerant varieties increase production in the Brazilian savanna. In the tropics and subtropics of Latin America and Asia, maize is double- or triple-cropped, sometimes planted in rotation or "relay-cropped" with wheat, rice, and occasionally, soybeans, whereas in temperate regions it is monocropped, or multicropped with legumes, cucurbits, and roots or tubers. In North America, it is planted in rotation with soybeans.

Yields average 2.5 tons per hectare in developing countries, where maize is more often a component of less input-intensive multicrop systems, and 6.2

tons per hectare in industrialized countries, where maize tends to be input-intensive and single-cropped. The U.S. Midwest, which produced more than half of the total world supply of maize in the early 1950s, continued to dominate production in the early 1990s, with 210.7 million tons, followed by China (97.2 million tons), and then Brazil (25.2 million tons), Mexico (14.6 million tons), France (12.2 million tons), India (9.2 million tons), and the countries of the former Soviet Union (9.0 million tons). Developing countries overall account for 64 percent of maize area and 43 percent of world harvests (FAO 1993). The United States, China, France, Argentina, Hungary, and Thailand together account for 95 percent of the world maize trade, which fluctuates between 60 and 70 million tons, most of which goes into animal feed.

Cultural Range

Maize serves predominantly as direct human food in its traditional heartlands of Mexico, Central America, the Caribbean, and the South American Andes, as well as in southern and eastern Africa, where the crop has replaced sorghum, millet, and sometimes roots and tuber crops in the twentieth century. The highest annual per capita intakes (close to 100 kilograms per capita per year) are reported for Mexico, Guatemala, and Honduras, where the staple food is tortillas, and for Kenya, Malawi, Zambia, and Zimbabwe, where the staple is a porridge. Maize is also an essential regional and seasonal staple in Indonesia and parts of China.

However, maize is considerably more significant in the human food chain when it first feeds livestock animals that, in turn, convert the grain into meat and dairy products. In the United States, 150 million tons of maize were harvested for feed in 1991; in Germany, three-fourths of the maize crop went for silage. In some developing countries, such as Pakistan, India, and Egypt, the value of maize fodder for bovines may surpass that of the grain for humans and other animals. In Mexico, the "Green Revolution" Puebla Project developed improved, tall (versus short, stiff-strawed) varieties in response to demands for fodder as well as grain.

Since World War II, processing for specialized food and nonfood uses has elevated and diversified maize's economic and nutritional significance. In the United States, for example, maize-based starch and sweeteners account for 20 million tons (15 million tons go to beverages alone), cereal products claim 3 million tons, and distilled products 0.3 million tons. Maize-based ethanol, used as a fuel extender, requires 10 million tons; and plastics and other industrial products also employ maize. The geographic and cultural ranges of maize are tributes to its high mutation rate, genetic diversity and adaptability, and continuing cultural selection for desirable characteristics.

Biology and Biodiversity

More than 300 races of maize, consisting of hundreds of lineages and thousands of cultivars, have been described. But the precise ancestry of maize remains a mystery, and geographical origins and distributions are controversial.

Biological Evolution

Teosinte (*Zea* spp.), a weedy grass that grows in Mexico and Guatemala, and *Tripsacum,* a more distantly related rhizomatous perennial, are maize's closest wild relatives. All three species differ from other grasses in that they bear separate male and female flowers on the same plant. Key morphological traits distinguishing maize from its wild relatives are its many-rowed ear compared to a single-rowed spike, a rigid rather than easily shattered rachis, a pair of kernels in each cupule compared to a single grain per cupule, and an unprotected or naked grain compared to seed enclosed in a hard fruitcase. Unlike the inflorescence structures of other grasses, maize produces a multirowed ear with hundreds of kernels attached to a cob that is enclosed by husks, which makes it amenable for easy harvest, drying, and storage.

Based on interpretations of evidence from cytology, anatomy, morphology, systematics, classical and molecular genetics, experimental breeding, and archaeology, there are three recognized theories about the origins of maize: (1) the ancestor of maize is annual teosinte (Vavilov 1931; Beadle 1939; Iltis 1983; Kato 1984); (2) maize evolved from an as yet undiscovered wild maize or other ancestor (Mangelsdorf 1974); and (3) maize derived from hybridization between teosinte and another wild grass (Harshberger 1896; Eubanks 1995). Although the most popular theory holds that teosinte is the progenitor, present evidence does not clearly resolve its genetic role. Firmer evidence supports the idea that introgression of teosinte germ plasm contributed to the rapid evolution of diverse maize land races in prehistory (Wellhausen et al. 1952). Teosintes–which include two annual subspecies from Mexico *(Z. mays* ssp. *mexicana* and ssp. *parviglumis),* two annual species from Guatemala *(Z. huehuetenangensis* and *Z. luxurians),* and two perennial species from Mexico *(Z. perennis* and *Z. diploperennis)* – have the same base chromosome number (n = 10) as maize and can hybridize naturally with it. Like maize, teosintes bear their male flowers in tassels at the summit of their main stems and their female flowers laterally in leaf axils. Although the ears of teosinte and maize are dramatically different, teosinte in architecture closely mimics maize before flowering, and – so far – no one has demonstrated effectively how the female spike might have been transformed into the complex structure of a maize ear.

Tripsacum spp. have a base chromosome number of n = 18 and ploidy levels ranging from $2n$ = 36 to

$2n = 108$. *Tripsacum* is distinctive from maize and teosinte because it bears male and female flowers on the same spike, with the staminate (male) flowers directly above the pistillate (female) flowers. This primitive trait is seen in some of the earliest prehistoric maize (on Zapotec urns from the Valley of Oaxaca, Mexico, c. A.D. 500–900, which depict maize with staminate tips) and also in some South American races. *Tripsacum* plants also frequently bear pairs of kernels in a single cupule, another maize trait. The ears of F1 *Tripsacum*-teosinte hybrids have pairs of exposed kernels in fused cupules and resemble the oldest archaeological maize remains from Tehuacan, Mexico (Eubanks 1995). Although the theory that domesticated maize arose from hybridization between an unknown wild maize and *Tripsacum* is no longer accepted, and crosses between *Tripsacum* and maize or annual teosinte are almost always sterile, crosses between *Tripsacum* and perennial teosinte have been shown to produce fully fertile hybrid plants (Eubanks 1995), and *Tripsacum* has potential as a source of beneficial traits for maize improvement.

Molecular evidence for maize evolution includes analyses of isozymes and DNA of nuclear and cytoplasmic genes. Results indicate that isozyme analysis cannot fully characterize genetic variation in *Zea,* and application of this technique to understanding evolutionary history is limited. In addition, certain maize teosintes *(Z. m. parviglumis* and *Z. m. mexicana),* thought to be ancestral to maize, may actually postdate its origin. In sum, the origins of maize remain obscure.

Geographic Origin and Distribution

Most scientists concur that maize appeared 7,000 to 10,000 years ago in Mesoamerica, but controversy surrounds whether maize was domesticated one or more times and in one or more locations. Based on racial diversity and the presence of teosinte in Mexico but not Peru, N. I. Vavilov (1931) considered Mexico to be the primary center of origin. The earliest accepted archaeological evidence comes from cave deposits in Tehuacan, Puebla, in central Mexico. The cobs found there ranged from 19 to 25 millimeters (mm) long and had four to eight rows of kernels surrounded by very long glumes. The remarkably well-preserved specimens provide a complete evolutionary sequence of maize dating from at least as far back as 3600 B.C. up to A.D. 1500. Over this time, tiny eight-rowed ears were transformed into early cultivated maize and then into early tripsacoid maize, ultimately changing into the Nal Tel-Chapalote complex, late tripsacoid, and slender popcorn of later phases (Mangelsdorf 1974). An explosive period of variation, brought about by the hybridization of maize with teosinte, began around 1500 B.C. (Wilkes 1989).

From Mexico, maize is thought to have moved south and north, reaching Peru around 3000 B.C. and North America sometime later. However, pollen identified as maize was present with phytoliths in preceramic contexts in deposits dated to 4900 B.C. in Panama and in sediments dated to 4000 B.C. in Amazonian Ecuador. Although the identification of maize pollen and phytoliths (as opposed to those of a wild relative) remains uncertain, some investigators (Bonavia and Grobman 1989) have argued that such evidence, combined with maize germ plasm data, indicates the existence of a second center of domestication in the Central Andean region of South America, which generated its own distinct racial complexes of the plant between 6000 and 4000 B.C. Fully developed maize appeared later in the lowlands (Sanoja 1989).

Maize arrived in North America indisputably later. Flint varieties adapted to the shorter nights and frost-free growing seasons of the upper Midwest evolved only around A.D. 1100, although maize had been introduced at least 500 years earlier. Ridged fields later allowed cultivators to expand the growing season by raising soil and air temperatures and controlling moisture. In the Eastern Woodlands, 12-row (from A.D. 200 to 600) and 8-row (from around 800) varieties supplemented the existing starchy-seed food complexes (Gallagher 1989; Watson 1989).

Germ Plasm and Genetic Diversity

Gene banks have collected and now maintain 90 to 95 percent of all known genetic diversity of maize. The largest collections are held by the Vavilov Institute (Russia) and the Maize Research Institute (Yugoslavia), which contain mostly Russian and European accessions. The genetically most diverse New World collections are maintained at the National Seed Storage Laboratory in the United States, CIMMYT and the Instituto Nacional de Investigaciones Forestales y Agropecuarios (INIFAP – the National Institute of Forestry and Agricultural Research) in Mexico, the National Agricultural University in Peru, the National Agricultural Research Institute in Colombia, the Brazilian Corporation of Agricultural Research (EMBRAPA), the Instituto de Nutricion y Tecnologia de los Alimentos (INTA – the Institute of Nutrition and Food Technology) at the University of Chile, Santiago, and the National Agricultural Research Institute (INIA) in Chile. International maize breeding programs operate at CIMMYT and at the International Institute for Tropical Agriculture (IITA), which interface with national maize breeding programs in developing countries (Dowswell, Paliwal, and Cantrell 1996).

The germ plasm collections begun by the Rockefeller Foundation and the Mexican Ministry of Agriculture in 1943 (which classified maize according to productiveness, disease resistance, and other agronomic characteristics) have since been supplemented by the collections of international agricultural research centers that treat additional genetic, cytological, and botanical characteristics (Wellhausen et al. 1952;

Mangelsdorf 1974). All contribute information for the contemporary and future classification and breeding of maize.

Maize Classifications

Maize plants range from 2 to 20 feet in height, with 8 to 48 leaves, 1 to 15 stalks from a single seed, and ears that range from thumb-sized (popcorn) to 2 feet in length. The different varieties have different geographical, climatic, and pest tolerances. The mature kernel consists of the pericarp (thin shell), endosperm (storage organ), and embryo or germ, which contains most of the fat, vitamins, and minerals and varies in chemical composition, shape, and color.

The principal maize classifications are based on grain starch and appearance – these characteristics influence suitability for end uses. In "flints," the starch is hard. In "dents," the kernel is softer, with a larger proportion of floury endosperm and hard starch confined to the side of the kernel. "Floury" varieties have soft and mealy starch; "pop" corns are very hard. "Sweet" corns have more sugar, and "waxy" maizes contain starch composed entirely of amylopectin, without the 22 percent amylose characteristic of dents.

Dents account for 95 percent of all maize. The kernels acquire the characteristic "dent" when the grain is dried and the soft, starchy amylose of the core and the cap contract. Most dent maize is yellow and is fed to livestock; white dents are preferred for human food in Mexico, Central America, the Caribbean, and southern Africa. Flint maize, with its hard outer layer of starch, makes a very good-quality maize meal when dry-milled. It stores more durably than other types because it absorbs less moisture and is more resistant to fungi and insects. Flints germinate better in colder, wetter soils, mature earlier, and tend to perform well at higher latitudes. Popcorns are extremely hard flint varieties; when heated, the water in the starch steam-pressures the endosperm to explode, and the small kernels swell and burst.

Sweet corns are varieties bred especially for consumption in an immature state. A number of varieties of sweet corn, exhibiting simple mutations, were developed as garden vegetables in the United States beginning around 1800. Sweet varieties known as *sara chulpi* were known much earlier in the Andes, where they were usually parched before eating. Floury maizes are grown in the Andean highlands of South America, where they have been selected for beer making and special food preparations *(kancha),* and in the U.S. Southwest, where they are preferred for their soft starch, which grinds easily. Waxy varieties are grown for particular dishes in parts of Asia and for use in industrial starches in the United States.

In addition, maize grains are classified by color, which comes mostly from the endosperm but is also influenced by pigments in the outer aleurone cell layer and pericarp. Throughout most of the world, white maize is preferred for human consumption and yellow for animal feed, although Central and Mediterranean Europeans eat yellow maize and indigenous Americans carefully select blue (purple, black), red, and speckled varieties for special regional culinary or ritual uses. Color is probably the most important classification criterion among New World indigenous cultivators, who use color terms to code information on the ecological tolerances, textures, and cooking characteristics of local varieties.

Breeding

The early indigenous cultivators of maize created "one of the most heterogeneous cultivated plants in existence" (Weatherwax 1954: 182). They selected and saved seed based on ear form, row number, and arrangement; kernel size, form, color, taste, texture, and processing characteristics; and plant-growth characteristics such as size, earliness, yield, disease resistance, and drought tolerance. Traditional farmers planted multiple varieties as a hedge against stressors, and Native American populations have continued this practice in the United States (Ford 1994) and Latin America (Brush, Bellon, and Schmidt 1988; Bellon 1991). However, only a small fraction of the biodiversity of traditional maize was transported to North America, to Europe, from Europe to Asia and Africa, and back to North America.

During all but the last hundred years, maize breeding involved open-pollinated varieties – varieties bred true from parent to offspring – so that farmers could select, save, and plant seed of desirable maize types. Hybrid maize, by contrast, involves crossing two inbred varieties to produce an offspring that demonstrates "hybrid vigor," or heterosis (with yields higher than either parent). But the seed from the hybrid plant will not breed true. Instead, new generations of hybrid seed must be produced in each succeeding generation through controlled crosses of the inbred lines. Consequently, save for producing their own crosses, farmers must purchase seed each cultivation season, which has given rise to a large hybrid seed industry, particularly in developed countries.

Hybrid maize had its beginnings in the United States in 1856 with the development by an Illinois farmer of Reid Yellow Dent, a mixture of Southern Dent and Northern Flint types that proved to be high-yielding and resistant to disease. There followed a series of scientific studies demonstrating that increased yields (hybrid vigor) resulted from the crossing of two inbred varieties. W. J. Beal, an agrobotanist at Michigan State University, in 1877 made the first controlled crosses of maize that demonstrated increased yields. Botanist George Shull, of Cold Spring Harbor, New York, developed the technique of inbreeding. He showed that although self-pollinated plants weakened generation after generation, single crosses of inbred lines demonstrated heterosis, or hybrid vigor. Edward East, working at the Connecticut Agricultural Experimental Station during the same period, developed single-cross inbred hybrids with 25 to 30 percent higher yields than the best open-pollinated varieties. A student of East's, D. F. Jones, working with Paul Mangelsdorf, in 1918 developed double-cross hybrids, which used two single-cross hybrids rather than inbred lines as parents and overcame the poor seed-yields and weakness of inbred lines so that hybrid seeds became economically feasible.

By the late 1920s, private seed companies were forming to sell high-yield hybrid lines. Henry A. Wallace, later secretary of agriculture under U.S. president Franklin Roosevelt, established Pioneer Hi-Bred for the production and sale of hybrid seed in 1926, in what he hoped would herald a new era of productivity and private enterprise for American agriculture. From the 1930s through the 1950s, commercial hybrids helped U.S. maize yields to increase, on average, 2.7 percent per year. By the mid-1940s, hybrids covered almost all of the U.S. "Corn Belt," and advances were under way in hybrid seeds that were adapted to European, Latin American, and African growing conditions. Another quantum leap in yields was achieved after World War II through chemical and management techniques. New double- and triple-cross hybrids responsive to applications of nitrogen fertilizers substantially raised yields in the 1960s, and again in the 1970s, with the release of a new generation of fertilizer-responsive single-cross hybrids that were planted in denser stands and protected by increased quantities of pesticides. In the 1980s, however, concerns about cost reduction, improved input efficiency, and natural resource (including biodiversity) conservation supplanted the earlier emphasis on simply increasing yields, with the result that yields remained flat.

Breeders also have been concerned with diversifying the parent stock of inbred hybrids, which are formed by the repeated self-pollination of individual plants and which, over generations, become genetically uniform and different from other lines. To prevent self-pollination when two inbred lines are crossed to produce a hybrid, the tassels are removed from the male parent. Discovery of lines with cytoplasmic male sterility allowed this labor-intensive step to be eliminated, but although it was desirable for the seed industry, the uniform germ plasm carrying this trait (Texas [T] male-sterile cytoplasm) proved very susceptible to Southern Corn Leaf Blight. Indeed, in 1970, virtually all of the U.S. hybrid maize crop incorporated the male sterility factor, and 15 to 20 percent of the entire crop was lost. Researchers and the seed industry responded by returning to the more laborious method of detasseling by hand until new male-sterile varieties could be developed (National Research Council 1972).

Since the 1940s, international agricultural "campaigns against hunger" have been transferring maize-breeding technologies (especially those involving hybrid seed) to developing countries. Henry Wallace, mentioned previously, spearheaded the Rockefeller Foundation's agricultural research programs in Mexico and India, both of which emphasized hybrid maize. Nevertheless, in Mexico the maize agricultural sector remains mostly small-scale, semisubsistent, and traditional, and in much of Latin America, the public seed sector has been unreliable in generating and supplying improved seeds for small farmers working diverse environments; probably no more than 20 percent of Mexico's, 30 percent of Central America's, and 15 percent of Colombia's maize production has resulted from modern improved varieties (Jaffe and Rojas 1994). The Puebla Project of Mexico, which aimed to double the maize yields of small farmers by providing improved seeds, chemical packages, and a guaranteed market and credit, had only spotty participation as maize farming competed unsuccessfully with nonfarming occupations.

Agricultural research programs in British colonial Africa in the 1930s also emphasized the development of hybrid maize seed, an emphasis that was revived in Kenya, Zimbabwe, and Malawi in the 1960s and became very important in the 1980s (Eicher 1995). Zimbabwe released its first hybrid in 1949, and Kenya did the same with domestically produced hybrids in 1964. An advanced agricultural infrastructure in these countries has meant that the rate of adoption of hybrids is extremely high, and in Zimbabwe, the yields achieved by some commercial farmers approach those seen in Europe and the United States. In Ghana, the Global 2000 agricultural project, supported by the Sasakawa Africa Association, has sought to demonstrate that high yields are attainable if farmers can be assured quality seeds, affordable fertilizers, and market access. The success of hybrids in these contexts depends on timely and affordable delivery of seed and other inputs, particularly fertilizers. Tanzania, from the late 1970s through the 1980s, provided a case study of deteriorating maize production associated with erratic seed supply, elimination of fertilizer subsidies, inadequate market transportation, and insufficient improvement of open-pollinated varieties (Friis-Hansen 1994).

Under optimal conditions, hybrids yield 15 to 20 percent more than the improved open-pollinated varieties, and breeders find it easier to introduce particular traits – such as resistance to a specific disease – into inbred hybrid lines. The uniform size and maturation rate of hybrids are advantages for farmers who wish to harvest and process a standard crop as a single unit. From a commercial standpoint, hybrids also carry built-in protection against multiplication because the originator controls the parent lines, and the progeny cannot reproduce the parental type.

Conditions are rarely optimal, however, and a corresponding disadvantage is that the yields of hybrid seeds are unpredictable where soil fertility, moisture, and crop pests are less controlled. Although the introduction of disease-resistant traits may be easier with hybrids, the very uniformity of the inbred parent lines poses the risk of large-scale vulnerability, as illustrated by the case of the Southern Corn Leaf Blight. Rapid response by plant breeders and seed companies to contain the damage is less likely in countries without well-organized research and seed industries. Farmers in such countries may also face shortages of high-quality seed or other inputs, which potentially reduces the yield advantage of hybrid seed. Indeed, in years when cash is short, farmers may be unable to afford the purchase of seed or other inputs, even when available, and in any event, they lack control over the price and quality of these items – all of which means a reduction in farmer self-reliance. Analysts of public and private agricultural research systems further argue that the elevated investment in hybrids reduces the funds available for improving open-pollinated varieties and that some of the yield advantage of hybrids may result from greater research attention rather than from any intrinsic superiority.

Agricultural Research in Developing Countries

In 1943, the Rockefeller Foundation, under the leadership of Norman Borlaug, launched the first of its "campaigns against hunger" in Mexico, with the aim of using U.S. agricultural technology to feed growing populations in this and other developing countries. In 1948, the campaign was extended to Colombia, and in 1954 the Central American Maize Program was established for five countries. In 1957, the program added a maize improvement scheme for India, which became the Inter-Asian Corn Program in 1967. The Ford and Rockefeller Foundations together established the International Center for the Improvement of Maize and Wheat in Mexico in 1963, the International Center for Tropical Agriculture in Colombia in 1967, and the International Institute for Tropical Agriculture in Nigeria in 1967. These centers, with their maize improvement programs, became part of the International Agricultural Research Center Network of the Consultative Group on International Agricultural Research, which was established with coordination among the World Bank, and the Food and Agriculture Organization of the United Nations (FAO) in 1971. The International Plant Genetic Research Institute, also a part of this system, collects and preserves maize germ plasm.

Additional international maize research efforts have included the U.S. Department of Agriculture (USDA)–Kenyan Kitale maize program instituted during the 1960s; the French Institute for Tropical Agricultural Research, which works with scientists in former French colonies in Africa and the Caribbean region; and the Maize Research Institute of Yugoslavia. The Inter-American Institute of Agricultural Sciences (Costa Rica), Centro de Agricultura Tropical para Investigacíon y Enseñanzas (Costa Rica), Safgrad (Sahelian countries of Africa), Saccar (southern Africa), Prociandino (Andes region), and Consasur (Southern Cone, South America) are all examples of regional institutions for maize improvement (Dowswell et al. 1996).

Cultural History

Middle and South America

In the United States, which is its largest producer, maize is business, but for indigenous Americans maize more often has been considered a divine gift, "Our Mother" (Ford 1994), "Our Blood" (Sandstrom 1991), and what human beings are made of (Asturias 1993). Archaeological evidence and ethnohistorical accounts indicate that ancient American civilizations developed intensive land- and water-management techniques to increase production of maize and thereby provision large populations of craftspeople and administrators in urban centers. Ethnohistory and ethnography depict the maize plant in indigenous thought to be analogous to a "human being," and lexica maintain distinctive vocabularies for the whole plant, the grain, foods prepared from the grain, and the plant's parts and life stages (seedling, leafing, flowering, green ears, ripe ears), which are likened to those of a human. Indigenous terms and usage symbolically identify the maize plant and field (both glossed in the Spanish *milpa*) with well-being and livelihood. In addition, the four principal maize kernel colors constitute the foundation of a four-cornered, four-sided cosmology, coded by color.

An inventive indigenous technique for maize preparation was "nixtamalization" (alkali processing). Soaking the grain with crushed limestone, wood ash, or seashells helped loosen the outer hull, which could then be removed by washing. This made the kernel easier to grind and to form into a nutritious food end product, such as the tortilla in Mexico and Central America or the distinctive blue *piki* bread of the U.S. Southwest. In South America, maize was also consumed as whole-grain *mote.*

Tortillas, eaten along with beans and squash seeds (the "triumvirate" of a Mesoamerican meal), constitute a nutritious and balanced diet. In Mexico and Central America, dough is alternatively wrapped in maize sheaths or banana leaves. These steamed maize-dough *tamales* sometimes include fillings of green herbs, chilli sauce, meat, beans, or sugar. Additional regional preparations include gruels *(atoles,)* prepared by steeping maize in water and then sieving the liquid (a similar dish in East Africa is called *uji*); ceremonial beverages made from various maize doughs (*pozole,* which can also refer to a corn stew with whole grains, or chocolate *atole*); and special seasonal and festival foods prepared from immature maize (including spicy-sweet *atole* and *tamales*). Green corn – a luxury food for those dependent on maize as a staple grain (because each ear consumed in the immature stage limits the mature harvest) – can be either roasted or boiled in its husk.

Andean populations also made maize beers *(chicha)* of varying potency, which involved soaking and sprouting the grain, then leavening it by chewing or salivation (Acosta 1954). Brewed maize comprised a key lubricant of Incan social life (Hastorf and Johannessen 1993). Unfortunately, by the early period of Spanish occupation, indigenous leaders were reported to be having difficulty controlling intoxication, a problem heightened when *chicha* was spiked with cheap grain alcohol – a Spanish introduction.

Other special indigenous preparations included green corn kernels boiled with green lima beans, a dish introduced to the English on the East Coast of North America. The Hopi of the North American Southwest prepared *piki,* or "paper-bread," from a fine cornmeal batter spread on a stone slab lubricated with seed oil (from squash, sunflower, or watermelon seeds). They colored their cornbread a deep blue (or other colors) by adding extra alkalies and other pigments.

All parts of the maize plant were used by indigenous peoples. Tender inner husks, young ears, and flowers were boiled as vegetables, and fresh silks were mixed into tortilla dough. The Navajo prepared a soup and ceremonial breads from maize pollen; sugary juices were sucked out of the pith and stems; and even the bluish-black smut, *Ustilago maydis,* was prepared as a "mushroom" delicacy. Maize ear-sheaths wrapped tamales, purple sheaths colored their contents, and husks served as wrappers for tobacco. Maize vegetation was put into the food chain, first as green manure and, after Spanish livestock introductions, as animal fodder. The dried chaff of the plant was shredded for bedding material, braided into cord and basketry, and used to make dolls and other toys. Corn silks were boiled into a tea to relieve urinary problems, and the cobs served as stoppers for jugs, or as fuel. The stalks provided both a quick-burning fuel and construction material for shelters and fences. These uses continued during the Spaniards' occupation, which added poultry and ruminants as intermediary consumers of maize in the food chain and animal manure as an element in the nitrogen cycle. Indigenous peoples generally ate maize on a daily basis, reserving wheat for festival occasions, whereas those of Spanish descent raised and consumed wheat as their daily bread.

North America

In contrast to the Spaniards, English settlers in North America adopted maize as the crop most suited to survival in their New World environment and learned from their indigenous neighbors how to plant, cultivate, prepare, and store it. Although seventeenth-century Europeans reviled maize as a food fit only for desperate humans or swine (Gerard 1597; Brandes 1992), in North America the first colonials and later immigrants elevated the crop to the status of a staple food. For all Americans, it became a divine gift, a plentiful base for "typical" national and regional dishes, and a crop for great ritual elaboration, annual festivals, husking bees, shows, and later even a "Corn Palace" built of multicolored cobs (in Mitchell, North Dakota). In the process, maize became "corn," originally the generic term for "grain," shortened from the English "Indian corn," a term that distinguished colonial exported maize (also called "Virginia wheat") from European wheat and other grains.

Corn nourished the U.S. livestock industry, the slave economy, and westward expansion. It served as the foundation of the typical U.S. diet – high in meat and dairy products, which are converted corn – and, indeed, of the U.S. agricultural economy. North American populations of European and African ancestry historically turned maize into breads, grits, and gruels. They ate corn in the forms of mush; "spoon bread" (a mush with eggs, butter, and milk); simple breads called "hoecakes" (or "pone"); whole grains in "hominy"; and mixed with beans in "succotash." Coarsely ground "grits" were boiled or larded into "crackling bread," "scrapple," "fritters," and "hush puppies," or were sweetened with molasses and cooked with eggs and milk into "Indian pudding." Culinary elaborations of green corn, for which special varieties of sweet corn were bred, ranged from simple roasted (which caramelizes the sugar) or boiled "corn on the cob" with butter, to chowders and custards. Scottish and Irish immigrants fermented and distilled corn mash into corn whiskey ("white lightning" or "moonshine") or aged and mellowed it into bourbon, a distinctively smooth American liquor named for Bourbon, Kentucky, its place of origin.

Nineteenth-century food industries added corn syrup, oil, and starch to the processed repertoire, and then corn "flakes," the first of a series of breakfast cereals that promoters hoped would improve the healthfulness of the American diet. Popcorn, a simple indigenous food, by the mid-nineteenth century was popped in either a fatted frying pan or a wire gauze basket, and by the end of the century in a steam-driven machine, which added molasses to make Cracker Jacks, a popular new American snack first marketed at the 1893 Columbian Exposition in Chicago. By the late twentieth century, popcorn had become a gourmet food, produced from proprietary hybrid varieties, such as Orville Redenbacher's Gourmet Popping Corn, which boasted lighter, fluffier kernels and fewer "dud" grains and could be popped in a microwave (Fussell 1992). Twentieth-century snack foods also included corn "chips" (tortillas fried in oil). Moreover, North Americans consume large quantities of corn products as food additives and ingredients, such as corn starch, high-fructose syrup, and corn oil, as well as in animal products.

Europe

Maize, introduced by Christopher Columbus into Spain from the Caribbean in 1492–3, was first mentioned as a cultivated species in Seville in 1500, around which time it spread to the rest of the Iberian peninsula. It was called *milho* ("millet" or "grain") by Portuguese traders, who carried it to Africa and Asia (the name survives in South African "mealies," or cornmeal).

Spreading across Europe, maize acquired a series of binomial labels, each roughly translated as "foreign grain": In Lorraine and in the Vosges, maize was "Roman corn"; in Tuscany, "Sicilian corn"; in Sicily, "Indian corn"; in the Pyrenees, "Spanish corn"; in Provence, "Barbary corn" or "Guinea corn"; in Turkey, "Egyptian corn"; in Egypt, "Syrian dourra" (i.e., sorghum); in England, "Turkish wheat" or "Indian corn"; and in Germany, "Welsch corn" or "Bactrian typha." The French *blé de Turquie* ("Turkish wheat") and a reference to a golden-and-white seed of unknown species introduced by Crusaders from Anatolia (in what turned out to be a forged Crusader document) encouraged the error that maize came from western Asia, not the Americas (Bonafous 1836). De Candolle (1884) carefully documented the sources of the misconstruction and also dismissed Asian or African origins of maize on the basis of its absence from other historical texts. But inexplicably, sixteenth- and seventeenth-century herbalists appear to describe and illustrate two distinct types of maize, one "definitely" from tropical America, the other of unknown origin (Finan 1950).

English sources, especially J. Gerard's influential *Herball* (1597: Chapter 14), assessed "Turkie corne" to be unnourishing, difficult to digest, and "a more convenient food for swine than for man." Such disparagement notwithstanding, climate and low-labor requirements for its cultivation favored maize's dispersal. By the end of the sixteenth century, it had spread from southern Spain to the rest of the Iberian peninsula, to German and English gardens, and throughout Italy, where, by the seventeenth century, it constituted a principal element of the Tuscan diet. In both northwestern Iberia and northern Italy, climate favored maize over other cereals and gave rise to cuisines based on maize breads *(broa* and *borona)* and *polenta.* By the eighteenth century, maize had spread across the Pyrenees and into eastern France, where it became a principal peasant food and animal fodder.

A century earlier, maize had penetrated the Balkan Slavonia and Danube regions, and Serbs were reported to be producing *cucurutz* (maize) as a field crop at a time when other grains were scarce. By the mid-eighteenth century, it was a staple of the Hapsburg Empire, especially in Hungary. By the end of the eighteenth century, fields of maize were reported on the route between Istanbul and Nice, and it had likely been an earlier garden and hill crop in Bulgaria. Maize appears to have entered Romania in the beginning of the seventeenth century, where it became established as a field crop by midcentury. T. Stoianovich (1966) traces the complex of Greek-Turkish and Romanian-Transylvanian names for maize across the region and shows how the crop was incorporated into spring planting and autumn harvest rites of local peoples. In these regions, maize, which was more highly productive, replaced millet and, especially in Romania, has been credited with furthering a demographic and agricultural-socioeconomic transition. In the nineteenth century, Hungary was a major producer, along with Romania; by the mid-1920s, the latter country was the second largest exporter of maize (after Argentina) and remained a major producer and exporter through 1939. Romania maintained its own research institute and developed its own hybrids (Ecaterina 1995).

In contrast to the potato – the other major crop from the New World – maize appears to have been introduced across Europe with little resistance or coercion. In Spain, Italy, and southern France, its high seed-to-harvest ratio, relatively low labor requirements, high disease resistance, and adaptability allowed the plant to proceed from botanical exotic to kitchen-garden vegetable to field crop, all within a hundred years (Langer 1975). Throughout Europe, maize was prepared as a gruel or porridge because its flour lacked the gluten to make good leavened bread, although it was sometimes mixed into wheat flour as an extender. Although the custom of alkali processing, or that of consuming maize with legumes, had not accompanied the plant from the New World to the Old, maize provided a healthy addition to the diet so long as consumers were able to eat it with other foods. In the best of circumstances, it became a tasty culinary staple. In the worst, undercooked moldy maize became the food of deprivation, the food of last resort for the poor, as in Spain, where for this reason, maize is despised to this day (Brandes 1992).

Curiously, maize was never accepted in the British realm, where it continued to be "an acquired taste," a sometime famine or ration food, or a grain to feed livestock. During the great Irish famine of 1845, the British government imported maize for food relief – to keep down the prices of other foods and provide emergency rations for the poor. Maize boasted the advantages of being cheap and having no established private "free trade" with which government imports might interfere. Unfortunately, Ireland lacked the milling capacity to dry, cool, sack, and grind it, and in 1846 a scarcity of mills led to the distribution of the whole grain, which was described as irritating rather than nourishing for "half-starving people" (Woodham-Smith 1962). Maize shortly thereafter began to play an important role in British famine relief and as ordinary rations for workers in Africa.

Africa

Portuguese traders carried maize to eastern Africa in the sixteenth century, and Arab traders circulated it around the Mediterranean and North Africa. During the seventeenth century, maize traveled from the West Indies to the Gold Coast, where, by the eighteenth century, it was used as a cheap food for provisioning slaves held in barracoons or on shipboard during the Middle Passage. By the end of the eighteenth century, maize was reported in the interior of Africa (the Lake Chad region of Nigeria), where it appears to have replaced traditional food plants in the western and central regions, especially the Congo, Benin, and western Nigeria, although cassava – because it was less vulnerable to drought and locusts – later replaced maize in the southern parts of Congo (Miracle 1966) and Tanzania (Fleuret and Fleuret 1980).

By the end of the nineteenth century, maize had become established as a major African crop. People accustomed to eating it as the regular fare in mines or work camps, or as emergency rations, now demanded it when conditions returned to normal or when they returned home. Consumption also increased following famine years because people were able to sow earlier-maturing varieties, and even where sorghum remained the principal staple, maize became a significant seasonal food that was consumed at the end of the "hungry season" before other cereals ripened. The British also promoted African maize as a cash crop for their home starch industry.

Today in Africa, ecology, government agricultural and marketing policies, and the cost of maize relative to other staple or nonstaple crops are the factors influencing the proportion of maize in household production and consumption (Anthony 1988). Major shifts toward maize diets occurred in the latter part of the twentieth century, when improved varieties and extension programs, as well as higher standards of living, meant that people could enjoy a more refined staple food – with less fiber – without feeling hungry. Researchers in postcolonial times have developed hybrids adapted to African conditions, but these have met with mixed reactions. In Zimbabwe, where small farmers are well organized and can demand seed and access to markets, most of them plant improved hybrids (Bratton 1986; Eicher 1995). By contrast, in Zambia, smallholders continue to grow traditional varieties for a number of reasons, including the high cost of hybrid seed, shortages of seed and input supplies, inadequate storage facilities, and a culinary preference for varieties that are flintier. The latter are preferred because they have a higher extraction rate when mortar-pounded (superior "mortar yield"), they produce superior porridge, and they are more resistant to weevils. However, even where introduction of improved disease-resistant varieties has been successful, as in northern Nigeria, the gains will be sustainable only if soils do not degrade, the price of fertilizer remains affordable, markets are accessible, and research and extension services can keep ahead of coevolving pests (Smith et al. 1994).

African cuisines favor white maize, which is prepared as a paste or mush and usually eaten as warm chunks dipped in stews or sauces of meat, fish, insects, or vegetables. In eastern and southern Africa, maize is first pounded or ground before being boiled into a thick porridge. But in western Africa, *kenkey* is prepared from kernels that are first soaked and dehulled before being ground, fermented, and heated. *Ogi* is a paste prepared by soaking the kernels, followed by light pounding to remove the pericarp and a second soaking to produce a bit of fermentation. The bran is strained away, and the resulting mass cooked into a paste, mixed with the dough of other starchy staples, and baked into an unleavened bread or cooked in oil. Maize gruels can be soured or sweetened, fermented into a light or a full beer, or distilled. The kernels are also boiled and eaten whole, sometimes with beans, or beaten into a consistency like that of boiled rice. Alternatively, the grains can be parched before boiling, or cooked until they burst. Immature ears are boiled or roasted, and the juice from immature kernels flavored, cooked, and allowed to jell.

Asia

Portuguese introductions of maize to Asia likely occurred in the early 1500s, after which the grain was carried along the western coast of India and into northwestern Pakistan along the Silk Route. By the mid-1500s, maize had reached Honan and Southeast Asia, and by the mid-1600s it was established in Indonesia, the Philippines, and Thailand. In southern and southwestern China during the 1700s, raising maize permitted farming to expand into higher elevations that were unsuitable for rice cultivation, and along with white and sweet potatoes, the new crop contributed to population growth and a consequent growing misery (Anderson 1988). From there, maize spread to northern China, Korea, and Japan.

In the 1990s, maize was a staple food in selected regions of China, India, Indonesia, and the Philippines. Among grains in China, it ranked third in importance (after rice and wheat, but before sorghum, which it has replaced in warmer, wetter areas and in drier areas when new hybrids became available). Maize is consumed as steamed or baked cakes, as mush, in noodles mixed with other grains, and as cracked grain mixed with rice. It is the principal grain in the lower mountains of western and southern China and in much of the central North, and it increasingly serves as a food for the poor. Immature maize is eaten as a vegetable, and baby corn is an important specialty appreciated for its crunchy texture.

In Indonesia, maize is the staple food of some 18 million people (Timmer 1987). Farmers have responded favorably to new technologies and government incentives, such as quick-yielding varieties, subsidized fertilizers, and mechanical tilling and shelling devices. They demand improved seed and subsidized chemicals and carefully match seed varieties to local seasonal conditions in environments that (in places) allow for triple cropping (rice-maize-maize, rice-maize-soy, or rice-maize-cassava sequences). In the 1980s, breeders reportedly could not keep up with the demand for improved white varieties, which cover 35 percent of the area sown in maize and are preferred for human consumption. Humans still consume 75 percent of Indonesia's maize directly, and it is particularly important as a staple in the preharvest "hungry season" before the main rice harvest. Rice remains the preferred staple; the proportion of maize in the diet fluctuates relative to the price of maize versus rice and consumer income.

Summary of Culinary History

Kernels of the earliest forms of maize were probably parched on hot stones or in hot ash or sand. Small hard seeds, in which starch was tightly packed, also lent themselves to popping. Both Mexican and Peruvian indigenous populations grew selected popcorn varieties, which, among the Aztecs, were burst like flowers or hailstones for their water god. Parched maize, sometimes mixed with other seeds, was ground into *pinole,* a favorite lightweight ration for travelers that could be eaten dry or hydrated with water.

Maize grains more commonly were wet-ground – boiled and then ground with a stone quern or pounded with wooden implements (the North American indigenous procedure outside of the Southwest). After soaking the kernels in alkaline and washing to remove the hulls, native peoples either consumed the grains whole (as hominy) or wet-ground them into a dough used to form tortillas (flat cakes), *arepas* (thick cakes), or *tamales* (leaf-wrapped dough with a filling). The arduous process of grinding, which could require up to half of a woman's workday, was later taken over by water- or engine-powered mills; the time-consuming process of shaping tortillas by hand was facilitated by wooden or metal tortilla "presses"; and very recently, the entire process of tortilla manufacture has been mechanized. In 1995, the people of Mexico consumed 10 million tons of tortillas, each ton using 10,000 liters of water to soak and wash the kernels, water that, when dumped, created rivers of calcium hydroxide. An interdisciplinary team has formed a 1995 "Tortilla Project" to create a water-sparing, energy-efficient machine that will turn out a superior nutritional product with no pollutants.

Dry-grinding, characteristic of nonindigenous processing, produces whole maize "meal," "grits," or "flour," which can be "decorticated" (bran removed) or "degerminated" (most bran and germ removed), a separation process also called "bolting," to produce a more refined flour and an end product that stores longer. Hominy is the endosperm product left over after the pericarp is removed and the germ loosened; "pearl" or "polished" hominy has the aleurone layer removed as well. Although separating the bran and germ decreases the vitamin and mineral value, it makes the oil and residual "germ cake," pericarp, and hulls more easily available for livestock feed.

Simple, boiled maize-meal porridges, which combine whole or degermed meal with water, are the most common forms of maize dishes. In the United States, it is cornmeal mush; in Italy, *polenta;* in Romania, *mamaliga;* and in Africa, *nshima, ugali,* or *foo foo.* In Italy, *polenta* often includes grated cheese and extra fat, and in Yugoslavia, the corn mush contains eggs and dairy products. Maize meal, when mixed with water or milk, can be shaped into simple unleavened flat breads or cakes and baked over an open fire, or in an oven. These were called *hoecakes* in the early United States.

In Asia, maize is "riced"; the cracked kernels are boiled and consumed like the preferred staple of the region. Indeed, improved maize varieties must meet the processing criteria of cracking and cooking to resemble rice. Maize starch, especially in central Java, is processed into flour for porridge, noodles, and snack food. Green maize is also consumed.

Industrial Processing

Industrial processing utilizes either wet or dry milling. Wet milling steeps kernels in water, separates germ from kernel, and then separates germ into oil and meal portions. Each 100 kilograms (kg) of maize yields 2 to 3 kg of oil. Corn oil is popular for its ability to withstand heat, its high level of polyunsaturates, and its flavorlessness. The meal portions of the kernel become starch, gluten, and bran.

The dried starch portion is used in the food, textile, and paper industries. Starch, processed into glucose syrup or powder and high-fructose or dextrose products, sweetens three-fourths of the processed foods in the United States, especially confections and baked goods. In 1991, high-fructose corn syrup, manufactured by an enzyme-isomerization process that was first introduced in the 1960s, accounted for more than half of the U.S. (nondiet) sweetener market (National Corn Growers Association 1992).

Dry milling processes about 2 percent of the U.S. maize crop into animal feeds, beers, breakfast cereals, and other food and industrial products. In a tempering/degerming process the majority of the pericarp and germ are removed, and the remaining bulk of the endosperm is dried and flaked into products such as breakfast cereal. Whole (white) grains are ground into hominy grits and meal. These products, because they still contain the oily germ, have superior flavor but shorter shelf life. Industrialized alkali processing produces a dough that is turned into tortillas, chips, and other "Mexican" snacks.

Special maize varieties are also being bred for "designer" industrial starches. One, high in amylose starch, is used to create edible wrappers for pharmaceuticals, feeds, and foods. Another "super slurper" absorbs up to 2,000 times its weight in moisture and is employed in disposable diapers and bedpads. Still another is being developed into less-polluting road "salt," and other corn starches are being tailored into biodegradable plastic bags, cups, and plates. All told, industrial maize preparations place thousands of different maize-derived items on modern supermarket shelves, including flours and meals for breads and puddings, starch as a thickener, maize ("Karo") syrups or honeys as sweeteners, high-fructose and dextrose syrups as sweetening ingredients in beverages and baked goods, and processed cereals as breakfast or snack foods. Maize-based cooking oils, chips, beers, and whiskeys complete the spectrum. In fact, almost all processed foods (because they contain additives of starch or fat) contain some maize, as do almost all animal products, which are converted maize (Fussell 1992).

Animal Feed Products

Maize is the preferred feedgrain for animals because it is so rich in fat and calories; its high-starch/low-fiber content helps poultry, swine, cattle, and dairy animals convert its dry matter more efficiently than with other grains; it is also lower in cost. Feeds are formulated from whole, cracked, or steam-flaked grains and optimally supplemented with amino acids, vitamins, and minerals to meet the special nutritional requirements of particular domesticated animals. In industrial processing, by-products remaining after the oil and starch have been extracted – maize gluten, bran, germ meal, and condensed fermented steepwater (from soaking the grain), which is a medium for single-cell protein – also go into animal feed.

Silage uses the entire maize plant – which is cut, chopped, and allowed to ferment – to nourish dairy and beef cattle and, increasingly, swine. In developing countries, fresh or dried vegetation and substandard grains are household commodities used to produce animal products. When the entire maize plant (and, in traditional fields, its associated weeds) serves as a feedstuff, it surpasses all other plants in average yield and digestible nutrients per hectare (Dowswell et al. 1996).

Nutrition

Maize provides 70 percent or more of food energy calories in parts of Mexico, Central America, Africa, and Romania. In these regions, adult workers consume some 400 grams of maize daily, a diet marginally sufficient in calories, protein, vitamins, and minerals, depending on how the maize is processed and the supplementary foods with which it is combined. Maize is a better source of energy than other cereal grains because of its higher fat content. Ground maize meal has 3,578 calories per kg, mostly carbohydrate, with about 4.5 percent "good" fat (fat-rich varieties are double this figure), and is high in essential linoleic and oleic fatty acids. It contains about 10 percent protein, roughly half of which is zein that is low in the amino acids lysine and tryptophan. The protein quality is enhanced in traditional Latin American maize diets by alkali processing and consumption with legumes that are high in lysine. Potatoes, if eaten in sufficient quantity, also yield a considerable amount of lysine and consequently often complement maize in highland South America and parts of Europe. Of course, incorporating animal proteins improves the nutritional quality of any diet with grain or tubers as the staple.

Maize is also naturally low in calcium and niacin, but calcium, niacin, and tryptophan content are all enhanced by traditional alkali processing (in which the kernels are cooked and soaked in a calcium hydroxide – lime or ash – solution), which adds calcium and increases the available tryptophan and niacin in the kernels or dough. White maize, usually the favored type for human food, is also low in vitamin A, although this nutrient is higher in properly stored yellow maize. Moreover, in its traditional heartland, maize is combined with chilli peppers, other vegetables, and various kinds of tomatoes and spices, all of which enhance the amount of vitamin A delivered to the consumer, along with other vitamins and minerals. In Africa and Asia, additional vitamins and minerals are added to maize diets when wild or cultivated greens, other vegetables, peanuts, and small bits of animal protein are combined in a sauce. Potash, burned from salt grasses, also enhances the otherwise poor mineral content of the diet (FAO 1953).

Diseases Associated with Maize

Pellagra and protein-deficiency disease (kwashiorkor) are historically associated with maize diets. In addition, as recently as the 1950s, rickets, scurvy, and signs of vitamin A deficiency have all been reported among populations consuming maize diets in Central Europe and eastern and southern Africa. Such deficiency diseases disappear with dietary diversification, expansion of food markets, and technological efforts to improve the micronutrient quality of maize diets.

Pellagra

Pellagra, now understood to be a disease caused in large part by niacin deficiency, was first observed in eighteenth-century Europe among the very poor of Spain, then Italy, France, Romania, Austria, southern Russia, the Ottoman Empire, and outside of Europe in Egypt, South Africa, and the southern United States. It was associated with extreme poverty and usually seen among land-poor peasants, whose diet centered much too heavily on maize. The main symptoms were described as the "three Ds" (diarrhea, dermatitis, and dementia), and four stages were recognized, from malaise, to digestive and skin disorders, to neurological and mental symptoms, and finally, wasting, dementia, and death (Roe 1973).

Although maize was adopted as a garden crop and within 100 years after its appearance was a field crop over much of the European continent, the disease manifested itself only when economic conditions had deteriorated to the point that pellagra victims ("pellagrins") could afford to eat only poorly cooked, often rotten maize. In Spain, this occurred in the 1730s; up to 20 percent of the population may still have been afflicted in the early twentieth century. In Italy, peasants also may have been suffering from the "red disease" as early as the 1730s. Despite efforts to protect the purity of the maize supply and improve diets through public granaries, bakeries, and soup kitchens, the disease persisted until the 1930s, when changes in diet were brought about by improved standards of living and the demise of the tenant-farmer system. In France, where maize had been sown since the sixteenth century and in some areas had expanded into a field crop by the late seventeenth, maize was not widely grown as a staple until the late eighteenth and early nineteenth centuries, when it became the main crop of the southern and eastern regions of the country and was accompanied by pellagra among destitute peasants. The physician Theophile Roussel recommended that the disease be prevented by changing the diet and agriculture so that there was less emphasis on maize. The government responded with legislation encouraging alternative crop and livestock production along with consumption of wheat, and by the early twentieth century, pellagra had largely been eliminated.

In the late nineteenth century, pellagra was reported by a British physician, Fleming Sandwith, in Egypt and South Africa. The disease was also present in the southern United States, although it did not reach epidemic proportions until the first decade of the twentieth century. In epidemiological studies begun in 1914, Joseph Goldberger, a physician working for the Public Health Service, determined that the disease was not contagious but *was* dietary. Furthermore, it was associated not so much with the consumption of maize as with the economic inability to obtain and consume other protective foods along with maize. For prevention and cure, Goldberger prescribed milk, lean meat, powdered yeast, and egg yolks. At the household level, he recommended more diversified farming, including milk cows and more and better gardens.

Goldberger traced the correlation between epidemic pellagra and economic downturns and demonstrated how underlying socioeconomic conditions restricted diets and caused dietary deficiencies among tenant farmers, who ordinarily ate mostly maize and maize products. The number of cases declined in the worst depression years (1932–4) because, when there was no market for cotton, farmers produced diversified food crops and garden vegetables for home consumption. Goldberger also demonstrated that pellagra mimicked "blacktongue" in dogs and used them as experimental animals to find what foods might prevent pellagra. He conceptualized the "pellagra-preventive" factor to be a water-soluble vitamin but could not identify it (Terris 1964). It was not until 1937 that C. A. Elvehjem and his colleagues demonstrated that nicotinic acid cured blacktongue in dogs, a finding carried over to demonstrate that nicotinic acid prevented pellagra in humans. Lest the public confuse nicotinic acid with nicotine, the Food and Drug Administration adopted the name "niacin" for their vitamin fortification program (Roe 1973: 127), which was designed to eliminate nutrition-deficiency diseases, and in southern states tended to include cornmeal and grits as well as wheat flours. Diversification and improvement of diet associated with World War II production, employment, and high-quality food rations mostly spelled an end to pellagra in the United States.

Since the 1940s, maize diets and pellagra have also been associated with imbalanced protein intake and selected amino acid deficiency. G.A. Goldsmith (1958) demonstrated that dietary tryptophan converts to nicotinic acid in humans at a ratio of 1:45, and anthropologists working with nutritional chemists were able to demonstrate that alkali processing of maize in traditional indigenous diets made more niacin and tryptophan available (Katz, Hediger, and Valleroy 1974). Traditional processing and food combinations also make more isoleucine available relative to leucine, and it has been suggested that excess leucine is another antinutritional factor in maize. Although pellagra has been eliminated in industrialized countries, it remains a plague among poor, maize-eating agriculturalists in southern Africa, where it was reported throughout the 1960s in South Africa, Lesotho, and Tanzania, and in Egypt and India among people who lack access to wheat.

Protein Deficiency

Another nutritional deficiency disease historically associated with diets high in maize is kwashiorkor, conventionally classified as a protein-deficiency disease and associated especially with weanlings and hungry-season diets in Africa (Williams 1933, 1935). Since the 1960s, international maize-breeding programs have sought to overcome lysine deficiency directly, thus giving maize a much better-quality protein. Maize breeders at Purdue University in Indiana, who were screening maize for amino acid contents, isolated the mutant "Opaque-2" gene and developed a variety that had the same protein content as conventional maizes but more lysine and tryptophan.

Although this variety possessed a more favorable amino acid profile, its yields were lower, its ears smaller, its chalky kernels dried more slowly, and it carried unfavorable color (yellow), texture, and taste characteristics. Its softer, more nutritious, and moister starch was more easily attacked by insects and fungi, and its adhesive properties did not make a good tortilla. Mexican researchers at CIMMYT in the 1970s and 1980s eliminated these deficiencies and in the mid-1980s introduced Quality Protein Maize (QPM) with favorable consumer characteristics. The remaining step was to interbreed this superior type with locally adapted varieties. But by the 1980s, nutritionists were questioning the importance of protein or selective amino-acid deficiencies as high-priority problems and focusing instead on improving access to calories. QPM became a technological solution for a nutritional deficiency no longer of interest, and CIMMYT was forced to end its QPM program in 1991. However, national programs in South Africa, Ghana, Brazil, and China are using QPM to develop maize-based weaning foods and healthier snacks, as well as a superior animal feed (Ad Hoc Panel 1988).

Additional Strategies for Nutritional Improvement

Strategies for improving maize diets focus on new varieties with higher protein quality and essential vitamin contents, better storage, wiser milling and processing, fortification, and dietary diversification. Conventional breeding and genetic engineering have enhanced essential amino acid profiles, especially lysine and methionine contents, although end products so far are principally superior feeds for poultry and pigs. Maize transformation by means of electroporation and regeneration of protoplasts was achieved in 1988, and subsequently by *Agrobacterium* (Rhodes et al. 1988). The first commercial varieties, with added traits of herbicide resistance and superior protein quality, were released in 1996. To improve protein content, maize meals are also fortified with soybean protein meal or dried food yeast *(Tortula utilis).* Nutritional enhancement through breeding or blending are alternatives to diversifying human (or animal) diets with legumes or animal foods.

Improperly stored maize, with moisture contents above 15 percent, also favor the growth of fungi, the most dangerous being *Aspergillus flavus,* which produces aflatoxin, a mycotoxin that causes illness in humans and animals. Efforts are being taken to eliminate such storage risks and losses.

Future Prospects

Maize has been expanding in geographical and cultural scope to the point where the world now harvests more than 500 million tons on all continents, and the crop is being increasingly directed into a number of nonfood uses, especially in industrialized countries. The supply of maize should continue to increase in response to a growing demand for animal products (which rely on maize feed), for food ingredients industrially processed from maize (such as good-quality cooking oil), and for convenience foods and snack foods (Brenner 1991). The biological characteristics of maize that have always favored its expansion support the accuracy of such a prediction: Its adaptability, high yields, high extraction rate, and high energy value deliver higher caloric yields per unit area than wheat or rice, and its high starch and low fiber content give the highest conversion of dry matter to animal product. Technology, especially biotechnology, will influence overall yields as well as nutritive value and processing characteristics. Genetic engineering has already allowed seed companies to market higher protein-quality maize designed to meet the specific nutritional needs of poultry and livestock. Other varieties have been designed to tolerate certain chemicals and permit higher maize yields in reduced-pest environments. The introduction of a male sterility trait, developed by Plant Genetic Systems (Belgium) in collaboration with University of California researchers, is expected to reduce the costs of manual or mechanical detasseling, estimated to be $150 to $200 million annually in the United States and $40 million in Europe (Bijman 1994).

Yet, the favorable agricultural, nutritional, and economic history of maize notwithstanding, the grain presents problems. As we have seen, maize diets have been associated with poverty and illness, especially the niacin-deficiency scourge, pellagra, and childhood (weanling) malnutrition. Moreover, the highly productive inbred hybrids, such as those that contain the trait for cytoplasmic male sterility, have created new genetic and production vulnerabilities (National Research Council 1972). Hybrid seeds also may increase the economic vulnerability of small-scale semisubsistence farmers who cannot afford to take advantage of new agricultural technologies and, consequently, find themselves further disadvantaged in national and international markets. Finally, and paradoxically, maize (like the potato) has been associated with increasing hunger and suffering in Africa (Cohen and Atieno Odhiambo 1989) and Latin America (Asturias 1993).

II.A.5 Millets

The caryopses of grasses have been harvested as human food since long before the advent of agriculture. Numerous species are still regularly harvested in Africa and Asia during times of scarcity. Among the many hundreds of species harvested as wild cereals, 33 species belonging to 20 genera were domesticated. Their cultivated cereals are dependent on humans for survival because they have lost the ability of natural seed dispersal and have become adapted to cultivated fields.

Cereals are grown on an estimated 730 million hectares and produce about 1,800 million metric tons of grain annually. Wheat, maize, and rice account for at least 80 percent of the annual world cereal production. Barley, sorghum, oats, rye, and pearl millet represent about 19 percent of cereal grains produced, and the remaining 1 percent of production comes from the other 19 grass species that are still grown as human food. These species are minor in terms of total world cereal production, but some are important components of agriculture in Africa and Asia (de Wet 1989).

Cereals that do not belong to the wheat *(Triticum),* barley *(Hordeum),* oats *(Avena),* maize *(Zea),* or rice *(Oryza)* genera are commonly referred to as millets (de Wet 1989).

American Millets

The first cultivated cereal in the Americas appears to have been a species of *Setaria* (Callen 1965, 1967). Archaeological records indicate that this millet was an important source of food in the Valley of Mexico and in northeastern Mexico before the domestication of maize. E. O. Callen (1967) demonstrated a steady increase in size of caryopses of this millet over 1,500 years of use as a cereal. The species, however, never lost the ability of natural seed dispersal. It was displaced by maize as a cereal during the fifth millennium B.C., but later enjoyed a temporary resurgence in importance when it was probably harvested from weed populations that invaded maize fields.

The archaeological record indicates that another native cereal was cultivated in the southeastern United States before the introduction of maize about 3,000 years ago (Wills 1988). Maygrass (*Phalaris caroliniana* Walt.) was a common component of early agricultural settlements of the region (Chomko and Crawford 1978). It has been proposed that this species was planted by the inhabitants of these early settlements, as they were located well outside the natural range of maygrass (Cowan 1978). Morphological evidence of its domestication, however, is absent.

Two native grass species besides maize, mango (*Bromus mango* Desv.), and sauwi (*Panicum sonorum* Beal) were fully domesticated in the Americas by early farming communities. Mango is the only cereal known to have become extinct in historical times (Cruz 1972). Its cultivation was confined to central Chile. In 1782, it was recorded that the Aracanian Indians of that region grew "el Mango," a kind of rye, and "la Tuca," a kind of barley (Parodi and Hernandez 1964). Claudio Gay, who visited the province of Chiloe in 1837, collected specimens of this cereal that are currently on file at the herbarium of the Natural History Museum in Paris. He was probably the last botanist to see *B. mango* grown as a cereal inasmuch as it was replaced during the eighteenth century by wheat and barley introduced to the New World by European settlers.

Mango was grown as a biannual. In the past, farmers allowed animals to graze on mango fields during the first year and harvested it as a cereal at the end of the next summer (Gay 1865). It is surprising that a biannual species should have been domesticated. However, it may have been the only grass in the region that lent itself to domestication. J. Ball (1884) recorded that the people of northwestern Argentina and adjacent territories harvested a species of *Bromus* as a wild cereal.

Sauwi, another native American, was extensively grown along the flood plains of the Rio Grande until the late nineteenth century (Palmer 1871; Elsasser 1979). It was sown as soon as the water receded (Kelly 1977). Today sauwi is grown only by the Warihios of the southeastern Sonora and adjacent Chihuahua of Mexico (Nabhan and de Wet 1984).

The species *Panicum sonorum* occurs as part of the natural vegetation along the western escarpment of the Sierras from southern Arizona to Honduras. It is an aggressive colonizer and often occurs in large continuous populations. It is relished by grazing animals and harvested as a wild fodder by farmers in the Mexican states of Chihuahua and Sonora. Cultivated sauwi differs conspicuously from wild *P. sonorum* in having larger spikelets that tardily disarticulate from inflorescences at maturity. Sauwi was probably domesticated by farmers who also grew other crops. It is found in an archaeological context associated with beans and cucurbits (Kaemlein 1936). This cereal is a potentially promising fodder crop in semiarid regions of Africa and Asia.

Wild rice of North America (*Zizania aquatica* L.) is the only grass species domesticated as a cereal by present-day plant breeders. Early European explorers were impressed by the extensive use of this wild grass. In 1778, Jonathan Carver reported that wild rice was the most valuable of all the native wild food plants of the country (Carver 1778: 522–5). It had been harvested as a cereal from rivers and lakes in the northern states and adjacent Canada since long before recorded history (Coville and Coves 1894; Jenks 1900; Larsen 1939). Charred remains of wild rice caryopses found in threshing pits date from well before contact with Europeans (Ford and Brose 1975). Wild rice is now harvested from wild populations on a commercial scale, and it is also grown in paddies because such harvests cannot meet demand.

Wild rice was only domesticated very recently (de Wet and Oelke 1979). But the species does not readily lend itself to domestication: Caryopses rapidly lose viability after harvest if not stored underwater or in mud, and the species does not thrive in stagnant water. Therefore, domestication involved a combination of selection for spikelets that persisted on the panicle at maturity and the development of a cropping system that took advantage of natural adaptations of the species.

Wild rice is now successfully grown on a commercial scale. Paddies are constructed so that a minimum water depth of 15 centimeters (cm) can be maintained. These are flooded and seeded in early spring. Germination is rapid, and water level is maintained until the crop matures. Fields are drained, and the crop is mechanically harvested.

African Millets

The Near Eastern cereals, wheat and barley, have been cultivated in North Africa since at least the late fifth millennium B.C. (Clark 1976). However, these temperate cereals are poorly adapted for cultivation in the tropics south of the Sahara, where eight tropical African grass species were locally domesticated.

Sorghum (*Sorghum bicolor* [L.] Moench) is the most important native African cereal. It is grown on some 50 million hectares and produces up to 80 million metric tons of grain annually, primarily for human food or animal feed. Wild sorghum is widely distributed south of the Sahara in the Sudanian climatic zone, which receives 600 to 800 millimeters (mm) of annual rainfall and extends into the wetter Guinean zone. It became a cultivated cereal at least 5,000 years ago (Connah 1967: 25; de Wet 1978; Wendorf et al. 1992).

Pearl millet (*Pennisetum glaucum* [L.] R. Br.), also called bulrush millet, is the second most important native African cereal. It is cultivated across the arid and semiarid tropics of Africa and Asia where no other cereal consistently produces a harvest because of low annual rainfall and high soil temperatures. Pearl millet is grown on about 14 million hectares in Africa and 11 million hectares in India and Pakistan. In areas where annual rainfall exceeds 600 mm in the African and Indian tropics, pearl millet is usually replaced by sorghum as a dry land crop, and in locations where annual rainfall is over 1,200 mm, finger millet or maize becomes the cereal of choice.

The species *Penisetum glaucum* (pearl millet) is morphologically complex. O. Stapf and C. E. Hubbard (1934) recognized 13 cultivated, 15 weed, and 6 wild taxa of this complex species. W. D. Clayton (1972), by contrast, recognized 2 wild species, 2 weed taxa, and 1 cultivated complex. J. N. Brunken (1977), however, demonstrated that these taxa are conspecific. Wild taxa are often difficult to distinguish from weed taxa, which, in turn, grade morphologically into cultivated taxa. Agricultural weeds, known as shibras in West Africa, often resemble cultivated pearl millet, except for their natural seed dispersal. The involucres of cultivated pearl millet do not disarticulate at maturity. Shibras are common in the cultivated pearl millet zone of West Africa and the Sudan. They also occur in southern Angola and Namibia.

Wild pearl millet taxa occur extensively from coastal Senegal and Mauritania to northeastern Ethiopia in the Sahelo-Sudanian (350 to 600 mm annual rainfall) zone. They also extend into the Sudanian (600 to 800 mm) bioclimatic zone and are found along the foothills of mountains in the Central Sahara. Wild taxa are aggressive colonizers of disturbed habitats and are often weedy around villages.

Cultivated pearl millet is genetically and morphologically variable (Brunken 1977; Clement 1985; Marchais and Tostain 1985). Inflorescences range in shape from cylindrical to broadly elliptic and in length from 5 to 200 centimeters. Large inflorescences are commonly produced on plants with single culms, whereas small- to medium-sized inflorescences are produced on plants that tiller.

Four races of pearl millet were recognized by Brunken, J. M. J. de Wet, and J. R. Harlan (1977).

1. Race typhoides is grown across the range of pearl millet cultivation and is characterized by obovate caryopses that are obtuse and terete in cross section. Inflorescences are variable in length, but usually several times longer than wide, and more or less cylindrical in shape.
2. Race nigritarum differs from typhoides, primarily, in having obovate caryopses that are angular in cross section. It is the dominant pearl millet of the eastern Sahel from Sudan to Nigeria.
3. The principal pearl millet in the Sahel west of Nigeria is race globosum. It has large, globose caryopses, and commonly large, candle-shaped inflorescences.
4. Race leonis is the pearl millet common to Sierra Leone, Senegal, and Mauritania. It has oblanceolate caryopses with the apex acute.

Pearl millet could have been domesticated anywhere along the southern fringes of the Sahara (Harlan 1971). Botanical evidence indicates that the *Pennisetum violaceum* complex, as recognized by Clayton (1972), is the progenitor of domesticated pearl millet.

J. D. Clark (1976) suggested that cereal cultivation spread from the Near East to North Africa during the fifth millennium B.C. and subsequently became established across North Africa. With the onset of the present dry phase in North Africa, cultivation of these Mediterranean cereals was eventually confined to the coastal belt, and those farmers forced south by the expanding desert domesticated native grasses as cereals (Clark 1964).

Along the southern fringes of the expanding desert, the most abundant tropical grass species that invites domestication is *P. violaceum.* Its colonizing ability gives rise to large populations that facilitate its harvesting as a wild cereal. Indeed, P. J. Munson (1976) presented archaeological evidence of such harvesting along the southwestern fringes of the Sahara dating as far back as 3,000 years, and O. Davies (1968) reported archaeological remains of cultivated pearl millet in northern Ghana dated at about the same time. Cultivated pearl millet eventually reached India as a cereal some 2,500 years ago (Rao et al. 1963).

Wild pearl millet is a typical desert grass. It produces large numbers of caryopses that can withstand heat and drought and remain dormant in the soil until conditions become favorable for germination. Caryopses germinate rapidly after the first good rains of the season, and seedlings quickly extend roots into the subsurface soil layers. Plants tiller profusely, go dormant under heat or drought stress, and produce new tillers when conditions become favorable for growth and reproduction. The strategy for survival in such a harsh environment is opportunism with respect to moisture availability and tolerance with respect to high temperature.

Cultivated pearl millet retains these adaptations. It grows and develops rapidly under conditions of adequate soil moisture and elevated temperatures, and thus can take advantage of a short growing season, to survive short periods of severe drought, and to resume growth when water becomes available again. Comparisons among genotypes indicate that differences in time of flowering under stress are the major component of yield differences among cultivars (Bidinger, Mahalakshmi, and Rao 1987). This suggests that the high degree of variability in time to flower among landrace populations is the result of natural selection for early flowering and, thus, escape from drought in dry years, and farmer selection for late flowering plants with large inflorescences in wet years (de Wet, Peacock, and Bidinger 1991). These adaptations make pearl millet the dominant cereal in the Sahelo-Sudanian zone of Africa and in semiarid regions of Zambia, Zimbabwe, Namibia, Angola, northwestern India, and adjacent Pakistan.

Finger millet (*Eleusine coracana* [L.] Gaertn.) is another native African cereal that was introduced into India during the first millennium B.C. (Vishnu-Mittre 1968). Finger millet is cultivated in wetter and cooler seasonal rainfall zones of southern Africa on about 1 million hectares and is a major cereal in the Lake Victoria region, particularly in eastern Uganda. In India, finger millet is grown on about 3 million hectares from Uttar Pradesh to Bihar and south to Tamil Nadu and Karnataka, with the states of Andhra Pradesh, Karnataka, and Tamil Nadu the major producers of this cereal. This wide distribution of finger millet has led to considerable controversy over the place of its original domestication and the identity of its wild progenitor (Hilu and de Wet 1976).

Two wild species closely resemble finger millet in gross morphology: *Eleusine indica* [L.] Gaertn., which is widely distributed in both Africa and Asia; and *E. africana* Kennedy-O'Byrne, which is predominantly African. P. J. Greenway (1945) suggested that finger millet had an African origin and that its wild progenitor is *E. africana.* But J. Kennedy-O'Byrne (1957) proposed that *E. indica* gave rise to Indian cultivars and *E. africana* to African cultivars.

More recent cytogenetic and morphological evidence indicates that *E. africana* is the closest wild relative of finger millet. Finger millet is a tetraploid with $2n = 36$ chromosomes, as is *E. africana,* that crosses with the cereal to produce fertile hybrids. Derivatives of such crosses are obnoxious weeds of cultivation in eastern Africa. *Eleusine indica* is a diploid ($2n = 18$) and genetically isolated from the cereal.

In their work, K. W. Hilu and de Wet (1976) taxonomically recognized finger millet as *E. coracana,* subspecies *coracana,* and the wild and weedy African complex as *E. coracana,* subspecies *africana.* Wild finger millet is a common grass along the eastern and southern African highlands and is harvested during times of scarcity.

The antiquity of finger millet cultivation in eastern Africa is not known with certainty (Harlan, de Wet, and Stemler 1976). Impressions of wild, and possibly cultivated, finger millet spikelets occur on potsherds from Neolithic settlements at Kadero in Central Sudan that date back about 5,000 years (Klichowska 1984). Further archaeological evidence presented by Hilu, de Wet, and Harlan (1979) suggests that a highly evolved race of finger millet was grown at Axum, in Ethiopia, by the first century A.D. If these dates are correct, finger millet is the oldest known domesticated tropical African cereal.

This conclusion is not impossible. The concept of agriculture could have been introduced from West Asia into the Highlands of East Africa before the domestication of sorghum and pearl millet along the southern fringes of an expanding Sahara. The Near Eastern cultigens, wheat and barley, are adapted for cultivation on these highlands, and their introduction into eastern Africa could also have led to the domestication of native grasses as cereals.

Finger millet is variable in respect to inflorescence morphology, which is associated with selection and isolation of cultivars by farmers, rather than ecogeographical adaptation. Morphologically similar cultivars are widely grown, and African and Indian cultivars are often difficult to distinguish on the basis of morphology.

Five races of cultivated finger millet were recognized by de Wet and colleagues (1984b). Race coracana is grown across the range of finger millet cultivation in Africa and India. These cultivars resemble subspecies *africana* in having a well-developed central inflorescence branch. Inflorescence branches are 5 to 19 in number, essentially straight, and 6 to 11 cm long. In India, race coracana is often sown as a secondary crop in fields with pearl millet or sorghum.

The most common finger millets in both Africa and India belong to race vulgaris, which is also grown as a cereal in Indonesia. Inflorescence branches are straight, reflexed, or incurved, with all three types frequently occurring in the same field. In India, this race is often planted as a dry-season crop following the harvest of irrigated rice, and in the eastern hills it is often sown in nurseries and transplanted with the first rains of the season to assure an early harvest.

With incurved inflorescence branches, race compacta resembles vulgaris cultivars, but the inflorescences are larger and the lower inflorescence branches are always divided in compacta. These cultivars are commonly known as cockscomb finger millets. Indian cultivars have a branch located some distance below the 4 to 14 main inflorescence branches, but African cultivars usually lack this lower branch. The race is grown in northeastern India, Ethiopia, and Uganda.

Race plana is grown in Ethiopia, Uganda, and the western and eastern ghats of India. Spikelets are large and arranged in two moderately even rows along the rachis, giving young inflorescence branches a ribbon-like appearance. Florets are often so numerous that they almost surround the rachis at maturity.

Race elongata is morphologically the most distinct of the five races of finger millet. Inflorescence branches are long and reflexed at maturity. Cultivars grown in Malawi have inflorescence branches up to 24 cm long. More common are cultivars with inflorescence branches of 10 to 15 cm. Race elongata is grown on the East African highlands and the hills of eastern India.

At least 1 million hectares of finger millet are planted in Africa each year. It is the preferred cereal for brewing beer and is an important food crop in Uganda, Ethiopia, Malawi, Zambia, and Zimbabwe. In India, finger millet is extensively grown by tribal people on the eastern and western ghats and by commercial farmers in Andhra Pradesh and Tamil Nadu. The area under cultivation in India is close to 3 million hectares. H. Doggett (1989) indicates that land planted with finger millet in India increased by about 3 percent annually in the 1980s. Average yield per hectare also increased from 704 kilograms (kg) in the 1950s to over 1,000 kg in the 1990s as a result of breeding African germ plasm into Indian cultivars. In East Africa a breeding program is in progress to develop cytoplasmic-genetic male sterile populations, an effort which could facilitate the production of hybrid cultivars and contribute substantially to yield increases in both Africa and India.

Tef, *Eragrostis tef* (Zucc.) Trotter is an endemic and highly valued cereal of the Ethiopian Highlands (Costanza, de Wet, and Harlan 1979). The grain is used to make *injera,* an unleavened bread that is a staple in Ethiopia, and to brew beer. The wild ancestor of tef has not yet been positively identified, but *Eragrostis pilosa* (L.) P. Beauv., a common grass on the Ethopian highlands, is a strong possibility. T. Kotschy (1862) reported that the grains of this wild species were harvested as a food by the Sudanese while they waited for sorghum to mature. The antiquity of tef cultivation is also not known, but its popularity suggests domestication before the introduction of wheat and barley to East Africa from the Near East. W. Stiehler (1948) suggested that tef became widely distributed on the Ethiopian highlands only during the rise of the monarchy.

W. C. Harris (1844: 349) noted that 2 races of tef with brown grain and 2 with white grain were sold in Ethiopian markets. A. Trotter (1918) recognized 7 varieties of tef on the basis of spikelet and grain color.

Two species of *Digitaria* are endemic cultivated cereals of the Sahelo-Sudanian climatic zone of West Africa (Chevalier 1950; Porteres 1976). True fonio (*Digitaria exilis* [Kippist] Stapf) is grown from Senegal to Lake Chad, and black fonio (*D. iburua* Stapf) is grown on the Togo highlands and in Nigeria (de Wet 1977). The wild progenitors of these fonios are not known. In West Africa, *Digitaria barbinodis* Henrard, *D. ciliaris* Vanderyst, *D. longiflora,* and *D. ternata* (Hochst.) Stapf (Retz.) Persoon are aggressive wild colonizers and are harvested as cereals during times of scarcity.

Stapf (1915) pointed out morphological similarities between black fonio and *D. ternata,* and between fonio and *D. longiflora.* Fonio is a smaller grass than black fonio. It has 2 to 4 racemes per inflorescence, whereas black fonio has inflorescences with 4 to 10 racemes. Weedy races of fonio occur in Nigeria. Cultivated fonios differ from these weeds only in having lost their natural ability to disperse seeds efficiently.

R. Porteres (1976) recorded that fonio is harvested from some 721,000 acres annually, providing food to more than 3 million people during the most difficult months of the year. Fonios were already important in the fourteenth century when the traveler Ibn Batuta noted that they were extensively available in the markets between Outala in Mauritania and Bamako in Mali (Lewicki 1974: 37–8).

Little research has been done to improve the already impressive yield potential of fonios. Their adaptation to marginal agricultural land, tolerance to drought, and popularity as a food assure their survival as cereals in the arid Sahelian and Sudanian climatic zones of West Africa.

Animal fonio (*Brachiaria deflexa* [Schumach.] C. E. Hubb. ex Robynsis) is a weed that is commonly harvested as a wild cereal across the savanna of Africa. Farmers often encourage animal fonio to invade sorghum and maize fields, where it matures about two months before the major crop is harvested (de Wet 1977). It is sown as a cereal only on the West African Futa Jalon Highlands (Porteres 1951).

Grass weeds differ from their domesticated close relatives primarily in being spontaneous, rather than sown, and in retaining the ability of natural seed dispersal (Harlan, de Wet, and Price 1973). They do not require harvesting or sowing by humans to survive.

Avena abyssinica Hochst. is a weedy, semidomesticate of the Ethiopian highlands (Ladizinsky 1975). It is harvested, threshed, used, and sown with the wheat or barley that it accompanies as a weed. Such cultural practices lead to a loss of natural seed dispersal ability, and as the species is not consciously sown by humans, it has become an obligate weed in cultivated fields.

Indian Millets

Wheat, rice, sorghum, pearl millet, finger millet, foxtail millet, and maize are the most important cereals grown in India. Seven indigenous cereals, mostly grown on marginal agricultural land, were domesticated in India.

Raishan (*Digitaria cruciata* [Nees] A. Camus) and adlay (*Coix lacryma-jobi* L.) are native in the wet tropics of northeastern India. Raishan is grown by the Khasi people of Assam in India and by hill tribes in Vietnam. H. B. Singh and R. K. Arora (1972) reported that this cereal is grown in Assam as a secondary crop in maize or vegetable fields. It is sown in April or May and harvested in September and October. Plants tiller profusely, and culms of individual plants are tied together at time of flowering to facilitate harvesting. Mature inflorescences are rubbed by hand to collect the grains. Dehusked grains are boiled as rice or ground into flour. Raishan is also an important fodder crop in Assam, and it could become a similarly significant fodder in other tropical regions of the world.

Adlay is grown under shifting cultivation from Assam to the Philippines (Arora 1977). It was probably domesticated in tropical eastern India and introduced into Southeast Asia, but it is also possible that adlay was independently domesticated as a cereal in both India and the Philippines. The greatest diversity of cultivated adlay occurs in the Philippines (Wester 1920).

The fruit cases of wild adlay (Job's tears) are used as beads. Fertile female spikelets of all wild *Coix* species are individually enclosed by an involucre that is indurated, glossy, and colored white, gray, or black. The involucres of cultivated adlay are papery, allowing for easy removal of the caryopses from the fruit cases. Adlay grains are cooked as rice or ground into flour to be used in baking bread. Adlay is often grown on banks between rice paddies.

The other five indigenous Indian cereals were probably domesticated in semiarid India where they still form an important part of dryland agriculture.

Sama (*Panicum sumatrense* [Roth.] ex Roem. et Schult.) is grown in India, Nepal, Sikkim, and western Myanmar (de Wet, Prasada Rao, and Brink 1984a). It is an important cereal in the eastern ghats of Andhra Pradesh and adjacent Orissa. Sama is tolerant to drought and produces a crop even in the poorest agricultural soil. It is commonly sown as a mixture with foxtail millet in sorghum or pearl millet fields, where it matures and is harvested first, followed by foxtail millet and sorghum or pearl millet. Mixed planting provides a supply of cereals starting about two months after planting to the end of the rainy season. A robust race is sometimes planted as a single crop and is an important cereal in the hills of eastern India.

Primitive cultivars of sama resemble the widely distributed *Panicum psilopodium* Trin., except for their persistent spikelets. This wild species crosses naturally with sama to produce fertile hybrids. Derivatives of such hybrids occur as weeds in and around cultivated fields.

Sama has been grown as a cereal in India for at least 4,500 years. S. A. Weber (1991: 107–8) pointed out that carbonized grains of sama are common at the early Harappan agricultural site of Rodji.

Sawa (*Echinochloa colona* [L.] Link) is grown in India, Nepal, and Sikkim (de Wet et al. 1983a). Cultivated kinds of sawa are also known taxonomically as *E. utilis* Ohwi et Yabuno. It is morphologically allied to Japanese millet (*Echinochloa cruss-galli* [L.] P. Beauv.), but sawa is tropical rather than temperate in its distribution. Furthermore, these tropical and temperate domesticated species are genetically isolated from one another (Yabuno 1966). Sawa was probably domesticated in India, whereas Japanese millet seems to have originated in northwestern China. Some Indian cultivars of sawa differ from weedy *E. colona* only in having spikelets that disarticulate tardily rather than readily at maturity, as is common in wild grasses. These weedy sawas frequently occur with cultivated races in the same field, and sawa could have been domesticated originally by an accidental harvest of weed sawas in fields where other cereals were planted.

Four races of sawa are recognized. Races have little geographic distinctiveness but are recognized and maintained by farmers. Race stolonifera resembles wild *E. colona,* except for persistence of spikelets in the cereal and disarticulation of spikelets at maturity in the weed. Race robusta has large inflorescences and is widely grown. It crosses with stolonifera. Derivatives of such hybridization gave rise to the stoloniferous race intermedia. The most distinct race is laxa. It is grown in Sikkim and is characterized by long and slender racemes.

In Africa, *Echinochloa colona* is also an aggressive colonizer of cultivated fields. D. M. Dixon (1969) identified grains of *E. colona* among plant remains from intestines of mummies excavated at Naga ed-Dar in Egypt. The species was probably harvested as a wild cereal in ancient Egypt along the flood plain of the Nile, a practice that remains common today in times of scarcity.

Kodo (*Paspalum scrobiculatum* L.) is an important cereal in Kerala and Tamil Nadu and a minor cereal in India north to Rajasthan, Uttar Pradesh, Bihar, and West Bengal. The species occurs wild across the Old World tropics (Clayton and Renvoize 1982). It is an aggressive colonizer of disturbed habitats and lends itself to domestication. Wild kodo is a perennial, whereas the cultivated cereal is grown as an annual.

Some cultivars of kodo millet root at lower nodes of their decumbent culms to produce new flowering culms after the first harvest. Kodo occurs in the agricultural record of India starting 3,000 years ago (Kajale 1977; Vishnu-Mittre 1977). Little racial evolution has occurred in Kodo millet.

The commonly grown kodo millet resembles spontaneous kinds in having racemes with spikelets arranged in two regular rows on one side of a flattened rachis. Two types of inflorescence aberrations occur occasionally in fields of kodo. In one variant, spikelets are arranged along the rachis in two to four irregular rows, rather than two regular rows. In the other variant, the spikelets are arranged in several irregular rows at the lower part of racemes and become two regular rows near the tip of the racemes. These aberrant plants are more robust and have fewer and better synchronized tillers than common kodo millet. Introgression with weed kodo makes it impossible for farmers to maintain these high-yielding genotypes, although they are carefully selected to provide seed for the next season (de Wet et al. 1983b). Farmers in southern India correctly believe that Kodo millet grains can be poisonous after a rain. The reason for this toxicity is ergot infection.

Korali (*Setaria pumila* [Poir.] Roem. et Schult.) and peda sama (*Brachiaria ramosa* [L.] Stapf) are domesticated Indian weeds that are widely distributed in tropical Africa and Asia. They are often harvested as wild cereals in times of scarcity and are cultivated only by the hill tribes of southern India. Wild and cultivated kinds of both korali and peda sama cross to produce aggressive colonizer populations. Farmers tend to keep the domesticated kinds pure through seed selection.

Eurasian Millets

Four millets – crab grass (*Digitaria sanguinalis* [L.] Scopoli), proso millet (*Panicum milliaceum* L.), foxtail millet (*Setaria italica* [L.] P. Beauv.), and Japanese millet (*Echinochloa crus-galli* [L.] P. Beauv.) – are widely distributed across temperate Europe and Asia.

Crab grass (*D. sanguinalis*) is a cosmopolitan weed. It became semidomesticated in southeastern Europe after having been harvested for millennia. Crab grass never completely lost the ability of natural seed dispersal because it was commonly harvested by swinging a basket to collect the mature grains. The species is an aggressive natural colonizer of disturbed habitats, including cultivated fields. It was a popular cereal in southern Europe during Roman times (Körnicke 1885: 279–84) and was still widely grown as mana or bluthirse in southeastern Europe during the first quarter of the nineteenth century. Crab grass was probably independently domesticated in several parts of its range. It is currently grown as a minor cereal in the Caucasus of Russia and in Kashmir.

Japanese millet *(Echinochloa crus-galli)* is a grass of temperate Eurasia. The barnyard grass found in the American Midwest is an introduced weed race of *E. crus-galli. Echinochloa oryzoides* (Ard.) Fritsch, the common weed of rice cultivation, is also distantly related to *E. crus-galli.* Japanese millet is grown as a cereal in China, Korea, and Japan. Cultivated kinds are sometimes, incorrectly, classified as *E. frumentacea* (Roxb.) Link. Little is known about the antiquity of this cereal. H. Helmqvist (1969) suggested that the species was grown in Sweden during the Bronze Age when the climate was milder than it is today. It is no longer grown as a cereal anywhere in Europe.

The genus *Panicum* is widely distributed throughout the warmer parts of the world and is of considerable economic importance. Several species are grown as fodder, others are harvested as wild cereals in times of scarcity, and still others are obnoxious weeds. Proso millet *(Panicum miliaceum)* was once widely cultivated in temperate Europe and Asia but has largely been replaced as a cereal by wheat.

The closest wild relative of proso millet, *Panicum miliaceum* var. *ruderale* Kitagawa is native to central China (Kitagawa 1937). In morphology, it resembles weed races of proso millet that occur across temperate Eurasia but is a less aggressive colonizer than the weed. These weeds represent derivatives of cultivated proso millet that regained the ability of natural seed dispersal through mutation (Scholz 1983).

Proso millet has been grown in central China for at least 5,000 years (Cheng 1973), and it is still grown on about 1.5 million hectares in China. It is also an important cereal in Mongolia, Korea, and northern India. A cultivar of proso millet with glutinous endosperm is favored in China, where its flour is used to make bread. Nonglutinous cultivars are grown in Mongolia and India, and the grains are cooked as rice.

Proso millet has been grown in southern Europe for at least 3,000 years (Neuweiler 1946). It became widely distributed as a cereal in Europe during the Bronze Age. Its popularity declined during the twentieth century, and proso millet is now grown in Europe primarily as a feed for caged birds. It is extensively variable. Five cultivated races are recognized. They are artifacts of selection by farmers and have no ecogeographic validity.

Race miliaceum resembles wild var. *ruderale* in having numerous decumbent culms, each with several racemes. Its inflorescences are large, with spreading branches that commonly lack spikelets at the base. This is the basic race from which the other races were selected under cultivation. It is grown across the range of proso millet cultivation.

Race patentissimum resembles miliaceum in its lax panicles with spreading branches having a sterile zone at the base. Inflorescences, however, become curved at maturity because of the weight of the spikelets. Patentissimum is the common proso millet in India, Bangladesh, Pakistan, and Afghanistan. It is also grown in Turkey, Hungary, Russia, and China. Race patentissimum probably reached India from central Asia during historical times.

Races contractum, compactum, and ovatum are often difficult to distinguish from one another. They represent the highest evolved cultivars of proso millet. Inflorescences are more or less elliptic in shape. Spikelets are crowded along the panicle branches in compactum and ovatum. These branches are erect when young and become curved at maturity. Ovatum cultivars usually have smaller inflorescences than race compactum and are grown in Russia, Turkey, and Afghanistan. Compactum cultivars are grown in Japan, Russia, Iran, and Iraq. In race contractum the lower part of panicle branches are free of spikelets. Race contractum is grown in Europe, Transcaucasian Russia, and China.

Foxtail millet, *Setaria italica,* is grown as a cereal in southern Europe, in temperate Asia, and in tropical India. Its closest wild relative is the cosmopolitan weed, green foxtail (*S. italica viridis* [L.] Thell.). The latter is primarily an urban weed, but as a robust race it is also an obnoxious weed of agriculture (Pohl 1966). This giant green foxtail is derived from introgression between cultivated and wild races.

The antiquity of foxtail millet as a cereal is uncertain. The species could have been domesticated across its range of natural distribution from Europe to Japan (de Wet, Oestry-Stidd, and Cubero 1979). It has been grown as a cereal in China for at least 5,000 years (Cheng 1973) and in Europe for at least 3,000 years (Neuweiler 1946). Foxtail millet was an important cereal during the Yang-shao culture phase in China. Evidence of foxtail millet in storage jars, and the association of farming implements with the Yang-shao culture, suggest that the cereal was cultivated rather than harvested from wild populations (Ho 1975). In Europe foxtail millet commonly occurs in early farming sites in Austria and Switzerland (Neuweiler 1946).

Cultivated foxtail millets are commonly divided into two cultivated complexes. The Chinese-Korean complex with large, pendulous inflorescences is recognized as race maxima, and the European complex with smaller and more erect cultivars is called race moharia (Dekaprelevich and Kasparian 1928). An Indian complex, race indica, was identified by K. E. Prasada Rao and colleagues (1987). The Indian race was derived from moharia through selection for adaptation to the tropics. It is an important cereal among hill tribes of southern India, where it is frequently grown as a mixed crop with sorghum or pearl millet.

F. Körnicke (1885: 238–44) recorded that canary grass (*Phalaris canariensis* L.) was grown as a cereal in southern Europe until the nineteenth century. Flour produced from its grain was mixed with wheat flour for making bread. It is still grown as a feed for birds but no longer used as a human food (Febrel and Carballido 1965). Nothing is known about the antiquity of canary grass as a cereal, and it is probably of recent domestication.

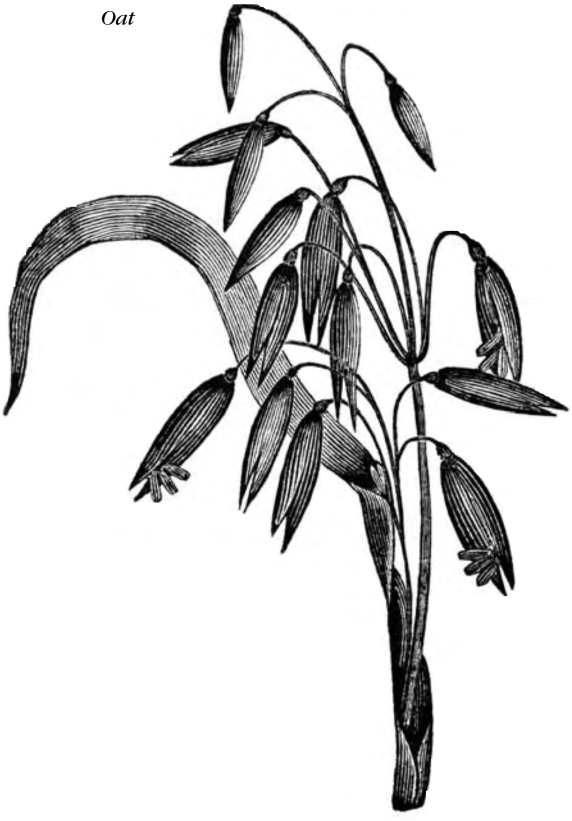
II.A.6 ~ Oat

Oat (*Avena* L.) includes 29 to 31 species (depending on the classification scheme) of wild and domesticated annual grasses in the family Gramineae (Poaceae) that comprise a polyploid series, with diploid, hexaploid, and tetraploid forms (Baum 1977; Leggett 1992). The primary cultivated species are hexaploids, *A. sativa* L. and *A. byzantina* C. Koch, although 5 other species have to some extent been cultivated for human consumption. These are the tetraploid *A. abyssinica* Hochst and the diploids *A. strigosa* Schreb., *A. brevis* Roth., *A. hispanica* Ard., and *A. nuda* L. Nevertheless, oat consumed in human diets this century has been almost exclusively hexaploids.

The separation of the two cultivated hexaploids is based on minor, and not always definitive, morphological differences and is of more historical than contemporary relevance. *A. byzantina* (red oat) was the original germ plasm base of most North American fall-sown cultivars, whereas *A. sativa* was the germ plasm base of spring-sown cultivars. Late twentieth-century breeding populations in both ecogeographic regions contain intercrosses of both species. This has led to the almost exclusive use of the term *A. sativa* in describing new cultivar releases.



Oat

Oat is the fifth most economically important cereal in world production after wheat, rice, corn, and barley. It is cultivated in temperate regions worldwide, especially those of North America and Europe, where it is well adapted to climatic conditions of adequate rainfall, relatively cool temperatures, and long days (Sorrells and Simmons 1992).

Oat is used primarily for animal feed, although human consumption has increased in recent years. Human food use is estimated at 16 percent of total world production and, among cereals as foods, oat ranks fourth after wheat, rice, and corn (Burnette et al. 1992). Oat is valued as a nutritious grain; it has a high-quality protein and a high concentration of soluble fiber, and is a good source of minerals, essential fatty acids, B vitamins, and vitamin E (Peterson 1992). Humans generally consume oats as whole-grain foods, which include ready-to-eat breakfast foods, oatmeal, baked goods, infant foods, and granola-type snack bars (Burnette et al. 1992). For human food, the inedible hull (lemma and palea) must be removed, leaving the groat for further processing. A hull-less trait, governed by two or three genes, causes the caryopsis or groat to thresh free of the lemma and palea, as does the wheat caryopsis. There is a renewed interest in hull-less oat in Europe and the Americas, especially for feed use. Several modern hull-less cultivars are available.

Origin and Domestication

The history of oat domestication parallels that of barley (*Hordeum vulgare* L.) and wheat (*Triticum* spp.), the primary domesticated cereals of the Middle East. The primacy of wheat and barley in the Neolithic revolution was due to advantages that their progenitor species had over other local candidates, such as *A. sterilis* L. and *A. longiglumis* Dur.: local abundance, large seed weight and volume, absence of germination inhibitors, and lower ploidy levels (Bar-Yosef and Kislev 1989). In the archaeological record, wild oat appears as weedy admixtures in cultivated cereals prior to, and for several millennia following, the Neolithic revolution. Nondomesticated *Avena* spp. have been identified in archaeological deposits in Greece, Israel, Jordan, Syria, Turkey, and Iran, all dating from between about 10500 and 5000 B.C. (Hopf 1969; Renfrew 1969; Hansen and Renfrew 1978; Hillman, Colledge, and Harris 1989).

Wheat and barley remained predominant as cereal cultivation spread through Europe between the seventh and second millennium B.C. (Zohary and Hopf 1988). The precise time and location of the domestication of oat from the weedy component of these cereals is unknown, but it is believed that oat had an adaptive advantage (over the wheat and barley germ plasm in cultivation at that time) in the cloudier, wetter, and cooler environments of northern Europe.

Support for this theory is provided by Pliny (A.D. 23–79), who noted the aggressive nature of weed oat in cereal mixtures in moist environments (Rackham 1950). Z. V. Yanushevich (1989) reported finding *Avena* spp. in Moldavian and Ukrainian adobe imprints dated as early as 4700 B.C. It is not known if these were cultivated types. However, Z. Tempir, M. Villaret-von Rochow (1971), and U. Willerding (Tempir and the latter are cited in Zohary and Hopf 1988), working in central Europe, found evidence of domesticated oat dating from the second and first millennia B.C. That evidence (which is often a reflection of one of the first steps in the domestication of oat and other cereals) is the elimination of the seed dispersal mechanism. In domesticated oat, the spikelets remain intact on the plant long after ripeness, whereas in the wild species, spikelets abscise and fall from the plant soon after maturity (Ladizinsky 1988).

In China, oat has been cultivated since early in the first millennium A.D. It remains a staple food in north China and Mongolia (Baum 1977), and the hull-less or "naked" oat has been associated with the Chinese production. But despite the cultivation of oat elsewhere, the grain was of minor interest to the Greeks, who considered it a weed; moreover, Egyptian foods are not known to have contained oat and, unlike so many other foods, there is no reference to it in the Bible (Candolle 1886; Darby, Ghalioungui, and Grivetti 1977; Zohary 1982).

During the first century A.D., however, Roman writers began making references to oat (White 1970). Pliny described a fall-sown, nonshattering "Greek-oat" used in forage production and noted that oatmeal porridge was a human staple in Germany. Dioscorides described the medicinal qualities of oat and reported it to be a natural food for horses (Font Quer 1962). Analyses of the gut contents of a mummified body from the same era (recovered from an English bog) revealed that small quantities of *Avena* species, together with wheat and barley, were consumed in the final meal (Holden 1986).

J. R. Harlan (1977) believed that oat domestication occurred separately at each ploidy level, with the diploids domesticated primarily as fodder crops in the Mediterranean area and subsequently widely cultivated throughout northern and eastern Europe, particularly on poor, upland soils. The tetraploid *A. abyssinica,* found exclusively in the highlands of Ethiopia, is an intermediate form between a truly wild and a fully domesticated type. It is a tolerated admixture in cereal production because of the belief that it improves the quality of malt (Harlan 1989). There is, however, disagreement among researchers as to the hexaploid progenitor of cultivated hexaploid oat. Three species – *A. sterilis* L. (Coffman 1946; Baum 1977), *A. hybrida* Petrem. (Baum 1977), and *A. fatua* L. (Ladizinsky 1988) – have been suggested. *A. maroccana* Gdgr. and *A. murphyi* Ladiz. are believed to represent the tetraploid base for cultivated hexaploids (Ladizinsky 1969). These two species have a narrow geographic distribution, confined as they are to southern Spain and Morocco.

From the Roman Era to the Nineteenth Century

Since the Roman era, oat has maintained its dual role as food and feed. In overall European production it has ranked behind wheat, barley, and, in some areas, rye (*Secale cereale* L.). Its prominence in the human diet continued to be greater in northern Europe than in other regions.

During the Middle Ages in northern Europe, a typical three-year crop rotation was fallow followed by wheat followed by oat or barley (Symon 1959). P. D. A. Harvey (1965) provided detailed records from one English village; these most likely reflected usual thirteenth-century production practices. Wheat was planted on half of the total cereal hectarage, with oat planted on one-half to three-quarters of the remaining land. The yield of the oat crop was about five seeds per seed planted, very low by today's standards. Wheat was the cash crop, whereas the oat crop was employed on the farms for feeding horses and cattle; in addition, oat straw was likely an important animal bedding. Lastly, another significant hectarage was planted with barley and oat together, and a small quantity of this mixed crop was used to produce malt. It is interesting to note that Arthur Young (1892) reported similar production practices in Ireland during the mid–eighteenth century.

Oat in the Western Hemisphere

Oat, both wild and cultivated, entered the Americas by two routes (Coffman 1977). *A. byzantina,* as well as the wild-weedy *A. fatua* L. and *A. barbata* Pott ex Link, were all introduced to southern latitudes by the Spaniards. *A. sativa* (and probably *A. fatua*) was transported by the English and other Europeans to the northern colonies. In seventeenth-century colonial agriculture, oat grain was fed to horses and mixed with rye and pea (*Pisum arvense* L.) for cattle feed (Bidwell and Falconer 1925). Where Scottish colonists predominated, it sometimes contributed to the human diet, although oat was not widely grown in the southern colonies of British North America (Grey and Thompson 1933). E. L. Sturtevant (1919) noted that Native Americans in California gathered wild oat and used it in breadmaking.

Oat cultivation moved west with frontier farming. Typical pioneer farmers planted maize (*Zea mays* L.) and some potatoes in the newly turned sod; this was followed the second year with small grains (Bidwell and Falconer 1925). Oat yields of 70 bushels per acre (3,760 kilograms per hectare) were achieved in Indiana by 1838 (Ellsworth 1838). To the north, in Canada, nineteenth-century pioneers relied less on maize and more on wheat and oat.

During the twentieth century, oat production in North America has been concentrated in the north central United States and the prairie provinces of Canada. Spring-sown oat is grown in these areas, whereas fall-sown, or "winter," oat is grown in the southern and southwestern United States (and parts of Europe). Fall sowing permits the crop to grow during mild weather in late autumn and early spring and to mature prior to the onset of high summer temperatures. Fall-sown oat is grazed for winter forage in the southwestern United States. The northern limits of fall-sown production are Kentucky, southern Pennsylvania, and Virginia. Although oat thrives in cooler climates than do wheat and barley, it is more at risk from freezing temperatures than those cereals.

The foundation germ plasm for spring-sown oat in the United States and Canada consists of three Russian cultivars (Kherson, Green Russian, and White Russian), a Swedish cultivar (Victory), and a Greek cultivar (Markton). All five heterogeneous cultivars were introduced into North America during the late nineteenth or early twentieth centuries (Coffman 1977).

The foundation germ plasm for fall-sown oat in the United States comprises two heterogeneous cultivars, Winter Turf and Red Rustproof. Winter Turf was probably introduced from northern Europe, and it may have been cultivated since colonial times (Coffman 1977). Red Rustproof was introduced from Mexico and became very popular after the Civil War. Cultivars resulting from selections within this heterogeneous germ plasm dominated production from Virginia to Texas and California until well into the twentieth century. Fall-sown oat in the United States is used as feed and does not contribute to the human diet. This is not a reflection of its nutritional value; rather, it reflects the proximity of processing mills to the centers of spring oat production in the north central United States and Canada. Oat grain has a relatively low density, which makes transportation expensive.

Progress from Plant Breeding

Oat cultivar improvement through plant selection began in Europe approximately 200 years ago, but, prior to the late nineteenth century, the intensity of the effort remained small by modern standards. In parallel with the development of other cereal grains, oat breeding activity increased worldwide during the early twentieth century. Oat breeding has remained a public sector activity, with a few notable exceptions, but some of these public sector programs in North America are dependent on the financial support of private sector endusers in the food industry. Comprehensive histories of oat breeding have been produced by T. R. Stanton (1936); F. A. Coffman, H. C. Murphy, and W. H. Chapman (1961); and M. S. McMullen and F. L. Patterson (1992).

The progression of methodologies utilized in oat improvement has been similar worldwide. The initial method was the introduction of heterogeneous cultivars from one production region to another for direct cultivation. This was gradually replaced by the development of cultivars from plant selections made within these heterogeneous introductions now growing in a new environment. The third step in the progression was the selection of cultivars from within breeding populations developed by sexual hybridization between parents with complementary arrays of desirable traits. In general, the end product of such a program was a homogeneous pure line cultivar. In the United States, the era of introduction lasted from colonial times to the beginning of the twentieth century. The era of selection within introductions as the predominant source of new cultivars extended from approximately 1900 to 1930. Since that time, the majority of cultivars have resulted from hybridization.

Common themes in oat breeding research during the twentieth century have included field, laboratory, and greenhouse methodologies to improve efficiency of selection for an array of agronomic, disease- and insect resistance, morphologic, and grain-quality traits. In addition, there have been Mendelian and quantitative genetic studies to investigate inheritance and expected progress from selection for these traits; studies of the evolution of species within the genus *Avena;* and, recently, the use of nonconventional techniques centered around biotechnology. This body of work has provided extensive knowledge of the basic biology of oat and has fostered direction and efficiency in applied oat improvement.

Throughout the twentieth century, breeding efforts have been directed at the improvement of grain yield, straw strength, test weight, and resistance to disease and insect pests. Additional efforts have been directed towards groat percentage, kernel weight, and winter hardiness. The cumulative results of these breeding efforts have included notable improvements in all of these areas (Lawes 1977; Rodgers, Murphy, and Frey 1983; Wych and Stuthman 1983; Marshall 1992; Lynch and Frey 1993), as well as the maintenance of disease and insect resistance levels. Yield improvements were not associated with specific phenotypic characteristics (as, for example, with reduced-height genes in wheat) or with germ plasm source, but modern cultivars appeared more adapted, both to high productivity and to heat- and drought-stressed environments, than older cultivars. R. D. Wych and D. D. Stuthman (1983) reported increases in biomass, total N, groat N, and nitrogen harvest index. In general, tillers per plant and kernels per panicle either have remained unchanged or have been reduced. The importance of increased biomass has been emphasized as a route to further yield increases (Moser and Frey 1994). This biomass must result from improved growth rate rather than extended growth duration, and harvest index must be maintained at present levels (Takeda and Frey 1976; Reysack, Stuthman, and Stucker 1993).

Much effort has been directed toward the identification and utilization of novel sources of disease resistance in cultivar development. Crown rust (*Puccinia coronata* Cda. var. *avenae* Fraser and Led.), stem rust (*P. graminis* Pers. f. sp. *avenae* Ericks. and E. Henn.), loose smut (*Ustilago avenae* [Pers.] Rostr.), powdery mildew (*Erysiphe graminis* DC. f. sp. *avenae* Em. Marchal), and barley yellow dwarf virus have received the most attention. For several decades, breeders have been utilizing the wild hexaploid *A. sterilis* as a source of genes for protection against crown rust and other pathogens. Other, more distantly related, species have been utilized to a lesser extent (Sharma and Forsberg 1977; Aung and Thomas 1978). Multiline oat cultivars were developed in the midwestern United States as an alternative strategy for crown rust control (Frey, Browning, and Simons 1985). A multiline cultivar is a mixture of several phenotypically similar genotypes, but each genotype contains a different gene for crown rust resistance. Multilines differ from most late-twentieth-century oat cultivars in that they are not homogeneous pure lines.

Breeding for improved grain composition – that is, groat protein, groat oil, and beta-glucan content – has been emphasized during the past 25 years. Although test weight is the primary quality factor used in purchasing oat, high-yielding cultivars with elevated groat protein levels have been released with regularity during the past 20 years. The range of groat protein in these cultivars is 18 to 21 percent versus 14 to 17 percent in conventional cultivars. The impetus behind this work is the enhancement of the feed value of oat, the maintenance of its standing as a traditional breakfast food, and the increase of its potential for use in the specialty food market (for example, as a protein additive). It is noteworthy that because of the predominance of the globulin fraction in oat storage protein, oat protein quality does not decrease with increases in groat protein percentage (Peterson 1976).

Although an overall negative association between grain yield and groat protein percentage is found in oat, studies consistently report the occurrence of high-protein transgressive segregates with overall agronomic superiority. When breeders have used protein yield (grain yield × groat protein concentration) as the unit of selection, they have been effective in improving both traits simultaneously (Kuenzel and Frey 1985; McFerson and Frey 1991).

Among other findings of importance to the improvement of oat protein are that groat protein is polygenically inherited, but heritability levels are moderate; that gene action is primarily additive; and that genes from *A. sativa* and *A. sterilis* may act in a complementary fashion (Campbell and Frey 1972; Iwig and Ohm 1976; Cox and Frey 1985). Breeders have been directing most of their efforts to the wild *A. sterilis* species as a source of genes with which to increase groat protein percentage and protein yield. Other species, such as *A. fatua* and *A. magna,* have been identified as potentially valuable resources as well (Thomas, Haki, and Arangzeb 1980; Reich and

Brinkman 1984). Oat researchers believe that a further 4 to 5 percent increase in groat protein over that of current high-protein cultivars is a reasonably obtainable breeding objective.

Groat oil content in cultivars typically ranges between 3.8 and 11 percent (Hutchinson and Martin 1955; Brown, Alexander, and Carmer 1966). Approximately 80 percent of the lipid in the groat is free lipid (ether extracted), and triglycerides are the most abundant component of oat oil. Most of the total lipid is found in the bran and starchy endosperm (Youngs, Püskülcü, and Smith 1977). Oat has never been utilized as an oilseed crop, but its mean lipid content is higher than that of other temperate cereal grains. No oat cultivar has been released based solely on elevated oil content, but considerable effort has been expended on studies of this trait, with the goal of alteration through breeding. Initial interest was related to the improvement of the energy value of oat as a livestock feed. Subsequently, V. L. Youngs, M. Püskülcü, and R. R. Smith (1977) indicated that high groat oil concentration could also increase food caloric production, and K. J. Frey and E. G. Hammond (1975) estimated that oat cultivars with 17 percent groat oil (combined with present levels of protein and grain yield) would compete with Iowa soybeans as an oilseed crop for the production of culinary oil.

Inheritance of oil content was studied in crosses of cultivated oat with *A. sterilis* and *A. fatua,* and results indicated that oil content was polygenically inherited, that additive gene effects predominated, that environmental influences were minor, that transgressive segregation was common, and that heritability was high (Baker and McKenzie 1972; Frey, Hammond, and Lawrence 1975; Luby and Stuthman 1983; Thro and Frey 1985; Schipper and Frey 1991a). Thus, when a concerted effort was made to improve groat oil content and oil yield (grain yield × groat oil concentration), the results were impressive (Branson and Frey 1989; Schipper and Frey 1991b). Agronomically desirable lines with up to 15 percent groat oil content were developed rather rapidly. Lower seed and test weights were associated with high groat oil content. Subsequently, lines with oil as high as 18 percent were produced (K. J. Frey, personal communication).

The major fatty acids of oat are palmitic (16:0), stearic (18:0), oleic (18:1), linoleic (18:2), and linolenic (18:3). Of these, palmitic, oleic, and linoleic constitute 95 percent of the fatty acids measured. Oleic and linoleic are comparable in quantity and may be controlled by the same genetic system (Karow and Forsberg 1985). Increased lipid content is correlated with an increase in oleic acid and a decrease in palmitic, linoleic, and linolenic acids (Forsberg, Youngs, and Shands 1974; Frey and Hammond 1975; Youngs and Püskülcü 1976; Roche, Burrows, and McKenzie 1977).

The oil content of advanced breeding lines is monitored routinely by breeders, but fatty acid content is not usually determined. Both simple and polygenic inheritance is involved in the expression of fatty acid content, but heritabilities are moderate to high (Thro, Frey, and Hammond 1983; Karow and Forsberg 1984). Selection for increased oil content should be accompanied by the monitoring of fatty acid composition, with particular attention to palmitic and linoleic acid, if conservation of the fatty acid composition of oat is desired.

Oat genotypes range in beta-glucan concentration from about 2.5 to 8.5 percent (D. M. Peterson and D. M. Wesenberg, unpublished data), but the range in adapted genotypes is narrower (Peterson 1991; Peterson, Wesenberg, and Burrup 1995). Several plant breeders have begun to make crosses with high beta-glucan germ plasm in an attempt to develop cultivars specially suited for human food. High beta-glucan oats are unsuited for certain animal feeds, especially for young poultry (Schrickel, Burrows, and Ingemansen 1992).

World Oat Production

The countries of the Former Soviet Union (FSU), North America, and Europe account for 90 percent of the world's oat production (Table II.A.6.1). Australia produces 4 percent and the People's Republic of China less than 2 percent.

The highest yields are obtained in the United Kingdom, Denmark, Germany, France, the former Czechoslovakia, New Zealand, and Sweden. Cool, moist summers, combined with intensive management practices, are commonplace in these countries. Large-scale producers, such as the United States, Canada, and the FSU, sacrifice high yield per hectare for less intensive management practices. Oat is adapted to cool, moist environments and is sensitive to high temperatures from panicle emergence to physiological maturity. It is more tolerant of acid soils than are other small grains, but less so of sandy or limestone soils. Although oat is adapted to cool temperatures, it is not as winter hardy as wheat or barley. Thus, the bulk of the world's production comes from spring-sown cultivars.

Of the major producers, only the FSU increased production and hectarage over the past three decades. Expanding livestock numbers coupled with the more favorable growing environment in northern regions have made oat more attractive than wheat or barley. The FSU now accounts for 40 percent of world production. All other major producers, including Canada, the United States, Germany, and Poland, have had declining production and hectarage during the same period. Production has declined by 33 percent in Poland and 61 percent in the United States and France. Overall, world production has declined by 23 percent and hectarage by 27 percent, whereas yield per hectare has increased 6 percent over the past 30 years. But production did increase in Australia, New Zealand, South America, Mexico, and Africa during the same period.

The reasons for the generally downward trend in

oat production have included competition from crops that produce higher levels of energy and protein (such as maize and soybeans), the decline of oat use as a feed grain, changing crop rotation patterns, and government commodity programs that are more favorable to the growing of other crops. Although 79 percent of the crop is used for feed worldwide, changes in production and use in such countries as the United States have resulted in up to 42 percent of the crop going for food and seed in recent years. Over the past decade, the United States has imported an amount equivalent to 14 percent of its annual production.

Oat Milling

The milling of oat for human food typically involves several steps: cleaning, drying, grading, dehulling, steaming, and flaking. In addition, a cutting step may be inserted after dehulling (Deane and Commers 1986). The purpose of oat milling is to clean the grain, remove the inedible hull, and render the groat stable and capable of being cooked in a reasonable time. The history of oat usage for human food is associated with the development of milling technology, which evolved slowly over the millennia and more rapidly over the past two centuries. Most of the early advancements in oat milling were ancillary to improvements in wheat milling.

Primitive peoples prepared oat by crushing the grains between two rocks. As the respective rocks wore into an oval and cup shape, a mortar and pestle were developed. This evolved into the saddlestone, where the grain was ground in a saddlelike depression by the forward and back action of an oval stone. The next development was the quern, which appeared, according to R. Bennett and J. Elton (1898), about 200 B.C.

The quern was a distinct advancement, in that the action involved a rotating stone and a stationary one, rather than an oscillatory movement. The rotating stone typically had a handle for applying the motive force and a hole in the center through which the grain was fed. Further developments included the grooving of the flat surfaces to provide a cutting edge and a channel for the flour, groats, and hulls to be expelled (Thornton 1933). In more sophisticated mills, additional stones were used – one to remove the hull and a second to crush the groat (Lockhart 1983).

Over the next 1,500 years or so, the principal advancements were in the power source, evolving from human-powered to animal-powered, and later to the use of water and wind to turn the stone. In Scotland, the first water-powered mills were in existence by the eleventh century (Lockhart 1983). By the late eighteenth century, the newly developed steam engine was applied to grain mills. Such advances over the centuries allowed the use of larger and larger stones and, thus, increased the capacity of the mills.

Winnowing (separating the hulls from the groats) was originally accomplished by throwing the mixture into the air on a windy hill, the heavier groats falling onto sheets laid on the ground. Later, this step was done in barns situated so that the doors, open at each end, allowed the prevailing breeze to blow away the hulls (Lockhart 1983). A variety of home kilns were also developed to dry oat grains, rendering them easier to mill and imparting a toasty flavor.

The next major advance in oat milling came with the 1875 invention of a groat-cutting machine by Asmus Ehrrichsen in Akron, Ohio. The groats could now be cut into uniform pieces for a higher quality meal. Prior to this development, the crushing of groats had meant a mixture of fine flour and more or less coarse bits of endosperm that made an inferior meal when cooked. Steel-cut oats were also less liable to become rancid than the crushed grain. Steel-cut oats, available today as Scotch oats, were quite popular until superseded by the innovation of oat flakes.

Rollers, known as far back as the 1650s, were used for crushing groats, much as stones had been used. But in the 1870s it was discovered that when partially cooked groats were rolled, they formed flakes. The production and marketing of oat flakes, which began in the 1880s with a pair of small oat processors, was adopted by the (then fledgling) Quaker Oats Company (Thornton 1933: 149–52). Moreover, steel-cut oats as well as whole groats could be flaked, the former producing a faster-cooking product because of its thinner, smaller flakes.

Stones were used to remove oat hulls up until about 1936, when they were replaced with impact hullers. Impact hulling involves introducing the oats to the center of a spinning rotor that propels them outward against a carborundum or rubber ring. The impact removes the hull with minimum groat breakage. This huller has a better groat yield and is more energy efficient than stones (Deane and Commers 1986).

More recent developments in oat products include instant oats, flaked so thin that they cook by the addition of boiling water, and oat bran. Oat bran, the coarse fraction produced by sieving ground groats, contains a higher proportion of soluble fiber (predominantly beta-glucan), useful for lowering high levels of cholesterol (Ripsin et al. 1992).

Current practice in milling oats has been detailed by D. Deane and E. Commers (1986) and by D. Burnette and colleagues (1992) (Figure II.A.6.1). The first steps involve cleaning and grading. Other grains, foreign matter, and weed seeds are removed by a series of separations according to size and density on screens, disc separators, graders, and aspirators. At the same time, oat is separated into milling grade and other grades (light oats, pin oats, slim oats, and double oats), which are used for animal feed. The milling-grade oat is then subjected to drying in ovens to reduce the moisture from about 13 percent to 6 to 7 percent, followed by cooling. Alternatively, the drying may be delayed until after the hulls are removed. Dried oat has tougher groats and is less subject to breakage during the dehulling process.

The huller produces a mixture of groats, hulls, and broken pieces, and these are separated by air aspiration. The groats are separated by size and passed on to the cutting or flaking machinery. Groats that are steel cut into two to four pieces formerly were available as Scotch oats but are now used mostly for other products. The whole and the steel-cut groats are steamed and rolled, producing regular or quick-cooking flakes, respectively. Oat flour is made by grinding oat flakes, steel-cut groats, or middlings. It is used in ready-to-eat breakfast foods and other products. Oat bran is produced by sieving coarsely ground oat flour.

Uses of Oat

Although archaeological records indicate that primitive peoples employed oat as a food source, the first written reference to its use was Pliny's observation that the Germans knew oat well and "made their porridge of nothing else" (Rackham 1950). Oatmeal porridge was an acknowledged Scottish staple as early as the fifth century A.D. (Kelly 1975). Porridge was prepared by boiling oatmeal in water, and it was consumed with milk, and sometimes honey, syrup, or treacle (Lockhart 1983). Brose, made by adding boiling water to oatmeal, was of a thicker consistency. In Ireland during the same period, oatmeal porridge was consumed in a mixture with honey and butter or milk (Joyce 1913). Popular in Scotland were oatcakes, prepared by making a dough of oatmeal and water and heating it on a baking stone or griddle, and, in fact, oatcakes are still produced in Scotland by commercial bakeries as well as in the home. In England, a fourteenth-century tale recounted that in times of economic stress, the poor of London ate a gruel of oatmeal and milk (Langland 1968), and in 1597, J. Gerrard indicated that oat was used to make bread and cakes as well as drink in northeast England (Woodward 1931). Because oat flour lacks gluten and produces a flat cake, it must be mixed with wheat flour for breadmaking. This was probably a common practice, which extended the quantity of the more valuable, and perhaps less productive, wheat. Gerrard also described medicinal uses of oat to improve the complexion and as a poultice to cure a "stitch" (Woodward 1931).

Young (1892) noted that potatoes (*Solanum tuberosum* L.) and milk were the staple foods of the common people in most of Ireland, but this diet was supplemented occasionally with oatmeal. Following the potato crop failure of 1740, however, oatmeal became the main ingredient in publicly provided emergency foods (Drake 1968).

Both Young and Adam Smith (1776) discussed the diets of the common people of the time. Smith was critical of the heavy dependence on oat in Scotland and believed that potatoes or wheat bread staples produced a healthier population. Young was not critical of oat, but he believed that the relatively healthy rural population in Ireland resulted from consumption of milk in addition to potatoes, rather than the more commonplace ale or tea consumed in England. In mid-nineteenth-century England, the highest-paid factory workers ate meat daily, whereas the poorest ate cheese, bread, oatmeal porridge, and potatoes (Engels 1844). However, oatmeal was a popular breakfast food among the wealthy.

Although oat was produced in the North American colonies from the time of the earliest settlements, it was not considered a human food except in a few predominantly Scottish settlements. A small quantity of oat was imported from Europe and typically sold in drug stores to invalids and convalescents. That oat had medicinal value had been known since Roman times (Woodward 1931; Font Quer 1962), but it was believed, erroneously, that domestically produced oat was not suitable for human consumption. Most nineteenth-century cookbooks in the United States either contained no recipes for oatmeal or suggested it as food for the infirm (Webster 1986). Indeed, the idea of humans consuming oats was a subject of ridicule by humorists and cartoonists in several national publications (Thornton 1933).

The selling of domestically produced oatmeal for human consumption in the United States began in earnest at the end of the nineteenth century, and its increasing popularity with the public can be attributed to the improved technology of producing rolled oat flakes, selling them in packages instead of in bulk, and a marketing strategy of portraying oatmeal as a healthful and nutritious product (Thornton 1933). The story of the marketing of oatmeal to the North American public is notable because it represented the first use of mass marketing techniques that are commonplace today (Marquette 1967).

New food uses for oat continue to be developed and marketed to a generally receptive public. The popularity of ready-to-eat breakfast cereals, many of which are oat based or contain some oat, has contributed to the increased food demand for oat. In the hot cereal market, instant oat products are achieving a greater market share due to consumers' preference for quick breakfast products requiring little, if any, preparation. Research on the effects of oat bran on blood cholesterol levels has also increased demand for oat bran products from health-conscious consumers. Oat is a popular ingredient in breads, cookies, and infant foods.

Nutritional Value

The nutritional value of oat has long been recognized. Although there was no scientific basis for nutritional claims in the Middle Ages, surely it was known that a staple diet of oat supported people accustomed to hard physical labor. Jean Froissart, a historian of the fourteenth century, wrote that Scottish soldiers carried with them, on their horses, bags of oat and metal plates upon which to cook oatcakes (Lockhart 1983). Oat consumption increased markedly in Scotland in the eighteenth century, coincident with a drop in meat consumption (Symon 1959), and much of the Scottish diet during the eighteenth century was oat.

As the science of nutrition developed in the twentieth century, scientists began to measure human needs for vitamins, minerals, essential amino acids and fatty acids, and energy. Foods were analyzed to ascertain their content of these essentials, and cereals, in general, and oat, in particular, were recognized as important contributors to human nutrition. But because of certain deficiencies, grains by themselves could not be considered "complete" foods.

The primary constituent of oat is starch, which constitutes from 45 to 62 percent of the groat by weight (Paton 1977). This percentage is lower than that of other cereals because of the higher levels of protein, fiber, and fat. Oat starch is highly digestible, and oat is a good energy source. Oat protein is higher than that of most other cereals (15 to 20 percent, groat basis) and contains a better balance of essential amino acids (Robbins, Pomeranz, and Briggle 1971). Nevertheless, lysine, threonine, and methionine are contained in less than optimal proportions. The oil content of oat is also higher than that of other cereals, ranging from about 5 to 9 percent for cultivated varieties (Youngs 1986), but genotypes with extreme values have been identified (Brown and Craddock 1972; Schipper and Frey 1991b). Oat oil is nutritionally favorable because of a high proportion of unsaturated fatty acids, including the essential fatty acid, linoleic acid.

The mineral content of oat is typical of that of other cereals (Peterson et al. 1975). Oat provides a significant proportion of manganese, magnesium, and iron and is also a source of zinc, calcium, and copper. Although high in phosphorus, much of this is unavailable as phytic acid. Oat also contains significant amounts of several vitamins – thiamin, folic acid, biotin, pantothenic acid, and vitamin E (Lockhart and Hurt 1986) – but contains little or no vitamins A, C, and D.

In developed countries where food for most people is abundant, the emphasis in nutrition has changed from correcting nutrient deficiencies to avoiding excessive consumption of saturated fats, refined sugar, and cholesterol while consuming foods high in carbohydrate and fiber. Diets containing whole-grain cereals fit well into this prescription for healthful eating. Oat, along with barley, contains a relatively high amount of beta-glucan, a soluble fiber that has been shown in numerous studies to lower the cholesterol levels of hypercholesterolemic subjects (Ripsin et al. 1992).

This knowledge spawned a plethora of products made from oat bran, because it was established that the bran fraction contained a higher concentration of beta-glucan than did whole oat. Although the marketplace has now discarded a number of these products that contained nutritionally insignificant quantities of oat bran, there is a definite place for oat bran in therapy for high blood cholesterol.

II.A.7 Rice

Economic and Biological Importance of Rice

Rice in Human Life

Among the cereals, rice and wheat share equal importance as leading food sources for humankind. Rice is a staple food for nearly one-half of the world's population. In 1990, the crop was grown on 145.8 million hectares of land, and production amounted to 518.8 million metric tons of grain (paddy, rough rice). Although rice is grown in 112 countries, spanning an area from 53° latitude north to 35° south, about 95 percent of the crop is grown and consumed in Asia. Rice provides fully 60 percent of the food intake in Southeast Asia and about 35 percent in East Asia and South Asia. The highest level of per capita rice consumption (130 to 180 kilograms [kg] per year, 55 to 80 percent of total caloric source) takes place in Bangladesh, Cambodia, Indonesia, Laos, Myanmar (Burma), Thailand, and Vietnam.

Although rice commands a higher price than wheat on the international market, less than five percent of the world's rice enters that market, contrasted with about 16 percent of the wheat. Low-income countries, China and Pakistan, for example, often import wheat at a cheaper price and export their rice.

Biological Value in Human Nutrition

Although rice has a relatively low protein content (about 8 percent in brown rice and 7 percent in milled rice versus 10 percent in wheat), brown rice (caryopsis) ranks higher than wheat in available carbohydrates, digestible energy (kilojoules [kJ] per 100 grams), and net protein utilization. Rice protein is superior in lysine content to wheat, corn, and sorghum. Milled rice has a lower crude fiber content than any other cereal, making rice powder in the boiled form suitable as infant food. For laboring adults, milled rice alone could meet the daily carbohydrate and protein needs for sustenance although it is low in riboflavin and thiamine content. For growing children, rice needs to be supplemented by other protein sources (Hegsted 1969; Juliano 1985b).

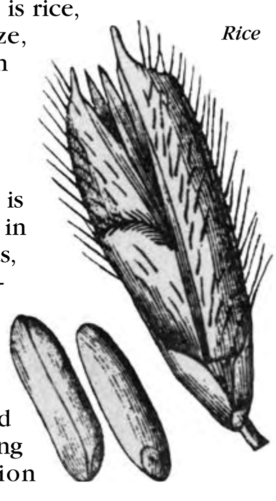
The Growing Importance of Rice

On the basis of mean grain yield, rice crops produce more food energy and protein supply per hectare than wheat and maize. Hence, rice can support more people per unit of land than the two other staples (Lu and Chang 1980). It is, therefore, not surprising to find a close relationship in human history between an expansion in rice cultivation and a rapid rise in population growth (Chang 1987).

As a human food, rice continues to gain popularity in many parts of the world where other coarse cereals, such as maize, sorghum and millet, or tubers and roots like potatoes, yams, and cassava have traditionally dominated. For example, of all the world's regions, Africa has had the sharpest rise in rice consumption during the last few decades.

Rice for table use is easy to prepare. Its soft texture pleases the palate and the stomach. The ranking order of food preference in Asia is rice, followed by wheat, maize, and the sweet potato; in Africa it is rice or wheat, followed by maize, yams, and cassava (author's personal observation).

In industrial usage, rice is also gaining importance in the making of infant foods, snack foods, breakfast cereals, beer, fermented products, and rice bran oil, and rice wine remains a major alcoholic beverage in East Asia. The coarse and silica-rich rice hull is finding new use in construction



Rice

materials. Rice straw is used less in rope and paper making than before, but except for modern varieties, it still serves as an important cattle feed throughout Asia. Because rice flour is nearly pure starch and free from allergens, it is the main component of face powders and infant formulas. Its low fiber content has led to an increased use of rice powder in polishing camera lenses and expensive jewelry.

Botany, Origin, and Evolution

Botany

Rice is a member of the grass family (Gramineae) and belongs to the genus *Oryza* under tribe Oryzeae. The genus *Oryza* includes 20 wild species and 2 cultivated species (cultigens). The wild species are widely distributed in the humid tropics and subtropics of Africa, Asia, Central and South America, and Australia (Chang 1985). Of the two cultivated species, African rice (*O. glaberrima* Steud.) is confined to West Africa, whereas common or Asian rice (*O. sativa* L.) is now commercially grown in 112 countries, covering all continents (Bertin et al. 1971).

The wild species have both diploid ($2n = 2x = 24$) and tetraploid ($2n = 4x = 48$) forms, while the two cultigens are diploid and share a common genome (chromosome group). Incompatibility exists among species having different genomes. Partial sterility also shows up in hybrids when different ecogeographic races of *O. sativa* are hybridized. The cultivated species of *Oryza* may be classified as semiaquatic plants, although extreme variants are grown not only in deep water (up to 5 meters) but also on dry land (Chang 1985).

Among the cereals, rice has the lowest water use efficiency. Therefore, rice cannot compete with dryland cereals in areas of low rainfall unless irrigation water is readily available from reservoirs, bunds, and the like. On the other hand, the highest yields of traditional varieties have been obtained in regions of cloudless skies, such as in Spain, California, and northern Japan (Lu and Chang 1980).

The "wild rice" of North America is *Zizania palustris* (formerly *Z. aquatica* L. [$2n = 30$]), which belongs to one of the 11 related genera in the same tribe. Traditionally, this species was self-propagating and harvested only by Native Americans in the Great Lakes area. Now it is commercially grown in Minnesota and northern California.

Origin

The origin of rice was long shrouded by disparate postulates because of the pantropical but disjunct distribution of the 20 wild species across four continents, the variations in characterizing and naming plant specimens, and the traditional feud concerning the relative antiquity of rice in India versus China. Among the botanists, R. J. Roschevicz (1931) first postulated that the center of origin of the section *Sativa* Roschev., to which *O. glaberrima* and *O. sativa* belong, was in Africa and that *O. sativa* had originated from multiple species. A divergent array of wild species was proposed by different workers as the putative ancestor of *O. sativa* (Chang 1976b).

Several workers considered "*O. perennis* Moench" (an ambiguous designation of varying applications) as the common progenitor of both cultigens (Chang 1976b). A large number of scholars had argued that Asian rice originated in the Indian subcontinent (South Asia), although A. de Candolle (1884), while conceding that India was more likely the original home, considered China to have had an earlier history of rice cultivation

On the basis of historical records and the existence of wild rices in China, Chinese scholars maintained that rice cultivation was practiced in north China during the mythological Sheng Nung period (c. 2700 B.C.) and that *O. sativa* of China evolved from wild rices (Ting 1961). The finding of rice glume imprints at Yang-shao site in north China (c. 3200–2500 B.C.) during the 1920s reinforced the popular belief that China was one of the centers of its origin (Chinese Academy of Agricultural Sciences 1986).

Since the 1950s, however, rice researchers have generally agreed that each of the two cultigens originated from a single wild species. But disputes concerning the immediate ancestor of *O. sativa* persist to this day (Chang 1976b, 1985; Oka 1988). A multidisciplinary analysis of the geographic distribution of the wild species and their genomic composition in relation to the "Glossopterid Line" (northern boundary) of the Gondwanaland fragments (Melville 1966) strongly indicated the Gondwanaland origin of the genus *Oryza* (Chang 1976a, 1976b, 1985). This postulate of rice having a common progenitor in the humid zones of the supercontinent Pangaea before it fractured and drifted apart can also explain the parallel evolutionary pattern of the two cultigens in Africa and Asia respectively. It also reconciles the presence of closely related wild species having the same genome in Australia and in Central and South America. Thus, the antiquity of the genus dates back to the early Cretaceous period of more than 130 million years ago.

Evolution

The parallel evolutionary pathway of *O. glaberrima* in Africa and of *O. sativa* in Asia was from perennial wild - → annual wild - → annual cultigen, a pattern common to other grasses and many crop plants. The parallel pathways are:

Africa: *O. longistaminata* - → *O. barthii* - → *O. glaberrima.*
Asia: *O. rufipogon* - → *O. nivara* - → *O. sativa.*

This scheme can resolve much that has characterized past disputes on the putative ancestors of the two cultigens. Wild perennial and annual forms having the same A genome are present in Australia and in Central and South America, but the lack of incipient agriculture in Australia and of wetland agronomy in tropical America in prehistoric times disrupted the final step in producing an annual cultigen.

It needs to be pointed out that the putative ancestors, especially those in tropical Asia, are conceptually wild forms of the distant past, because centuries of habitat disturbance, natural hybridization, and dispersal by humans have altered the genetic structure of the truly wild ancestors. Most of the wild rices found in nature today are hybrid derivatives of various kinds (Chang 1976b; 1985). The continuous arrays of variants in natural populations have impaired definitive studies on the wild progenies (Chang 1976b; Oka 1988).

The differentiation and diversification of annual wild forms into the early prototypes of cultigen in South and mainland Southeast Asia were accelerated by marked climatic changes during the Neothermal age of about 10,000 to 15,000 years ago. Initial selection and cultivation could have occurred independently and nearly concurrently at numerous sites within or bordering a broad belt of primary genetic diversity that extends from the Ganges plains below the eastern foothills of Himalaya, through upper Burma, northern Thailand, Laos, and northern Vietnam, to southwest and southern China.

From this belt, geographic dispersal by various agents, particularly water currents and humans, lent impetus to ecogenetic differentiation and diversification under human cultivation. In areas inside China where winter temperatures fell below freezing, the cultivated forms (cultivars) became true domesticates, depending entirely on human care for their perpetuation and propagation. In a parallel manner, the water buffalo was brought from the swamps of the south into the northern areas and coevolved as another domesticate (Chang 1976a).

In West Africa, *O. glaberrima* was domesticated from the wild annual *O. barthii* (Chevalier 1932); the latter was adapted primarily to water holes in the savanna and secondarily to the forest zone (Harlan 1973). The cultigen has its most important center of diversity in the central Niger delta. Two secondary centers existed near the Guinean coast (Porteres 1956).

Cultivation of the wild prototypes preceded domestication. Rice grains were initially gathered and consumed by prehistoric people of the humid regions where the perennial plants grew on poorly drained sites. These people also hunted, fished, and gathered other edible plant parts as food. Eventually, however, they developed a liking for the easily cooked and tasty rice and searched for plants that bore larger panicles and heavier grains.

The gathering-and-selection process was more imperative for peoples who lived in areas where seasonal variations in temperature and rainfall were more marked. The earlier maturing rices, which also tend to be drought escaping, would have been selected to suit the increasingly arid weather of the belt of primary diversity during the Neothermal period. By contrast, the more primitive rices of longer maturation, and those, thus, more adapted to vegetative propagation, would have survived better in the humid regions to the south (Chang 1976b; 1985). In some areas of tropical Asia, such as the Jeypore tract of Orissa State (India), the Batticoloa district (Sri Lanka), and the forested areas of north Thailand, the gathering of free-shattering grains from wild rice can still be witnessed today (Chang 1976b; Higham 1989).

Antiquity of Rice Cultivation

Although the differentiation of the progenitors of *Oryza* species dates back to the early Cretaceous period, the beginning of rice cultivation was viewed by Western scholars as a relatively recent event until extensive excavations were made after the 1950s in China and to a lesser extent in India. Earlier, R. J. Roschevicz (1931) estimated 2800 B.C. as the beginning of rice cultivation in China, whereas the dawn of agriculture in India was attributed to the Harappan civilization, which began about 2500 B.C. (Hutchinson 1976).

Thus far, the oldest evidence from India comes from Koldihwa, U.P., where rice grains were embedded in earthen potsherds and rice husks discovered in ancient cow dung. The age of the Chalcolithic levels was estimated between 6570 and 4530 B.C. (Vishnu-Mittre 1976; Sharma et al. 1980), but the actual age of the rice remains may be as recent as 1500 B.C. (Chang 1987). Another old grain sample came from Mohenjodaro of Pakistan and dates from about 2500 B.C. (Andrus and Mohammed 1958). Rice cultivation probably began in the upper and middle Ganges between 2000 and 1500 B.C. (Candolle 1884; Watabe 1973). It expanded quickly after irrigation works spread from Orissa State to the adjoining areas of Andhra Pradesh and Tamil Nadu in the Iron Age around 300 B.C. (Randhawa 1980).

In Southeast Asia, recent excavations have yielded a number of rice remains dating from 3500 B.C. at Ban Chiang (Thailand); 1400 B.C. at Solana (Philippines); and A.D. 500 at Ban Na Di (Thailand) and at Ulu Leang (Indonesia). Dates between 4000 and 2000 B.C. have been reported from North Vietnam (Dao 1985) but have not yet been authenticated.

These various reports have been summarized by T. T. Chang (1988, 1989a). The widely scattered findings are insufficient to provide a coherent picture of agricultural development in the region, but rice cultivation in mainland Southeast Asia undoubtedly preceded that in insular Southeast Asia (Chang 1988). The paucity of rice-related remains that were confined to upland sites in northern Thailand could be attributed to the sharp rise in sea level around the Gulf of Thailand during the four millennia between 8000 and 4000 B.C. Floods inundated vast tracts of low-lying land amid which rice chaffs and shell knives for cutting rice stalks were recently found at Khok Phanom Di near the Gulf and dated from 6000 to 4000 B.C. (Higham 1989).

For the Southeast Asian region, several geographers and ethnobotanists had earlier postulated that the cultivation of root crops predated rice culture (Sauer 1952; Spencer 1963; Yen 1977). Yet, this hypothesis falters in view of the apparently rather recent domestication (c. 2000 B.C.) of yams in the region (Alexander and Coursey 1969). In many hilly regions, vegeculture probably preceded dryland rice cultivation, but not in wetland areas. In the cooler regions, rice grains were crucial to early cultivators who could store and consume the harvest during the winter months.

Prior to the 1950s, the belief in the antiquity of rice cultivation in China was based on mythical writings in which "Emperor Shen Nung" (c. 2700 B.C.) was supposed to have taught his people to plant five cereals, with rice among them (Candolle 1884; Roschevicz 1931; Ting 1949; Chatterjee 1951). This view, however, was questioned by many non-Chinese botanists and historians because of the paucity of wild rices in China (or rather the paucity of information on the wild rices) and the semiarid environment in north China (Chang 1979b, 1983). Yet in the 1920s, the discovery of rice glume imprints on broken pottery at the Yang-shao site in Henan (Honan) by J. G. Andersson and co-workers (Andersson 1934) was important in linking Chinese archaeology with agriculture. The excavated materials were considered Neolithic in origin and the precise age was not available, though K. C. Chang later gave this author an estimated age of between 3200 and 2500 B.C.

Extensive diggings in the Yangtze basin after the 1950s yielded many rice remains that pushed back rice culture in China even further into antiquity (Chang 1983). The most exciting event was the finding in 1973–4 of carbonized rice kernels, rice straw, bone spades, hoe blades *(ssu),* and cooking utensils that demonstrated a well-developed culture supported by rice cultivation at the He-mu-du (Ho-mu-tu) site in Zhejiang (Chekiang) Province dated at 5005 B.C. (Chekiang Provincial Cultural Management Commission and Chekiang Provincial Museum 1976; Hsia 1977).

The grains were mostly of the *hsien* (Indica) type but included some *keng* (Sinica or Japonica) and intermediate kernels. The discovery also indicated the existence of an advanced rice-based culture in east China that vied in antiquity and sophistication with the millet-based culture in north China as represented by the Pan-po site in Shenxi (Shensi). Another site at Luo-jia-jiao in Zhejiang Province also yielded carbonized rice of both ecogeographic races of a similar age estimated at 7000 B.P. (Chang 1989a). In a 1988 excavation at Peng-tou-shan site in Hunan Province, abundant rice husks on pottery or red burnt clay as well as skeletal remains of water buffalo were found. The pottery was dated at between 7150 and 6250 B.C. (uncorrected carbon dating). Diggings in neighboring Hubei (Hupei) Province yielded artifacts of similar age, but the grain type could not be ascertained (Pei 1989). Excavations in Shenxi also produced rice glume imprints on red burnt clay dated between 6000 and 5000 B.C. (Yan 1989).

In contrast to all this scholarly effort on the antiquity of rice cultivation in Asia, our understanding of the matter in West Africa rests solely on the writing of R. Porteres (1956), who dates it from 1500 B.C. in the primary Niger center, and from A.D. 1000 to A.D. 1200 in the two Guinean secondary centers.

Chinese history also recorded that rice culture was well established in Honan and Shenxi Provinces of north China during the Chou Dynasty (1122 to 255 B.C.) by Lungshanoid farmers (Ho 1956; Chang 1968). During the Eastern Chou Dynasty (255 to 249 B.C.), rice was already the staple food crop in the middle and lower basins of the Yangtze River (Ting 1961). Wild rices were amply recorded in historical accounts; their northern limit of distribution reached 38° north latitude (Chang 1983).

Based on the above developments, it appears plausible to place the beginning of rice cultivation in India, China, and other tropical Asian countries at nearly 10,000 years ago or even earlier. Since rice was already cultivated in central and east China at 6000 to 5000 B.C., it would have taken a few millennia for rice to move in from the belt to the south of these regions. The missing links in the history of rice culture in China can be attributed to the dearth of archaeological findings from south China and the relatively recent age of rice remains in southwest China (1820 B.C. at Bei-yan in Yunnan) and south China (2000 B.C. at Shih Hsiah in Kwangtung). These areas represent important regions of ecogenetic differentiation or routes of dispersal (Chang 1983).

Linguistic Evidence

A number of scholars have attempted to use etymology as a tool in tracing the origin and dispersal of rice in Asia. The Chinese word for rice in the north, *tao* or *dao* or *dau,* finds its variants in south China and Indochina as *k'au* (for grain), *hao, ho, heu, deu,* and *khaw* (Ting 1961; Chinese Academy of Agricultural Sciences 1986). Indian scholars claimed that the word for rice in Western languages had a Dravidian root and that *ris, riz, arroz,* rice, *oruza,* and *arrazz* all came from *arisi* (Pankar and Gowda 1976). In insular Southeast Asia, the Austronesian terms *padi* and *paray* for rice and *bras* or *beras* for milled rice predominate (Chinese Academy of Agricultural Sciences 1986; Revel 1988).

On the other hand, Japanese scholars have also emphasized the spread of the Chinese words *ni* or *ne* (for wild rice) and *nu* (for glutinous rice) to Southeast Asia (Yanagita et al. 1969). N. Revel and coworkers (1988) have provided a comprehensive compilation of terms related to the rice plant and its parts derived from the linguistic data of China, Indochina, insular Southeast Asia, and Madagascar. Yet among the different disciplinary approaches, linguistic analyses have not been particularly effective in revealing facts about the dispersal of rice by humans. In part, this is because the ethnological aspects of human migration in the Southeast Asian region remain in a state of flux. (For various viewpoints see *Asian Perspectives* 1988: 26, no.1.)

Geographic Dispersal and Ecogenetic Diversification

Early Dispersal

The early dissemination of rice seeds (grains) could have involved a variety of agents: flowing water, wind, large animals, birds, and humans. The latter have undoubtedly been most effective in directed dispersal: Humans carried rice grains from one place to another as food, seed, merchandise, and gifts. The continuous and varied movements of peoples in Asia since prehistoric times have led to a broad distribution of early *O. sativa* forms, which proliferated in ecogenetic diversification after undergoing the mutation-hybridization-recombination-differentiation cycles and being subjected to both natural and human selection forces at the new sites of cultivation. In contrast, *O. glaberrima* cultivars exhibit markedly less diversity than their Asian counterparts, owing to a shorter history of cultivation and narrower dispersal. The contrast is amplified by other factors as shown in Table II.A.7.1.

Initial dispersal of *O. sativa* from numerous sites in its primary belt of diversity involved a combination of early forms of cultivars and associated wild relatives, often grown in a mixture. Biological findings and historical records point to five generalized routes from the Assam-Meghalaya-Burma region. Rice moved: (1) southward to the southern Bengal Bay area and the southern states of India and eventually to Sri Lanka; (2) westward to Pakistan and the west coast of India; (3) eastward to mainland Southeast Asia (Indochina); (4) southeastward to Malaysia and the Indonesian islands; and (5) northeastward to southwest China, mainly the Yunnan-Kweichow area, and further into east, central, and south China. The early routes of travel most likely followed the major rivers, namely, Brahmaputra, Ganges, Indus, Mekong, and Yangtze. Routes of sea travel, which came later, were from Thailand and Vietnam to the southern coastal areas of China, from Indonesia to the Philippines and Taiwan, and from China to Japan, as well as from China to Korea to Japan. These routes are summarized in Map II.A.7.1.

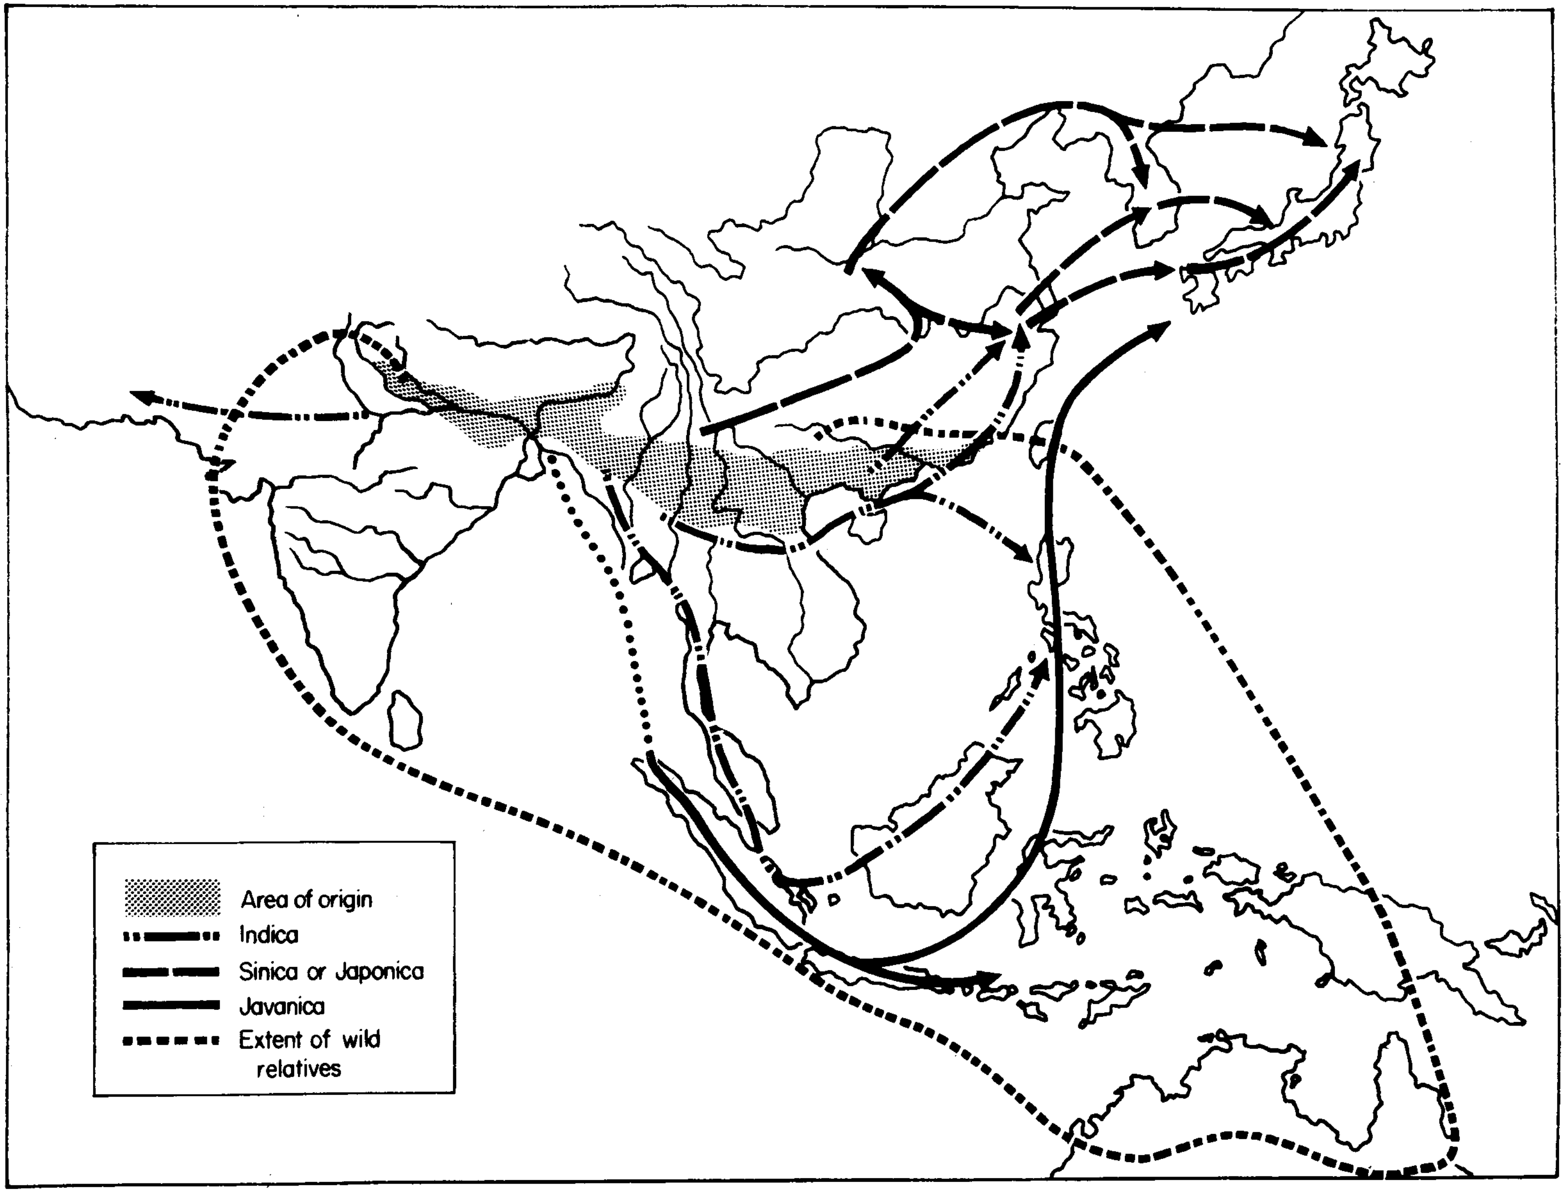
Table II.A.7.1 *Contrast in diversification:* Oryza sativa *vs.* glaberrima

Factor	Asia	W. Africa
Latitudinal spread	10° C–53° N	5° N–17° N
Topography	Hilly	Flat
Population density	High	Low
Movement of people	Continuous	Little
Iron tools	Many	None or few
Draft animals	Water buffalo and oxen	?

On the basis of ancient samples of rice hulls collected from India and Indochina, covering a span of 10 centuries up to around A.D. 1500, three main groups of cultivars (the Brahmaputra-Gangetic strain, the Bengal strain, and the Mekong strain) have been proposed by T. Watabe (1985). The Mekong strain originating in Yunnan was postulated to have given rise to the Indochina series and the Yangtze River series of cultivars; the latter consisted mainly of the *keng* rices of China. It should be pointed out, however, that the ecogenetic diversification processes following dispersal and the cultivators' preferences could have added complications to the varietal distribution pattern of the present, as later discussions will reveal.

Ecogenetic Differentiation and Diversification

During the early phase of human cultivation and selection, a number of morphological and physiological changes began to emerge. Selection for taller and larger plants resulted in larger leaves, longer and thicker stems, and longer panicles. Subsequent selection for more productive plants and for ease in growing and harvesting led to larger grains. It also resulted in increases in: (1) the rate of seedling growth; (2) tillering capacity; (3) the number of leaves per tiller and the rate of leaf development; (4) the synchronization of tiller development and panicle formation (for uniform maturation); (5) the number of secondary branches on a panicle; and (6) panicle weight (a product of spikelet number and grain weight). Concurrently, there were decreases or losses of the primitive features, such as: (1) rhizome formation; (2) pigmentation of plant parts; (3) awn length; (4) shattering of grains from the panicle; (5) growth duration; (6) intensity of grain dormancy; (7) response to short day length; (8) sensitivity to low temperatures; and (9) ability to survive in flood waters. The frequency of cross pollination also decreased so that the plants became more inbred and increasingly dependent on the cultivators for their propagation (by seed) and perpetuation (by short planting cycles) (Chang 1976b).



Area of origin
Indica
Sinica or Japonica
Javanica
Extent of wild relatives

Map II.A.7.1. Extent of wild relatives and spread of ecogeographic races of *O. sativa* in Asia and Oceania. (Adapted from Chang 1976b.)

When rice cultivars were carried up and down along the latitudinal or altitudinal clines or both, the enormous genetic variability in the plants was released, and the resulting variants expressed their new genetic makeup while reacting to changing environmental factors. The major environmental forces are soil properties, water supply, solar radiation intensity, day length, and temperature range, especially the minimum night temperatures. Those plants that could thrive or survive in a new environment would become fixed to form an adapted population – the beginning of a new ecostrain – while the unadapted plants would perish and the poorly adapted plants would dwindle in number and be reduced to a small population in a less adverse ecological niche in the area.

Such a process of differentiation and selection was aided by spontaneous mutations in a population or by chance outcrossing between adjacent plants or both. The process could independently occur at many new sites of cultivation and recur when environmental conditions or cultivation practices changed. Therefore, rich genetic diversity of a secondary nature could be found in areas of undulating terrain where the environmental conditions significantly differed within a small area. The Assam and Madhya Pradesh states and Jeypore tract of India, the island of Sri Lanka, and Yunnan Province of China represent such areas of remarkable varietal diversity (Chang 1985).

Proliferation into Ecogeographic Races and Ecotypes

Continuous cultivation and intense selection in areas outside the conventional wetlands of shallow water depth (the paddies) have resulted in a range of extreme ecotypes: deepwater or floating rices that can cope with gradually rising waters up to 5 meters (m) deep; flood-tolerant rices that can survive days of total submergence under water; and upland or hill rices that are grown under dryland conditions like corn and sorghum. The varying soil-water-temperature regimes in the Bengal Bay states of India and in Bangladesh resulted in four seasonal ecotypes in that area: *boro* (winter), *aus* (summer), transplanted *aman* (fall, shallow water), and broadcast *aman* (fall, deep water). In many double-cropping areas, two main ecotypes follow the respective cropping season: dry (or off) and wet (or main) (Chang 1985).

In broader terms, the wide dispersal of *O. sativa* and subsequent isolation or selection in Asia has led to the formation of three ecogeographic races that differ in morphological and physiological characteristics and are partially incompatible in genetic affinity: Indica race in the tropics and subtropics; javanica race in the tropics; and sinica (or japonica) race in the temperate zone. Of the three races, indica is the oldest and the prototype of the other two races as it retains most of the primitive features: tallness, weak stems, lateness, dormant grains, and shattering panicles.

The sinica race became differentiated in China and has been rigorously selected for tolerance to cool temperatures, high productivity, and adaptiveness to modern cultivation technology: short plant stature, nitrogen responsiveness, earliness, stiff stems, and high grain yield. The javanica race is of more recent origin and appears intermediate between the other two races in genetic affinity, meaning it is more cross-fertile with either indica or sinica. Javanica cultivars are marked by gigas features in plant panicle and grain characters. They include a wetland group of cultivars (*bulu* and *gundil* of Indonesia) and a dryland group (hill rices of Southeast Asia).

The picture of race-forming processes is yet incomplete (Chang 1985). Many studies have relied heavily on grain size and shape as empirical criteria for race classification. Some studies employed crossing experiments and hybrid fertility ratings. Other workers recently used isozyme patterns to indicate origin and affinity. Controversies in past studies stemmed largely from limited samples, oversimplified empirical tests, and reliance on presently grown cultivars to retrace the distant past. The latter involved a lack of appreciation for the relatively short period (approximately 5 to 6 centuries) that it takes for a predominant grain type to be replaced by another (Watabe 1973), which was probably affected by the cultivator's preference. Most of the studies have also overlooked the usefulness of including amylose content and low temperature tolerance in revealing race identity (Chang 1976b, 1985). It should also be recognized that early human contacts greatly predated those given in historical records (Chang 1983), and maximum varietal diversity often showed up in places outside the area of primary genetic diversity (Chang 1976b, 1985).

Parallel to the expansion in production area and dispersal of the cultivars to new lands during the last two centuries was the growth of varietal diversity. In the first half of the twentieth century, before scientifically bred cultivars appeared in large numbers, the total number of unimproved varieties grown by Asian farmers probably exceeded 100,000, though many duplicates of similar or altered names were included in this tally (Chang 1984 and 1992).

The Spread of Asian Rice

Historical records are quite revealing of the spread of Asian rice from South Asia, Southeast Asia, and China to other regions or countries, though exact dates may be lacking. In the northward direction, the Sinica race was introduced from China into the Korean peninsula before 1030 B.C. (Chen 1989). Rice cultivation in Japan began in the late Jomon period (about 1000 B.C., [Akazawa 1983]), while earlier estimates placed the introduction of rice to Japan from China in the third century B.C. (Ando 1951; Morinaga 1968). Several routes could have been involved: (1) from the lower Yangtze basin to Kyushu island, (2) from north China to Honshu Island, or (3) via Korea to northern Kyushu; *hsien* (Indica) may have arrived from China, and the Javanica race traveled from Southeast Asia (Isao 1976; Lu and Chang 1980). The areas that comprised the former Soviet Union obtained rice seeds from China, Korea, Japan, and Persia, and rice was grown around the Caspian Sea beginning in the early 1770s (Lu and Chang 1980).

From the Indian subcontinent and mainland Southeast Asia, the Indica race spread southward into Sri Lanka (before 543 B.C.), the Malay Archipelago (date unknown), the Indonesian islands (between 2000 and 1400 B.C.), and central and coastal China south of the Yangtze River. *Hsien* or Indica-type grains were found at both He-mu-du and Luo-jia-jiao sites in east China around 5000 B.C. (Lu and Chang 1980; Chang 1988). The *keng* or sinica rices were likely to have differentiated in the Yunnan-Kweichow region, and they became fixed in the cooler northern areas (Chang 1976b). On the other hand, several Chinese scholars maintain that *hsien* and *keng* rices were differentiated from wild rices inside China (Ting 1961; Yan 1989). The large-scale introduction and planting of the Champa rices (initially from Vietnam) greatly altered the varietal composition of *hsien* rices in south China and the central Yangtze basin after the eleventh century (Ho 1956; Chang 1987).

The javanica race had its origin on the Asian mainland before it differentiated into the dryland ecotype (related to the aus type of the Bengal Bay area and the hill rices of Southeast Asia) and the wetland ecotype *(bulu* and *gundil)* of Indonesia. From Indonesia, the wetland ecotype spread to the Philippines (mainly in the Ifugao region at about 1000 B.C.), Taiwan (at 2000 B.C. or later), and probably Ryukyus and Japan (Chang 1976b, 1988).

The Middle East acquired rice from South Asia probably as early as 1000 B.C. Persia loomed large as the principal stepping stone from tropical Asia toward points west of the Persian Empire. The Romans learned about rice during the expedition of Alexander the Great to India (c. 327–4 B.C.) but imported rice wine instead of growing the crop. The introduction of rice into Europe could have taken different routes: (1) from Persia to Egypt between the fourth and the first centuries B.C., (2) from Greece or Egypt to Spain and Sicily in the eighth century A.D., and (3) from Persia to Spain in the eighth century and later to Italy between the thirteenth and sixteenth centuries. The Turks brought rice from Southwest Asia into the Balkan Peninsula, and Italy could also have served as a stepping stone for rice growing in that region. Direct imports from various parts of Asia into Europe are also probable (Lu and Chang 1980).

In the spread of rice to Africa, Madagascar received Asian rices probably as early as 1000 B.C. when the early settlers arrived in the southwest region. Indonesian settlers who reached the island after the beginning of the Christian era brought in some Javanica rices. Madagascar also served as the intermediary for the countries in East Africa, although direct imports from South Asia would have been another source. Countries in West Africa obtained Asian rice through European colonizers between the fifteenth and seventeenth centuries. Rice was also brought into Congo from Mozambique in the nineteenth century (Lu and Chang 1980).

The Caribbean islands obtained their rices from Europe in the late fifteenth and early sixteenth centuries. Central and South America received rice seeds from European countries, particularly Spain, during the sixteenth through the eighteenth centuries. In addition, there was much exchange of cultivars among countries of Central, South, and North America (Lu and Chang 1980).

Rice cultivation in the United States began around 1609 as a trial planting in Virginia. Other plantings soon followed along the south Atlantic coast. Rice production was well established in South Carolina by about 1690. It then spread to the areas comprising Mississippi and southwest Louisiana, to adjoining areas in Texas, and to central Arkansas, which are now the main rice-producing states in the South. California began rice growing in 1909–12 with the predominant cultivar the sinica type, which can tolerate cold water at the seedling stage. Rice was introduced into Hawaii by Chinese immigrants between 1853 and 1862, but it did not thrive as an agro-industry in competition with sugarcane and pineapple (Adair, Miller, and Beachell 1962; Lu and Chang 1980).

Experimental planting of rice in Australia took place in New South Wales in 1892, although other introductions into the warmer areas of Queensland and the Northern Territories could have come earlier. Commercial planting in New South Wales began in 1923 (Grist 1975). The island of New Guinea began growing rice in the nineteenth century (Bertin et al. 1971).

The dissemination of Asian rice from one place to another doubtless also took place for serendipitous reasons. Mexico, for example, received its first lot of rice seed around 1522 in a cargo mixed with wheat. South Carolina's early plantings of rice around 1685–94 allegedly used rice salvaged from a wrecked ship whose last voyage began in Madagascar (Grist 1975; Lu and Chang 1980).

In addition, the deliberate introduction of rice has produced other unexpected benefits. This occurred when the Champa rices of central Vietnam were initially brought to the coastal areas of South China. In 1011–12 the Emperor Chen-Tsung of the Sung Dynasty decreed the shipment of 30,000 bushels of seed from Fukien Province into the lower Yangtze basin because of the grain's early maturing and drought-escaping characteristics. But its subsequent widespread use in China paved the way for the double cropping of rice and the multiple cropping of rice and other crops (Ho 1956; Chang 1987).

As for African rice *(O. glaberrima),* its cultivation remains confined to West Africa under a variety of soil-water regimes: deep water basins, water holes in the savannas, hydromorphic soils in the forest zone, and dryland conditions in hilly areas (Porteres 1956; Harlan 1973). In areas favorable for irrigated rice production, African rice has been rapidly displaced by the Asian introductions, and in such fields the native cultigen has become a weed in commercial plantings.

It is interesting to note that the African cultigen has been found as far afield as Central America, most likely as a result of introduction during the time of the transatlantic slave trade (Bertin et al. 1971).

Cultivation Practices and Cultural Exchanges

Evolution of Cultivation Practices

Rice grains were initially gathered and consumed by prehistoric peoples in the humid tropics and subtropics from self-propagating wild stands. Cultivation began when men or, more likely, women, deliberately dropped rice grains on the soil in low-lying spots near their homesteads, kept out the weeds and animals, and manipulated the water supply. The association between rice and human community was clearly indicated in the exciting excavations at He-mu-du, Luo-jia-jiao, and Pen-tou-shan in China where rice was a principal food plant in the developing human settlements there more than 7,000 years ago.

Rice first entered the diet as a supplement to other food plants as well as to game, fish, and shellfish. As rice cultivation expanded and became more efficient, it replaced other cereals (millets, sorghums, Job's tears, and even wheat), root crops, and forage plants. The continuous expansion of rice cultivation owed much to its unique features as a self-supporting semiaquatic plant. These features include the ability of seed to germinate under both aerobic and anaerobic conditions and the series of air-conducting aerenchymatous tissues in the leafsheaths, stems, and roots that supply air to roots under continuous flooding. Also important are soil microbes in the root zone that fix nitrogen to feed rice growth, and the wide adaptability of rice to both wetland and dryland soil-water regimes. It is for these reasons that rice is the only subsistence crop whose soil is poorly drained and needs no nitrogen fertilizer applied. And these factors, in turn, account for the broad rice-growing belt from the Sino-Russian border along the Amur River (53°N latitude) to central Argentina (35°S).

Forces crucial to the expansion and improvement of rice cultivation were water control, farm implements, draft animals, planting methods, weed and pest control, manuring, seed selection, postharvest facilities, and above all, human innovation. A number of significant events selected from the voluminous historical records on rice are summarized below to illustrate the concurrent progression in its cultivation techniques and the socio-politico-economic changes that accompanied this progression.

Rice was initially grown as a rain-fed crop in low-lying areas where rain water could be retained. Such areas were located in marshy, but flood-free, sites around river bends, as found in Honan and Shenxi Provinces of north China (Ho 1956), and at larger sites between small rivers, as represented by the He-mu-du site in east China (Chang 1968; You 1976). Early community efforts led to irrigation or drainage projects. The earliest of such activities in the historical record were flood-control efforts in the Yellow River area under Emperor Yu at about 2000 B.C. Irrigation works, including dams, canals, conduits, sluices, and ponds, were in operation during the Yin period (c. 1400 B.C.).

A system of irrigation and drainage projects of various sizes were set up during the Chou Dynasty. Large-scale irrigation works were built during the Warring States period (770–21 B.C.). By 400 B.C., "rice *[tao]* men" were appointed to supervise the planting and water management operations. The famous Tu-Cheng-Yen Dam was constructed near Chendu in Sichuan (Szechuan) Province about 250 B.C., which made western Sichuan the new rice granary of China.

Further developments during the Tang and Sung dynasties led to extensive construction of ponds as water reservoirs and of dams in a serial order to impound fresh water in rivers during high tides. Dykes were built around lake shores to make use of the rich alluvial soil (Chou 1986), and the importance of water quality was recognized (Amano 1979).

Among farm implements, tools made from stone (spade, hoe, axe, knife, grinder, pestle, and mortar) preceded those made from wood and large animal bones (hoe, spade); these were followed by bronze and iron tools. Bone spades along with wooden handles were found at the He-mu-du site. Bronze knives and sickles appeared during Shang and Western Chou. Between 770 and 211 B.C. iron tools appeared in many forms. The iron plow pulled by oxen was perfected during the Western Han period. Deep plowing was advocated from the third century B.C. onward. The spike-tooth harrow *(pa)* appeared around the Tang Dynasty (sixth century), and it markedly improved the puddling of wet soil and facilitated the transplanting process. This implement later spread to Southeast Asia to become an essential component in facilitating transplanted rice culture there (Chang 1976a). Other implements, such as the roller and a spiked board, were also developed to improve further the puddling and leveling operations.

Broadcasting rice grains into a low-lying site was the earliest method of planting and can still be seen in the Jeypore tract of India and many parts of Africa. In dry soils, the next development was to break through the soil with implements, mainly the plow, whereas in wetland culture, it was to build levees (short dikes or bunds) around a field in order to impound the water. In the latter case, such an operation also facilitated land leveling and soil preparation by puddling the wet soil in repeated rounds.

The next giant step came in the transplanting (insertion) of young rice seedlings into a well-puddled and leveled wet field. Transplanting requires the raising of seedlings in nursery beds, then pulling them from those beds, bundling them, and transporting them to the field where the seedlings are thrust by hand into the softened wet soil. A well-performed transplanting operation also requires seed selection, the soaking of seeds prior to their initial sowing, careful management of the nursery beds, and proper control of water in the nursery and in the field. The transplanting practice began in the late Han period (A.D. 23–270) and subsequently spread to neighboring countries in Southeast Asia as a package comprised of the water buffalo, plow, and the spike-tooth harrow.

Transplanting is a labor-consuming operation. Depending on the circumstances, between 12 and close to 50 days of an individual's labor is required to transplant one hectare of rice land (Barker, Herdt, and Rose 1985). On the other hand, transplanting provides definite advantages in terms of a fuller use of the available water, especially during dry years, better weed control, more uniform maturation of the plants, higher grain yield under intensive management, and more efficient use of the land for rice and other crops in cropping sequence.

Despite these advantages, however, in South Asia the transplanting method remains second in popularity to direct seeding (broadcasting or drilling) due to operational difficulties having to do with farm implements, water control, and labor supply (Chang 1976a).

Variations of the one-step transplanting method were (1) to interplant an early maturing variety and a late one in alternating rows in two steps (once practiced in central China) and (2) to pull two-week-old seedlings as clumps and set them in a second nursery until they were about one meter tall. At this point, they were divided into smaller bunches and once more transplanted into the main field. This method, called double transplanting, is still practiced in Indochina in anticipation of quickly rising flood waters and a long rain season (Grist 1975).

Weeds in rice fields have undoubtedly been a serious production constraint since ancient times. The importance of removing weeds and wild rice plants was emphasized as early as the Han Dynasty. Widely practiced methods of controlling unwanted plants in the southern regions involved burning weeds prior to plowing and pulling them afterward, complemented by maintaining proper water depth in the field. Fallowing was mentioned as another means of weed control, and midseason drainage and tillage has been practiced since Eastern Chou as an effective means of weed control and of the suppression of late tiller formation by the rice plant.

Different tools, mainly of the hoe and harrow types, were developed for tillage and weed destruction. Otherwise, manual scratching of the soil surface and removal of weeds by hand were practiced by weeders who crawled forward among rows of growing rice plants. Short bamboo tubes tipped with iron claws were placed on the finger tips to help in the tedious operation. More efficient tools, one of which was a canoe-shaped wooden frame with a long handle and rows of spikes beneath it, appeared later (Amano 1979: 403). This was surpassed only by the rotary weeder of the twentieth century (Grist 1975: 157).

Insect pests were mentioned in Chinese documents before plant diseases were recognized. The *Odes* (c. sixth century B.C.) mentioned stemborers and the granary moth. During the Sung Dynasty, giant bamboo combs were used to remove leaf rollers that infest the upper portions of rice leaves. A mixture of lime and tung oil was used as an insect spray. Kernel smut, blast disease, and cold injury during flowering were recognized at the time of the Ming Dynasty. Seedling rot was mentioned in the *Agricultural Manual* of Chen Fu during South Sung (Chinese Academy of Agricultural Sciences 1986).

The relationship between manuring and increased rice yield was observed and recorded more than two thousand years ago. The use of compost and plant ash was advocated in writings of the first and third centuries. Boiling of animal bones in water as a means to extract phosphorus was practiced in Eastern Han. Growing a green manuring crop in winter was advised in the third century. The sixth century agricultural encyclopedia *Ch'i-Min-Yao-Shu* (Ku undated) distinguished between basal and top dressings of manure, preached the use of human and animal excreta on poor soils, and provided crop rotation schemes (Chang 1979b).

Irrigation practices received much attention in China because of the poor or erratic water supply in many rice areas. Therefore, the labor inputs on water management in Wushih County of Jiangsu Province in the 1920s surpassed those of weeding or transplanting by a factor of two (Amano 1979: 410), whereas in monsoonal Java, the inputs in water management were insignificant (Barker et al. 1985: 126).

Because of the cooler weather in north China, irrigation practices were attuned to suitable weather conditions as early as the Western Han: Water inlets and outlets were positioned directly opposite across the field so as to warm the flowing water by sunlight during the early stages of rice growth. Elsewhere, the inlets and outlets were repositioned at different intervals in order to cool the water during hot summer months (Amano 1979: 182). The encyclopedia *Ch'i-Min-Yao-Shu* devoted much space to irrigation practices: Watering should be attuned to the weather; the fields should be drained after tillage so as to firm the roots and drained again before harvesting.

In order to supplement the unreliable rainfall, many implements were developed to irrigate individual fields. The developments began with the use of urns to carry water from creeks or wells. The urn or bucket was later fastened to the end of a long pole and counterbalanced on the other end by a large chunk of stone. The pole was rested on a stand and could be swung around to facilitate the filling or pouring. A winch was later used to haul a bucket from a well (see Amano 1979 for illustrations).

The square-pallet chain pump came into use during the Eastern Han; it was either manually driven by foot pedaling or driven by a draft animal turning a large wheel and a geared transmission device (Amano 1979: 205, 240). The chain pump was extensively used in China until it was replaced by engine-driven water pumps after the 1930s. The device also spread to Vietnam. During hot and dry summers, the pumping operation required days and nights of continuous input. Other implements, such as the water wheel in various forms, were also used (Amano 1979; Chao 1979).

Although deepwater rice culture in China never approached the scale found in tropical Asia, Chinese farmers used floating rafts made of wooden frames and tied to the shore so as to grow rice in swamps. Such a practice appeared in Late Han, and the rafts were called *feng* (for frames) fields (Amano 1979: 175).

Many rice cultivars are capable of producing new tillers and panicles from the stubble after a harvest. Such regrowth from the cut stalks is called a ratoon crop. Ratooning was practiced in China as early as the Eastern Tsin period (A.D. 317–417), and it is now an important practice in the southern United States. Ratooning gives better returns in the temperate zone than in the tropics because the insects and diseases that persist from crop to crop pose more serious problems in the tropics.

Seed selection has served as a powerful force in cultivar formation and domestication. Continued selection by rice farmers in the field was even more powerful in fixing new forms; they used the desirable gene-combinations showing up in the plantings to suit their farmer's different needs and fancies. The earliest mention of human-directed selection in Chinese records during the first century B.C. was focused on selecting panicles with more grains and fully developed kernels. Soon, varietal differences in awn color and length, maturity, grain size and shape, stickiness of cooked rice, aroma of milled rice, and adaptiveness to dryland farming were recognized. The trend in selection was largely toward an earlier maturity, which reduced cold damage and made multiple cropping more practical in many areas. The encyclopedia *Ch'i-Min-Yao-Shu* advised farmers to grow seeds in a separate plot, rotate the seed plot site in order to eliminate weedy rice, and select pure and uniformly colored panicles. The seeds were to be stored above ground in aerated baskets, not under the ground. Seed selection by winnowing and floatation in water was advised.

Dryland or hill rice was mentioned in writings of the third century B.C. (Ting 1961). During Eastern Tsin, thirteen varieties were mentioned; their names indicated differences in pigmentation of awn, stem and hull, maturity, grain length, and stickiness of cooked rice (Amano 1979). Varieties with outstanding grain quality frequently appeared in later records. Indeed, a total of 3,000 varieties was tallied, and the names were a further indication of the differences in plant stature and morphology, panicle morphology, response to manuring, resistance to pests, tolerance to stress factors (drought, salinity, alkalinity, cool temperatures, and deep water), and ratooning ability (You 1982). The broad genetic spectrum present in the rice varieties of China was clearly indicated.

Harvesting and processing rice is another laborious process. The cutting instruments evolved from knives to sickles to scythe. Community efforts were common in irrigated areas, and such neighborly cooperation can still be seen in China, Indonesia, the Philippines, Thailand, and other countries. Threshing of grains from the panicles had been done in a variety of ways: beating the bundle of cut stalks against a wooden bench or block; trampling by human feet or animal hoofs; beating with a flail; and, more recently, driving the panicles through a spiked drum that is a prototype of the modern grain combine (see Amano 1979: 248–54 for the ancient tools).

Other important postharvest operations are the drying of the grain (mainly by sun drying), winnowing (by natural breeze or a hand-cranked fan inside a drum winnower), dehusking (dehulling), and milling (by pestle and mortar, stone mills, or modern dehulling and milling machines). Grains and milled rice are stored in sacks or in bulk inside bins. In Indonesia and other hilly areas, the long-panicled Javanica rices are tied into bundles prior to storage.

To sum up the evolutionary pathway in wetland rice cultivation on a worldwide scale, cultivation began with broadcasting in rain-fed and unbunded fields under shifting cultivation. As the growers settled down, the cultivation sites became permanent fields. Then, bunds were built to impound the rain water, and the transplanting method followed. As population pressure on the land continued to increase, irrigation and transplanting became more imperative (Chang 1989a).

The entire range of practices can still be seen in the Jeypore Tract and the neighboring areas (author's personal observations). The same process was retraced in Bang Chan (near Bangkok) within a span of one hundred years. In this case, the interrelationships among land availability, types of rice culture, population density, labor inputs, and grain outputs were documented in a fascinating book entitled *Rice and Man* by L. M. Hanks (1972).

In the twentieth century, further advances in agricultural engineering and technology have to do with several variations in seeding practices that have been adopted to replace transplanting. Rice growers in the southern United States drill seed into a dry soil. The field is briefly flushed with water and then drained. The seeds are allowed to germinate, and water is reintroduced when the seedlings are established. In northern California, pregerminated seeds are dropped from airplanes into cool water several inches deep. The locally selected varieties are able to emerge from the harsh environment (Adair et al. 1973).

Recently, many Japanese farmers have turned to drill-plant pregerminated seed on wet mud. An oxidant is applied to the seed before sowing so as to obtain a uniform stand of plants. For the transplanted crop, transplanting machines have been developed not only to facilitate this process but also to make commercial raising of rice seedlings inside seed boxes a profitable venture. As labor costs continue to rise worldwide, direct seeding coupled with chemical weed control will be the main procedures in the future.

For deepwater rice culture, rice seeds are broadcasted on dry soil. The seeds germinate after the monsoon rains arrive. The crop is harvested after the rains stop and the flooding water has receded.

For dryland rice, seeds are either broadcasted, drilled, or dropped (dibbled) into shallow holes dug in the ground. Dibbling is also common in West Africa. Dryland (hill or upland) rice continues to diminish in area because of low and unstable yield. It has receded largely into hilly areas in Asia where tribal minorities and people practicing shifting cultivation grow small patches for subsistence.

Rice Cultivation and Cultural Exchanges

The expansion of rice cultivation in China involved interactions and exchanges in cultural developments, human migration, and progress in agricultural technology. Agricultural technology in north China developed ahead of other regions of China. Areas south of the Yangtze River, especially south China, were generally regarded by Chinese scholars of the north as primitive in agricultural practices. During travel to the far south in the twelfth century, one of these scholars described the local rain-fed rice culture. He regarded it as crude in land preparation: Seed was sown by dibbling, fertilizer was not used, and tillage as a weeding practice was unknown (Ho 1969).

However, the picture has been rather different in the middle and lower Yangtze basins since the Tsin Dynasty (beginning in A.D. 317) when a mass migration of people from the north to southern areas took place. The rapid expansion of rice cultivation in east China was aided by the large-scale production of iron tools used in clearing forests and the widespread adoption of transplanting.

Private land ownership, which began in the Sung (beginning in A.D. 960), followed by reduction of land rent in the eleventh century and reinforced by double cropping and growth in irrigation works, stimulated rice production and technology development. As a result, rice production south of the Yangtze greatly surpassed rice production in the north, and human population growth followed the same trend (Ho 1969; Chang 1987). Thus, the flow of rice germ plasm was from south to north, but much of the cultural and technological developments diffused in the opposite direction.

Culinary Usage and Nutritional Aspects

Rice Foods

Before the rice grain is consumed, the silica-rich husk (hull, chaff) must be removed. The remaining kernel is the caryopsis or brown rice. Rice consumers, however, generally prefer to eat milled rice, which is the product after the bran (embryo and various layers of seed coat) is removed by milling. Milled rice is, invariably, the white, starchy endosperm, despite pigments present in the hull (straw, gold, brown, red, purple or black) and in the seed coat (red or purple).

Parboiled rice is another form of milled rice in which the starch is gelatinized after the grain is precooked by soaking and heating (boiling, steaming, or dry heating), followed by drying and milling. Milled rice may also be ground into a powder (flour), which enters the food industry in the form of cakes, noodles, baked products, pudding, snack foods, infant formula, fermented items, and other industrial products.

Fermentation of milled glutinous rice or overmilled nonglutinous rice produces rice wine *(sake).* Vinegar is made from milled and broken rice and beer from broken rice and malt. Although brown rice, as well as lightly milled rice retaining a portion of the germ (embryo), are recommended by health-food enthusiasts, their consumption remains light. Brown rice is difficult to digest due to its high fiber content, and it tends to become rancid during extended storage. Cooking of all categories of rice is done by applying heat (boiling or steaming) to soaked rice until the kernels are fully gelatinized and excess water is expelled from the cooked product. Cooked rice can be lightly fried in oil to make fried rice. People of the Middle East prefer to fry the rice lightly before boiling. Americans often add salt and butter or margarine to soaked rice prior to boiling. The peoples of Southeast Asia eat boiled rice three times a day, including breakfast, whereas peoples of China, Japan, and Korea prepare their breakfast by boiling rice with excess water, resulting in porridge (thick gruel) or *congee* (thin soup).

Different kinds of cooked rice are distinguished by cohesiveness or dryness, tenderness or hardness, whiteness or other colors, flavor or taste, appearance, and aroma (or its absence). Of these features, cohesiveness or dryness is the most important varietal characteristic: High amylose (25 to 30 percent) of the starchy endosperm results in dry and fluffy kernels; intermediate amylose content (15 to 25 percent) produces tender and slightly cohesive rice; low amylose content (10 to 15 percent) leads to soft cohesive (aggregated) rice; and glutinous or waxy endosperm (0.8 to 1.3 percent amylose) produces highly sticky rice. Amylopectin is the other – and the major – fraction of rice starch in the endosperm.

These four classes of amylose content and cooked products largely correspond with the designation of Indica, Javanica, Sinica (Japonica), and glutinous. Other than amylose content, the cooked rice is affected by the rice–water ratio, cooking time, and age of rice. Hardness, flavor, color, aroma, and texture of the cooked rice upon cooling are also varietal characteristics (Chang 1988; Chang and Li 1991).

Consumer preference for cooked rice and other rice products varies greatly from region to region and is largely a matter of personal preference based on upbringing. For instance, most residents of Shanghai prefer the cohesive *keng* (Sinica) rice, whereas people in Nanjing about 270 kilometers away in the same province prefer the drier *hsien* (Indica) type. Tribal people of Burma, Laos, Thailand, and Vietnam eat glutinous rice three times a day – a habit unthinkable to the people on the plains. Indians and Pakistanis pay a higher price for the basmati rices, which elongate markedly upon cooking and have a strong aroma. People of South Asia generally prefer slender-shaped rice, but many Sri Lankans fancy the short, roundish *samba* rices, which also have dark red seed coats. Red rice is also prized by tribal people of Southeast Asia (Eggum et al. 1981; Juliano 1985c) and by numerous Asians during festivities, but its alleged nutritional advantage over ordinary rice remains a myth. It appears that the eye appeal of red or purple rice stems from the symbolic meaning given the color red throughout Asia, which is "good luck."

The pestle and mortar were doubtless the earliest implements used to mill rice grains. The milling machines of more recent origin use rollers that progressed from stone to wood to steel and then to rubber-wrapped steel cylinders. Tubes made of sections of bamboo were most likely an early cooking utensil, especially for travelers. A steamer made of clay was unearthed at the He-mu-du site dating from 5000 B.C., but the ceramic and bronze pots were the main cooking utensils until ironware came into use. Electric rice cookers replaced iron or aluminum pots in Japan and other Asian countries after the 1950s, and today microwave ovens are used to some extent.

Nutritional Considerations

Rice is unquestionably a superior source of energy among the cereals. The protein quality of rice (66 percent) ranks only below that of oats (68 percent) and surpasses that of whole wheat (53 percent) and of corn (49 percent). Milling of brown rice into white rice results in a nearly 50 percent loss of the vitamin B complex and iron, and washing milled rice prior to cooking further reduces the water-soluble vitamin content. However, the amino acids, especially lysine, are less affected by the milling process (Kik 1957; Mickus and Luh 1980; Juliano 1985a; Juliano and Bechtel 1985).

Rice, which is low in sodium and fat and is free of cholesterol, serves as an aid in treating hypertension. It is also free from allergens and now widely used in baby foods (James and McCaskill 1983). Rice starch can also serve as a substitute for glucose in oral rehydration solution for infants suffering from diarrhea (Juliano 1985b).

The development of beriberi by people whose diets have centered too closely on rice led to efforts in the 1950s to enrich polished rice with physiologically active and rinse-free vitamin derivatives. However, widespread application was hampered by increased cost and yellowing of the kernels upon cooking (Mickus and Luh 1980). Certain states in the United States required milled rice to be sold in an enriched form, but the campaign did not gain acceptance in the developing countries. After the 1950s, nutritional intakes of the masses in Asia generally improved and, with dietary diversification, beriberi receded as a serious threat.

Another factor in keeping beriberi at bay has been the technique of parboiling rough rice. This permits the water-soluble vitamins and mineral salts to spread through the endosperm and the proteinaceous material to sink into the compact mass of gelatinized starch. The result is a smaller loss of vitamins, minerals, and amino acids during the milling of parboiled grains (Mickus and Luh 1980), although the mechanism has not been fully understood. Parboiled rice is popular among the low-income people of Bangladesh, India, Nepal, Pakistan, Sri Lanka, and parts of West Africa and amounts to nearly one-fifth of the world's rice consumed (Bhattacharya 1985).

During the 1970s, several institutions attempted to improve brown rice protein content by breeding. Unfortunately, such efforts were not rewarding because the protein content of a variety is highly variable and markedly affected by environment and fertilizers, and protein levels are inversely related to levels of grain yield (Juliano and Bechtel 1985).

Production and Improvement in the Twentieth Century

Production Trends

Prior to the end of World War II, statistical information on global rice production was rather limited in scope. The United States Department of Agriculture (USDA) compiled agricultural statistics in the 1930s, and the Food and Agriculture Organization of the United Nations (FAO) expanded these efforts in the early 1950s (FAO 1965). In recent years, the *World Rice Statistics* published periodically by the International Rice Research Institute (IRRI) provides comprehensive information on production aspects, imports and exports, prices, and other useful information concerning rice (IRRI 1991).

During the first half of the twentieth century, production growth stemmed largely from an increase in wetland rice area and, to a lesser extent, from expansion of irrigated area and from yields increased by the use of nitrogen fertilizer. Then, varietal improvement came in as the vehicle for delivering higher grain yields, especially in the late 1960s when the "Green Revolution" in rice began to gather momentum (Chang 1979a).

Rice production in Asian countries steadily increased from 240 million metric tons during 1964–6 to 474 million tons in 1989–90 (IRRI 1991). Among the factors were expansion in rice area and/or irrigated area; adoption of high-yielding, semidwarf varieties (HYVs); use of nitrogen fertilizers and other chemicals (insecticides, herbicides, and fungicides); improved cultural methods; and intensified land use through multiple cropping (Herdt and Capule 1983; Chang and Luh 1991).

Asian countries produced about 95 percent of the world's rice during the years 1911–40. After 1945, however, Asia's share dropped to about 92 percent by the 1980s, with production growth most notable in North and South America (IRRI 1991; information on changes in grain yield, production, annual growth rates, and prices in different Asian countries is provided in Chang 1993b; Chang and Luh 1991; David 1991; and Chang 1979a).

But despite the phenomenal rise in crop production and (in view of rapidly growing populations) the consequent postponement of massive food shortages in Asia since the middle 1960s, two important problems remain. One of these is food production per capita, which advanced only slightly ahead of population growth (WRI 1986). The other is grain yield, which remained low in adverse rain-fed environments – wetland, dryland, deepwater, and tidal swamps (IRRI 1989). In fact, an apparent plateau has prevailed for two decades in irrigated rice (Chang 1983). Moreover, the cost of fertilizers, other chemicals, labor, and good land continued to rise after the 1970s, whereas the domestic wholesale prices in real terms slumped in most tropical Asian nations and have remained below the 1966–8 level.

This combination of factors brought great concern when adverse weather struck many rice areas in Asia in 1987 and rice stocks became very low. Fortunately, weather conditions improved the following year and rice production rebounded (Chang and Luh 1991; IRRI 1991).

However, the threat to production remains. In East Asia, five years of favorable weather ended in 1994 with a greater-than-usual number of typhoons that brought massive rice shortages to Japan and South Korea. And in view of the "El Niño" phenomenon, a higher incidence of aberrant weather can be expected, which will mean droughts for some and floods for others (Nicholls 1993).

Germ Plasm Loss and the Perils of Varietal Uniformity

Rice is a self-fertilizing plant. Around 1920, however, Japanese and U.S. rice breeders took the lead in using scientific approaches (hybridization selection and testing) to improve rice varieties. Elsewhere, pureline selection among farmers' varieties was the main method of breeding.

After World War II, many Asian countries started to use hybridization as the main breeding approach. Through the sponsorship of the FAO, several countries in South and Southeast Asia joined in the Indica-Japonica Hybridization Project during the 1950s, exchanging rice germ plasm and using diverse parents in hybridization.

These efforts, however, provided very limited improvement in grain yield (Parthasarathy 1972), and the first real breakthrough came during the mid-1950s when Taiwan (first) and mainland China (second) independently succeeded in using their semidwarf rices in developing short-statured, nitrogen-responsive and high-yielding semidwarf varieties (HYVs). These HYVs spread quickly among Chinese rice farmers (Chang 1961; Huang, Chang, and Chang 1972; Shen 1980).

Taiwan's semidwarf "Taichung Native 1" (TN1) was introduced into India through the International Rice Research Institute (IRRI) located in the Philippines. "TNI" and IRRI-bred "IR8" triggered the "Green Revolution" in tropical rices (Chandler 1968; Huang et al. 1972). Subsequent developments in the dramatic spread of the HYVs and an associated rise in area grain yield and production have been documented (Chang 1979a; Dalrymple 1986), and refinements in breeding approaches and international collaboration have been described (Brady 1975; Khush 1984; Chang and Li 1991).

In the early 1970s, China scored another breakthrough in rice yield when a series of hybrid rices (F_1 hybrids) were developed by the use of a cytoplasmic pollen-sterile source found in a self-sterile wild plant ("Wild Abortive") on Hainan Island (Lin and Yuan 1980). The hybrids brought another yield increment (15 to 30 percent) over the widely grown semidwarfs.

Along with the rapid and large-scale adoption of the HYVs and with deforestation and development projects, innumerable farmers' traditional varieties of all three ecogenetic races and their wild relatives have disappeared from their original habitats – an irreversible process of "genetic erosion." The lowland group of the javanic race *(bulu, gundill)* suffered the heaviest losses on Java and Bali in Indonesia. Sizable plantings of the long-bearded *bulus* can now be found only in the Ifugao rice terraces of the Philippines.

In parallel developments, by the early 1990s the widespread planting of the semidwarf HYVs and hybrid rices in densely planted areas of Asia amounted to about 72 million hectares. These HYVs share a common semidwarf gene (sd_1) and largely the same cytoplasm (either from "Cina" in older HYVs or "Wild Abortive" in the hybrids). This poses a serious threat of production losses due to a much narrowed genetic base if wide-ranging pest epidemics should break out, as was the case with hybrid maize in the United States during 1970–1 (Chang 1984).

Since the early 1970s, poorly educated rice farmers in South and Southeast Asia have planted the same HYV in successive crop seasons and have staggered plantings across two crops. Such a biologically unsound practice has led to the emergence of new and more virulent biotypes of insect pests and disease pathogens that have overcome the resistance genes in the newly bred and widely grown HYVs. The result has been heavy crop losses in several tropical countries in a cyclic pattern (Chang and Li 1991; Chang 1994).

Fortunately for the rice-growing world, the IRRI has, since its inception, assembled a huge germ plasm collection of more than 80,000 varieties and 1,500 wild rices by exchange and field collection. Seeds drawn from the collection not only have sustained the continuation of the "Green Revolution" in rice all over the world but also assure a rich reservoir of genetic material that can reinstate the broad genetic base in Asian rices that in earlier times kept pest damage to manageable levels (Chang 1984, 1989b, 1994).

Outlook for the Future

Since the dawn of civilization, rice has served humans as a life-giving cereal in the humid regions of Asia and, to a lesser extent, in West Africa. Introduction of rice into Europe and the Americas has led to its increased use in human diets. In more recent times, expansion in the rice areas of Asia and Africa has resulted in rice replacing other dryland cereals (including wheat) and root crops as the favorite among the food crops, wherever the masses can afford it. Moreover, a recent overview of food preferences in Africa, Latin America, and north China (Chang 1987, personal observation in China) suggests that it is unlikely that rice eaters will revert to such former staples as coarse grains and root crops. On the other hand, per capita rice consumption has markedly dropped in the affluent societies of Japan and Taiwan.

In the eastern half of Asia, where 90 to 95 percent of the rice produced is locally consumed, the grain is the largest source of total food energy. In the year 2000, about 40 percent of the people on earth, mostly those in the populous, less-developed countries, depended on rice as the major energy source. The question, of course, is whether the rice-producing countries with ongoing technological developments can keep production levels ahead of population growth.

From the preceding section on cultivation practices, it seems obvious that rice will continue to be a labor-intensive crop on numerous small farms. Most of the rice farmers in rain-fed areas (nearly 50 percent of the total planted area) will remain subsistence farmers because of serious ecological and economic constraints and an inability to benefit from the scientific innovations that can upgrade land productivity (Chang 1993b). Production increases will continue to depend on the irrigated areas and the most favorable rain-fed wetlands, which now occupy a little over 50 percent of the harvested rice area but produce more than 70 percent of the crop. The irrigated land area may be expanded somewhat but at a slower rate and higher cost than earlier. Speaking to this point is a recent study that indicates that Southeast Asia and South Asia as well, are rapidly depleting their natural resources (Brookfield 1993).

With rising costs in labor, chemicals, fuel, and water, the farmers in irrigated areas will be squeezed between production costs and market price. The latter, dictated by government pricing policy in most countries, remains lower than the real rice price (David 1991). Meanwhile, urbanization and industrialization will continue to deprive the shrinking farming communities of skilled workers, especially young men. Such changes in rice-farming communities will have serious and widespread socioeconomic implications.

Unless rice farmers receive an equitable return for their efforts, newly developed technology will remain experimental in agricultural stations and colleges. The decision makers in government agencies and the rice-consuming public need to ensure that a decent living will result from the tilling of rice lands. Incentives must also be provided to keep skilled and experienced workers on the farms. Moreover, support for the agricultural research community must be sustained because the challenges of providing still more in productivity-related cultivation innovations for rice are unprecedented in scope.

Although the rice industry faces formidable challenges, there are areas that promise substantial gains in farm productivity with the existing technology of irrigated rice culture. A majority of rice farmers can upgrade their yields if they correctly and efficiently perform the essential cultivation practices of fertilization, weed and pest control, and water management.

On the research front, rewards can be gained by breaking the yield ceiling, making pest resistance more durable, and improving the tolerance to environmental stresses. Biotechnology will serve as a powerful force in broadening the use of exotic germ plasm in *Oryza* and related genera (Chang and Vaughan 1991). We also need the inspired and concerted teamwork of those various sectors of society that, during the 1960s and 1970s, made the "Green Revolution" an unprecedented event in the history of agriculture.

Lastly, control of human population, especially in the less-developed nations, is also crucial to the maintenance of an adequate food supply for all sectors of human society. Scientific breakthroughs alone will not be able to relieve the overwhelming burden placed on the limited resources of the earth by uncontrolled population growth.

II.A.8 ~ Rye

Rye As a Grass

Rye (*Secale cereale* L.) is closely related to the genus *Triticum* (which includes bread wheat, durum wheat, spelt, and the like) and has sometimes been included within that genus (Mansfeld 1986: 1447). In fact, it was possible to breed Triticale, a hybrid of *Triticum* and *Secale,* which is cultivated today (Mansfeld 1986: 1449).

Cultivated rye *(Secale cereale)* is also so closely related genetically to the wild rye *(Secale montanum)* that both species would appear to have had the same ancestors. Yet to say that the cultivated rye plant derived from the wild one is an oversimplification because both plants have been changing their genetic makeup since speciation between the wild and cultivated plants first occurred.

The cultigen *Secale cereale* was brought to many parts of the world, but wild rye still grows in the area where cultivated rye originated, which embraces the mountains of Turkey, northwestern Iran, Caucasia, and Transcaucasia (Zohary and Hopf 1988: 64–5; Behre 1992: 142).

The distribution area of wild rye is slightly different from the area of origin of other Near Eastern crops. Wild rye is indigenous to areas north of the range of the wild *Triticum* and *Hordeum* species; these areas have a more continental climate with dry summers and very cold, dry winters. The environmental requirements of cultivated rye reflect these conditions of coldness and dryness: It has a germination temperature of only 1 to 2 degrees Centigrade, which is lower than that of other crops. Indeed, low temperatures are necessary to trigger sprouting (Behre 1992: 145), and the plant grows even in winter if the temperature exceeds 0 degrees Centigrade, although rye can suffer from a long-lasting snow cover. In spring it grows quickly, so that the green plant with unripe grains reaches full height before the summer drought begins (Hegi 1935: 498–9). Obviously, these characteristics make rye a good winter crop. It is sown in autumn, grows in winter and spring, and ripens and is harvested in summer – a growth cycle that is well adapted to continental and even less favorable climatic conditions. There is also another cultigen of rye – summer rye – which is grown as a summer crop. But because of a low yield and unreliability, it is rather uncommon today (Hegi 1935: 497).

Clearly, then, the constitution of the wild grass ancestor of cultivated rye is reflected in the cultivated crop. Rye is predominantly grown as a winter crop, on less favorable soils, and under less favorable climatic conditions than wheat.

The Question of Early Cultivation

There is evidence for the ancient cultivation of rye in the Near East dating back to the Neolithic. Gordon Hillman (1975: 70–3; 1978: 157–74; see also Behre 1992: 142) found cultivated rye in aceramic early Neolithic layers of Tell Abu Hureyra in northern Syria and also at Can Hasan III in central Anatolia. Hillman reports that there were entire rachis internodes at these sites, proof that the selective pressures of cultivation were operating, because only a plant with a nonbrittle rachis can be harvested efficiently. It is not clear, however, if rye was actually cultivated at these Neolithic sites or whether the plant only underwent such morphological adaptations while being sown and harvested as a weedy contaminant of other crops.

To this day, rye remains a vigorous weed in Near Eastern wheat and barley fields, and its nonbrittle rachis internodes resemble a cultivated plant in spite of the fact that it is not intentionally sown. It is harvested together with the more desirable wheat and barley as a "maslin crop" (a crop mixture), and, in climatically unfavorable years, the rye yield is often better than the yield of barley or wheat in these fields. Even an examination of the harvested crop may give the false impression that the rye has been deliberately cultivated. It is interesting to note that such "volunteer" rye is called "wheat of Allah" by Anatolian peasants (Zohary and Hopf 1988: 64) because it is assumed that God "sent" a crop in spite of the bad weather conditions that were unfavorable to the sown wheat.

Possibly this process of unintentionally cultivating rye, while intentionally cultivating wheat and barley, also took place in the early Neolithic fields of Tell Abu Hureyra and Can Hasan III that Hillman investigated. So we do not know if rye was deliberately grown as a crop in its own right or if it was only "wheat of Allah." It is the case that Hillman's evidence for the early cultivation of rye in the Near East contradicts an earlier opinion by Hans Helbaek (1971: 265–78), who assumed that rye derived from central rather than western Asia.

Rye As a Weed

Rye reached Europe at the dawn of the region's Neolithic Revolution, but probably as a weed. Angela M. Kreuz (1990: 64, 163) has discovered rye remains in Bruchenbrücken, near Frankfurt, in central Germany. This site is dated to the earliest phase of the Linearbandkeramik, which is the earliest phase of agriculture in central Europe. Similarly, Ulrike Piening (1982: 241–5) found single rye grains in a Linearbandkeramik settlement at Marbach, near Stuttgart, in southern Germany. But at both sites only single rye grains were found among great amounts of grains of other species. The same is the case with the few other early rye finds in Europe (Piening 1982: 242–4; Behre 1992: 142–3). Thus, the evidence appears to indicate that rye existed during the early phase of agricultural development in Europe as a weed, and an uncommon one at that.

In the Neolithic, however, most grain cultivation took place on fertile loess soils situated in regions where typical winter crop weeds were not present. Such conditions did not favor rye expansion and, consequently, there was little opportunity to compare the durability of rye to that of *Triticum* species, as was the case with the development of the "wheat of Allah" in the maslin crop fields in the Anatolian mountains.

The proportions of rye, however, were greater in some grain assemblages from Bronze Age sites. Many have assumed that rye was cultivated as a Bronze Age crop, especially in eastern central Europe (Körber-Grohne 1987: 44), but the evidence remains scarce and questionable (Behre 1992: 143). Yet spelt *(Triticum spelta),* a grain similar to rye, was commonly grown in this region during the Bronze Age (Körber-Grohne 1987: 74). Because spelt was normally cultivated as a winter crop, spelt grain assemblages from archaeological sites are contaminated with winter crop weed seeds (Küster 1995: 101). Thus, it could be that the beginning of winter crop cultivation favored the expansion of winter rye as a weed in spelt fields. This was probably the case especially in areas less favorable to agriculture that were being cultivated from the Bronze Age forward, as, for example, in some areas of the Carpathians and the Alps, where rye pollen grains have been recorded several times in layers dating to the Bronze Age (Küster 1988: 117). Definitive evidence of an early rye expansion to the Alps, however, awaits more extensive plant macrofossil examination in these marginal agricultural areas high up in the mountains.

Rye As a Secondary Cultivated Crop

Spelt cultivation, possibly as a winter crop, expanded during the Pre-Roman Iron Age to other parts of Europe (Körber-Grohne 1987: 74), as agriculture itself spread to areas with less fertile soils, such as those of sand and gravel in northern central Europe. These soils, as well as the local ecological conditions of humid climate and light snow cover, favor a winter crop plant that grows during mild winter days and in the spring but will not suffer from summer drought on sandy soils.

Pollen (Küster 1988: 117; Behre 1992: 148) and macrofossil evidence (Behre 1992: 143) show that rye became more common during the Pre-Roman Iron Age, perhaps in those winter crop fields on the less favorable soils just described. At this point, rye was still growing as a weed, but because it had the qualities of a cultivated plant under these ecological conditions, rye eventually predominated in fields planted with spelt. This success is typical of secondary plants that are cultivated by chance within stands of other crops.

Karl-Ernst Behre (1992: 143) has compiled a list of the most ancient finds of pure, or possibly pure, rye cultivated during the Iron Age in Europe. This shows concentrations in the eastern Alps, the countries around the Black Sea, and the western and northern marginal areas of Europe.

But rye became more common during the Roman Age, as populations grew, thus increasing the demand for food. During this time, ever greater amounts of lands with less fertile soils were brought under cultivation, and the expansion of winter crop cultivation provided more reliable and greater yields. Abundant *Secale* grains have been discovered on some Roman sites, giving the impression that rye was cultivated as a main crop (Behre 1992: 143–5). It is, however, unlikely that the Romans themselves propagated rye (with which they were unfamiliar) because climate militated against its growth in the Mediterranean region (Behre 1992: 145). Only a few Roman Age sites outside the Roman Imperium have been examined by archaeobotanists so far, but there is clear evidence that rye was grown outside the Empire as a main crop. A detailed study from an area in northern Germany has shown that the shift to rye cultivation took place during the second century A. D. (Behre 1992: 146).

A few hypotheses for the increased importance of rye have been put forward. For one, rye may have been imported from areas outside to sites inside the Imperium (Dickson and Dickson 1988: 121–6), which suggests increased demand, and, in what is not necessarily a contradiction, Behre (1992: 149–50) emphasizes that the expansion of rye during the Roman Age reflects the improvement of harvesting methods beyond the earlier technique of plucking the grain ear by ear. Because all cultivars depend on harvesting for seed dispersal, such a thorough method would not have favored the expansion of rye. But during the Iron Age and Roman times, harvesting methods grew more sophisticated, and the advent of new mowing equipment made rye's dispersal more likely.

Another hypothesis involves climatic deterioration as an explanation for the expansion of rye. To date, however, there is no clear evidence for climatic change during the Roman Age. Most likely then, by way of summary, the major reasons for the increased importance of rye cultivation were the expansion of agriculture to more marginal fields, the growing importance of winter crops, and changing harvesting methods.

Medieval Rye Cultivation

During the Middle Ages, rye became a very important crop in many parts of Europe. As agriculture was introduced to marginal mountainous landscapes, the cultivation of rye was frequently the best alternative. More important, although the acid, sandy soils in northern and north-central Europe became exhausted from overcropping, the custom developed of enriching them with "plaggen," which was heath, cut down and transported from the heathlands to the farmlands (Behre 1992: 152). Although this caused a further impoverishment of the already relatively infertile heathlands, such a practice made it possible to control the fertility of marginal fields and to grow crops near the settlements. On these soils "eternal rye cultivation" (Behre 1992: 152) became possible, allowing cropping every year.

In other regions where rye replaced spelt, as for example in southern Germany, such a replacement resulted from practical reasons (Rösch, Jacomet, and Karg 1992: 193–231). Because spelt is a hulled crop, the grains must be dehusked after threshing. This is not necessary with rye or wheat, but the latter is very sensitive to diseases caused by primitive storage conditions in damp environments. Thus, because it was easier to store rye than wheat, and easier to process rye than spelt, rye replaced spelt in many places during the period between the Roman Age and the Middle Ages (Rösch et al. 1992: 206–13). In other areas, of course, such as the mountains of the Ardennes in Belgium and northern France, and the area around Lake Constance, spelt has been grown until recent times and was never replaced by rye.

The relative importance of a grain crop in the various areas of Germany can be determined from the language of historical documents. This is because the term *Korn* ("corn") signifies the most important crop over the ages. So it is interesting to find that in regions where rye cultivation predominated during the Middle Ages and early modern times, the term *Korn* is connected with rye, but in others it is associated with spelt or wheat.

Rye crossed the Atlantic to the New World with colonists heading to both the south and the north of North America. In the south, Alexander von Humboldt, who visited Mexico at the turn of the nineteenth century, discovered rye growing "at heights where the cultivation of maize would be attended with no success" (Humboldt 1972: 97). In addition, he reported that the plant was seldom attacked by a disease that in Mexico "frequently destroys the finest wheat harvests when the spring and the beginning of the summer have been very warm and when storms are frequent" (Humboldt 1972: 104).

In the north, where rye was also extensively cultivated in colonial New England, symptoms of ergotism (a disease caused by ingestion of the ergot fungus that infects many grains, but especially rye) are believed to have often been manifested by the population. Such symptoms (especially those of nervous dysfunction), are seen to have been present in the Salem witchcraft affair, in the "Great Awakening," and in epidemics of "throat distemper" (Matossian 1989). Certainly ergotism had a long and deadly history in Europe, beginning before the early Middle Ages. Some 132 epidemics were counted between 591 and 1789, the last occurring in France during the time of the "Great Fear," which just preceded the French Revolution and which some have seen as leading to it (Haller 1993).

In conclusion, although rye has been said to be our "oldest crop," and baking company advertisements call rye bread the traditional bread, as we have seen, this is certainly not the case. Only gradually did this crop, which began as a weed among cultigens, grow to prominence. But it has also traveled as far from its origins as the United States and Canada (Körber-Grohne 1987: 40), where the winters are cold enough to stimulate the germination of the grains – the same stimulus rye plants received in the mountains of the Near East before they spread out into eastern, central, northern, and western Europe.

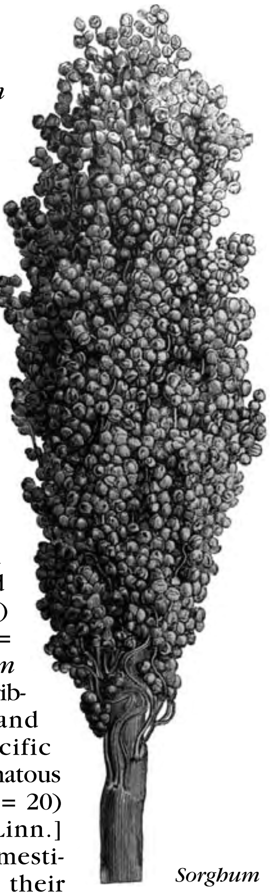
II.A.9 Sorghum

Grain sorghum (*Sorghum bicolor* [Linn.] Moench) is a native African cereal now also widely grown in India, China, and the Americas. Sorghum ranks fifth in world cereal grain production, and fourth in value (after rice, wheat, and maize) as a cereal crop. It is grown on 40 to 50 million hectares annually, from which up to 60 million metric tons of grain are harvested. In Africa and Asia traditional cultivars are grown, usually with low agricultural inputs, and average yields are below 1 metric ton per hectare. But more than 3 metric tons of grain are harvested per acre in the Americas, where farmers plant modern sorghum hybrids. Sorghum is more tolerant to drought and better adapted for cultivation on saline soils than is maize. It holds tremendous promise as a cereal to feed the rapidly expanding populations of Africa and Asia. In the Americas it is replacing maize as an animal feed.

Morphology and Distribution



Sorghum

The grass genus *Sorghum* Moench is one of immense morphological variation. It is taxonomically subdivided into sections *Chaetosorghum, Heterosorghum, Parasorghum, Stiposorghum,* and *Sorghum* (Garber 1950), and these sections are recognized as separate genera by W. D. Clayton (1972). The genus *Sorghum* is here recognized to include: (1) a complex of tetraploid (2n = 40) rhizomatous taxa (*S. halapense* [Linn.] Pers.) that are widely distributed in the Mediterranean region and extend into tropical India; (2) a rhizomatous diploid (2n = 20) species (*S. propinquum* [Kunth] Hitchc.) that is distributed in Southeast Asia and extends into adjacent Pacific Islands; and (3) a nonrhizomatous tropical African diploid (2n = 20) complex (*S. bicolor* [Linn.] Moench) that includes domesticated grain sorghums and their closest wild and weedy relatives (de Wet and Harlan 1972). Genetic introgression is common where wild rhizomatous or spontaneous nonrhizomatous taxa become sympatric with grain sorghums, and derivatives of such introgression have become widely distributed as weeds in sorghum-growing regions.

The domesticated sorghum complex is morphologically variable. It includes wild, weed, and domesticated taxa that are divided by J. D. Snowden (1936, 1955) among 28 cultivated species, 13 wild species, and 7 weed species. Following the classification of cultivated plants proposed by Jack R. Harlan and J. M. J. de Wet (1972), the wild taxa are recognized as subspecies *verticilliflorum* (Steud.) de Wet, the weed taxa as subspecies *drummondii* (Steud.) de Wet, and the grain sorghums as subspecies *bicolor* (de Wet and Harlan 1978).

Subspecies *verticilliflorum* includes races verticilliflorum, arundinaceum, virgatum, and aethiopicum. These grade morphologically and ecologic ally so completely into one another that they do not deserve formal taxonomic rank. This subspecies is indigenous to tropical Africa but has become widely distributed as a weed in tropical Australia (de Wet, Harlan, and Price 1970). It differs from grain sorghum primarily in being spontaneous rather than cultivated and in being capable of natural seed dispersal.

Verticilliflorum is the most widely distributed, and morphologically the most variable, race of the subspecies. It extends naturally across the African savannah, from Senegal to the Sudan and South Africa. It is distinguished from the other races by its large and open inflorescences with long and spreading branches. Verticilliflorum is an aggressive colonizer of naturally disturbed habitats, and it often forms large continuous populations in flood plains. It is commonly harvested as a wild cereal in times of scarcity.

Race arundinaceum is distributed along the margins of tropical forests of the Congo basin. It is sympatric with verticilliflorum along the transition zone between savannah and forest, and the races introgress. Derivatives of such hybridization aggressively colonize areas of forest that are cleared for agriculture. Arundinaceum is typically characterized by large and open inflorescences with long branches that become pendulous at maturity.

Race virgatum occurs along stream banks and irrigation ditches in arid regions of tropical northeastern Africa. Wild populations are harvested as a cereal during times of famine. It is widely sympatric with race verticilliflorum, and gene exchange between them is common. It typically has smaller inflorescences than verticilliflorum.

Race aethiopicum is drought tolerant. It extends across the West African Sahel and into the Sudan. In flood plains, it frequently forms large continuous populations and is harvested as a wild cereal. The distribution and habitat of aethiopicum rarely overlap with the other races. It is characterized by large spikelets that are densely tomentose.

Subspecies *drummondii* is an obligate weed derived through introgression between subspecies *verticilliflorum* and cultivated grain sorghums. It became widely distributed across tropical Africa as part of cereal agriculture. Morphological variation is extensive as a result of hybridization among the different races of grain sorghum and different races of close wild relatives. Stabilized derivatives of such introgression accompanied the cereal to India and the highlands of Ethiopia. Weeds often resemble grain sorghums in spikelet morphology, but they retain the ability of natural seed dispersal.

Grain sorghums also introgress with the Eurasian *S. halepense* to form diploid or tetraploid weedy derivatives. Johnson grass of the American Southwest and some sorghums of Argentina are tetraploid derivatives of such introgression. Diploid derivatives of hybridization between grain sorghum and Johnson grass have recently become obnoxious weeds in the American corn belt.

Subspecies *bicolor* includes all domesticated grain sorghums. The 28 cultivated species recognized by Snowden (1936) are artifacts of sorghum cultivation. They represent selections by farmers for specific adaptations and food uses, and they do not deserve formal taxonomic rank. Grain sorghums are classified by Harlan and de Wet (1972) into races bicolor, kafir, caudatum, durra, and guinea. Sorghums belonging to different races hybridize where they are grown sympatrically, and cultivars have become established that combine characteristics of two or more of these races. Extensive racial evolution took place in Africa before sorghum was introduced as a cereal into Asia (Harlan and Stemler 1976).

Race bicolor resembles spontaneous weedy sorghums in spikelet morphology, but all cultivars depend on harvesting for seed dispersal. Mississippi chicken corn probably represents a derivative of abandoned cultivated race bicolor that entered America during the slave trade. It is spontaneous and must have regained the ability of natural seed dispersal through mutation. Bicolor sorghums are characterized by open inflorescences, having spikelets with long and clasping glumes that enclose the grain at maturity. Some cultivars of race bicolor are relics of the oldest domesticated sorghums, whereas others are more recent derivatives of introgression between evolutionally advanced cultivars and spontaneous sorghums.

Bicolor sorghums are widely distributed in Africa and Asia but are rarely of major economic importance because of their low yield. Cultivars survive because they were selected for specific uses. They are grown for their sweet stems (chewed as a delicacy), for the high tannin content of the grains (used to flavor sorghum beer), and for use as fodder. Cultivars often tiller profusely, which tends to make their sweet stems desirable as fodder for livestock in Africa.

Race kafir is the most common cultivated sorghum south of the equator in Africa. It never became widely distributed in India and China, probably because of limited trade between southern Africa and India or the Near East before colonial times. Race kafir is characterized by compact inflorescences that are cylindrical in shape. Spikelets have glumes that tightly clasp the usually much longer mature grain. Sorghum has been replaced by maize in areas with high rainfall, but kafir sorghums remain the most important cereal crop of the southern savannahs in areas with between 600 and 900 millimeters (mm) of annual rainfall. At the drier limits of agriculture, sorghum is replaced as a cereal by pearl millet. In the wettest parts, sorghum competes as a food cereal not only with maize but also with finger millet. The grain of kafir sorghums is commonly high in tannin. This provides partial protection against bird damage and confers resistance to grain molds that reduce grain quality. Tannin also, however, reduces the digestibility of porridges produced from kafir sorghums, which today are grown mainly to produce malt for the making of a highly nutritious beer. This beer is commercially produced in Zimbabwe and South Africa.

Race caudatum is distinguished by its asymmetrical grains. The grain is usually exposed between the glumes at maturity, with the embryo side bulging and the opposite side flat or concave. Inflorescences range from very compact to rather open with spreading branches. Caudatum cultivars are highly adaptive and are grown in areas with as low as 350 mm and as high as 1,000 mm of annual rainfall. Selected cultivars are resistant to fungal leaf diseases, to ergot of the grain, and to infestation by insects or the parasitic striga weed. Caudatum sorghums are a major food source of people speaking Chari-Nile languages in the Sudan, Chad, Uganda, northeastern Nigeria, and Cameroon (Stemler, Harlan, and de Wet 1975). Along the flood plains of the Niger River in Chad, caudatum sorghums are grown in nurseries and transplanted to cultivated fields as flood waters recede (Harlan and Pasguereau 1969). The grains are ground into flour from which a fermented porridge is produced. Caudatum sorghums are also commercially grown in Nigeria for the production of malt used in the brewing industry.

Race durra is the most drought tolerant of grain sorghums. Selected cultivars mature in less than three months from planting, allowing escape from terminal drought stress in areas with short rainy seasons. The name *durra* refers to the Arabic word for sorghum, and the distribution of durra sorghums in Africa is closely associated with the spread of Islam across the Sahel. The grain is also extensively grown in the Near East, China, and India. Inflorescences are usually compact. Spikelets are characteristically flattened and ovate in outline, with the lower glume either creased near the middle or having a tip that is distinctly different in texture from the lower two-thirds of the glume. Grains are cooked whole after decortication or are ground into flour to be prepared as porridge or baked into unleavened bread.

Race guinea is distinguished by long glumes that tightly clasp the obliquely twisted grain, which becomes exposed between them at maturity. Inflorescences are large and often open, with branches that become pendulous at maturity. These are adaptations for cultivation in areas with high rainfall, and guinea is the principal sorghum of the West African Guinea zone with more than 800 mm of annual rainfall. Guinea sorghums are also grown along the high-rainfall highlands from Malawi to Swaziland and in the ghats of Central India. It is a principal food grain in West Africa and Malawi. In Senegal, the small and hard grains of an indigenous cultivar are boiled and eaten, similar to the way rice is prepared and consumed in other parts of the world. In Malawi, the sweet grains of a local cultivar are eaten as a snack while still immature. Guinea sorghums are valued for the white flour that is produced from their tannin-free grains.

Intermediate races recognized by Harlan and de Wet (1972) include sorghum cultivars that are not readily classifiable into any one of the five basic races. They combine characteristics of race bicolor with those of the other four basic races, of guinea and caudatum, or of guinea and kafir. Cultivars with intermediate morphologies occur wherever members of basic races are grown sympatrically in Africa. Intermediate cultivars have become widely distributed in India. Modern high-yielding sorghum hybrids combine traits of races kafir, durra, and caudatum in various combinations.

Domestication and Evolutionary History

Cereal domestication is a process, not an event. Domestication is initiated when seeds from planted populations are harvested and sown in human-disturbed habitats (in contrast to naturally disturbed habitats), and it continues as long as the planting and harvesting processes are repeated in successive generations (Harlan, de Wet, and Price 1973). The initial ability to survive in disturbed habitats is inherent in all wild grasses that were adopted as cereals. In fact, as aggressive colonizers, they can form large continuous colonies in naturally disturbed habitats. This weedy characteristic of these plants facilitates harvesting and eventually leads to their domestication. Sowing in cultivated fields reinforces adaptation for survival in disturbed habitats, and harvesting of sown populations selects against mechanisms that facilitate natural seed dispersal. Thus, domesticated cereals have lost the ability to compete successfully for natural habitats with their wild relatives. They depend on farming for suitable habitats and on harvesting and sowing for seed dispersal.

There is little doubt that subspecies *verticilliflorum* gave rise to grain sorghums under domestication. This spontaneous complex of tropical African sorghums is an aggressive colonizer of naturally disturbed habitats, and because it forms large continuous stands, it remains a favorite wild cereal of nomads as well as farmers during times of food scarcity. Snowden (1936) and R. Porteres (1962) have suggested that race arundinaceum (of forest margins) gave rise to guinea sorghums, the desert race aethiopicum to durra sorghums, and the savannah race verticilliflorum to kafir sorghums. Distribution and ethnological isolation certainly suggest three independent domestications of grain sorghum. This, however, is unlikely. Close genetic affinities between specific cultivated races and the spontaneous races with which they are sympatric resulted from introgression. Such introgression continues between grain sorghums and their close, spontaneous relatives. Racial evolution of advanced cultivated races resulted from selection by farmers who grew bicolor sorghums for specific uses, and from natural adaptations to local agro-ecological environments.

The wild progenitor of cultivated sorghums is the widely distributed race verticilliflorum. It could have been domesticated anywhere across the African savanna. Jack Harlan (1971) proposes that sorghum was taken into cultivation along a broad band of the savanna from the Sudan to Nigeria, where verticilliflorum is particularly abundant. H. Dogget (1965) previously had suggested that the initial domestication occurred in the northeastern quadrant of Africa, probably undertaken by early farmers in Ethiopia who learned from the ancient Egyptians how to grow barley and wheat. These two Near Eastern cereals have been grown in Egypt and along the Mediterranean coast of North Africa since at least the fifth century B.C. (Clark 1971).

Tropical agriculture in Africa must have started in the savannah along the southern fringes of the Sahara (Clark 1976, 1984). Archaeological evidence indicates that pearl millet (*Pennisetum glaucum* [Linn.] R. Br.), sorghum, and finger millet (*Eleusine coracana* [Linn.] Gaertn.) were among the earliest native cereals of the savannah to be domesticated.

J. S. Wigboldus (1991) has suggested that there is little evidence to indicate cereal cultivation south of the Sahara before the ninth century of the Christian era. Archaeological evidence, however, indicates that cereal agriculture in the African savanna is much older than this. Inhabitants of the Dhar Tichitt region of Mauritania, extending from the middle of the second to the middle of the first millennium B.C., evidently experimented with the cultivation of native grasses (Munson 1970). During the first phase of settlement, bur grass (*Cenchrus biflorus* Roxb.) seems to have been the most common grass harvested as a wild cereal. It is still extensively harvested in the wild as a source of food during times of scarcity. In the middle phases, *Brachiaria deflexa* (Shumach.) Hubbard, now cultivated on the highlands of Mali (Porteres 1976), and *Pennisetum glaucum,* now grown as pearl millet across the Sahel, became equally common, as shown by their impressions on potsherds. In later phases, starting about 1000 B.C., impressions of what is almost certainly domesticated pearl millet became dominant (Munson 1970). It is not possible, however, to determine whether pearl millet was domesticated at Dhar Tichitt or whether this cereal was introduced to these settlements from other parts of the West African Sahel.

Tropical African grasses were also grown as cereals in eastern Africa before the beginning of the Christian era. Potsherds from a Neolithic settlement at Kadero in the central Sudan, dated to between 5,030 and 5,280 years ago, reveal clear impressions of domesticated sorghum and finger millet spikelets and grains (Klichowska 1984). Both cereals are today extensively grown in eastern and southern Africa. Indirect evidence of early sorghum and finger millet cultivation in Africa comes from the presence of these African cereals in Neolithic settlements of India, dated to about 1000 B.C. (Weber 1991). Other archaeological evidence indicates that sorghum cultivation spread from eastern Africa to reach northeastern Nigeria not later than the tenth century A.D. (Connah 1967) and, together with pearl millet and finger millet, reached southern Africa not later than the eighth century A.D. (Shaw 1976).

That native grasses were grown as cereals not less than 3,000 years ago along the southern fringes of the Sahara is not surprising. Wheat and barley were grown in Egypt and along the Mediterranean coast of North Africa by the latter part of the fifth millennium B.C. (Shaw 1976), and the knowledge of cereal agriculture reached the highlands of Ethiopia some 5,000 years ago. These Near Eastern cereals cannot be grown successfully as rain-fed crops in lowland tropics. Experimentation with the cultivation of native grasses in the semiarid tropical lowlands seems a logical next step in the development of African plant husbandry. Nor is the absence of domesticated sorghum in West Africa before the tenth century A.D. surprising. Sorghum is poorly adapted to the arid Sahel, where finger millet was domesticated and remains the principal cereal, and an abundance of wild food plants and animals probably made agriculture in the Guinea zone less productive than hunting and gathering during the beginnings of plant husbandry in tropical Africa. Racial evolution gave rise to races guinea, caudatum, durra, and kafir and is associated with adaptation to agro-ecological zones and the isolation of different ethnic groups who adopted sorghum cultivation. Morphological differentiation took place in Africa, except for race durra that may have evolved in Asia after sorghum cultivation became established in southwestern Asia.

Race guinea's open panicles and spikelets with widely gaping glumes are adaptations for successful cultivation in high-rainfall areas. The glumes enclose the immature grain to protect it from infection by grain molds, but they gape widely at maturity to allow the grain to dry rapidly after a rain and thus escape damage. Guinea sorghums, which probably evolved in Ethiopia, are still grown in the Konso region, and from there they may have spread along the mountains south to Swaziland and west to the Guinea coast. Cultivated sorghum belonging to race guinea was already growing in Malawi during the ninth century A.D. (Robbinson 1966). Today, almost half the sorghum production in Nigeria comes from guinea sorghums.

Kafir sorghums evolved south of the equator and never became widely distributed outside the southern African savanna. They are probably relatively recent in origin. Kafir sorghums became associated with Iron Age Bantu settlements only during the eighth century A.D. (Fagan 1967; Phillipson and Fagan 1969). Kafir sorghums are genetically more closely allied to local verticilliflorums than to other spontaneous sorghums. This led Y. Schechter and de Wet (1975) to support Snowden's (1936) conclusion that race kafir was independently domesticated from other sorghums in southern Africa. It is more likely, however, that kafir sorghums were derived from introduced bicolor sorghums that introgressed with local wild sorghum adapted to the arid southern savanna.

As already mentioned, race durra is the most drought-tolerant of all grain sorghums. Their wide distribution in semiarid Asia caused Harlan and A. B. L. Stemler (1976) to propose that durra sorghums evolved in West Asia from earlier introductions of race bicolor. Archaeological remains indicate that bicolor sorghums were grown in India not later than the early first millennium B.C. (Weber 1991). Durras remain the common cultivated sorghums in semiarid Asia. In Africa, they are grown across the Sahel, and their distribution seems to be associated with the expansion of Islam across North Africa.

The cultivation of caudatum sorghums is closely associated in Africa with the distribution of people who speak Chari-Nile languages (Stemler, Harlan, and de Wet 1975). Caudatum sorghums probably represent selections from race bicolor in the eastern savannah during relatively recent times. Bicolor sorghums were important in the Sudan as late as the third century A.D., and archaeological sorghum remains from Qasr Ibrim and Jebel et Tomat in the Sudan belong to race bicolor (Clark and Stemler 1975). The beautifully preserved sorghum inflorescences from Qasr Ibrim date from the second century (Plumley 1970). The only known archaeological remains of caudatum are those from Daima, dated A.D. 900 (Connah 1967). Introgression of caudatum with durra sorghums of the Sahel and with guinea sorghums of West Africa gave rise to a widely adapted complex that is extensively used in modern sorghum breeding.

The spread of sorghum as a cereal to Asia is poorly documented. Carved reliefs from the palace of Sennacherib at Nineveh are often cited as depicting cultivated sorghum (see Hall 1928, plates 30 and 32). But these plants were actually the common reed (*Phragmites communis* Trin.) growing along the edges of a marsh with pigs grazing among them, certainly not a habitat for growing sorghum. Similar plants appear in imperial Sassanian hunting scenes from Iran (for illustrations, see Reed 1965).

In the Near East, sorghum is an important cereal only in Yemen. Sorghum probably reached India directly from East Africa during the latter part of the second century B.C. (Vishnu-Mittre and Savithri 1982), and in India, race durra evolved. From India durra sorghum was introduced to China, probably during the Mongol conquest (Hagerthy 1940), and to the Sahel during the expansion of Islam across northern Africa. Introduction into the New World most likely started with the slave trade between Africa and the Americas. The weedy Mississippi chicken corn may represent an escape from cultivation dating back to colonial times.

Sorghum As a World Cereal

Sorghum is an important rain-fed cereal in the semiarid tropics. Production in recent years has been between 50 and 60 million metric tons of grain harvested from around 45 million hectares. The major production areas are North America (excluding Mexico) with 34 percent of total world production, Asia (32 percent), Africa (26 percent), and South America (6 percent). The Caribbean, Meso America, and South America together account for about 17 percent of world sorghum production, with Mexico producing almost 59 percent of this amount. Potential yield of improved sorghum hybrids under rain-fed agricultural conditions is well over 6 metric tons per hectare. Actual maximum yields are closer to 4 metric tons, and average yields are about 1.5 metric tons per hectare. Sorghum is often grown on marginal agricultural land. In Africa and Asia, where local cultivars are still extensively grown with a minimum of agricultural inputs, average yield is well below 1 metric ton per hectare. Sorghum is grown as a cereal for human consumption in Africa and Asia and as animal feed in the Americas and Australia. Sorghum is also extensively grown as a fodder crop in India.

Sorghum production in Africa extends across the savanna in areas with as little as 300 mm and as much as 1,500 mm of annual rainfall. At the drier limits of its range, sorghum is replaced in Africa by pearl millet, in India by pearl millet or foxtail millet (*Setaria italica* [Linn.] P. Beauv.), and in China by foxtail millet. In areas with more than 900 mm of annual rainfall, maize has replaced sorghum across tropical Africa since its introduction from America during the sixteenth century.

Major factors limiting yield in Africa are infestation of cultivated fields by *Striga* (a parasitic weed) and the abundance of birds that feed on sorghum grain before it is ready for harvest. Some degree of resistance to bird damage is conferred by high tannin content in developing grains. Tannin, unfortunately, reduces the desirability of sorghum as a cereal grain. Digestibility is improved through fermentation, and fermented food products produced from sorghum grain are extensively used where high tannin cultivars are grown.

Striga is parasitic on most cereals and several broad-leaved crops grown in Africa and India. It produces large numbers of seeds and can become so abundant that fields eventually have to be abandoned. Control of *Striga* requires high agricultural inputs, the most important of which is high soil fertility and weeding. Neither is affordable under conditions of subsistence farming. Some local sorghum cultivars are resistant to *Striga,* but these have low grain yield. Attempts to transfer genes for resistance into more desirable genotypes of sorghum are high in priority for breeding projects in West and East Africa, where *Striga* has become a particularly obnoxious weed.

In Asia, the major sorghum-producing countries are China, India, Thailand, Pakistan, and Yemen. In Thailand, sorghum is grown as a dry-season crop, after a rain-fed crop, usually maize, has been harvested. In India, sorghum is grown as a rain-fed crop (kharif) or a dry-season crop (rabi), usually following rice or cotton on soils with good moisture retention. Kharif sorghum is usually mixed with pigeon pea in the field. Sorghum matures and is harvested after 90 to 120 days, allowing the season-long–developing pigeon pea an opportunity to mature without competition.

Kharif sorghums were selected for their ability to mature before the end of the rainy season in order to escape terminal drought stress that severely reduces yield. These cultivars are highly susceptible to infection by grain molds, which greatly reduces the desirability of kharif sorghum as a cereal grain. Market samples have revealed that in central and southern India as much as 70 percent of food sorghum grown during the rainy season is infected with grain molds. Cultivars with high tannin content in developing grains are resistant to infection by grain molds, but their flour yields a poor-quality unleavened bread, the major product of sorghum preparation as a food in India. Long-term breeding programs to produce grain-mold–resistant sorghums with grain acceptable to consumers have consistently failed.

Rabi sorghums escape infection by grain molds as they are grown in the dry season, but yields are low because of terminal drought stress. Prices in the market for these sorghums, however, are sufficiently attractive to make rabi sorghum a major crop in India. Production is well below demand, and attempts to shorten the growing season of rabi sorghums to escape drought and at least maintain yield potential are showing promise. Terminal drought stress commonly leads to lodging of these sorghums because of a combination of infection by stem rot fungi and plant senescence. Lodging makes harvesting difficult and contributes to reduced grain quality. To improve stalk quality and overcome lodging, plant breeders in India introduced genes for delayed senescence into high-yielding cultivars. This allows grain harvest when the stalk is still juicy and the leaves are green. Delayed senescence also greatly improves fodder quality. The stalks of both kharif and rabi sorghums are in demand as animal feed. Around urban areas, the demand by the dairy industry for fodder far exceeds the supply, and farmers often derive a higher income from sorghum stalks than sorghum grain.

Shortage of sorghum grain as a food largely excludes its use as animal feed in Africa and Asia. The grain is eaten in a variety of preparations that vary within and between regions. Grains are ground into flour from which unleavened bread is baked, or the flour is used to produce both fermented and unfermented porridges. The grains are also cracked or decorticated and boiled like rice, or whole grains are popped in heated oil.

Commercial grain sorghum production in Africa and Asia is determined by the availability of reliable supplies of the much-preferred rice, wheat, or maize. Only where these three cereals are not available at competitive prices is sorghum an important commercial crop. In China, sorghum is commercially grown for the production of a popular alcoholic beverage. It is used as a substitute for barley malt in the Nigerian beer industry. In southern Africa, a highly nutritious, low-alcohol beer is commercially produced from sorghum malt and flour, and in Kenya sorghum is used to produce a widely accepted baby food. However, attempts in many countries to replace wheat flour partially with sorghum flour in the baking industry have, so far, met with limited success, even though the quality of the bread is acceptable.

In the Americas, sorghum production is determined by demand for the grain as an animal feed. World feed use of sorghum has reached 40 million metric tons annually, with the United States, Mexico, and Japan the main consumers (Food and Agriculture Organization 1988). These three countries used almost 80 percent of the world's sorghum production in 1993. Although North American demand for sorghum grain has stabilized, in South America, where more than 1 million hectares are under sorghum cultivation, demand exceeds production by about 10 percent annually. This shortfall, predicted to increase throughout the next decade, is now mostly made up by imports from the United States. In the quest for self-sufficiency in animal feed, sorghum cultivation in South America is expanding into areas too dry for successful production of maize and into the seasonally flooded Llanos (with acid soils), where sorghum is more productive than maize.

In Asia, the area under sorghum cultivation is declining to make room for the production of fruits, vegetables, and other foods needed to supply rapidly increasing urban populations. Grain production, however, has remained essentially stable in Asia during the last decade because farmers increasingly grow improved cultivars associated with improved farming practices. This allows production to keep pace with demand, except during drought years when the demand for sorghum as human food far exceeds production.

In several African countries, population increase exceeds annual increase in food production. The Food and Agriculture Organization of the United Nations predicted that 29 countries south of the Sahara would not be able to feed their people as the twenty-first century opened. The concomitant increase in demand for cereals will have to be met by the expansion of production into marginal agricultural land, the growing of improved cultivars, and improved farming practices. Pearl millet is the cereal of necessity in areas with between 300 and 600 mm of annual rainfall, and sorghum is the most successful cereal to grow in areas with between 600 and 900 mm of annual rainfall. Because of that, the future of sorghum as a food cereal in Africa and Asia, and as a feed grain in the Americas and Australia, seems secure.

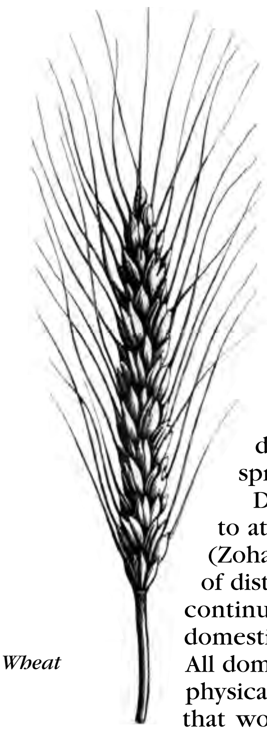
II.A.10 Wheat

Wheat, a grass that today feeds 35 percent of the earth's population, appeared as a crop among the world's first farmers 10,000 years ago. It increased in importance from its initial role as a major food for Mediterranean peoples in the Old World to become the world's largest cereal crop, feeding more than a billion people in the late twentieth century (Feldman 1976: 121). It spread from the Near East, where it first emerged in the nitrogen-poor soils of a semiarid Mediterranean climate, to flourish in a wide range of environments – from the short summers of far northern latitudes, to cool uplands, to irrigated regions of the tropics. The real story of its origins



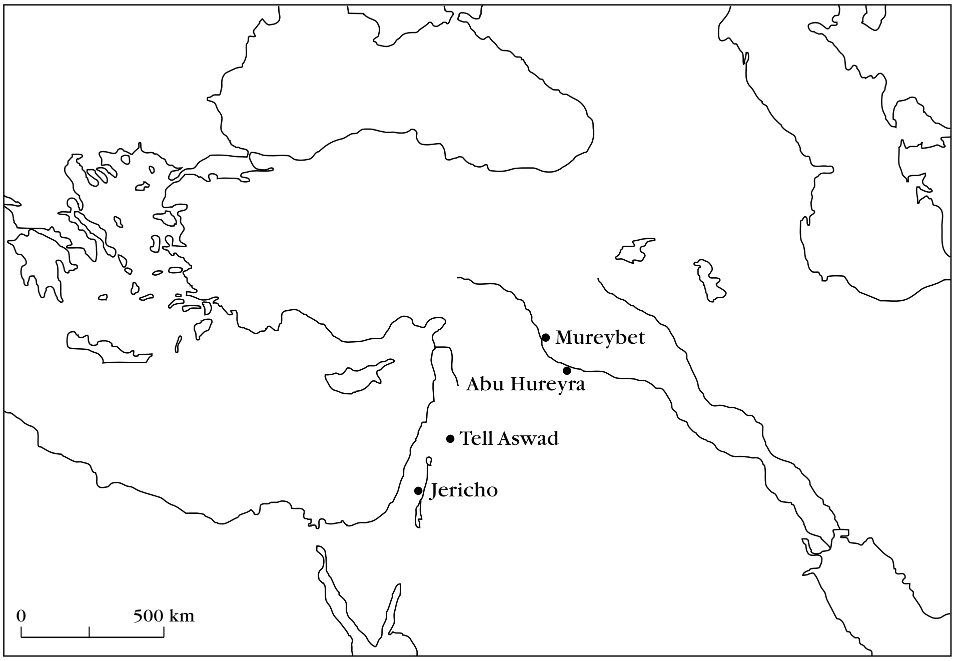
Wheat

disappeared from memory many millennia in the past, although some farming peoples still recount tales of how they received other cultivated plants from gods, animate spirits, heroic ancestors, or the earth itself. But today we must use botanical and archaeological evidence to trace the story of wheat's domestication (implying a change in a plant's reproduction, making it dependent on humans) and its spread.

Domesticated wheats belong to at least three separate species (Zohary 1971: 238) and hundreds of distinct varieties, a number that continues to increase because the domestication of wheat continues. All domesticated wheat has lost the physical and genetic characteristics that would allow it aggressively to reseed and sprout by itself – losses which clearly distinguish domesticated wheats from wild relatives. Furthermore, both the remarkable geographic distribution of domesticated wheat and the species' very survival depend on human beings. If no one collected wheat seeds and planted them in cleared, fertile ground, waving fields of grain soon would support hundreds of weeds, to be replaced by wild plants, and perhaps eventually by saplings and forests. Domesticated wheat and humans help each other in a relationship known as "mutualism" (Rindos 1984: 255).

Although humans domesticated wheat, one may argue that dependence on wheat also domesticated humans. The switch from gathering food to producing food, dubbed the "Neolithic Revolution" by V. Gordon Childe (1951: 74, orig. 1936), ultimately and fundamentally altered human development. Both wheat and barley, destined to feed the great civilizations of Mesopotamia, Egypt, Greece, and Rome, originated in the Near East, the earliest cradle of Western civilization (Map II.A.10.1). And with food production came great social and technological innovations. For example, because cereals can be stored year-round, early farmers could settle together in larger groups during the seasons when low food availability formerly had forced hunter–gatherers to disperse into small groups. Furthermore, by producing a surplus of cereal food, farmers could support others – people with specialized crafts, administrators, religious castes, and the like. Thousands of years later, cities emerged and empires arose. Clearly, the domestication of a cereal that has fed the Western world (and much of the rest of the world as well) holds a special place in the study of the origins of our foods.

Map II.A.10.1. The Ancient Near East showing sites mentioned in the text.



The Origins of Wheat and Barley Agriculture

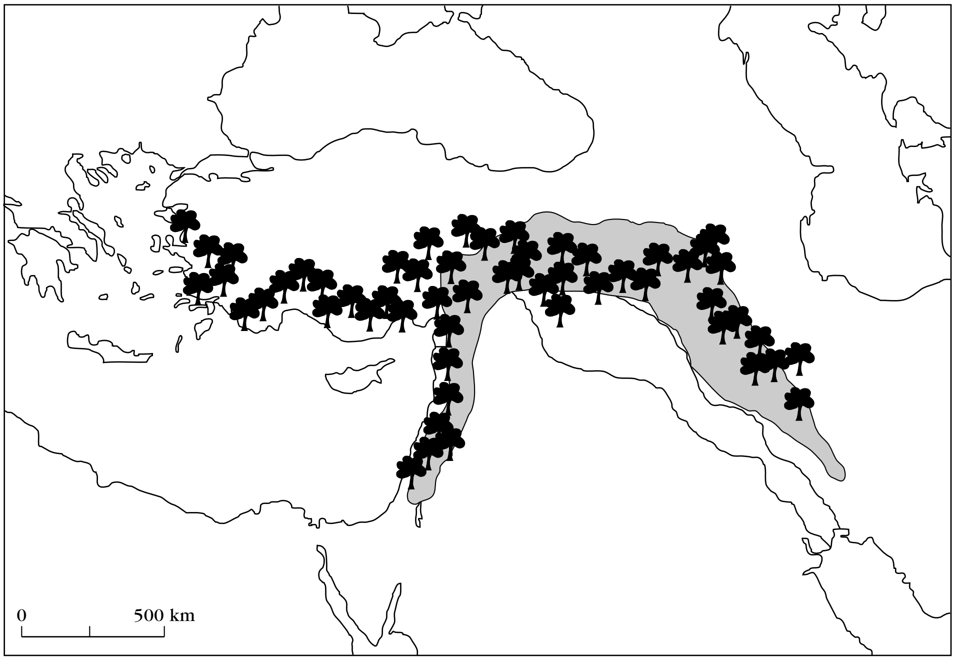
While archaeologists recognize the momentous developments set in motion by food production in the ancient Near East, they continue to debate the essential factors that first caused people to begin farming wheat and barley.[1] How did agriculture begin? Which people first domesticated plants? Why did they do so when they did? And why did farming begin in only a few places? Answers to these questions are significant because with the domestication of wheat, humankind began the shift from hunting and gathering food to producing it. This change in lifestyle set humans on a new evolutionary course, and their society and environment were never the same after farming was established. Because wheat was one of the first crops to be farmed, its role in this fundamental shift has attracted much study, resulting in a variety of models to explain the process of domestication and its causes in the Near East.

The Process of Cereal Domestication

To domesticate wheat, humans must have manipulated wild wheats, either through selective gathering or deliberate cultivation, with the latter implying activities such as preparing ground, sowing, and eliminating competing plants. We owe much of our understanding of the details of this process to the work of several botanists and archaeologists. A Russian botanist, Nikolai Vavilov (1951), for example, discovered that the greatest diversity in the gene pool of wild wheats and barleys is in Southwest Asia. Where diversity is greatest, plants have been growing, fixing mutations, and interbreeding longest. Thus, it can be concluded that Southwest Asia was the ancestral homeland of these plants (Zohary 1970a: 33–5), and subsequent searches for the first farmers have concentrated on this region.

Robert Braidwood, an archaeologist from the University of Chicago, further refined the criteria for the homeland of wild wheats by identifying their modern ecological range, as the semiarid Mediterranean woodland belt known as the "hilly flanks" of the Fertile Crescent (Braidwood 1960: 134) (Map II.A.10.2). He reasoned that prefarming peoples had adapted culturally and ecologically to specific environments over long periods (a process he dubbed "settling in") and that the first wheat farmers had already been living among natural stands of wild wheat.

One of Braidwood's students and a great archaeologist in his own right, Kent V. Flannery, advocated explaining the origins of agriculture in terms of the process of plant domestication. His major contribution to modeling wheat domestication in the Near East stemmed from his recognition that plant domestication may have been the final result in a subtle chain of events that originated with changes in human food procurement occurring much earlier than the actual transition to agriculture (Flannery 1969, 1973: 284). Flannery's "Broad Spectrum Revolution" portrays a shift in human ecology whereby humans began exploiting many previously minor food



Map II.A.10.2. The Near East with modern "hilly flanks" and Mediterranean woodlands.

sources such as cereals, fish, small game, and water fowl. Ultimately they came to depend on these food sources (1969: 79).

Flannery particularly emphasized the importance of moving cultigens (manipulated but not necessarily domesticated plants) on which humans depended "to niches to which [they were] not adapted" (Flannery 1965: 1251; Wright 1971: 460; Rindos 1984: 26–7). Thus, as people relocated to accommodate shifting population densities (Binford 1968: 332), they attempted to produce rich stands of cereals outside their natural range (Flannery 1969: 80). Such an effort would have helped domesticate wild wheats by preventing relatively rare genetic variants from breeding with the large pool of wild wheat types growing in their natural ranges.

David Rindos (1984) has described the general process of plant domestication from an evolutionary perspective, using the principles of natural selection and mutualistic relationships (coevolution) to describe how cereals, for example, would have lost their wild characteristics. In mutualistic relationships, domesticates and humans enhance each other's fitness, or ability to reproduce. In the case of wheat, women and men began to collect wild seeds in increasing quantities for food, while at the same time inadvertently selecting and replanting seeds from the plants best suited to easy harvesting (Harlan, de Wet, and Price 1973: 311; Kislev 1984: 63). Within a few generations, cultivated wheat plants became dependent on the harvesting process for survival, as wild self-planting mechanisms disappeared from the traits of cultivated wheats (Wilke et al. 1972: 205; Hillman and Davies 1990). The elimination of wild reseeding characteristics from a plant population ultimately accounted for the domestication of wheats.

The Causes of Cereal Domestication

Because the first evidence for agricultural societies occurs at the beginning of the Holocene (our present epoch) after a major climatic change, several archaeologists found a climatic explanation for the origins of agriculture to be plausible. Childe, for example, maintained that agriculture began at the end of the Pleistocene when climate change caused a lush landscape to dry up and become desert. Populations of humans, animals, and plants would have been forced to concentrate at the few remaining sources of water: Their enhanced propinquity would have provided increased opportunity for experimentation and manipulation (Childe 1952: 23, 25). Childe believed that agriculture started in the oases of North Africa and Mesopotamia, and although these locations were probably incorrectly targeted, some of his other hypotheses now seem essentially correct (Byrne 1987; McCorriston and Hole 1991: 60).

Lewis Binford (1968: 332–7) also indicated the importance of climate change when he emphasized the resource stress experienced by permanently settled coastal populations hard-pressed by rising sea levels (also the result of climatic changes at the end of the Pleistocene). He pointed out, however, that population pressure in marginal zones (settled when rising sea levels flooded coastlines and forced populations to concentrate in smaller areas) would "favor the development of more effective means of food production" from lands no longer offering ample resources for scattered hunter-gatherers (1968: 332). Mark Cohen (1977: 23, 40–51) suggested that population growth filled all available land by the end of the Pleistocene; such dense populations eventually would have experienced the population pressure envisioned by Binford.

These ideas, however, only sharpened the question of why agriculture emerged in only a few regions. Accordingly, several archaeologists sought prerequisites – social or technological developments – that may have caused certain "preadapted" groups of hunter-gatherers to adopt farming in the Near East (Hole 1984: 55; Bar-Yosef and Belfer-Cohen 1989: 487; Rosenberg 1990: 409; McCorriston and Hole 1991: 47–9). Robert Braidwood thought that agriculture appeared when "culture was ready to achieve it" (Braidwood in Wright 1971: 457). For example, sedentism, which appeared for the first time just prior to agriculture (Henry 1985: 371–4, 1989: 219), would have profoundly affected the social relations in a group. Sedentary people can store and safeguard larger amounts of food and other goods than can mobile people. Stored goods increase the possibility of prestige being accorded to a relatively few individuals, since more opportunities now exist for redistribution of surplus goods through kinship alliances – the more goods a person distributes to dependents, the greater his prestige (Bender 1978: 213). As we have seen with contemporary sedentary hunter-gatherers, competition between leaders for greater alliance groups arguably stimulates an intensification of productive forces, which in turn provides a "major incentive for the production of surplus" (Godelier 1970: 120; Bender 1978: 213–14, 1981: 154). Perhaps wheat was such a desired surplus.

In parts of Southwest Asia, where sedentism appears to have preceded the development of agriculture (Henry 1981, 1989: 38–9; Bar-Yosef and Belfer-Cohen 1989: 473–4; Moore 1991: 291), it may have been the case that the causes of sedentism also contributed to the shift to food production (Moore 1985: 231; Henry 1989; Watson 1991: 14). On the other hand, Michael Rosenberg (1990: 410–11) argues that increasingly sharper territorial perceptions were the consequences of concentrated resource exploitation in such territories by hunter-gatherer groups already committed to mutualistic exploitation of plant resources.

A combination of factors probably best explains the domestication of cereals and the shift to agriculture in the Near East. Paleoenvironmental evidence indicates that forests widely replaced a drier steppic cover (van Zeist and Bottema 1982). This has prompted Andrew Moore (1985: 232) to suggest that improved resources (resulting from climatic factors) enabled hunter–gatherers to settle; afterward their populations grew in size, so that ultimately they experienced the sort of resource stress that could have led to intensive manipulation of plants. Donald Henry (1985, 1989) also credits climatic change, several thousand years before agriculture emerged, with causing greater availability of wild cereals, which led increasingly to their exploitation. With this came dependence in the form of a sedentary lifestyle near wild cereal stands, and ultimately domestication during an arid spell when resources grew scarce.

Ecological factors play a major role in another combination model, in which the adaptation of wild cereals to a seasonally stressed environment is viewed as an explanation for the rise of agriculture in the Near East. Herbert Wright, Jr. (1977) was the first to recognize an association between the hot, dry summers and mild, wet winters that characterized Mediterranean climates and the expansion of wild, large-seeded, annual cereals. He suggested that these plants were absent from Southwest Asia in the late Pleistocene. Modern climatic models, in conjunction with archaeological evidence and ecological patterns, distinctly point to the southern Levant – modern Israel and Jordan – as the region where wheat farming first began 10,000 years ago (COHMAP 1988; McCorriston and Hole 1991: 49, 58). There, as summers became hotter and drier, plants already adapted to survive seasonal stress (summer drought), including the wild ancestors of wheat and barley, spread rapidly as the continental flora (adapted to cooler, wetter summers) retreated. Some hunter–gatherer groups living in such regions also experienced seasonal shortages of their erstwhile dependable plant resources. One group, the Natufians, named after the Wadi an Natuf in Israel (where archaeologists first found their remains) probably compensated for seasonal stress by increasingly exploiting the large-seeded annual wild wheats and barleys.

These various approaches, spanning nearly 50 years of research in the Near East, have all contributed to an increasingly sophisticated appreciation of the causes and the process of wheat domestication. Based on data that either fit or fail to fit various models, many specific refutations appeared for each model, but these lie beyond the scope of this chapter. In addition, opinions on the process of domestication in the Near East still differ as follows:

1. Was the process fast or slow (Rindos 1984: 138–9; Hillman and Davies 1990: 213)?
2. Did domestication take place once or on many independent occasions (Ladizinsky 1989: 387; Zohary 1989: 369; Blumler 1992: 100–2)?
3. Was domestication primarily the result of biological processes (Binford 1968: 328–34; Flannery 1969: 75–6; Cohen 1977; Hayden 1981: 528–9; Rindos 1984) or the product of social changes (Bender 1978)?
4. Can the domestication process be linked to major changes in the global ecosystem (Childe 1952: 25; Binford 1968: 334; Wright 1977; Byrne 1987)?

Most archaeologists now believe that a complex convergence of multiple factors (climatic changes, plant availability, preadaptive technology, population pressure, and resource stress) accounts for the emergence of agriculture 10,000 years ago in the southern Levant (Hole 1984: 55; Moore 1985; Henry 1989: 40–55, 231–4; McCorriston and Hole 1991: 60; Bar-Yosef and Belfer-Cohen 1992: 39). However, there is still little consensus regarding the rapidity of the shift or the importance to be accorded to any single factor.

Archaeological Evidence for the Domestication of Wheat

The Evidence

The earliest remains of domesticated plants are the charred seeds and plant parts found on archaeological sites that date to the beginning of the Neolithic period. Unfortunately, other evidence for the use of plant foods in the past rarely shows exactly which plants were eaten. For example, grinding stones, sickles, and storage pits all indicate increased plant use and storage during the Early Neolithic period (about 10,000 to 8,000 years ago) (Table II.A.10.1), but they do not indicate which plants were processed (Wright 1994). In fact, such artifacts could have been used to process many kinds of plants and plant tissues, including many grasses, reeds, nuts, and tubers.

Table II.A.10.1. *Prehistoric cultures of the Near East*

Date	Period	Economy	Material culture
12,500–10,200 B.P.	Natufian	Hunting, gathering plants, and perhaps cultivating wild cereals	Grinding stones, storage pits, and sickles
10,200–9600 B.P.	Prepottery Neolithic A (PPNA)	Farming domesticates and hunting	Sickle blades, mudbrick architecture, axes, larger villages
9600–7500 B.P.	Prepottery Neolithic B (PPNA)	Farming domesticates and herding domesticated animals	Lime plaster, polished axes

Following the discovery of Neolithic crop plants (Hopf 1969), archaeologists have employed many analytical techniques to determine (1) whether even earlier peoples also cultivated plants, (2) whether such earlier uses of plant resources would have resulted in domestication, and (3) whether the first farmers originated in the region(s) where domesticated wheat first was found. The ultimate aim of such a quest, of course, has been to resolve the question of whether the earliest charred remains of domesticated wheat actually indicate the first wheat farmers.

In aiming at an answer, one must know the plant resources used by preagrarian hunter-gatherers and how the cultivation practices of the first farmers differed from plant use by their predecessors (Hillman 1989; Hillman, Colledge, and Harris 1989: 240–1). This knowledge, however, has proved elusive, largely because most direct evidence for prehistoric human use of plants has decayed or disappeared. Tools and pits may have been used for processing a wide range of plants. Chemical residues that allow archaeologists to specify *which* plants were eaten during the Early Neolithic period and the preceding Natufian period seldom have been preserved or examined (Hillman et al. 1993). Microscopic studies of the sheen left on flint sickle blades indicate that peoples using these tools reaped cereals (Unger-Hamilton 1989; Anderson 1991: 550), although it is impossible to ascertain which species.

Chemical composition of human bone also provides limited clues to plant consumption. For example, the ratio of strontium to calcium (Sr/Ca) in Natufian and Neolithic skeletons indicates that some early farmers eventually relied more heavily on animal foods than did their immediate Natufian predecessors (Sillen 1984; Smith, Bar-Yosef, and Sillen 1984: 126–8; Sillen and Lee-Thorp 1991: 406, 408). None of these isotopic data, however, have come from the very first farming populations (Pre-pottery Neolithic A); furthermore, such analyses cannot identify the specific plants that the first farmers ate.

The Sites

Neolithic sites with remains of domesticated wheat and other crops are the earliest known farming sites. But practices known to Neolithic farmers surely existed among their Natufian predecessors (Unger-Hamilton 1989) who for the first time in human history used large amounts of cereal processing equipment – grinding stones, sickle blades, storage pits – and lived year-round on one site (Bar-Yosef and Belfer-Cohen 1989: 468–70; Henry 1989: 195, 211–14, 219; Tchernov 1991: 322–9). Yet none of the Natufian sites excavated thus far have revealed domesticated wheat.

Furthermore, the presence of domesticated plants on Neolithic sites, more than any other evidence, has defined our perception of a major economic difference between the first Neolithic farmers and their hunter–gatherer predecessors. Natufians may indeed have cultivated cereals, although they never apparently domesticated them, and traditions of cereal cultivation in conjunction with other gathering and hunting strategies probably persisted long into the Neolithic era when cereal farmers shared the Near East with other groups of people who were not especially committed to cultivation.

A few exceptional excavations have recovered plant remains from pre-Neolithic sites, but most of these have not yet been fully analyzed. The site of Abu Hureyra, along the banks of the Middle Euphrates River in northern Syria, yielded an abundance of charred plant remains reflecting the harvest of many types of wild seeds and fruits: These were gathered primarily in the local environments of the Late Pleistocene – steppe and steppe-forest, wadi banks, and the Euphrates River valley bottom (Hillman et al. 1989: 258–9).

The plant economy of Abu Hureyra's Epipaleolithic hunter-gatherers, however, does not appear to have led directly to farming. The site was abandoned at the time when farming began elsewhere (Moore 1975: 53, 1979: 68), and the evidence for a wide diversity of plants without evidence of intensive use of any particular one (Hillman et al. 1989: 265) is inconsistent with most models of cereal domestication (e.g., Harlan 1967; Rindos 1984; Henry 1989: 55, 216–17, 228; Hillman and Davies 1990: 212).

Instead, most models assume that cereal domestication followed intensive cereal exploitation by hunter-gatherers. At about the time that people abandoned Abu Hureyra, the sedentary inhabitants of nearby Tell Mureybet began to harvest two-seeded wild einkorn wheat and wild rye with unprecedented intensity (van Zeist and Bakker-Heeres 1984: 176–9; Hillman et al. 1993: 106). Although this type of wild wheat never developed into a domesticated plant (Zohary 1971: 239; van Zeist 1988: 58), the pattern of intensive cereal use at Tell Mureybet mirrors the type of economic pattern suggested for the Natufians from the southern Levant, where no plant remains from Epipaleolithic sites have been fully analyzed (Colledge 1991).

The southern Levant is where the earliest domesticated wheat appears. In the period known as the Pre-pottery Neolithic A (approximately 9,000 to 10,000 years ago[2]), the early farming site of Jericho (in the Jordan Valley) has two types of domesticated wheat grains, einkorn and emmer (Hopf 1969: 356, 1983: 581) (Table II.A.10.2). Some of the oldest dates from Jericho can be questioned (Burleigh 1983: 760; Bar-Yosef 1989: 58), and domesticated wheat seeds from Jericho may actually be several hundred years younger than the oldest Neolithic radiocarbon dates (10,500–10,300 years ago) suggest.

Table II.A.10.2. *Principal wheat types*

Wheat *(Triticum)* types					
Botanical name	English name	Ploidy	Rachis	Glumes	Remarks
T. boeoticum var. *aegilopoides*	Wild einkorn	2x[a] AA	Brittle	Tight[b]	Spikelets 1-grained, ancestor of einkorn wheat, modern range in Taurus mts.[c]
T. boeoticum var. *thaoudar*	Wild einkorn	2x AA	Brittle	Tight	Spikelets 2-grained, collected wild in northern Levantine Neolithic,[d] modern range in western Anatolia[e]
T. monococcum	Einkorn	2x AA	Tough	Tight	Domesticated primitive wheat
T. dicoccoides	Wild emmer	4x AABB	Brittle	Tight	Ancestor to emmer, modern range is basalt uplands of Syria, Jordan, Israel, and Taurus[f]
T. dicoccum	Emmer	4x AABB	Tough	Tight	Most favored wheat of the ancient world, widely cultivated, India-Britain
T. durum	Macaroni wheat	4x AABB	Tough	Free	Widely used for pasta, derived from emmer
T. turgidum	Rivet/cone	4x AABB	Tough	Free	Recent (16th C.) species (like *T. polonicum,* 17th C.), derived from macaroni wheat, occasionally branched spikelets
Many other varieties/species		4x AABB	Tough	Free	
T. timopheevii	Timopheevii wheats	4x AAGG	Tough	Free	Group of allotetraploids sharing only 1 genome with emmer and durum wheats; they arose independently in eastern Turkey[g]
T. aestivum	Bread wheat	6x AABBDD	Tough	Free	Major modern cereal crop widely grown; glutin, a sugar, allows yeast to reproduce, thus dough made from this flour rises; must appear after tetraploid wheats (see also *T. spelta*)
T. spelta	Spelt	6x AABBDD	Brittle	Tight	Range in northern Europe, possibly preceded bread wheat,[h] only a relic crop today
No wild hexaploid wheats					
T. speltoides	Goat-faced grasses	2x BB	Brittle	Tight	Probably contributed half the chromosomes of wild emmer
T. tauschii (= *Aegilops squarrosa*)	Goat-faced grasses	2x DD	Brittle	Tight	Contributed glutin and cold-hardiness to crosses with tetraploid wheats, modern distribution Central Asia and Transcaucasia

[a] Ploidy refers to the number of chromosome sets. Diploid plants have 2 sets of chromosomes, whereas tetraploids (4 sets) may arise, as in the case of some wheats, when different diploid plants cross to produce fertile offspring that carry chromosome sets from both parents. Hexaploids (with 6 sets) arise from the crossing of a diploid and tetraploid.

[b] Glumes adhere tightly to grain, protecting it from predators and spoilage. This wild characteristic is not lost until the appearance of free-threshing wheats (with loose glumes easily releasing grains), such as macaroni and bread wheat. Loose glumes apparently were secondarily selected for, since the wheats with this characteristic ultimately derive from glume wheats, such as emmer (Zohary 1971: 240, 243).

[c] Harland and Zohary 1966; Zohary 1971: 239; van Zeist 1988: 54.

[d] van Zeist 1970: 167–72; van Zeist and Bakker-Heeres 1984 (1986): 183–6, 198; Watkins, Baird and Betts 1989: 21.

[e] Harlan and Zohary 1966; Zohary 1971: 239; van Zeist 1988: 54.

[f] Harlan and Zohary 1966; Zohary 1971: 240; Limbrey 1990. One significant advantage of allotetraploidy in plants (chromosome pairs inherited from two ancestor plants) is that the additional genome often increases ecological tolerance in plants so that allotetraploids may occupy the geographic ranges of both parent plants as well as their overlap (Grant 1981).

[g] Lilienfeld 1951: 106, but see Zohary 1971: 241–2.

[h] Zeven (1980: 31) suggests that the expected evolutionary path of wheats would have emmer (a glume wheat) cross with a wild grass (also with tight glumes) to produce spelt wheat: The same wild grass would later cross with durum derived from a mutant emmer strain to produce bread wheat. Mitigating against this scenario is the very early appearance of bread wheat in archaeological sites (Helbaek 1966) and the genetic evidence suggesting that free-threshing characters easily and quickly may become fixed in a population (Zohary and Hopf 1988: 46). Bread wheat probably quickly followed the appearance of hexaploid spelt wheat.

Today Jericho lies at the edge of a spring whose outflow creates an oasis in the arid summer landscape of the Jordan Valley. This alluvial fan, created by winter streams flowing from the Judean hills, nourishes palms and summer crops in the midst of a shrubby wasteland, but the area looked different during the Early Neolithic. Most of the sediment accumulated around the site of the early farming village at Jericho has washed downslope since the Neolithic (Bar-Yosef 1986: 161), perhaps because the shady glades of wild trees – pistachio, fig, almond, olive, and pear (Western 1971: 36, 38; 1983) – were stripped from the surrounding hillsides thousands of years ago. The Neolithic inhabitants planted some of the earliest wheat ever farmed, and they depended on the supplemental water provided by the spring and flowing winter streams to ensure their harvests.

The farmers at Jericho necessarily managed water: Floods frequently threatened to damage their habitations and storage areas. They built terrace walls and dug ditches to divert the flow (Bar-Yosef 1986: 161; compare Kenyon 1979: 26–7) from their small round and lozenge-shaped houses with their cobble bases and mud-brick walls (Kenyon 1981: 220–1). Their apparent choice of supplementally watered land to grow wheat was unprecedented, for wild wheats had hitherto thrived on dry slopes at the edge of Mediterranean forest (Limbrey 1990: 46, 48).

The only other site that has yielded domesticated wheat from the same general era as Jericho is the site of Tell Aswad about 25 kilometers southeast of Damascus, Syria (Contenson et al. 1979; Contenson 1985). In the earliest midden layers of this prehistoric settlement, along the margins of a now-dried lake, archaeologists recovered domesticated emmer wheat along with barley and domesticated legumes such as lentils and peas. Any former dwellings had long since been destroyed, perhaps because structures consisted largely of wattle (from reeds) and daub (Contenson et al. 1979: 153–5).

Today Tell Aswad lies outside the green Damascus oasis on a dusty, treeless plain occupied by the modern international airport, but its former setting was quite different. We know from charred seeds of marshy plants, historical accounts of the environment (van Zeist in Contenson et al. 1979: 167–8), and pollen studies (Leroi-Gourhan in Contenson et al. 1979: 170) that the lake once adjacent to the site was much larger; in addition, there were many wild trees adapted to a semiarid Mediterranean forest-steppe (pistachios, figs, and almonds). Pollen of species such as myrtle and buckthorn (*Rhamnus* spp.) may indicate rainfall greater than the annual 200 millimeters today (Leroi-Gourhan in Contenson et al. 1979: 170). Under wetter conditions, farmers were probably able to grow wheat and other crops. When it was drier, they probably used the extra moisture afforded by the lake and autumn flooding to grow wheats beside the lake shores.

Tell Aswad and Jericho are critical sites in the history of wheat agriculture. To be sure, we cannot be certain that the farmers who settled at the edge of Lake Ateibe (Tell Aswad) and near the spring feeding into the Jordan Valley at Jericho were the first people ever to grow domesticated wheat because archaeologists will never know for certain if earlier evidence awaits discovery elsewhere.

It is interesting to note, however, that contemporary evidence in adjacent regions suggests that people had not domesticated plants by 8000 B.C. In the Nile Valley of Egypt, for example, farming appears much later, around 5000 B.C. (Wenke 1989: 136), and in northern Syria on such early settlements as Tell Mureybet, people exploited wild, not domesticated, wheats and rye (van Zeist 1970: 167–72; van Zeist and Bakker-Heeres 1984: 183–6, 198; Hillman et al. 1993: 106). Recent research in the Taurus Mountains of southeastern Turkey has focused on early settled communities that apparently were not intensively exploiting wild or domesticated cereals (Rosenberg et al. 1995). Southern Mesopotamia, where the first cities emerged, saw agricultural settlements only in later times (Adams 1981: 54), and the surrounding mountains continued to support pastoralists and hunter-gatherers long after farming appeared in the southern Levant.

Botanical Evidence

Taxonomy

Botanical and ecological evidence for the domestication of wheat and its differentiation into many species also partially contributes to an understanding of where and when the first domestication occurred. Many different morphological forms of wheat appear in the archaeological record, even as early as the Neolithic deposits at Jericho, Tell Aswad, and Tell Mureybet along the northern Euphrates River (van Zeist 1970: 167–72; van Zeist and Bakker-Heeres 1984: 183–6, 198). The different forms of wild and domesticated wheats are of incalculable value to archaeologist and botanist alike, for these different plants that can be distinguished from archaeological contexts allow botanists and ecologists to identify wild and domesticated species and the conditions under which they must have grown.

The forms recognized archaeologically, moreover, may not always conform to wheat classification schemes used by modern breeders and geneticists. Wheat classification is complex and confusing, for hundreds of varieties have appeared as wheat farming spread around the world. Although many different kinds of wheat can be readily distinguished by their morphological characteristics (such as red or black awns, hairy glume keels, spikelet density), other varieties can cross-fertilize to combine characters in a perplexing array of new plants. The great variability in the visible characteristics of wheats has led to confusion over how to classify different species – a term employed in its strictest sense to describe reproductively isolated organisms (Mayr 1942; Baker 1970: 50–1, 65–6). In the case of wheat, many botanists commonly accept as distinct species morphologically distinct types that can readily cross to form fertile hybrids with other so-called species (Zohary 1971: 238).

Because botanists rely on both morphological and genetic characteristics to identify different wheats, classificatory schemes (of which many exist, for example, Percival 1921; Schiemann 1948; Morris and Sears 1967; Löve 1982) must take both aspects into account (Zohary 1971: 236–7; but compare Baker 1970). Using morphological traits, taxonomists originally split wild and cultivated wheats into at least a dozen different taxa, many of which are highly interfertile. Geneticists, however, maintain that all domesticated wheats belong to four major groups that produce only sterile crosses; furthermore, they include the wild grass genus, *Aegilops,* in the *Triticum* genus, since several taxa of wild *Aegilops* contributed chromosome sets (genomes) to domesticated wheats by crossing with wild wheat plants (Zohary 1971: 236).

Many of the wheats distinguished by taxonomists, however, lose their identifying genetic signatures when charred, abraded, and preserved for thousands of years in archaeological sites. Because fragile genetic material only recently has been demonstrated to have survived this process (Brown et al. 1993), morphological features that can be used to distinguish different wheat types have made traditional taxonomic schemes (based on morphology) of great value to archaeologists. Furthermore, some of the major behavioral characteristics of cultivated and wild wheats do have morphological correlates that endure in the archaeological record. These features also reflect significant events in the domestication of wheat (Figure II.A.10.1).

The most significant of these morphological features is rachis (segmented stem) durability. Wild wheats and wild *Aegilops,* a morphologically distinct grass genus with species capable of crossing with many wheats, have a rachis capable of shattering, once the grains have matured, into pieces bearing one or two grains. These pieces, or spikelets, taper at their bases and carry stiff hairs that act as barbs to facilitate the spikelets' entry into cracks in the soil. In wild wheats, grains are tightly enclosed in tough glumes that protect them from predation.

In domesticated wheats, these features vanish. The rachis fails to shatter when ripe, a feature particularly important to humans who harvest using sickles – the tools introduced by Natufian and early Neolithic groups (Hillman and Davies 1990: 172–7) (Figure II.A.10.2). In the relatively pure stands of wild wheats, at the margins of Mediterranean oak forests where agriculture began, harvesting methods would fundamentally affect the domestication process (Harlan

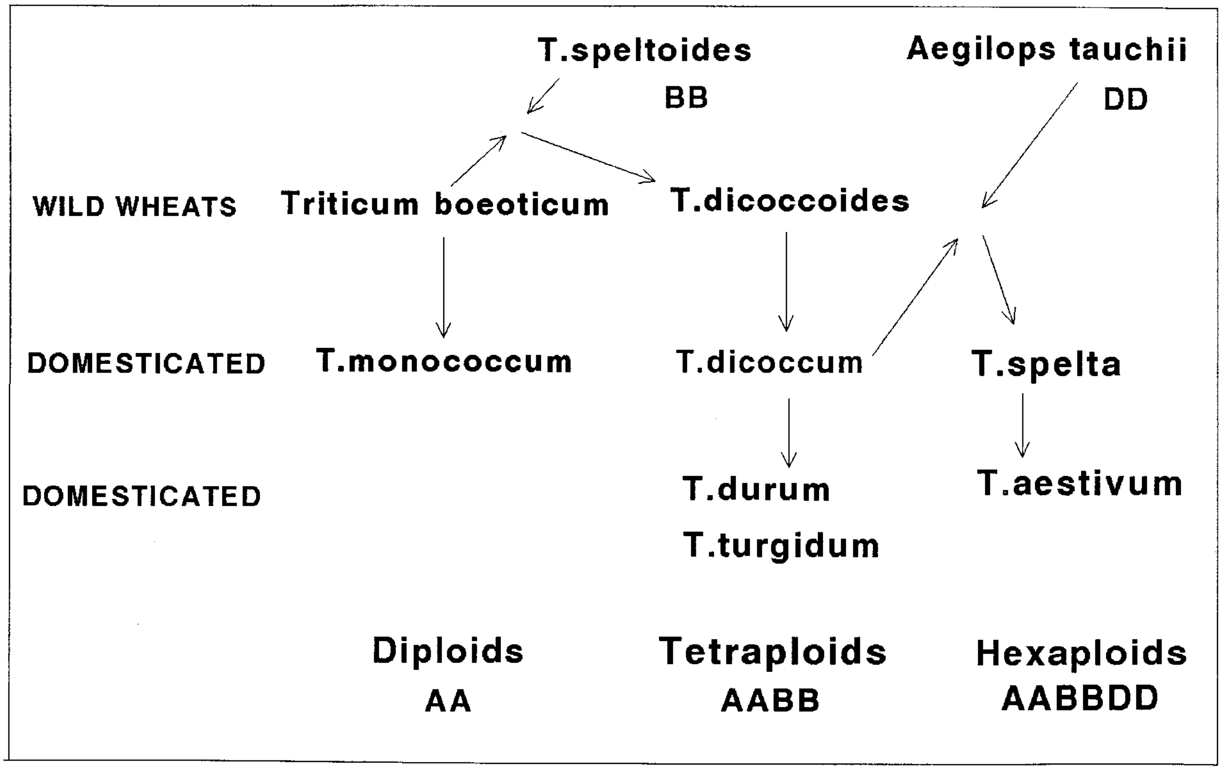

Figure II.A.10.1. Related wheats and goat-faced grasses. (After Zohary 1970b: 241; Hillman, personal communication, 1984).

1967, 1989; Bohrer 1972; Wilke et al. 1972: 205; Hillman and Davies 1990: 172–7). Harvesters use fairly violent motions when equipped with sickles or when uprooting plants to harvest straw and seed. These methods tend to shatter ripe ears, leaving for collection either immature seed (unfit for germination the following year if replanted) or relatively rare genetic mutants with tough rachises. Although these rare plants reproduce poorly in the wild, they are ideal for cultivation, as ripe seed can regenerate if replanted (Helbaek in Braidwood and Howe 1960: 112–13). By unconscious selection (Rindos 1984: 86–9) for a tough rachis gene, harvesters may replace a wild population with a domesticated one in as few as 20 to 30 years (Hillman and Davies 1990: 189).

Wild and domesticated cereals often can be distinguished when examining rachis fragments in archaeological plant remains (for example, Bar-Yosef and Kislev 1986; Kislev, Bar Yosef, and Gopher 1986: 198–9; compare Bar-Yosef and Belfer-Cohen 1992: 37–8). The earliest known domesticated wheats from Tell Aswad exhibit tough rachises (van Zeist and Bakker-Heeres 1982: 192–6). At the same period, the wheats intensively harvested along the Middle Euphrates River at Tell Mureybet (van Zeist 1970: 167–72; van Zeist and Bakker-Heeres 1984: 183–6, 198) and in northern Mesopotamia at the site of Qeremez Dere (Watkins, Baird, and Betts 1989: 21) remained wild, perhaps partly because of a harvesting technique that favored the proliferation of brittle-rachis types in the population. For example, beating wild grass heads over baskets to collect seed was a technique widely employed in many parts of the world where no domestication occurred (Bohrer 1972: 145–7; Wilke et al. 1972: 205–6; Harlan 1989; Nabhan 1989: 112–18). Although baskets and wooden beaters have a low probability of surviving in archaeological sites in the Near East, the remarkable paucity of sickle blades at Tell Mureybet (Cauvin 1974: 59) would support a suggestion that people may have harvested wild cereals by a different method from that used at Jericho and Tell Aswad, where sickle blades are more common.

Cytogenetic Evidence

The results of modern genetic studies have also contributed incomparably to disentangling the history of domesticated wheat. In an effort to improve modern strains of bread wheat and to discover new genetic combinations, biologists have compared the genetic signatures of different varieties, types, and species of wheats. Genetic differences and similarities have allowed specialists to trace relationships among various forms of wild and domesticated wheats and to determine which wild wheats were ancestral to domesticates.

All of the relationships described in Figure II.A.10.1 and Table II.A.10.2 have been confirmed by genetic tests (Zohary 1989: 359). Of particular importance to domestication, the work of H. Kihara has largely defined the cytogenetic relationships between emmer, durum, and hexaploid wheats (Lilienfeld 1951). Domesticated emmer wheat shares close genetic affinities with its wild progenitor *(Triticum dicoccoides = Triticum turgidum* subsp. *dicoccoides)* and is largely a product of unconscious human selection for a tough rachis. Durum wheats and rivet wheats likewise received their 2 chromosome sets from wild emmer (Zohary 1971: 239) and probably are secondarily derived from domesticated emmer through selection for free-threshing characteristics, larger seeds, and various ecological tolerances (for example, Percival 1921: 207, 230–1, 241–3).

Hexaploid wheats, which belong in a single cytogenetic taxon (Zohary 1971: 238; Zohary and Hopf 1993: 24), have no wild hexaploid ancestors: They emerged as a result of a cross between domesticated tetraploid wheats (which may or may not have been free-threshing) and a wild grass native to continental and temperate climates of central Asia (Zohary and Hopf 1988: 46). This implies that hexaploid wheats emerged only when tetraploid wheats spread from the Mediterranean environment to which they were adapted. From archaeological evidence of the spread of farming, one assumes that hexaploid wheats appeared after 7500 B.C.[3] True bread wheats with loose glumes probably came from spelt ancestors, but only two slight genetic changes produce loose glumes (Zohary and Hopf 1988: 46), implying that the mutations may occur easily and become rapidly fixed in a domesticated population.

Cytogenetic studies also have suggested that domestication occurred in only one population of wild wheats, from which all modern conspecific cultigens (of the same species) are derived. All the varieties and species of tetraploid wheats have the same basic genetic constitution as wild emmer wheat (AABB genomes)[4] rather than timopheevii wheat (AAGG). This indicates that if multiple domestications had occurred, timopheevii wheat, which is morphologically indistinguishable from wild emmer, would have been systematically ignored. A more parsimonious explanation is that of Daniel Zohary (1989: 369), who suggests that emmer wheat was domesticated once and passed from farming community to community (see also Runnels and van Andel 1988). Archaeological evidence on Crete and in Greece (Barker 1985: 63–5) indicates that fully domesticated wheats were introduced to Europe from the Near East (Kislev 1984: 63–5). An alternative hypothesis – that hunter-gatherers in Europe independently domesticated emmer and einkorn from native wild grasses (Dennell 1983: 163) – has little supporting evidence. Botanists using cytogenetic evidence, however, may more easily recognize evidence for single domestication than for multiple events, genetic traces of which can be obscured by other biological and historical processes (Blumler 1992: 99, 105).

Ecology of Wheats

Perhaps it will never be possible to determine unequivocally whether wheat species were domesticated in one place or in several locations. Nevertheless, the ecological constraints limiting the growth of different species, varieties, and forms of wild and domesticated wheats narrow greatly the possibilities of where and under what ecological circumstances wheat may have been domesticated. Ecological constraints have been examined both on a macro and micro scale, and both scales contribute significantly to our understanding of wheat domestication.

On a macro scale, the geographic distributions of discrete species or varieties of wild wheats provide ecological ranges within which, or indeed adjacent to which, researchers locate wheat domestication and the origins of agriculture (Harlan and Zohary 1966) (Maps II.A.10.3–5). Using modern wild wheat distributions, botanists and archaeologists have singled out the southern Levant and Taurus range as the most likely source of domesticated emmer and einkorn (Harlan and Zohary 1966; Zohary 1971: 239–42), although bread wheats may have quickly evolved from spelt wheat somewhere in the Caspian region (Zohary 1971: 244; Zeven 1980: 32). Timopheevii wheats represent merely a later independent domestication of tetraploids in eastern Anatolia and Georgia. The conclusions of Vavilov, Braidwood, Flannery, Harlan, and D. Zohary depend greatly on modern geographical distributions of wild wheats.

Nevertheless, a serious problem in using the modern ranges of wild wheats is the assumption that these ranges reflect the former natural extent of wild species. In the past 10,000 years in the Near East, climates as well as human land use patterns have fluctuated. Grazing, deforestation, and suppression of natural forest fires have had a profound effect on vegetation (Naveh and Dan 1973; Naveh 1974; Le Houérou 1981; Zohary 1983), altering not only plant distributions but the character of entire vegetation zones (McCorriston 1992).

Water, light, and soil properties determine growth on a local scale within the geographic ranges of wheats. Wheat plants, like many other crops, require land free of competition from established plants that tap water and block light and where the seed may embed itself in the earth before ants or other predators discover it (Hillman and Davies 1990: 164; Limbrey 1990: 46).

Truly wild einkorn and emmer typically thrive on the open slopes at the margins of scrub-oak forests: They are poor competitors in nitrogen-rich soils typical of weedy habitats, such as field margins, habitation sites, and animal pens (Hillman and Davies 1990: 159, 160; Hillman 1991; McCorriston 1992: 217; compare Blumler and Byrne 1991). These latter sites readily support domesticated glume wheats (emmer and einkorn). Their wild relatives prefer clay soils forming on "basalt or other base-rich fine-grained rocks and sediments under warm climates with a marked dry season" (Limbrey 1990: 46). Indeed, some evidence suggests that wild wheats were first harvested from such soils (Unger-Hamilton 1989: 100; Limbrey 1990: 46).

Early farming sites like Jericho, Tell Aswad, and Mureybet, however, were located beside alluvial soils in regions of low rainfall where supplemental watering from seasonal flooding and high water tables would have greatly enhanced the probability that a wheat crop would survive in any given year. If the wild wheats originally were confined to the upland basaltic soils, they must have been deliberately moved to alluvial fields in the first stages of domestication (Sherratt 1980: 314–15; McCorriston 1992: 213–24; compare Hillman and Davies 1990). Removal of a plant from its primary habitat often causes a genetic bottleneck (Lewis 1962; Grant 1981) whereby the newly established population is fairly homogeneous because its genetic ancestry comes from only a few plants. This tends greatly to facilitate domestication (Ladizinsky 1985: 196–7; Hillman and Davies 1990: 177–81).

The Spread of Domesticated Wheats from the Near East

Deliberate planting of wheat in new habitats (supplementally watered alluvial soils) is one of only a few known events in the earliest spread of wheat farming. Archaeologists understand very poorly the processes and constraints that led to the spread of wheat into different environments and regions of the Near East. They understand far better the spread of agriculture in Europe because of research priorities set by Childe and other Western archaeologists who identified the arrival of domesticated wheat in Europe around 6000 B.C. (Barker 1985: 64; Zohary and Hopf 1988: 191) as an event of critical significance in the history of humankind (viewed from a European perspective).

Thus, in contrast with the Near East, in Europe the process of transition from different styles of hunting and gathering to a predominantly agricultural economy and the adaptation of crops such as wheat to new environments has received intense archaeological and theoretical consideration. The progress of Neolithic settlement across the plains of Greece and Italy, up the Balkans and into the river basins of central and eastern Europe, across the forested lands, and into the low countries encompasses many regional archaeologies and localized theoretical explanations. Wheat accompanied the Neolithic nearly everywhere in Europe, although by the time farming took hold in Britain around 3500 B.C., the cultivated varieties of einkorn, emmer, and spelt must have tolerated colder and longer winters, longer daylight during the ripening season, and greatly different seasonal rainfall than that of the Mediterranean lands from which the crops originated.

Wheat also spread out of the Near East to Africa, where it could be found in northern Egypt after 5000 B.C. (Wenke 1989: 136; Wetterstrom 1993: 203–13). With other introduced crops, wheat fueled the emergence of cultural complexity and replaced any indigenous attempts at agriculture initiated in subtropical arid lands to the south (Close and Wendorf 1992: 69). Because most wheats require cool winters with plentiful rain, the plant never spread widely in tropical climates where excessive moisture during growing and ripening seasons inhibits growth and spurs disease (Lamb 1967: 199; Purseglove 1985: 293). But the grain also spread to South Asia where as early as 4000 B.C. hexaploid wheats were cultivated at the Neolithic site of Mehrgarh (Pakistan) (Costantini 1981). By the third millennium B.C., the Indus Valley civilization, city-states in Mesopotamia, and dynastic Egypt all depended on domesticated wheat and other cereals.

In the sixteenth century, colonists from the Old World brought wheat to the New World: The Spanish introduced it to Argentina, Chile, and California where the cereal flourished in climates and soils that closely resembled the lands where it already had been grown for thousands of years (Crosby 1986; Aschmann 1991: 33–5). The political and social dominance of European imperialists in these new lands and the long history of wheat farming in the Old World – where crop and weeds had adapted to a wide range of temperature, light, and rainfall conditions (Crosby 1986) – largely accounts for the fact that wheat is one of the world's most significant crops today. Its domestication is a continuing process, with yearly genetic improvements of different strains through breeding and new gene-splicing techniques (Heyne and Smith 1967).

Summary

Botanical and archaeological evidence for wheat domestication constitutes one of the most comprehensive case studies in the origins of agriculture. Some of the issues discussed in this chapter remain unresolved. For many of the domesticated wheats, including the primitive first wheats (einkorn and emmer), the integration of botanical and archaeological evidence indicates where and approximately when people entered into the mutualistic relationship that domesticated both humans and their wheats. Less is understood about the origins of hexaploid wheats, largely because the results of archaeological investigations in central Asia have long been inaccessible to Western prehistorians.[5] From botanical studies, however, we can (1) trace the wild ancestors of modern wheats, (2) suggest that isolated events led to the domestication of each species, and (3) reconstruct the environmental constraints within which the first farmers planted and reaped.

Yet, some debate still continues over the question of how wheat was domesticated. Did people in many communities independently select easily harvested plants from weedy wild emmer growing on their dump heaps (Blumler and Byrne 1991)? Or did they, as most believe, deliberately harvest and sow fully wild wheats and in the process domesticate them (Unger-Hamilton 1989; Hillman and Davies 1990; Anderson-Gerfaud, Deraprahamian, and Willcox 1991: 217)? Related questions, of course, follow: Did this latter process happen once or often, and did the first true farmers move these wild plants to seasonally flooded or supplementally watered soils as part of the domestication process?

Scholars also continue to discuss why people began to domesticate wheat in the first place some 10,000 years ago as part of the larger question of the origins of agriculture. Although most agree that many factors were involved in the Near East and that they converged at the end of the Pleistocene, there is no agreement about which factor or combination of factors was most important (for example, Graber 1992; Hole and McCorriston 1992). But because there are no written Neolithic versions of the original crop plants (compare Hodder 1990: 20–1), it is up to us – at the interdisciplinary junction of archaeology and botany – to continue to reconstruct this evolutionary and cultural process in human history.

Joy McCorriston

Endnotes

1. This review is summarily brief; for more thorough treatment, the reader should consult other sources, especially G. Wright 1971, Henry 1989, and Watson 1991. As theoretical explanations for domestication of wheats and barley overlap considerably, both are discussed in this chapter.
2. Neolithic dates are generally quoted as uncorrected radiocarbon dates because exact calendar dates are unknown. The basis for radiocarbon dates is a ratio of carbon isotopes in the earth's atmosphere, but this ratio varies at different times. For later periods, analysts correct for the variation in atmospheric carbon isotope ratios by comparing radiocarbon dates with exact dendrochronological (tree-ring) calendrical dates. Unfortunately, the sequence of old timbers necessary for tree-ring dates does not extend back as far as the Neolithic in the Near East, leaving archaeologists without a dendrochronological calibration scale to correct their radiocarbon dates. Although some progress has been made with isotopically dated coral reefs, there are still problems with variation in atmospheric carbon isotope ratios at different periods. Archaeologists should continue to quote uncalibrated dates.
3. This inference is conservatively based on the dates of proven Neolithic (PPNB) wheat farmers in the Taurus mountains and northeastern Syria and Iraq. Although both areas are poorly known archaeologically in the early Neolithic (Pre-pottery period, they fall within the modern range of the wild goat-faced grass *(Aegilops tauschii)*. Since *A. tauschii* contributed genetic tolerance for cold winters (continental and temperate climates) the hexaploid wheats (Zohary, Harlan, and Vardi 1969; Zohary and Hopf 1993: 50), and since hexaploid wheats emerged after the domestication of tetraploids (Zohary and Hopf 1988; 46), the appearance of domesticated emmer in the PPNB (after approximately 7500 B.C.) (van Zeist 1970:10) serves as a *terminus post quem* for the domestication of hexaploid wheats.
4. Kihara defined as a genome "a chromosome set . . . a fundamental genetical [sic] and physiological system whose completeness as to the basic gene content is indispensable for the normal development of gones [the special reproductive cells] in haplo- and zygotes in diplophase" (Lilienfeld 1951: 102). In diploid plants, the genome represents all chromosomes of the plant; in allotetraploids, the genome is derived from the chromosomes of both contributing ancestral plants.
5. A recently initiated research project seeks to clarify agricultural origins in the Caspian region at the site of Jeitun in the Kara Kum desert of Turkmenia (see Harris et al. 1993).

II.B

Roots, Tubers, and Other Starchy Staples

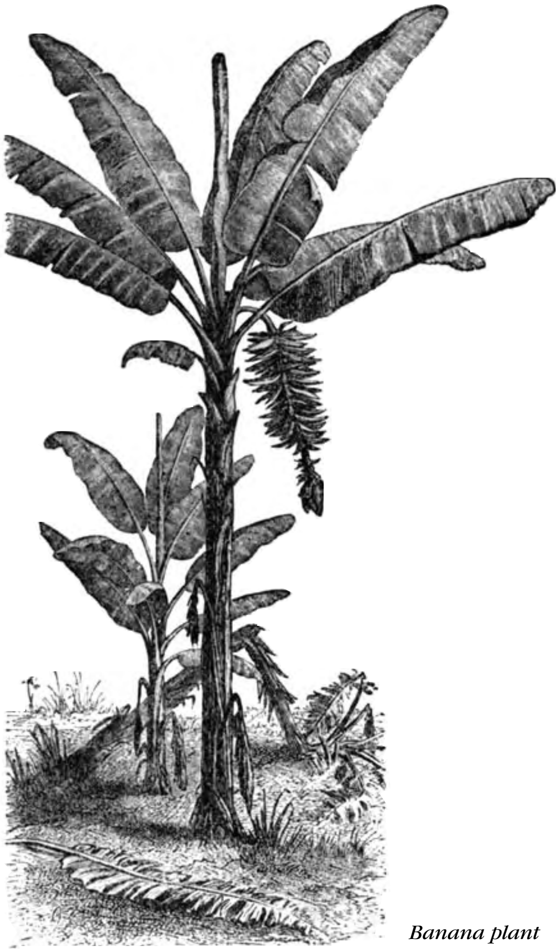
II.B.1 Bananas and Plantains

Bananas represent one of the most important fruit crops, second only to grapes in the volume of world production (Purseglove 1988). J. F. Morton (1987) indicates that bananas are the fourth largest fruit crop after grapes, citrus fruits, and apples. Bananas and plantains are starchy berries produced by hybrids and/or sports of *Musa acuminata* Colla and *Musa balbisiana.* Rare genome contributions from another species may have occurred but are not yet well documented (Simmonds 1986). Additionally, *fe'i* bananas are obtained from *Musa troglodytarum.* Bananas may be differentiated from plantains on the basis of moisture content, with bananas generally averaging 83 percent moisture and plantains 65 percent (but intermediate examples may also be found) (Lessard 1992). Bananas may be eaten raw or cooked. Plantains are usually eaten cooked. Commonly, bananas which are eaten raw are referred to as dessert bananas. Throughout this essay, the term "bananas" is used to refer to both bananas and plantains.

Bananas, being primarily carbohydrates (22.2 to 31.2 percent), are low in fats, cholesterol, and sodium. Potassium levels are high (400 milligrams to 100 grams of pulp). Bananas are also good sources of ascorbic acid, 100 grams providing 13.3 to 26.7 percent of the U.S. RDA (Stover and Simmonds 1987). During ripening, the starch component is gradually converted to simple sugars (fructose, glucose, and sucrose), while the moisture content of the pulp increases. The time of conversion to simple sugars can also be used to differentiate plantains/cooking bananas (later conversion) from bananas that are eaten raw (earlier conversion).

Banana Plants

Bananas are monocarpic (fruiting once, then dying), perennial, giant herbs that usually are propagated via lateral shoots (suckers). Leaves are produced by a single apical meristem, which typically forms only a low short stem or pseudobulb. The leaves are tightly rolled around each other, producing a pseudostem with a heart of young, emerging, rolled leaves ending with the terminal production of a huge inflorescence (usually sterile) and, finally, the starchy fruits: bananas or plantains.



Banana plant

Banana suckers emerge from axillary buds on the pseudobulb, thus providing a means of propagation as the fruits are commonly sterile. Suckers are either left in place as a part of a "mat," which includes the parent plant, or they may be removed for planting at new sites. Within a year after a sucker has been planted at a new site, the flowering stem will emerge at the apex of the pseudostem. The flowering stem will gradually bend over, producing a pendulous inflorescence (except in *fe'i* bananas, which have an erect inflorescence).

At the apical end of the stem are sterile male flowers, protected by large, often reddish, bracts (reduced or modified leaves). Higher up the stem are rows of biseriately (in two series) arranged female (or hermaphroditic) flowers (Masefield et al. 1971). The banana fruits developing from the rows of flowers are commonly called "hands," with the individual fruits called "fingers" (Stover and Simmonds 1987). The entire inflorescence, having matured as fruit, may be called a "bunch."

Climate and Soil

Bananas are almost entirely restricted to largely tropical wet zones of the earth. Practically all banana cultivations fall within 30° latitude north and south of the equator (Simmonds 1966), with most of the large growing areas in the tropics between 20° north and south latitude. Bananas are very susceptible to cold temperatures and to drying environments. Their growth is limited by temperature in areas where water is not limited and by water availability in the warmest climates. A mean monthly temperature of 27° C is optimal, with temperatures below 21° C causing delayed growth (Purseglove 1988). Bananas are found growing under optimal conditions in wet or humid tropics when there are at least eight months per year with a minimum of 75 millimeters of rain per month (Stover and Simmonds 1987). Bananas also grow best under intense sunlight, with shading causing delayed growth, although the fruits may be sunburned, turning black, if exposed to excessive radiation.

Bananas will grow, and even produce fruit, under very poor conditions but will not produce an economically viable crop unless planted in relatively deep, well-drained soil (Morton 1987). Bananas can grow on loam, rocky sand, marl, volcanic ash, sandy clay, and even heavy clay, as long as water is not excessively retained in the soil matrix. Well drained, slightly acidic alluvial soils of river valleys offer optimal edaphic conditions.

General Uses

As already mentioned, banana and plantain fruits may be either cooked or eaten raw. The major usage of bananas is as a starch source for local consumption by tropical traditional cultures. Banana starch may be consumed in a variety of products (see the section on *Cultural Uses*), with the bulk of the consumption consisting of very simple sugars mixed with fibers. The fruits represent significant exports from developing countries, particularly in the Neotropics. Bananas are very susceptible to damage during storage and shipping, which has certainly limited their value as foods imported into temperate, industrialized nations.

Where bananas are locally grown, the nonfruit parts of the plants are employed for a variety of purposes. Banana leaves are commonly used in addition to the fruits, with some varieties producing more desirable leaves than fruits. Fresh banana leaves serve as wrapping material for steamed or cooked foods and also as disposable meal platters. Fresh leaves are used medicinally in Rotuma, Samoa, and Fiji for the treatment of a variety of disorders, including headaches, menstrual cramps, and urinary tract infections. Young, unfolded leaves are employed as topical remedies for chest ailments, and the stem juice is used to treat gonorrhea (Uphof 1968).

Juice from fresh banana leaves occasionally serves as a light brown dye or stain. Because of their 30 to 40 percent tannin content, dried banana peels are used to blacken leather (Morton 1987). Dried leaves may be woven as house screens or be a source of fibrous strings for simple weaving or short-term structure construction. Dried leaves may also be employed to absorb salt water for transport to distant locations, where they are burned to produce a salty ash seasoning. Dried green plantains, ground fine and roasted, have reportedly served as a substitute for coffee (Morton 1987), and banana leaves have even been rolled as cigarette wrappers.

Of growing importance is the use of banana plants and fruits in livestock feed (Stover and Simmonds 1987; Purseglove 1988; Babatunde 1992; Cheeke 1992; Fomunyam 1992) and in shading or intercropping with yams, maize, cocoa, coconuts, areca nuts, and coffee (Stover and Simmonds 1987; Swennen 1990). Livestock are fed either dried and crushed fruits or fresh waste fruits and pseudostems with the leaves. Pigs, cattle, and rabbits have all been fed experimentally with mixtures of bananas and banana waste products. When used for intercropping or shading, bananas serve mainly as shade from intense sunlight for the crop of primary interest, but they also provide an intermediate crop while the farmer is waiting for production of his primary crop: cocoa, coconuts, areca nuts, or coffee.

Leaves of the related species *M. textilis* Nee have been used in and exported from the Philippines as a fiber source in the form of abaca. The abaca fiber is applied to the production of ropes, twines, hats, mats, hammocks, and other products requiring hard, strong fibers (Brown 1951; Purseglove 1988).

Biology

More than 500 varieties of bananas are recognized worldwide, although many of these are probably closely related lineages with differing regional names. Extensive research into the genetics, taxonomy, propagation, and distribution of bananas has been carried out by N. W. Simmonds (1957; 1962) and R. H. Stover (Stover and Simmonds 1987).

Taxonomy

Bananas and plantains have been taxonomically referenced by many different scientific names, including *Musa paradisiaca* L., *M. corniculata* Lour., *M. nana* Lour., and *M. sapientum* L. Each of these names is misleading, giving reference to a variety or group of varieties within a hybrid complex of extensively cultivated clones arising from *M. acuminata* Colla and *M. balbisiana* Colla. Simmonds (1962) suggested that the Latin binomials previously mentioned should all be abandoned and replaced by a designation of the clonal lineage represented by the ploidy (chromosome repetition number) and relative contributions of each of the diploid parent species.

The lineages are represented as groups of varieties/clones that share common ploidy levels and relative proportions of ancestral features (*M. acuminata* represented by "A" and *M. balbisiana* by "B"). Simmonds developed a system of scoring each variety on the basis of 15 characters, noting those characters present from the "A" and "B" parents. Additionally, many nonancestral (derived) somatic mutations have been identified, and these can be employed to differentiate the lineages of hybrids/autopolyploids (Stover and Simmonds 1987). It is possible that future systematic studies of bananas will use these ancestral and derived features as plesiomorphic (ancestral) and apomorphic (unique or derived) characters in cladistic and phenetic determinations of the relationships of banana cultivars.

Simmonds's designations are applied as follows for the common bananas with some examples of varieties within each group:

Group AA: Varieties 'Nino', 'Paka', 'Pisang lin', 'Sucrier', and 'Thousand Fingers'. These are primitive diploids found in Malesia, New Guinea, the Philippines, and East Africa.

Group AB: Varieties 'Ney Poovan' and some 'Lady's Fingers'. These diploid hybrids from India are of minor importance.

Group AAA: Varieties 'Cavendish', 'Dwarf Cavendish', 'Gros Michel', 'Highgate', and 'Robusta'. These varieties consist of African and Malesian triploids, which were important in the initial development of the commercial banana trade (mainly 'Gros Michel'), and remain important in much of the present trade ('Dwarf Cavendish').

Group AAB: Varieties 'Ae Ae', 'Apple', 'Brazilian', 'Giant Plantains', 'Hua Moa', 'Red holene', and 'Rhino horn'. These are triploids producing the lower moisture content fruits generally called plantains, which were initially developed in southern India.

Group ABB: Varieties 'ce Cream', 'Kru', 'Orinco', and 'Praying Hands'. These are triploids originating in India, the Philippines, and New Guinea. They are important staples in Southeast Asia, Samoa, and parts of Africa (Purseglove 1988).

Additionally, tetraploid (4 times the base chromosome number) hybrids AAAA, ABBB, AAAB, and AABB have also been produced, but these are presently of little importance. They may, however, become important in the future (Purseglove 1988).

Fe'i bananas (*Musa troglodytarum* L.) differ from other common edible bananas in that they are diploids with erect inflorescences, have red-orange juice, and are not derived from hybrids of sports of *M. acuminata* or *M. balbisiana. Fe'i* bananas are prepared as plantains (cooked), having flesh which is rich orange-yellow to reddish in color.

Propagation

The clonal groups are propagated vegetatively with constant selection for desired traits (fruit elegance, flavor, and so forth, and resistance to diseases such as Panama disease, or to nematodes or corm borers). Of the 500 varieties of bananas that are recognized, about half are diploids, with most of the remainder being triploids (Purseglove 1988). Bananas take from 2 to 6 months or more to produce an inflorescence from a new sucker shoot.

Bananas can reproduce by seeds (in the wild primitive varieties) or, as is primarily the case, by suckers (in most cultivated and wild varieties). The suckers may be removed and planted in new locations to expand the range of the variety. Bananas moved from Malesia to Oceania, Africa, and Central America and the Caribbean by means of transplanted suckers.

Diseases

Bananas are afflicted with diseases caused by fungi, bacteria, and viruses. Fungal diseases include Sigatoka leaf spot, crown rot, anthracnose, pitting disease, brown spot, diamond spot, fusarial wilt (Panama disease), freckle disease, and rust. Bacterial infections include Moko, banana finger rot, and rhizome rot. "Bunchy top" is the only widespread virus that attacks bananas. It is transmitted by an aphid vector and can be controlled with insecticides (Stover and Simmonds 1987).

Bananas are also susceptible to damage from nematodes, insect larvae, and adult insects. Caterpillar defoliators are common but do not usually cause sufficient destruction to impact production levels. Boring worms cause some damage to the pseudostems and rhizomes, but nematodes account for most of the damage to those tissues. Thrips and beetles chew and suck on the pseudostems, fruits, and suckers, leaving unsightly scars that reduce the market value of the fruits. Nematodes can cause significant damage, particularly to the commercial 'Cavendish' varieties. The nematodes will commonly attack plants that have been weakened by other pathogens, such as Sigatoka leaf spot, which promotes rotting of the pseudostem, rhizome, and roots.

Of the pathogens listed, fusarial wilt (Panama disease) and Sigatoka leaf spot have had the greatest impact on both the local and commercial production of bananas. Fusarial wilt wrought devastating losses of bananas in the Neotropics between 1910 and 1955, causing commercial banana producers to switch from the 'Gros Michel' variety to 'Cavendish' varieties, which are more resistant to fusarial wilt. Sigatoka leaf spot involves three closely related fungi that destroy the banana leaves and decrease transportability of the fruits (Stover and Simmonds 1987).

History

The wild ancestors of edible bananas (*M. acuminata* Colla and *M. balbisiana* Colla), except for the *fe'i* bananas, are centered in Malesia, a term that refers to the entire region from Thailand to New Guinea – roughly the main trading area of the Malay mariners. Simmonds (1962) has indicated that probably crosses and/or autopolyploidy of these wild ancestors originally took place in Indochina or the Malay Archipelago. Subspecies of *M. acuminata* have also been transported to locations as distant as Pemba, Hawaii, and Samoa, where they may have contributed to the production of new varieties.

The subspecies *malaccensis* produces edible diploid fruits via parthenocarpy and female sterility. These characters would have been fostered by human selection and vegetative propagation, transforming bananas from jungle weeds into a productive crop (Purseglove 1988). According to Simmonds (1962):

> Edibility arose in subsp. *malaccensis* near the western edge of the range of *M. acuminata,* and, perhaps, in other subspecies independently; male-fertile edible clones were carried to other areas and intercrossed and outcrossed to local wild forms, generating new phenotypes and new structural chromosome combinations in the process; selection retained the best and the most sterile of these, which, under prolonged clonal propagation, accumulated still more structural changes until, finally, total sterility supervened and clonal propagation became obligatory.

Distribution

A Burmese legend relates that humans first realized bananas could be eaten when they observed birds eating them. The common Burmese generic name for bananas is *hnget pyaw,* meaning "the birds told" (Simmonds 1957; Lessard 1992). Fijians tell a story about a young girl whose lover disappeared while holding her hands in farewell. He was replaced by a banana sucker, which grew "hands" of banana "fingers" that represented the outstretched hands of the lost lover (Reed and Hames 1993).

Bananas are thought to have been distributed from western Melanesia into eastern Melanesia, Polynesia, and Micronesia during the time of aboriginal migrations into these areas. Linguistic evidence indicates a common center of origin of some Polynesian or Micronesian banana varieties in Indo-Malaysia. The movements of these varieties can be traced through two dispersals. The first involved movement into the Philippines, then into Micronesia and, eventually, Polynesia. The second dispersal involved movement into Melanesia first, with a secondary dispersal into parts of Polynesia (Guppy 1906). In the later dispersal, seeded varieties and the *fe'i* bananas constituted the initial wave of introduction, followed by successive waves of nonseeded varieties imported from west to east, penetrating into Oceania such that more varieties may be found in western, and fewer in eastern, Oceania. (This is a general trend for the common banana varieties but not for the *fe'i* bananas, which have the greatest diversity in the extreme east of the distribution.)

Bananas may initially have been introduced into Africa by Arab traders who brought the plants from Malaysia. But they may also have arrived earlier with Indonesians who brought the fruit to Madagascar. Or, of course, they could have been introduced even earlier by unknown individuals from unknown sources. Regardless, the plants subsequently spread across tropical Africa from east to west. Simmonds (1957) indicates that the banana entered the Koran as the "tree of paradise." The generic name *Musa* is derived from the Arabic word *mouz,* meaning banana (Purseglove 1988). Linnaeus applied the name *Musa paradisiaca* as a reference to this ancient terminology.

The name "banana" came from the Guinea coast of West Africa and was introduced along with the plant into the Canary Islands by the Portuguese (Purseglove 1988). At least one clone was taken from the Canary Islands to Hispaniola in 1516. Bananas were carried as food for slaves who originated in areas of traditional banana cultivation, and J. W. Purseglove (1988) surmises that 1516 may mark the first introduction of bananas into the Caribbean and tropical America. Alternatively, bananas may have arrived in the Neotropics via the Spanish trade route from the Philippines. The Spaniards used the name *plátano* for bananas, from which the term "plantain" has been derived (Purseglove 1988).

The Economic Importance of Bananas

The secondary centers of banana distribution in Africa, Central America, and the Caribbean have become the greatest consumers and exporters of bananas. Estimates of the total banana production of the world range from 20 to 40 million tons (Simmonds 1966; Stover and Simmonds 1987), with 4 to 5 million tons per year entering international trade (Morton 1987; Purseglove 1988: 376). Africa is the largest producer of bananas, with some sources saying that half of the world's bananas are produced there. But most African bananas are consumed locally, although some are exported to Europe. Ecuador (the world's largest banana exporter), Colombia, Costa Rica, Honduras, Jamaica, and Panama all export bananas to the United States and Europe, whereas the Philippines and Taiwan export bananas to other Asian countries, particularly Japan.

Three-fourths of internationally traded bananas are grown in Central and South America and the Caribbean, with much of this trade controlled by the United Fruit Company and the Standard Fruit Company. The former has enormous land concessions, regional shipping interests, and distribution networks within the United States (Purseglove 1988). United Fruit developed its economic empire beginning in 1874 in Costa Rica, and subsequently expanded throughout the region. The bananas produced were all of the 'Gros Michel' variety until 1947, when because of increasing losses from Panama disease, the 'Robusta' and other disease-resistant varieties began to replace the 'Gros Michel.' Panama disease (causing leaves to wilt and die) and Sigatoka disease (causing decay spots on leaves and either death of the plant or a greatly reduced crop output) are the two major diseases that have limited the international economic potential of bananas and have also driven the study and introduction of various disease-resistant varieties of the fruit. The economic value of bananas in international trade is, however, a secondary consideration; their major importance is in providing basic local nutrition for many rural populations in tropical, Third World countries.

It is interesting to note that both the *fe'i* bananas and the common bananas have attained their greatest agricultural and human importance in areas far removed from their centers of origin. *Fe'i* bananas originated in Melanesia, spreading and diversifying into the central Pacific, and the common bananas originated in Malesia, spreading and diversifying in Africa, Oceania, India, and, most recently, the Neotropics.

Specific Cultural Usages

Southeast Asia

The origin of bananas was probably within the cultures that developed in Malaysia, Indonesia, Thailand, and Burma. These cultures have long traditions of banana usage. Mature fruits are commonly eaten, but in addition, young fruits are pickled and male buds are consumed as a vegetable in Malaysia and Thailand. Sap from the variety 'Pisang klutum' is mixed with soot and used to give a black color to bamboo basketwork in Java. Also in Java, the fruit stems surrounded by the leaf sheaths of the 'Pisang baia' variety are employed in the preparation of a type of sweetmeat (Uphof 1968). Flowers may be removed from the buds and used in curries in Malaysia. Ashes from burned leaves and pseudostems serve as salt in the seasoning of vegetable curries. Banana plants may be placed in the corners of rice fields as protective charms, and Malay women may bathe with a decoction of banana leaves for 15 days after parturition (Morton 1987).

Although Southeast Asia/Malesia is considered to be the origin of the distribution of bananas, it is important to note that bananas never became as important there as they did in parts of Africa, Oceania, and, more recently, the Neotropics, although production of bananas is increasing in Southeast Asia (Morton 1987; Sadik 1988). Such a relative lack of importance is perhaps connected with the presence of two other competing Southeast Asian starch crops: rice and sago. Rice offers a storable starch source with potentially greater stability of production and yield than bananas. Sago palms of the genus *Metroxylon* are present throughout Malesia in the same areas in which bananas may be found. But as sago production drops off and disappears, there is increased dependence upon bananas and increased diversity in some varieties, including the *fe'i* bananas.

Two areas that certainly must have received some of the earliest diffusions of bananas out of Malesia are the Philippines and India. In these areas, banana cultivation became much more important and variations in usage evolved. Filipinos eat not only the cooked or raw fruits of fresh banana but also the flowers. They employ the leaves and sap medicinally and extract fibers from the leaves. Young inflorescences are eaten both boiled as a vegetable and raw in salads (Brown 1951).

Banana fibers are used in the production of ropes and other products that require durability and resistance to saltwater. Fibers from the sheathing leafstalks are employed in the manufacture of a light, transparent cloth known as "agna" (Brown 1951). Wild banana leaves are used extensively as lining for cooking pots and earthen ovens and for wrapping items that are to be sold in markets. The Filipinos have effectively developed the banana as an export crop with up to a half million tons sent yearly to Japan (Morton 1987).

In India, "the banana plant because of its continuous reproduction is regarded by Hindus as a symbol of fertility and prosperity and the leaves and fruits are deposited on doorsteps of houses where marriages are taking place" (Morton 1987). Virtually the entire above-ground portion of the banana plant is eaten in India. The fruits are cooked or eaten raw, with no clear distinction between plantains and bananas. The young flowers are eaten raw or cooked. The pseudostem may be cooked and eaten as a vegetable or may be candied with citric acid and potassium metabisulphite. India is currently the leading producer of bananas in Asia, with virtually the entire crop employed for domestic purposes (Morton 1987).

Africa

In Africa, bananas reach their greatest importance as a starchy food (Purseglove 1988). Throughout African regions where bananas grow, 60 million people (34 percent of the population) derive more than 25 percent of their calories from plantains and bananas (Wilson 1986). Within Africa, many tropical traditional cultures have come to depend heavily upon bananas as a starch source (Sadik 1988). For example, the Buganda in Uganda typically consume 4 to 4.5 kilograms of bananas per person daily. Tanzanians and Ugandans produce large quantities of beer from bananas ripened evenly in pits. These bananas, after becoming partially fermented, are trampled to extract the juice, which is then mixed with sorghum flour and old beer and allowed to ferment for 12 or more hours. The beer is drunk by people of all ages and has become an important part of the diet (Purseglove 1988).

Sweetmeats, made from dried banana slices, serve as famine foods, preserves, and desserts. Flour can be produced from ripe or unripe fruits, and the flowers are employed as an ingredient in confections. Banana flour is sometimes called Guiana arrowroot, a reference to its importance in West Africa (Uphof 1968). The fruits can be used medicinally for children who are intolerant of more complex carbohydrates and for adults with various intestinal complaints (Purseglove 1988). Additionally, banana pseudostem fibers are used as fishing line in parts of West Africa (Morton 1987).

In West Africa, as in many other parts of the world, bananas are grown in compound gardens and in and around village backyards (Swennen 1990). Proximity to the human population allows for harvesting of the unevenly ripening bananas, a few at a time from each bunch, and the human presence wards off birds and other animals that eat the fruits. In this situation, banana plants typically grow on local refuse dumps, which become rich in nutrients from decaying food products. Banana plants growing in rich soils tend to produce larger bunches, which may become so heavy that the plant falls over. Traditional farmers will place one or more prop poles under the base of growing bunches in order to keep the plants upright.

Oceania

Fried or steamed bananas are staples in many Polynesian cultures. Rotumans serve fried bananas as part of meals containing other dishes; alternatively, an entire meal may consist of fried bananas. Banana fruits are frequently grated or pounded, mixed with coconut cream and fruit juices, and served as a thick beverage. Banana bunches are often found hanging at the edges of cookhouses and ceremonial structures in which a celebration is occurring. Hung in a cookhouse, bananas will slowly ripen over a period of days or weeks, allowing for gradual usage of the bunch. Bananas hung for ceremonial feasts and celebrations will be pit ripened (see below) in advance so that the entire bunch may be eaten ripe on the same day.

Many bananas ripen unevenly, with the more basal (usually higher on a pendulous raceme) fruits ripening first. In these cases, the basal bananas will have ripened and fallen off or been eaten before the apical fingers have even begun to ripen. This natural tendency makes it difficult to cut and use an entire bunch of bananas at one time. A traditional method, which is often used in Polynesia (and elsewhere) to promote even ripening and to increase the rate of ripening, is as follows: A pit (approximately 1 to 2 meters deep) is dug in the ground. It is made sufficiently large to hold several bunches of bananas (up to 10 to 15). The pit is lined with leaves, and fires are built in the edges of the pit. Unripened, but mature, banana bunches are cut from the pseudostems and placed in the pit. The bananas are covered with leaves and the fires are stoked to burn slowly. The pit is covered with soil and left for 3 to 7 days. This process both heats the bananas and extracts oxygen from within the pit. When the pit is opened, the bunches of bananas are found to be entirely and uniformly ripened. Perhaps this ripening process occurs because of increased concentrations of the ethylene produced by the earliest ripening bananas. This in turn would speed the ripening of neighboring fingers, and the exclusion of oxygen and insects would prohibit deterioration of the fruits that ripened first (Stover and Simmonds 1987). The speed of the process is increased by the heat generated by the slowly smoldering fires.

The Neotropics

Neotropical tribes, such as the Waimiri Atroari of Brazilian Amazonia, have incorporated bananas into their diets as both food and beverage. Other neotropical traditional cultures have incorporated bananas not only as food but also as medicinals for stomach ulcers, as antiseptics, and as antidiarrheal remedies (Milliken et al. 1992).

As already mentioned, three-quarters of the worldwide production of bananas for international trade is produced in Central and South America and the Caribbean. This trade is extremely important to the local economies in Colombia, Costa Rica, Honduras, Jamaica, and Panama. The significance of bananas in the United States and Europe has been entirely a function of production in the Neotropics.

The United States

Bananas commonly obtained in the United States may be 'Dwarf Cavendish' or 'Gros Michel' varieties or clones closely related to the 'Dwarf Cavendish' (Simmonds 1986). About 12 percent of the world production of bananas involves these AAA cultivars (Stover and Simmonds 1987). The bananas eaten in temperate countries are typically picked prior to ripening of any of the bananas in a bunch. The bunches are broken down into individual "hands" for shipping from the tropics. Bananas are shipped – usually within 24 hours of harvest – in containers that maintain low storage temperatures from 12° C to –25° C. The unripe bananas may be stored for up to 40 days under controlled conditions of cool temperatures and ethylene-free environments. When ripening is desired, the temperature is raised to 14 to 18° C and ethylene gas is sprayed on the bananas, resulting in rapid, uniform ripening in 4 to 8 days (Stover and Simmonds 1987).

II.B.2 Manioc

A tropical root crop, manioc is also known as cassava, *mandioca, aipim,* the tapioca plant, and *yuca.* The term cassava comes from the Arawak word *kasabi,* whereas the Caribs called the plant *yuca* (Jones 1959). The word manioc, however, is from *maniot* in the Tupí language of coastal Brazil; *mandioca* derives from *Mani-óca,* or the house of Mani, the Indian woman from whose body grew the manioc plant, according to Indian legends collected in Brazil (Cascudo 1984). Domesticated in Brazil before 1500, *Manihot esculenta* (Crantz), formerly termed *Manihot utilissima,* is a member of the spurge family (Euphorbiaceae), which includes the rubber bean and the castor bean (Cock 1985).

The manioc plant is a perennial woody shrub that reaches 5 to 12 feet in height, with leaves of 5 to 7 lobes that grow toward the end of the branches. The leaves are edible and may be cooked like spinach, but in terms of food, the most significant part of the plant is its starchy roots, which often reach 1 to 2 feet in length and 2 to 6 inches in diameter. Several roots radiate like spokes in a wheel from the stem, and each plant may yield up to 8 kilograms of roots (Jones 1959; Cock 1985; Toussaint-Samat 1992).

There are two principal varieties of manioc – the sweet and the bitter. The sweet varieties have a shorter growing season, can be harvested in 6 to 9 months, and then can simply be peeled and eaten as a vegetable without further processing. If not harvested soon after maturity, however, sweet manioc deteriorates rapidly. The bitter varieties require 12 to 18 months to mature but will not spoil if left unharvested for several months. Thus, people can harvest them at their leisure. The main disadvantage to the bitter varieties is that they may contain high levels of cyanogenic glycosides, which can cause prussic-acid poisoning if the roots are not processed properly (Jones 1959; Johns 1990).

An obvious question is that given the threat of poisoning, why would Amerindians have domesticated such a plant? The answer lies in its many advantages. It is a crop that does well in the lowland tropics where there is a warm, moist climate and no frost, although there are "cold-tolerant varieties" of the plant in the Andes (Cock 1985). In addition, manioc yields good results on soils of low fertility, and it will also tolerate acidic soils more readily than other food staples. One of the most important characteristics of manioc, however, is its ability to survive natural disasters, such as droughts. When other food crops dry up, people survive on manioc roots. Similarly, where storms frequently sweep the land, high winds do not kill the roots, even if they damage the foliage. New shoots soon form, while the roots continue to nourish people and prevent starvation.

Manioc roots are also resistant to locust plagues (an important consideration in Africa) and to destructive predators, such as wild pigs, baboons, and porcupines (Johns 1990). Once processed, manioc can be preserved and stored in a tropical climate as *farinha* (manioc meal) or as a bread (*pan de tierra caliente,* as it was called by late colonial Mexicans [Humboldt 1811]). To produce more manioc plants, farmers do not have to set aside edible roots; instead, they use stem cuttings or seeds to propagate the plant (Cock 1985).

As a food, manioc is very versatile because it can be boiled in a mush, roasted, baked, and even consumed as a pudding (tapioca) or alcoholic beverage (Aguiar 1982). When fresh, the manioc root is primarily a starch, a source of carbohydrates. But the leaf has protein and vitamin A, and the fresh roots may contain calcium, vitamin C, thiamine, riboflavin, and niacin. However, the nutritional value of the roots varies with processing, as vitamins may be leached, and even destroyed, when they are soaked and boiled (Jones 1959). Thus, as a rule, manioc must be supplemented with other foodstuffs in order for a population to avoid malnutrition. In many parts of the world, especially Asia, it also serves as an animal feed.

William Jones (1959: 29) has observed that modern methods for processing manioc roots derive from Indian methods. In order to consume the bitter varieties, they had to detoxify the plant by grating and soaking it to remove the toxic chemicals (Johns 1990). To prepare the coarse meal, known as *farinha de mandioca* (also *farinha de pau*) in Brazil, women, who traditionally process manioc in Amerindian societies, have to wash, peel, and scrape the roots. Some prehistoric populations in South America and the Caribbean even used their upper front teeth in processing manioc.

Using a flat piece of wood studded with small pointed stones as a grater, women convert the roots into a snowy white mass, which is then placed in a *tipiti,* a long cylindrical basket press similar to a Chinese "finger trap." The two ends of the *tipiti* are pulled apart, with one end tied to the ground and the other to the branch of a tree. After the excess liquid has been squeezed out, the pulpy mass is removed, put through a sieve, and then placed on a flat ceramic griddle or metal basin where it is toasted over a low fire. The *farinha* can be kept for months and then eaten dry or mixed with water as a gruel (Jones 1959; de Léry 1990; Toussaint-Samat 1992; and personal observation, Tikuna village, Peru, 1975).

Origins

Although scholars agree that manioc was domesticated in the Americas, there is doubt about the exact location, even though the largest variety of species survive in Brazil. Possible areas of origin include Central America, the Amazon region, and the northeast of Brazil. Milton de Albuquerque (1969), a specialist on manioc in Amazonia, reported that the most primitive form of the plant is found in central Brazil in the state of Goiás, a region subject to prolonged dry seasons, but he believes that the backlands of the state of Bahia are its most probable point of origin. The oldest archaeological records in Brazil, however, come from the Amazon region, where ceramic griddles used in manioc preparation have been found in pre-Columbian sites (Lathrap 1970; Roosevelt 1980).

Of much greater antiquity, however, are remains of the manioc plant that have been discovered in South American excavations in and near the Casma Valley of northern Peru. These have been dated to 1785 B.C. (Langdon 1988). In Mexico, cassava leaves that are 2,500 years old have been found, along with cassava starch in human coprolites that are 2,100 to 2,800 years old (Cock 1985). Preclassic Pacific coast archaeological sites in Mesoamerica have yielded evidence of manioc, which was a staple of the Mayan civilization (Tejada 1979; Morley and Brainerd 1983). The quality of the evidence for manioc in Mesoamerica has led some authors to believe that manioc was first domesticated in Central America rather than Brazil, or that there may have been two regions of origin. Another possibility might be that bitter manioc was domesticated in northern South America, whereas sweet cassava was domesticated in Central America (Cock 1985).

Archaeological evidence for ancient manioc usage also exists in the Caribbean. According to Suzanne Levin (1983: 336), manioc griddles have been found in archaeological excavations in the Lesser Antilles on islands such as St. Kitts, St. Vincent, Antigua, and Martinique. Both the Arawaks and Caribs utilized them, and as they migrated to the islands from South America, they undoubtedly carried with them manioc and the technological knowledge necessary to propagate, cultivate, and process it.

When the Spanish reached the Caribbean and Central America, they discovered the indigenous populations cultivating manioc, a plant they termed *yuca.* Thus, the earliest European description of manioc dates from 1494. In describing the first voyage of

Columbus, Peter Martyr referred to "venomous roots" used in preparing breads (Pynaert 1951). The Portuguese encountered manioc after 1500 on the coast of Brazil. Other sixteenth-century observers, such as the German Hans Staden [1557] (1974) and the Frenchman Jean de Léry [1578] (1990), have left valuable descriptions of what the Brazilians term the most Brazilian of all economic plants because of its close links to the historical evolution of Brazil (Aguiar 1982).

As the Portuguese divided Brazil into captaincies and contested the French for its control, they employed their slaves, both Indian and African, in cultivating food crops, including manioc. Unlike other areas of the Americas, where Europeans refused to adopt Amerindian crops such as amaranth, in sixteenth-century Brazil manioc rapidly became the principal food staple of coastal settlers and their slaves. As the most fertile lands in Pernambuco and the Recôncavo of Bahia were converted to sugar plantations, less prosperous farmers grew manioc on more marginal lands for sale to planters and to people in nearby towns.

When the Dutch invaded Brazil in the seventeenth century, they mastered the Brazilian system of large-scale sugar cultivation, as well as the Brazilian system of food production for plantation slaves, meaning essentially manioc cultivation. After the Dutch were expelled from Brazil in 1654, they carried the Brazilian system to the Caribbean and, henceforth, West Indian planters, such as those on Martinique, "obliged" African slaves to cultivate food crops, including manioc, on their provision grounds (Tomich 1991). Thus, manioc became a part of the slave diet in the Caribbean as in Brazil.

Manioc also enabled fugitive slaves living in maroon communities or in *quilombos* in Brazil to survive on marginal lands in remote or difficult terrain. Although descriptions of manioc cultivation in *quilombos* have usually surfaced in Brazilian records only upon the destruction of *quilombos,* such as Palmares (*Relação das guerras feitas aos Palmares* . . . [1675–1678] 1988), Richard Price (1991) has been able to document the cultivation of manioc over two hundred years by the Saramaka maroons of Suriname and their descendants. They raised it in the 1770s as well as in the 1970s (Price 1991).

Manioc, which was closely linked to plantation slavery in the Americas, was also the food staple that enabled the conquest of the tropics. In the pre-Columbian period, a bread made from manioc permitted long-distance trade and exploration in South America as well as lengthy war expeditions. During the European conquest, the Spanish and Portuguese forces in the tropics rapidly adopted manioc bread. Later, rations were doled out to troops fighting the frontier wars of tropical Latin America, and even in twentieth-century Brazil, military forces received "farinha de guerra" (war meal) to sustain them in their garrisons (Cascudo 1984). The *Bandeirantes* from São Paulo, who explored Brazil's vast interior and discovered gold in the late seventeenth century, were able to do so because of manioc. The Guaraní Indians they pursued and often enslaved in Paraguay also raised manioc (as their ancestors had done for millennia) in the Jesuit missions that gave them refuge (Reff 1998).

In addition to slaves, maroons, soldiers, and explorers, free peasants also subsisted on manioc in Brazil, existing on the margins of plantation society and in the interior. In cultivating manioc for their own subsistence, they frequently produced a surplus, which they sold to planters and to townspeople. Often black and mulatto dependents *(agregados)* of the great sugar planters, these peasants escaped slavery by raising manioc and marketing it (Karasch 1986). Manioc thus supported the emergence of a free peasantry in the shadow of the Latin American plantation societies.

By the end of the colonial period, manioc had emerged as the principal food staple of the enslaved and impoverished in tropical Latin America and, as such, its cultivation, transportation, and commerce contributed greatly to the internal economy of Latin America. Unfortunately for the Latin Americans, however, manioc did not find a niche in global trade because the Portuguese had long before introduced the plant to the rest of the tropical world.

Africa

From Brazil, the Portuguese carried manioc to their stations along the Upper Guinea coast in West Africa and to the Kingdom of Kongo in northern Angola. Although manioc was not readily adopted in sixteenth-century West Africa, it was successfully introduced into the Kingdom of Kongo in what is now the modern country of Angola. Jones (1959) attributes the success of manioc in central Africa to the close ties between the Portuguese and the BaKongo beginning in the 1480s. An oral tradition with reference to the first Portuguese on the Congo-Angola coastline in the 1480s describes the arrival of "white men" who "brought maize and cassava and groundnuts and tobacco" (Hall 1991: 169).

The first documented reference to manioc comes a century later in 1593 in a letter from Sir Richard Hawkins regarding the seizure of a Portuguese ship engaged in the slave trade. Its cargo was, he reported, "meale of cassavi, which the Portingals call *Farina de Paw* [sic]. It serveth for marchandize in Angola, for the Portingals foode in the ship, and to nourish the negroes which they should carry to the River of Plate" (Jones 1959: 62). Thus, by the late sixteenth century, manioc meal was already an item of trade in Angola, as well as a food for the slaves in transit to the Americas. It would serve as a staple of the slave trade until that trade's effective abolition in the mid-nineteenth century.

By the 1660s, manioc was an important food in northern Angola, according to a pair of Europeans who visited Luanda. Oral traditions from nearby areas stress the borrowing of manioc techniques from the Kingdom of Kongo; its use as a vegetable (the sweet variety?) before the people learned more complex processing techniques; and the crop's resistance to locusts. As Jones notes, the Africans who most enthusiastically adopted manioc were those living in the tropical rain forests of the Congo Basin, rather than the people of the grasslands, where maize, millet, or sorghum were cultivated.

In the Americas, the culture of manioc had been perfected by forest peoples, and in Africa, too, it was the forest peoples who welcomed this addition to their food supply. Clearly, it was an important addition, and more than 300 years later, the people of Zaire and Congo continued to consume manioc at an average of about 1 kilogram per person per day, which would have supplied over 1,000 calories. They also utilized cassava leaves as a source of vegetable protein in sauces and soups (Cock 1985: 10).

In West Africa, however, the cultivation of manioc spread more slowly. First introduced from Brazil to Portuguese Guiné and the island of São Tomé, the root had become an important food crop on São Tomé and the islands of Principe and Fernando Pó by 1700, but it found little acceptance on the mainland until the nineteenth century. At the end of the seventeenth century, William Bosman, a Dutch factor at El Mina (now Ghana), identified the foodstuffs of Liberia, Ghana, Dahomey, and Benin as yams and maize. He also listed millet, rice, sweet potatoes, beans, and groundnuts. Apparently, the Africans had accepted the American crops of corn, beans, and groundnuts but not manioc. As Jones (1959) notes, this may have been because farmers could treat corn as another cereal crop, and sweet potatoes were similar to yams. But another reason is that the complex processing methods required by manioc could only have been mastered through close ties to people familiar with them, and the Portuguese did not have the same kind of colonial relationship with the West African states that they did with Angola.

Extensive manioc cultivation did develop in the early nineteenth century, however, as former slaves returned from Brazil to West Africa. In 1910, for example, a Dahoman chief reported the oral tradition that a returned Brazilian (Francisco Felix da Souza) "had taught the Dahomans how to prepare manioc so they could eat it without becoming ill." Returned ex-slaves from Brazil in the 1840s also spread manioc cultivation in western Nigeria (Ohadike 1981: 389). Thus, Africans who had learned to process manioc into *farinha* while enslaved in Brazil played a key role in instructing those in West Africa how to utilize it. There it became known as *gari* or *garri* (Jones 1959).

The further diffusion of manioc in West Africa in the nineteenth and twentieth centuries was linked to European colonialism. As European labor demands disrupted traditional systems of food production, the colonialists sought new food crops to ward off hunger and famine. Migratory workers also dispersed knowledge of manioc cultivation inland from the coast. D. C. Ohadike (1981) argues that the influenza pandemic of 1918 that disrupted traditional agriculture based on yams contributed to the adoption of manioc in the lower Niger because of widespread hunger. Although the Portuguese had introduced manioc to the Niger Delta centuries earlier (Hall 1991), Africans did not choose to use it until the twentieth century because they preferred to cultivate yams (Ohadike 1981). Manioc is now well established as a staple crop in the wetter regions of West Africa (Cock 1985).

Exactly when Europeans imported manioc into East Africa is less certain. It seems improbable that the Portuguese delayed introducing manioc to their colony of Mozambique until 1750, as the historian Justus Strandes claims (Jones 1959). But if Strandes is correct, then the French may have been first to do it when, around 1736, the French governor, Mahé de la Bourdonnais, had manioc brought from Brazil to the island of Mauritius in the Indian Ocean (Pynaert 1951). Two years later, the French Compagnie des Indes introduced manioc to Réunion, an island near the large island of Madagascar across from Mozambique.

The French also sent manioc plants from Brazil to the French islands near Madagascar, where an initial attempt to plant manioc proved a disaster. Africans there were clearly unfamiliar with bitter manioc. When they tried to eat the fruits of their first harvest, they died of poisoning (Hubert and Dupré 1910). After this tragedy, both the French and Africans learned how to process bitter manioc, and they spread the plant and its processing technology to other small islands near Madagascar. At some point, manioc was also transferred from Réunion to Madagascar, where it became a major staple (Fauchère 1914).

During this period while the French were active in the Indian Ocean, the Portuguese, sometime before 1740, may have introduced manioc along with pineapple and corn to the coast of Tanzania and Kenya. Once established on the East African coast, principally the island of Zanzibar and the town of Mozambique, manioc cultivation progressed inland to the great lakes of Tanganyika and Victoria. In the nineteenth century, manioc plants from the east coast met manioc introduced from the Congo Basin. By that time, manioc cultivation had crossed central Africa from west to east, with Africans rather than European colonialists playing the key role in its diffusion (Jones 1959).

The delay in the introduction of manioc to East Africa until the eighteenth century has been attributed by Jones (1959) to the lack of an intensive colonial presence or to a lack of incentive for its introduction because, before 1800, most East African slaves were exported to Arabia, Persia, or India. Moreover, East Africa lacked dense forests, and much of the terrain was covered with wooded savannah so that environmental conditions were not as propitious as in the Congo basin. Even as late as 1850, Jones (1959: 84) concludes, "manioc was either absent or unimportant in most of East Africa . . . except right along the coast and in the vicinity of Lake Tanganyika." Its cultivation spread thereafter, however, because British and German colonial officers required its planting as a famine reserve – a role it has continued to play to the present day.

Manioc is now cultivated throughout Africa, excluding the desert north and the far south, and its range is still extending, as it is often the only crop that farmers can cultivate under conditions of low soil fertility, drought, and locust plagues. In part, the twentieth-century diffusion of manioc in Africa may be closely connected with recent population growth – but as a consequence, rather than a cause. As more and more people have put pressure on the types of fertile lands suitable for yams, millet, and sorghum, the land-poor have had to turn to manioc to ward off hunger. Thus, if population growth continues, manioc may become even more central than it now is to African economies and diets.

Asia

In addition to diffusing manioc to Africa, Europeans also transported the American crop to Asia, although Polynesians may have also introduced it into the Pacific via Easter Island. The first Asian region to receive manioc from the Europeans was the Philippines (Philippines, 1939). Variously termed *balinghoy, Kamoteng-Kahoy,* or *Kamoteng-moro,* manioc was brought to the Philippines by early Spanish settlers. Apparently, manioc plants traveled via Spanish ships across the Pacific from Mexico. As in West Africa, however, its cultivation grew slowly, and it was noted in the late 1930s that manioc in the Philippines "has not been as extensive as in other tropical countries" (Philippines 1939: 3). It had, however, evolved as a major crop in the Mindanao area of the Philippines by the 1980s (Centro Internacional de Agricultura Tropical [CIAT] 1986).

By the seventeenth century, manioc was found in the Moluccas, and by 1653 was being grown on Ambon, one of the outer islands of Indonesia (Pynaert 1951; CIAT 1986). It is likely that the Portuguese brought it to Goa (India) in the early eighteenth century. Additional plants were imported to India from South America in 1794, and from the West Indies in 1840 (Cock 1985). As of 1740, manioc was being raised on Java, and plants taken from there were introduced to Mauritius (CIAT 1986) shortly after the French brought the first manioc plants from Brazil. Thus, Brazilian plants met varieties evolved in Asia on a small island in the Indian ocean.

Mauritius then served as a distribution point for manioc into Sri Lanka (formerly Ceylon), the island at the tip of India, where the Dutch governor, Willem Jacob van de Graaff, introduced it in 1786. Subsequent importations were recorded in 1821 and 1917, and these, too, were from Mauritius. Since then, manioc has been cultivated by peasants, and it is "consumed mainly by the poorest people" (CIAT 1986: 115).

By 1800, manioc cultivation in tropical Asia stretched from Ceylon to the Philippines. It had not, however, replaced Asia's main staple, rice, although it was becoming "the most important" of the American crops "in terms of volume produced" (CIAT 1986: 171). An upland crop in tropical Asia, manioc has served to supplement inadequate supplies of rice, and it was most widely accepted in the land-scarce regions of Java in Indonesia and Kerala in southern India. As in Africa in the nineteenth century, those who convinced or required the inhabitants to accept this famine reserve were the European colonialists, in this case the Dutch in Java and the British in India (CIAT 1986).

European colonialists were especially active in diffusing manioc cultivation and processing techniques in the nineteenth century. They first established a processing and export industry in Malaya in the 1850s and subsequently developed a trade in tapioca with Europe (Cock 1985). In 1886, the Singapore Botanic Gardens introduced new manioc plants to Malaysia (Cock 1985). The Dutch followed by transporting manioc plants from their South American colony of Suriname to Java in 1854. By the early twentieth century, manioc was flourishing (Pynaert 1951), and its cultivation has continued to expand since then.

By the 1980s, at least one-fourth of all manioc grown in Asia was located in Indonesia, with the greatest share on Java (CIAT 1986). Sometime around 1850, manioc was introduced into Thailand, where it has become very popular in the eastern seaboard provinces. Since 1956 it has spread to the northeastern, western, and upper-central provinces of Thailand (CIAT 1986).

The British played a major role in the diffusion of manioc cultivation in southern India, where it was most widely accepted, especially in Kerala. Apparently it was introduced quite late to Calcutta (1794) and Serampur in 1840 (Pynaert 1951). Since then, manioc has evolved in India as a supplementary food staple. It is often consumed as a traditional steam-cooked breakfast dish called *puttu,* or marketed for *sago* (tapioca pearl), starch, and cattle feed (CIAT 1986). It is also a staple food in parts of Myanmar (formerly Burma) (Cock 1985).

Five hundred years after the Europeans discovered manioc, the yield of this American crop abroad has surpassed yields in its homeland. In 1982, the world's manioc production was estimated at 129 million tons, with Asia and Africa accounting for about three-fourths of this production and Latin America contributing only one-fourth.

In tropical Asia, manioc production was nearly 46 million tons in 1982, half of which came from Thailand. The two other major Asian producers were Indonesia and India (CIAT 1986). All this followed upon two decades of rapid growth in manioc production with a doubling of output during the period. The most rapid increases occurred in Thailand, in part due to exports to the European Economic Community. Although manioc is also grown in southern China, mainly on the dryland slopes of Guangdong province and the Guangxi Zhuang autonomous region, accurate statistics for the People's Republic of China are hard to come by. The primary use of manioc in China, however, appears to be as animal feed, especially for hogs (CIAT 1986). It is also grown in Taiwan (Cock 1985).

The Pacific Islands

The final region of manioc production, at present, is the Pacific Islands. In general, scholars have maintained that manioc was not introduced to the Pacific Islands until the mid-nineteenth century. Robert Langdon, however, suggests a different history of diffusion to Oceania. He has recently reported the discovery of a Spanish manuscript recording the presence of *yuca* (a word used in Peru for manioc) on Easter Island in 1770. Captained by Felipe Gonzalez, the expedition sailed from Peru, to reach Easter Island in late 1770. Those who went ashore observed fields of *yuca* under cultivation as well as sweet potatoes, another American crop.

Obviously, the question that this raises is how manioc had reached an island 2,000 miles from South America, unless it had been carried there by Amerindians before Columbus, as Thor Heyerdahl has long argued. Certainly Langdon (1988: 324) observes that the presence of manioc on Easter Island in 1770 "greatly strengthens the case for prehistoric American Indian influence on Easter Island and other islands of eastern Polynesia." In any case, it seems that manioc has now been documented in the Pacific 80 years before Captain Louis A. Bonard took the plant to Tahiti in 1850, from which it spread rapidly to other Pacific islands, where it is now cultivated (CIAT 1986; Langdon 1988).

Conclusion

From a present-day perspective, the contribution of the American crop, manioc, to the world's food supply has largely been unheralded except by Brazilians, by a few historians such as William Jones in his classic *Manioc in Africa,* and by French officials such as Paul Hubert and Emile Dupré in *Le Manioc,* which provides a global view of manioc cultivation as of 1910. Historians have recognized the historical significance of other American crops that played a major role in European history, but it may well be that manioc's historical impact and diffusion have been slighted because it is a tropical, Third World crop.

Nevertheless, manioc has been as significant to the historical evolution of tropical countries, such as Brazil and Zaire, as the potato has been to that of European countries, such as Ireland and Germany. As world population growth continues into the twenty-first century, manioc may assume an even greater role, enabling the rural poor in developing countries to survive hunger and famine. This versatile food crop, which can overcome drought, survive typhoons and locust plagues, and reproduce on marginal soils, may well make a significant difference in population survival in the tropics in the twenty-first century.

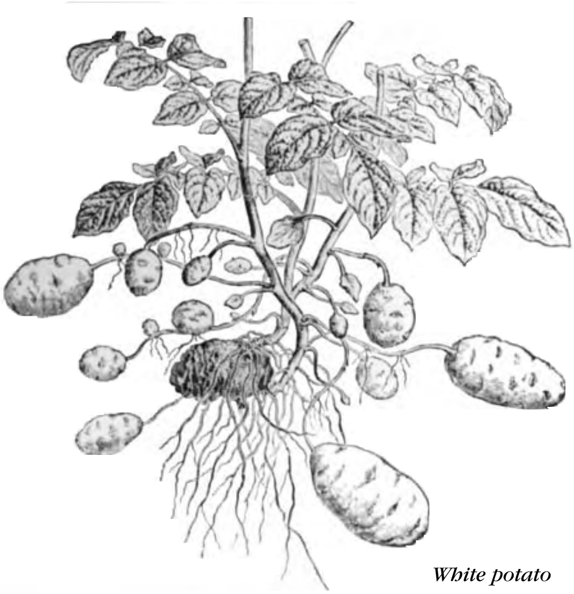
II.B.3 Potatoes (White)

This chapter presents the paradoxical history of the potato *(Solanum tuberosum)* in human food systems. It is now the fourth most important world food crop, surpassed only by wheat, rice, and maize. In five centuries, this diverse and adaptable tuber has spread from its original South American heartland in the high Andes to all elevation zones in temperate regions of all the continents, and, lately, its production has been increasing most rapidly in the warm, humid, tropical Asian lowlands during the dry season (Vander Zaag 1984).

In the course of its history, the potato adapted, and was adopted, as a highland subsistence crop on all continents. In Europe, it was originally an antifamine food but then became a staple. In Africa and Asia, it has been a vegetable or costaple crop. The potato has been credited with fueling the Industrial Revolution in eighteenth-century Europe but blamed for the mid-nineteenth-century Irish famine. Over three centuries, it also became a central and distinctive element of European regional, and then national, cuisines. Although "late blight" has continued to plague those dependent on potatoes for sustenance (CIP 1994), the potato's popularity has nevertheless grown since the end of World War II, particularly in its forms of standardized industrially produced potato fries, chips, and other frozen and processed "convenience" foods. Acceptance of standard fries (with burgers) and packaged chips symbolizes the "globalization of diet," as McDonald's, Pepsico, and other transnational food firms move potatoes around the world yet another time in their successful creation and marketing of a universal taste for these products.



White potato

In addition, the 1972 creation of an International Potato Center (CIP) in Lima, Peru, with its regional networks, has greatly accelerated the introduction of improved potato varieties and supporting technologies throughout the developing world.

R. N. Salaman's monumental volume charted *The History and Social Influence of the Potato* (1949) – a book that was edited and reprinted in 1985 by J. G. Hawkes, who updated archaeological and agronomic histories and then subsequently issued his own study (Hawkes 1990). The archaeological evidence for the origins of potato domestication is still fragmentary (for example, Hawkes 1990). However, collections, characterizations, and taxonomies of both wild and cultivated forms (Ochoa 1962; Huaman 1983; Hawkes and Hjerting 1989) continue to progress and are generating conclusions about evolutionary relationships that can now be tested with additional cytoplasmic and molecular data from crossability trials (Grun 1990). Such conclusions can also be tested by complementary ethnohistorical, social historical, and culinary historical data (Coe 1994).

Recent biological and cultural histories are recounted in several volumes by CIP (CIP 1984; Horton and Fano 1985; Horton 1987; Woolfe 1987), which also issues an *Annual Report* and a *Potato Atlas.* Key breeding and agronomic advances are also reported in *The Potato Journal, American Potato Journal, European Potato Journal, Potato Research, Proceedings of the Potato Association of America,* and reports by the potato marketing boards of major producing countries. All are contributing to worldwide understanding and utilization of potatoes, which exhibit perhaps the greatest amount of biodiversity of any major food crop (Hawkes and Hjerting 1989: 3), with matching cultural diversity in food and nonfood uses.

The Potato in South America: Origins and Diffusion

Cultivated potatoes all belong to one botanical species, *Solanum tuberosum,* but it includes thousands of varieties that vary by size, shape, color, and other sensory characteristics. The potato originated in the South American Andes, but its heartland of wild genetic diversity reaches from Venezuela, Colombia, Ecuador, Peru, Bolivia, Argentina, and Chile across the Pampa and Chaco regions of Argentina, Uruguay, Paraguay, and southern Brazil and northward into Central America, Mexico, and the southwestern United States. There are more than 200 wild potato species in this wide habitat that extends from high cold mountains and plateaus into warmer valleys and subtropical forests and drier semiarid intermontane basins and coastal valleys.

The greatest diversity in wild potato species occurs in the Lake Titicaca region of Peru and Bolivia, where the potato probably was domesticated between 10,000 and 7,000 years ago. *Solanum tuberosum* most likely was domesticated from the wild diploid species *S. stenotomum,* which then hybridized with *S. sparsipilum* or other wild species to form the amphidiploid *S. tuberosum* that evolved from the short-day northern Andean subspecies *andigena,* via additional crosses with wild species, into the subspecies *tuberosum,* which had a more southerly, longer-day distribution (Grun 1990; Hawkes 1990). Frost resistance and additional pest and disease resistance were introduced later via hybridizations with additional wild species, which allowed potatoes to be grown at altitudes up to 4,500 meters.

Archaeological Evidence

Fossilized remains of possibly cultivated tubers found on a cave floor in Chilca Canyon suggest that the potato was cultivated at least from about 7,000 years ago, although it is not possible to tell whether these were wild, "dump heap," or already garden acquisitions (Ugent 1970). Potato remains (along with those of sweet potato and manioc) from Ancon-Chillon (to the north of Lima) date from 4,500 years ago; northern coastal remains from the site of Casma date from between 4,000 and 3,500 years ago (Ugent et al. 1982). It is surmised that cultivated varieties were being planted on terraces at intermediate altitudes, extending from the river valleys into the high mountains, by the middle initial period between 4,000 and 3,500 years ago. Coastal remains from the monumental preceramic site of El Paraiso (3,800 to 3,500 years ago) suggest a mixed subsistence strategy, including unspecified *Solanum* plants that might be potatoes (Quilter et al. 1991).

Art provides additional testimony for the potato's centrality and for the antiquity of processed potatoes in pre-Columbian Andean culture. Fresh and freeze-dried potatoes are depicted in ceramics of the Moche people of northern Peru (A.D. 1 to 600), on urns in Huari or Pacheco styles from the Nazca Valley (650 to 700), and later Chimu-Inca pots (Hawkes 1990). Post-contact-period Inca wooden beakers also depict potato plants and tubers.

South American civilizations and states were based on vertically integrated production and consumption systems that included seed crops (especially maize, secondarily quinoa) at lower altitudes, potatoes and other tubers at higher altitudes, and llamas (camelids) to transport goods between zones. Hillside terracing conserved moisture and soils and encouraged the selection of multiple cultivars of a number of species that fit into closely spaced ecological niches. Ridged, raised, or mounded fields (still used for potato cultivation around Lake Titicaca) were a type of specialized field system that saved moisture and also protected against frost. In addition to making use of short-term storage in the ground, Andean peoples stored potatoes in fresh or processed forms. Huanaco Viejo and other Inca sites reveal extensive tuber storage areas, constructed in naturally cool zones, where indigenous farmers (or their rulers) stored whole tubers with carefully managed temperature, moisture, and diffused light to reduce spoilage (Morris 1981). Traditional freeze-drying techniques took advantage of night frosts, sunny days, and running water at high elevation zones and allowed potatoes to provide nourishment over long distances and multiple years, as dehydrated potatoes moved from higher to lower altitudes, where they were traded for grain and cloth.

Biocultural Evolution

As South American cultivators expanded into many closely spaced microenvironmental niches, they selected for thousands of culturally recognized potato varieties of differing sizes, colors, shapes, and textures, with characteristics that provided adequate resistance to pests, frost, and other stressors. At higher altitudes, cultivators selected for bitter varieties of high alkaloid content that were detoxified and rendered edible by freeze-drying (Johns 1990). Culturally directed genetic diversification continues up to the present, as Andean farmers allow wild specimens to grow and hybridize with cultivars, conserving biodiversity while diffusing risk (Ugent 1970; Brush 1992).

The botanical history of the cultivated potato is slowly being assembled by considering together the findings from plant scientists' genetic and taxonomic studies, archaeologists' interpretations of archaeological and paleobotanical remains, and ethnographers' observations and analogies from contemporary farming, food processing, and storage. Plant scientists continue to explore wild and cultivated habitats in the potato's heartland, where they find wild potato species that offer a tantalizing range of useful characteristics to protect against frost; against fungal, viral, and bacterial infections; and against nematodes and insects (for example, Ochoa 1962; Ochoa and Schmiediche 1983). Carnivorous, sticky-haired species, such as *Solanum berthaultii,* devour their prey; others repel them pheronomically by mimicking the scent of insects under stress (Hawkes and Hjerting 1989).

Added into the botanical and archaeological data mix are culinary historians' insights from agricultural, botanical, lexical, and food texts. Guaman Poma de Ayala, shortly after Spanish penetration, depicted and described plow-hoe potato and maize cultivation in his chronicle of the Incas (1583–1613) (Guaman Poma de Ayala 1936). Dictionaries that record concepts of the sixteenth-century Aymara peoples from Peru describe time intervals in terms of the time it took to cook a potato (Coe 1994)!

Indigenous peoples also developed detailed vocabularies to describe and classify potatoes, as well as myths and rituals to celebrate the tubers' importance. Even after conversion to Catholicism, they continued to use potatoes in their religious festivals; for example, garlands of potatoes are used to decorate the image of the Virgin Mary at the festival of the Immaculate Conception in Juli, Peru (Heather Lechtman, personal communication).

Indigenous Potato Products

Indigenous use of potatoes has included the development of processing methods to extend their nutritional availability and portability. In high altitude zones, selected varieties undergo freezing, soaking, and drying into a product called *chuño* that is without unhealthful bitter glycoalkaloids, is light and easily transported, and can be stored for several years. To render *chuño* (freeze-dried potato), tubers are frozen at night, then warmed in the sun (but shielded from direct rays). Next, they are trampled to slough off skins and to squeeze out any residual water, and then they are soaked in cold running water.

After soaking for 1 to 3 weeks, the product is removed to fields and sun-dried for 5 to 10 days, depending on the cloud cover and type of potato. As these tubers dry, they form a white crust, for which the product is labelled "white *chuño*" (in contrast to "black *chuño,*" which eliminates the soaking step). Another processing method involves soaking the tubers without prior freezing for up to a month, then boiling them in this advanced stage of decay. R. Werge (1979) has commented that the odor of this ripening process is "distinctive and strong" and has noted that, as a rule, this product is consumed where it is produced.

Chuño has a long history of provisioning both highland and lowland Andean populations; it was described by early Spanish chroniclers (for example, José de Acosta 1590) and also mentioned in accounts of sixteenth-century mine rations, in which Spanish mine managers complained about its high price. It is curious that one seventeenth-century source mentioned *chuño* as a source of fine white flour for cakes and other delicacies, although it was usually considered to be a lower-class native food (Cobo 1653). Ordinarily, *chuño* is rehydrated in soups and stews.

Another native product is *papa seca* ("dehydrated potato"), for which tubers are boiled, peeled, cut into chunks, sun-dried, and then ground into a starchy staple that is eaten with pork, tomatoes, and onions. *Papa seca* is consumed more widely than *chuño* in urban and coastal areas and can now be purchased in supermarkets.

In areas of frost, potatoes traditionally were also rendered into starch. Traditional products, however, are in decline, as household labor to produce them is now redirected toward higher-value cash employment or schooling. In addition, such traditional products tend to be thought of as inferior, "poor peasant" foods, so that those with cash income and access to store-bought pasta or rice consume these starches instead.

Biodiversity

Declining potato diversity, a byproduct of the insertion of higher-yielding "improved" varieties into South American field systems, is another reason for the fading of traditional potatoes and potato products. Traditional Andean potato farmers sow together in a single hole as many as 5 small tubers from different varieties and even species, and keep up to 2 dozen named varieties from 3 or 4 species (Quiros et al. 1990; Brush 1992). A particular concern has been whether genetic diversity erodes with the introduction of modern varieties and greater integration of local farmers into regional and national markets. Traditional varieties adapted to lower altitudes (where 75 percent of modern varieties are planted) are at greater risk than those of more mountainous terrains, which are less suited to the cultivation of irrigated, marketable, new varieties. So far, ethnographic investigations do not confirm the conventional wisdom that modern varieties generally compete successfully and eliminate traditional races. Although changes in cropping strategies allocate more land to new, improved varieties, thus reducing the amount of land allocated to traditional varieties, the midaltitude regions that grow modern varieties intensively tend also to devote small areas to older varieties that farmers maintain to meet ritual, symbolic, or preferential local food needs (Rhoades 1984; Brush 1992). In these commercial production zones, the land area allocated to traditional varieties appears to vary with income, with better-off households more likely to maintain larger plots.

Greater production of certain native varieties is actually encouraged by market opportunities. On-farm conservation of potato biodiversity has therefore been favored by the economics of particular native as well as introduced potato varieties, by vertical biogeography, and by persistent cultural customs calling for multiple traditional varieties (Brush, Taylor, and Bellon 1992), and there remains a large amount of as-yet unexploited population variability encoded in folk taxonomies (Quiros et al. 1990). Uniform sowings of improved varieties tend to replace older varieties only in the best-irrigated, midaltitude areas, where farmers harvest and sell an early crop and thus enjoy higher returns for the "new" potatoes. Traditional varietal mixes, however, continue to be grown in higher elevation zones where more extreme and risky environments encourage farmers to propagate a larger variety of them. But unless on-farm conservation programs are encouraged, it may only be a matter of time before erosion occurs.

Andean farmers' ethnotaxonomies ("folk classifications") continue to be studied by anthropologists and plant scientists to learn more about the ways in which traditional peoples recognize and organize plant information. These folk classifications, in most instances, recognize more distinctions than those captured by modern botanical taxonomies, and they also indicate the high value traditional peoples put on maintaining crop species biodiversity as a strategy to reduce risk of total crop failures. The more plant scientists improve their ability to understand the molecular biology, cytology, biochemistry, and genetics of the potato, the more they return to this traditional, natural, and cultural heartland to collect ancient wild and cultivated types and cultural knowledge about how to use potatoes.

In addition, traditional peoples developed ways to store and process potatoes, so that their availability could be extended greatly in time and over space. Agricultural and food scientists, in studying archaeological evidence of cold storage bins (Morris 1981) and contemporary practices (Rhoades 1984), have adopted and disseminated techniques, such as diffused lighting for storage areas and freeze-drying, as ways to increase the potato's food value in other parts of the world. This return to indigenous knowledge at a time of international diffusion of modern molecular technologies is one paradoxical dimension of the potato's history.

The Potato in Europe

Sixteenth-century Spanish explorers, who first observed the potato in Peru, Bolivia, Colombia, and Ecuador, compared the unfamiliar tuber food crop to truffles and adopted the Quechua name, *papa.* The first specimens, arguably short-day *S. tuberosum* ssp. *andigena* forms from Colombia, probably reached Spain around 1570. From there, the potato spread via herbalists and farmers to Italy, the Low Countries, and England, and there was likely a second introduction sometime in the following twenty years. Sir Francis Drake, on his round-the-world voyage (1577 to 1580), recorded an encounter with potatoes off the Chilean coast in 1578, for which British and Irish folklore credits him with having introduced the potato to Great Britain. But this could not have been the case because the tubers would not have survived the additional two years at sea. All European potato varieties in the first 250 years were derived from the original introductions, which constituted a very narrow gene pool that left almost all potatoes vulnerable to devastating viruses and fungal blights by the mid–nineteenth century. *S. tuberosum* ssp. *tuberosum* varieties, introduced from Chile into Europe and North America in the 1800s, represented an ill-fated attempt to widen disease resistance and may actually have introduced the fungus *Phytophthora infestans,* or heightened vulnerability to it. This was the microbe underlying the notorious nineteenth-century Irish crop failures and famine.

Herbal Sources

The potato's initial spread across Europe seems to have involved a combination of Renaissance scientific curiosity and lingering medieval medical superstition. Charles de l'Ecluse or Clusius of Antwerp, who received two tubers and a fruit in 1588 from Philippe de Sivry of Belgium, is credited with introducing the plant to fellow gardeners in Germany, Austria, France, and the Low Countries (Arber 1938). The Swiss botanist Caspar Bauhin first described the potato in his *Phytopinax* (1596) and named it *Solanum tuberosum* esculentum. He correctly assigned the potato to the nightshade family (Solanum) but otherwise provided a highly stylized, rather than scientific, drawing (1598) and gossiped that potatoes caused wind and leprosy (probably because they looked like leprous organs) and "incited Venus" (that is, aroused sexual desire), a characterization that led to folkloric names such as "Eve's apple" or "earth's testicles." Such unhealthful or undesirable characteristics probably contributed to potatoes being avoided in Burgundy (reported in John Gerard's *The Herball,* 1597) and in other parts of Europe. As a result of such persistent negative folklore, the introduction of the potato, a crop recognized by European leaders to have productive and nutritive capacities superior to those of cereal grains (particularly in cold and dry regions), was stymied for years in Germany and Russia.

Gerard – whose printed illustration in his *Herball* of 1597 provided the first lifelike picture of the potato plant, depicting leaves, flowers, and tubers (the plate was revised with careful observation in the later edition of 1633) – appears to have been fascinated by the plant, even wearing a potato flower as his boutonniere in the book's frontispiece illustration. But he also obscured the true origins of *Solanum tuberosum* by claiming to have received the tubers from "Virginia, otherwise called Norembega," and therefore naming them "potatoes of Virginia." The inaccurate name served to distinguish this potato from the "common potato," *Batata hispanorum* ("Spanish potato") or *Ipomoea batatas* ("sweet potato"). Additionally, "Virginia" at the time served the English as a generic label for plants of New World (as opposed to European) origin. *The Oxford English Dictionary* contains an entry labeling maize as "Virginia wheat," although it makes no reference to Gerard's "potato from Virginia."

Alternatively, Gerard may have confused a tuber truly indigenous to Virginia, *Glycine apios* or *Apios tuberosa,* with the *Solanum* potato after sowing both tubers together and then attributing an English origin to the tuber of greater significance in order to please his sovereign, Queen Elizabeth (Salaman 1985; Coe 1994). In any case, the false designation and folklore persisted into the next century, by which time potatoes had entered the agricultural economy of Ireland. A legend of Ireland credits the potato's introduction to the wreck of the Spanish Armada (1588), which washed some tubers ashore (Davidson 1992). Whatever its origins, William Salmon, in his herbal of 1710, distinguished this "Irish" (or "English") potato from the sweet potato, and "Irish potato" became the name by which "white" (as opposed to "sweet") potatoes were known in British colonies.

Eighteenth- and Nineteenth-Century Diffusions

The original short-day, late-yielding varieties illustrated in Gerard's and other herbals had by the eighteenth century been replaced by farmers' selections for early-maturing varieties that were better suited to the summer day length and climate of the British Isles. The new varieties' superior yield of calories per unit of land made subsistence possible for small farmers who had lost land and gleaning rights with the rise of scientific agriculture and the practice of enclosure. Potatoes also provided a new, cheap food source for industrial workers; Salaman (1949), William McNeill (1974), and Henry Hobhouse (1986) were among the historians who saw the potato as having encouraged the rapid rise of population that brought with it the Industrial Revolution.

Potatoes also spread across Italy and Spain. The Hospital de la Sangre in Seville recorded purchases of potatoes among its provisions as early as 1573 (Hawkes and Francisco-Ortega 1992). By 1650, potatoes were a field crop in Flanders, and they had spread northward to Zeeland by 1697, to Utrecht by 1731, to Overijssel by 1746, and to Friesland by 1765. In some high-altitude areas, they were originally adopted as an antifamine food, but the harsh winter of 1740, which caused damage to other crops, hastened potato planting everywhere. By 1794, the tubers had been accepted as an element of the Dutch national dish, a hot pot of root vegetables (Davidson 1992). Toward the end of the eighteenth century, potatoes had become a field crop in Germany, which saw especially large quantities produced after famine years, such as those from 1770 to 1772 and again in 1816 and 1817. Their popularity was increased not only by natural disasters (especially prolonged periods of cold weather) but also by the disasters of wars, because the tubers could be kept in the ground, where stores were less subject to looting and burning by marauding armies.

Such advantages were not lost on such European leaders as Frederick the Great, who, in 1774, commanded that potatoes be grown as a hedge against famine. Very soon afterward, however, potatoes proved to be not so safe in time of war. The War of the Bavarian Succession (1778 to 1779), nicknamed the *Kartoffelkrieg* ("potato war"), found soldiers living off the land, digging potatoes from the fields as they ravaged the countryside. The war ceased once the tuber supply had been exhausted (Nef 1950).

This war in Germany unintentionally provided the catalyst for popularization of the potato in France. A French pharmacist, A. A. Parmentier, had been a German prisoner of war and forced to subsist on potatoes. He survived and returned to Paris, where he championed the tuber as an antifamine food. His promotional campaign saw Marie Antoinette with potato flowers in her hair and King Louis XVI wearing them as boutonnieres. But widespread potato consumption in France still had to wait another century because, at a time when bread and soup were the French dietary staples, potato starch added to wheat flour produced an unacceptably soggy bread that was too moist to sop up the soup (Wheaton 1983). Widespread utilization of the whole potato in soup or as fries did not occur until well into the following century; even at the time of Jean François Millet's famous "Potato Planters" painting (1861), many French people still considered potatoes unfit for humans or even animals to eat (Murphy 1984).

From the middle eighteenth through nineteenth centuries, potatoes finally spread across central and eastern Europe into Russia. At the end of the seventeenth century, Tsar Peter the Great had sent a sack of potatoes home, where their production and consumption were promoted first by the Free Economic Society and, a century later, by government land grants. But "Old Believers" continued to reject potatoes as "Devil's apples" or "forbidden fruit of Eden," so that as late as 1840, potatoes were still resisted. When, in that year, the government ordered peasants to grow potatoes on common land, they responded with "potato riots" that continued through 1843, when the coercive policy ceased. But, in the next half-century, the potato's obvious superiority to most grain crops and other tubers encouraged its wider growth, first as a garden vegetable and then, as it became a dietary staple, as a field crop (Toomre 1992).

The Social Influence of the Potato

European writers credited the potato with the virtual elimination of famine by the early nineteenth century, without necessarily giving the credit to state political and economic organization and distribution systems (Crossgrove et al. 1990; Coe 1994). Larger-scale potato production subsequently provided surpluses that supported a rise of population in both rural agricultural and urban industrial areas. Potatoes were adopted widely because they grew well in most climates, altitudes, and soils and were more highly productive than grains in both good years and bad. During the seventeenth and eighteenth centuries, selection for earliness and yield gave rise to clones that were better adapted to European temperate, longer-summer-day growing conditions and could be harvested earlier. By the end of the eighteenth century, many varieties were in existence, some specified for human consumption, others as food for animals (Jellis and Richardson 1987). Agricultural workers across Europe increasingly grew potatoes on small allotments to provide food that was cheaper than wheat bread and also inexpensive fodder in the form of substandard tubers. Grains and potatoes, together with the flesh and other products of a few farm animals, provided an economically feasible and nutritionally adequate diet.

No less an authority than Adam Smith, in *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776), estimated that agricultural land allocated to potatoes yielded three times the food/nutrient value of land planted with wheat, so that more people could be maintained on a given quantity of land. Even after workers were fed and the stock replaced, more surplus was left for the landlord. Favorably contrasting the nourishment and healthfulness of potatoes with that of wheat, Smith noted:

> The chairmen, porters, and coalheavers in London, and those unfortunate women who live by prostitution, the strongest men and the most beautiful women perhaps in the British dominions, are said to be, the greatest part of them, from the lowest rank of people in Ireland, who are generally fed with the root.

The single outstanding disadvantage of the potato was that stocks could not be stored or carried over from year to year because the tubers rotted (Smith 1776, Volume 1, Book 1, Chapter 11, Part 1: 161–2).

By this time, potatoes were also providing cheap food for growing industrial populations. Low-cost provisions enabled industrialists to keep wages low (Salaman 1985). Indeed, in both rural and urban areas, more than three centuries of resistance to potatoes was overcome. The tuber had been variously regarded as poisonous, tasteless, hard to digest, and an aphrodisiac; some thought of it as pig food, others as famine food or food for the poor, but such prejudices gradually faded as potatoes became the most affordable food staple. Yet, at the same time, the growth of a potato-dependent population in Ireland elicited dire predictions of calamity (by Thomas Malthus, for one), for potatoes were already proving vulnerable to various diseases. Dependent populations were especially at risk because potatoes could neither be stored for more than a few months nor be easily transported into areas of famine, and because those within such populations tended to be politically powerless and economically exploited. For all these reasons, although Ireland suffered a devastating blight that ruined the potato crop from 1845 to 1848, it might accurately be said that the Irish famine was a man-made disaster that could have been prevented or mitigated by timely British emergency relief and greater noblesse oblige on the part of better-off Irish countrymen.

The Potato and Ireland

The history of the potato in Ireland has been summarized by C. Woodham-Smith (1962), A. Bourke (1993), and C. Kinealy (1995), among others. Such accounts trace the way in which the potato, along with the "conacre" system of land and labor allocation and the "lazy-bed" system of potato cultivation, came to dominate Irish agriculture as British landlords made less and less land and time available for their Irish workers' self-provisioning. The advent of more scientifically based agriculture and the enclosure of common lands had left many landless by the end of the eighteenth century. The "conacre" custom (or economy) allowed landless peasants to rent small plots for 11-month periods in return for agricultural services to the landlord. Peasants managed to feed themselves on such minuscule holdings by setting up raised "lazy" beds in which they placed tubers, then covered them with manure, seaweed, and additional soil to protect them from moisture.

Average yields of potatoes were 6 tons per acre, in contrast with less than 1 ton per acre for wheat or oats. In 1845, the potato crop occupied 2 million acres, and a 13.6 million ton harvest was anticipated, of which slightly less than half would have gone to humans. But grains were higher-value crops, and expansion of roads into the hinterlands during the early decades of the nineteenth century meant that grains could be more easily transported than they previously had been. Thus, values for (grain) export agriculture rose and competed more fiercely with subsistence crops for land. Conacres shrank, and many workers migrated seasonally to Scotland for the harvest, thereby reducing consumption at home and earning additional money for food. This was yet another route by which the potato and its associated social institutions "fed" the industrial economy (Vincent 1995).

"Late blight" *(Phytophthora infestans),* having ravaged potato crops in North America, disrupted this highly vulnerable agroeconomic and social context in the 1840s. The blight first appeared in late July 1845 in the Low Countries, spreading from there to England and finally to Ireland, where the poor farming population had no alternative foods to fall back on. It is ironic that late blight probably was introduced into Europe via new potato varieties that had been imported from the Western Hemisphere to counter epidemics of fungal "dry rot" and viral "curl" that had plagued previous decades. Although some scientists had observed that copper sulfate (as a dip for seed or an application for foliage) offered plants protection against what later came to be understood as fungal diseases, the science of plant pathology and pesticides was not yet far advanced, and no preventive or ameliorative steps were taken. "Bordeaux mixture," an antifungal application suitable for grape vines and potatoes, was not tried until the 1880s.

The blight of 1845 savaged 40 (not 100) percent of the crop, but infected tubers were allowed to rot in the fields, where they incubated the spores of the following years' disasters. In 1846, ideal weather conditions for late blight aided the rapid infection of early tubers, so that barely 10 percent of the crop was salvaged. But in the aftermath of the less-than-total disaster of 1845, the 1846 emergency was largely ignored by the British government, which failed to suspend the Corn Laws and continued both to export Irish grain and to forbid emergency grain imports. Taxes continued to be enforced, evictions soared, and relief measures, which included food-for-work and soup kitchens, were too few and too late. Bourke (1993), among others, blamed the English as well as the Irish landlords, a well-off greedy few who benefited from the political and economic policies that impoverished the masses.

Sickness accompanied hunger through 1848, with the result that more than a million and a half Irish people either died or emigrated in search of sustenance. Neither the population nor its potato production ever recovered, although to this day, Ireland's per capita potato consumption (143 kilograms [kg] per year) surpasses that of rival high consumers in Europe (the Portuguese consume 107 kg per year and Spaniards 106 kg) (Lysaght 1994).

The potato also remains an enduring "polysemous symbol," celebrated in Irish literature and culinary arts. In the writings of James Joyce, the potato serves as talisman, as signifier of heroic continuity, but also as a symbol of deterioration and decadence (Merritt 1990). Joyce's references to typical Irish national dishes have been collected, with recipes, into a cookbook entitled *The Joyce of Cooking* (Armstrong 1986).

Later European Developments

European descendants of the original *S. tuberosum* ssp. *andigena* clones were virtually wiped out with the arrival of late blight in the mid–nineteenth century. They were replaced by ssp. *tuberosum* varieties that also – like their predecessors – hybridized readily across subspecies. A single clone, named "Chilean Rough Purple Chili," has accounted for a large proportion of subsequent European and North American potatoes, including the "Early Rose" and "Russet Burbank" varieties, the latter of which was introduced into the United States in 1876. In addition to Russet Burbank, several very old varieties still predominate in the United States and Europe, notably "Bintje," introduced into the Netherlands in 1910, and "King Edward," introduced into the United Kingdom in 1902 (Hermsen and Swiezynski 1987). Attempts to broaden the genetic base for breeding accelerated in the 1920s and 1930s, with N. I. Vavilov's Russian expedition that collected frost- and blight-resistant varieties from South America and, subsequently, with the British Empire (later Commonwealth) Potato Collecting Expedition (Hawkes 1990).

Blights and viruses notwithstanding, the potato played an ever-expanding role in European food economies. Epitomized in Vincent Van Gogh's "Potato Eaters" of 1885, but more nobly so in Millet's "Potato Planters" of 1861, potatoes on the European mainland came to symbolize the rugged, honest peasant, wresting life and livelihood from the soil. In England, eastern Europe, and Russia, potatoes played significant nutritional roles during ordinary times and assumed extraordinary nutritional roles in war years (Salaman 1985). Even today they remain the fallback crop in times of turmoil, as was seen in Russia in the severe months of 1992, following glasnost and the reorganization of the economy. An article the same year in the *New Scientist* reported that Russian citizens were planting potatoes everywhere, even illegally in the Losinskii Ostrove National Park, and attempting to steal potatoes from farms!

Europeans were directly responsible for the introduction of potatoes into North America, where they were well established by the eighteenth century. In addition, potatoes accompanied colonists to India, to French Indochina (CIP 1984), to China (Anderson 1988), and to New Zealand where, in the nineteenth century, the Maoris adopted them on the model of other tuber crops (Yen 1961/2). Potatoes also entered Africa with Belgian, British, French, and German colonists, who consumed them as a vegetable rather than as a staple starch. The largest recent expansion of potato cultivation has been in former European colonies, where people in the nineteenth century regarded the tuber as a high-value garden crop and prestigious European vegetable but since then (perhaps in conjunction with the end of colonialism) have come to view it as a staple or costaple garnish and snack (Woolfe 1987).

Potatoes in Developing Countries

In Asia and Africa, the potato has filled a number of production and consumption niches, and its history on these continents has been similar to that in Europe. Once again, despite its advantages as an antifamine, high-elevation alternative to grain, with particular virtues during conflicts, the potato was at first resisted by local farmers, who believed it to be poisonous. In the highest elevation zones, such as the Nepalese Himalayas (Fürer-Haimendorf 1964) and the upper reaches of Rwanda (Scott 1988), potatoes took root as a new staple food crop and contributed to subsistence, surplus, and population expansion. The plants were promoted by savvy rulers, who used demonstration, economic incentives, or coercion to overcome farmers' superstitions and resistance (CIP 1984). In Africa, as in Europe, the popularity of the tubers increased in wartime because they could be stored in the ground.

With the 1972 creation of the International Potato Center (CIP) and its mission to increase potato production and consumption in developing countries while protecting biodiversity, the introduction of improved potato varieties has accelerated around the world. CIP's activities, along with the operation of diverse market forces, have resulted in some African and Asian countries rapidly becoming areas of high potato consumption. Prior to its most recent civil conflict, Rwanda in some localities witnessed per capita consumption as high as 153 to 200 kg per year (Scott 1988) – higher than that in any Western European country, including Ireland. If Rwanda can reattain peace, and agronomic and credit constraints on production and infrastructural limits on marketing could be removed, production could expand much farther and faster from the "grassroots," as it has in neighboring Tanzania. There, local farmers in recent years have developed the potato as a cash crop – the result of the introduction of several new varieties brought back by migrant laborers from Uganda, the diffusion of other varieties from Kenya, and the comparative advantage of raising potatoes relative to other cash or subsistence crops (Andersson 1996).

The potato offers excellent advantages as a subsistence crop because of its high yields, low input costs, and favorable response to intensive gardening techniques (for example, Nganga 1984). But potato promotions in Africa ominously echo the terms in which eighteenth- and nineteenth-century British observers praised the tuber. Scientists and political economists should be ever vigilant in ensuring that the potato is not again employed as a stopgap measure in contexts of great social inequality and food/nutritional insecurity, where vulnerability to late blight (or any other stressor) might lead to a repetition of the Great (nineteenth-century Irish) Hunger. Techniques of "clean" seed dissemination and mixed cropping strategies that "clean" the soil are designed to help prevent such calamities now and in the future. But all highlight the need to monitor pests and improve breeding materials so that resistant varieties of the potato are easily available to farmers who have become increasingly reliant on it for food and income.

The same cautions hold for Asia, where production and consumption of potatoes is expanding because of the market as well as international agricultural interests. Since the 1970s, the greatest rate of increase has been in the warm, humid, subtropical lowlands of Asia, where potatoes are planted as a dry-season intercrop with rice or wheat (Vander Zaag 1984), providing income and relief from seasonal hunger (Chakrabarti 1986). The surge in potato production has been spurred in some cases by new seeding materials and techniques. In Vietnam in the 1970s and 1980s, the Vietnamese and CIP introduced superior, blight-resistant clones that could be multiplied by tissue culture and micropropagation methods. Some enterprising farming families then took over the labor-intensive rapid multiplication, so that by 1985, three household "cottage industries" were supplying 600,000 cuttings for some 12,000 farmers (CIP 1984). Production in other Asian nations has also accelerated (for example, in Sri Lanka) as a result of government promotions and policies that have banned imports of all (including seed) potatoes since the 1960s (CIP 1984).

In Central America and the Caribbean, financial incentives and media promotion have been used to increase production and consumption of potatoes in places unaccustomed to them, such as the Dominican Republic, where the state offered credit and guaranteed purchase to potato farmers after the country experienced a rice deficit (CIP 1984). Similarly, during post-hurricane disaster conditions of 1987, Nicaraguans were encouraged to eat more potatoes – these shipped from friendly donors in the Soviet bloc. In South American countries, campaigns are underway to encourage farmers to grow more potatoes for sale as well as for home consumption, as in Bolivia, where economists hope that as part of diversified employment strategies, an increased production and sale of improved potato varieties can have a multiplier effect, reducing unemployment and increasing access to food (Franco and Godoy 1993). But all of these programs highlight the need to reconcile production and income concerns with the protection of biodiversity and reduction of risks.

Maintaining and Utilizing Biodiversity

Modern scientific attempts to broaden the genetic base for potato breeding began with European scientific expeditions in the 1920s and 1930s, including the already-mentioned Russian (Vavilov 1951) and British collections. Today, major gene banks and study collections are maintained at the Potato Introduction Center, Sturgeon Bay, Wisconsin; the Braunschweig-Volkenrode Genetic Resources Center (Joint German-Netherlands Potato Gene Bank); the N. I. Vavilov Institute of Plant Industry in Leningrad; and the International Potato Center (CIP) in Lima. Major potato-producing countries publish annual lists of registered varieties, standardized to report on agronomic characteristics (disease and pest resistances, seasonality, and environmental tolerances) and cooking and processing qualities (industrial-processing suitability for fries, chips, or dehydration; or home-processing aspects, such as requisite cooking times for boiling, baking, roasting, or frying). Additional consumer descriptors include color, texture, flavor, and the extent of any postcooking tendency to blacken or disintegrate.

Acceptably low alkaloid content is the main chemical toxicity concern, especially because glycoalkaloids are often involved in pest-resistance characteristics introduced during plant breeding. In one historical example, U.S. and Canadian agricultural officials were obliged to remove a promising new multiresistant variety (named "Lenape") from production because a scientist discovered its sickeningly high alkaloid content (Woolfe 1987).

Since the 1960s, new varieties have been protected by plant breeders' rights and, internationally, by the *Union Pour la Protection des Obtentions Végétales* (UPOV), which uses a standard set of 107 taxonomic characters to describe individual potato cultivars. UPOV is designed to facilitate exchanges among member countries and so accelerate the breeding process. Collection, conservation, documentation, evaluation, exchange, and use of germ plasm are also regulated by descriptor lists produced in cooperation with the International Bank for Plant Genetic Resources (IBPGR).

The pace of new varietal introductions is accelerating as more wild species of potential utility for potato improvement are identified and genetically tapped for useful traits that are transferred with the assistance of biotechnology. Wild potatoes with resistance to one pathogen or pest tend to be susceptible to others and may have undesirable growth, tuber, or quality (especially high alkaloid) characteristics. Conventional breeding still requires 12 to 15 years to develop new varieties that include desirable – and exclude undesirable – genes. Protoplast fusion, selection from somaclonal variation, and genetic engineering via *Agrobacterium tumefaciens* are some "unconventional" techniques that promise to widen the scope and quicken the pace of varietal improvement, especially once the genes that control important traits have been characterized. The latter process is facilitated by advances in genetic linkage mapping (Tanksley, Ganal, and Prince 1992) and in practical communication among conventional breeding and agronomic programs (Thomson 1987) that set objectives.

European countries (such as the Netherlands, which has a highly successful seed-potato export business) have been contributing to the development of varieties with superior tolerance for environmental stressors, especially heat and drought, as potato production grows in subtropical countries of Asia and Africa (Levy 1987). Innovative breeding programs also include social components that respond to economic concerns, such as that growing potatoes for market contributes to women's household income. A Dutch-sponsored program in Asia built up a potato network of women social scientists, nutritionists, and marketing experts along these lines. CIP, in consultation with professionals from national programs, coordinates research and varietal development as well as collection and characterization of germ plasm (seed material) from wild resources.

The Significance of CIP

The International Potato Center (CIP) which grew out of the Mexican national potato program funded by the Rockefeller Foundation, is part of the Consultative Group on International Agricultural Research. It provides a major resource and impetus for strategic studies that tap the genetic and phenotypic diversity of the potato and accelerate the introduction of useful characteristics into new cultivars. Since 1972, CIP has built and maintained the World Potato Collection of some 13,000 accessions, characterized as 5,000 cultivars and 1,500 wild types. In addition to South American programs, CIP potato campaigns extend from the plains of India, Pakistan, and Bangladesh to the oases of North Africa and the highlands and valleys of Central Africa.

CIP's major technical activities include an effective population breeding strategy, "clean" (pest- and disease-free) germ-plasm distribution, virus and viroid detection and elimination, agronomy, integrated pest management, tissue culture and rapid multiplication of seed materials, advancement of true potato seed as an alternative to tubers or microtubers, and improvement of storage practices. In the 1990s, a principal thrust of research has been to generate seed materials resistant to late blight, which has reemerged in a more virulent, sexually reproducing form (Niederhauser 1992; Daly 1996).

Strategies involve breeding for multi-gene ("horizontal") rather than single-gene resistance, development and dissemination of true potato seed (which does not disseminate the fungus), and integrated pest management that relies on cost-effective applications of fungicides (CIP 1994). Training, regional networks, and participatory research with farmers are additional dimensions of CIP programs. Collaborative networks offer courses that allow potato specialists to interact and address common problems. In addition, CIP also pioneered "farmer-back-to-farmer" research, whereby effective techniques developed by farmers in one part of the world are shared with farmers in other geographic areas. For example, as already mentioned, reduction of postharvest losses through diffused-light storage is a technique that CIP researchers learned from Peruvian farmers and then brokered to farmers in Asia and Africa (CIP 1984; Rhoades 1984).

CIP also extends its networking to international food purveyors, such as McDonald's and Pepsico – transnational corporations interested in developing improved, pest-resistant, uniformly shaped, high-solid-content potato varieties to be used in making standardized fries. One goal of such enterprises is to develop local sources of supply of raw potatoes for the firms' international franchises, an accomplishment that would improve potato production and income for developing-country farmers and also reduce transportation costs (Walsh 1990). Although principally engaged in agricultural research and extension, CIP also studies consumption patterns, which can improve the potato's dietary and nutritional contributions while eliminating waste (Woolfe 1987; Bouis and Scott 1996).

Dietary and Nutritional Dimensions

Potatoes – simply boiled, baked, or roasted – are an inexpensive, nutritious, and ordinarily harmless source of carbohydrate calories and good-quality protein, and potato skins are an excellent source of vitamin C. Because a small tuber (100 grams [g]) boiled in its skin provides 16 mg of ascorbic acid – 80 percent of a child's or 50 percent of an adult's daily requirement – the potato is an excellent preventive against scurvy. Potatoes are also a good source of the B vitamins (thiamine, pyridoxine, and niacin) and are rich in potassium, phosphorus, and other trace elements. Nutritive value by weight is low because potatoes are mostly water, but consumed in sufficient quantity to meet caloric needs, the dry matter (about 20 percent) provides the micronutrients just mentioned, an easily digestible starch, and nitrogen (protein), which is comparable on a dry-weight basis to the protein content of cereals and, on a cooked basis, to that of boiled cereals, such as rice- or grain-based gruels (Woolfe 1987).

Potato protein, like that of legumes, is high in lysine and low in sulfur-containing amino acids, making potatoes a good nutritional staple for adults, especially if consumed with cereals as a protein complement. Prepared in fresh form, however, tubers are too bulky to provide a staple for infants or children without an energy-rich supplement. Food technologists are hopeful that novel processing measures may manage to convert the naturally damp, starchy tuber (which molds easily) into a light, nutritious powder that can be reconstituted as a healthful snack or baby food. They also hope to make use of potato protein concentrate, derived either directly by protein recovery or from single-cell protein grown on potato-processing waste (Woolfe 1987). Both advances would minimize waste as well as deliver new sources of nutrients for humans and animals, rendering potato processing more economical. Containing contaminants in industrial potato processing is still very expensive, but sun-drying, a cottage or village industry in India and other Asian countries, holds promise as an inexpensive way to preserve the potato and smooth out seasonal market gluts.

Preservation looms as a large issue because fungus-infected, improperly stored, and undercooked potatoes are toxic for both humans and livestock. Storage and preparation also can diminish the tuber's sensory and nutritional qualities. Sweetening (enzyme conversion of starch), lipid degradation, and discoloration or blackening are signs of deterioration that reduces palatability and protein value. Storage in direct sunlight raises glycoalkaloid content. Other antinutritional factors, such as proteinase inhibitors and lectins, which play a role in insect resistance in some varieties, are ordinarily destroyed by heat, but undercooking, especially when fuel is limited, can leave potatoes indigestible and even poisonous.

Dietary Roles

Although peeling, boiling, and other handling of potatoes decrease micronutrient values, they remove dirt, roughage, and toxins, as well as render potatoes edible. In their Andean heartland, potatoes have always been consumed fresh (boiled or roasted) or reconstituted in stews from freeze-dried or sun-dried forms. They have been the most important root-crop starchy staple, although other cultivated and wild tubers are consumed along with cereals, both indigenous (maize and quinoa) and nonindigenous (barley and wheat). Despite the importance of the potato, cereals were often preferred. For example, Inca ruling elites, just prior to conquest, were said to have favored maize over potatoes, perhaps because the cereal provided denser carbohydrate-protein-fat calories and also was superior for brewing. For these reasons, the Inca may have moved highland peasant populations to lowland irrigated valley sites, where they produced maize instead of potatoes (Earle et al. 1987; Coe 1994). In South America today, potatoes are consumed as a staple or costaple with noodles, barley, rice, and/or legumes and are not used for the manufacture of alcohol. In Central America and Mexico, they are consumed as a costaple main dish or vegetable, in substitution for beans.

In Europe, potatoes historically were added to stews, much like other root vegetables, or boiled, baked, roasted, or fried with the addition of fat, salt, and spices. Boiled potatoes became the staple for eighteenth- and nineteenth-century Irish adults, who consumed up to 16 pounds per person per day in the absence of oatmeal, bread, milk, or pork. These potatoes were served in forms that included pies and cakes (Armstrong 1986). In eastern Europe and Russia, potatoes were eaten boiled or roasted, or were prepared as a costaple with wheat flour in pasta or pastries. In France, by the nineteenth century, fried potatoes were popular, and potatoes were also consumed in soup. In France, Germany, and northern and eastern Europe, potatoes were used for the manufacture of alcohol, which was drunk as a distinct beverage or was put into fortified wines (Bourke 1993). In Great Britain and North America, there developed "fish and chips" and "meat and potatoes" diets. In both locations, potatoes comprised the major starchy component of meals that usually included meat and additional components of green leafy or yellow vegetables.

In former European colonies of Asia and Africa, potatoes were initially consumed only occasionally, like asparagus or other relatively high-cost vegetables, but increased production made them a staple in certain areas. In central African regions of relatively high production, potatoes are beaten with grains and legumes into a stiff porridge, or boiled or roasted and eaten whole. Alternatively, in many Asian cuisines they provide a small garnish, one of a number of side dishes that go with a main staple, or they serve as a snack food consumed whole or in a flour-based pastry. Woolfe (1987: 207, Figure 6.7) has diagrammed these possible dietary roles and has described a four-part "typology of potato consumption" that ranges from (1) potato as staple or costaple, a main source of food energy eaten almost every day for a total consumption of 60 to 200 kg per year; to (2) potato as a complementary vegetable served one or more times per week; to (3) potato as a luxury or special food consumed with 1 to 12 meals per year; to (4) potato as a nonfood because it is either unknown or tabooed. For each of these culinary ends, cultural consumers recognize and rank multiple varieties of potatoes.

Culinary Classifications

In the United States, potato varieties are sometimes classified, named, and marketed according to their geographical location of production (for example, "Idaho" potatoes for baking). They are also classified by varietal name (for example, Russet Burbank, which comes from Idaho but also from other places and is good for baking) and by color and size (for example, small, red, "White Rose," "Gold Rose," "Yukon Gold," or "Yellow Finn," which are designated tasty and used for boiling or mashing). Varieties are also characterized according to cooking qualities that describe their relative starch and moisture content. High-starch, "floury" potatoes are supposed to be better for baking, frying, and mashing; lower-starch, "waxy" potatoes are better for boiling, roasting, and salads (because they hold their shape); and medium-starch, "all-purpose" potatoes are deemed good for pan-frying, scalloping, and pancakes.

Cookbooks (for example, McGee 1984) suggest that relative starch content and function can be determined by a saltwater test (waxy potatoes float, floury varieties sink) or by observation (oval-shaped, thick-skinned potatoes prove better for baking, whereas large, round, thin-skinned potatoes suit many purposes). Specialized cookbooks devoted entirely to the potato help consumers and home cooks make sense of this great diversity (Marshall 1992; see also O'Neill 1992), offering a wide range of recipes, from simple to elegant, for potato appetizers (crepes, puff pastries, fritters, pies, and tarts); potato ingredients, thickeners, or binders in soups; and potato salads, breads, and main courses. They detail dishes that use potatoes baked, mashed, sauteed, braised, or roasted; as fries and puffs (*pommes soufflés* is folklorically dated to 1837 and King Louis Philippe), and in gratinées (baked with a crust); as well as potato dumplings, gnocchi, pancakes, and even desserts. Potato cookbooks, along with elegant presentations of the tubers in fine restaurants, have helped transform the image of the potato from a fattening and undesirable starch into a desirable and healthful gourmet food item.

Mass production over the years has produced larger but more insipid potatoes that are baked, boiled, and mashed, mixed with fats and spices, fried, or mixed with oil and vinegar in salads. Running counter to this trend, however, has been a demand in the 1990s for "heirloom" (traditional) varieties, which increasingly are protected by patent to ensure greater income for their developers and marketers. In the United States, heirloom varieties are disseminated through fine-food stores, as well as seed catalogues that distribute eyes, cuttings, and mini-tubers for home gardens. There is even a Maine-based "Potato of the Month Club," which markets "old-fashioned" or organically grown varieties (O'Neill 1992) to people unable to grow their own.

Breeders are also scrambling to design new gold or purple varieties that can be sold at a premium. In

1989, Michigan State University breeders completed designing a "perfect" potato ("MICHIGOLD") for Michigan farmers: Distinctive and yellow-fleshed, this variety was tasty, nutritious, high yielding, and disease resistant, and (its breeders joked), it would not grow well outside of Michigan's borders (from the author's interviews with Michigan State University scientists). Also of current importance is a search for exotic potatoes, such as the small, elongated, densely golden-fleshed "La Ratte" or "La Reine," which boasts "a flavor that hints richly of hazelnuts and chestnuts" (Fabricant 1996). These return the modern, North American consumer to what were perhaps the "truffle-like" flavors reported by sixteenth-century Spaniards encountering potatoes for the first time. Such special varieties also may help to counter the trend of ever more industrially processed potato foods that has been underway since the 1940s.

Industrially Processed Potato Foods

Since the end of World War II, processed products have come to dominate 75 percent of the potato market, especially as frozen or snack foods. Seventy percent of Idaho-grown and 80 percent of Washington-grown potatoes are processed, and the proportion is also growing in Europe and Asia (Talburt 1975). Freeze-dried potatoes received a boost during the war years, when U.S. technologists are reported to have visited South America to explore the ancient art of potato freeze-drying and adapt it for military rations (Werge 1979). Since World War II, the development of the frozen food industry and other food-industry processes and packaging, combined with a surging demand for snack and "fast" (convenience) foods, have contributed to the increasing expansion of industrially processed potato products in civilian markets. By the 1970s, 50 percent of potatoes consumed in the United States were dehydrated, fried, canned, or frozen, with close to 50 percent of this amount in the frozen food category. The glossy reports of mammoth food purveyors, such as Heinz, which controls Ore-Ida, proudly boast new and growing markets for processed potatoes (and their standby, ketchup) in the former Soviet Union and Asia.

The other large growth area for fried potatoes and chips has been in the transnational restaurant chains, where fries (with burgers) symbolize modernization or diet globalization. Unfortunately, the "value added" in calories and cost compounds the nutritional problems of consumers struggling to subsist on marginal food budgets, as well as those of people who are otherwise poorly nourished. For less affluent consumers, consumption of fries and other relatively expensive, fat-laden potato products means significant losses (of 50 percent or more) in the nutrients available in freshly prepared potatoes – a result of the many steps involved in storage, processing, and final preparation. Although processed potato foods are not "bad" in themselves, the marginal nutritional contexts in which some people choose to eat them means a diversion of critical monetary and food resources from more nutritious and cost-effective food purchases. The health risks associated with high amounts of fat and obesity are additional factors.

Potato: Present and Future

Potato consumption is on the rise in most parts of the world. In 1994, China led other nations by producing 40,039,000 metric tons, followed by the Russian Federation (33,780,000), Poland (23,058,000), the United States (20,835,000), Ukraine (16,102,000), and India (15,000,000) (FAO 1995). Average annual per capita consumption is reported to be highest in certain highland regions of Rwanda (153 kg), Peru (100 to 200 kg), and highland Asia (no figures available) (Woolfe 1987), with the largest rate of increase in lowland Asia.

Expansion of potato production and consumption has resulted from the inherent plasticity of the crop; the international training, technical programs, and technology transfer offered by CIP and European purveyors; the ecological opportunities fostered by the "Green Revolution" in other kinds of farming, especially Asian cereal-based systems; and overarching political-economic transformations in income and trade that have influenced local potato production and consumption, especially via the fast-food industry. The use of potatoes has grown because of the ease with which they can be genetically manipulated and because of their smooth fit into multivarietal or multispecies agronomic systems, not to mention the expanding number of uses for the potato as a food and as a raw industrial material.

Genetic Engineering

The potato already has a well-developed, high-density molecular linkage map that promises to facilitate marker-assisted breeding (Tanksley 1992). Coupled with its ease of transformation by cellular (protoplast fusion) or molecular (*Agrobacterium*-assisted) methods, and useful somaclone variants, the potato is developing into a model food crop for genetic engineering. By 1995, there was a genetically engineered variety, containing bt-toxin as a defense against the potato beetle, in commercial trials (Holmes 1995). Where the potato is intercropped rather than monocropped, it also encourages scientists to rethink the agricultural engineering enterprise as a multicropping system or cycle, within which agronomists must seek to optimize production with more efficient uses of moisture, fertilizer, and antipest applications (Messer 1996). Resurgent – and more virulent – forms of late blight, as well as coevolving virus and beetle pests, are the targets of integrated pest management that combines new biotechnological tools with more conventional chemical and biological ones.

Potatoes continue to serve as a raw material for starch, alcohol, and livestock fodder (especially in Europe). In addition, they may soon provide a safe and reliable source of genetically engineered pharmaceuticals, such as insulin, or of chemical polymers for plastics and synthetic rubbers. Inserting genes for polymer-making enzymes has been the easy step; regulating production of those enzymes relative to natural processes already in the plant is the next, more difficult, one (Pool 1989). A cartoonist (Pool 1989) captured the irony of saving the family farm – whereby small farmers, on contract, grow raw materials for plastics – by portraying the classic Midwestern "American Gothic" farmer husband and wife standing pitchforks in hand, before a field of plastic bottles!

Potato Philanthropy

With less irony, potatoes have come to serve as a model crop for philanthropy. The Virginia-based Society of St. Andrew, through its potato project, has salvaged more than 200 million pounds of fresh produce, especially potatoes, which has been redirected to feed the hungry. Perhaps the memory of Ireland's potato famine continues to inspire acts of relief and development assistance through such organizations as Irish Concern and Action from Ireland, which, along with Irish political leaders (for example, Robinson 1992), reach out to prevent famine deaths, especially as the people of Ireland mark the 150th anniversary of the Great Hunger.

Concluding Paradoxes

In the foregoing history are at least four paradoxes. The first is the potato's transformation in Europe from an antifamine food crop to a catalyst of famine. Ominously, the principal reliance on this species, which makes possible survival, subsistence, and surplus production in high-elevation zones all over the world, and which yields more calories per unit area than cereals, "caused" the Irish famine of 1845–8 and continues to make other poor rural populations vulnerable to famine.

Paradoxical, too, has been the transformation of this simple, naturally nutritious, inexpensive source of carbohydrate, protein, and vitamins into a relatively expensive processed food and less-healthy carrier of fat in the globalization of french fries and hamburgers.

A third paradox is the enduring or even revitalized importance of Andean source materials for the global proliferation of potatoes. Advances in agronomy and varietal improvement have made the potato an increasingly important and diverse crop for all scales and levels of production and consumption across the globe. But in the face of such geographic and culinary developments, the traditional South American potato cultures continue to present what to some scientists is a surprising wealth of biological, ecological, storage, and processing knowledge (Werge 1979; Rhoades 1984; Brush 1992). The management of biological diversity, ecology of production, and storage and processing methods are three areas in which indigenous agriculture has continued to inform contemporary potato research. Thus, despite dispersal all over the globe, scientists still return to the potato's heartland to learn how to improve and protect the crop.

A fourth paradox is that potatoes may yet experience their greatest contribution to nutrition and help put an end to hunger, not directly as food but as a component of diversified agro-ecosystems and an industrial cash crop. Since their beginnings, potatoes have always formed a component of diversified agro-livestock food systems. Historically, they achieved their most significant dietary role when grown in rotation with cereals (as in Ireland). Today, they are once again being seasonally rotated within cereal-based cropping systems. Because potatoes are intercropped, they stimulate questions about how biotechnology-assisted agriculture can be implemented more sustainably. So far, plant biotechnologists have considered mainly the host-resistance to individual microbes or insects, and never with more than one crop at a time. But adding potatoes to cereal crop rotations encourages scientists, as it does farmers, to look more closely at the efficiency with which cropping systems use moisture and chemicals, and to ask how subsequent crops can utilize effectively the field residues of previous plantings in order to save water and minimize pollution.

Efforts to integrate potatoes into tropical cropping systems, particularly those in the tropical and subtropical lowlands of southern and southeastern Asia, are stimulating such inquiries. Thus, potatoes, perhaps the first crop cultivated in the Western Hemisphere, are now contributing to a revolution of their own in the newest agricultural revolution: the bio- or gene revolution in Asia. In addition, potatoes may also help to save family farms in the United States and Europe by providing income to those growing the crop for plastic.

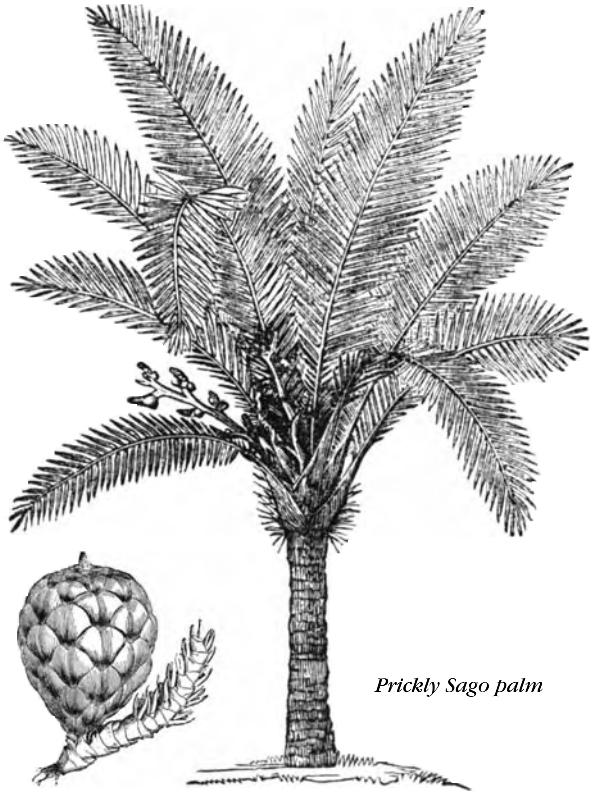
II.B.4 Sago

Sago is an edible starch derived from the pith of a variety of sago palms, but mostly from two species of the genus *Metroxylon* – *M. sagu* and *M. rumphii.* The sago palms flower only once (hapaxantic) and are found in tropical lowland swamps. Other genera of palms that yield sago starch include *Arecastrum, Arenga, Caryota, Corypha, Eugeissona, Mauritia,* and *Roystonea.* In all, there are about 15 species of sago palms distributed in both the Old World and the New, with the most significant of these, *M. sagu,* located mainly on the islands of the Malay Archipelago and New Guinea. As a staple foodstuff, only the *Metroxylon* genus appears to be in regular use, generally among populations located in coastal, lacustrine, or riverine areas. Worldwide, sago provides only about 1.5 percent of the total production of starch and, consequently, is fairly insignificant as a global food source (Flach 1983). It is processed into flour, meal, and pearl sago, and is often used for thickening soups, puddings, and other desserts.



Prickly Sago palm

Sago starch is extracted in a variety of ways, although the general process is similar from area to area. The trunk of a felled palm is chopped into sections and then split vertically to allow the pith to be removed. The extracted pith is ground and then repeatedly washed and strained. The strained material is allowed to dry, and the result is pellets of sago starch. When processed in this manner, the average yield of one palm (of 27 to 50 feet meters in height) generally ranges between 130 and 185 kilograms (kg) of sago, which can feed a family of between two and four persons for up to three months.

History, Cultivation, and Production

History

The early history of sago palm use as a food is still unclear. Ethnologists and anthropologists have generally relied on native myths and legends to judge when it was introduced into the diets of many groups worldwide. Some, such as E. Schlesier and F. Speiser, have tended to believe that the sago palm has been utilized as a food source in the Pacific islands since prehorticultural days. J. B. Avé (1977), for example, has stated that Neolithic and Mesolithic artifacts found in insular Southeast Asia included tools used in sago preparation. Although this suggests that sago has been cultivated since ancient times, paleohistorians are not so sure. E. Haberland and others, for example, have contended that sago consumption was a postagricultural development (Ruddle et al. 1978).

By most accounts, the sago palm was essential to the early inhabitants of Southeast Asia, and was probably one of the first plants they exploited as part of their subsistence strategy (Avé 1977; Rhoads 1982; Flach 1983). Geographer Carl O. Sauer believed that the plant's domestication took place there, where people in freshwater areas were able to employ native palms in a variety of ways, including the production of starch, drugs, and fish poisons, as well as fishing nets and lines (Isaac 1970). According to the folk history of the Melanau of Sarawak, the tribe has "always eaten sago," even though they claim that rice, not sago, is their staple food (Morris 1974).

Sago, however, has also been an important food source for peoples in other parts of the world. Evidence, although limited, indicates that during the Chinese Tang Dynasty (618 to 907), sago starch from palms grown in southeast China came to rival milled grain for use in making cakes. Additionally, the nutritive value of *Metroxylon* sago was discussed in the *Pen Ts'ao Kang mu* (The Great Herbal), and *Caryota* palms are mentioned in Ki Han's *Nan Fang Ts'ao Mu Chuang* ("Account of the Flora of the Southern Regions") (Ruddle et al. 1978). For the peoples of the Southwest Pacific, sago palms have been important from ancient times to the present; stands of *M. sagu* and *M. rumphii* have provided staple foods over the centuries for many millions of people (McCurrach 1960).

In the Western Hemisphere, the use of sago starch has been less common, although *Arecastrum romanzoffianum, Mauritia flexuosa,* and *Roystonea oleracea* are all varieties that have provided nutritional relief during times of food scarcity. For example, many Paraguayan peasants are said to have survived on sago in the 1870s, following the devastation wrought by the war of the Triple Alliance. And some peoples, such as the Warao Indians of Venezuela, continue to utilize *M. flexuosa* as a dietary staple (Ruddle et al. 1978).

Properties

Sago palms generally reach maturity at about 15 years of age, at which time the tree develops its enormous mass of pith. The pith makes up approximately 68 to 74 percent of the total weight of the tree, whereas the starch content of the pith constitutes about 25 to 30 percent of the pith weight. Raw sago from *Metroxylon* spp. will yield a range of approximately 285 to 355 calories per 100 grams. Nutritionally, about 70 to 90 percent of raw sago is carbohydrate, 0.3 percent is fiber, and 0.2 percent is protein. Although it has a negligible fat content, sago does contain various minerals, including calcium (10 to 30 milligrams [mg]), phosphorus (approximately 12 mg), and iron (0.7 to 1.5 mg) (Peters 1957; Barrau 1960; Platt 1977; Ruddle et al. 1978).

Sago supplies energy needs, but because it is deficient in most other nutrients, its consumption must be complemented with other foods that yield good-quality proteins as well as a range of vitamins. Climate and other environmental factors generally dictate the supplements. In some areas of New Guinea, for example, the inhabitants use leaves and other greens (sometimes grown on platforms raised above water or in limited garden space) along with the products of fishing and hunting. Another source of animal protein is the sago grub, especially for those groups located inland from the wetlands and rivers. Still others have supplemented their diet with coconuts, tubers, roots, and pulses, in addition to greens (Barrau 1960).

Location

The first Western description of sago consumption appears to be that penned by Marco Polo during his travels to Indonesia in the thirteenth century. Polo wrote "Of the Sixth Kingdom, named Fanfur, where Meal is procured from a certain Tree," with the "meal" in question clearly sago starch. A few centuries later, S. Purchas, during his travels in Sumatra, also mentioned sago as a food source (along with rice and millet) (Ruddle et al. 1978). In 1687, W. Dampier noted that sago was one of the more common foods at Mindanao (Tan 1980).

Toward the end of the nineteenth century, sago palms were observed in a number of regions of the world, and Ceram, Borneo, and Sarawak were mentioned as areas of starch production. Today, a survey of sago use would encompass a vast area, ranging over Malaysia and the Pacific Islands (Boulger 1889; Flach 1983).

Sago is fairly common in the western Pacific, where cultivated stands of the palm cover an estimated 10,000 hectares (Firth 1950). It is also present throughout much of the southwestern Pacific area. In Papua New Guinea, for example, there are approximately 1,000,000 hectares of wild sago stands and 20,000 hectares of cultivated stands. Similarly, in Indonesia there are 1 million hectares of wild stands and 128,000 hectares that are cultivated. Rounding out the major areas of sago palm stands are Malaysia with 33,000 hectares of cultivated stands and Thailand and the Philippines with 5,000 hectares each (Flach 1983).

Unlike most plants, the sago palm has not been geographically dispersed, and in experimenting with ways to introduce this crop to new areas, M. Flach (1983) discovered a number of possible reasons for the failure of previous attempts. His own efforts failed in Surinam, probably the result of inadequate care of the plants. An attempt in the south Sudan also failed, most likely because of that region's low humidity. Flach did have success in Vietnam, where a sago palm stand succeeded at Can Tho. But, as he discovered, there are two additional factors that make it difficult to disperse sago palms. One is the problem of obtaining generative material, and the other is the cumbersome size of the vegetative material (Flach 1983).

Moreover, depending on location, the peoples of the different sago palm regions of the world call the palms by a great variety of names. The Papuans, for example, have 23 names for *Metroxylon* and sago. In pidgin English, it is *saksak.* In other areas of New Guinea, the sago palm is known as *abia, aisai, akiri, ambe, api, baiao, balega, barian, da, dou, fi, ipako, na, nafa, ndana, no, poi, pu,* and *wariani.* In the New Hebrides, it is known as *natangora.* In the Fiji Islands, sago is referred to as *ota* or *oat* and as *soqo* or *soqa,* and in the Moluccas it is *lapia.* In Indonesia, sago is known as *rambia, rembia, rembi,* and *rumbia,* along with other similar cognates (Barrau 1960).

Scientific Description

The most important palm trees in sago production are from the genus *Metroxylon,* a term that comes from the Greek words *metra,* meaning "heart of a tree," and *xylon,* meaning "wood" (Whitmore 1973). *Metroxylon sagu* and *Metroxylon rumphii* are economically the most important species in the genus (Flach 1983) and appear to be closely related, as they are found in wild stands mixed together with what appear to be intermediates (Flach 1983).

M. sagu and *M. rumphii* share a great number of characteristics, as well as the common name "sago palm." It is thought that *M. rumphii* originated in Malaysia, New Guinea, and Fiji, whereas *M. sagu* originated in western New Guinea and the Moluccas. The trunks of the two species reach a height of approximately 10 to 15 meters and are generally about 45 centimeters (cm) in diameter (McCurrach 1960; Whitmore 1973). Their leaves grow to 600 or more centimeters in length, and the leaflets are about 60 to 120 cm long and 2.5 to 7.6 cm broad. The flower stalk, which appears above the leaves, is 4 to 5 meters in length. The flower stalk of *M. rumphii* is black and covered with spines, whereas that of *M. sagu* lacks spines. The fruit produced is spherical, dull yellow, and about 5 cm in diameter. The growth cycle of the sago palm ranges from 8 to 17 years (McCurrach 1960; Flach 1983). Although their ideal temperature range has not yet been determined, it is known that sago palms thrive in areas where the temperature only occasionally drops below 15° C.

What is known about the natural habitat of the sago palms has been gleaned largely from observations in environments where they now grow. Indeed, with so little information available, scientists have been forced to study conditions in the natural habitat as well as the centers of cultivation to glean what they can (Flach 1983). Typical of natural habitats are the swamp forests of sago palms in New Guinea, where fresh water is abundant (Barrau 1960).

Outside of swamps, if a climate is too wet, grasses tend to take over and limit propagation. If, on the other hand, the climate is too dry, taller trees will win in competition with the sago palm. It has been suggested that sago palms might survive under drier conditions if well tended. Although sago palms are relatively tolerant of salinity, if the water becomes too brackish, other trees in the vicinity, such as the nipa palm *(Nipa fruiescens),* tend to take over the swamp (Ruddle et al. 1978).

To the conditions of the sago palm's natural habitat, Rhoads (1982) has added the proviso that they are generally "alluvial freshwater swamps" that are frequently located inland from the mouths of large rivers. He has also noted that the mineral soils in which sago palms grow best, especially those high in organic content, need regular flooding for the consistent replacement of nutrients and to discourage the growth of taller trees that keep out sunlight (Rhoads 1982).

Numerous other palms can be sources of sago starch, but they are not so fruitful as *M. sagu* and *M. rumphii.* G. S. Boulger (1889) noted that "inferior" sago could generally be obtained from the Gomuti palm *(Arenga saccharifera),* the Kittool palm *(Caryota urens),* and the Cabbage palm *(Corypha umbraculifera).* In the East Indies, sago could be gotten from *Raphia flabelliformis, Phoenix farinifera,* and *M. filare,* and in South America from *Mauritia flexuosa* and *Guilielma speciosa* (Boulger 1889). There are also a number of *Metroxylon* species in Oceania, including *amicarum, bougainvillense, warburgii, vitiense, upolense, salmonense,* and, presumably, *oxybracteatum* (Ohtsuka 1983).

In South America, additional sago-producing palms have been identified among four different genera: *Syagrus, Copernicia, Mauritia,* and *Manicaria;* moreover, many South American tribes have extracted sago from *Syagrus romanzoffianum* and *Copernicia cerifera* (Wilbert 1976).

Sago Palm Grove Management

Rhoads (1982) determined three general methods of sago palm grove management. The first is simply the process of harvesting sago trees for starch, which (even if only an unintended result) does increase the vitality of the grove: The cutting of palm trunks allows more sunlight to reach nearby shoots, a process that enhances growth and helps to ensure the maturation of at least one sucker, and the damage caused during harvesting by fallen palms and by the construction of work sites in the grove tends to give young sago palm shoots advantages over competitors. Such "unintended management" can be very important to the maintenance and promotion of a sago palm grove (Rhoads 1982).

A second process of sago palm management, termed "horticulture" by Rhoads (1982), involves the planting of suckers or the nurturing and replanting of seedlings. This method, however, is either rare or poorly documented.

A third method of "palm cultivation" involves both the planting of suckers and conscious efforts to change the environment in ways that will promote sago palm growth. One process in which the environment is changed is the creation of artificial swamps by damming streams to flood the groves. Another, observed by Rhoads, is the clearing of the canopy of higher trees to promote sago palm growth. Groves are also sometimes laid out higher up on the slopes of mountains to provide more sunlight for the palms (Rhoads 1982).

Generic Sago Extraction Process

Although sago extraction methods differ somewhat throughout cultures and regions, there are procedures common to all. At the "domestic level," the entire process of sago extraction takes place in the grove itself, thus eliminating the need to transport heavy palm trunks (Flach 1983). Felling the tree occurs when the flowering of the palm indicates that the starch content is at a maximum (Flach 1983). It is also possible to estimate the starch content by taking a small slice from the palm trunk and sampling the starch, either by chewing the pith or by allowing the starch to dry on the axe. If the starch content is too low to merit harvesting the palm, the sample hole is patched with mud (Flach 1983).

If the palm is ready for harvesting, it is felled with an axe, after which the trunk is split lengthwise. (In an alternative method, only the bark is split – and removed.) The pith, when exposed, is "rasped" with a chopper or small hoe (Flach 1983). In the past, choppers were often constructed out of bamboo, but modern choppers are more generally made of metal. The pith is rasped at a straight angle to the fiber while the worker sits on the trunk. The resulting mixture of fiber and rasped pith is next placed on a kind of trough made from palm leaves that has a sieve attached to the lowest end (Flach 1983).

At this point, water is added and kneaded into the mixture to start it flowing, whereupon fibers are caught by the sieve while the starch, suspended in water, flows through the sieve and is collected in a tank, perhaps an old canoe. The starch eventually settles to the bottom, whereas the extra water flows over the side of the tank. The fibrous materials are given to pigs, ducks, and chickens to consume. With this process, it is possible to produce approximately 1 kg of dry starch per hour (Flach 1983).

Larger, although still "small-scale," extraction operations require waterways to transport the sago palm trunks to a processing plant. There they are cut into sections of about 1 to 1.2 meters in length that are easier to work with than entire trunks (Flach 1983). Extraction methods employed at such facilities follow the general model already outlined, although at times different instruments and processes are employed (Flach 1983).

Rasping, for example, is done with a variety of instruments. A board with nails driven through it is sometimes used, but there are also numerous types of engine-powered raspers. At times, a "broad side rasper," which runs parallel to the bark, is employed (Flach 1983).

The kneading and sieving process also varies at the extraction plants. At some, the mixture is trampled, whereas at others a slowly revolving mesh washer constructed of wood or metal is used. Still other plants employ horizontal screen washers or spiral screw washers. It is also possible to combine mechanical stirring with a mesh washer to process the overflow (Flach 1983).

Small ponds are often utilized for the settling process, although another method involves "settling tables." This has the advantage of settling the largest and "cleanest" starch granules – those that bring the highest price on the market – first. The smaller granules, which may contain clay, settle later and yield a grayish, low-quality flour (Flach 1983). Sunlight is often the sole drying agent for the processed starch.

Water quality is a key factor in the entire procedure: Poor water tends to yield sago starch of lesser quality. The refuse created in the production of sago is only of value if domestic animals are nearby. When this is not the case, the refuse is often simply discarded behind plant buildings, creating a stench that is noticeable at quite some distance (Flach 1983).

Extraction Methods in Different Areas

In New Guinea, good use is made of natural stands of sago palms, as well as planted seedlings and suckers. In the swampy lowlands, the semiwild stands require only a minimum of pruning. Those who plant and harvest sago palms throughout the year make periodic visits to the various groves to determine the proper time for harvest (Barrau 1960; Ooman 1971; Ohtsuka 1983).

Sago extraction is usually done by extended family groups in New Guinea. The men fell the palm, making the cut approximately 40 to 70 centimeters above the ground. Next, using axes, they remove half of the surface wood (2 to 4 cm thick) in order to expose the pith. While this is going on, the women construct troughs in which the sago starch will be washed out. Once the men have exposed the pith, the women scrape it out of the trunk and pound it into a mass (Barrau 1960; Ohtsuka 1983).

For starch extraction, the Papuans employ an *abol,* a tool made from two hard sticks and a toughened string of cane that is used much like an adze. (In fact, adze-like tools are common throughout New Guinea.) The actual cutting implement is most often made of stone, wood, or sharpened bamboo, although in areas that have contact with Europe, metal piping is frequently employed (Barrau 1960; Ohtsuka 1983).

In New Guinea, as is typical elsewhere, leaves, a trough, and a sieve are used in the kneading and straining process. The starch-bearing liquid is collected in pans made from leaves or leafstalks, then partly dried and wrapped with palm leaves, usually in the shape of a cylinder or a cone. In one study, it was observed that five women, in about 8.5 hours of extracting, sieving, and drying, were able to produce 54.7 kg of sago (Barrau 1960; Ohtsuka 1983).

In Malaysia, the average yield per sago palm has been estimated at between 113 and 295 kg. The fallen palm tree is cut into logs of 120 to 183 cm in length for rasping. The tools used in rasping have evolved from the *palu,* a sharpened bamboo cylinder with a long wooden handle (which caused many leg injuries), to the *garut,* a wooden board with nails, to mechanized scraping machines, introduced in 1931. One such device consists of a spinning metal disc with serrated edges. Kneading is usually done by trampling, and drying takes place in the sun (Knight 1969; Whitmore 1973).

The extraction process that takes place in a factory is quite similar to the more primitive methods already described. In Singapore, for example, an axe is used to remove the bark, and a two-man nail board is employed in the rasping process. Care is taken to process sago trees in the order in which they arrive at the factory, so as to prevent spoilage. The extracted sago is made into blocks, mixed with water, and then blocked again. They dry in the sun, with occasional turning.

Tikopia provides an example of sago extraction in the western Pacific, where the task proceeds during the rainy season because excess water is readily available. Hoops of iron are used to scrape the trunk after the bark is removed; before iron was introduced, sharp coconut shells were employed. If the work is to be performed in the village instead of in the field, the trunk is cut into sections. Kneading is done in coconut-leaf mesh baskets and the material is then sieved. A trough is filled with the water-and-starch solution and covered with coconut and sago fronds. After the starch has settled, the water is poured off, and the sago is dried and made into flour (Firth 1950).

In South America, where the Warao Indians extract sago from *Manicaria saccifera,* the methods, again, vary only a little from those employed elsewhere. After the tree is felled, the bark is removed, and an adze or hoe *(nahuru)* is utilized to rasp the pith. This hoe typically consists of a blade made of *Mauritia* bark, with a handle constructed of rounded wood and a binding consisting of a two-ply cord made from *Mauritia* bast. The trough employed in the process is made from the trunk of the *temiche* palm. After water has been added to the pith and the mixture kneaded through a strainer, a ball of light brown sago is made.

In South America, sago extraction practices may be part of a disappearing tradition, as the starch is slowly giving way to other agricultural staples, even among the tribes who have used it since prehistoric times (Wilbert 1976).

Sago As Food

It is mainly in New Guinea and neighboring islands that *Metroxylon* has been exploited as a food. A typical swamp grove will have approximately 25 palms per acre per year ready for felling. These will yield a total of about 2,837 to 3,972 kg of crude starch, which will provide from 7 to 10 million calories to its consumers. Sago can be used like any other starch, and peoples familiar with it have developed numerous ways of preserving and consuming it (Boulger 1889; Barrau 1960; Flach 1983).

In the swamp areas of New Guinea, where sago is a staple, the average daily ration per person is a little less than a kilogram, with individual consumption ranging from a bit over 0.5 kg to about 1.5 kg per day. Such quantities of sago deliver from 1,700 to about 4,000 daily calories, which the average family in New Guinea devotes 10 days of each month to acquiring (Ooman 1971).

Preservation

Left dry, sago becomes moldy and spoils. But the starch can be stored by simply placing it in a basket, covering it with leaves, and sprinkling water on it from time to time. With moisture, sago ferments and forms lactic acid, which prevents spoiling. If pottery is available, fresh sago is placed in a jar and covered with water (Barrau 1960; Ooman 1971; Flach 1983).

There are, however, methods of storing sago in a dry state. One is to make sago paste into briquettes by dehydrating it rapidly on a surface above a fire. This method permits the sago to be kept for about one month. Sago can also be dried in the sun, although it is said that this makes it taste "flat" (Barrau 1960; Flach 1983). In general, Papuans tend to think that dried sago loses its flavor.

Supplements

As has been mentioned, nutritional supplements are vital to a diet centering on sago. It must be eaten with some fish or meat (or other whole protein) and with vegetables to provide consumers with a satisfactory intake of the chief nutrients. Thus, in New Guinea, the peoples reliant upon sago, who supplement their diet with fish, hunted game, sago grubs, sago palm heart, leaves, and nuts, probably enjoy a relatively well-balanced diet (Ooman 1971; Dwyer 1985).

Sago Foods

After harvesting, it is common for some of the just-produced sago to be eaten immediately. The women usually prepare it by wrapping a portion in palm leaves or packing it into a section of cane (actually rattan, *Calamus* spp.) and baking it (Ohtsuka 1983). Sometimes, before the sago is baked in a fire, it is mixed with grated coconut or with bean flour (Flach 1983). The remainder of the freshly harvested sago is then wrapped in dry palm fronds to be carried back to the village (Ohtsuka 1983).

The starch is prepared in a number of ways. In areas with pottery, a sago porridge is often served along with condiments, grains, fish, and meat. A biscuit of sago is also made by those who have pottery. In what was Netherlands New Guinea, for example, a sago biscuit was baked in an earthenware mold, which served as the oven.

Areas without pottery will often bake sago paste, rolled in green leaves, in a hot stone oven. This produces a flat cake that often has grated coconut, meat, fish, or greens mixed into it. A cake with grated coconut is called *sago senole.* Sago briquettes, wrapped in sago leaves, are referred to as *sago ega. Sago bulu* comes from the cooking of sago paste in green bamboo. A roasted stick of sago paste is called *sago boengkoes.*

In Borneo, sago pellets are used occasionally as a substitute for rice (Barrau 1960). A sago ash may also be produced by burning the wide part of the sago leaf midrib. This can be an important nutritional supplement providing sodium, potassium, calcium, and magnesium.

Pearl sago – another common product from sago starch – is made by pressing wet sago flour through a sieve and then drying it in a pan while stirring continuously. The "pearls" formed are round, and the outer part of the sago pearl gelatinizes to hold them together. Pearl sago is an important ingredient in soups and puddings (Flach 1983). In Sarawak, wet sago flour is mixed with rice polishings and cooked into pearl form, creating an "artificial rice," certainly a more nutritious food than polished rice. Flach believes that this product has potential as a substitute for rice in Southeast Asia (Flach 1983).

In Tikopia, sago is often made into a flour that is considered a delicacy by those who produce it. On occasion, sago is mixed with other foods to add body, flavor, and softness. Big slabs of sago are also baked for many days in large ovens, and then put aside for times of famine. However, this sago product is considered virtually "unpalatable" by its makers (Firth 1950).

Sago is also employed in foods that are more common in other parts of the world. For example, sago starch can be used in high-fructose syrup as a partial replacement for sucrose (Flach 1983). Sago has also been experimentally added to bread flour. It has been found that adding 10 percent sago to the recipe can improve the quality of the bread produced, although adding more will lower it (Flach 1983).

In addition to the consumption of the palm pith, other parts used as food include the inner shoot of the crown (as fruit or snack), sap from the male inflorescence (boiled into palm sugar, fermented as vinegar or distilled spirit), and the inner kernel (cooked in syrup as a dessert) (Lie 1980). Overall, the uses of sago are as varied as those of other starches.

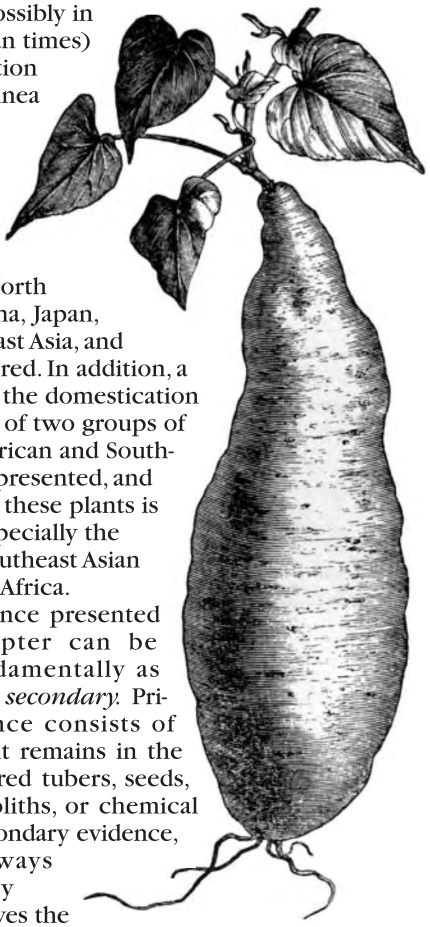
II.B.5 Sweet Potatoes and Yams

The sweet potato (*Ipomoea batatas,* Lam.) and the yams (genus *Dioscorea*) are root crops that today nurture millions of people within the world's tropics. Moreover, they are plants whose origin and dispersals may help in an understanding of how humans manipulated and changed specific types of plants to bring them under cultivation. Finally, these cultivars are important as case studies in the diffusion of plant species as they moved around the world through contacts between different human populations.

This chapter reviews the questions surrounding the early dispersals of these plants, in the case of the sweet potato from the New World to the Old, and in the case of yams their transfers within the Old World. In so doing, the sweet potato's spread into Polynesia before European contact is documented, and the issue of its penetration into Melanesia (possibly in pre-Columbian times) and introduction into New Guinea is explored. Finally, the post-Columbian spread of the sweet potato into North America, China, Japan, India, Southeast Asia, and Africa is covered. In addition, a discussion of the domestication and antiquity of two groups of yams, West African and Southeast Asian, is presented, and the spread of these plants is examined, especially the transfer of Southeast Asian varieties into Africa.



Sweet potato

The evidence presented in this chapter can be viewed fundamentally as *primary* and *secondary.* Primary evidence consists of physical plant remains in the form of charred tubers, seeds, pollen, phytoliths, or chemical residuals. Secondary evidence, which is always significantly weaker, involves the use of historical documents (dependent on the reliability of the observer), historical linguistics (often impossible to date), stylistically dated pictorial representations (subject to ambiguities of abstract representation), remanent terracing, ditches or irrigation systems (we cannot know which plants were grown), tools (not plant specific), and the modern distribution of these plants and their wild relatives (whose antiquity is unknown).

The Sweet Potato

In general, studies of the origin of domesticated plants have first attempted to establish genetic relationships between these plants and some wild ancestor. In the case of the sweet potato, all evidence employed by previous archaeological, linguistic, and historical investigators establishes its origins in the New World.

The remains of tubers excavated from a number of archaeological sites in Peru provide the most persuasive evidence for this conclusion. The oldest evidence discovered to date is from the central coast region at Chilca Canyon where excavated caves, called Tres

Ventanas, yielded remains of potato (*Solanum* sp.), of jicama *(Achirhizus tuberosus),* and of sweet potato *(Ipomoea batatas)* (Engel 1970: 56). The tubers were recovered from all levels, including a level in Cave 1 dated to around 8080 B.C.

These plants were identified by Douglas Yen who could not determine if they were wild or cultivated species, although he observed that wild tuber-bearing sweet potatoes today are unknown (Yen 1976: 43). Whether they ever existed is another matter, but at least the findings in these cases suggest the consumption of "wild" sweet potato at 8000 B.C. in Peru, or more radically, a domesticated variety (Hawkes 1989: 488). If the latter is the case, sweet potatoes would be very ancient in the New World, raising the possibility that perhaps sweet potatoes were the earliest major crop plant anywhere in the world.

Sweet potato remains were also present at a Preceramic site, Huaynuma, dating around 2000 B.C., and at an Initial Period site, Pampa de las Llamas-Moxeke in the Casma Valley, dating from around 1800 to 1500 B.C. (Ugent, Pozorski, and Pozorski 1981: 401–15). In addition, remains have been found at the Early Ceramic Tortugas site in the Casma Valley (Ugent and Peterson 1988: 5).

Still other sweet potato remains in Peru were discovered at Ventanilla, dating from around 2000 to 1200 B.C., the Chillon Valley (Patterson and Lanning 1964: 114), the central coast in the third phase of the Ancon sequence dating 1400 to 1300 B.C. (Patterson and Moseley 1968: 120), and the third Colinas phase dating 1300 to 1175 B.C. (Patterson and Mosely 1968: 121).

Thus, archaeological evidence gives a date of *at least* 2000 B.C. for the presence of the domesticated sweet potato in the New World, while suggesting a possible domesticated form as early as 8000 B.C.

The Botanical Data

In the past, a precise identification of the ancestor of the sweet potato was hampered by a lack of taxonomic concordance. However, Daniel Austin's proposal (1978: 114–29) of a Batatas complex with eleven closely related species represents a significant revision. With other species it includes *I. trifida,* which is often identified as the key species for the origin of *Ipomoea batatas* (Orjeda, Freyre, and Iwanaga 1990: 462–7). In fact, an *I. trifida* complex, to include all plants of the section Batatas that could cross with *I. batatas,* has been proposed (Kobayashi 1984: 561–9).

In the early 1960s, a wild Mexican species of *Ipomoea* (No. K–123) that was cross-compatible and easily hybridized in reciprocal crosses was identified (Nishiyama 1961: 138, 1963: 119–28). Though it resembled the sweet potato, it lacked domesticated traits (Nishiyama 1961: 138, 1963: 119–28). Cytological studies showed K–123 had a chromosome number (n = 45) similar to the sweet potato, and it was identified as *I. trifida* (Nishiyama, Miyazakim, and Sakamoto 1975: 197–208). One concern with K–123 was that it might be a feral sweet potato (Austin 1983: 15–25). But other research proposed that *I. leucantha* was crossed with a tetraploid *I. littoralis* to produce the hexaploid *I. trifida,* with the sweet potato selected from this hexaploid (Martin and Jones 1986: 320).

Critical to the debate is the discovery of the natural production of 2*n* pollen in 1 percent of diploid *I. trifida* (Orjeda, Freyre, and Iwanaga 1990: 462–7). The 2*n* pollen is larger than the *n* pollen, and the diploid populations of *I. trifida* exhibit gene flow between diploids and tetraploids (Orjeda, Freyre, and Iwanaga 1990: 462). Fundamentally, crosses between *n* and 2*n* pollens make various 2×, 3×, 4×, 5×, and 6× combinations of the *I. trifida* complex possible and could result in 6× combinations leading to the sweet potato (Orjeda, Freyre, and Iwanaga 1990: 466). The plants exhibiting this feature come predominantly from Colombia in northwest South America (Orjeda, Freyre, and Iwanaga 1990: 463).

While this new evidence shows how the sweet potato could have arisen from *I. trifida,* the present evidence fails to account for the enlarged storage tuber, nonclimbing vines, red periderm color, and orange roots of the sweet potato (Martin and Jones 1986: 322). It is interesting to note the report of Masashi Kobayashi (1984: 565) that some Colombian varieties of *I. trifida* produce tuberous roots at high elevations. Typically, these plants are found at much lower elevations of between 5 to 20 meters (m) above sea level in Columbia, although some occur at about 1000 m.

Given these observations, it should be mentioned that it is often assumed, after a new species arose through sexual reproduction, that it reached a static stage and that vegetative multiplication has nothing to do with the origin of new forms (Sharma and Sharma 1957: 629). In the various researches into the origin of the sweet potato, investigators have assumed the species arose through sexual reproduction, but karyotypic alterations in somatic cells are common in vegetative reproducing plants, and speciation can occur at those points (Sharma and Sharma 1957: 629). The sweet potato is known to send out roots from the nodes, which will bear small potatoes (Price 1896: 1); therefore, it is possible that karyotypic alterations occurred in the daughter forms, giving rise to new forms, as in some species of *Dioscorea.* This is important because spontaneous mutations occur quite often, and the sweet potato mutates easily using gamma and X rays (Broertjes and van Harten 1978: 70).

In summary, 20 years ago, the singling out of any one species of *Ipomoea* as the ancestral form of the sweet potato represented no more than an educated guess (O'Brien 1972: 343; Yen 1974: 161–70). But today the evidence points strongly to the *I. trifida* complex of plants found in northwestern South America.

Dispersal

Present evidence shows that the sweet potato was introduced into Europe, Asia, Africa, and Australia after Christopher Columbus reached the New World. There is no data to indicate that the plant was known to the ancient civilizations of China, Egypt, Babylon, Persia, Rome, Greece, or India (Cooley 1951: 378), but there is evidence of a pre-Columbian introduction into Oceania. Therefore, in this section, a pre-Columbian and a post-Columbian spread of the sweet potato is outlined, starting with the post-Columbian transfer.

The Post-Columbian Spread

Europe. The sweet potato was introduced into Europe via Spain at the end of the fifteenth century by Christopher Columbus and Gonzolo Fernandez de Oviedo (de Candolle 1959: 55). From this beginning, it spread to the rest of Europe and was called *batata* and *padada* (Cooley 1951: 379).

United States. The sweet potato was brought to Londonderry in New Hampshire by the Scotch-Irish in 1719 (Safford 1925: 223). Yet sweet potatoes are mentioned as growing in Virginia in 1648, and perhaps as early as 1610. Further, they are mentioned in 1781 by Thomas Jefferson (Hedrick 1919: 315). They were also reportedly introduced into New England in 1764, and in 1773 the Indians in the South were reported to be growing them (Hedrick 1919: 315–16).

China. Ping-Ti Ho writes that two theories exist for the introduction of sweet potatoes into China. The first involves an overseas merchant who brought the plants from Luzon, which were given to the governor of Fukien in 1594 to alleviate a famine (Ho 1955: 193). The second claim suggests that sweet potatoes arrived via the southern port of Chang-chou, but no specific date of this alleged introduction is known (Ho 1955: 193). Ping-Ti Ho indicates that whereas the former story may be true, the sweet potato was already in China by 1594, having been observed by 1563 in the western prefecture Ta-li, near Burma (Ho 1955: 193–4). Ho concludes that the introduction could have been either overland or by sea via India and Burma, well before the generally accepted date of 1594.

Japan. An English factory at Hirado was allegedly responsible for first introducing the sweet potato to Japan about 1615. It did not, however, "catch on," and the plant was reintroduced from China in about 1674 to stave off a famine (Simon 1914: 716, 723–4).

India and Southeast Asia. The sweet potato was introduced into India by the Portuguese who brought it to Macão via Brazil (Zavala 1964: 217). Moreover, a Portuguese influence in the spread of the plant to Ambon, Timor, and parts of the northern Moluccas is indicated linguistically, since names for the plant are variations of the word *batata* (Conklin 1963: 132).

In Malaysia the sweet potato is called Spanish tuber (Conklin 1963: 132). In the Philippines it is called *camote* (Merrill 1954: 161–384), whereas in Guam it is called both *camote* and *batat* (Hornell 1946: 41–62; Conklin 1963: 129–36). In the Moluccas and on Cebu it is called *batat* (Merrill 1954: 161–384). The names themselves indicate the source of the plant, since the Portuguese used the Arawak term *(batata),* whereas the Spanish employed the Nahuatl one *(camote).*

Africa. Harold Conklin (1963: 129–36) reports that the terms for the sweet potato take the form "*batata, tata, mbatata,* and the like" from much of the African continent south of the Sahara. The other most widespread term is *bombe, bambai, bambaira,* or *bangbe,* with the Indian trade center of Bombay the etymological source of the word and its pronunciation. Names for sweet potato not falling into these categories have a small geographic distribution or are found only in closely related languages, but as lexical entries, they refer to indigenous yams or other root crops. From these data Conklin concludes that the sweet potato was introduced into Africa by the Portuguese from Brazil, probably early in the slave-trade period of the sixteenth century (Conklin 1963: 129–36). In addition, its introduction into West Africa, specifically Angola, probably coincided with Paulo Diasde Novais's charter of colonization in 1571, which included provisions for peasant families from Portugal with "all the seeds and plants which they can take from this kingdom and from the island of São Tomé" (Boxer 1969: 30).

The Portuguese ports of Mozambique probably saw the introduction of the *batata* from India as well, although the presence of the word *batata* cannot always be taken as indicative of a Portuguese association. Their language became the *lingua franca* along the coasts of Africa and Asia (Boxer 1969: 55).

The word *bambai,* by contrast, is obviously linked to the city of Bombay, but that port was not significant in the India trade network until the British acquired it in 1662. Consequently, for the word Bombay to be associated with the sweet potato in Africa suggests either a British connection or possibly Indian clerks and merchants involved with British colonization. Consequently, Bombay's involvement in introducing the sweet potato to Africa could have been as early as the last quarter of the seventeenth century or as late as the nineteenth (O'Brien 1972: 347).

Thus, the evidence seems to suggest that the sweet potato was introduced into Africa by the Portuguese from Brazil and Lisbon in the sixteenth century. A later spread of the plant possibly occurred via British influence in the late seventeenth through nineteenth centuries.

The Pre-Columbian Spread

Polynesia. The traditional view is that the sweet potato was introduced into Polynesia by the Spanish, who brought it to the Philippines in 1521 (Dixon 1932: 41). Moreover, its name in the Philippines, *camote,* is generically related to the Nahuatl *camotl* and *camotili* (Merrill 1954: 317–18). Another point linked to this theory is that the earliest European Pacific explorers, Alvaro de Mendaña and Pedro Fernandez de Quiros, did not mention the plant by 1606, although they had visited the Marquesas, Santa Cruz, the Solomons, and New Hebrides (Yen 1973: 32–43).

Yet scholars have also argued that the sweet potato was introduced into Polynesia long before Ferdinand Magellan's 1521 voyage, based on the fact that sweet potatoes were found to be a major part of the economies of the islands located at the points defining the triangle of Polynesia, at the time of their discovery – these being New Zealand in 1769, Hawaii in 1778, and Easter Island in 1722 (Dixon 1932: 45).

Further support for the antiquity of the sweet potato in Polynesia has to do with the very large numbers of varieties found in the South Seas: 48 in New Zealand (Colenso 1880: 31–5), 24 in Hawaii (Handy 1940: 133–5), 16 in the Cook Islands, and 22 in New Guinea (Yen 1961: 368, 371).

Twenty years ago the best evidence to document an early introduction of the sweet potato to Polynesia was historical linguistics that had reconstructed the word for sweet potato in Proto-Polynesian to *kumala* (O'Brien 1972: 349–50). Over the years, other scholars have scrutinized the proposed antiquity of the word for sweet potato, and believe that a Proto-Polynesian origin of the word is plausible (Pawley and Green 1971: 1–35; Biggs 1972: 143–52; Clark 1979: 267–8).

Such linguistic evidence establishes a base line for the antiquity of the sweet potato in Polynesia, and when combined with archaeological information about the peopling of the Pacific, it is possible to hypothesize the approximate time of entry of the plant to the region. Jesse Jennings (1979: 3) suggests a Polynesian presence on Tonga and Samoa around 1100 and 1000 B.C., respectively, with an initial thrust east into the Marquesas by A.D. 300. This early appearance was probably associated with the Lapita penetration of western Polynesia at around 1500 B.C. from Melanesia (Bellwood 1978: 53).

And finally, in the past ten years, another line of secondary evidence has been investigated in New Zealand, where prehistoric storage facilities and man-made soils had been discovered (Leach 1979: 241–8, 1984, 1987: 85–94).

However, much *primary evidence* also exists to indicate a pre-Columbian introduction of the sweet potato into Polynesia.

Hawaiian Islands. Archaeological evidence for antiquity of the sweet potato in Hawaii has been found in the form of a carbonized tuber from a fireplace within a "middle" phase domestic structure at Lapakahi. The fireplace is dated A.D. 1655 ± 90 with a corrected date of A.D. 1635 ± 90 or A.D. 1515 ± 90, giving a range of A.D. 1425 to 1765 (Rosendahl and Yen 1971: 381–3). James Cook visited Hawaii in 1778, and so it would seem that this tuber was incinerated at least 13 years prior to his arrival and potentially as many as 263 years before.

Easter Island. The sweet potato was the major crop plant on Easter Island when it was discovered by Jacob Roggeveen in 1722. Charred remains of the plant were recovered there from a fireplace dating A.D. 1526 ± 100 (Skjolsvold 1961: 297, 303). This gives a range between A.D. 1426 to 1626, making the plant remains pre-European by at least 96 years.

New Zealand. In New Zealand, Maori traditions of reconstructing lineage genealogies back to A.D. 1350 recount the arrival of some mysterious "fleet" with the sweet potato and other domesticated plants and animals aboard (Golson 1959: 29–74). Archaeological evidence for the early presence of the sweet potato may exist in the form of ancient storage pits. Jack Golson, for example, (1959: 45) has argued that pits excavated at the fourteenth-century Sarahs Gully site, may have been storage pits for sweet potatoes (kumara). To R. Garry Law (1969: 245) as well, sites like Kaupokonui, Moturua Island, Skippers Ridge, and Sarahs Gully give evidence of widespread kumara agriculture by A.D. 1300.

Primary archaeological evidence was furnished by Helen Leach (1987: 85) with her discovery of charred sweet potato tubers in a burned pit at a *pa* site from (N15/44) the Bay of Islands. Locally called "Haratua's pa," the site is prehistoric, as are the charred sweet potatoes, a point that seems to confirm that these pits were used to store them (Sutton 1984: 33–5).

In addition to the charred tubers at the Bay of Islands, a single charred tuber was discovered at Waioneke, South Kaipara (Leach 1987: 85), a "classic" Maori site 100 to 300 years old (Rosendahl and Yen 1971: 380). Helen Leach (personal communication, letter dated 13 Feb. 1992) notes that no European artifacts were present, and therefore she considers "these kumara pre-European in origin."

Central Polynesia. The most exciting recent evidence dealing with the antiquity of the sweet potato in Polynesia is the discovery of charred *kumara* tubers at site MAN-44 on Margaia Island in the Cook Island group dated at A.D. 1000 (Hather and Kirch 1991: 887–93). The presence of charred remains this early seems to establish beyond doubt a pre-Columbian introduction into Polynesia.

Micronesia. In the Carolinas, infrared spectroscopy analyses of organic residues found on pottery has documented the presence of the sweet potato (and taro) at the Rungruw site in the southern part of Yap at about A.D. 50 (Hill and Evans 1989: 419–25). The presence of rice and banana at about 200 B.C. at the same site was also established (Hill and Evans 1989: 419–25). Yap and the Carolinas are near the northern fringe of Melanesia.

Melanesia. The spread of the sweet potato into Melanesia appears to be the result of Polynesian and European introduction, with the former probably ancient. When the Solomons were discovered, there was no mention of the plant, although taro and yams were reported (Mendana 1901: 212). Because Polynesians were present in the Solomons, it is possible that they brought the plant, since the word *kumala* is found in Melanesian pidgin on the islands (O'Brien 1972: 356).

The term *kumala* is used in New Caledonia and may be pre-European (Hollyman 1959: 368). The sweet potato was in this area in 1793 (Hollyman 1959: 368), and was grown, in lesser quantities than present, in precontact Fiji (Frazer 1964: 148). Finally, there is evidence of the plant's presence in the New Hebrides at the time of discovery (Dixon 1932: 42–3).

New Guinea. New Guinea is the one region of Oceania where the sweet potato is of profound economic importance today. It is more widely grown in the western part of the island than in the east (Damm 1961: 209) and is of great importance in the highlands of Irian New Guinea (Damm 1961: 209). Among the inhabitants of Wantoat Valley in highland Papua, the sweet potato is the only important cultivated food (Damm 1961: 212–3).

Dating the introduction of the sweet potato into New Guinea, however, is a problem. Some historical data point to a late entry. For example, it was introduced into the Morehead district by missionaries (Damm 1961: 210) and was even more recently introduced to the Frederick-Hendrick Island region (Serpenti 1965: 38). Moreover, a survey of plants and animals in 1825–6 revealed no sweet potatoes on the islands west of New Guinea, on the island of Lakor, on the Arru and Tenimber islands, and the southwest coast of Dutch New Guinea (Kolff 1840). The plant ecologist L. J. Brass has suggested that the sweet potato came from the west some 300 years ago, carried by birds of paradise and by hunters and traders in the Solomons region (Watson 1965: 439), which may point to a European introduction.

Introduction to the South Pacific

The primary evidence available today suggests that the sweet potato had a prehistoric introduction into Polynesia and Micronesia at around the time of Christ, while the linguistic evidence points to its presence during Proto-Polynesian times. If Proto-Polynesian was the language of the Lapita culture populations, then the sweet potato was present in Oceania possibly as early as 1500 B.C. Given these new data, the next question must be about the mechanism that facilitated its transfer into Oceania at this early date, since the plant is definitely a New World species.

In attempting to answer that question, a number of researchers over the years have been struck by the similarity between the Polynesian words for sweet potato *(kumala, kumara)* and the word *cumara* found in some Quechua language dictionaries (Brand 1971: 343–65). This, in turn, has led to the suggestion that the sweet potato came to Polynesia from Peru, with Quechua speakers playing some role.

Alternately, Donald Brand (1971: 343–65) argues that the word was Polynesian and introduced into the Andes by the Spanish. He notes that archaeologists, historians, and philologists consider coastal Ecuador, Peru, and Chile to have been occupied by non-Quechuan and non-Aymaran people until shortly before the arrival of the Spanish. The languages spoken would have been Sek, Yungan, and Chibchan, and their terms for sweet potato were *chapru, open,* and *unt.* The Quechua word is *apichu* and is reported along with the words *batatas, ajes,* and *camotes* in the literature and dictionaries of Peru, whereas the word *cumara* is found only in dictionaries, and *cumar* proper occurs only in the Chichasuyo dialect of Quechua (Brand 1971: 361–2).

If it is true that the Spanish introduced the word, then one need not explain its presence in Polynesia as the result of people going or coming from the New World. And if the word *kumala* is Proto-Polynesia, then the term was created by the Polynesians for a plant in their cosmos.

But this still leaves the question of how it might have entered that cosmos. Since the tuber cannot float at all, let alone the thousands of miles separating Oceania and northwest South America, only two explanations appear possible: Transference was accomplished by either a human or a nonhuman agent.

A human agency might have involved a vessel with sweet potatoes aboard drifting from the New World and being cast upon one of the islands of western Polynesia, like Samoa. If any members of the crew survived, they might well have passed along the South American name for the plant. On the other hand, if an empty vessel reached an inhabited island, it would have been examined along with its cargo, and the sweet potato, looking a great deal like a yam, might have been treated like one until its particular features were known. Finally, during a vessel's long drift, rain water might have accumulated within it, in which case the tubers would have begun to grow, taking hold first in the vessel and then in the soil of some uninhabited island, ultimately becoming feral. Later people finding both the island and the plants would have redomesticated and named them.

An alternative possibility would be transfer by a natural agent. Sweet potato tubers cannot float, but its seeds are more mobile, making birds a likely vehicle. Indeed, Douglas Yen (1960: 373) has suggested the possibility of birds as an agent, and Ralph Bulmer (1966: 178–80) has examined the role of birds in introducing new varieties of sweet potato into gardens in New Guinea by dropping seeds. Bulmer observed that the golden plover, a bird that ranges over Polynesia, is a casual visitor to the west coast of the Americas as far south as Chile. These birds are strong fliers and could have carried the small, hard sweet potato seeds either in their digestive tracts or adhering to mud on their feet.

Another potential nonhuman agent was proposed by J. W. Purseglove (1965: 382–3), who noted that some species of *Ipomoea* are strand plants and are distributed by sea. He points out that dried sweet potato capsules with several seeds can float. Because the Polynesian sweet potatoes are very distinctive, he suggests that this distinctiveness is the predictable result of an introduction by a few seeds. Purseglove also observes that introduced crop plants have a considerable advantage if major pests and diseases have not been transferred.

At present, all of these scenarios are only speculative, but an accidental introduction would explain how the plant reached the area early, and yet account for the absence of other useful New World products (manioc, maize, and so forth), which might have been transferred if any sustained exchange between living people had been involved.

The Yams

Although a number of wild members of *Dioscorea* are edible, there are four domesticated yams that are important to agricultural development: *D. alata* and *D. esculenta* from Southeast Asia, and *D. rotundata* and *D. cayenensis* from West Africa. A fifth domesticated yam, *D. trifida,* is found in the New World (Hawkes 1989: 489), but was not especially significant because of the presence of the sweet potato, manioc (cassava), and potato (Coursey 1975: 194) and, thus, has not been a specific focus of research.

The Southeast Asian varieties are interesting because aspects of their spread into Polynesia can be linked to the spread of the sweet potato, whereas African varieties are significant for the role they played in the development of the kingdoms of West Africa. Like the sweet potato, there is no evidence of the use of yams in classical antiquity, but historical data point to their presence in China in the third century A.D. and in India by A.D. 600 (Coursey 1967: 13–14).

The Botanical Data

The family *Dioscoroeaceae* has hundreds of species, and the *Dioscorea* is its largest genus. In general, the New World members have chromosome numbers that are multiples of nine and the Old World species multiples of ten (Ayensu and Coursey 1972: 304). The section including the food yams typically has $2n = 40$, but higher degrees of polyploidy do occur (Coursey 1967: 43–4). For example, *D. alata* has $2n = 30$ to 80; *D. esculenta* has $2n = 40, 60, 90, 100$; *D. rotundata* has $2n = 40$; and *D. cayenensis* has $2n = 40, 60$, and 140. *D. trifida,* the New World domesticated yam, has $2n = 54, 72$, and 81 (Coursey 1976a: 71).

The two yams domesticated in Southeast Asia have been major constituents (along with taro, plantains, bananas and breadfruit) of root crop agriculture in the region, and throughout Oceania before European contact. According to D. G. Coursey (1967: 45), *D. alata,* or the "greater yam," is native to Southeast Asia and developed from either *D. hamiltonii* Hook. or *D. persimilis* Prain et Burk. It is unknown in the wild state and today is the major yam grown throughout the world (Coursey 1967: 45–6). *D. esculenta,* or the "lesser yam," is a native of Indochina, has smaller tubers than the "greater yam" (Coursey 1967: 51–2), and occurs in both wild and domesticated forms (Coursey 1976a: 71). The two native African yams, probably ennobled in the yam belt of West Africa, are *D. rotundata* Poir., the white Guinea yam, and *D. cayenensis* Lam., the yellow Guinea yam (Coursey 1967: 11, 48, 58). The most prominent English-speaking scholars to work on the genus *Dioscorea* have been I. H. Burkill and D. G. Coursey (1976b, 1980; see also Coursey 1967: 28 for further discussion). Indeed, Coursey, the preeminent yam ethnobotanist, has developed a detailed theory of their domestication and antiquity in Africa.

Nonetheless, African yams have not received the attention of plant scientists that they need and deserve, especially in terms of cytological research and breeding programs (Broertjes and van Harten 1978: 73–4). This omission is particularly regrettable in light of their ancient importance, but is doubtless the result of yams being displaced by New World cultivars like maize, sweet potato, and manioc in many parts of Africa.

The lack of botanical research, however, allows plenty of room for controversy. For example, some botanists separate West African yams into two species, whereas others argue that there are insufficient criteria (basically, tuber flesh color) to separate them. They suggest the existence of a *D. cayenensis-rotundata* complex under the rubric of one species, *D. cayenensis* (Miege 1982: 377–83).

D. G. Coursey, as mentioned, identifies the two yams as *D. rotundata* Poir., and *D. cayenensis* Lam. (Coursey 1967: 11, 48, 58). He suggests that the former is unknown in the wild, being a true cultigen, and it may have developed from *D. praehensilis* Benth. (Coursey 1967: 59). The latter, however, is found in both a wild and domesticated condition (Coursey 1967: 48), which may indicate that the wild *D. cayenensis* is the ancestor of the domesticated *D. cayenensis.*

J. Miege (1982: 380–1) states that *D. cayenensis* is a complex cultigen most probably made up of several wild species: *D. praehensilis* Benth. for the forest varieties; and *D. sagittifolia* Pax., *D. lecardii* De Wild., *D. liebrechtsiana* De Wild., and *D. abyssinica* Hochst. ex. Kunth for the savanna and preforest types. An implication of the argument that these two domesticated species are but subspecies of *D. cayenensis* is that both the white and yellow Guinea yams could have risen from wild forms of *D. cayenensis.*

Clearly, such uncertainties will only be resolved by concerted research focused not only upon taxonomic issues but especially on cytological ones. A whole series of breeding and cross-breeding studies are essential, and it would be particularly useful to determine whether *Dioscorea* polyploidy is related to 2*n* pollen as it is in *Ipomoea.*

Transformation and Dispersal

As we noted, the four major domesticated yams come from Southeast Asia and West Africa, respectively. This section examines data, primary and secondary, for their antiquity and their movement throughout the world.

Southeast Asia. In the late 1960s, charred and uncharred botanical material was recovered from excavations at Spirit Cave in Thailand. It was associated with the Hoabinhian complex, dated to around 10,000 to 7000 B.C., and was used to argue for the early development of agriculture in Southeast Asia (Gorman 1969, 1970). Later, however, these materials were critically reexamined by Yen (1977: 567–99), who concluded that most of the remains were not domesticates. Yen thought that early yam domestication could not be inferred from these remains, but that it was probably reasonable to suspect that wild yam was being eaten at that time (Yen 1977: 595).

The fundamental evidence for the antiquity of domesticated Southeast Asian yams and other cultivars is linguistic and lies within words for the whole assemblage of plants and animals making up Southeast Asian root crop agriculture. Robert Blust, a linguist, notes (1976: 36) that Proto-Austronesian speakers had pigs, fowl, and dogs and cultivated a variety of root and tree crops including taro, yams, sago, breadfruit, sugarcane, and banana (Blust 1976: Table II.B.6.1). The linguist Ross Clark reports that words for all the crop plants important in Polynesia horticulture – yam, taro, bananas, sugarcane, and sweet potato – reconstruct to Proto-Polynesian (Clark 1979: 267–8). In relation to this, it should be mentioned that a Lapita site on Fiji, dating between 1150 to 600 B.C., has primary evidence for aspects of this economy in the form of bones of dogs, chickens, and pigs (Hunt 1981: 260).

Helen Leach (1984: 20–1) believes that a series of 21 roundish holes about 35 centimeters (cm) in diameter and some 60 cm deep excavated within a 33 square meter area at Mt. Olo in Samoa implies yam cultivation, for she reports that large yams on Fiji and in other parts of Melanesia are planted in individual holes 60 cm in diameter and 45 cm deep. She also argues for the antiquity of root crop agriculture at Palliser Bay in New Zealand through indirect evidence such as storage pits, garden boundaries, old ditches, and "made-soils" (Leach 1984: 35–41). Susan Bulmer (1989: 688–705) makes these same points, but emphasizes the importance of forest clearance, which in New Zealand appears as early as A.D. 400. Indeed, the antiquity of root crop agriculture in New Guinea is documented by this same type of indirect evidence, and Jack Golson outlines a five-phase model of agricultural development and intensification based upon a whole series of field drainage systems that can be dated as early as 7000 B.C (Golson 1977: 601–38).

In sum, the evidence, though more indirect than direct, supports the notion that the domestication of the Southeast Asian yams, *D. alata* and *D. esculenta,* is very ancient, maybe as early as 4500 B.C. This being the case, what of their dispersal?

The first dispersal is clearly associated with its transfer by Proto-Austronesian–speaking peoples throughout the Southeast Asian tropical world. However, the diffusion of these people is in some dispute. For example, Peter Bellwood (1985: 109) argues that the original Pre-Austronesians were located in Taiwan, whence they moved to the Philippines and from there to parts of Indonesia like Borneo, Java, Sumatra, and Malaya, then into the Moluccas, and finally into New Guinea and Oceania (Melanesia, Micronesia, and Polynesia). But Wilhelm Solheim (1988: 80–2) suggests that Pre-Austronesians developed around 5000 B.C. in Mindanao and the northeast Indonesia regions. He argues against Taiwan as a homeland because of the difficulties posed by winds and currents for sailing south to the Philippines. William Meacham (1988: 94–5), however, considers the languages of south China to have been Mon-Khmer, not Austronesian, and argues that these people could not have migrated to Taiwan and from there south into the Philippines. Rather, Meacham suggests, the homeland of the Proto-Austronesians is somewhere in the triangle defined by Taiwan, Sumatra, and Timor, basically encompassing modern Indonesia.

Regardless of which theory of a Proto-Austronesian homeland is correct, once the Proto-Oceanic languages of that family began to differentiate, they also began to provide linguistic evidence for yams and other cultivars. Thus, yams were in Melanesia by 2000 B.C., in Micronesia by 2000 to 1000 B.C., and in eastern Polynesia by 1500 B.C. The bulk of western Polynesia received yam horticulture (depending on when a specific island group was occupied) sometime between A.D. 1 and 1000 (Bellwood 1985: 121).

In addition, the transfer of Southeast Asian yams with Austronesian speakers to regions outside this early core area is documented. They were present in China in the third century A.D. and in India by A.D. 600 (Coursey 1967: 13–14). To the west, yams were introduced (principally *D. alata*) into Madagascar, probably between the eleventh and fifteenth centuries A.D. By the end of the sixteenth century, *D. alata* was grown in West Africa, from whence it was transferred to the New World by a Dutch slaver in 1591 (Coursey 1967: 15–6).

Africa. The student of African yams, D. G. Coursey, argues (1967: 13; 1975: 203; 1976a: 72) that the use of *D. cayenensis* and *D. rotundata* is ancient, and he proposes the following scenario for the process of yam domestication in West Africa (1980: 82–5). He suggests:

1. that hunter-gatherers, before 60,000 B.P. (before the present), utilized many species of wild yam;
2. that the Sangoan and Lupemban Paleolithic stone industries, c. 45,000 to 15,000 B.P., developed hoes or picks to excavate hypogeous plants, including the yams, and at this time started to develop ritual concepts and sanctions to protect these and other plants;
3. that sometime around 11,000 B.P., with the contraction of West Africa forest and savanna environments and appearance of proto-Negro people, microlithic industries developed which point to new human/environment interactions; these interactions involved selection and protection of favored species, particularly nontoxic yams; and this greater control led to population increases, movement into forest environments and a planting of wild plants – a "protoculture" with a final result being the understanding that one could replant stored tubers;
4. that by 5,000 to 4,000 B.P. Neolithic grain-crop people from the Sahara belt, influenced by Middle Eastern agriculturalists, moved south and interacted with yam "protoculturalists" and from this relationship yam-based agriculture developed;
5. and finally, around 2,500 B.P., with the advent of ironworking, West Africa people could expand deeper into the forest which ecologically favored yam over grain crops, and yam growing populations could achieve numerical superiority over grain farmers and create complex culture systems.

Although this model seems reasonable for the most part, the problems of documenting the domestication of West African yams are similar, and in some cases identical, to those associated with Southeast Asia. Here, too, primary evidence is lacking (Shaw 1976: 108–53).

Preliminary research on yam ennoblement, which was begun in 1977 in Nigeria, has led to the discovery that digging wild yams even with modern tools like machetes, shovels, and spades, let alone digging sticks, was arduous work (Chikwendu and Okezie 1989: 345). Wild yams could not be excavated like domesticated ones. They have long, sharp thorns all over their roots, and in addition to cutting through the yam roots, one has to cut through the tangled roots of the forest itself. A pick-like tool would only get caught between the roots. Trenching around a yam patch was the best procedure, but it still took several days just to dig up the first yam (Chikwendu and Okezie 1989: 345). This finding in turn casts some doubt on Coursey's proposal (1967: 13, 1975: 203) that the pick-like stone tools and Lupemban "hoes" of the Sangoan period were used for grubbing yams.

As with research on the Southeast Asian yams, indirect evidence like forest clearance and linguistics is our main avenue of inference. M. A. Sowunmi (1985: 127–9) reports significant changes in pollen counts from a Niger Delta soil core occurring around 850 B.C. He notes a sudden increase in oil-palm pollen and an increase in weed pollens associated with cultivated land, accompanied by a decrease in pollen of rain forest components, such as *Celtis* sp. and *Myrianthus arboreus.* Because there is no evidence of environmental change at that time, he concludes that humans artificially opened the forest for agricultural purposes. Because oil palm and yams are the main cultivars of aboriginal West African agriculture, he believes that these data document their appearance on a large scale.

It should be noted that, on the one hand, iron hoes, axes, and knives appeared in Nigeria (with the Nok complex) only about 300 years later, around 550 B.C. On the other hand, the site of Iwo Eleru has polished groundstone axes, dating as early as 4000 B.C., that could have been used in forest clearance, and Coursey (1967: 197–205, 1976b: 397) argues that yams were grown before the development of an iron technology because many of the peoples of West Africa have strong prohibitions against the use of iron tools in their important New Yam festivals.

Linguistics, as mentioned, is another source of information. Kay Williamson's study (1970: 156–67) of names for food plants within the Kwa Branch of the Niger-Congo family (spoken in the Niger Delta region) isolated "three main layers of names; ancient West African plants, crops of the Malaysian complex introduced long ago, and more recent introductions over the last five hundred years" (Williamson 1970: 163). The oil palm and the yam (*D. cayenensis-rotundata* complex) belong to the oldest layer; the banana, plantain, and water yam *(D. alata)* occurred in the Malaysian layer; and such plants as maize and manioc (cassava) are more recent introductions from the New World some five hundred years ago.

Williamson does not assess the antiquity of the words for yam and oil palm in calendar years, but P. J. Darling (1984: 65) proposes that the Proto-Kwa language dates from between 4,000 and 10,000 years ago. Although he calls these Proto-Kwa speakers Late-Stone-Age hunter-gatherers, it seems clear that as they had words for major domesticated plants, they must already have been farmers. It is interesting that the more recent end of this date range matches Coursey's model for yam "protoculturalists" quite well. Finally, Proto-Niger-Congo not only has the word for yam (and cow and goat) but also the root meaning "to cultivate," and Proto-Niger-Congo may date back to at least 6000 B.C. (Ehret 1984: 29–30).

Thus, the evidence, though indirect, does point to the existence of yam usage and the concept of cultivation at around 6000 B.C. and forest clearance at about 850 B.C., presumably for the purpose of producing oil palms and yams on a wider scale. All of this in turn suggests an antiquity for agriculture in Africa far greater than believed by many scholars, which probably can best be explained in terms of an independent agricultural development in West Africa. Yet the West African yams had no dispersal beyond their region of origin until they were transferred to the tropical New World in association with the slave trade.

Summary

Three main waves of dispersal are associated with the spread of the sweet potato, in what Yen (1982: 20–1) calls the *kumara, kamote,* and *batatas* lines of transfer. The best-known and documented transfer was the post-Columbian spread via Europeans associated with the latter two lines. The Spanish, or *kamote* line, introduced the sweet potato into Europe, the Philippines, Guam, and Malaysia. From the Philippines it was then carried to China and from China ultimately to Japan. English immigrants transmitted it to the United States, English traders brought it to Japan (though it was not accepted), and English missionaries introduced it in parts of Melanesia and Australian New Guinea.

The Portuguese, or *batatas* line, introduced the sweet potato into India and Africa, Ambon, Timor, the northern Moluccas, and Cebu. The African introduction was from the Portuguese into Angola and Mozambique, as well as to Africa via Bombay through English associations with that trade center in India. Apparently the plant was carried from Burma to China after the Indian introduction.

The *kumara* line, the earliest, is associated with the appearance of the sweet potato in Oceania. This transfer has intrigued scholars for years. New primary evidence, combined with linguistic and historical data, point to a pre-Columbian spread somewhere into eastern Polynesia or even into northern Melanesia by the time of Christ. From this region the plant spread to all points of the Polynesia triangle. It then moved to parts of Melanesia via the Polynesians, and traveled from Melanesia into New Guinea. The transfer into New Guinea was probably accomplished by Melanesians, possibly bird of paradise hunters or migrants settling on the southeast coast. Though some specific areas of New Guinea received the plant from Europeans, in general it was first spread by Melanesians and then by Papuans from the coast into the highlands, probably through the Markham Valley. The way in which early sweet potatoes reached New Guinea cannot presently be determined, but in the light of the Yap data it could be earlier then generally supposed.

The establishment of the sweet potato in many areas of Micronesia, parts of central Polynesia, and sections of Dutch New Guinea, including Lakor and the Arru and Tenimber islands, was prevented by ecological conditions unsuitable to its growth.

Yams also had several waves of dispersal. The Southeast Asian yams moved through the region beginning about 4500 B.C, and on into Oceania by 1500 B.C. They arrived in India and China in the first millennium A.D., and early in the second millennium entered Madagascar. From East Africa they moved to West Africa by the sixteenth century, and at the end of the sixteenth century came to the tropical New World.

General Conclusions

This survey on the problem of the origin and dispersal of the sweet potato and of yams indicates the following. First, the sweet potato originated in northwestern South America around 8000 B.C., in association with the initial development of tropical-forest root crop agriculture. The actual botanical ancestor is probably the result of various n and $2n$ crosses within the *I. trifida* complex.

Primary evidence of the pre-Magellan introduction of the sweet potato into central Polynesia is established at around A.D. 1000, and even earlier, A.D. 50, in Micronesia on Yap. When combined with the archaeology of Oceania, these data suggest, conservatively, that the plant arrived in eastern Polynesia, maybe in the Fiji area, by about 500 B.C. Alternatively, the plant was dispersed by Lapita people sometime between 1500 to 500 B.C. during their movement through Melanesia. From Melanesia it was carried to New Guinea by Melanesians at an unknown date, but this could have taken place prior to the arrival of the Europeans.

The transference between Polynesia and the New World would seem to have been the result of either human accident or natural causes. An introduction by the casting up of a vessel upon some island of eastern Polynesia is possible, but it is equally possible that the plant was spread by natural agents, such as birds carrying seeds or by floating seed capsules. Both these hypotheses need further examination.

The post-European introduction of the sweet potato into Africa, North America, Europe, India, China, Japan, the Philippines, the Moluccas, and other islands in the Indonesian area was the result of Spanish, Portuguese, and English trade, exploration, colonization, and missionization.

The five ennobled yams were domesticated in Southeast Asia, West Africa, and tropical America, respectively, although the last region is not especially important to this study. Southeast Asian yams were probably domesticated before 4500 B.C., whereas the West African yams could be as old as 6000 B.C. but were probably domesticated by the first millennium B.C. The possible botanical ancestors of these yams are a subject of debate, and considerable cytological and taxonomic research is needed before this issue will be resolved. Needless to say, these ancestors will be found to have been native to each respective area.

Patricia J. O'Brien

I wish to thank Dr. Roger Green of the University of Auckland, Dr. Helen Leach of the University of Otago, Dr. Patrick V. Kirch of the University of California at Berkeley, and Dr. Donald Ugent of Southern Illinois University for kindly answering my questions about their research, and also for generously sharing with me reprints of their work.

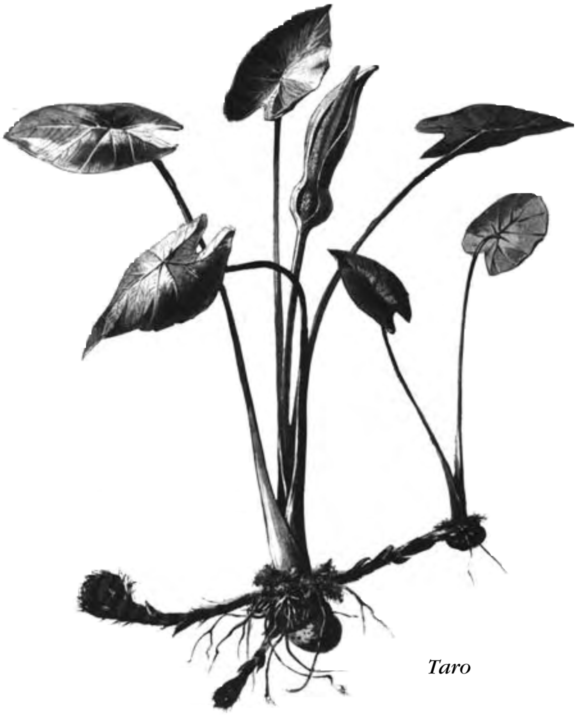
II.B.6 Taro

Taro is the common name of four different root crops that are widely consumed in tropical areas around the world. Taro is especially valued for its starch granules, which are easily digested through the bloodstream, thus making it an ideal food for babies, elderly persons, and those with digestive problems. It is grown by vegetative propagation (asexual reproduction), so its spread around the world has been due to human intervention. But its production is restricted to the humid tropics, and its availability is restricted by its susceptibility to damage in transport.

Taro is most widely consumed in societies throughout the Pacific, where it has been a staple for probably 3,000 to 4,000 years. But it is also used extensively in India, Thailand, the Philippines, and Southeast Asia, as well as in the Caribbean and parts of tropical West Africa and Madagascar (see Murdock 1960; Petterson 1977). Moreover, in the last quarter of the twentieth century taro entered metropolitan areas such as Auckland, Wellington, Sydney, and Los Angeles, where it is purchased by migrants from Samoa and other Pacific Island nations who desire to maintain access to their traditional foods (Pollock 1992).

Although taro is the generic Austronesian term for four different roots, true taro is known botanically as *Colocasia esculenta,* or *Colocasia antiquorum* in



Taro

some of the older literature. We will refer to it here as Colocasia taro. False taro, or giant taro, is the name applied to the plant known botanically as *Alocasia macrorrhiza.* It is less widely used unless other root staples are in short supply. We will refer to it as Alocasia taro.

Giant swamp taro is the name used for the plant known as *Cyrtosperma chamissonis.* This is a staple crop on some atolls, such as Kiribati, and is also grown in low-lying areas of larger islands. We will refer to it as Cyrtosperma taro. The fourth form of taro has been introduced into the Pacific and elsewhere much more recently. It is commonly known as tannia, kongkong, or American taro, but its botanical name is *Xanthosoma sagittifolium.* It has become widely adopted because it thrives in poorer soils and yields an acceptable food supply. We will refer to it as Xanthosoma taro.

The starch-bearing root, termed corm or cormlet, of these four plants makes a major contribution to the human diet, and even the leaves are occasionally used as food, as in the case of young Colocasia leaves. The leaves are also employed as coverings for earth ovens and as wrappings for puddings that are made from the grated starch root and baked in an earth oven. The large leaves of Cyrtosperma taro also provide a good substitute for an umbrella.

Botanical Features

All the taros are aroids of the Araceae family, so we would expect to find close similarities among them. They grow in tropical climates with an adequate year-round rainfall. All taros must be propagated vegetatively, as they do not have viable seeds. Consequently their production for food crops has been engineered by human intervention. Both the corms and the leaves are acrid to some degree, particularly before they are cooked, and cause an unpleasant irritation of the skin and mouth (Tang and Sakai 1983; Bradbury and Holloway 1988).

Colocasia Taro

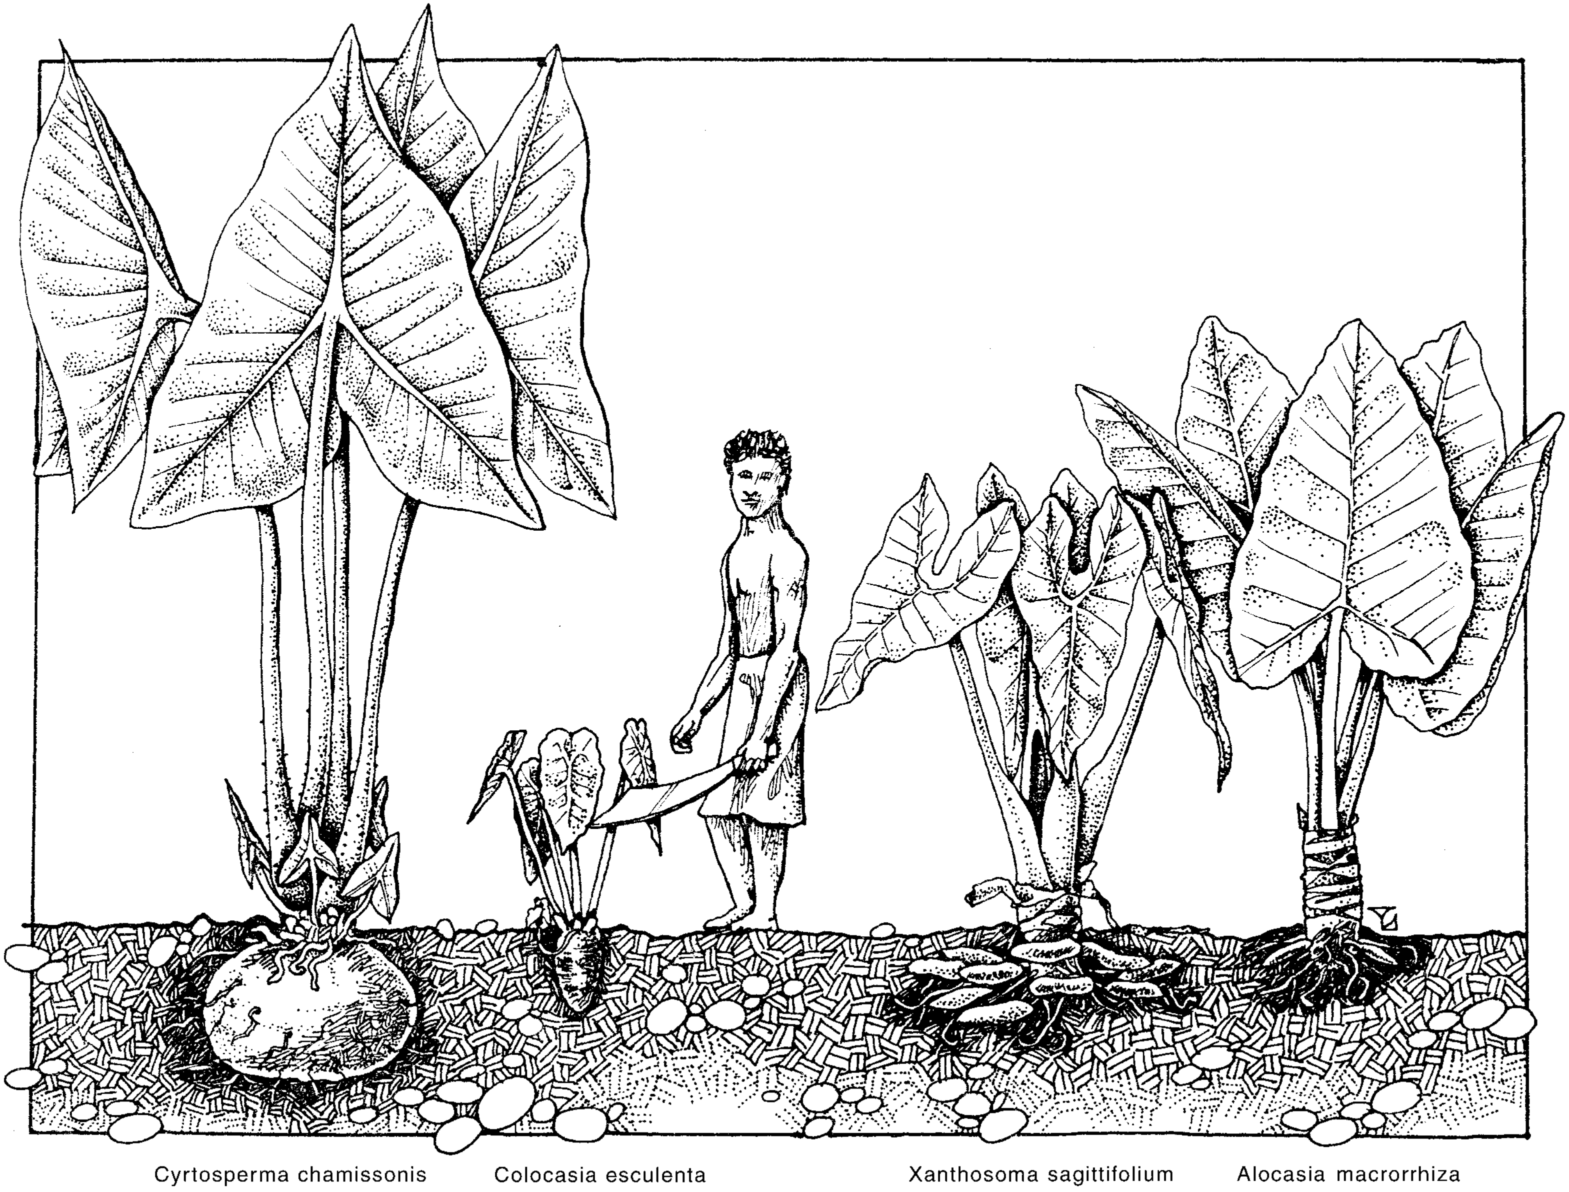
The Colocasia taro plant consists of an enlarged root or corm, a number of leafstalks, and leaves. The leaves are the main visible feature distinguishing Colocasia from the other taros, particularly Xanthosoma (see Figure II.B.6.1). The Colocasia leaf is peltate, or shield-shaped, with the leafstalk joining the leaf about two-thirds of the way across it. Varieties of Colocasia taro differ in the color of the leafstalk, the shape and color of the leaf and veins, and the number of fully developed leaves. They also differ in the shape, flesh color, and culinary qualities of their tubers. The varieties are recognized by individual names, particularly in those societies in the Pacific where the plant is a major foodstuff. For example, 70 local names were recorded in Hawaii and 67 in Samoa (Massal and Barrau 1956; Lambert 1982). Indeed, fully 722 accessions have been recorded in collections of root crops in South Pacific countries (Bradbury and Holloway 1988).

Colocasia taro can be grown on flooded or irrigated land and on dry land. The planting material consists of the corm plus its leafstalks, minus the leaves. Taros in Fiji are sold this way in the market, so that the purchaser can cut off the root for food and plant the topmost part of the root plus leafstalks, known as a sett, to grow the next crop of taro. Harvesting one taro root therefore yields the planting material for the next crop. The root takes about 7 to 10 months to mature. Once the corm has been cut or damaged, taro rots quickly, making it difficult to ship to distant markets.

Alocasia Taro

Sometimes known as giant taro, or *kape* in Polynesian languages, Alocasia taro is a large-leafed plant that is grown for its edible stem rather than for the root. The fleshy leaves are spear-shaped and can reach more than a meter in length. The stem and central vein of the leaf form a continuous line. The leaves of this taro are not usually eaten.

The edible part is the large and long (a half meter or more), thickened underground stem that may weigh 20 kilograms (kg). It is peeled and cut into pieces to be cooked in an earth oven or boiled.



Cyrtosperma chamissonis
Colocasia esculenta
Xanthosoma sagittifolium
Alocasia macrorrhiza

Figure II.B.6.1. Four types of taros. (Illustration by Tim Galloway).

Alocasia taros are very acrid, as they contain a high concentration of calcium oxalate crystals in the outer layers of the stem. These crystals are set free by chewing and can cause irritation in the mouth and throat if the stem is not thoroughly cooked. The calcium oxalate content increases if the plant is left in the ground too long. For this reason some societies consider Alocasia taro fit for consumption only in emergencies. But in Tonga, Wallis, and Papua New Guinea, varieties with very low oxalate content have been selectively grown to overcome this problem (Holo and Taumoefolau 1982). Twenty-two accessions are held in collections of root crops for the South Pacific (Bradbury and Holloway 1988).

Cyrtosperma Taro

Cyrtosperma taro, called giant swamp taro, also has very large leaves, sometimes reaching 3 meters in height. In fact, a swamp taro patch towers over those working in it. The leaves are spear-shaped and upright, the central vein forming a continuous line with the stem. The edible corm grows to some 5 kg in size, depending on the variety.

This taro prefers a swampy environment and will withstand a high level of water, provided it is not inundated by seawater. It is grown in Kiribati under cultivation techniques that have been carefully developed over several hundred years (Luomala 1974).

Cyrtosperma taro is a highly regarded foodstuff in Kiribati and in Yap, as well as on other atolls in Micronesia and in the Tuamotus. It is also cultivated in the Rewa district of southeast Fiji, and evidence of its former cultivation can be found in northern Fiji, Futuna, and Wallis, where it is employed today as an emergency crop. It is rarely cultivated outside the Pacific.

Xanthosoma Taro

Xanthosoma taro, by contrast, is much more widespread than Cyrtosperma taro and may be found in many tropical areas, including those on the American and African continents, as well as in the Pacific, where several varieties are now being cultivated (Weightman and Moros 1982). Although it is a very recent introduction to the islands relative to the other three taros, it has become widely accepted as a household crop because it is easy to grow, it can be intercropped with other subsistence foods in a shifting cultivation plot, and it tolerates the shade of a partially cleared forest or of a coconut or pawpaw plantation. It cannot stand waterlogging.

The principal tuber of Xanthosoma is seldom ≠harvested because it also contains calcium oxalate crystals. Rather, the small cormlets are dug up, some being ready 7 to 10 months after planting. These are about the size of a large potato, weighing up to half a kilo.

In appearance Xanthosoma taro is often confused with Colocasia taro, the term "eddoe" being used for both. The main difference between them is in the leaf structure; the Xanthosoma leaf is hastate, an arrow or spearhead shape, and not peltate, so that the leafstalk joins the leaf at the edge, giving it a slightly more erect appearance than the Colocasia leaf (see Figure II.B.6.1). The distinctive feature of the Xanthosoma leaf is its marked vein structure together with a marginal vein.

Production

As already noted, all of the taros must be propagated vegetatively as none of them produce viable seeds naturally. They thus require human intervention both for introduction to a new area and for repeated production of a food supply. This factor further strengthens the likelihood of selection of particular varieties that have more desirable attributes as food, such as reduced acridity and suitability to particular growing conditions. The planting material for all the taros is either a sucker or the sett (consisting of the base of the petioles and a 1-centimeter section from the top of the corm).

Dryland or upland cultivation is the most widespread form of cultivation of Colocasia taro, which grows best in a warm, moist environment. It can be grown between sea level and 1,800 meters (m) where daily average temperatures range between 18 and 27 degrees Celsius (C), with rainfall of about 250 centimeters (cm) annually. The setts or suckers are placed in a hole made with a digging stick, with a recommended spacing between plants of 45 cm by 60 cm to produce good-sized corms. Yield will increase with higher planting density (De La Pena 1983).

Irrigated or wetland Colocasia taro is grown in prepared beds in which, to prevent weed seed germination, water is maintained at a level of 5 cm before planting and during the growth of the setts until the first leaves unfurl. The beds may be a few feet across, beside a stream or well-watered area, or they may be in an area some 2 to 3 acres in size, depending on the land and water available. After the first leaves appear, the beds are frequently covered with whole coconut fronds to shade the young plants from the sun.

Irrigated taro planted at a density of 100,000 plants/ha yields 123.9 tons/ha. With 10,000 plants/ha the yield is 41.4 tons/ha (De La Pena 1983: 169–75). Clearly, the more intense techniques developed for wetland cultivation produce a higher yield. But these techniques are suited only to areas where the right conditions pertain, and on the Pacific Islands such areas are limited because of the nature of the terrain. Dryland taro is, thus, more versatile.

Colocasia taro, whether upland or irrigated, may be harvested after a growing period ranging from 9 to 18 months, depending on the variety and the growing conditions. In Fiji some varieties are harvestable at 9 to 11 months after planting, whereas in Hawaii harvest takes place from 12 to 18 months after planting in the commercial fields.

The subsistence farmer, by contrast, harvests only those taros needed for immediate household use. The farmer will cut off the setts and plant them in a newly cleared area of land or in a different part of the irrigated plot. Thus, any one household will have several taro plots at different stages of growth to maintain a year-round supply and to meet communal obligations for feasts and funerals.

Pests and pathogens are a greater problem for Colocasia taro than for the other varieties. Both the leaves and the corm are subject to damage during the growing period from a range of pests and biotic agents (Mitchell and Maddison 1983). In the Pacific, leaf rot and corm rot have been the most serious diseases, spreading rapidly through whole plantations, particularly in Melanesia (Ooka 1983). In fact, these diseases were so severe in the early 1970s that some societies in the Solomons ceased taro consumption and switched to the sweet potato. West Samoa has recently lost its entire crop due to these diseases.

Alocasia is interplanted with yams and sweet potatoes in Tonga and Wallis where it is grown in shifting cultivation plots. The planting material is usually the larger suckers (although cormlets may also be used). These are placed in holes 10 to 25 cm deep, preferably between July and September. If planted with spacing of 1.5 m by 1.5 m Alocasia will yield 31 tons/ha, with an average kape root stem weighing 8 to 10 kg and reaching 1.5 m in length. The plant suffers few pests, is weeded when convenient, and is harvested a year after planting (Holo and Taumoefolau 1982: 84).

Swamp Cyrtosperma production has been culturally elaborated in some Pacific societies so that it is surrounded by myth and secrecy (see Luomala 1974 for Kiribati). The planting material may be a sett or a young sucker, and in Kiribati this is placed in a carefully prepared pit that may be several hundred years old, to which mulch has been constantly added. Each new plant is set in a hole with its upper roots at water level, surrounded by chopped leaves of particular plants chosen by the individual planter and topped with black humic sand. It is encased in a basket of woven palm fronds, to which more compost mixture is added as the plant grows. The larger cultivars are spaced at 90 cm by 90 cm; smaller ones are spaced more closely.

A pit is likely to consist of Cyrtosperma plants at various stages of growth. A corm may be harvested after 18 months – or it may be left for 15 years, by which time it is very fibrous and inedible but still brings prestige to the grower's family when presented at a feast. Yield is uneven due to different cultivation practices but may reach 7.5 to 10 tons/ha. An individual corm may weigh 10 to 12 kg (Vickers and Untaman 1982).

Xanthosoma taro is best grown on deep, well-drained, fertile soils. It tolerates shade and so can be interplanted with other crops such as coconuts, cocoa, coffee, bananas, and rubber, or with subsistence crops such as yams. The planting material is the cormlet or a sett, but the former grows more quickly than the latter. These can be planted at any time of year but grow best if planted just before onset of the rainy season. If they are spaced at 1 m by 1 m, the yield is about 20 tons/ha. The plant, which has few pests or diseases, produces a number of cormlets the size of large potatoes. These can be harvested after six months, but they bruise easily, reducing storage time (Weightman and Moros 1982).

Different planting techniques have been developed over time in order to provide a foodstuff that suits both the palate of those eating it and the local growing conditions. Most taro (dryland Colocasia, Alocasia, and Xanthosoma) is grown under dryland conditions with reasonable rainfall, and it seems likely that the aroids were all originally dryland plants (Barrau 1965). Because the techniques involved in the cultivation of wetland Colcasia and swamp Cyrtosperma taro are more arduous than those of dryland cultivation, one suspects that these plants were encouraged to adapt to wetland conditions, probably to meet specific food tastes.

Origins

Colocasia and Alocasia taro are among the oldest of the world's domesticated food plants. Both apparently have an Asian origin, possibly in India or Burma (Massal and Barrau 1956), but because they consist of vegetal material that has no hard parts, they leave almost no trace in the archaeological record. As a consequence, there has been much room for debate about the early development of the taros.

Some of the debate has centered on the question of whether root crop domestication preceded that of cereals, such as millet and rice, in the Southeast Asia region. Most authorities now agree that root crops came first (e.g., Chang 1977), although C. Gorman (1977) considered rice and taro as sister domesticates. In an overview of the evidence, M. Spriggs (1982) argued that root crops, including taro, were early staples in Southeast Asia, with rice becoming a staple much later.

The time depth is also problematic. It has been suggested that the early agricultural phase of slash-and-burn, dryland cultivation in Southeast Asia took place some 8,000 to 10,000 years ago, with a sequence of dominant cultigens proceeding from root crops to cereals (Hutterer 1983). Dryland taro may have been cultivated for some 7,000 years or more, with wetland (Colocasia) taro forming part of a second stage of development of Southeast Asian food crops (Bellwood 1980).

Prehistorians have given much more attention to wetland taro irrigation techniques and those used in the production of paddy rice than they have to dryland practices. This is because wetland techniques are said to mark technological innovation and, thus, to be associated with a more complex level of social organization than that required in the production of dryland taro or rice (e.g., Spriggs 1982 for Vanuatu; Kirch 1985 for Hawaii). Yet this does not necessarily mean that foodstuffs produced by irrigation had greater importance in the diet than their dryland counterparts. We need to know the importance of such crops in the food consumption and exchange systems of those people who chose to develop a more complex mode of production. For a food to be considered a staple, the proportion of dietary content is the important aspect, as opposed to the techniques of production or the size of the production units.

Ease of cooking may constitute another reason that taro preceded rice. A hole lined with stones, in which a fire was lit, became an oven with limited tools. The whole taro root could be cooked thoroughly in such an oven, together with fish or pork or other edibles. To cook rice, by contrast, required some form of utensil in which to boil the rice to make it edible, either in the form of cakes, or as a soup.[1]

But if taro, whether Colocasia or Alocasia, had advantages that suggest it was an earlier domesticated foodstuff than rice, its disadvantages lay in its bulk and post-harvest vulnerability. However, advantages outweighed disadvantages, so it is not surprising that these two forms of taro spread as widely as they did across Oceania and into Africa.

Despite its antiquity, however, the origin of Alocasia taro has not attracted as much attention as that of Colocasia taro; similarly, we know more about the origin of Xanthosoma taro than we do about Cyrtosperma taro. This is partly because the Alocasia and Cyrtosperma taros are not as widely used as the other two and partly because, even where they are used as foods (save for Cyrtosperma in Kiribati and Yap), they are not the main foodstuff.

Alocasia taro has its origins either in India (Plucknett 1976) or in Sri Lanka (Bradbury and Holloway 1988) but has been grown since prehistory throughout tropical southeast Asia, as well as in China and Japan (Petterson 1977). Cyrtosperma, by contrast, was said to have been first domesticated either in the Indo-Malaya region (Barrau 1965) or in Indonesia or Papua New Guinea, where it has wild relatives (Bellwood 1980). Both Alocasia and Cyrtosperma taros are abundant in the Philippines, where a number of different varieties of each are known (Petterson 1977). Cyrtosperma remains, discovered there by archaeologists, suggest that it was cultivated at least from A.D. 358 (Spriggs 1982), indicating that there was sufficient time to develop a range of plant types yielding less acridic starch foods.

In their reconstruction of the early forms of the Austronesian language, A. Pawley and R. Green (1974) include words for Alocasia, Colocasia, and Cyrtosperma taros, indicating a time depth in the Pacific of some 3,000 to 4,000 years. Thus, all three plants have probably been domesticated and exchanged for over 5,000 years in tropical Southeast Asia.

Xanthosoma taro differs from the other three aroids in having its homeland in tropical America. Little is known about the Xantharoids before the twentieth century, as J. Petterson (1977) points out in her thesis on the dissemination and use of the edible aroids. But she does offer us one possible reconstruction of the spread of what she calls American taro. It was "a most ancient domesticate of the Western hemisphere," said to have originated in the Caribbean lowlands along the northern coast of South America.

By the time Europeans reached the Americas, Xanthosoma taro had diffused south into northwest South America and north across the Antilles and Central America where several varieties were known.[2] Exactly where Xanthosoma was consumed at this time, and who consumed it, is unclear, although later on taro roots served as an important foodstuff for slaves on sugar plantations.

Geographic Spread

The four aroids have spread around the tropical areas of the world, with Colocasia and Xanthosoma more widely cultivated than Alocasia and Cyrtosperma taros. A range of varieties of each has been developed by human selectivity, and all four are extensively utilized by the island societies of Oceania.

Colocasia taro was carried from its South Asia homeland in both an easterly and a westerly direction, probably some 6,000 years ago (Bellwood 1980). Moving east it became established in Thailand, Malaysia, Indonesia, and the Philippines and from there was carried by canoe into Papua New Guinea, the Marianas, and henceforth into Micronesia and Polynesia (Petterson 1977; Yen 1980; Hutterer 1983; Pollock 1992). The Malay name *tales* is the base of the common term taro as widely used today. In the four areas of Oceania the Colocasia root has gained a reputation as a highly valued foodstuff that also has prestige value (though not as high as Dioscorea yams). Today it is still cultivated as a food in Hawaii, the Marquesas, Tahiti, the Cooks, the Solomons, and Papua New Guinea. It remains a major foodstuff in Samoa, Tonga, Wallis, Futuna, Fiji, and Vanuatu.[3]

The easterly spread of Colocasia taro across the islands of the Pacific is today associated by prehistorians with the development of Lapita culture some 6,000 years ago. Lapita culture is a construct by prehistorians of a period in the settlement of the Pacific, with the spread of a particular form of pottery as its hallmark. Associated with this culture is the cultivation of Colocasia taro in particular, but Alocasia taro as well.

How sophisticated irrigation technology was introduced by these people moving out of Southeast Asia has not been clearly established. It seems likely that dryland taro could have been introduced to a wider range of environments in the Pacific and, thus, was in existence earlier than irrigated or wetland taro.

For our purposes the important consideration is how these production techniques influenced the acceptability of the crop as a foodstuff. Because people in the Pacific today assert that irrigated taro is softer and less acrid, it is likely that the wetland Colocasia taro has undergone more specific selection than the dryland version, depending on how the root was prepared as a food. For the most part it was cooked whole in the earth oven, to be eaten in slices with accompaniments (as discussed in the next section). But in Hawaii, Rapa, and a few small islands it was employed mainly as *poi,* a fermented product made from either upland or wetland taro. The dietary uses of Colocasia taro are thus likely to have influenced which plants were selected for replanting and the techniques (whether wet or dry) of production. Moreover, appropriate cooking techniques had to be developed, as well as methods for overcoming the acridity.

In its westward spread, Colocasia taro was planted in India, where it still forms part of the diets of some societies today. It reached Madagascar where it became widely established between the first and eleventh centuries A.D. It was carried further westward in two branches, one along the Mediterranean and the other across Africa south of the Sahara.

The plant attained significance in West Africa where it has been grown ever since. In the Mediterranean region, it was flourishing in Egypt at the time of Alexander's expedition, where it was known as the Egyptian water lily and Egyptian beans. Virgil and Pliny both referred to the Colocasia plant in their writing, with the latter noting that "when boiled and chewed it breaks up into spidery threads" (quoted in Petterson 1977: 129). Colocasia taro has continued in importance in Egypt and also in Asia Minor and Cyprus until recently when it became too expensive to produce (Petterson 1977).

Colocasia taro reached the Iberian Peninsula probably by about A.D. 714, along with sugar cane. In both West Africa and Portugal the term *enyame* came to be applied to the Colocasia taro and was picked up by other Europeans as a generic name for all unfamiliar root crops. Thus, to English explorers yams meant any number of root crops, including both yams and Colocasia taro (Petterson 1977).

The latter also reached tropical America from the east, and it became a secondary foodstuff for Peruvian, Ecuadorean, and Amazonian peoples, as well as for those of the Caribbean, where it is known as dasheen or eddoe (Petterson 1977: 185). It seems likely that Colocasia taro was carried by the Iberians in their westward explorations and then brought from Africa to feed slaves during the Middle Passage.

By contrast, Alocasia taro has not traveled so widely. It was carried from Southeast Asia mainly into the islands of Oceania where it has been domesticated on some atolls in Micronesia and Polynesia, as well as on some high islands, such as Samoa, Tonga, Wallis, and Fiji. On those islands where it is grown, a number of different varieties of the plant have been developed locally. In all these places the Alocasia taro makes a significant contribution to the diet.

Its westward spread from Indonesia to India was less prolific (Plucknett 1976). Today, Alocasia plants can be found growing as ornamentals in both tropical and subtropical areas, such as Florida (Petterson 1977) and in the northern part of the north island of New Zealand. They do not, however, serve as food.

Cyrtosperma is a small genus that is used as food almost exclusively in the Oceania region.[4] But Xanthosoma taro spread from its homeland along the northern coast of South America out into the northern part of South America and through tropical Central America. It may have been of some importance as a food in Classic Maya civilization (c. A.D. 200–900).[5]

Spanish and Portuguese contacts with America led to the dispersal of Xantharoids into Europe (they were grown in England as a curiosity in 1710) and, probably, into Africa where they may have died out and then been reintroduced. The root was allegedly brought to Sierra Leone in 1792 by former North American slaves who had fled to Nova Scotia after the American Revolution. However, the generally accepted date for the introduction of Xanthosoma taro to sub-Saharan Africa is April 17, 1843, when missionaries carried the American taro from the West Indies to Accra, Ghana.

It subsequently spread from West Africa to Uganda and through the Cameroons and Gabon to attain varying levels of importance. Beyond Africa, it traveled along Portuguese trading lines to India and the East Indies, following a similar route as the sweet potato. But it has not become an important food crop in Asia, except in the Philippines whence it spread to Malaysia (Petterson 1977).

Xanthosoma was introduced to the Pacific only in the last 200 years, probably via Hawaii (Barrau 1961) and Guam in contact with the Philippines (Pollock 1983). Its spread across the Pacific was aided by missionary activity as much as by island exchange, and the names used in Pacific societies today for Xanthosoma taro suggest the routes of transferal.

Taros As Food

Taro is a very important foodstuff in those societies that use it, both in the household and also for feasts and exchanges. But in terms of world food crops, the taros are considered of marginal importance. They rank behind bananas and root crops, such as cassava, sweet potatoes, and yams, in amounts consumed (Norman, Pearson, and Searle 1984: 221). Nonetheless, taros do have potential in promoting diversification of the world food supply and could make a significant contribution if greater agronomic investment was made. The Root Crops program of the Food and Agriculture Organization of the United Nations (FAO) is attempting to address some of these issues, as is the work of the Australian Centre for International Agricultural Research (ACIAR) (Bradbury and Holloway 1988).

In the Pacific, people have a higher regard for taros than any of the other seven common starchy foods (Pollock 1992). Cassava outranks taros in terms of the tons per hectare produced, but that is because it is a good "safety" crop that will grow in poorer soils and can be harvested as needed when the more preferred starches are in short supply. Yet householders in most Pacific societies would not offer cassava to an honored guest or make it their contribution to a celebration; rather they would go to some lengths to procure Colocasia taro or Dioscorea yams or breadfruit for such purposes. In fact, Colocasia taro, yams, and breadfruit are at the very top of the list for everyday consumption in the Pacific and for exchanges and presentation at feasts. They are also the most expensive of the local foods on sale in the urban markets. The other three taros may be maintained as secondary or fallback foods, but the reputation of a rural family still rests in large part on its ability to produce a good supply of Colocasia taro, together with the other desirable crops, for self-maintenance (Pollock et al. 1989).

The taros (and other starch foods) form the major part of the daily diet of Pacific Island people living on their own land today, much as they have in the past. They are the main substance of daily intake, eaten once a day in the past, but now twice a day. Taros, and the other starches, provide the bulk of the food, the "real" food (*kakana dina* in Fijian), but are accompanied by a small portion of another foodstuff such as fish, coconut, or shellfish to form what we call a meal in English. If just one of them is eaten without the other, then people are likely to say that they have not eaten, because the two parts are essential to the mental, as well as physical, satisfaction that food confers (Pollock 1985).

Taro maintains this importance in the minds of contemporary Pacific Islanders living in metropolitan areas such as Wellington. The root may be expensive and hard to find, but these people make a great effort to obtain Colocasia taro for special occasions, such as a community feast, or for a sick Samoan or Tongan who may request a piece of taro to feel better.[6]

According to the accounts left by missionaries and other visitors to the Pacific in the nineteenth century, the amounts of taro (particularly Colocasia taro) consumed by Fijians and Tongans, for example, were prodigious. They especially noted the consumption patterns of chiefs, suggesting that all this taro was a cause of their obesity. We have less information, however, regarding the ordinary people's consumption (see Pollock 1992).

But in Tahiti, and probably elsewhere in the Pacific, food consumption generally varied from day to day and week to week. Europeans were amazed at how Tahitians could cross the very rugged interior of their island, going for four days with only coconut milk to drink, yet when food was available, they consumed very large amounts. Because food habits were irregular, one advantage of taro was that it made the stomach feel full for a long period of time.

Along with notions of routine introduced to the islands by missionaries and administrators came the concept of meals, which usually occur twice daily in rural areas. Taro might be eaten at both the morning and evening meals, and a schoolchild or an adult may carry a couple of slices of taro in a packed lunch. Indeed, schools in Niue are encouraging schoolchildren to bring their lunch in the form of local foods rather than bread and biscuits (Pollock 1983, field notes). Thus, today, an adult may consume a daily total of about 2 kg of Colocasia taro or other starch every day for 365 days of the year.

To a great extent such emphasis on local foodstuffs is the work of local Pacific food and nutrition committees, formed in the early 1980s, that have publicized the benefits of taro and other starches. But in urban areas of the Pacific, taros are scarce, and thus an expensive luxury food. In a Fijian or Samoan marketplace, four Colocasia taros (only enough to feed two adults for one meal) may sell for 5 or 6 dollars, with the other family members having to eat rice or cassava or Xanthosoma taro instead. Those promoting the use of local foods are endeavoring to bring down the price of taros. But to do so requires more agricultural input and other diversifications within the economy.

Colocasia taros are also an essential component of Pacific feasts where they take pride of place, alongside the pigs (used only at feasts), fish, turtle, or (today) beef. Early visitors to the Pacific were amazed at the immense walls of Colocasia taros and yams, topped off with pigs, that formed part of a presentation at a special occasion such as the investiture of a new chief in Fiji or Wallis in the 1860s. These food gifts were contributed by households closely associated with the community hosting the feast and were redistributed to those attending. A great amount of food had to be consumed at these feasts, as there was no means of preserving it (Pollock 1992).

Conversely, there were times when food was very scarce, as after a cyclone or a tidal wave, or during a drought. Such disasters witnessed the Colocasia taro plants damaged and rotted and the Cyrtosperma broken by the wind, so the people had to resort to dryland taro or Alocasia taro or other starches. In very severe cases (such as the devastating cyclone Val in December 1991 on Western Samoa), households had nothing but fallen coconuts and emergency foods, such as Alocasia taro, to rely on.

Exchanges of both planting material and of harvested taros have constituted a method of adjusting such irregularity in food availability in the Pacific. Before the development of international aid in the 1960s and 1970s, taros and other starches were harvested in Tonga to aid neighbors and relatives in Wallis, Western Samoa, and Fiji. This process of exchange not only enabled families and villages to survive hard times, but it also cemented social relations between whole island nations. In addition, the process of exchange supported the development of a diversified gene pool of the various taros.

Cooking and Processing

All the taros must be cooked very thoroughly because of the oxalic acid crystals in the outer layer of the corm and in the leaves. Thorough cooking reduces the toxicity, and the earth oven allows whole taros to be covered and steamed on hot rocks for two hours or more. In most Pacific societies such an earth oven was made once a day, and in rural areas this is still the case. Boiling on a stove may be quicker, but it is more costly in fuel (Pollock 1992).

Pacific Island people today prefer taro cooked whole and then cut into slices for presentation to the household. Taro must be cooked as quickly as possible after harvesting to retain the best flavor and to avoid decay. Before cooking, each corm or stem of taro is carefully peeled, a process that can produce a skin irritation for those unaccustomed to it, again due to the oxalic acid crystals. The corms or stems are placed either in a coconut leaf basket or on banana leaves around the edge of the earth oven, with the fish (or pig if it is a feast) in the center, and the whole is covered first with leaves, then earth to allow the contents to steam. The oven is opened some two hours later. For special occasions, "puddings" may be made from grated taro mixed with coconut cream and baked in the earth oven.

One of the few societies to develop a processed form of taro was that in Hawaii, where fermented taro was eaten as *poi.* This was made by steaming, peeling, grinding, and straining the corms to yield a thick paste of 30 percent solids, known as "ready-to-mix" *poi,* or if more water was added to yield a thinner paste of 18 percent solids, known as "ready-to-eat" *poi.* Hawaiians refer to the thickness of *poi* as one-finger, two-finger, or three-finger *poi.* Either irrigated or dryland Colocasia taro can be used for making *poi,* but different varieties of Colocasia taro are not mixed.

The thick paste ferments very rapidly due to lactobacilli fermentation, reaching an acidity level of 3.8 by the third day. Hawaiians would wrap the very thick paste, known as *'ai pa'i,* in *ti* leaves until needed. The addition of a little water to the desired portion was all that was required for serving highly esteemed *poi* to accompany fish or pork. The very thin paste, by contrast, lasts only three to four days unrefrigerated, and refrigerated *poi* becomes so rubbery that it is considered inedible (Moy and Nip 1983; Standal 1983; Pollock 1992).

Commercialization

Taros are sold whole and unprocessed in the Pacific. In Fiji, where the petioles are left attached to the corm, Colocasia taros are sold by the bundle of three or four tied together. In Tonga and Western Samoa, Colocasia taros are sold by the corm alone, but again in groups of four or more for a given price. The stems of Alocasia taros are sold by the piece, while the cormlets of Xanthosoma taro are sold by the basket, as are sweet potatoes and other root crops.

More of the crop is sold through middlemen in Fiji and Samoa, although producers themselves use family members as agents.[7] Cyrtosperma taro is seldom sold in these larger markets, except in Tarawa, Kiribati, and Kolonia, Yap.

None of these root crops is very durable, so those marketing taro aim for quick sales. Damaged taros will deteriorate rapidly, hence great care is taken in both the harvesting process for market and in removing the tops in Tonga and Samoa to inflict as little damage to the corm as possible.

As early as 1880, Papeete in the Society Islands became a center for the redistribution of local produce (Pollock 1988). From such small waterside markets have grown the large market centers found around the tropical world today (some covering several acres). In each Pacific Island (and Caribbean Island) there is at least one such market in the urban center, and in larger islands, such as Fiji and Papua New Guinea, there are several markets in the various urban centers. These markets have grown in size and diversity over the last 20 years, as urban populations have increased. Only small amounts of taro are sold through supermarkets (Pollock 1988).

Out-migration of populations from the Pacific Islands (and the Caribbean) to metropolitan centers, such as Auckland, Wellington, Sydney, Honolulu, and Los Angeles, has also stimulated the overseas sale of taros, mainly Colocasia. The Tongan, Samoan, and Cook Islands populations are becoming sizable in those centers where demand for taro, mainly for celebratory occasions, has increased. Taro is available in urban markets, such as Otara in Auckland, and in vegetable shops, especially those where Polynesian communities are located. Prices are high, but families will make sacrifices to present some taro when needed to maintain family honor.

Before these outlets provided a steady supply, the various communities made private arrangements to import boxes of taro from their home islands. As a wider supply has become available and the communities have grown, each community has focused its demand on taro from its own island of origin, claiming that it tastes better. Samoans will track down stores that sell Samoan taro, whereas Tongans and

Rarotongans go in search of taros from their home islands. Island people themselves are acting more and more as the agents and middlemen, with the whole process promoting the production of taro varieties that will endure sea transport.

Taros are also imported in cooked form to New Zealand by returning residents. In Samoa or Niue, puddings are packed either in a chest freezer or a cardboard box and carried as part of the passenger's personal luggage. In New Zealand and Australia the families of the passenger then share in this produce "from home." Such is their social value that several hundred dollars may be spent in overweight luggage in order to transport local foods in this manner.

Another form of commercialization promoted by food and nutrition committees in various Pacific Islands is the use of taro (mainly Colocasia, both corm and leaves) along with other local foods, by hotels, to give tourists a new taste experience. Hawaii has long provided *luau* feasts for its visitors, which included a small portion of *poi* and pork, salmon, and coconut pudding. Now Fiji runs competitions in which chefs from leading hotels create recipes that make use of local foods, including taro. This practice, in turn, is leading to increased cooperation with the agriculture authorities to assist producers in regularizing production to supply the hotels.

In Hawaii, where processed taro has been marketed as *poi* for some 75 years, sales to Hawaiians and to the tourist hotels are supplemented by demand for *poi* in the mainland United States to help individuals suffering from allergies and digestive problems. As a consequence of this activity, Hawaii is the one place in the Pacific where taro plantations have become heavily commercialized and are run by companies rather than by family units.

Taro chips are now being manufactured in various centers around the Pacific. Local companies are selling their product, promoted by food and nutrition committees, in Fiji and Samoa with reasonable success. In Hawaii, entrepreneurial companies, such as Granny Goose Foods, are marketing taro chips alongside the traditional potato chips, thereby drawing taro into the lucrative snack industry.

In other parts of the tropical world, Colocasia taro may be processed into flour or flakes for commercial purposes. A product *Arvi* has been developed by the Central Food Technological Research Institute in Mysore, India, that consists of flour made from Colocasia taro. The corms are washed, peeled, and cut into slices, which are kept immersed in water overnight, then washed again and immersed for another three hours. The slices are blanched in boiling water for five minutes, then sun-dried before being ground into flour. A similar process has been used to make taro flour in Nigeria. The flour can be mixed with wheat flour for baking.

A process for making instant taro flakes has been tried in Taiwan and in Nigeria whereby smoke-dried slices are stored away for later eating. Freezing taro has not been very successful, though a local variety was processed for freezing in Shanghai (Moy and Nip 1983). Taro leaves mixed with coconut cream, known in Samoa as *palusami,* have been canned with reasonable success, but the corm does not can well.

Nutritional Value

The nutritional value of taro has changed over the many years since it was first domesticated. Its users have selected plants that were less toxic, produced larger, less fibrous corms, and better suited their tastes. Such a selection process was facilitated by vegetative propagation, and many different cultivars were developed over time. However, a large proportion of these cultivars have been lost due to lack of interest in root crops by cereal-based colonial powers. Today the FAO and the South Pacific Commission are trying to preserve as many different cultivars in the Pacific as possible so as to increase the diversity of available food crops. Colocasia taro has many more different cultivars than the other three types of taro, indicating its preferred status and its longtime use as a food. The cultivars have different nutritional attributes.

The taro corms of the four different types vary slightly in their composition (see Table II.B.6.1 for details of composition of the four types of taro). All the corms consist mainly of starch and moisture and are high in fiber. They yield between 70 and 133 calories (or 255 and 560 kilojoules) per 100-gram portion, with Alocasia having the lowest range and Xanthosoma taro the highest. The amount of protein varies considerably from 1.12 percent to 2.7 percent depending on the type of taro, its geographical source, and the variety. The corms are also a good source of minerals, particularly calcium, for which Cyrtosperma taro is particularly notable (Standal 1982; Bradbury and Holloway 1988).

Taro leaves consist mainly of moisture and fiber. They are high in protein with a generally higher overall mineral content than the corms. It is only the young leaves of Colocasia taro that are eaten as a rule, although no difference in chemical composition has been found between leaves viewed as edible and those viewed as inedible (Bradbury and Holloway 1988). The use of the leaves as a wrapping in preparations, such as Samoan *palusami,* adds value to the diet on those special occasions when such a dish is served. Food and nutrition committees are trying to encourage the greater use of leaves, but they are not part of the traditional diet.

The fermented form of taro paste developed long ago by Hawaiians has been found to be a highly digestible product suitable for babies, adults with digestive problems, and those with allergies to cereals. The starch granules are small enough to pass readily into the digestive system. This attribute has led to the commercialization of *poi* (Standal 1983).

Table II.B.6.1. *Nutritional value of the four types of taros*

	Energy		Protein	Fat	C.H.O.	Ca	Iron	Vit. A	Thiamine	Riboflavin	Niacin	Vit. C	Waste A.C.
	(Kcal)	(MJ)	(g)	(g)	(g)	(mg)	(mg)	(µg)	(mg)	(mg)	(mg)	(mg)	(%)
Taro (Calocasia)	113	0.47	2.0	–	26.0	25	1.0	–	0.100	0.03	1.0	5	20
Taro, giant (Alocasia)	70	0.29	0.6	0.1	16.9	152	0.5	–	0.104	0.02	0.4	–	–
Taro, swamp (Cyrtosperma)	122	0.51	0.8	0.2	29.2	577	1.3	–	0.027	0.11	1.2	–	–
Xanthosoma	133	–	2.0	0.3	31.0	20	1.0	–	1.1	0.03	0.5	10.1	?

Clearly, taro has considerable merits as a food. It is readily cooked in an earth oven with minimal equipment, or it can be boiled or baked on a stove. It provides a high-bulk foodstuff rich in fiber, with acceptable amounts of vegetable protein and calcium. There is enough variety of cultivars to yield different tasting corms (if taste is an important consideration). But these merits have not been recognized widely enough, an issue the FAO Root Crops Program in the South Pacific is attempting to rectify through agricultural development (Sivan 1984; Jackson and Breen 1985). Simultaneously, food and nutrition committees, through their promotion of local foods, are endeavoring to counter the colonial legacy that bread is best.

Summary

Taro has evolved as a food over several thousand years, as people in tropical areas have selected attributes that suit their needs. Those needs included both consumption and production factors, as well as processing techniques. In the Pacific area, where the taros are most widely used, the people have relied heavily on three forms, Colocasia, Alocasia, and Cyrtosperma, along with the other starches such as yams, breadfruit, and bananas as the main elements in their daily diets, eaten together with a small accompanying dish. Xanthosoma taro has been added to this inventory in the last 200 years, as it will grow in poor soils and can be less acrid.

Vegetation propagation allowed a high degree of selectivity. Factors including the taste of the corm and its size, color, moisture, and acridity have determined over time which setts were replanted and which were discarded.

Most taro has been grown in dryland conditions. The selection of varieties of Colocasia taro that would grow in water is a further development, as is the very specialized technique for raising Cyrtosperma taro on atolls where the salinity of the water is a problem.

Little development has taken place to diversify the edible product. The corms are peeled and cooked in an earth oven by steaming for a couple of hours and are then served in slices. More recently, boiling has been introduced, but it gives a less acceptable flavor.

Ongoing development of the taros was curtailed, to some extent, by colonial Europeans whose preferred food was bread. Taros and other root crops were considered by these newcomers as a mark of the backward nature of these societies, and the colonists introduced crops of a commercial nature, such as cotton, vanilla, sugar cane, and, more recently, coffee and cocoa. These crops were planted on the best land, and taros were relegated to less desirable areas. The result has been not only a loss of many varieties of taro formerly used but also a scarcity of taros for sale in the markets today over and above those needed for household supply.

Only during the last decade of the twentieth century have the root crops, including taro, merited the attention of agricultural specialists. The worldwide pressure for a more differentiated crop base than just the seven basic food crops has led to programs such as the FAO Root Crops Program and ACIAR's identification of the potential of root crops in the South Pacific. With political independence in the 1960s and 1970s, small nations in the tropics have seen the need to become more self-reliant by reducing their high food import bills. The former importance of the taros has been recognized, and these countries are now taking steps to reestablish them agronomically and economically as a key local crop. The recognition of the importance to health of dietary fiber adds another dimension to taro's desirability. Exports of taro to migrants in metropolitan areas have stimulated the need for particular farming expertise as well as the development of marketing and processing techniques.

Taro has survived a major hiatus in the nineteenth and twentieth centuries that might have seen it eliminated as a crop or dismissed as one of backward, underdeveloped tropical countries. But cereals, even rice, will not grow readily in many of these tropical areas, whereas the taros are a flexible crop that suits shifting cultivation so that farmers can vary the size of their crops from month to month depending on demand. Nutritionally, taro is very good, especially when complemented with fat from fish or pork. Given agronomic support, taro has great potential for further contributions to the world food supply, and finally, it is a crop that has endured thanks to people's strong preference for it as their traditional food.

Nancy J. Pollock

Notes

1. It is ironic that rice has been introduced into modern-day Pacific diets as an emergency foodstuff that is easily transferred from metropolitan countries as a form of food aid to assist cyclone-stricken nations, such as Samoa in 1991. As such, it forms a substitute for locally grown taro, which is badly affected by salt inundation and wind breaking off the leaves, thus causing the corms to rot.
2. See Petterson (1977: 177) for a map of the spread of Xanthosoma taro around central and northern South Africa in contrast with the spread of Colocasia taro in the same area.
3. See Pollock (1992) for a listing of the importance of various starch staples in Pacific societies.
4. See Barrau (1965: 69) for a map showing its origins and distribution in Southeast Asia and the Pacific.

II.C

Important Vegetable Supplements

II.C.1 ~ Algae

Algae are eukaryotic photosynthetic micro- and macroorganisms found in marine and fresh waters and in soils. Some are colorless and even phagotrophic or saprophytic. They may be picoplankton, almost too small to be seen in the light microscope, or they could be up to 180 feet long, such as the kelp in the kelp forests in the Pacific Ocean.

Algae are simple, nucleated plants divided into seven taxa: (1) Chlorophyta (green algae), (2) Charophyta (stoneworts), (3) Euglenophyta (euglenas), (4) Chrysophyta (golden-brown, yellow-green algae and diatoms), (5) Phaeophyta (brown algae), (6) Pyrrophyta (dinoflagellates), and (7) Rhodophyta (red algae). A taxon of simple, nonnucleated plants (prokaryotes) called Cyanobacteria (blue-green bacteria) is also included in the following discussion as they have a long history as human food.

Algae are eaten by many freshwater and marine animals as well as by several terrestrial domesticated animals such as sheep, cattle, and two species of primates: *Macaca fuscata* in Japan (Izawa and Nishida 1963) and *Homo sapiens.* The human consumption of algae, or phycophagy, developed thousands of years ago, predominantly among coastal peoples and, less commonly, among some inland peoples. In terms of quantity and variety of species of algae eaten, phycophagy is, and has been, most prevalent among the coastal peoples of Southeast Asia, such as the ancient and modern Chinese, Japanese, Koreans, Filipinos, and Hawaiians.

History and Geography

The earliest archaeological evidence for the consumption of algae found thus far was discovered in ancient middens along the coast of Peru. Kelp was found in middens at Pampa, dated to circa 2500 B.C. (Moseley 1975); at Playa Hermosa (2500–2275 B.C.); at Concha (2275–1900 B.C.); at Gaviota (1900–1750 B.C.); and at Ancon (1400–1300 B.C.) (Patterson and Moseley 1968). T. C. Patterson and M. E. Moseley (1968) believe that these finds indicate that marine algae were employed by the ancient Peruvians to supplement their diets.

Other types of seaweeds were also found in middens at Aspero, Peru, and dated to 2275 to 1850 B.C. by Moseley and G. R. Willey (1973) and at Asia, Peru, and dated to 1314 B.C. (Parsons 1970). Additionally, unidentified algae were found in middens at numerous sites, among them Padre Aban and Alto Salaverry (2500–1800 B.C.); Gramalote, Caballo Muerte (2000–1800 B.C.); Cerro Arena, Moche Huacas (200 B.C. to A.D. 600); and Chan Chan (A.D. 1000–1532) (Pozorski 1979; Raymond 1981).

Furthermore, much evidence exists to indicate a marine algae presence in ancient Peru. The base of the temples at Las Haldas, for example, which date circa 1650 B.C., contained quantities of seaweed and shellfish (Matsuzawa 1978). Small stalks of a seaweed were found in a Paracas mummy bundle (Yacovleff and Muelle 1934: 134), and the giant kelp *Macrocystis humboldtii* was pictured on an ancient Nazca vase (Yacovleff and Herrera 1934–5). In recent times, the native peoples of the Andean highlands have retained the right to come down to the coast, gather and dry seaweed, and transfer it to the mountains, where algae has great value and can be used in place of money. Used as a condiment to flavor soups and stews, dried seaweed minimizes the ravages of hypothyroidism, which is endemic in the Andes (Aaronson 1986). Early visitors reported that dried seaweed was also eaten with vinegar after dinner and sold in the marketplace as a kneaded dry product (Cobo 1956). The cyanobacteria *Nostoc* spp. (called *cushuro, llucllucha,* or *kochayuyo*) grow in Andean lakes and ponds and are also presently used as food (Aldave-Pajares 1965–66; Gade 1975; Browman 1981; and Table II.C.1.1), as they were in early Spanish colonial times (Cobo 1956) and, possibly, in Inca times as well (Guaman Poma de Ayala 1965–6).

Table II.C.1.1. *Algae and blue-green bacteria eaten in contemporary Chile and Peru*

Species	Common name	Eaten as[a]
Cyanobacteria		
Nostoc commune	*cushuro*[b]	*picantes*
	elulluchcha[b]	–
	kocha-yuya[b]	–
Nostoc parmeloides	*llullcha*[b]	–
Nostoc pruniforme	*cushuro, cusuro*[b]	*chupe*
	crespito[b]	*locro*

Ulva fasciata costata	*lechuquita de rio*[b]	*picante*
Ulva lactuca	*luche verde*[d]	–
Ulva pappenfussii	*cochayuyo*[b]	–
Phaeophyta		
Durvillea antartica	*cochayuyo*[c,d]	–
Lessonia nigrescens	*tinilhue*[c]	–
Macrocystis integrifolia	*huiro*[d]	–
Macrocystis pyrifera	*huiro*[d]	*ceviche*
Rhodophyta		
Gigartina chamissoi	*cochayuyo*[b]	–
	chicorea del mar[c]	–
Gigartina glomerata	*cochayuyo*[b]	*ceviche*
	yuyo[b]	*picantes*
	mococho[b]	soup
Gigartina paitensis	*mococho*[b]	soup
	cochayuyo[b]	*picantes*
Gracillaria verrucosa	*pelillo*[c]	–
Iridaea boryana	*luga*[c]	–
Porphyra columbina	*luche*[c]	–
Porphyra leucosticta	*cochayuyo*[b]	*picantes*
Prionitis decipiens	*piscuchaqui*[b]	*picantes*
Rhodoglossum denticulatum	*cochayuyo*[b]	*ceviche* *picantes* soup

[a] Common names for Peruvian food from Polo (1977).

[b] Polo (1977).

[c] Dillehay (1989).

[d] Masuda (1985).

Note: Ceviche is a soup with algae, small pieces of fish, lemon, and hot pepper.

Chupe is a soup with milk, algae, eggs, potatoes, and cheese.

Cochayuyo is from the Quecha *cocha* (lagoon or pond) and *yuyo* (herb or vegetable).

Cuchuro is from the Quecha for wavy.

Pachayuo is from the Quechua *pacho* (soil) and *yuyo* (vegetable).

Picantes is a stew made of algae, pieces of fish, potatoes, and hot pepper.

Locro is a maize and meat stew with algae.

Mazamorro is a stew made with pieces of algae and other ingredients.

Moving north in the Americas, *Spirulina maxima,* or *Spirulina geitleriai* (a blue-green bacterium known as *tecuitlatl* [stone excrement] in Nahuatl, the Aztec language), has been eaten in the Valley of Mexico since the beginning of the Spanish colonial period (c. 1524) and was consumed even prior to Aztec times (Furst 1978). Other cyanobacteria, such as *Phormidium tenue* and *Chroococcus turgidus* (called *cocolin* and *Nostoc commune* [*amoxtle* in Nahuatl]), are gathered for consumption from the lakes and ponds of the Valley of Mexico and, very likely, have been since time immemorial (Ortega 1972).

In Africa, another species of cyanobacterium, *Spirulina platensis,* grows abundantly in Lake Chad and is collected, dried, and made into a sauce. It is widely consumed by the Kanembu people of Chad (Leonard and Compère 1967; Delpeuch, Joseph, and Cavelier 1975).

In China, the earliest reference to algae as food occurs in the *Book of Poetry* (800–600 B.C.) (Chase 1941), and Wu's *Materia Medica* indicates that the seaweed *Ecklonia* was utilized as food and medicine as early as 260 to 220 B.C. Another type of seaweed, *Porphyra,* was also used as food according to the *Qiminyaoshu* (A.D. 533–44).

Gloiopeltis furcata has been collected in southern Fujian Province since the Sung Dynasty (A.D. 960–1279) (Tseng 1933), and C.-K. Tseng (1987) states that *Laminaria japonica (haidi)* has been eaten there for about 1,000 years. Several other types of algae were also consumed, according to the *Compendium of Materia Medica (Bencaigangmu)* of the Ming Dynasty (1368–1644), edited by L. Shizhan (1518–93). These included: *Cladophora* spp., *Codium fragile, Ecklonia kurone, Enteromorpha prolifera, Enteromorpha* spp., *Euchema muricatum, Gelidium divaricatum, Gloeopeltis furcata, Gracilaria verrucosa, Laminaria japonica, Monostroma nitidum, Nostoc sphaeroides, Prasiola sinensis, Porphyra* sp., and *Ulva lactuca.*

The cyanobacterium *Nostoc commune* has been eaten in China for the last 400 years (Chu and Tseng 1988), and a related species, *Nostoc coerulum,* was served in this century at a dinner given by a mandarin for a French ambassador (Tilden 1929; Montagne 1946–7). According to Tseng (1990), the large-scale cultivation of the seaweed *Gloiopeltis furcata* began in Fujian Province during the Sung Dynasty.

In Japan, the eating of algae is also an ancient practice. Seaweed was apparently eaten by the early inhabitants of Japan, as it has been found with shells and fish bones at human sites in the Jomon period (10,500–300 B.C.) and the Yayoi period (200 B.C. to A.D. 200) (Nisizawa et al. 1987). In A.D. 701, the emperor established the Law of Taiho in which seaweeds (*Gelidium, Laminaria, Porphyra,* and *Undaria* spp.) were among the marine products paid to the court as a tax (Miyashita 1974).

The blue-green bacterium *Nostoc verrucosum,* currently known as *ashitsuki nori,* was mentioned in *Man Yo Shu* by Yakomichi Otomi in the oldest anthology of 31-syllable odes dating to A.D. 748. Ode number 402 translates: "Girls are standing on the shores of the Wogami-gawa River in order to pick up *ashitsuki nori.*" According to the *Wamyosho* (the oldest Chinese–Japanese dictionary in Japan), 21 species of marine algae (brown, green, and red) were eaten by Japanese during the Heiam era (A.D. 794–1185) (Miyashita 1974). In *The Tale of the Genji,* written by Murasake Shikibu (A.D. 978), a marine alga, *Codium fragile,* is mentioned as a food (Hiroe 1969). The Greeks and Romans apparently disliked algae and, seemingly, made no use of them as human food, although they were used as emergency food for livestock. Virgil (70–19 B.C.) called algae *vilior alga* (vile algae), and Horace (65–8 B.C.) seems to have shared his opinion (Newton 1951; Chapman 1970).

The seaweed *Rhodymenia palmata* was eaten in Iceland as early as A.D. 960, according to the *Egil Saga* (Savageau 1920). *Alaria esculenta* (bladderlocks) was (and still is) consumed in Scotland, Ireland, Iceland, Norway, and the Orkney Islands, where it is called alternatively "honey-ware," "mirkles," and "murlins." *Laminaria digitata* ("tangle") is also eaten in Scotland, and *Rhodymenia palmata* ("dulse") is used as food in Iceland, Scotland, and around the Mediterranean, where it is an ingredient in soups and ragouts. Similarly, *Laurencia pinnatifida* ("pepper dulse") is eaten in Scotland, and *Porphyra laciniata* ("purple laver") is used as a condiment in the Hebrides (Johnston 1970).

Algae and Cyanobacteria as Human Food Today

Algae (Chlorophyta, Phaeophyta, and Rhodophyta) and cyanobacteria are now consumed in all countries that possess marine coasts as well as in countries where algae are abundant in lakes, streams, ponds, and rivers. Consumers range from surviving Stone Age peoples to modern hunter-gatherers, to agricultural folk, to industrial peoples.

Algae are used as foods in a wide variety of ways. They are served raw in salads and pickled or fermented into relish. They make a fine addition to soups, stews, and sauces, and are used as condiments. Algae are also roasted, employed as a tea, and served as a dessert, a sweetmeat, a jelly, or a cooked vegetable (see Table II.C.1.2 for countries in which algae are eaten as food and the form of the food).

In industrialized countries, algal products like agar, alginates, and carrageenans are extracted from some seaweeds and used to replace older foods or to create new foods or food combinations.

Table II.C.1.2. *Algae eaten by humans now and in the past*

Species name	Country	Local name	Use	Reference
Cyanophyta				
Aphanothece sacrum	Japan	–	Food	Zaneveld 1950; Watanabe 1970
Brachytrichia quoyi	China	–	Food	Chu and Tseng 1988

Seaweeds as Fertilizer and Animal Fodder

Seaweeds have been exploited for fertilizer by coastal farmers for centuries (if not millennia) in Europe, North America, the Mediterranean, and Asia (Booth 1965; Waaland 1981). Roman writings from the second century A.D. contain the oldest known evidence of seaweed as a fertilizer (Newton 1951). Seaweed was plowed into fields where it rotted, replenishing the soil with essential minerals. Alternatively, the seaweed was dried and burned, and the ash used as fertilizer, or the fields were "limed" with coralline algae and the sands derived from them (Waaland 1981). Regardless of the method, nitrogen, phosphate, and potassium were delivered to the soil, along with other compounds that may serve as plant growth stimulants, by the use of algae as a fertilizer.

The Gross Chemical Composition of Algae

The gross chemical composition of algae is shown in Table II.C.1.3, where several properties are readily apparent. Although they are relatively poor in carbohydrates (including fiber) and relatively rich in lipids, microalgae are remarkably rich in protein and, thus, a good source of nutrients for humans as well as domestic animals (Aaronson, Berner, and Dubinsky 1980).

Table II.C.1.3. *The gross chemical composition of edible algae (percentage of dry weight)*

5. FAO (1970)

Algae, especially marine algae, may also contain unusual amino acids not normally found in protein and iodoamino acids (Fattorusso and Piattelli 1980). By contrast, macroalgae are poor in proteins and lipids, but relatively rich in carbohydrates and minerals.

The caloric value of edible algae ranges from 4,405 to 5,410 calories per gram for the Cyanophyta; 4,700 to 4,940 for the Chlorophyta; 4,160 to 5,160 for the Phaeophyta; and 3,290 to 5,400 for the Rhodophyta (Cummins and Wuycheck 1971). The digestibility of seaweeds ranges from 39 to 73 percent, with a net energy availability of 48 to 67 percent (Kishi et al. 1982).

Amino Acid Composition

The amino acid composition of algae and their proteins is shown in Table II.C.1.4. The algae have a full complement of the amino acids found in the animal and plant proteins consumed by humans. The concentration of essential amino acids required by humans is very close to the standards set for human foods by the Food and Agriculture Organization of the United Nations (FAO 1970).

Polysaccharides

Algae contain a variety of carbohydrates that serve as energy storage sources or provide structural strength to cell walls and matrices. The storage polysaccharides include mannitol and laminaran or chrysolaminaran in Chrysophyta and Phaeophyta; amylose and amylopectin in Chlorophyta; and Floridean starch in Rhodophyta. The structural polysaccharides include cellulose in the Chlorophyta (or its xylan equivalent in some Chlorophyta and Rhodophyta) and in the mannan of the Phaeophyta. Phaeophyta and Chlorophyta also contain anionic polysaccharides, such as alginic acid, in their cell walls and sulfated glucuronoxylofucans,

fucoidan, and ascophyllan as storage polysaccharides. Additionally, the Rhodophyta contain galactans (agar and carrageenans) (see Lewin 1974; McCandless 1981). The cyanobacteria have peptidoglycan cell walls and may contain polyglucan granules or polyphosphates as energy storage molecules (Dawes 1991).

Hydrocolloids

Hydrocolloids are water-soluble gums (polysaccharides) commonly obtained from seaweed or other plants that have been employed since antiquity to thicken foods and today are used to thicken, to emulsify, or to gel aqueous solutions in many industries (Spalding 1985). The major hydrocolloids are: (1) agar, which is obtained from species of the red algal genera – *Gelidium, Gracilaria, Pterocladia;* (2) alginates, obtained from species of brown algal genera – *Ascophyllum, Ecklonia, Eisenia, Laminaria, Macrocystis, Nereocystis, Sargassum;* and (3) carrageenans, also obtained from species of the red algal genera – *Ahnfeltia, Chondrus, Euchema, Furcellaria, Gigartina, Gymnogongrus, Hypnea, Iridaea, Phyllophora.* Hydrocolloids have great importance in the food industries, where they are employed in the production of such varied products as glazes, icings, frostings, toppings, frozen foods, cereals, bread, salad dressings, flavors, sausage casings, puddings, desserts, candies, marshmallows, processed meat products, cheese, jams, pie fillings, and sauces (Spalding 1985).

Vitamins and Other Growth Factors

Algae can also be an excellent source of water-soluble and fat-soluble vitamins (Table II.C.1.5). The concentration of specific vitamins in algae varies from species to species and depends on conditions of algal growth, handling, storage, and methods of preparation for eating, as well as on the number of microorganisms found on the surface of macroalgae, which also may be responsible for some of the B vitamins attributed to macroalgae (Kong and Chan 1979).

Tocopherols are a metabolic source of vitamin E, and they are found in most types of algae as alpha-tocopherol. The Fucaceae family of brown algae contains delta-homologues of tocopherol as well as alpha-tocopherol (Jensen 1969), and seaweeds contain 7 to 650 micrograms per gram (Ragan 1981).

Algae can also contain vitamin C and beta-carotene, which are among the nutrients presently thought to protect cells against powerful oxidizing agents such as ozone, lipid peroxides, and nitrogen dioxide, and are, consequently, recommended in the diet (Calabrese and Horton 1985; Kennedy and Liebler 1992; Krinsky 1992). Vitamin C is found in all seaweeds in concentrations up to 10 milligrams per gram (Ragan 1981). The fat-soluble vitamin A is synthesized from beta-carotene by humans, and beta-carotene is found in comparatively large amounts in many algae eaten by humans, such as those species in the Chlorophyta, Phaeophyta, Rhodophyta taxa, and blue-green bacteria, as well as other algal taxa (Goodwin 1974).

[a] Number of species examined for fatty acids in above references.

Ash and Water Content of Algae

As Table II.C.1.3 indicates, seaweeds mostly comprise water and ash. T. Yamamoto and colleagues (1979) examined the ash content of marine algae collected in Japanese waters and found it to vary from 4 to 76 percent. J. H. Ryther, J. A. De Boer, and B. E. Lapointe (1978) found that the wet weight of several seaweeds cultured in Florida consisted of about 10 to 16 percent dry material, 32 to 50 percent of which was minerals. The seaweed ash of *Eisenia bicyclis* includes the following elements (in order of decreasing concentration): potassium, calcium, sodium, phosphorus, magnesium, strontium, zinc, iron, boron, aluminum, copper, titanium, nickel, vanadium, chromium, cobalt, molybdenum, and gallium (Yamamoto et al. 1979). Marine algae can contain up to 5 milligrams of iodine per gram of dried algae, although the amount varies from species to species and from one part of the seaweed to another (Grimm 1952).

Lipids

Algal lipids include the saponifiable lipids: fatty acids (acylglycerols, phosphoglycerides, spingolipids, and waxes) and the nonsaponifiable lipids (terpenes, steroids, prostaglandins, and hydrocarbons). As already noted, microalgae are far richer in lipids than macroalgae (Table II.C.1.3), and algae that grow in colder waters contain more unsaturated fatty acids than do algae that thrive in warm waters. Algae supply nutrients, especially lipids, when they are eaten directly as food, but they can also pass on their nutrients indirectly when they are consumed by zooplankton, which are subsequently eaten by other invertebrates and vertebrates. Algal nutrients are then passed along to humans when they eat invertebrates and vertebrates, such as shellfish and shrimp, and fish or fish-eating birds and mammals, respectively.

Fatty Acids

Algae contain varying amounts of saturated and unsaturated fatty acids (Table II.C.1.6). Algae are rich in alpha- and gamma-linolenic acids and unusually rich in polyunsaturated fatty acids.

Steroids

Steroids are found in all eukaryotic algae, composing between 0.02 to 0.38 percent of their dry weight. Many different steroids, including sterols, are specific to one species of algae. For example, cholesterol is found in large amounts in Rhodophyta, but Phaeophyta and blue-green bacteria contain comparatively smaller amounts (Nes 1977).

Essential Oils

Seaweeds often have a characteristic odor of iodine and bromine when freshly isolated from the sea. Some brown seaweeds, however, may have a unique odor, due to 0.1 to 0.2 percent (wet weight) of essential oils (of which the major hydrocarbons are dictyopterene A and B), which impart a characteristic odor and flavor to the seaweeds belonging to the genus *Dictyopteris* found in Hawaii and known there as *limu lipoa. Limu lipoa* is used in Hawaii to season raw fish, meats, and stews. It was one of the only spices known in old Hawaii and was used in Hawaiian recipes much the same as other cultures used pepper and sage (Moore 1976).

Pharmacologically Active Compounds

Algae can possess small amounts of pharmacologically active molecules that affect humans. The polyunsaturated fatty acids of marine seaweeds in the diet may reduce blood pressure in humans; eicosanoids (including prostaglandins) are important biological regulators in humans; and eicosapentaenoic acids may influence the inflammatory process in humans (Beare-Rogers 1988). Algae are known to produce relatively large amounts of polyunsaturated fatty acids (Ackman 1981) and eicosanoids (Jiang and Gerwick 1991). Small amounts of 3-iodo- and 3,5-diiodotyrosine, triiodothyronine, and thyroxine are found in many brown and red seaweeds (Ericson and Carlson 1953; Scott 1954). Betaines have been found in most marine algae and several seaweeds regularly eaten in Japan (Blunden and Gordon 1986). These include the green algae, *Monostroma-nitidum, Ulva pertusa, Enteromorpha compressa,* and *E. prolifera,* and the red alga, *Porphyra tenera,* which, in experiments, have lowered the blood cholesterol of rats (Abe 1974; Abe and Kaneda 1972, 1973, 1975).

Some freshwater and marine cyanobacteria contain protease inhibitors, which can affect protein digestion; about 7 percent of the algal cultures examined by R. J. P. Cannell and colleagues (1987) were positive for protease inhibitors.

Algae contain a large variety of phenols, especially the marine brown and red algae. Some phenols are antimicrobial, and others have been found to be anticancer agents (Higa 1981).

Anthelminthic compounds have been associated with seaweeds for hundreds of years, if not longer. More recently, anthelminthic compounds with neurotoxic properties, such as alpha-kainic acid and domoic acid, were isolated from *Digenea simplex* (Ueyanagi et al. 1957), *Chondria armata* (Daigo 1959), and also from diatoms (Fritz et al. 1992).

H. Noda and colleagues (1990) have reviewed the antitumor activity of the aqueous extracts of several seaweeds, as well as 46 species of marine algae (4 green, 21 brown, and 21 red algae). Certain species of brown algae *(Scytosiphon lomentaria, Lessonia nigrescins, Laminaria japonica, Sargassum ringgolianism),* red algae, *(Porphyra yezoensis* and *Eucheuma gelatinae),* and the green alga *Enteromorpha prolifera* were found to have significant activity against Ehrlich carcinoma in mice. However, the cancer-causing polyaromatic hydrocarbon, 3,4-benzopyrene, has been reported in commercially sold nori (*Porphyra* spp.) (Shirotori 1972; Shiraishi, Shirotori, and Takahata 1973).

Algae, like other plants, contain a variety of compounds, such as amino acids, ascorbic acid, carotenoids, cinnanmic acids, flavonoids, melanoidins, peptides, phosphatides, polyphenols, reductones, tannins, and tocopherols. These molecules may act as reducing agents or free radical interrupters, as singlet oxygen quenchers, and as inactivators of preoxidant metals, thus preventing the formation of powerful oxidizers and mutagens (Tutour 1990).

One seaweed (as yet unidentified), called *limu mualea,* was thought to be highly poisonous in Hawaii (Schönfeld-Leber 1979), and a number of algae and some cyanobacteria produce secondary metabolites that are toxic to humans. Certainly, as with other aquatic organisms, eating algae from polluted waters is hazardous because of potential contamination by microbial pathogens (viruses, bacteria, fungi, or protozoa), toxic metals or ions, pesticides, industrial wastes, or petroleum products (see Jassley 1988 for a review).

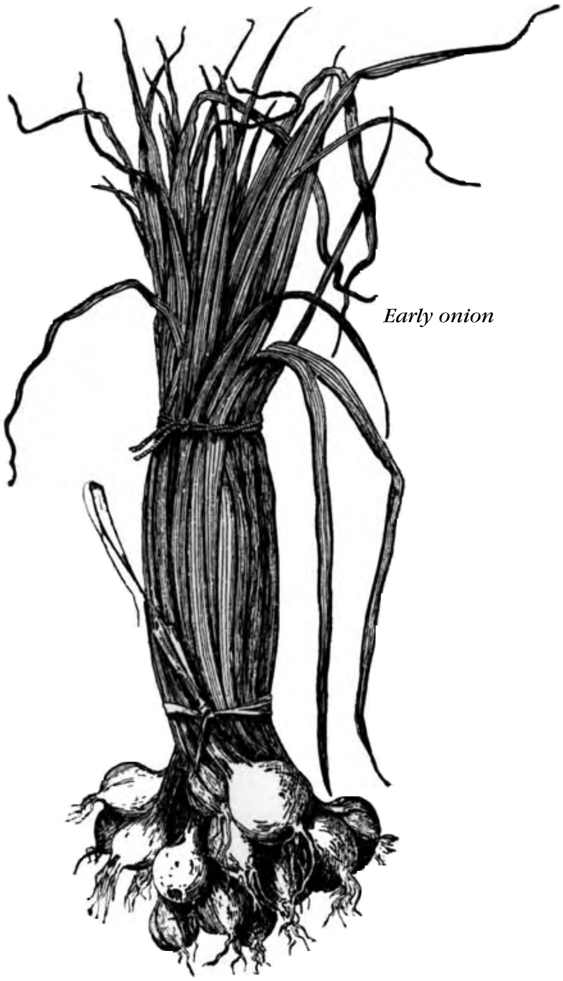
II.C.2 ~ The *Allium* Species (Onions, Garlic, Leeks, Chives, and Shallots)

The genus *Allium* comprises more than 600 different species, which are found throughout North America, Europe, North Africa, and Asia. Approximately 30 species have been regularly used for edible purposes (although less than half of these are subject to cultivation), with the most important being onions, garlic, leeks, chives, and shallots.

In terms of their common botanical characteristics, alliums are mainly herbaceous plants, incorporating various underground storage structures made up of rhizomes, roots, and bulbs. The foliar leaves alternate, often sheathing at the base to give the superficial impression that they originate from an aboveground stem. As a rule, the flower cluster, or inflorescence, is umbrella-like, with all the flower stalks radiating from the same point (umbel); the flowers are pollinated by insects; the fruits take the form of a capsule or berry; and the seeds are numerous and endospormic.

This genus is placed in the lily family. Most, but not all, of the species possess the pungent odor typical of onion and garlic. In addition to alliums, species of *Ipheion, Adenocalymma, Androstephium, Esperocallis, Talbaghia, Nectarosiordum, Nilula,* and, possibly, *Descurainia* produce pungent odors (Fenwick and Hanley 1985a).



Early onion

Onions

History

Antiquity. The onion *(Allium cepa)* may have originated in Persia (Iran) and Beluchistan (eastern Iran and southwestern Pakistan). But it is also possible that onions were indigenous from Palestine to India. They have been known and cultivated for many thousands of years and no longer grow wild. Their range – virtually worldwide – now includes China, Japan, Europe, northern and southern Africa, and the Americas (Hedrick 1972).

The consumption of onions is depicted in the decoration of Egyptian tombs dating from the Early Dynasty Period, c. 2925–c. 2575 B.C. During the Old Kingdom, c. 2575–c. 2130 B.C., onions were used as religious offerings. They were put on altars and, as is known from mummified remains, were employed in preparing the dead for burial (placed about the thorax and eyes, flattened against the ears, and placed along the legs and feet and near the pelves). Flowering onions have often been found in mummies' chest cavities (Jones and Mann 1963). If Juvenal (Roman poet and satirist, c.A.D. 55–127) is to be believed, a particularly delicious onion was worshiped as a god by certain groups in ancient Egypt (Hyams 1971).

The Greek historian Herodotus reported that onions, along with radishes and garlic, were a part of the staple diet of the laborers who built the Great Pyramid at Giza (2700–2200 B.C.) (Jones and Mann 1963). Egyptian onions were said to be mild and of an excellent flavor, and people of all classes (save for priests, who were prohibited from eating them) consumed them both raw and cooked (Hedrick 1972).

In Sumeria (southern Iraq), onions were grown and widely used for cooking 4,000 years ago (Fenwick and Hanley 1985a), and both garlic and onions have been unearthed at the royal palace at Knossos in Crete (Warren 1970). Minoan voyages from the eastern Mediterranean (2000–1400 B.C.) doubtless helped in dispersing alliums from that region.

The ancient Greek physician Hippocrates (460–375 B.C.) wrote that onions were commonly eaten, and Theophrastus (c. 372–287 B.C.) listed a number of onion varieties, all named after places where they were grown: Sardian (from western Turkey), Cnidian (from southern Turkey), Samothracian (from a Greek island in the northeast Aegean), and Setanian (possibly from Sezze or Setia in central Italy) (Jones and Mann 1963; Warren 1970).

Asia. According to Charaka, a Hindu physician of the second century A.D., the onion (as in ancient Egypt) was thought not to be a suitable food for persons pursuing the spiritual life. Thus, the onion was taboo for orthodox Brahmins, Hindu widows, Buddhists, and Jains (Hyams 1971).

In China, the fifth-century treatise on agriculture, *Ch'i-min-yao-shu* (Essential Arts for the People) by Chia Ssu-hsieh, described the cultivation of *ts'ung,* or spring onion (*Allium fistulosum* L.), along the Red River valley (Li 1969). Infusions of onion have long been used in China as a treatment for dysentery, headache, and fever (Hanley and Fenwick 1985).

In 1886, Kizo Tamari, a Japanese government official, stated that in his country, onions did not have globular bulbs but were grown like celery and had long, white, slender stalks (Hedrick 1972). Interestingly, some modern Japanese communities forbid the cultivation, but not the consumption, of the spring onion (Kuroda 1977).

Europe. Columella (Lucius Junius Moderatus Columella), a Spanish-born Roman agriculturalist of the first century A.D., wrote of the *Marsicam,* which the country people called *unionem* (a term that may be the origin of the English word "onion" and the French *oignon*) (Fenwick and Hanley 1985a). Columella's contemporary, the Roman gourmet Apicius (Marcus Gavius Apicius), created several recipes that employed onions, although he viewed the vegetable as a seasoning rather than a food in its own right (Fenwick and Hanley 1985a).

Writing at about the same time as Apicius, Dioscorides (a Greek military physician) described onions as long or round and yellow or white, and provided detailed discussions of the uses of garlic, onion, and other alliums as medicinal plants (Jones and Mann 1963; Warren 1970).

Still another contemporary, Pliny the Elder, told his readers that the round onion was the best and that red onions were more highly flavored than white. His *Natural History* described six types of onions known to the Greeks: Sardian, Samothracian, Alsidenian, Setanian, the split onion, and the Ascalon onion (shallot). Pliny claimed onions to be effective against 28 different diseases (Fenwick and Hanley 1985a). Then, later on in the first millennium, Palladius (Rutilius Taurus Aemilianus Palladius), a Roman agriculturist in about the fourth century (or later), gave minute directions for culturing onions and comprehensively described their cultivation (Hedrick 1972).

By the beginning of the second millennium, many accounts of foodstuffs were being penned by monks. For example, Peter Damian (1007–72), the founder of a reformed congregation of Benedictines in central Italy, indicated that he permitted a moderate dish of edible roots, vegetables – mostly onions, leeks, and chickpeas – and fruit on days when fasting was not prescribed. These meals were eaten both cooked and uncooked, and sometimes enlivened with oil on special feast days (Lohmer 1988).

The German Dominican monk and scientist Albertus Magnus (1193–1280) did not include onions in his lists of garden plants, but garlic and leeks were represented there, suggesting the esteem in which they were held. Onions, however, were exotic plants understood to have favorable effects on fertility by generating sperm in men and lactation in women (Mauron 1986).

By the sixteenth century, onions were no longer exotic. The Portuguese physician Amatus Lusitanus (1511–68) wrote that they were the commonest of vegetables, occurring in red and white varieties, and had sweet, strong, and intermediate qualities. The German physician and poet Petrus Laurembergius (1585–1639) described some of these qualities, writing of the Spanish onion as oblong, white, large, and excelling all others in sweetness and size; he further reported that at Rome, the Caieta variety brought the highest price, but at Amsterdam the most valued variety was the St. Omer.

A nutritional revolution occurred in the nineteenth century, when food items previously monopolized by the upper classes became available to all. The defeat of scurvy began with the addition to the diet of potatoes and onions, which were progressively supplemented with other legumes and fruits. By the middle of the nineteenth century, deaths from tuberculosis were in decline. Among other things, this was the product of the continuing introduction into the diet of foods containing vitamins A, C, and E, as well as meat and fish, which provide the amino acids vital to the creation of antibodies (Knapp 1989).

The Americas. It is probable that the men of Christopher Columbus's crews sowed onions on Hispaniola as early as 1494, and Hernando Cortés reportedly encountered onions, leeks, and garlic on his march to Tenochtitlan in 1519. Interestingly, native Mexicans apparently had a lengthy acquaintance with this Eurasian plant, because it had a name – *xonacatl* (Hedrick 1972).

Onions were mentioned as cultivated in Massachusetts as early as 1629, in Virginia in 1648, and at Mobile, Alabama, in 1775. By 1806, six varieties of onions were listed as esculents in American gardens. In 1828, the potato onion (multiplier onion) was described as a vegetable of late introduction into the United States, and by 1863, 14 varieties were mentioned (Hedrick 1972; Toma and Curry 1980).

Recent production statistics. The major producers of dry onions (cured but not dehydrated) in 1996 were (in metric tons) China (9,629,895), India (4,300,000), the United States (2,783,650), Turkey (1,900,000), Japan (1,262,000), Iran (1,199,623), Pakistan (1,097,600), and Spain (1,018,100), and total world production was 37,456,390 metric tons. The major producers of spring onions (scallions) were Mexico (702,478), Korea (553,000), Japan (545,600), China (282,329), Turkey (230,000), and Nigeria (200,000), and world production was 3,540,595 metric tons.

The major exporters of onions in 1996 were the Netherlands, India, the United States, Argentina, Spain, Mexico, Turkey, and New Zealand. Major importers were Germany, the Russian Federation, Brazil, Malaysia, Saudi Arabia, and the United Arab Emirates.

Horticulture and Botany

Botany. The common onion is known only in cultivation. Propagation is usually by division, although some strains may also produce seed. Spring onions, used mainly in salads, are always grown from seed and harvested young. Pickling onions are made small by planting them close together (Traub 1968).

Onion leaves are the thickened bases of the normal leaves from the previous season. The bulb is composed of fleshy, enlarged leaf bases; the outermost leaf bases do not swell but become thin, dry, and discolored, forming a covering (Fenwick and Hanley 1985a). The onion usually flowers in the spring. Honeybees prefer the nectar of *A. cepa* to that of *A. fistulosum* (green onions) (Kumar and Gupta 1993).

Cultivation. Two crops of onions are grown each year in the United States. That of the spring is grown in Arizona, California, and Texas. The summer crop, much larger, consists of nonstorage produce, mostly from New Mexico, Texas, and Washington, and storage produce, grown mainly in Colorado, Idaho, Michigan, New York, Oregon, and Washington (Fenwick and Hanley 1985a).

Onions grow best in fine, stone-free, well-irrigated soils. Their comparatively thick, shallow roots require high levels of nitrogen, phosphorous, and potassium for maximum yield. The onion does not compensate for water stress and is sensitive to salinity. Flavor maturation and bulb development are affected by high temperature, high light intensity, soil moisture, and nitrogen deficiency (Brewster 1977a, 1977b). Increased flavor strength is associated with higher levels of applied sulfate (Platenius 1941; Kumar and Sahay 1954). Bulb formation depends upon increased daylength, but the daylength period required varies greatly between cultivars (Austin 1972).

Intercropping and rotation. Onions are the highest-yielding and most profitable inter- or border-crop for finger millet *(Eleusine coracana)* wherever it is grown (Siddeswaran and Ramaswami 1987). With tomatoes, planting four rows of onions (15 centimeters apart) between two rows of tomatoes has provided a 36 percent higher tomato equivalent yield without significantly affecting the number, average weight, and marketable yield of the tomato fruits. The tomato and onion combination also provides the highest net returns and maximum profit (Singh 1991).

Harvesting. Mature onions suffer lower storage losses than those harvested early. As onions reach maturity, the tops soften just above the bulb junction and cause the leaves to fall over. They are usually harvested when most of the plants are in this state

(Kepka and Sypien 1971; Rickard and Wickens 1977). Harvesting methods depend on the size of the crop, the climate, and regional or national practices (Jones and Mann 1963).

After harvesting, unless the crop is immediately sent to market, curing is necessary. The purpose of curing is to dry the skins and the top of the onion, forming an effective barrier against attack by microorganisms and, at the same time, minimizing the weight loss of the bulb. The onion is cured when the neck is tight, the outer scales are dry, and 3 to 5 percent of the original bulb weight is lost (Thompson, Booth, and Proctor 1972).

Curing can be natural or artificial. Windrowing, the traditional method in Britain, leaves the onions in the field, with the leaves of one row protecting the bulbs in the next. Direct exposure of the bulbs to the sun, especially under moist conditions, may lead to fungal damage (Thamizharasi and Narasimham 1993). In many countries, the onions are braided into bunches and hung up to dry (Thompson 1982).

Artificial curing techniques include forced heated air, vacuum cooling, cold storage, and infrared irradiation (Buffington et al. 1981). A small-capacity dryer has been developed in India (Singh 1994).

Storage. In addition to effective harvesting and curing, the critical factors for successful storage are cultivar type, storage conditions, and storage design. Losses from rotting and sprouting are more important than those from desiccation. Onions best suited for long-term storage (up to six months) usually have high amounts of dry matter and soluble solids, a long photoperiod during bulb maturation, and strong pungency. Red onions store better than white ones (Jones and Mann 1963; Thompson et al. 1972).

Temperature and relative humidity are the most important factors in storage conditions. Cold storage produces the best results but is not feasible in the tropics, where high-temperature storage may be effective, because dormancy is longer at 0° C and at 30° C than in between (10–15° C). Humidity should be about 70 to 75 percent (Robinson, Browne, and Burton 1975). Controlled-atmosphere storage losses depends on the quality and condition of the crop prior to storage (Adamicki and Kepka 1974).

In storage design, aeration is important for curing the onions and ventilating the heap. Consequently, slatted floors (or a similar layout, so that air can move through the bulbs from below) are employed. The onions are positioned so that air flows throughout the heap; otherwise, the moist, warm air retained in the middle leads to sprouting or rotting. The heaps should not be more than 8 feet high, and – especially where temperature, aeration, and humidity control are difficult – shallow heaps are recommended (Hall 1980).

Gamma irradiation is an effective inhibitor of sprouting in onion and garlic bulbs. Studies have shown that eating irradiated onions does not harmfully affect animals or their offspring, but irradiation can cause discoloration, may not affect rotting, and may make onions more susceptible to aflatoxin production (Van Petten, Hilliard, and Oliver 1966; Van Petten, Oliver, and Hilliard 1966; Priyadarshini and Tulpule 1976; Curzio and Croci 1983).

Pathogens and Pests

Fungi

DOWNY MILDEW. Downy mildew (*Peronospora destructor* [Berk.] Casp.) was first reported in England in 1841. It is now widespread and particularly prevalent in cool, moist climates such as the coastal regions bordering the North Sea in Britain and those of the northwestern (Washington, Oregon, and California) and northeastern (New York and New England) United States. This fungus attacks onions, garlic, leeks, and chives alike. Early infection may kill young plants, and survivors can be dwarfed, pale, and distorted. Later infection causes chlorosis and yellowing of the leaves and stems. Some plants may be systemically infected and, if used for propagation, can serve as sources of inoculum in the seed crop.

When infected, the bulb tissue tends to soften and shrivel, and the outer fleshy scales become amber-colored, watery, and wrinkled. Underlying scales may appear healthy and yet be heavily infected. The fungus commonly overwinters in young autumn-sown onions whose leaves have been infected by neighboring summer crops.

Downy mildew can be controlled by growing onions on uncontaminated land without adjacent diseased crops. Good-quality, noninfected onions should be used, and planting should be done on open, well-drained land (Fenwick and Hanley 1985a).

WHITE ROT. White rot (*Sclerotium cepivorum* Berk.) was first noted in mid-nineteenth-century England and, like downy mildew, infects all the alliums under scrutiny in this chapter. The fungal attack is favored by dry soil and cool conditions. It develops rapidly between 10° C and 20° C and is inhibited above 24° C, although periods of dry weather can lead to devastating attacks in the field. When young plants are attacked, the disease spreads rapidly. External signs are yellowing and necrosis of leaf tips. Roots and bulbs are also affected. The bulb scales become spongy, are covered with fluffy white mycelium, and develop black sclerotia. The fungus appears to overwinter as sclerotia, and, in fact, the sclerotia may survive 8 to 10 years or more in the absence of host plants. Growing seedlings and sets for transplanting in noninfected soil, and the use of long rotations, are of some benefit in controlling this fungus. Chemical treatment with mercuric chloride, lime, and 2,6-dichloro-4-nitroaniline have also proven effective (Fenwick and Hanley 1985a).

ONION SMUDGE. Common now in Europe and the United States, onion smudge (*Collectotrichum circinans* [Berk.] Vogl.) was first reported in England in 1851. It affects mainly white varieties of onion but has been reported in shallots and leeks. It is confined to the necks and scales, where it causes blemishes, reducing the market value of the crop. Rarely attacking the active growing parts of the plant, it is confined on colored onions to unpigmented areas on the outer scales of the neck. Onion smudge requires warm, moist conditions (10° C to 32° C, optimum 26° C). Conidia, or fungal spores, are produced abundantly and are scattered by spattering rain. With suitable conditions, a conidial spore will germinate within a few hours. Pungent onions resist smudge better than mild ones. Crop rotation, good husbandry, and carbamate sprays can minimize the damage. Drying the onions in hot air may be necessary, and curing under dry, well-ventilated conditions is important (Fenwick and Hanley 1985a).

ONION SMUT. Probably originating in the United States in the late nineteenth century and first reported in Britain in 1918, onion smut (*Urocystis cepulae* Frost) attacks bulb and salad onions as well as leeks, shallots, chives, and garlic. Infection occurs from two to three weeks after sowing, and a high percentage of the infected plants subsequently die. Elongated, leaden streaks discolor the scales and the growing leaves, which can also become thickened and malformed. The streaks develop into smut sori, which rupture and release spores that can survive up to 20 years in soil. Measures to control this fungus include avoiding infected areas, pelleting seed with hexachlorobenzene, dusting with thiram or ferbane, and applying fungicides (Fenwick and Hanley 1985a).

NECK ROT. Caused by three different species of *Botrytis,* neck rot is probably the most widely distributed and most destructive disease of onions in storage. It was first reported in Germany (1876) and then in the United States (1890) and Britain (1894). Infection occurs in the field but is usually not noticed until harvesting occurs. The first signs are a softening of bulb scales and the development of sunken brown lesions; a definite border between fresh and diseased tissue can be seen. The bulb desiccates and collapses. If the onions are stored in moist conditions, a secondary spread may take place. Infection occurs primarily from spores dispersed by wind or water before, during, or after harvest. White onions seem more susceptible than yellow or colored varieties, and pungent onions are less affected than mild-flavored varieties. Practical controls are thin sowing, careful handling during harvest, and providing optimal storage conditions. Zineb and other chemicals, including carbamate sprays, reduce infection, and in recent years, benomyl seed dressings have also been used effectively (Fenwick and Hanley 1985a).

Bacteria

SOFT ROT. The soft rot pathogen *(Erwinia carotovora)* enters onions through wounds that occur during harvest, transportation, and storage, or in the necks of uncured or slow-curing varieties. The infection usually starts at the bulb neck, with external signs of sponginess and a foul-smelling exudate from the neck when the bulb is squeezed. Soft rot occurs most commonly in humid weather and is transported by the onion maggot, which is itself contaminated by the rotting vegetation it consumes and, consequently, lays eggs carrying the bacteria. Control involves avoiding damage to the bulbs during and after harvest, drying them thoroughly and rapidly, using the lowest practicable storing temperature, and eliminating all damaged bulbs (Fenwick and Hanley 1985a; Wright, Hale, and Fullerton 1993). Also important is moving bulbs under cover and drying them if wet weather is expected during field-curing (Wright 1993).

Viruses. "Aster yellows," spread by the six-spotted leafhopper *(Macrosteles facifrons),* is an important viral disease of onion as well as of carrot, barley, celery, endive, lettuce, parsley, potato, and salsify. Yellowing young leaves are followed by the appearance of yellowed shoots; and roots become small and twisted. Control measures consist of reducing or eradicating the leafhopper population where aster yellows is prevalent (Fenwick and Hanley 1985a).

Nematodes. The bulb and stem nematode (*Ditylenchus dipsaci* [Kuhn] Filipjer) is widespread in the Mediterranean region but has also been found on onions and garlic in the United States, on onions in Brazil and England, and on onions and chives in Holland. It causes a condition known as "onion bloat." Dead plant tissue can contain dormant nemas, which are probably an important source of infestation. Chloropicren/steam fumigation and other treatments have proven effective, but bromine-containing nematocides should be avoided. Both onion and garlic are bromine-sensitive and will not produce good crops for up to 12 months if bromine residues are present in the soil.

Ditylenchus dipsaci is widespread in southern Italy, where it reproduces on several wild and cultivated plant species. Among vegetables, the most severely damaged are onion and garlic, but broad bean, pea, and celery also suffer damage. In the Mediterranean area, the nematode mainly infects host plants from September to May, but reproduction is greatest in October, November, March, and April, when soil moisture, relative humidity, and temperatures are optimal. Symptoms of nematode attack are apparent in the field from late February to April and in nurseries during October and November. As a result, early crops are damaged more than late crops. Nematodes survive in the soil and in plant residues. However, seeds from infested plants, except those of broad bean and pea, have rarely been found to harbor nematodes. The use of seeds, bulbs, and seedlings free of nematodes is a prerequisite for successful crop production. Cropping systems, soil treatments with fumigant and nonvolatile nematocides, and soil solarization of infested fields are recommended for effective and economic nematode control (Greco 1993).

Insects. Although many insects can attack onions, the two major culprits are the onion thrip (*Thrips tabaci* Lind.) and the onion maggot, the larval stage in the development of the onion fly (*Hylemya antiqua* Meig.). The onion thrip punctures leaves and sucks the exuding sap, leaving whitish areas on the leaves. Infestation is worse in very dry seasons and can often lead to the destruction of entire crops. Effective chemicals are available to control this pest, and results have shown that a 40 percent bulb-yield reduction occurs on nontreated plots as compared with treated ones (Domiciano, Ota, and Tedardi 1993).

The onion maggot is a pest of considerable economic importance. Both the fly and its eggs are carriers of the soft rot pathogen *E. carotovora* Holland. The adult female lays 30 to 40 eggs in the soil around the onion plant or on the onion itself, especially where plants are damaged, decaying, or already infected with larvae. Good husbandry, the destruction of onion waste, and chemicals such as aphidan, EPBP, fensulfothion, fonofos, malathion, or phoxim are used to control the onion fly and its offspring (Fenwick and Hanley 1985a).

Processing

Dehydrated onion pieces. After grading and curing, onions are peeled using lye or the flame method, whereby the roots and outer shell are burnt off in an oven, and the charred remnants are removed by washing. Next, the onions are sliced by revolving knives and dried by hot air forced upward through holes in the conveyor belt. For good storage and acceptable flavor stability, residual moisture content is about 4 to 5 percent. Moisture content can be reduced to the desired level in one to two hours (Gummery 1977). The onion pieces may then be used as such or converted into granules and flakes (or powder). Dehydrated onion pieces are widely employed in the formulation of sausage and meat products, soups, and sauces (Hanson 1975; Pruthi 1980).

Onion powder. Onion powder is used in cases where onion flavor is required but the appearance and texture of onions are not, as in dehydrated soups, relishes, and sauces. Onion powder is made by grinding dehydrated onion pieces or by spray-drying. For spray-drying, onions are washed free of debris, rinsed, and blended to a puree. Dextrose (30 to 40 percent by weight) is added, and the mixture spray-dried at temperatures below 68° C. It can be dried in four minutes at 65° C to 68° C. The treatment destroys all pathogenic bacteria while reducing the bacterial population, and the end product has excellent keeping properties (Gummery 1977).

Onion oil. Distillation of minced onions that have stood for some hours produces onion-essential oil. The oil is a brownish-amber liquid that contains a complex mixture of sulfur and other volatiles. The oil has 800 to 1,000 times the odor of a fresh onion, and its price may be 1,000 times more expensive as well. It is used for its solubility, lack of color, and strong aroma. However, onion oil cannot be standardized because its composition depends on the onion variety, ecological conditions, season, and processing (Heath 1981).

Onion juice. Onion juice is produced by expressing the bulbs, flash-heating the liquor obtained to a temperature of 140° C to 160° C, and immediately cooling it to 40° C. Next, the juice is carefully evaporated to approximately 72 to 75 percent dry matter to preserve it without chemical additives. The concentrated juice is pale brown in color and possesses a strong, fresh onion odor. Further evaporation to 82 to 85 percent solids darkens the product and gives it a cooked, toasted effect preferred by many. The sensory qualities are sometimes enhanced by returning the aromatic volatile condensate to the juice. The extract is often mixed with propylene glycol, lecithin, and glucose to yield an onion oleoresin that has a flavor 10 times that of onion powder and 100 times that of the original bulb (Heath 1981).

Onion salt. In the United States, onion salt is a mixture of dehydrated onion powder (18 to 20 percent), calcium stearate (an anticaking agent – 1 to 2 percent), and sodium chloride.

Pickled onions. Onions are pickled in a 10 percent salt solution and preserved in vinegar. Generally, silverskin or button onions are used because they give a translucent product with the desired firmness of texture. Lactic acid bacteria are the important fermentation organisms, and care must be taken to keep the solution at 10 percent salinity. Finally, the salt is leached from the onions with warm water, and the bulbs are placed in cold, spiced vinegar and stored in sealed glass jars (Fenwick and Hanley 1985a).

Nutrition

The nutritional content of onions varies by variety, ecological conditions, and climate. According to the Nutrition Data System of the University of Minnesota, 100 grams (g) (3.53 ounces or 0.44 cup) of onion provides 38 kilocalories of energy, 1.16 g of protein, 0.16 g fat, and 8.63 g of carbohydrate.

Using the standard of the *Recommended Dietary Allowances* (tenth edition) for a male between 18 and 25 years of age, approximately 100 g or one-half cup of fresh onion provides 10.7 percent of the Recommended Dietary Allowance (RDA) of vitamin C and 9.5 percent of folacin. Onions are high in potassium (157 milligrams [mg]) and low in sodium (3 mg). They contain small amounts of calcium, copper, iron, magnesium, manganese, molybdenum, phosphorus, selenium, and zinc (Raj, Agrawal, and Patel 1980). Other trace elements in onion are germanium, chromium, and lithium. Onions have no vitamin A and only small amounts of alpha-tocopherol, delta-tocopherol, thiamine, riboflavin, niacin, pantothenic acid, and vitamin B_6.

In addition, 100 g of onions contain only small amounts of three fatty acids: saturated palmitic acid (0.02 g), monounsaturated oleic acid (0.02 g), and polyunsaturated essential linoleic acid (0.06 g). They have 2.1 g of dietary fiber, no starch, and 89.68 g of water. Sucrose (1.3 g), glucose (2.4 g), and fructose (0.9 g) are present. All essential amino acids are present in onions. Arginine (0.16 g), which increases during maturation (Nilsson 1980), and glutamic acid (0.19 g) are the most abundant.

Chemistry

The color of red onions is due to cyanidin glycosides, anthocyanins that contain glucose molecules (Fuleki 1971). With yellow onions, quercetin, a flavonoid, and its glycosides are responsible for the color of the dry scales. The outer scales of onions have been used in Germany for dyeing Easter eggs and household fabrics (Perkin and Hummel 1896; Herrmann 1958). The flavonoid content is usually greatest in the outer leaves and may act as a protection against predators (Tissut 1974; Starke and Herrmann 1976a).

The phenolic compounds catechol and protocatechuic acid are found in greater quantities in colored onions than in white onions. The presence of these compounds in the outer dried scales is a contributing factor to the greater resistance of these types to smudge and neck rot diseases and to fungi-causing wild and soft rots (Walker and Stahman 1955; Farkas and Kiraly 1962).

The most important nonstructural polysaccharide in onion is a group of fructose polymers called fructans. Fructose commonly forms chains of 3 to 10 molecules, with chains of 3 and 4 molecules being the most common. It is thought that these polymers are used for storage carbohydrates and osmoregulation during bulb growth and expansion (Darbyshire and Henry 1978; Goodenough and Atkin 1981).

Onions contain pectins with high methoxyl content and of the rapid-setting kind. Pectin is used in the preparation of jellies and similar food products and is used by veterinarians as an antidiarrheal (Alexander and Sulebele 1973; Khodzhaeva and Kondratenko 1983). Onions also contain several sterols. Beta-sitosterol, cycloartenol, and lophenol are the most common, followed by campesterol. Beta-sitosterol is used as an antihyperlipoproteinemic (Oka, Kiriyama, and Yoshida 1974; Itoh et al. 1977).

Like garlic, onion has exhibited antioxidative activity, which can be increased by microwave heating or boiling. It has been shown that S-alkenyl cysteine sulfoxides are the most active components. Quercetin and other flavone aglycones also contribute to the total antioxidative capacities of onion and garlic extracts (Pratt and Watts 1964; Naito, Yamaguchi, and Yokoo 1981a, 1981b).

Onions produce thiamine propyldisulfide, which corresponds to the allithiamine formed in garlic from thiamine and allicin. Both compounds have been found effective against cyanide poisoning (Carson 1987).

Medicinal Use

Atherosclerotic. Onion is known to have a hypocholesterolemic effect, although not as strong as that of garlic (Bhushan et al. 1976). A study in China compared an onion-growing region to one without local onions. Both regions were similar in living standards, economic level, and dietary habits and customs. But people in the onion-growing region had a death rate from cardiovascular disease of 57 per 100,000 people, as compared with a cardiovascular-disease death rate in the other region of 167 per 100,000. The onion-growing region also had a significantly lower incidence of hypertension, retinal arteriosclerosis, hyperlipemia, and coronary artery disease (Sun et al. 1993).

Hypo- and hyperglycemic effects. A study has revealed that although a water extract of fresh or boiled onion did not affect fasting blood sugar in normal subjects, it did reduce the sugar levels in glucose-tolerance tests in a dose-dependent manner. From this result, it was suggested that onion has an antihyperglycemic effect instead of a hypoglycemic effect (Sharma et al. 1977).

The antihyperglycemic principle in onion has been tentatively identified as 2-propenyl propyl disulfide – a compound that has been found to lower the blood sugar and increase insulin levels but has not been observed to have any effect on free fatty-acid concentrations (Augusti 1974; Augusti and Benaim 1975). Another antihyperglycemic compound causing this effect is diphenylamine, found in onion and tea (Karawya et al. 1984).

Ill-effects of consumption. One problem with the consumption of onions is heartburn, but only among those predisposed to heartburn symptoms (Allen et al. 1990). Onions may also cause discomfort in people with ileostomies and children with Down's syndrome (Bingham, Cummings, and McNeil 1982; Urquhart and Webb 1985).

As early as 1909, cattle deaths were attributed to eating sprouting or decaying onions (Goldsmith 1909; Fenwick and Hanley 1985c). Clinical signs of the condition may include onion odor in breath and urine, tainting of milk, diarrhea, staggering, and collapse. Provided that the illness has not reached an irreversible point, the symptoms (which develop with a week of onion feeding) may decline when the offending ingredient is removed from the diet. Treatment may also include injection of B-complex vitamins with penicillin-streptomycin (Gruhzit 1931; Farkas and Farkas 1974; Kirk and Bulgin 1979).

Garlic

History

Antiquity. Cultivated in the Middle and Far East for at least 5,000 years, garlic *(Allium sativum)* is believed to have originated from a wild ancestor in central Asia and is, possibly, native to western Tartary (Turkestan). At a very early period, garlic was carried throughout the whole of Asia (except Japan), North Africa, and Europe. In ancient China, Egypt, and India, garlic – like onions – was a highly prized foodstuff (Hedrick 1972; Hanley and Fenwick 1985).

In Egypt, the consumption of garlic is shown in tomb art dating from the Early Dynastic Period (c. 2925–2575 B.C.). The Codex Elsers, an Egyptian medical papyrus dating from around 1500 B.C., described 22 garlic preparations employed against a variety of complaints, including headache, bodily weakness, and throat disorders (Fenwick and Hanley 1985a).

The Bible (Num. 11:5) reports that after their Exodus from Egypt (about 1450 B.C.), the Israelites complained to Moses about the lack of garlic, among other things: "We remember the fish which we used to eat free in Egypt, the cucumbers and the melons and the leeks and the onions and the garlic."

The Greeks, along with the Egyptians, regarded garlic as a defense against old age and illness, and athletes participating in the Olympic Games, (which began about 776 B.C.), regularly chewed it to improve stamina (Hanley and Fenwick 1985). Homer, the Greek poet from the eighth century B.C., worked garlic into his tales (Hedrick 1972), including a description of how Odysseus fended off Circe's magic using as antidote a plant "having black root and milk white flower" (Fenwick and Hanley 1985a: 202). Tradition has it that this plant was wild garlic (Fenwick and Hanley 1985a).

Hippocrates (c. 460–370 B.C.) recommended garlic for pneumonia and suppurating wounds, but warned that it "caused flatulence, a feeling of warmth on the chest and a heavy sensation in the head; it excites anxiety and increases any pain which may be present. Nevertheless, it has the good quality that it increases the secretion of urine" (Jones and Mann 1963; Warren 1970; Fenwick and Hanley 1985a: 202).

Asia. Garlic was introduced into China between 140 and 86 B.C. The Chinese word for garlic, *suan,* is written as a single character, which often indicates the antiquity of a word (Hyams 1971). A fifth-century Chinese treatise on agriculture *(Ch'i-min-yao-shu)* described the cultivation of *suan* along the Red River valley. Chinese leeks, shallots, and spring onions were also discussed, but garlic seems to have been the most important. In addition, *tse suan* – water garlic (*Allium nipponicum* L.) – was mentioned as both a pervasive weed and a cultivated plant (Li 1969). According to Marco Polo (c. A.D. 1254–1324), garlic was used as a complement to raw liver among the Chinese poor (Lucas 1966), and much mention is made of garlic in treatises written in China from the fifteenth to the eighteenth centuries (Hedrick 1972).

In India, an important fifth-century Sanskrit medical manuscript, the *Charaka-Samhita,* based on sources from perhaps five centuries earlier, attributed widespread curative properties to both garlic and onion. It was claimed that they possessed diuretic properties, were beneficial to the digestive tract, were good for the eyes, acted as heart stimulants, and had antirheumatic qualities (Fenwick and Hanley 1985a).

In the Ayurvedic (Sanskrit) and Unani Tibb (Greco-Arabic) systems, garlic has been employed both as a prophylactic and as a cure for a variety of diseases, including arteriosclerosis, cholera, colic, dysentery, dyspepsia, gastric and intestinal catarrh, and typhoid. Duodenal ulcers, laryngeal tuberculosis, and lupus have all been treated with garlic juice, and garlic preparations have been given for bronchiectasis, gangrene of the lung, pulmonary phthisis, and whooping cough (Fenwick and Hanley 1985a).

Today the use of garlic is especially prevalent in Asia, where garlic-based antibiotics are used extensively to replace or complement more sophisticated drugs (Hanley and Fenwick 1985). In addition, in rural villages of Karnataka, in southwestern India, garlic is prescribed for lactating women (Rao 1985).

Europe. Garlic was regularly mentioned in European literature as well, especially for its medicinal benefits. The Roman poet Virgil (79–19 B.C.), for example, in his *Second Idyll* described how Thestylis used the juices of wild thyme and garlic as a prophylactic against snake bites (Warren 1970). A bit later, Pliny the Elder, in his *Natural History,* recommended that garlic be "placed when the moon is below the horizon and gathered when it is in conjunction" (Fenwick and Hanley 1985a: 200) to remove the plant's pungent smell. He devised 61 garlic-based remedies for such conditions as hemorrhoids, loss of appetite, rheumatism, and ulcers (Jones and Mann 1963; Fenwick and Hanley 1985a).

The Romans apparently disliked garlic in general because of its strong scent, but it was fed to laborers to strengthen them and to soldiers to excite courage. The Romans also used garlic as a remedy for diabetes mellitus, and it is probable that it was similarly employed by the Egyptians and Greeks (Hanley and

Fenwick 1985). Carbonized garlic has been found at Pompeii and Herculaneum, which were destroyed in A.D. 79 (Meyer 1980).

The Greek military physician Dioscorides (A.D. 40–90) was clearly impressed with garlic, onion, and other alliums as medicinal plants. He advised garlic for baldness, birthmarks, dog and snake bites, eczema, leprosy, lice, nits, toothache, ulcers, and worms. He also suggested it as a vermifuge and diuretic and as a treatment for rashes and other skin disorders (Warren 1970; Fenwick and Hanley 1985a).

The cultivation of alliums in Western Europe is usually thought to have been stimulated by the Crusaders' contacts with the East in the eleventh, twelfth, and thirteenth centuries. However, much earlier, Charlemagne (742–814) had listed garlic in his *Capitulare de Villis* and mentioned it as of Italian origin (Fenwick and Hanley 1985a). During medieval times, garlic was less appreciated for its taste than for its allegedly favorable effect on sexual potency and performance (Mauron 1986).

Presumably, however, the latter was of little interest to St. Hildegard (1098–1179), a German abbess, mystic, and scientific observer who continued the focus on garlic as medicine by specifically mentioning it in her *Physica* as a remedy against jaundice. The herbal doctors Paracelsus (Philippus Aureolus Paracelsus, 1493–1541) and Lonicerus (Adam Lonitzer, 1528–86) emphasized the antitoxic properties of garlic and its effectiveness against internal worms. At about the same time, Italian physician and botanist Matthiolus (Pietro Andrea Mattioli, 1500–77) was recommending garlic against stomach chills, colics, and flatulence.

The word "garlic" is derived from the old English "gar" (meaning spear) and, presumably, refers to the garlic clove. Geoffrey Chaucer (c. 1342–1400) wrote of "Wel loved garleek, onyons and leekes" (Fenwick and Hanley 1985a: 200), and garlic's pungency was described by William Shakespeare. In *A Midsummer Night's Dream* (Act IV, Scene 1), Bottom tells his fellow actors to eat neither garlic nor onion, "for we are to utter sweet breath," and in *Measure for Measure* (Act III, Scene 2), Lucio criticizes the Duke, who "would mouth a beggar, though she smell brown bread and garlic." A contemporary of Shakespeare described King Henry IV of France as "chewing garlic and having breath that would fell an ox at twenty paces" (Fenwick and Hanley 1985a: 201).

Garlic's medicinal (and supposedly aphrodisiacal) powers were known in England in the sixteenth and seventeenth centuries, and the diarist Samuel Pepys (1633–1703) discovered that the custom in the French navy – to keep the sailors warm and prevent scurvy – was to issue garlic and brandy rations; the British Admiralty followed suit (Fenwick and Hanley 1985a).

At the turn of the nineteenth century, garlic in the form of inhalants, compresses, and ointments was used by the citizens of Dublin against tuberculosis, and the medicinal use of garlic is still common in Bulgaria, Japan, and Russia, among other places (Petkov 1986). In Russia, garlic-based antibiotics are widely employed, and on one occasion, 500 tonnes of garlic were imported to combat an outbreak of influenza (Fenwick and Hanley 1985a).

The Americas. Garlic was introduced to the Americas by the Spaniards. In Mexico, Cortés (1485–1547) apparently grew it, and by 1604, it was said in Peru that "the Indians esteem garlic above all the roots of Europe" (Hedrick 1972). By 1775, the Choctaw Indians of North America (Alabama, Louisiana, and Mississippi) were cultivating garlic in their gardens, and at the turn of the nineteenth century, American writers mentioned garlic as among their garden esculents (Hedrick 1972).

Garlic is widely used today in Latin America as a medicine as well as a food. In Guatemala, for example, it is prescribed for vaginitis by traditional healers, health promoters, and midwives (Giron et al. 1988) and is also employed against helminthic infection, both alone and in conjunction with commercial drugs (Booth, Johns, and Lopez-Palacios 1993). Argentine folk medicine prescribes garlic for antimicrobial use (Anesini and Perez 1993), and in the mountains of Chiapas in southeastern Mexico, Indian sheepherders use garlic and other alliums for veterinary purposes (Perezgrovas Garza 1990).

Production. The major producers of garlic in 1996 were (in metric tons) China (8,574,078), Korea (455,955), India (411,900), the United States (277,820), Egypt (255,500), and Spain (212,400), and world production was 11,633,800 metric tons. Major exporters in 1996 were China, Hong Kong, Singapore, Argentina, Spain, Mexico, and France, and major importers were Malaysia, Brazil, Indonesia, Singapore, the United Arab Emirates, Japan, the United States, and France.

In the United States, garlic production is confined mostly to California. Most of this crop is grown around the town of Gilroy, which calls itself the "garlic capital of the world" (Fenwick and Hanley 1985a).

Horticulture and Botany

Botany. Garlic is known only in its cultivated form but may be related to the wild *Allium longicuspis* of central Asia. Garlic bulbs develop entirely underground, and the plant is either nonflowering or flowers in the spring. Its leaves are flat and rather slender; the stem is smooth and solid. The bulbs are composed of several bulbils (cloves) encased in the white or pink skin of the parent bulb. Each clove is formed from two leaves, the outer cylindrical one being protective and the inner one a storage organ for the bud (Traub 1968).

Cultivation. Although it grows in a wide variety of soils, garlic flourishes best in rich, deep loams with plentiful moisture. Before planting, the bulbs should be dried, treated (e.g., with benomyl) to reduce rotting, and exposed to temperatures between 0° C and 10° C for four to eight weeks to ensure bulbing. Bulbs usually form and enlarge with long days and temperatures above 20° C. Plant spacing affects the size of the bulbs. Italian workers consider a spacing of 40 to 50 per square meter desirable. Doubling this density increases the yield by 50 percent, but then the bulbs are smaller and more suitable for processing than for the fresh market (Tesi and Ricci 1982). When the tops become dry and bend to the ground, harvesting is generally done by hand, although it can be done mechanically. Curing is usually carried out in the ground or in well-ventilated structures, and the dried bulbs can be stored.

Proper curing enables garlic to store well without careful temperature control. The best results are achieved when the bulbs are dried 8 to 10 days at 20° C to 30° C, followed by a reduction of temperature to 0° C with air circulation. Under these conditions, garlic bulbs can be stored from 130 to 220 days, depending on variety and how they were grown (IOS 1983).

Also effective in garlic storage is the application of maleic hydrazide prior to harvest (Omar and Arafa 1979), and gamma irradiation prevents storage losses without an adverse effect on taste, flavor, pungency, or texture (Mathur 1963). For cold storage conditions, it is recommended that garlic be harvested, dried, and packed away from all other crops except onions (Tesi and Ricci 1982).

Pathogens and Pests

The common pests and pathogens of garlic are those discussed in the section about onions.

Processing

Dehydrated garlic. As already mentioned, most of the garlic produced in the United States (90 percent) is grown and processed near the town of Gilroy, California. Gilroy also has the largest dehydration plant in the world, and in this region, more than 60,000 tons annually are processed into 25 different kinds of flakes, salts, and granules.

Dehydrated garlic can contain five times the flavor of the fresh clove, and garlic powder is used extensively in the manufacture of spiced sausages and other foods. To maintain flavor character and prevent lumping and hardening, the powder must be stored free of moisture. Flavor deterioration of stored garlic powder is maximal at 37° C and minimal between 0° C and 2° C. At room temperature, the product is best stored in cans. The packaging of garlic powder (at 6 percent moisture content) in hermetically sealed cans is best of all (Singh, Pruthi, Sankaran, et al. 1959; Singh, Pruthi, Sreenivasamurthy, et al. 1959).

Garlic flavoring. The volatile oil content of garlic is between 0.1 and 0.25 percent. The reddish-brown oil from the distillation of freshly crushed garlic cloves is rich in 2-propenyl sulfides. Often the oil itself is too pungent for efficient manufacturing use, so garlic juice – obtained in a similar manner to onion juice – is employed. Concentrating the juice produces oleoresin garlic, a dark-brown extract with approximately 5 percent garlic oil. The oleoresin has uniformity, good handling, and good processing characteristics.

Nutrition

As with onions, the nutrient content of garlic changes with variety, ecological conditions, and climate. One hundred grams (3.53 ounces, or 0.44 of a cup) of garlic provides about 149 kilocalories of energy, 6.36 g of protein, 0.5 g of fat, and 33.07 g of carbohydrate (Nutrition Coordinating Center 1994).

In light of the RDA standard for males between 18 and 25 years of age, approximately one-half cup of fresh garlic (100 g) would provide them with 10.1 percent of the recommended dietary allowance of protein, 22.6 percent of calcium (181 mg), 17 percent of iron (1.7 mg), 19.1 percent of phosphorus (153 mg), 13.3 percent of copper (0.3 mg), 20.3 percent of selenium (14.2 mg), 52 percent of vitamin C (31.2 mg), 13.3 percent of thiamine (0.2 mg), 10.9 percent of pantothenic acid (0.6 mg), and 61.5 percent of vitamin B_6 (1.23 mg). Garlic is high in potassium (401 mg/100 g), low in sodium (17 mg/100 g), and contains small amounts of magnesium, manganese, molybdenum, and zinc (Pruthi 1980; Raj et al. 1980). Other trace elements in garlic are cobalt, chromium, lithium, nickel, titanium, and vanadium. Garlic contains no vitamin A or E but does have small amounts of riboflavin, niacin, and folacin (National Research Council 1989).

Garlic (100 g) contains only small amounts of four fatty acids: 0.09 g of saturated palmitic acid, 0.01 g of monounsaturated oleic acid, 0.23 g of polyunsaturated essential linoleic acid, and 0.02 g of polyunsaturated essential linolenic acid. It has 4.1 g of dietary fiber, 14.7 g of starch, and 58.58 g of water. Sucrose (0.6 g), glucose (0.4 g), and fructose (0.6 g) are present, as are the essential amino acids – arginine (0.63 g) and glutamic acid (0.8 g) are the most abundant, followed by aspartic acid (0.49 g) and leucine (0.31 g).

Chemistry

Nonflavor compounds. Garlic contains polymers of fructose with up to 51 fructose molecules (Darbyshire and Henry 1981). It also yields pectin. Garlic pectin content includes galactose, arabinose, galacturonic acid, and glucose. It has a much higher viscosity than onion pectin, as well as a lower setting temperature and a longer setting time (Alexander and Sulebele 1973; Khodzhaeva and Kondratenko 1983).

Sterols found in garlic are stigmasterol, B-sitosterol, and campesterol (Oka et al. 1974; Stoianova-Ivanova, Tzutzulova, and Caputto 1980). Garlic also contains arachidonic and eicosapentaenic acids (Carson 1987).

Garlic has exhibited antioxidant activity in linoleic-acid and minced-pork model systems. This activity can be increased by microwave heating or boiling. It has been shown that S-alkenyl cysteine sulfoxides were the most active. Quercetin and other flavone aglycones also contribute to the total antioxidant capacities of onion and garlic extracts (Pratt and Watts 1964; Naito et al. 1981a, 1981b).

Allithiamin, discovered in the 1950s by Japanese researchers, is formed in garlic from thiamine and allicin and is absorbed faster in the intestinal tract than thiamine (Fujiwara 1976). Unlike thiamine, allithiamin is not degraded by thiaminase and appears more stable under conditions of heat (Hanley and Fenwick 1985). Allithiamin, which reacts with the amino acid cysteine to regenerate thiamine – yielding 2-propenylthiocysteine – has been found effective against cyanide poisoning (Carson 1987).

Flavor compounds. The first important studies on the composition of garlic oil were carried out by T. Wertheim in 1844 and 1845. While investigating the antibacterial properties of garlic in the 1940s, C. J. Cavallito and others discovered the thiolsulfinate allicin, the most important flavor component of fresh garlic (Carson 1987). This colorless oil is di(2-propenyl)thiolsulfinate. (In this chapter, 2-propenyl is used instead of allyl.) Allicin is probably the first thiolsulfinate isolated from natural sources (Carson 1987).

The compounds responsible for the flavor of alliums are produced from involatile precursors only when tissue maceration occurs. Gamma-glutamyl peptides, containing approximately 90 percent of garlic's soluble, organically bound sulfur, are present in significant amounts and may be the storage form of the flavor precursors (Virtanen 1965; Whitaker 1976). Under these circumstances, alkyl or alkenyl cysteine sulfoxides come into contact with an enzyme, alliinase, and hydrolysis occurs. The initially formed thiolsulfinates can break down to produce a range of organoleptically important sulfur compounds, including disulfides, trisulfides, higher sulfides, and thiols. The flavor properties of the different alliums depend on the types and amounts of these sulfur compounds (Hanley and Fenwick 1985).

Over 90 percent of the flavor-precursor content of garlic is located in the storage leaf (Freeman 1975). Alliin lyase is a major product of the storage bud (clove), accounting for 10 percent of its total protein. Deposits of alliinase are most pronounced around phloem tissue and are concentrated in the bundle sheaths. Little, if any, occurs in storage mesophyll that is not in contact with vascular bundles. This deposition in the clove may reflect the enzyme's role in protecting underground storage buds from decay and predation. Positioning near the phloem suggests that alliin lyase, or compounds related to its activity, may be translocated to and from the clove during development (Ellmore and Feldberg 1994). Alliinase is present in most, if not all, members of the genus *Allium,* and is also found in *Albizzia, Acacia, Parkia,* and *Lentinus* species.

Medicinal Use

Atherosclerotic. Medical claims for the efficacy of garlic against myriad complaints have been made for millennia and are still being made today as science continues to analyze the properties of this tasty vegetable and channel them to medical use.

The second-century Indian physician, Charaka, reported that onion and garlic prevented heart disease and acted as heart tonics (Fenwick and Hanley 1985c). Clots, which can cause strokes and heart attacks, are formed through the aggregation of platelets. Both garlic and onion have a demonstrated ability to inhibit platelet aggregation, possibly by interfering with prostaglandin biosynthesis (Ali et al. 1993).

In a double-blind, placebo-controlled study of 60 volunteers with cerebrovascular risk factors and constantly increased platelet aggregation, it was demonstrated that daily ingestion of 800 mg of powdered garlic (in the form of coated tablets), over four weeks, significantly decreased the ratio of circulating platelet aggregates and inhibited spontaneous platelet aggregation. The ratio of circulating platelet aggregates decreased by 10.3 percent; spontaneous platelet aggregation decreased by 56.3 percent (Kiesewetter et al. 1993).

Some garlic compounds that inhibit platelet aggregation have been identified. These are methyl (2-propenyl)trisulfide (the strongest), methyl (2-propenyl)disulfide, di(2-propenyl)disulfide, and di(2-propenyl)trisulfides. All these compounds are said to be formed from allicin, which is di (2-propenyl)thiosulfinate. There is some evidence that methyl(2-propenyl)trisulfide is more effective on a molar basis than aspirin (Makheja, Vanderhoek, and Bailey 1979; Ariga, Oshiba, and Tamada 1981; Bosia et al. 1983; Apitz-Castro, Badimon, and Badimon 1992; Lawson, Ransom, and Hughes 1992). Recently, a novel amino acid glycoside, (-)-N-(1′-beta-D-fructopyranosyl)-S-2-propenyl-L-cysteine sulfoxide, showed significant inhibition of in vitro platelet aggregation induced by ADP (adenosin diphosphate) and epinephrine (Mutsch-Eckner et al. 1993).

Garlic has also been shown to increase fibrinolytic activity, which inhibits clot formation (Bordia et al. 1978). An excellent epidemiological study of garlic and onion intake in the Jain community in India was done in 1979. Three groups with widely differing allium consumption patterns were chosen: those who had always abstained from onions and garlic; those who consumed only small amounts (<200 g onion, <10 g garlic per week); and those who consumed onions and garlic liberally (>600 g onion, >50 g garlic per week). The three groups were otherwise similar in regard to intake of calories, fat, and carbohydrates. Those who ingested the most alliums had the lowest level of plasma fibrinogen, which is used by the body in forming a blood clot with platelets (Sainani, Desai, Natu et al. 1979).

In a study of dried garlic consumption by 20 patients with hyperlipoproteinemia over a period of four weeks, fibrinogen and fibrinopeptide A significantly decreased by 10 percent. Serum cholesterol levels significantly decreased by 10 percent. Systolic and diastolic blood pressure decreased. ADP- and collagen-induced platelet aggregation were not influenced (Harenberg, Giese, and Zimmermann 1988).

The antithrombotic agents found in garlic that we know about are (E,Z)-ajoene, or (E,Z)4,5,9-trithiadodeca-1,6,11-triene 9-oxide, the major anticoagulant, di(2-propenyl)trisulfide, and 2-vinyl-4H-1,3-dithiene (Apitz-Castro et al. 1983; Block et al. 1984; Block 1992).

It is generally known that both fresh and boiled garlic decrease cholesterol and triglycerides. The Jain epidemiological study, mentioned previously, demonstrated not only that liberal use of onions and garlic decreased total cholesterol, low-density lipoprotein (LDL – the so-called bad cholesterol), and triglycerides, but also that those who consumed even small amounts of alliums were better protected than those who ate no onions or garlic (Sainani, Desai, Gorhe, et al. 1979).

One study, however, found that garlic increased cholesterol in people who had suffered a heart attack. A longer-term trial of garlic's effects on these people was undertaken and lasted 10 months. After 1 month, there was an increase in cholesterol, but thereafter it decreased, and after 8 months, it had declined by 18 percent. The initial increase in serum cholesterol in the heart patients who were fed garlic may have been caused by mobilization of lipid from deposits. Decreases of LDL occurred, and high-density lipoprotein (HDL – the "good" cholesterol) increased (Bordia 1981).

A multicentric, placebo-controlled, randomized study of standardized garlic-powder tablets in the treatment of hyperlipidemia (cholesterol levels over 200 mg/dl) was performed over a 16-week period. The total intake of garlic powder was 800 mg/day, standardized to 1.3 percent of alliin, (+)S-(2-propenyl)-L-cysteine, content (Stoll and Seebeck 1948). Cholesterol levels dropped 12 percent and triglyceride levels dropped 17 percent, with the best lowering effects seen in patients with cholesterol values between 250 to 300 mg/dl (Mader 1990).

To assess the effects of standardized garlic-powder tablets on serum lipids and lipoproteins, 42 healthy adults (19 men and 23 women), with a mean age of 52 (plus or minus 12 years), and with total serum cholesterol levels of 220 mg/dl or above, received, in a randomized, double-blind fashion, 300 mg of standardized garlic powder (in tablet form) three times a day for 12 weeks, or they received a placebo. Diets and physical activities were unchanged. Treatment with standardized garlic at 900 mg/day produced a significantly greater reduction in serum triglycerides and LDL cholesterol than did the placebo. LDL-C (low-density lipoprotein cholesterol) was reduced 11 percent by garlic treatment and 3 percent by placebo ($p < 0.05$), and the baseline total cholesterol level of 262 (plus or minus 34 mg/dl) dropped to 247 (plus or minus 40 mg/dl) ($p < 0.01$). The placebo group showed a change from 276 (plus or minus 34 mg/dl) to 274 (plus or minus 29 mg/dl) (Jain et al. 1993).

Part of the activity of garlic results from an interruption of normal cholesterol biosynthesis (Qureshi et al. 1983). Hepatic cell culture results indicate that the hypocholesterolemic effect of garlic proceeds, in part, from decreased hepatic cholesterogenesis, whereas the triacylglycerol-lowering effect appears to be the result of the inhibition of fatty-acid synthesis (Yeh and Yeh 1994). The garlic compounds di(2-propenyl)thiosulfinate (allicin), S-methyl-L-cysteine sulfoxide, and S-(2-propenyl)-L-cysteine sulfoxide lower cholesterol in animals (Itokawa et al. 1973; Augusti and Matthew 1975). The garlic compounds ajoene, methylajoene, 2-vinyl-4H-1,3-dithiin, di(2-propenyl)disulfide, and allicin inhibit cholesterol synthesis in rat livers by 37 to 72 percent (Sendl et al. 1992). There is some evidence that di(2-propenyl)-disulfide inactivates 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase (the major cholesterol synthesis enzyme) by forming an internal protein disulfide inaccessible for reduction and making the enzyme inactive (Omkumar et al. 1993). It has also been found that ajoene inactivates human gastric lipase, which causes less absorption of fat to occur in the digestion process and, therefore, lowers triacylglycerol levels (Gargouri et al. 1989).

Meta-analysis of the controlled trials of garlic's role in reducing hypercholesterolemia showed a significant reduction in total cholesterol levels. The best available evidence suggests that garlic, in an amount approximating one-half to one clove per day, decreased total serum cholesterol levels by about 9 percent in the groups of patients studied (Warshafsky, Kamer, and Sivak 1993; Silagy and Neil 1994).

Antimicrobial, antiviral, antihelminthic, and antifungal action. Garlic has been found to be more potent than 13 other spices in inhibiting *Shigella sonnei* (bacillary dysentery), *Staphylococcus aureus* (boils and food poisoning), *Escherichia coli* (indicator of fecal contamination), *Streptococcus faecalis* (indicator of fecal contamination), and *Lactobacillus casei* (found in milk and cheese) (Subrahmanyan, Krishnamarthy, et al. 1957; Subrahmanyan, Sreenivasamurthy, et al. 1957). A mouthwash containing 10 percent garlic extract has been shown to significantly reduce oral bacterial counts (Elnima et al. 1983). However, the antibacterial components of garlic are heat labile. Whole garlic bulbs can lose their antibacterial activity within 20 minutes in boiling water at 100° C (Chen, Chang, and Chang 1985).

Garlic may change the composition of intestinal microflora to favor lactic organisms that are beneficial in the absorption of dietary minerals (Subrahmanyan, Krishnamurthy, et al. 1957; Subrahmanyan, Sreenivasamurthy, et al. 1957). Lactic acid bacteria have been proven to be the least sensitive microorganisms to the inhibitory effects of garlic.

In general, garlic is effective against most gram-positive and gram-negative bacteria. Garlic extracts inhibit the coagulase activity of *S. aureus* (Fletcher, Parker, and Hassett 1974). The *Listeria monocytogenes* population of strain Scott A (a source of food poisoning) was decreased to less than 10 per milliliter in seven days by 1 percent garlic powder (Hefnawy, Moustafa, and Marth 1993). Garlic also inhibits *Vibrio parahemolyticus* (a gastroenteritis-causing pathogen in raw or improperly cooked fish or seafood) (Sato, Terao, and Ishibashi 1993).

Garlic has been found beneficial in cryptococcal meningitis, a frequently fatal disease (Fromtling and Bulmer 1978; Garlic in cryptococcal meningitis 1980; Caporaso, Smith, and Eng 1983). A commercial garlic extract, intravenously infused into two patients, caused their plasma titers of anti-*Cryptococcus neoformans* activity to rise twofold over preinfusion titers (Davis, Shen, and Cai 1990).

Thirty strains of mycobacteria, consisting of 17 species, were inhibited by various concentrations of garlic extract (1.34 to 3.35 mg/ml of agar media). Six strains of *Mycobacterium tuberculosis* required a mean inhibitory concentration of 1.67 mg/ml of media (Delaha and Garagusi 1985).

Garlic has proven effective in leprous neuritis. It is not certain whether this results from the vegetable's topical antibiotic activity or from garlic's ability to improve the thiamin status of the patient (Ramanujam 1962; Sreenivasamurthy et al. 1962).

Allicin, di(2-propenyl)thiosulfinate, the principal fresh-flavor component of garlic, is effective in the range of 1:125,000 against a number of gram-positive and gram-negative organisms. It inhibits the growth of some *Staphylococci, Streptococci, Vibrio* (including *Vibrio cholerae*), and *Bacilli* (including *Bacillus typhosus, Bacillus dysenteriae,* and *Bacillus enteritidis*) but is considerably weaker than penicillin against gram-positive organisms (Carson 1987). Allicin's effect is generally attributed to its interaction with biological -SH (sulfur) containing systems. If -SH-containing systems are necessary components for the growth and development of microorganisms, these processes will be inhibited by allicin. If the toxic compounds are exogenous, then reaction with allicin will lead to detoxification (Cavallito 1946; Wills 1956).

Garlic has exhibited antiviral activity against influenza B virus and herpes simplex type I (nongenital) but not against Coxsaki B1 virus, which, however, usually causes only a mild illness (Carson 1987). Clinical use of garlic preparations in the prevention and treatment of human cytomegalovirus infections is effective (Meng et al. 1993). Because the antiviral effect of garlic extract is strongest when it is applied continuously in tissue culture, it is recommended that the clinical use of garlic extract against cytomegalovirus infection be persistent, and the prophylactic use of garlic extract is preferable in immunocompromised patients (Guo et al. 1993).

The activity of garlic constituents against selected viruses, including herpes simplex virus type 1 (nongenital cold sores), herpes simplex virus type 2 (genital), parainfluenza virus type 3 (bronchitis and pneumonia), vaccinia virus (cowpox, the source of an active vaccine against smallpox), vesicular stomatitis virus (which causes cold sores in humans and animals), and human rhinovirus type 2 (the common cold), has been determined. In general, the virucidal constituents, in descending order, were: ajoene, allicin, 2-propenyl methyl thiosulfinate, and methyl 2-propenyl thiosulfinate (Weber et al. 1992). Ajoene has also shown some activity against human immunodeficiency virus (HIV) (Tatarrintsev et al. 1992).

The effect of serial dilutions of crude garlic extract on adult *Hymenolepis nana* (dwarf tapeworm) was studied to detect the minimal lethal concentration. Garlic was then employed in the treatment of 10 children infected with *H. nana* and 26 children infected with *Giardia lamblia* (giardiasis). Such treatment took the form of either 5 milliliters of crude extract in 100 milliliters of water in two doses per day, or two commercially prepared 0.6 mg capsules twice a day for three days. Garlic was found to be efficient and safe and to shorten the duration of treatment (Soffar and Mokhtar 1991). Garlic appears to affect adversely the development of the eggs of *Necator americanus* (hookworm) but has less effect on the hatched larvae (Bastidas 1969). Rectal garlic preparations may be effective in the treatment of pinworms (Braun 1974).

A single dose of ajoene on the day of malarial infection was found to suppress the development of parasitemia; there were no obvious acute toxic effects from the tested dose. The combination of ajoene and chloroquine, given as a single dose on the day of the infection, completely prevented the subsequent development of malarial parasitemia in treated mice (Perez, de la Rosa, and Apitz 1994).

Ajoene has also been shown to inhibit the proliferation of *Trypanosoma cruzi,* the causative agent of Chagas' disease. An important factor associated with the antiproliferative effects of ajoene against *T. cruzi* may be its specific alteration of the phospholipid composition of these cells (Urbina 1993).

Garlic inhibits the aflatoxin-producing fungi *Aspergillus flavus* and *Aspergillus parasiticus*

(Sharma et al. 1979). Garlic extract inhibits the growth and aflatoxin production of *A. flavus* (Sutabhaha, Suttajt, and Niyomca 1992), and garlic oil completely inhibits sterigmatocystin (a carcinogenic mycotoxin produced by *Aspergillus*) production (Hasan and Mahmoud 1993). Thiopropanal-S-oxide is one of the most active antiaflatoxin components (Sharma et al. 1979).

The ajoene in garlic has been shown to have antifungal activity. *Aspergillus niger* (a frequent cause of fungal ear infections) and *Candida albicans* (yeast) were inhibited by ajoene in concentrations of less than 20 micrograms per milliliter (Yoshida et al. 1987). Ajoene also inhibits the growth of the pathogenic fungus *Paracoccidioides brasiliensis* (South American blastomycosis, which starts in the lungs) (San Blas et al. 1993). Additional studies have shown ajoene to inhibit *Cladosporium carrionii* and *Fonsecaea pedrosoi* (both cause chromoblastomycosis, a fungal disease of the skin) (Sanchez-Mirt, Gil, and Apitz-Castro 1993).

Moreover, extracts of both garlic and onion have been shown to inhibit the growth of many plant-pathogenic fungi and yeasts. Garlic-bulb extracts are more active than onion extracts (Agrawal 1978). Garlic solutions of 1 to 20 percent have been effective against plant pathogens such as downy mildew in cucumbers and radishes, bean rust, bean anthracnose, tomato early blight, brown rot in stone fruits, angular leaf spot in cucumbers, and bacterial blight in beans (Pordesimo and Ilag 1976). Ajoene has been tested in greenhouse experiments, where it completely inhibited powdery mildew in tomatoes and roses (Reimers et al. 1993).

Anticarcinogenic. Some data have suggested an inverse relationship between garlic consumption and gastric cancer. In Shandong Province, China, the death rate from gastric cancer was found to be 3.45/100,000 population in Gangshan County (where garlic consumption is approximately 20 g per person per day), but in nearby Quixia County (where little garlic is eaten), the gastric cancer death rate was much higher, averaging 40/100,000 (Han 1993; Witte et al. 1996). A study of risk factors for colon cancer in Shanghai indicated that garlic was associated with a decreased relative risk (Yang, Ji, and Gao 1993). Some evidence to the same effect has been seen in Italy (Dorant et al. 1993).

Interviews with 564 patients with stomach cancer and 1,131 controls – in an area of China where gastric cancer rates were high – revealed a significant reduction in gastric cancer risk with increasing consumption of allium vegetables. Persons in the highest quartile of intake experienced only 40 percent of the risk of those in the lowest quartile. Protective effects were seen for garlic, onions, and other allium foods. Although additional research is needed before etiologic inferences can be made, the findings were consistent with reports of tumor inhibition following administration of allium compounds in experimental animals (You et al. 1989). Garlic has been shown to reduce cancer promotion and tumor yield by phorbol-myristate-acetate in mice (Belman 1983).

In isolated epidermal cells, at 5 μg per milliliter, garlic oil increased glutathione peroxidase activity and inhibited ornithine decarboxylase induction in the presence of various nonphorbol ester tumor promoters. The same oil treatment inhibited the sharp decline in the intracellular ratio of reduced glutathione to oxidized glutathione caused by the potent tumor promoter, 12-O-tetradecanoylphorbol-13-acetate. It was suggested that some of the inhibitory effects of garlic on skin tumor promotion may have resulted from its enhancement of the natural glutathione-dependent antioxidant protective system of the epidermal cells (Perchellet et al. 1986). The active compound appeared to be di(2-propenyl)trisulfide (Carson 1987).

Other medicinal uses. Garlic has been used to treat hypertension in China and Japan for centuries. Studies in 1921, 1948, and 1969 provided supporting evidence of garlic's antihypertensive ability (Loeper and Debray 1921; Piotrowski 1948; Srinivasan 1969).

In 1990, a study was published in which 47 outpatients with mild hypertension took part in a randomized, placebo-controlled, double-blind trial conducted by 11 general practitioners. The patients who were admitted to the study had diastolic blood pressures between 95 and 104 mm Hg. The patients took either a preparation of garlic powder or a placebo of identical appearance for 12 weeks. Blood pressure and plasma lipids were monitored during treatment at 4, 8, and 12 weeks. Significant differences between the placebo and garlic groups were found during the course of therapy. The supine diastolic blood pressure in the group taking garlic fell from 102 to 91 mm Hg after 8 weeks ($p < 0.05$) and to 89 mm Hg after 12 weeks ($p < 0.01$). Serum cholesterol and triglycerides were also significantly reduced after 8 and 12 weeks of treatment. In the placebo group no significant changes occurred (Auer et al. 1990).

Studies of natural selenium-rich sources have found that high-selenium garlic and onion may have some unique attributes. First, their ingestion does not lead to an exaggerated accumulation of tissue selenium, which both selenomethionine and Brazil nut may cause. Second, unlike selenite, they do not cause any perturbation in glutathione (an antioxidant) homeostasis. Third, they expressed good anticancer activity that was equal to, if not better than, that of selenite (Ip and Lisk 1994).

Garlic odor. Although the problem of onion and garlic breath was first investigated in 1935 (Haggard and Greenberg 1935), many folk remedies – such as strong coffee, honey, yogurt, milk, coffee beans, cloves, and, most commonly, parsley – have long been used (Sokolov 1975). Perhaps, however, there is excessive worry about garlic or onion on the breath. A recent study of male and female shoppers in Helsinki indicated that sweat and alcohol were thought to be the most annoying social odors and those of garlic and perfume or aftershave the least annoying (Rosin, Tuorila, and Uutela 1992).

Studies on the effect of garlic on breast milk have indicated that garlic ingestion significantly and consistently increases the intensity of the milk odor. It was found that infants were attached to the breast for longer periods of time and sucked more when the milk smelled of garlic. There was also a tendency for the infants to ingest more milk. However, if the mother ingested garlic pills regularly, there was no change in the infant's feeding behavior after its initial exposure (Mennella and Beauchamp 1991, 1993).

Leeks

History

As with onions and garlic, leek *(Allium porrum)* consumption is depicted in Egyptian tomb decorations of the Early Dynastic Period (c. 2925 B.C.–c. 2575 B.C.) (Jones and Mann 1963; Fenwick and Hanley 1985a). Leeks were also grown and widely used for cooking in Sumeria (southern Iraq) even earlier (Hanley and Fenwick 1985). In China, the fifth-century treatise on agriculture, *Ch'i-min-yao-shu* (Essential Arts for the People), by Chia Ssu-hsieh described the cultivation of *chiu* (Chinese leek, *Allium ramosum* L.) along the Red River valley, where it has doubtless been cultivated for many centuries (Li 1969).

Leeks were called *prason* in ancient Greece and *porrum* by the Romans. Pliny the Elder, the Roman naturalist, cited Aricia in central Italy as famous for its leeks, and the Emperor Nero (A.D. 37–68) reportedly ate them several days a month to clear his voice, which caused people to call him Porrophagus. The Romans introduced leeks to Britain, where they were widely cultivated by Saxon times (sixth century A.D.), and cottage vegetable plots were often referred to by the name "leac tun" (Hedrick 1972; Fenwick and Hanley 1985a).

Leeks were known in Europe throughout the Middle Ages and were believed – like onions and garlic – to be an erotic stimulant that increased sperm and stimulated desire, especially when prepared with honey, sesame, and almond (Mauron 1986).

In northern England, leek growing remains a serious and highly competitive business, with secrets of cultivation handed down from father to son. In addition, leeks have been the badge of Welshmen from time immemorial. Saint David (c. 495–589) is said to have suggested that the Welsh wear leeks in their hats to enable them to distinguish friend from foe in the heat of battle. Consequently, the leek is worn (and subsequently eaten) in Wales on St. David's Day (March 1) to celebrate the Welsh defeat of the Saxons in the year 633 (Hedrick 1972; Fenwick and Hanley 1985a).

Horticulture and Botany

The modern leek is not known in the wild. It probably originated in the Near East region around the eastern Mediterranean, where it was much eaten, and was distributed across Europe by the Romans (Traub 1968).

Cultivation. Although leek growing is popular in parts of Britain, commercial production of the plant is centered in France, Belgium, and the Netherlands, with France by far the most important grower (Hanley and Fenwick 1985). Production takes place mainly in Bouches-du-Rhône, Vaucluse, Haute Garonne, Ain, Ille et Vilaine, Manche, and especially in Nord and Loire-Atlantique.

Leeks grow well under most soil conditions but do best in deep loams and peat. Good drainage is essential, and the soil's Ph value should be near 7.0. Leeks can be sowed directly or grown in seedbeds and transplanted. Six varieties of leeks are grown in Britain to ensure year-round cultivation. Harvesting may be mechanical or by hand. A maximum yield of fresh weight and dry matter can be obtained after harvest in October or November (weeks 43 to 45), when nitrate content has decreased to a low and almost stable level (Kaack, Kjeldsen, and Mune 1993). Leeks are then trimmed, either in the field or at a packing station (Fenwick and Hanley 1985a). Leeks store well at 0° C (with 90 to 95 percent relative humidity) for up to 12 weeks (Vandenberg and Lentz 1974).

Nutrition

The Nutrition Data System of the University of Minnesota indicates that 100 g of leeks provides 32 kilocalories of energy, 1.83 g of protein, 0.19 g of fat, and 7.34 g of carbohydrate (Nutrition Coordinating Center 1994).

Approximately one-half cup of fresh leeks would give an 18- to 25-year-old male 9 percent of his RDA of calcium (72 mg), 14.8 percent of iron (1.48 mg), 31.3 percent of vitamin C (18.8 mg), and 32 percent of his folacin (64 mg). Leeks are high in potassium (276 mg/100 g), low in sodium (16 mg/100 g), and contain small amounts of copper, magnesium, phosphorus, selenium, and zinc. They have 38.42 mcg of vitamin A, 230.54 mcg of beta-carotene, and 0.46 mg of vitamin E (alpha-tocopherol 0.37 mg, beta-tocopherol 0.17 mg, gamma-tocopherol 0.17 mg, and delta-tocopherol 0.09 mg), as well as small amounts of thiamine, riboflavin, niacin, pantothenic acid, and vitamin B_6 (National Research Council 1989). All essential amino acids are present in leeks. Aspartic acid (0.17 g) and glutamic acid (0.38 g) are the most abundant, followed by arginine (0.13 g) and proline (0.12 g).

Chemistry

Nonflavor compounds. The flavonoids most often found in leeks have been quercetin, kaempferol, and their derivatives, usually mono- and diglycosides. These are generally found in higher concentrations in the epidermal layer of the leaves and protect the plant from ultraviolet radiation (Starke and Herrmann 1976b).

Leeks contain fructans, polymers of fructose usually having 3 to 12 fructose molecules. Fructose polymers of 12 molecules are the most common (Darbyshire and Henry 1981). Leeks also produce very long chain fatty acids (Agrawal, Lessire, and Stumpf 1984).

Chives

History

Chives *(Allium schoenoprasum)* originated in the north temperate zone. John Gerard (1545–1612), English botanist and barber-surgeon, included chives in his herbal, published in 1597. Described in 1683 as a pleasant sauce and food potherb, and listed as part of seedsmen's supplies in 1726, chives were losing favor in England by 1783. However, botanist E. Louis Sturtevant reported in the nineteenth century that Scottish families were still heavy chive consumers (Hedrick 1972).

Chives are cultivated for use in salads and soups, and many consider them an indispensable ingredient in omelets. They have been much used for flavoring in continental Europe, especially in Catholic countries. Chives were also included in an 1806 list of American esculents (Hedrick 1972).

Horticulture and Botany

Chives are the only one of the allium species native to both the Old World and the New (Simmonds 1976). Indeed, the plant's wild form occurs in Asia as well as in North America and Europe.

Chives flower in spring and summer, and bees are important for their fertilization (Nordestgaard 1983). The plants grow in dense clumps of narrow cylindrical leaves and taller hollow flower stems with globular heads. Their bulbs are elongated and only slightly swollen, but it is the leaves that are usually chopped and used as a garnish for other foods. The plant is mostly homegrown and is also used as an ornamental (Traub 1968).

Pathogens and Pests

As with onions, chives are subject to assault from downy mildew (*P. destructor* [Berk.] Casp.) and onion smut (*U. cepulae* Frost), as well as the bulb and stem nematode (*D. dispaci* [Kuhn] Filipjer).

Food Use and Nutrition

Chives are eaten fresh or dehydrated, the latter being the most common processed form today. The flavor of the chopped leaves remains stable for several months when deep-frozen or freeze-dried (Poulsen and Nielsen 1979).

As with the other alliums, the nutritional content of chives varies by variety, ecological conditions, and climate. One hundred grams of chives will generally provide about 30 kilocalories of energy, 3.27 g of protein, 0.73 g of fat, and 4.35 g of carbohydrate (Nutrition Coordinating Center 1994).

For a male between 18 and 25 years of age, approximately one-half cup of fresh chives delivers 11.5 percent of the RDA of calcium (92 mg), 16 percent of iron (1.6 mg), 12 percent of magnesium (42 mg), 43.4 percent of vitamin A (434.43 mcg RE), 96.8 percent of vitamin C (58.1 mg), and 52.5 percent of folacin (105 mg). Chives are high in potassium (296 mg) and low in sodium (3 mg). They contain small amounts of copper, phosphorus, and zinc. Chives have 2606.59 mcg of beta-carotene and 0.46 mg of vitamin E (alpha-tocopherol 0.37 mg, beta-tocopherol 0.17 mg, gamma-tocopherol 0.17 mg, and delta-tocopherol 0.09 mg) and small amounts of thiamine, riboflavin, niacin, pantothenic acid, and vitamin B_6 (National Research Council 1989).

Medicinal Use

Chives have some antibacterial effects (Huddleson et al. 1944). Extracts of onions and chives possess tuberculostatic activity against human, avian, and bovine strains. In fact, chives show rather more activity than onions and are only slightly less effective than streptomycin (Gupta and Viswanathan 1955). In addition, aqueous extracts of chives have exhibited significant activity against leukemia in mice (Caldes and Prescott 1973).

Shallots

History

Pliny the Elder, in his *Natural History,* mentioned the Ascalon onion (the shallot, *Allium ascalonicum*) as one of six types of onions known to the Greeks (Fenwick and Hanley 1985a). He wrote that it came from Ascalon in Syria, and Joseph Michaud's history of the Crusades affirmed this origin. Shallots were known in Spain, Italy, France, and Germany by 1554, had entered England from France by 1633, and were grown in American gardens by 1806 (Hedrick 1972).

Horticulture and Botany

Shallots were once viewed as a separate species, but botanists now consider them to be a variety of *A. cepa* L. They are cultivated ubiquitously (Hedrick 1972) but not extensively, save in the Netherlands and France (Fenwick and Hanley 1985a).

Food Use and Nutrition

Shallots can be dried in the field, weather permitting. They are employed as a seasoning in stews and soups but can also be used in the raw state, diced in salads, or sprinkled over steaks and chops. Shallots also make excellent pickles (Hedrick 1972).

As with the rest of the alliums, the nutritional content of shallots depends on variety, ecological conditions, and climate. According to the Nutrition Coordinating Center (1994), 100 g (3.53 ounces or 0.44 cup) of shallots yields 32 kilocalories of energy, 1.83 g of protein, 0.19 g of fat, and 7.34 g of carbohydrate.

One-half cup of fresh shallots provides a male between 18 and 25 years of age approximately 9 percent of the RDA of calcium (72 mg), 14.8 percent of iron (1.48 mg), 31.3 percent of vitamin C (18.8 mg), and 32 percent of folacin (64 mg) (National Research Council 1989). Shallots are high in potassium (276 mg) and low in sodium (16 mg). They contain small amounts of copper, magnesium, phosphorus, selenium, and zinc, and also have 38.42 mcg RE of vitamin A (230.54 mcg of beta-carotene) and 0.46 mg of vitamin E (alpha-tocopherol 0.37 mg, beta-tocopherol 0.17 mg, gamma-tocopherol 0.17 mg, and delta-tocopherol 0.09 mg), as well as small amounts of thiamine, riboflavin, niacin, pantothenic acid, and vitamin B_6.

Flavor Compounds

Shallots have the same flavor components as onions but generally contain more methyl, propyl, and (1-propenyl) di- and trisulfides (Dembele and Dubois 1973; Wu et al. 1982).

A study of the volatile oils from raw, baked, and deep-fried shallots identified sulfides, disulfides, trisulfides, thiophene derivatives, and oxygenated compounds. The oils from baked or fried shallots contain decreased amounts of alkyl propenyl disulfides and increased amounts of dimethyl thiophenes (Carson 1987).

II.C.3 Beans, Peas, and Lentils

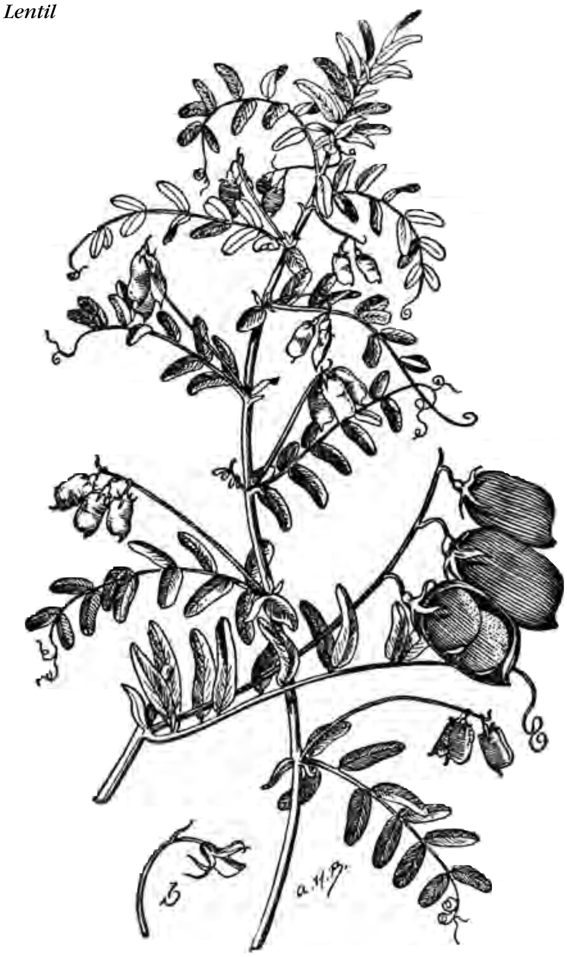
The Names

On Sunday, November 4, 1492, three weeks after his first landing in the New World, Christopher Columbus saw lands planted with "*faxones* and *fabas* very diverse and different from ours [those of Spain] and two days afterward, following the north coast of Cuba," he again found "land well cultivated with these *fexoes* and *habas* much unlike ours" (Hedrick 1931: 3).

In a transcription (Dunn and Kelley 1989: 132) from Columbus's diary, the Spanish phrase *faxones y favas* has been translated as "beans and kidney beans" (Morrison and Jane-Vigneras, cited by Dunn and Kelley 1989: 133). But considering what Columbus might have seen in the markets or kitchens of the fifteenth-century Iberian–Mediterranean world, *faxone* probably refers to the African–Asian cowpea *(Vigna unguiculata),* and *fava* surely means the fava (= *faba*), or broad bean *(Vicia faba),* long known in Europe and the Mediterranean–Asian world. Columbus's brief record presaged the long confusion and debate over the names and origins of some important food grain legumes. Had herbalists and botanical authors of the succeeding three centuries taken account of Columbus's recognition that these New World legumes were different from those of Europe, some of the confusion might have been avoided.

The beans, peas, and lentils (pulses, or food grain legumes) discussed in this chapter are legumes, treated in technical botanical literature as members of the very large family Fabaceae (= Leguminosae), subfamily Papilionoideae (having butterflylike flowers), although some taxonomists accord this group family status (Papilionaceae). The names of the species, however, are not changed by the differing positions taken by plant taxonomists on family nomenclature. The flowers of papilionaceous legumes have five petals consisting of one broad standard, two lateral wings, and two keel petals that clasp the 10 stamens and single ovary (which becomes the pod).

Lentil



The Latin and most frequently used English common names of the species of beans, peas, and lentils discussed in this chapter are enumerated in Table II.C.3.1, along with other species having similar names.

The European herbalists of the sixteenth century repeatedly attempted to reconcile their plant world with that of the ancients as represented by the fragmentary remains of the works of Theophrastus and Dioscorides. Their efforts, however, were destined to fail inasmuch as many of their subjects were novel plants newly introduced from the New World and from the reopened contact with Asia and coastal Africa. This nomenclatural dilemma is illustrated by an attempt to reconcile the name of a bean with the appropriate plant. J. P. Tournefort (1656–1708), a notable pre-Linnaean French botanist, sought to clarify the use of *boona* or *baiana* for the broad bean or fava by a well-known sixteenth-century herbalist:

> Dodonaeus [said Tournefort] called this kind of pulse "boona" in Latin, who [Dodonaeus] relying on a Germanism abuses his own language in order to appear learned but our Boona or Bean seem rather to be derived from the Italian word Baiana which Hermolaus says is the word used by those that sell new BEANS all over the state of Milan and along the Appenine mountains. . . . Garden beans are common and universal in Europe and are a great supply in dearth of Provisions in the spring and whole summer season. . . . The ancients and Dodonaeus believed that beans are windy and the greener the more so. (Tournefort 1730: 386)

Tournefort then disagreed on the suitability of beans in the diet and said that he would leave the hard dry beans to "the laboring men who can better digest them, but [even] those of delicate constitution and sedentary life digest green beans well enough if they eat them with butter and pepper [especially if they will] be at the pain to take off their skins" (Tournefort 1730: 386). Inasmuch as American *Phaseolus* beans had entered Europe by his lifetime, one could wonder whether Tournefort meant *Phaseolus* or *Vicia* "beans." However, his remark concerning the removal of "skins [seed coats]" should end any doubt.

Table II.C.3.1. *Beans, peas, and lentils*

Latin names	English common names
Lens culinaris Meddick.	lentil
Phaseolus acutifolius (A. Gray)	tepary
p. coccineus L. (syn. *P. multiflorus* Willd.)	scarlet runner, Windsor bean
P. lunatus L.	lima, butter, sieva bean
P. polyanthus (Greenm.)	polyanthus bean
P. vulgaris L.	common or kidney bean, haricot
Pisum sativum L.	pea, garden pea
Vicia faba L.	broad bean, horse bean, fava, haba
Other taxa mentioned in text	
Cicer arietinum L.	chickpea, bengal gram
Lablab purpureus (L.) Sweet (syn. *Dolichos lablab* L.)	hyacinth bean
Lathyrus sativus L.	chickling vetch, Khesari dhal
Lens culinaris ssp. *macrosperma* (Baumb) Barulina	large-seeded lentil
L. culinaris ssp. *microsperma* Barulina	small-seeded lentil
L. ervoides (Brign.) Grande	
L. nigricans (M. Bieb.) Godr.,	
L. orientalis (Bioss.) M. Popov	wild lentil
Vicia ervilia Willd.	erse, French lentil
V. sinensis (L.) Savi ex Hassk.	cowpea, black-eyed pea
Vigna unguiculata (L.) Walp. ssp. *unguiculata* (syn. *V. Sesquipeolis [L.] Fruhw.*)	

Sources: Adapted from Aykroyd and Doughty (1964), pp. 15–18, Purseglove (1968), Smartt (1990), Ladizinsky (1993), and other sources.

"Skins" refers to the seed coats. Where the broad bean and American *Phaseolus* beans are concerned, only the broad bean has its skin or testa customarily removed – probably to eliminate substances that are toxic for individuals having an inherited enzyme (glucose-6-phosphate dehydrogenase) deficiency. Even in a contemporary and remote Quechua-speaking community, located in the southern Andes in the vicinity of Cuzco at an altitude of 3,000 to 5,000 meters, which is unfavorable for *Phaseolus* cultivation, cooked *Vicia faba* seeds are always peeled before eating (Franquemont et al. 1990: 83). Because this enzyme-deficiency sensitivity to fava bean components evolved in human populations native to certain malarial regions of Eurasia and Africa (Strickberger 1985: 738), the custom in the Andes was probably introduced along with the fava bean.

Tournefort further assumed the responsibility for ending the quandary of post-Columbian botanists concerning the identity of the fava. He recognized that there was

> . . . much controversy among the botanists as to whether our bean be the bean of the ancients . . . that of the ancients was small and round [according to] Theophrastus, Dioscorides and others. But it is strange that a pulse so common should have come close to disuse and been replaced without anybody's knowing anything of this matter. (Tournefort 1730: 386)

The reason for the difference (and confusion), he went on, could be that "their faba was not arrived at the bigness that our Garden Bean now is." But however intriguing the evolutionary explanation, the writers of the classical period, whom he cites, may have been referring to the African–Asian cowpea, *Vigna unguiculata,* rather than one of the small-seeded races of the fava bean.

Contemporary linguistic sources (*Webster's Third New International Dictionary* 1971) derive the familiar English word "bean" from a root common to Old English, Old High German, and Old Norse that apparently once referred to the fava or faba bean, a staple of the Romans. Over the centuries, however, the word has grown to encompass seeds of other plants, including a multitude of legumes besides the fava, most of which belong to other genera – a terminological tangle that botany attempts to avoid through the use of scientific names (Table II.C.3.1).

The distinct identities of these two groups of food crops, favas and *Phaseolus* beans, were being established as seventeenth- and eighteenth-century botany ceased the attempt to reconcile the known species of that period with the fragmentary records of the classical authors. These advances were only the beginning of the solutions to the geographic, temporal, and cultural problems surrounding the origins of these foods.

The Search for Geographic Origins

The origins of most domesticated plants, meaning the time span, the wild relatives, and the conditions (both natural and human-influenced) under which divergences from wild ancestral stock took place, are remote in time and are matters of continued botanical and genetic inquiry.

For Europe and the Mediterranean Basin, sixteenth-century European herbalists turned for information to tradition, the observations of travelers, and the surviving books of classical authors. Linnaeus assimilated the writings of the herbalists and added his contemporary experience with eighteenth-century introductions and collections. Alphonse de Candolle (1964: v) in 1855, and especially in the 1886 edition of his *Origin of Cultivated Plants,* brought to the attention of botanists the utility of archaeological findings for supplementing plant morphology and taxonomy in adducing evidence for the geography of domestication.

In the twentieth century, N. I. Vavilov, following Candolle's pioneering work in geographical botany, embarked on his global, decades-long projects on the origin and genetic variation of cultivated plants. In 1926, Vavilov (1992: 22–7) organized a comparative chart of the morphology of cultivated species of the papilionaceous legumes and presented the rationale for botanical–genetic determination of the centers of origin of these and other crop plants. His geographic centers of origin for crop plants – which have been highly influential and much discussed in the literature of crop plant geography – included eight major and several minor centers (Vavilov 1992: 324–53). The lentil, the pea, and the broad bean were all traced to the Inner-Asiatic Center: northwestern India, Afghanistan, Tadzhikistan, Uzbekistan, and western China. The lentil and pea were also assigned by Vavilov to the Asia Minor Center (the Middle East, Iran, and Turkmenistan). The American common bean and lima bean were both assigned primary centers in the South Mexican–Central American Center, and the lesser-known species, scarlet runner beans and teparies, were also located there. The origin of the little-known polyanthus bean *(Phaseolus polyanthus)* has been documented in the same area (Schmit and Debouck 1991).

New World Beans: *Phaseolus*

The Pathway of Domestication in Phaseolus

The species of domesticated *Phaseolus* beans have shown parallel changes in structure and physiology and share some of these characteristics with the Old World grain legumes. J. Smartt (1990: 111) summarized his own findings and those of others on the nature of evolutionary changes in the *Phaseolus* cultigens. These are gigantism (increased size of seed and other plant parts); suppression of seed dispersal mechanisms (decreased tendency of pods to twist and discharge seeds); changed growth form (especially the loss of rampant vining); loss of seed dormancy; and other physiological and biochemical changes. The genetic bases for seed size, dispersal mechanisms, and growth form are partly understood, and some are even observable in archaeological specimens, in which wild *Phaseolus* beans can be readily distinguished from domesticates by both seed size and nondehiscent pod structure.

The common bean. It is clear in the writings of sixteenth-century herbalists, and later in the works of Linnaeus and Candolle, that the original home of the common bean was unknown to them. It was archaeological excavation on the arid coast of Peru in the last quarter of the nineteenth century that convinced Candolle (1964: 341–2) that *Phaseolus vulgaris* and *Phaseolus lunatus* had been cultivated in the Americas since pre-Columbian times.

At the time of contact with Europeans, varieties of the common bean were grown by Native Americans as far south as Chile and Argentina, and as far north as the valleys of the St. Lawrence and upper Missouri rivers. Edward Lewis Sturtevant (Hedrick 1972: 424) has noted that beans were observed to be in cultivation among Florida Indians by at least three explorers from 1528 to 1562, including Hernando de Soto (in 1539), who said that "the granaries were full of maes and small beans." The Natchez on the lower Mississippi grew beans as a "subsidiary crop" (Spencer et al. 1965: 410), and there is a 1917 description of traditional Hidatsa–Mandan cultivation of beans in hills between the rows of maize or occasionally "planted separately" (Spencer et al. 1965: 343). This observation suggests the planting of erect or semierect beans. Such beans are intermediate between strong climbers and truly dwarf nonclimbing beans. In California, outside of the lower Colorado River drainage where the Mohave grew tepary beans (as did other Yumans, along with maize, cucurbits, and other crops), bean agriculture began with the introduction of Mexican and European crops when the earliest Spanish missions were established. G. W. Hendry (1934) found a bit of seed coat of the common bean cultivar 'Red Mexican', or 'Pink', in a Spanish adobe brick dated 1791 at Soledad.

R. L. Beals (1932) mapped pre-1750 bean cultivation in northern Mexico and the adjacent southwestern and Gulf Coast United States using historical documents and reports by Spanish explorers. Bean distribution coincided with maize cultivation, extending from the Colorado River east to include the Rio Grande Pueblos, Zuni, and Hopi. The area of the eastern Apache in the Pecos River drainage, and of the Comanche, was nonagricultural. Beans were grown from eastern Texas, beginning with the Waco and the Kichai, eastward to the Atlantic.

Southwestern bean horticulture derives from Mexico. P. A. Gepts's (1988: 230) mapping of bean dispersal routes by means of the beans' protein structure corroborates this generally accepted view. Where water is the limiting factor in growth and production, as on the Hopi mesas, varieties having the dwarf or bush habit are planted. Where surface water is available or can be supplied, vining beans are planted with corn or, if planted separately, are provided with poles to climb upon. Except for the pinto or *garapata* group, the common beans collected during the years 1910 to 1912 by G. F. Freeman (1912) among the Papago and Pima do not appear in the archaeology of the southwestern United States. Instead, these beans represent introductions from the Mexican Central Highlands and may well have arrived during the Spanish colonial period.

According to E. F. Castetter and W. H. Bell (1942), the Papago planted teparies in July and harvested in October; the Pima planted twice, when the mesquite leafed out (late March to mid-April) and after the Saguaro harvest (July). The first planting was harvested in June, the second in October. The harvest of teparies and common beans was women's work. The plants were pulled, dried, and threshed on a clean, hard-packed soil floor in the open, in the field, or near the house. Different varieties were planted, harvested, and threshed separately. After threshing they were sealed in baskets or pots for protection from pests. Castetter and Bell (1942) and Freeman (1912) reported only bush beans in which the "vines" (sprawling plants) are grown separately from corn.

Vavilov (1992) and C. B. Heiser (1965) speculated on multiple American origins for the common bean, and substantial evidence has been adduced to show that common beans were domesticated independently in at least two distinct areas: Mesoamerica and Andean America (Kaplan 1981; Delgado Salinas 1988; Gepts 1988).

Lima beans. The lima and sieva beans were recognized by Linnaeus to belong to the same species, which he called *P. lunatus* to describe the "lunar" shape of the seeds of some varieties. The small-seeded or sieva types are natives of Mexico and Central America. These are distinct from the large-seeded South American lima beans, but can be crossed with them, and for this reason are considered to be of the same species. The sievas appear in the archaeological records of Mexico about 1,200 years ago, but do not occur in the known records of Andean archaeology. The large limas of South America, conversely, do not appear in the Mesoamerican or North American record. Seeds of the South American group have been found in Guitarrero Cave, the same Andean cave as the earliest common beans of South America, and have been 14-Carbon dated at the National Science Foundation, University of Arizona Accelerator Facility, to approximately 3,500 years ago (Kaplan 1995). The archaeological evidence of geographic separation coincides with contemporary observations of the distribution of both the wild and cultivated types. It seems clear that the two groups were domesticated independently. Both vining and bush forms are known, but the vining forms predominate in indigenous horticulture.

On the desert north coast of Peru, remains of the large-seeded lima group, dating to about 5,600 years ago (the preceramic period) (Kaplan 1995), were well preserved by the arid conditions and were so abundant that they must have constituted a major part of the diet. Ancient Peruvians even included depictions of beans in their imaginative painted ceramics and woven textiles. Painted pottery from the Mochica culture (A.D. 100–800) depicts running messengers, each carrying a small bag decorated with pictures of lima beans *(pallares).* Rafael Larco Hoyle (1943) concluded that the lima beans, painted with parallel lines, broken lines, points, and circles, were ideograms. Some of the beans that Larco Hoyle believed to be painted were certainly renderings of naturally variegated seed coats. Other depictions show stick-limbed bean warriors rushing to the attack. Textiles from Paracas, an earlier coastal site, are rich in bean depictions.

Scarlet runner beans. The cultivated scarlet runner bean (*Phaseolus coccineus* L., for the scarlet flowers) is not known in the archaeological record north of Durango, Mexico, where it was grown about 1,300 years ago (Brooks et al. 1962). It has undoubtedly been cultivated for a much longer period in the cool central highlands of Mexico and Guatemala, but in that region, archaeological specimens securely dated and identified as older than a few hundred years are wanting. Runner beans, both purple-seeded and white-seeded, have been collected among the Hopi in historic times, especially by Alfred Whiting during the 1930s.

Tepary beans. The tepary is one of the two cultivated species not to have been named by Linnaeus. The wild type was called *Phaseolus acutifolius* by the nineteenth-century Harvard botanist Asa Gray. However, it was not until the early years of the twentieth century that the cultivated types were recognized by the Arizona botanist, Freeman, to belong to Gray's species rather than simply being varieties of the common bean.

Teparies, now little-known as commercial beans, were cultivated in central Mexico 2,300 years ago (Kaplan 1994), and in Arizona, teparies were being grown 1,000 to 1,200 years ago (Kaplan 1967). Despite their antiquity and ancient distribution, teparies have been absent from village agriculture in historic times, except in the Sonoran Desert biome of northwestern Mexico, Arizona, and New Mexico, and in the area around Tapachula in the Mexican state of Chiapas and in adjacent Guatemala. They are grown and eaten by the Pima, Papago, and peoples of the lower Colorado River and by some "Anglo" enthusiasts for dryland-adapted crops. Because of their drought tolerance, they have been tested in many arid regions of the world.

Polyanthus beans. A fifth cultivated bean species, *P. polyanthus,* has long been known to be distinct from the other, better-known species, but only recently have its identity and distribution been documented (Schmit and Debouck 1991). To the best of my knowledge this bean of high elevations in Mexico and Central America has never entered into Old World cultivation.

The five *Phaseolus* beans are distinct species. They have different botanical names, applied by plant systematists on the basis of their structural differences. They have the same number of chromosomes ($2n = 22$) but do not freely hybridize. However, the domesticates do hybridize with some wild-growing populations that are regarded as their ancestral relatives.

The Antiquity of Phaseolus Beans: New Evidence

Uncovering the botanical and geographic origins of domesticated crops includes the search for their temporal origins. Candolle (1964), as noted previously, brought to the attention of plant scientists the utility of archaeological evidence in the quest for the temporal as well as the geographic origins of crop plants. The presence of *Phaseolus* beans on the arid coast of Peru in pre-Conquest graves of indigenous peoples did not indicate a specific calendar date for the remains, but it was convincing evidence that *Phaseolus* beans were present in the Americas before contact with European cultures. With the development of radiometric dating by the middle of the twentieth century, it became possible to determine the age of archaeological organic materials with significant precision. However, many of the published dates for the earliest crop plant remains, including beans (Kaplan 1981), are now being questioned because the 14-Carbon determinations of age are "contextual dates," meaning they are based on organic materials in the same strata with the bean remains but not on the beans themselves (Kaplan 1994).

Because of the tendency of small objects, like seeds, to move downward in archaeological contexts, some of the dates now in the literature are too early. The development of 14-Carbon dating by Atomic Mass Spectrometry (AMS), which measures very small samples, has allowed the dating of single bean seeds or pods, and in some instances has produced dates that disagree with the contextual dates. For example, a single bean-pod found in Coxcatlan Cave in the Tehuacan valley, in a content 6,000 to 7,000 years old, was AMS-dated to only 2,285 ±60 years ago (Kaplan 1967, 1994). An early date for beans in South America comes from Guitarrero Cave in the Peruvian Andes, where radiocarbon dates of plant debris are as old as 8,000 years (Kaplan, Lynch, and Smith 1973; Lynch et al. 1985). But the AMS 14-Carbon date for one seed embedded in this debris is 2,430 ±60 years old (Kaplan 1994). Disagreements over the accuracy of AMS dates (unpublished data) versus contextual 14-Carbon dates are being aired, and the debate will continue. However, an AMS date from New England (Bendremer, Kellogg, and Largy 1991) supports a contextual 14-Carbon date, which suggests the entry of common beans into northeastern North America (Ohio) about 1,000 years ago (Kaplan 1970). In the southwestern United States, AMS dates (Wills 1988: 128) of beans from a New Mexico cave agree with contextual dates (Kaplan 1981).

The wild types of all *Phaseolus* bean species are vining types, as the earliest domesticates must also have been; the dwarf-growing types came later. The earliest evidence now available for the presence of the dwarf, or bush, growth habit comes from an accelerator radiocarbon date of 1285 ±55 years ago for bean-plant remains from an archaeological cave site in the northeastern Mexican state of Tamaulipas. The vining or pole beans of each species were planted with corn so that they could depend on the stalks for support. The sprawling and dwarf types could be grown independent of support.

Tracing Bean Migrations

Molecular evidence. Phaseolin is the principal storage protein of *Phaseolus* bean seeds. Gepts (1988) has used the variation in phaseolin structure to trace the dispersal of contemporary common bean cultivars within the Americas and in the Old World. He has shown that the majority of the present-day cultivars of Western Europe, the Iberian Peninsula, Malawian Africa, and the northeastern United States originated in the Andes. The 'C' phaseolin type is found in highest frequency in the Americas in Chile and in the Iberian Peninsula among those Old World regions sampled.

Gepts has applied the phaseolin-structure method to questions of dispersal within the Americas, such as that of the traditional beans of the northeastern United States. There, a majority of the cultivated bean varieties of historic times are of the 'T' phaseolin type, which is the type that is most frequent in Western Europe and in the Andes south of Colombia. 'T' phaseolin is common elsewhere in South America but not in Mesoamerica. Indeed, in Mesoamerica and the adjacent southwestern United States, 'T' types make up only 8 percent and 2 percent, respectively, of the cultivated bean varieties. The archaeological record of crop plants in the northeastern United States is limited because of poor conditions for preservation (humid soils and no sheltered cave deposits), but those beans that have been found, although carbonized, are recognizable as a southwestern United States type (Kaplan 1970). This common bean type, which was dispersed from northwestern Arizona along with eight-rowed corn, must have been of the 'S' phaseolin type, which Gepts has found characteristic of 98 percent of contemporary southwestern common beans. It seems clear that historic-period northeastern bean cultivars are primarily South American, which could have reached the northeastern United States by way of sailing ships, directly from Peruvian and Chilean ports during the late eighteenth and early nineteenth centuries, or from England and France along with immigrants, or through seed importation.

In the foregoing, we see a dispersal pattern that was probably common in much of the New World, and especially in semiarid places in Mesoamerica and the greater Southwest. In dryland prehistoric sites, organic remains are well preserved in the archaeological record, and we see that prehistoric bean cultivars have often been eliminated, or reduced in frequency, by better-adapted (biologically, culturally, economically), introduced cultivars. Such a pattern suggests that Columbus's introduction of beans to Europe from the Caribbean Islands was soon augmented by later introductions from Andean agriculture bearing the 'C' phaseolin type.

Historical evidence. Success in tracing the dispersion of beans from their regions of origin rests to some extent on historical records. But such records are likely to be strongly biased. One of the richest sources of evidence is the body of data available from seed catalogs, magazines, and newspapers devoted to agriculture and horticulture. Such publications, however, are unevenly representative of the larger dispersion picture. The United States, parts of Latin America, and Western Europe may be better represented in this respect than are some other parts of the world. Specialized libraries and archives have preserved some of this published material in the United States for about 200 years. In the United States, the earliest sources for named varieties of garden plants are leaflets or advertisements for seeds newly arrived from England. In Portsmouth, New Hampshire, over a period from 1750 to 1784, 32 varieties of beans, including common beans, both vining and erect types, scarlet runner beans, possibly small-seeded limas, and fava beans, were listed for sale in the *New Hampshire Gazette* (documents courtesy of Strawbery Banke Museum, Portsmouth, N.H.). Earlier still, but less informative, are lists prepared for the guidance of colonists heading for English North America in the seventeenth century, who were advised to supply themselves with peas and (broad) beans, in addition to other vegetable seeds, garden tools, and weapons. We do not begin to detect evidence for the ingress of *Phaseolus* bean cultivars from England and France to the United States until the early nineteenth century.

The Old World: Broad Beans, Peas, and Lentils

As in much of the Americas, the Mediterranean world's combination of cereal grain and food grain legumes has been the foundation for both agriculture and the diet of settled farming communities.

William J. Darby and colleagues (Darby, Ghalioungui, and Grivetti 1977), in tracing food use in Pharaonic Egypt, found papyrus texts and archaeological remains to contain much evidence of food grain legumes in the daily life of the kingdom. Rameses II spoke of barley and beans in immense quantities; Rameses III offered to the Nile god 11,998 jars of "shelled beans." The term "'bean meal' [medicinal bean meal], so commonly encountered in the medical papyri," could apply to *Vicia faba,* to other legumes, or to the "Egyptian bean" (*Nelumbo nucifera* Gaertner, the sacred lotus), all of which have been found in tombs (Darby et al. 1977: II 683).

Fava beans were avoided by priests and others, but the reasons are not clear. The avoidance of favas by Pythagoras, who was trained by Egyptians, is well known, and it may have been that he shared with them a belief that beans "were produced from the same matter as man" (Darby et al. 1977: II 683). Other ancient writers gave different reasons for the taboo, such as self-denial by priests of a variety of foods, including lentils. And more recently, as already mentioned, favism, a genetically determined sensitivity (red blood cells deficient in glucose-6-phosphate dehydrogenase) to chemical components of fava beans, has suggested still another explanation for the avoidance of this food (Sokolov 1984).

Domestication

Structural change under domestication in fava beans, peas, and lentils is much like that in the *Phaseolus* beans, but there are important differences in what can be determined from archaeological samples. Pods of pulses in Middle Eastern sites are seldom found; hence, the loss of pod dehiscence has not been traced in archaeological materials from that region as it has in the Americas (Kaplan and MacNeish 1960; Kaplan 1986). In an effort to find good characters for distinguishing between wild and domesticated types in Middle East pulses, A. Butler (1989) has studied their seed coat structure but has found that the loss of seed dormancy (the impermeability of seed coats to water, which separates the wild types from the domesticates) cannot readily be detected by examination of the seed coats with scanning electron microscopy, or, at best, there is no single structural change that accounts for the difference between permeability and impermeability. Butler (1989: 402) notes that the surface of testa has been used to distinguish wild from cultivated taxa in Vicieae. With the exception of testa thickness in seeds of *Pisum,* no characters recorded in the seed coat of Vicieae can be associated directly with the presence or absence of hard seed coats. Evidence from seed anatomy of dormancy, and therefore of wildness, is lacking in Vicieae.

The origins and domestication of broad beans, peas, and lentils have been the focus of extensive research by plant geneticists and by archaeologists seeking to understand the foundations of agriculture in the Near East. D. Zohary (1989a: 358-63) has presented both genetic and archaeological evidence (not uncontested) for the simultaneous, or near simultaneous, domestication in the Near East of emmer wheat *(Triticum turgidum* ssp. *dicoccum),* barley *(Hordeum vulgare),* and einkorn wheat *(Triticum monococcum),* "hand in hand with the introduction into cultivation of five companion plants": pea *(Pisum sativum),* lentil *(Lens culinaris),* chickpea *(Cicer arietinum),* bitter vetch *(Vicia ervilia),* and flax *(Linum usitatissimum). V. faba* may also have been among these earliest domesticates (Kislev 1985).

Lentil

Lens culinaris (Lens esculenta), the cultivated lentil, is a widely grown species in a small genus. Archaeological evidence shows that it or its relatives were gathered by 13,000 to 9,500 years ago in Greece (Hansen 1992) and by 10,000 to 9,500 years ago in the Near East (Zohary and Hopf 1988). Candolle (1964) in 1885 wrote of its presence in the Bronze Age sites (the so-called Swiss Lake dwellings) in Switzerland. Lentil cultivation, by historic times, was important and well established in the Near East, North Africa, France, and Spain (Hedrick 1972), and had been introduced into most of the subtropical and warm temperate regions of the known world (Duke 1981: 111). With a production of about 38 percent of the world's lentils and little export (Singh and Singh 1992), the Indian subcontinent – a region in which food grain legumes are an especially important source of protein in the population's largely vegetarian diet – has made this crop one of its most important dietary pulses. Traditionally, two subspecies are recognized on the basis of seed size: *L. culinaris* ssp. *microsperma,* which are small-seeded, and *L. culinaris* ssp. *macrosperma,* which are large-seeded. The large-seeded form is grown in the Mediterranean Basin, in Africa, and in Asia Minor. The small-seeded form is grown in western and southwestern Asia, especially India (Duke 1981: 110-13).

According to G. Ladizinsky (1989: 377, 380) the genus *Lens* comprises *L. culinaris* and four wild species: *Lens nigricans, Lens ervoides, Lens odemensis,* and *Lens orientalis.* The same author, however, notes that the genus may be reclassified to reflect the genetic relationships of the species, thus: *L. culinaris* ssp. *odemensis,* ssp. *orientalis,* ssp. *culinaris; L. nigricans* ssp. *ervoides,* ssp. *nigricans.* Many populations of ssp. *orientalis* and *odemensis* are sufficiently close to ssp. *culinaris* to be used for breeding purposes. However, the chromosome structure within these subspecies indicates that the cultivated lentils evolved from the principal cytogenetic stock of ssp. *orientalis.* Because this cytogenetic stock ranges from Turkey to Uzbekistan (Ladizinsky et al. 1984), there is little evidence of where in this vast region domestication might have first occurred.

Lentil domestication. Ladizinsky (1987) has maintained that the gathering of wild lentils, and perhaps other grain legumes, prior to their cultivation could have resulted in reduced or lost seed dormancy, a factor of primary importance in the domestication of legumes. As an operational definition of cultivation, Ladizinsky accepted the proposal of Jack R. Harlan, who emphasized human activities designed to manage the productivity of crops and gathered plants. As part of the gathering or foraging process, such management could lead to changes in genetic structure and morphology of wild plants.

High rates of seed dormancy observed by Ladizinsky in wild *L. orientalis* populations demonstrated that they are ill-adapted to cultivation. Dormancy, a single-gene recessive trait, is absent from most of the lineages of domesticated *L. culinaris.* Nondormancy is determined by a single dominant allele. A loss of seed dormancy in lentil populations resulting from gathering practices, Ladizinsky (1979, 1987, 1993) has argued, is the result of establishing this mutant dominant allele in small populations where most of the lentil seeds produced are removed by human gathering. A patchy distribution of small populations of annual legume plants, low population density, and intensive gathering would be, under the conditions he defines, advantageous for the increase of the seed-dormancy-free trait. He has concluded that this process would have taken place in wild, noncultivated lentil (and probably in wild pea and chickpea) populations, and would have predisposed these populations to domestication. This, he maintained, was an evolutionary pathway different from that of the cereal grains for which dormancy of seeds is not a barrier to domestication.

Ladizinsky's views have been disputed by Zohary (1989b) and by M. A. Blumler (1991), who both criticized Ladizinsky's assumptions and conclusions. Blumler investigated Ladizinsky's mathematical model for the loss of dormancy in lentils and concluded that fixation of alleles for nondormancy, as a result of intensive human gathering, did not depend upon gathering at all. He further concluded that Ladizinsky's model would predict loss of dormancy under any circumstances and therefore was not tenable as a hypothesis for preagricultural domestication. He went on to propose that lentils, and possibly other legumes that were gathered and brought to camps, might inadvertently have been introduced to campground soils, but that the poorly competitive introductions would have had to be encouraged (cultivated) in order to survive. Blumler thus contested Ladizinsky's proposal that legumes could have been domesticated prior to actual cultivation and agreed with Zohary that the pathways of domestication in cereals and legumes were similar, and that legume cultivation followed upon the beginning of cereal cultivation.

As noted earlier in this chapter, the virtual absence of grain legume pods from archaeological sites in the Near East contrasts with the record of *Phaseolus* in the Americas. This circumstance makes it difficult to judge the merit of Ladizinsky's view that the forceful dissemination of seeds following pod dehiscence – a process resulting in the loss of much of a valuable food resource – can be circumvented by pulling whole plants. This would be one sort of gathering technique that could be considered predomesticative management. Accordingly, Ladizinsky placed a low value on the loss of pod dehiscence, or shattering in legumes, while agreeing with most of those concerned that the loss of shattering in cereal grains is of high value in the process of domestication.

Zohary, in response (1989b), accorded the suppression of the wild type of seed dispersal in grain legumes equal weight with the parallel process in the cereal grains. In so doing, he reinforced the argument that domestication in the Near Eastern cereal grains and grain legumes were similar processes. These provocative models for the transition of legumes, and other economic plants, from the wild to the domesticated state provide the basis for both field and theoretical tests. As more evidence is gathered, these theories will be revised repeatedly.

Because archaeological legume pods are seldom found among the plant remains of early Near Eastern societies, dehiscence versus nondehiscence of pods cannot be determined as it has been from New World bean remains. The appearance of seed nondormancy as a marker of the domesticated legume has not been made on the basis of archaeological materials for reasons noted previously in connection with Butler's study of seed coat structure. The archaeological record, however, does reveal changes in legume seed size in the Near East, such as small-seeded (diameter 2.5 to 3.0 millimeters) forms of lentil in early (seventh millennium B.C.) aceramic farming villages. By 5500 to 5000 B.C., lentils of 4.2 millimeters in diameter were present in the Deh Luran Valley of Iran, as reported by Hans Helbaeck (cited by Zohary and Hopf 1988: 89). Zohary and M. Hopf regarded the contrast in size between lentils of the early farming villages and those of 1,500 to 2,000 years later as a change under domestication.

Lentils spread into Europe with the extension of agriculture from the Near East in the sixth millennium B.C., where records of this crop and other legumes during the Bronze Age are less abundant than they are in the earlier Neolithic and later Iron Ages (Zohary and Hopf 1988: 87–9). Only their difference in size from the wild types *(L. orientalis* or *L. nigricans)* gives evidence for the development of domesticated lentils, which probably occurred in the Near East (Zohary and Hopf 1988: 91–2). These larger lentils appeared in the Near East as late as the end of the sixth millennium B.C., about 1,500 years after the establishment of wheat and barley cultivation (Zohary and Hopf 1988: 91). Although the archaeological and morphological evidence do not disclose the place of origin of the lentil, it is in the Near East where it occurs early in the large-seeded form and where *L. orientalis* is to be found. The lentil, however, is not mentioned as a food crop by F. J. Simoons (1991) in his comprehensive work on food in China.

Pea

Ever a source of confusion for readers of crop plant history and ethnobotany, common names often serve less to identify than to confound. "Pea" *(P. sativum),* as well as "bean," illustrates this problem. A name with Latin and Greek origins, "pea," in English, was formed from "pease," which took on the meaning of a plural; the "-se" was dropped by A.D. 1600 and the current form of the word was established (Oxford English Dictionary 1971). Pea is used combined with descriptives to form the names of numerous plants. In the context of this discussion of food grain legume origins, the important distinction is that between *P. sativum* and the grass pea or chickling pea (*Lathyrus sativus* L.), and the cowpea, black-eye pea, or black-eye bean *Vigna unguiculata.*

The grass pea is a minor crop in the Mediterranean Basin, North Africa, the Middle East, and India, and has been documented archaeologically in parts of this broad region since Neolithic times (Zohary and Hopf 1988: 109–10). In India, it is a weedy growth in cereal grain fields and is the cheapest pulse available (Purseglove 1968: 278). During times of famine, it has been consumed in significant amounts even though its consumption has caused a paralysis of the limb joints (Aykroyd and Doughty 1964).

The cowpea, an important crop in the tropics and subtropics, especially in Africa (Purseglove 1968: 322) and Southeast Asia (Herklots 1972: 261), appeared in the Mediterranean Basin in classical times (Zohary and Hopf 1988: 84). A plant mentioned in Sumerian records about 2350 B.C., under the name of *lu-ub-sar* (Arabic *lobia*), may have been a reference to the cowpea (Herklots 1972: 261).

Wild peas include *Pisum fulvum, Pisum elatius (P. sativum* ssp. *elatius),* and *Pisum humile (P. sativum* ssp. *humile, = Pisum syriacum).* Hybrids between *P. sativum* and *P. elatius* or *P. humile* are usually fertile, whereas hybrids between the cultivated pea and *P. fulvum* are fertile only when *P. fulvum* is the pollen parent (Ladizinsky 1989: 374–7). Zohary (1989a: 363–4) reports that similarities in chromosome structure between cultivated peas and *P. humile* populations in Turkey and the Golan Heights point to populations of *humile* having a particular chromosomal configuration (a reciprocal translocation) as the "direct" ancestral stock of the cultivated peas.

Peas were present in the early Neolithic preceramic farming villages (7500 to 6000 B.C.) of the Near East, and in large amounts with cultivated wheats and barleys by 5850 to 5600 B.C. They appear to have been associated with the spread of Neolithic agriculture into Europe, again together with wheat and barley (Zohary and Hopf 1988: 96–8). In central Germany, carbonized pea seeds with intact seed coats have been found dating from 4400 to 4200 B.C., and these show the smooth surface characteristic of the domestic crop. In Eastern Europe and Switzerland, pea remains have been found in late Neolithic or Bronze Age sites (Zohary and Hopf 1988: 97–8).

The date at which the pea entered China is not known, but along with the broad bean, it was called *hu-tou* or "Persian bean," which suggests an origin by way of the Silk Road in historic times (Simoons 1991: 74–5).

Vicia faba

Ladizinsky (1975) has investigated the genetic relationships among the broad bean and its wild relatives in the section *Faba* of the genus *Vicia.* He concluded that none of the populations of wild species, *Vicia narbonensis, Vicia galilaea,* or *Vicia haeniscyamus,* collected in Israel, can be considered the ancestor of the fava bean. Differences in the crossability, chromosome form, and chromosome number separate the broad bean from these relatives, as do differences in ranges of seed size, presence of tendrils, and epidermal hairs on the pods. Ladizinsky was careful to note that these characters may have evolved under domestication, but given the absence of evidence for derivation of the fava bean from its known relatives, he concluded that the place of origin of the broad bean could not have been in the Middle East.

Ladizinsky further drew attention to what he regarded as a paucity of broad bean remains only "circumstantial[ly]" identified in Neolithic sites of the Middle East and was led by these lines of evidence to conclude that the origin of *V. faba* had to be outside of this region. He further speculated that the occurrence of a self-pollinating wild form of the species in Afghanistan and areas adjacent might be the region in which the now cross-pollinating broad bean originated. Zohary (1977), however, interpreted the archaeological record quite differently, asserting that the distribution pattern of archaeological broad bean remains points to its domestication by the fourth or fifth millennium B.C. in the Mediterranean Basin.

The dates for the introduction of broad beans into China are not secure – perhaps the second century B.C. or later – but it has become an important crop in "many mountainous, remote or rainy parts of China at the present time especially in western China" (E. N. Anderson, cited by Simoons 1991: 75). The earliest introduction of broad beans into North America appears to have taken place in the early seventeenth century when Captain Bartholomew Gosnold, who explored the coast of New England, planted them on the Elizabeth Islands off the south shore of Massachusetts (Hedrick 1972: 594). Less than 30 years later, records of the provisioning and outfitting of the supply ship for New Plymouth list "benes" (and "pease") along with other seeds to be sent to the Massachusetts colony (Pulsifer 1861: 24).

Conclusion

The domestication of food grain legumes in the Americas and in the Mediterranean–West Asian region reveals important parallels. Both groups suppressed, at least in some varieties, the tendency to vine or grow rampantly. The seeds of both have markedly increased in size over their wild counterparts. Both groups have suppressed pod dehiscence, projectile seed dissemination, and seed dormancy, and in both regions, the seeds have functioned primarily as protein sources in predominantly cereal grain diets. Studies in genetics, molecular structure, and archaeology have contributed to an understanding of the origins of species and races within species. Nonetheless, uncertainties over important aspects of the origins and evolution under domestication remain, and are the subject of active multidisciplinary research.

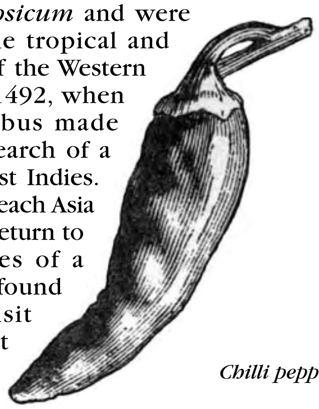
II.C.4 Chilli Peppers

Chilli peppers are eaten as a spice and as a condiment by more than one-quarter of the earth's inhabitants each day. Many more eat them with varying regularity – and the rate of consumption is growing. Although the chilli pepper is the most used spice and condiment in the world, its monetary value in the spice trade is not indicative of this importance because it is readily cultivated by many of its consumers.

Peppers are the fruit of perennial shrubs belonging to the genus *Capsicum* and were unknown outside the tropical and subtropical regions of the Western Hemisphere before 1492, when Christopher Columbus made his epic voyage in search of a short route to the East Indies. Although he did not reach Asia and its spices, he did return to Spain with examples of a new, pungent spice found during his first visit to the eastern coast of the Caribbean island of Hispaniola (now the Dominican Republic and Republic of Haiti). Today capsicums are not only consumed as a spice, condiment, and vegetable, but are also used in medicines, as coloring agents, for landscape and decorative design, and as ornamental objects.



Chilli pepper

History

For the peoples of the Old World, the history of capsicums began at the end of the fifteenth century, when Columbus brought some specimens of a red-fruited plant from the New World back to his sovereigns (Morison 1963: 216; Anghiera 1964: 225). However, the fruits were not new to humankind. When nonagricultural Mongoloid peoples, who had begun migrating across the Bering Strait during the last Ice Age, reached the subtropical and tropical zones of their new world, they found capsicums that had already become rather widespread. They had been carried to other regions by natural dispersal agents – principally birds – from their nuclear area south of both the wet forests of Amazonia and the semiarid cerado of central Brazil (Pickersgill 1984: 110). Plant remains and depictions of chillies on artifacts provide archaeological evidence of the use and probable cultivation of these wild capsicums by humans as early as 5000 B.C. By 1492, Native Americans had domesticated (genetically altered) at least four species (MacNeish 1967; Heiser 1976: 266; Pickersgill 1984: 113). No others have subsequently been domesticated.

In the West Indies, Columbus found several different capsicums being cultivated by the Arawak Indians, who had migrated from northeastern South America to the Caribbean Islands during a 1,200 year period beginning about 1000 B.C. (Means 1935; Anghiera 1964; Watts 1987). These migrants traveled by way of Trinidad and the Lesser Antilles, bringing with them a tropical capsicum that had been domesticated in their homeland. They also brought a word similar to *ají* by which the plant was, and still is, known in the West Indies and throughout its native South American habitat (Heiser 1969). Later, a second species reached the West Indies from Mesoamerica along with other food plants, such as maize (corn), beans, and squash (Sauer

1966: 54). It was this, more climatically adaptable pepper species that went forth, bearing the native Nahuatl name *chilli,* to set the cuisines of the Old World tropics afire (Andrews 1993a, 1993b).

The conquest of Mexico and, later, the mastery of Peru also revealed pepper varieties more suited climatically to cultivation in the temperate areas of Europe and the Middle East. And within 50 years after the first capsicum peppers reached the Iberian Peninsula from the West Indies, American chilli peppers were being grown on all coasts of Africa and in India, monsoon Asia, southwestern China, the Middle East, the Balkans, central Europe, and Italy (Andrews 1993a).

The first European depictions of peppers date from 1542, when a German herbal by Leonhart Fuchs described and illustrated several types of pepper plants considered at that time to be native to India. Interestingly, however, it was not the Spanish who were responsible for the early diffusion of New World food plants. Rather, it was the Portuguese, aided by local traders following long-used trade routes, who spread American plants throughout the Old World with almost unbelievable rapidity (Boxer 1969a).

Unfortunately, documentation for the routes that chilli peppers followed from the Americas is not as plentiful as that for other New World economic plants such as maize, tobacco, sweet potatoes, manioc (cassava), beans, and tomatoes. However, it is highly probable that capsicums accompanied the better-documented Mesoamerican food complex of corn, beans, and squash, as peppers have been closely associated with these plants throughout history. The Portuguese, for example, acquired corn at the beginning of the sixteenth century and encouraged its cultivation on the west coast of Africa (Jeffreys 1975: 35). From West Africa the American foods, including capsicums, went to the east coast of Africa and then to India on trading ships traveling between Lisbon and Goa on the Malabar Coast of western India (Boxer 1984).

The fiery new spice was readily accepted by the natives of Africa and India, who were long-accustomed to food highly seasoned with spices, such as the African melegueta pepper (*Aframomum melegueta,* also known as "grains of paradise"), the Indian black pepper *(Piper nigrum),* and ginger *(Zingiber officinale).* In fact, because the plants produced by the abundant, easily stored seeds were much easier to cultivate than the native spices, *Capsicum* became a less expensive addition to the daily diet and was soon widely available to all – rich and poor alike. Thus, within a scant 50 years after 1492, three varieties of capsicums were being grown and exported along the Malabar Coast of India (Purseglove 1968; Watt 1972).

From India, chilli peppers traveled (along with the other spices that were disseminated) not only along the Portuguese route back around Africa to Europe but also over ancient trade routes that led either to Europe via the Middle East or to monsoon Asia (L'obel 1576). In the latter case, if the Portuguese had not carried chilli peppers to Southeast Asia and Japan, the new spice would have been spread by Arabic, Gujurati, Chinese, Malaysian, Vietnamese, and Javanese traders as they traded traditional wares throughout their worlds. And, after Portuguese introduction, both birds and humans carried the peppers inland. Certainly, birds are most adept at carrying pepper seeds from island to island and to inaccessible inland areas (Ridley 1930; Procter 1968).

In the Szechuan and Hunan provinces in China, where many New World foods were established within the lifetime of the Spanish conquistadors, there were no roads leading from the coast. Nonetheless, American foods were known there by the middle of the sixteenth century, having reached these regions via caravan routes from the Ganges River through Burma and across western China (Ho 1955). The cuisines of southwestern Szechuan and Hunan still employ more chilli peppers than any other area in China.

Despite a European "discovery" of the Americas, chilli peppers diffused throughout Europe in circuitous fashion. Following the fall of Granada in 1492, the Spaniards established dominance over the western Mediterranean while the Ottoman Turks succeeded in installing themselves as the controlling power in northern Africa, Egypt, Arabia, the Balkans, the Middle East, and the eastern Mediterranean. The result was that the Mediterranean became, in reality, two separate seas divided by Italy, Malta, and Sicily, with little or no trade or contact between the eastern and western sections (Braudel 1976).

Venice was the center of the spice and Oriental trade of central Europe, and Venice depended on the Ottoman Turks for goods from the fabled Orient. From central Europe the trade went to Antwerp and the rest of Europe, although Antwerp also received Far Eastern goods from the Portuguese via India, Africa, and Lisbon. It was along these avenues that chilli peppers traveled into much of Europe. They were in Italy by 1535 (Oviedo 1950), Germany by 1542 (Fuchs 1543), England before 1538 (Turner 1965), the Balkans before 1569 (Halasz 1963), and Moravia by 1585 (L'Escluse 1611). But except in the Balkans and Turkey, Europeans did not make much use of chilli peppers until the Napoleonic blockade cut off their supply of spices and they turned to Balkan paprika as a substitute. Prior to that, Europeans had mainly grown capsicums in containers as ornamentals.

Well into the nineteenth century, most Europeans continued to believe that peppers were native to India and the Orient until botanist Alphonse de Candolle produced convincing linguistic evidence for the American origin of the genus *Capsicum* (Candolle 1852). In addition, during the 500 years since their discovery, chillies have become an established crop in the Old World tropics and are such a vital part of the cuisines that many in these regions are only now beginning to accept an American origin of the spice that is such an integral part of their daily lives.

It was only after the Portuguese had carried capsicums and other American plants to Africa, Asia, the Middle East, and Europe that the Spaniards played a significant role in the movement of New World crops to places other than Spain, Italy, and, perhaps, Western Europe. This began toward the end of the sixteenth century with the Manila–Acapulco galleon traffic which effected the transfer of numerous plants, as well as goods, between Mexico and the Orient (Schurz 1939).

Moreover, in North America, at approximately the same time that the Manila galleon trade was launched, the Spaniards founded the presidios of Saint Augustine, Florida (1565), and Santa Fe, New Mexico (1598). These settlements initiated Caribbean–Florida and Mexico–American Southwest exchanges of plants long before other Europeans began colonizing the east coast of North America. Interestingly, however, seventeenth-century English colonists introduced peppers from England via Bermuda to their eastern North American possessions (Laufer 1929: 242).

The Names of Chilli Peppers

That Columbus had not reached the Orient did not discourage him from calling the Caribbean Islands the "Indies," the natives "Indians," and the chilli pepper *pimiento* after the completely unrelated black pepper – *pimienta* – that he sought in the East.

The indigenous Arawaks called the fruit *axí,* which was the South American name they brought with them when they migrated north to the Antilles. Although the Spaniards transliterated this to *ají (ajé, agí),* they never adopted the Arawak word, either in the West Indies or in North America.

Nonetheless, in the Dominican Republic and a few other places in the Caribbean, and in much of South America, the pungent varieties are still called *ají. Uchu* and *huayca* are other ancient words used for capsicums by some Amerindian groups in the Andean area. In Spain, American peppers are called *pimiento* or *pimientón* (depending on the size) after *pimienta* (black pepper from India). In Italy, they are called *peperone,* in France, *piment,* and in the Balkans, *paprika.*

In Mexico, however, the Nahuatl-speaking natives called their fiery fruit *chilli.* The Nahuatl stem *chil* refers to the chilli plant. It also means "red." The original Spanish spelling was *chilli,* first used in print by Francisco Hernández (1514–78), the earliest European to collect plants systematically in the New World. But although in his writings (published in 1615) he interpreted the Nahuatl name for capsicums as chilli, that Spanish spelling was later changed to *chile* by Spanish-speaking people in Mexico. To the generic word "chilli" were added the terms that described particular chilli cultivars (two examples are *Tonalchilli,* "chilli of the sun or summer," and *Chiltecpin,* "flea chilli"). In Mexico today, the word *chile* refers to both pungent and sweet types and is used, in the Nahuatl style, combined with a descriptive adjective, such as *chile colorado* ("red chilli"), or with a word that indicates the place of origin, such as *chile poblano* ("chilli from Puebla"). The same Mexican variety can have different names in different geographic regions, in various stages of maturity, and in the dried state.

The Portuguese language uses *pimenta* for capsicums and qualifies the various types – *pimenta-da-caiena* (cayenne pepper), *pimenta-da-malagueta* (red pepper), *pimenta-do-reino* (black pepper), and *pimenta-da-jamaica* (allspice). *Pimentão* can mean pimento, red pepper, or just pepper. *Ají* and *chile* are not found in Portuguese dictionaries, and apparently the Portuguese did not carry those words with them in their travels.

The Dutch and the English were probably responsible for introducing the current capsicum names to the eastern part of the Old World. In Australia, India, Indonesia, and Southeast Asia in general, the term "chilli" ("chillies") or, sometimes, "chilly," is used by English speakers for the pungent types, whereas the mild ones are called capsicums. Each Far Eastern language has its own word for chillies – *prik* in Thai and *mirch* in Hindi, to name but two.

It is in the United States that the greatest confusion exists. Both the Anglicized spelling, "chili" (chilies), and the Spanish *chile (chiles)* are used by some for the fruits of the *Capsicum* plant, but chili is also used as a short form of *chili con carne,* a variously concocted mixture of meat and chillies. The *Oxford English Dictionary* designates "chilli" (after the Nahuatl) as the primary usage, calling the Spanish *chile* and the English chili both variants. *Webster's New International Dictionary,* however, prefers "chili" followed by the Spanish *chile* and the Nahuatl *chilli.* But "chilli" is the term most often used by English-speaking people outside the United States, and it is the spelling preferred by the International Board for Plant Genetic Resources (IBPGR) of the Food and Agriculture Organization of the United Nations (FAO).

Origin

It is difficult to determine exactly where the genus *Capsicum* originated because the nature of that genus is still not fully understood (Eshbaugh 1980). If the genus remains limited to taxa producing the pungent capsaicin, then the center of diversity occurs in an area from Bolivia to southwestern Brazil. But if the genus includes nonpungent taxa, a second center of diversity would center in Mesoamerica. Nonetheless, it is certain that the ancestor of all of the domesticates originated in tropical South America.

There are definite indications that *Capsicum* *annuum* originally was domesticated in Mesoamerica and *Capsicum chinense* in tropical northern Amazonia. *Capsicum pubescens* and *C. baccatum* seem to be more commonplace in the Andean and central regions of South America. Thus, the first two species were those encountered by the first Europeans, whereas the other two species were not found until later and are just now becoming known outside their South American home.

Diagnostic Descriptions

The genus *Capsicum* is of the family Solanaceae, which includes such plants as the potato, tomato, eggplant, petunia, and tobacco. The genus was first described in 1700, but that description has become so outdated as to be worthless. The taxonomy of the genus *Capsicum* is in a state of transition, and the taxa finally included may change if the description is expanded to encompass taxa with common traits but nonpungent fruits (Eshbaugh, personal communication).

Currently, the genus consists of at least 20 species, many of which are consumed by humans. Four of the species have been domesticated and two others are extensively cultivated. It is those six species, belonging to three separate genetic lineages, that are of concern to human nutrition.

Capsicum pubescens Ruiz and Pavón

The domesticated *C. pubescens* is the most distinctive species in the genus. The flowers have comparatively large purple or white (infused with purple) corollas that are solitary and erect at each node. Those blossoms, along with the wavy, dark brownish black seeds, are unique among the capsicums. This extremely pungent chilli was domesticated in the Andean region of South America, where it is commonly called *rocoto,* and it is still practically unknown in other parts of the world because it requires cool but frost-free growing conditions and a long growing season at relatively high elevations. Its many varieties include none that are sweet. The fleshy nature of the fruit causes rapid deterioration when mature, and, consequently, it neither travels nor stores well.

Capsicum baccatum var. pendulum (Willdenow) Eshbaugh

Capsicum baccatum var. *pendulum* is recognized by a flower with a cream-colored corolla marked with greenish-gold blotches near the base of each petal and anthers that are whitish-yellow to brown. It is solitary at each node. Although it is quite variable, the typical fruit is elongate with cream-colored seeds. It is indigenous to the lowlands and mid-elevations of Bolivia and neighboring areas. In much of South America, where all pungent peppers are called *ají, C. baccatum* is the "Andean *ají*" (Ruskin 1990: 197). Until recently, it has been little known outside South America. It is only in this species and the common annual pepper that nonpungent cultivars are known (Ruskin 1990: 198).

Capsicum annuum var. annuum Linné

The flowers of *C.* var. *annuum* are solitary at each node (occasionally two or more). The corolla is milky white and the anthers are purple. The variform fruit usually has firm flesh and straw-colored seeds. The pungent and nonpungent cultivars of this Mesoamerican domesticate now dominate the commercial pepper market throughout the world. A relationship between *C. annuum, C. chinense,* and *Capsicum frutescens* has caused the three to be known as the "*C. annuum* complex." This relationship, however, creates a taxonomic predicament, because some authorities still recognize the first two as distinct but have difficulty determining where *C. frutescens* fits into the picture.

Capsicum annum var. glabrisculum

Capsicum annum var. *glabrisculum* is a semiwild species known as bird pepper. This highly variable, tiny, erect, usually red pepper is cultivated commercially in the area around Sonora, Mexico, and seems to be in the process of domestication. It has a distinct flavor and high pungency and is avidly consumed throughout its natural range, which extends through the southernmost parts of the United States to Colombia. Birds are also keen consumers. These chillies, which have many vernacular names and almost as many synonyms (*Capsicum aviculare* is the most common), sell for 10 times the price of cultivated green bell peppers.

Capsicum chinense Jacquin

There are two or more small, white-to-greenish-white flowers with purple anthers per node of *C. chinense,* often hanging in clusters. The fruit is variform, with cream-colored seeds that tend to require a longer germination period than *C. annuum. C. chinense* was domesticated in the lowland jungle of the western Amazon River basin and was carried to the islands of the Caribbean before 1492. It has diffused throughout the world but to a much lesser degree than *C. annuum,* probably because it does not store or dry well. Nonetheless, it is becoming ever more widely appreciated by cooks and gardeners for its pungency, aroma, and unique flavor, and ever more important in medical, pharmaceutical, and food-industry applications because of its high capsaicin content. Although this morphologically distinct pepper is still considered to be a part of the *C. annuum* complex, there are those who question its position in the genus on genetic grounds.

Capsicum frutescens Linné

Some authors no longer list the semiwild *C. frutescens* as a sustainable species. Although it was once considered to be a member of the *C. annuum* complex, which included three white-flowered species thought to have a mutual ancestor, scholars now have considerable doubt as to the position of the first two in the genus. The small greenish-white flowers of *C. frutescens* have purple anthers. The small fruit with cream-colored seed is always erect, never sweet, and two or more occur at each node. The tabasco pepper is the only variety of this species known to have been cultivated commercially, and this activity has been limited to the Western Hemisphere.

Geographic Distribution

Following the arrival of the Europeans in the Western Hemisphere, the tropical perennial capsicum spread rapidly. It quickly became pantropic and the dominant spice and condiment in the tropical and subtropical areas of the world. In addition, it is an important green vegetable throughout the temperate regions, where it is grown as an annual. Concentrated breeding studies are producing *Capsicum* varieties that can be cultivated in environments quite different from the tropical home of the original.

Biology

Nutritional Considerations

Capsicums have a lot to recommend them nutritionally. By weight, they contain more vitamin A than any other food plant, and they are also a good source of the B vitamins. When eaten raw, capsicums are superior to citrus in providing vitamin C, although their production of vitamin C diminishes with maturity and drying and (as in all plant foods) is destroyed by exposure to oxygen. By contrast, vitamin A increases as peppers mature and dry and is not affected by exposure to oxygen.

Capsicums also contain significant amounts of magnesium and iron. Chillies, of course, are not eaten in large quantities, but even small amounts are important in cases where traditional diets provide only marginal supplies of vitamins and minerals.

The Pungent Principle

A unique group of mouth-warming, amide-type alkaloids, containing a small vanilloid structural component, is responsible for the burning sensation associated with capsicums by acting directly on the pain receptors in the mouth and throat. This vanilloid element is present in other pungent plants used for spices, like ginger and black pepper. Birds and certain other creatures, such as snails and frogs, do not have specific neuroreceptors for pungent vanilloid compounds as do humans and other mammals; consequently, their contact with capsaicinoids has no adverse effects (Nabhan 1985).

The vanillyl amide compounds or capsaicinoids (abbreviated CAPS) in *Capsicum* are predominantly (about 69 percent) capsaicin (C). Dihydrodcapsaicin (DHC) (22 percent), nordihydrocapsaicin (NDHC) (7 percent), homocapsaicin (HC) (1 percent), and homodihydrocapsaicin (HDHC) (1 percent) account for most of the remainder (Masada et al. 1971; Trease and Evans 1983). The primary heat contributors are C and DHC, but the delayed action of HDHC is the most irritating and difficult to quell (Mathew et al. 1971).

Three of these capsaicinoid components cause the sensation of "rapid bite" at the back of the palate and throat, and two others cause a long, low-intensity bite on the tongue and the middle palate. Differences in the proportions of these compounds may account for the characteristic "burns" of the different types of capsicum cultivars (McGee 1984: 12; Govindarajan 1986).

In both sweet and pungent capsicums, the major part of the organs secreting these pungent alkaloids is localized in the placenta, to which the seeds are attached, along with dissepiment (veins or cross walls) (Heiser and Smith 1953). The seeds contain only a low concentration of CAPS. The capsaicin content is influenced by the growing conditions of the plant and the age of the fruit and is possibly variety-specific (Govindarajan 1986: 336–8). Dry, stressful conditions will increase the amount of CAPS. Beginning about the eleventh day of fruit development, the CAPS content increases, becoming detectable when the fruit is about four weeks old. It reaches its peak just before maturity, then drops somewhat in the ripening stage (Govindarajan 1985). Sun-drying generally reduces the CAPS content, whereas the highest retention of CAPS is obtained when the fruits are air-dried with minimum exposure to sunlight.

Capsaicin is hard to detect by chemical tests. It has virtually no odor or flavor, but a drop of a solution containing one part in 100,000 causes a persistent burning on the tongue (Nelson 1910). The original Scoville Organoleptic Test has largely been replaced by the use of high-pressure liquid chromatography (HPLC), a highly reproducible technique for quantifying capsaicinoids in capsicum products. However, the results apply solely to the fruit tested, and therefore they are considered only as a general guide (Todd, Bensinger, and Biftu 1977). Capsaicin is eight times more pungent than the piperine in black pepper. But unlike black pepper, which inhibits all tastes, CAPS obstructs only the perception of sour and bitter; it does not impair the discernment of other gustatory characteristics of food.

Capsaicin activates the defensive and digestive systems by acting as an irritant to the oral and gastrointestinal membranes (Viranuvatti et al. 1972). That irritation increases the flow of saliva and gastric acids and also stimulates the appetite. These functions work together to aid the digestion of food. The increased saliva helps ease the passage of food through the mouth to the stomach, where it is mixed with the activated gastric juice (Solanke 1973). Ingesting CAPS also causes the neck, face, and front of the chest to sweat in a reflexive response to the burning in the mouth (Lee 1954). Very little CAPS is absorbed as it passes through the digestive tract (Diehl and Bauer 1978).

Capsaicin is not water soluble, but the addition of a small amount of chlorine or ammonia will ionize the CAPS compound, changing it into a soluble salt (Andrews 1984: 127) that can be used to rinse CAPS from the skin. Like many organic compounds, CAPS is soluble in alcohol. Oral burning can be relieved by lipoproteins, such as casein, that remove CAPS by breaking the bond it has formed with the pain receptors in the mouth (Henkin 1991). Milk and yoghurt are the most readily available sources of the casein. Because casein, and not fat, removes capsaicin, butter and cheese will not have the same effect as milk.

Studies of CAPS and its relationship to substance P, a neuropeptide that sends the message of pain to our brains, have led investigators to conclude that CAPS has the capacity to deplete nerves of their supply of substance P, thereby preventing the transmission of such messages (Rozin 1990).

Consequently, CAPS is now used to treat the pain associated with shingles, rheumatoid arthritis, and "phantom-limb" pain. It may prove to be a nonaddictive alternative to the habit-forming drugs used to control pain from other causes. It does not act on other sensory receptors, such as those for taste and smell, but is specific to pain receptors. Such specificity is becoming a valuable aid to medical research.

Aroma, Flavor, and Color

The flavor compound of capsicums is located in the outer wall of the fruit (pericarp): Very little is found in the placenta and cross wall and essentially none in the seeds (Figure II.C.4.1). Color and flavor go hand in hand because the flavoring principle appears to be associated with the carotenoid pigment: Strong color and strong flavor are linked. *Capsicum pubescens (rocoto)* and the varieties of *C. chinense* are more aromatic and have a decidedly different flavor from those of *C. annuum* var. *annuum.* The carotenoid pigments responsible for the color in capsicums make peppers commercially important worldwide as natural dyes in food and drug products. Red capsanthin is the most important pigment. All capsicums will change color from green to other hues – red, brown, yellow, orange, purple, and ripe green – as they mature.

Taste and smell are separate perceptions. Several aroma compounds produce the fragrance. The taste buds on the tongue can discern certain flavors at dilutions up to one part in two million, but odors can be detected at a dilution of one part in one billion. The more delicate flavors of foods are recognized as aromas in the nasal cavity adjacent to the mouth.

Cultivation Requirements

Peppers are best transplanted and not planted directly into the soil outdoors. The seeds should be started in greenhouse benches, flats, or hotbeds at

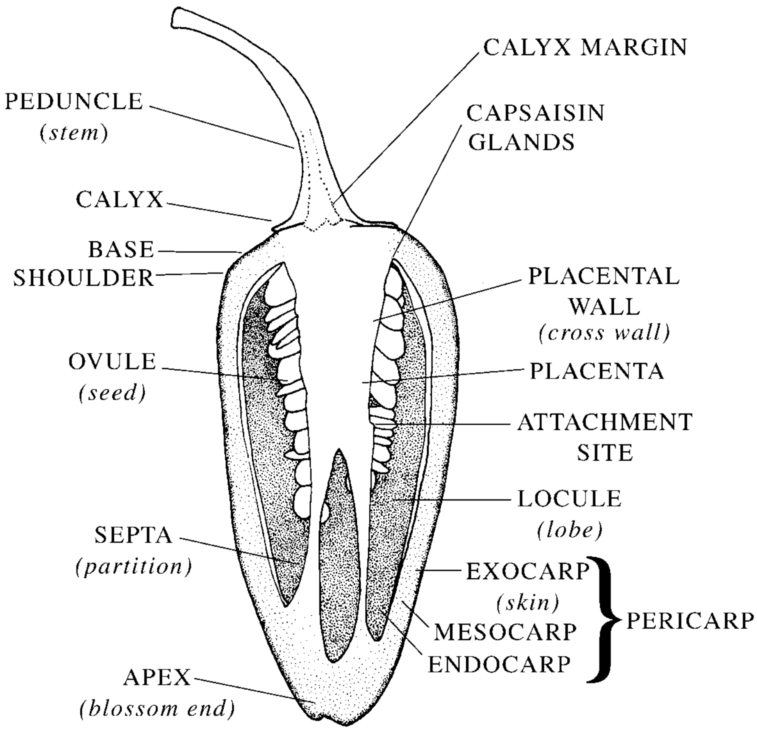


Figure II.C.4.1. Cross-section of a pepper. (Adapted from Andrews 1995.)

least six weeks before the first frost-free date. They ought to be sown as thinly as possible on a sterile medium and covered no deeper than the thickness of the seed. It is best to water them from the top, with care taken to not dislodge the seed. The seed or seedlings should never be permitted to dry or wilt from the time they are sown until they are transplanted and well started. Germination will require 12 to 21 days at a constant temperature of 21° C for *C. annuum* var. *annuum,* and longer for the other species.

When the true leaves are well formed, one may transplant the seedlings into containers or flats, containing equal parts peat, sand, and loam, and grow them at 21° C. After the plants attain a height of 12 to 15 centimeters (cm), and all danger of frost is past, they can be planted (deeply) in friable soil that is not below 13° C. The plants should be spaced 30 cm apart in rows 38 to 76 cm apart. Peppers require full sun and well-drained soil. They are warm-season plants that do better in a moderate climate, with the optimum temperature for good yields between 18.5° C and 26.5° C during fruit setting (Andrews 1984).

Economic and Other Uses

Perhaps no other cultivated economic plants have fruits with so many shapes, colors, and uses over such a widespread area of the earth as do those belonging to the genus *Capsicum.*

Before World War II, capsicums were eaten daily by one-fourth of the world's population, primarily in the pantropical belt and Korea. Since that time, their consumption as a condiment, spice, and vegetable has continued to increase annually and is no longer limited to the tropical and subtropical areas. Some of the more common food products made with chillies are curry powder, cayenne pepper, crushed red pepper, dried whole peppers, chili powder, paprika, pepper sauce, pickled and processed peppers, pimento, and salsa picante. In 1992, the monetary value of sales of salsa picante, a bottled sauce of Mexican origin made with chillies, onions, and tomatoes, overtook that of tomato catsup in the United States.

However, the use of capsicums goes beyond that of food. The florist and landscape industries have discovered the ornamental qualities of pepper plants to be of considerable value, and designers of tableware, home decorations, fabrics, and paper goods find them to be a popular decorative motif. The medical profession has discovered that certain folk-medicine practices employing chillies, some of which are prehistoric in origin, have merit. Capsaicin, the pungent alkaloid unique to capsicums, is being utilized in modern medicine to treat pain, respiratory disorders, shingles, toothache, and arthritis, and research into the properties of capsaicinoids continues.

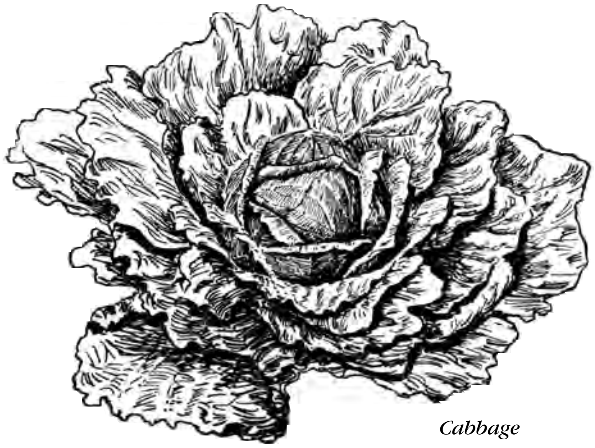
II.C.5 Cruciferous and Green Leafy Vegetables

Cruciferae (Brassicaceae), in the mustard family of the caper order (Capparales), are found on all continents except Antarctica. The cruciferae, so named because of the uniform, four-petaled flowers suggestive of a Greek cross, are an example of a natural family and demonstrate a large amount of diversity. Although most are weeds, the family includes significant food crop plants such as broccoli, cabbage, turnip, and radish. Cruciferae are most abundant in areas north of the equator and exhibit greatest variety in temperate and arid regions. The Mediterranean region is generally considered the site of the family's origination. Nonetheless, many of these cultigens appear to be native to northern Europe, and Reed C. Rollins (1993: 1) contends that the Irano-Turanian region of Eastern Europe and western Asia was the birthplace of at least some members of this plant family. A precise number of species and genera of the cruciferae is undetermined, although estimates range from 340 to 400 genera and 3,000 to 3,500 species (Vaughan, Macleod, and Jones 1976: vii; Rollins 1993: 2).

Taxonomy

The classification of cruciferae presents a challenge because of the large number of members and their unusually homogeneous nature (Hedge and Rechinger 1968: 1). But basic characteristics, both macroscopic and microscopic, mark the family as a whole. Typically the radial flower is characterized by the uniformity of its structure. This already mentioned flower type, four petals in the shape of a Greek cross,



Cabbage

is common to a large majority of this family's species. However, this pattern is altered by deviations, particularly in the structure of the stamen, flowers, and calyx. This is true of genera such as *Romanschulzia, Stanleya,* and *Warea,* and some species of *Streptanthus, Lepidium,* and *Megacarpaea* (Hedge and Rechinger 1968: 1–2; Rollins 1993: 2).

The fruits of the cruciferae, like the floral construction, are fundamentally homogeneous but can demonstrate significant variation in morphology. They play a key role in classification, along with developmental aspects of the plants, such as lifespan, floral maturation, seed germination, and possibly variations in sepal or petal formations (Hedge and Rechinger 1968: 1–2; Rollins 1993: 3).

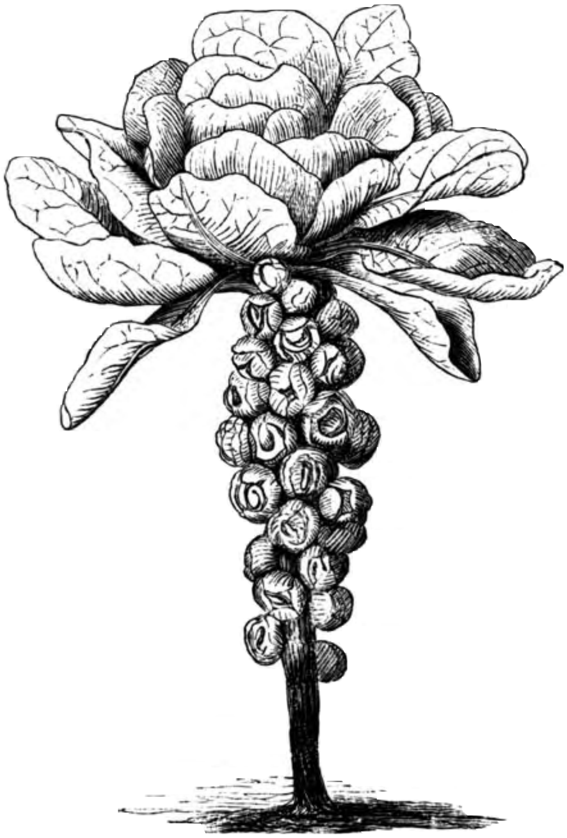
In addition to a wide variety of macroscopic characteristics, several microscopic features may help identify the cruciferae group, such as the cell shape and configurations, as well as seed mucus (Hedge and Rechinger 1968: 2). A survey of the cruciferae group reveals one of the widest ranges of taxonomic characteristics among plant families, encompassing about 20 usable traits, sometimes existing in six or more states. Because of this high number of features, it is not unusual for authorities to emphasize different characteristics, resulting in, at times, a rather varied system of classification (Hedge and Rechinger 1968: 2).

The focus of this chapter is only on those genera and species associated with food or food products. Most of these species fall within *Brassica,* the best-known genus. Its 35 to 50 species and numerous varieties originated primarily in Europe, the Mediterranean, and Eurasia and include *Brassica oleracea* (cabbage, kale and collards, broccoli, cauliflower, Brussels sprouts, and kohlrabi, also known as *Brassica caulorapa*); *Brassica pekinensis* (Chinese cabbage); *Brassica nigra* (black mustard, also known as *Sinapis nigra*); *Brassica alba* (table mustard, also known as *Sinapis alba*); *Brassica juncea* (leaf mustard, also known as *Sinapis juncea*); *Brassica napobrassica* (rutabaga); and *Brassica rapa* or *Brassica campestris* (turnips). There are, however, other significant food-producing members of this family, such as *Raphanus sativus* (radish) and *Nasturtium officianale* (watercress).

Cruciferae as a Cultivated Food Source

In Europe wild ancestors of the turnip and radish were gathered in prehistoric times, and most of these vegetables have been cultivated and used since the earliest days of recorded history. They are discussed extensively by classical Greek scholars like Theophrastus, and Roman writers, including Marcus Porcius Cato and Lucius Junius Moderatus Columella, as well as in chronicles of food and daily life in medieval and Renaissance Europe, such as *The Four Seasons of the House of Cerruti* (Spencer 1984). This book, compiled in the late 1300s, is based on the manuscript of an eleventh-century Arab physician living in northern Italy. The work describes the foods, drinks, and spices common in that region, along with practices considered good for health. Many cruciferous vegetables were grown during medieval and early modern times in the kitchen gardens of Europe, and particularly Britain, to be eaten in stews and salads.

Brussels sprouts



Then cabbage and its varieties were frequently referred to as "cole" or "coleworts," hence the name "coleslaw" for the popular side dish made with shredded cabbage. In Russia, cabbage, and to a lesser extent, turnips and radishes were important food crops. Along with radishes, a large number of *Brassica* varieties are found in China, where they have been used for centuries. Today, as in earlier periods, the durable and hardy plants of the Cruciferae family continue to play an important part in diets around the globe, and one that seems to increase in importance as more is learned of their nutritional and disease-preventive nature.

Cabbage and Its Varieties

Brassica oleracea includes some of the most significant vegetables used today, such as broccoli, cauliflower, Brussels sprouts, and of course, countless cabbages. With the exception of Brussels sprouts and kohlrabi, cabbage and its varieties have probably been cultivated since before recorded history (Toussaint-Samat 1992: 690). Wild cabbage, the early form of *B. oleracea,* was a small plant also known as "sea cabbage." Its leaves were firm and fleshy, fortified by mineral salts from the seawater it grew near, and even today *B. oleracea* can be found growing wild along the coasts of the English Channel.

Although there are approximately 400 species of cabbage, they can be divided into five groups. The first includes the familiar round, smooth-leafed cabbages that may be white, green, or red, as well as wrinkled-leafed varieties like Savoy. The second group comprises pointed cabbages like European spring and Chinese cabbages. A third category consists of cabbages with abnormally large, budding stems, as for example, Brussels sprouts. Green curly types such as kale represent a fourth group. These are used especially for animal food or for decoration of dishes for presentation, although kale is also featured in some famous soups, and collard greens make frequent appearances on many tables. The last category is made up of flowering cabbages such as cauliflower and broccoli (Toussaint-Samat 1992: 693).

Cabbage. Cabbage is the most durable and successful variety of *B. oleracea.* It is a versatile plant that can be found growing in almost every climate in the world, ranging from subarctic to semitropical. Such an ability to adapt to a wide variety of climatic conditions has enabled the vegetable to survive since prehistoric times. Although initially grown for its oily seeds, cabbage began to be used as a vegetable after people discovered that its green leaves were edible raw or cooked. Its consumption was confined to Asia and to Europe, however, as Neolithic Near Eastern peoples, Hebrews, and Egyptians did not use the plant.

In ancient Greece the writer Theophrastus noted three types of cabbage: curly-leafed, smooth-leafed, and wild. While comparing the curly-leafed and the smooth-leafed varieties he observed that one bore either inferior seeds or none whatsoever. Unfortunately, he did not identify the one to which he referred, but he did say that the curly-leafed kind had better flavor and larger leaves than the smooth-leafed variety. Theophrastus described wild cabbage as having small round leaves with many branches and leaves. The plant had a strong medicinal taste and was used by physicians to ease or cure stomach problems (Theophrastus 1977, 2: 85).

The Roman agronomist Cato the Elder (234–149 B.C.) also noted the medicinal value of cabbage, which, he contended, "surpasses [that of] all other vegetables." Whether eaten cooked or raw, cabbage was believed beneficial to digestion and to be an excellent laxative. Acknowledging the same three types of cabbage identified by Theophrastus, Cato agreed that the wild variety held the best medicinal value and wrote that it could be used as a poultice for all types of wounds, sores, or swellings. In addition, he advised "in case of deafness, macerate cabbage with wine, press out the juice, and instil warm into the ear, and you will soon know that your hearing is improved" (Cato 1954: 151, see also 141, 145). Both the Greeks and Romans believed that eating cabbage during a banquet would prevent drunkenness, and it has been pointed out that "the B vitamins contained in cabbage leaves do seem to have soothing and oxygenating qualities, very welcome when the mind is clouded by the fumes of alcohol. Research at a Texan *[sic]* university extracted a substance from cabbage which is useful in the treatment of alcoholism" (Toussaint-Samat 1992: 691).

In addition, cabbage was apparently inimical to fruits that could provide alcohol. Greek and Roman writers noted that cabbage was "hostile" to grapevines used for making wine. This is thought to be true even today: "Mediterranean farmers never plant it near vineyards in case bees transfer its odour to the bunches of grapes. Nor is it grown near beehives, because it might taint the flavour of the honey" (Toussaint-Samat 1992: 691).

Don Brothwell and Patricia Brothwell (1969) have written that the Romans favored two cabbage varieties known as *cymae* and *cauliculi* and pointed out that some scholars have mistaken *cauliculi* for Brussels sprouts when it was actually cabbage shoots or cabbage asparagus. *Cymae* is usually interpreted as sprouting broccoli and was apparently affordable only by the wealthier elements of Roman society. Moreover, by the time of Julius Caesar (100–44 B.C.), the Romans had enlarged cabbage, lavishing such attention on it and cultivating it to such a size that the poor of Rome could not afford to buy it (Toussaint-Samat 1992: 692). This interest in cabbage by the wealthy was apparently new because the vegetable had seldom been mentioned since the work of Cato, suggesting dietary distinctions between wealthier and poorer Romans that limited the consumption of ordinary cabbage to the latter. According to Brothwell and Brothwell (1969: 118), "this is borne out by Juvenal's satire describing the differences between the food of the patron and that of his poor client – the patron has olives to garnish his excellent fish, the client finds cabbage in his 'nauseous dish.' "

Although the Romans introduced garden varieties of cabbage to northern Europe and Britain, it was not an entirely new food plant in these regions. On the basis of linguistic evidence, Anne C. Wilson (1974: 195) has pointed out that wild cabbage was used as a food source by Iron Age Celts living along the Atlantic coast of Europe prior to their migration to the British Isles. When the Romans did introduce their garden varieties of cabbage, she suggested the Celts favored an open-headed variety because of its similarity to this wild cabbage. However, due to the constant threat of famine during this era, the Celts continued to depend on the hardier wild variety as a safeguard against starvation (Wilson 1974: 196–7).

The fourteenth-century book *The Four Seasons,* mentioned previously, indicates that cabbage continued to enjoy a reputation for medicinal value in Renaissance Italy, although the work mentions some sources that thought cabbage bad for the blood and found its only redeeming quality to be its ability to "clear obstructions," of what kind we are left to wonder. On a less obscure note, cabbage was believed able to "restore a lost voice," and if its juice was cooked with honey and used sparingly as eyedrops it was believed to improve vision (Spencer 1984: 102).

Carroll L. Fenton and Herminie B. Kitchen (1956) divided cultivated cabbage into two main types – the hard-headed and the loose-headed, or Savoy cabbage. It is most likely that loose-headed cabbage evolved directly from wild cabbage found near the Mediterranean and Atlantic coasts of Europe. Its ridged leaves form a head at the top of a very short stalk. By contrast, hard-headed cabbage leaves are wound tightly around each other and around the stalk or "heart." It is believed that hard-headed cabbage developed in northern Europe. Because it does not grow well in warm climates, the Greeks and Romans did not cultivate it. Thus, it was probably developed by the Celts and has been cultivated by the Germans since ancient times. By the 1300s, hard-headed cabbage was common in England, and British soldiers introduced it in Scotland before 1650 (Fenton and Kitchen 1956: 74; Toussaint-Samat 1992: 692).

At first cabbage was an important crop in individual family plots known as kitchen gardens, but by the eighteenth century in England the cultivation of cabbage, along with many other vegetables, had expanded beyond kitchen gardens to the fields (Wilson 1974: 329; Braudel 1981, 1: 170). As early as 1540, Jacques Cartier grew hard-headed cabbages in Canada, and Native Americans used his seeds to plant cabbages along with beans, squash, and corn (Fenton and Kitchen 1956: 74).

In the nineteenth and twentieth centuries the Russians have been among the world's most important consumers of hard-headed cabbage – an item of diet that has been a fundamental part of Russian cuisine for many centuries. It has been especially enjoyed pickled or prepared as cabbage soup called *shchii.* Usually flavored with meat fat or small chunks of meat, this soup consists of chopped cabbage, barley meal, salt, and a touch of *kvass* (Smith and Christian 1984: 252, 275–6).

Collards and kale. Collards (collard greens) and kale are varieties of *B. oleracea* that do not form heads. In fact, kale is very similar to sea cabbage (Fenton and Kitchen 1956: 72), and the primary difference between collard greens, a type of kale, and kale itself is leaf shape. Kale has a short, thick stalk and crinkly blue-green leaves that grow on leaf-stems, whereas collard greens have smooth, broad, yellowish green leaves (Fenton and Kitchen 1956: 72). Although the precise area of origin of collards and kale is unknown, it was most likely in Asia Minor or in the Mediterranean region, where both have been cultivated since prehistoric times. The Greeks and Romans grew several varieties of both kale and collard greens at least 2,200 years ago, followed about 200 years later by Germans and Saxons in northern Europe. They, or quite possibly the Romans, brought these plants to France and Great Britain. For nearly a thousand years kale and collards were the main winter vegetables in England. European colonists carried the seeds to the Americas. Kale and collards were cultivated in western Hispaniola before 1565, and by colonists in Virginia by at least 1669.

Most collards are similar in appearance, but kale has many varieties, some short and some very tall, such as a type of kale grown in England that reaches 8 or 9 feet in height. Today in the United States collards are grown predominantly in the South. An old and popular variety, 'Georgia collards', is characterized by stems 2 to 4 feet high, with leaves growing only at the top. Others include the 'Blue Stem', 'Green Glaze', 'Louisiana', and 'Vates Non-Heading'. Kale's principal types are 'Scotch', 'Blue', and 'Siberian' (Fenton and Kitchen 1956: 72–4; Carcione and Lucas 1972: 63–4).

Broccoli and cauliflower. Although well known today, broccoli and cauliflower are varieties of *B. oleracea* that are rarely mentioned in historical sources, despite being two of the oldest cultivated cabbage varieties. This may be because they were not well differentiated in those sources from the more recognizable cabbage. Jane O'Hara-May (1977: 251) has noted that in Elizabethan England the term "cabbage" referred to "the compact heart or head of the plant," whereas the entire plant was known as cabbage-cole or colewort, a term applied to all varieties of cabbage.

Both broccoli and cauliflower, also called varieties of colewort, were cultivated "over 2,500 years ago in Italy or on the island of Cyprus" (Fenton and Kitchen 1956: 76), and broccoli, at least, was a part of Greek and Roman diets more than 2,000 years ago, although apparently it did not reach England until after 1700. When broccoli was introduced, in all likelihood it came from Italy because the English called it "Italian asparagus." In North America, broccoli was referred to in an 1806 book on gardening and grown regularly by Italian immigrants in private plots, but it was largely unknown to the public until the 1920s. It was because of effective marketing on the part of the D'Arrigo Brothers Company, which grew the vegetable, that demand for broccoli skyrocketed in the early 1930s, and it became "an established crop and an accepted part of the American diet" (Fenton and Kitchen 1956: 76; Carcione and Lucas 1972: 23). Today a major variety of broccoli is the 'Italian Green' or 'Calabrese', named after the Italian province of Calabria. Its large central head consists of bluish-green flower buds, called curds. 'De Cicco' is another popular variety that resembles the Calabrese but is lighter green in color. Chinese broccoli, also known as *Gai Lon,* "is more leaf than flower." It is light green in color, with small flower buds and large leaves on a long shank (Carcione and Lucas 1972: 23).

Through selective cultivation of sprouting broccoli, gardeners of long ago were able to produce ever larger clusters that were lighter in color and eventually became cauliflower broccoli and cauliflower. In ancient Greece cauliflower was popular, but after that its popularity declined in the West, where it was little used until the era of Louis XIV (Toussaint-Samat 1992: 691). The vegetable reached England toward the end of the Elizabethan era as part of an influx of new vegetables from Italy and France (Wilson 1974: 362; Braudel 1981, 1: 223), and, in a list of 18 coleworts compiled in 1633, was identified as "Cole Florie" or "Colieflorie" and sold in London markets as "Cyprus coleworts" (O'Hara-May 1977: 251).

Although it is unclear when cauliflower arrived in North America, a number of varieties could be found in seed catalogs by the 1860s (Fenton and Kitchen 1956: 76; Carcione and Lucas 1972: 34). In all European countries, cauliflower is primarily a summer vegetable. It is very popular in Italy – the leading producer in Europe – where it comes in both bright purple and bright green colors. In the United States, typically, one can find only creamy, ivory-white cauliflower. Three of the most widely cultivated varieties in the United States are of the snowball type: 'Early Snowball', 'Super Snowball', and 'Snowdrift'. A larger, more leafy kind is the 'Danish Giant' grown primarily in the American Midwest (Carcione and Lucas 1972: 34; Toussaint-Samat 1992: 694).

Kohlrabi. A variety of *B. oleracea,* kohlrabi is just 400 to 500 years old and thus a relative newcomer to the cabbage genus of *Brassica.* It is one of the few vegetables with an origin in northern Europe. First described in 1554, kohlrabi was known in Germany, England, Italy, and Spain by the end of the sixteenth century. Documentation of its cultivation in the United States dates from 1806. Its common name, kohlrabi, is derived from the German *Kohl,* meaning cabbage, and *Rabi,* meaning turnip. It was developed by planting seeds from thick, juicy-stemmed cabbage, and the plants evolved into a turnip shape, characterized by slender roots at the bottom, a swelling of the stem into a turnip-sized bulb just above the ground, and leaves similar to those of a turnip sprouting on top (Fenton and Kitchen 1956: 77; Carcione and Lucas 1972: 66). Although more delicate, the kohlrabi's taste resembles that of a turnip. Europeans grow frilly-leafed varieties of kohlrabi for ornament, whereas in the United States the two common varieties are both food plants (Carcione and Lucas 1972: 66).

Brussels sprouts. Less than 500 years old and native to northern Europe, Brussels sprouts are also a recent addition to *B. oleracea.* Described as early as 1587, the plant supposedly got its name as the result of its development near the city of Brussels, Belgium. Brussels sprouts were cultivated in England in the seventeenth century and appear to have been introduced into the United States in the nineteenth century, although exactly when, where, and by whom is unclear (Fenton and Kitchen 1956: 76–7; Carcione and Lucas 1972: 25; Wilson 1974: 203).

Mustard

Often found growing in fields and pastures, the mustard varieties *B. nigra* and *B. alba* are characterized by leaves with deep notches and small yellow flowers with four petals forming the shape of a Greek cross, typical of the Cruciferae (Fenton and Kitchen 1956: 66). These mustard varieties evolved from weeds growing wild in central Asia into a food source after humans learned that their pungent seeds improved the taste of meat – a not unimportant discovery in ancient times, when there was no refrigeration and meat was usually a bit tainted (Fenton and Kitchen 1956: 66). Once mustard became recognized as a spice, it was commercially cultivated, and traders carried the seed to China and Japan, Africa, Asia Minor, and Europe.

The Greeks and the Romans first used mustard for medicinal purposes by creating ointments from the crushed seeds and prescribing the leaves as a cure for sore muscles. According to Pliny the Elder, the first-century Roman writer, mustard "cured epilepsy, lethargy, and all deep-seated pains in any part of the body" (1938, I: 64), and also, mustard was an "effective cure for hysterical females" (Carcione and Lucas 1972: 64). In addition to medical applications, the Greeks and Romans came to use the seeds as a spice and the boiled leaves as a vegetable. The Romans also pulverized mustard seeds and added them to grape juice to prevent it from spoiling. This practice later appeared in England, where grape juice was called "must" and both seeds and plants were known as mustseed. Over time, the spelling evolved from "mustseed" to "mustard" (Fenton and Kitchen 1956: 66–7).

By the time of the Middle Ages, mustard was popular as a condiment that seasoned food and stimulated the appetite; it was also used to treat gout and sciatica and as a blood thinner. Caution was advised, however, in smelling mustard powder, although the risk of its rising to the brain could be averted by using almonds and vinegar in its preparation (Spencer 1984: 47).

Of the two varieties of mustard that were cultivated in the United States before 1806, both "ran wild," becoming weeds, as did another type, the Indian mustard, grown for greens (Fenton and Kitchen 1956: 67–8). Today, India, California, and Europe supply most of the world's mustard. Joe Carcione and Bob Lucas noted that wild mustard, also called "Calutzi," colors the California hills a brilliant yellow in springtime. Commercially grown types include 'Elephant Ears', which have large plain leaves, and the curly-leafed varieties, 'Fordhood Fancy' and 'Southern Curled' (Carcione and Lucas 1972: 64). The dry seeds are crushed to produce oil and ground into powder, which is the basis of the condiment.

Chinese Brassica

A large variety of green vegetables are grown in China, and prominent, particularly in the north, are several types of *Brassica* that are native Chinese cultigens. As with cruciferous vegetables in general, their exact classifications are controversial and difficult to sort out. The most common are *B. pekinensis, Brassica chinensis,* and *B. juncea.* The long, cylindrical-headed *B. pekinensis,* known as *Pai ts'ai,* or Chinese cabbage, and by numerous colloquial names in different languages, has white, green-edged leaves wrapped around each other in a tall head reminiscent of celery. The nonheaded *B. chinensis,* identified as *ch'ing ts'ai* in Mandarin and *pak choi* in Cantonese, has dark green, oblong or oval leaves resembling chard, growing on white stalks. Descriptions of *pak choi* and *pai ts'ai* exist in Chinese books written before the year A.D. 500, although both were probably developed even earlier. However, it was not until the early twentieth century that they became commonly known in North America (Fenton and Kitchen 1956: 68; Anderson and Anderson 1977: 327), ironically at a time when Chinese immigration into the United States and Canada was all but nonexistent. It is possible that their expanded use in North America came with the growth of second and third generations of Chinese populations in North America.

Brassica juncea, recognized as *chieh ts'ai* in Mandarin and *kaai choi* in Cantonese, has characteristics similar to *B. chinensis.* Also important in China are *Brassica alboglabra,* named *kaai laan* in Cantonese, which are similar to collard greens; *B. campestris,* the Chinese rapeseed that is a major oil-producing crop (canola oil in the West); and several minor crops including *B. oleracea,* recently introduced from the West. Although quite distinctive, the Cantonese *choi sam* or "vegetable heart" is considered to be a form of *B. chinensis* (Anderson and Anderson 1977: 327).

Along with radishes, these *Brassica* cultigens are the most significant "minor" crops grown in southern China and, combined with rice and soybeans, constitute the diet of millions. Cabbage or mustard greens stir-fried in canola oil and seasoned with chillies or preserved soybean constitutes a nutritionally sound meal without the use of animal products or plants that require large areas of land and are overly labor intensive. Chinese *Brassica* varieties produce large yields and are available throughout the year, particularly in south China (Anderson and Anderson 1977: 328).

Radish

According to Reay Tannahill (1988: 11), radishes, *R. sativus,* were part of the diet of prehistoric hunter–gatherer cultures of Europe and have been grown and eaten, especially pickled, in the Orient for thousands of years. Because of the radish's antiquity and the many varieties that have been cultivated all over the Old World, including the Orient, its precise origin is obscure. Early radishes were probably large enough to be used as a food and not merely as a salad decoration or appetizer. The leaves may also have been eaten as greens (Brothwell and Brothwell 1969: 110).

Cultivated radish varieties were transported across Asia to Egypt about 4,000 years ago, where the Egyptians "ate radish roots as vegetables and made oil from the seeds" (Fenton and Kitchen 1956: 69; see also Darby, Ghalioungui, and Grivetti 1977, II: 664). Two radishes were discovered in the necropolis of Illahoun (Twelfth Dynasty), and the leaves and roots of the specific Egyptian radish variety *aegyptiacus* have been identified (Darby et al. 1977: 664). Fenton and Kitchen claimed that pictures of radishes were chiseled into the walls of a temple at Karnak, on the River Nile (Fenton and Kitchen 1956: 69). According to William J. Darby, Paul Ghalioungui, and Louis Grivetti, however, the evidence of radish use in ancient Egypt is primarily literary, particularly from Pliny's *Natural History.* They pointed out that in all likelihood radishes in Egypt were valued for oil produced from their seeds rather than as a food product. The Egyptians also considered the radish to be of medicinal value in curing a now unknown disease called *Phtheiriasis.* Poorer Egyptians employed radish oil as an inexpensive method of embalming, using it as an enema for emptying the intestines (Darby et al. 1977: 664, 785).

Theophrastus observed that in ancient Greece there existed five varieties of radishes: 'Corinthian', 'Cleonae', 'Leiothasian', 'Amorea', and 'Boeotian'. He noted that those types with smooth leaves had a sweeter and more pleasant taste, and those having rough leaves tasted sharp. Unfortunately, he did not associate varieties with leaf type (Theophrastus 1977, 2: 81–3). Fenton and Kitchen suggested that the Greeks were so fond of radishes that they used golden dishes to offer them to their god Apollo, whereas silver dishes were sufficient for beets, and turnips warranted only bowls of lead (Fenton and Kitchen 1956: 69).

Columella's instructions about the cultivation of radishes establishes their presence in Rome (Columella 1960, 3: 157, 165–9), and Pliny also wrote about the common use of radishes. He indicated that they were grown extensively for their seed oil, but that as a food, he found them a "vulgar article of diet" that "have a remarkable power of causing flatulence and eructation" (Brothwell and Brothwell 1969: 110).

Radishes were introduced to England by the occupying Romans and were known to Anglo-Saxon and Germanic peoples by the early medieval era. Like cabbage, radishes were common in English kitchen gardens by the fifteenth century (Wilson 1974: 196–7, 205), and they reached England's American colonies early in the seventeenth century. Europeans occasionally ate raw radishes with bread, but more common was the use of the roots in a sauce served with meat to stimulate the appetite. So highly did the great Italian composer Gioacchino Rossini regard radishes that they were one of the *Four Hors d'Oeuvres* in his famous opera. For others, however, radishes have inspired mistrust. A *Plague Pamphlet,* printed in London in 1665, noted that the appearance of the dread disease was the result of "eating radishes, a cat catter wouling, . . . immoderate eating of caviare and anchoves, tame pigeons that flew up and down an alley, [and] drinking strong heady beer" (Carcione and Lucas 1972: 104).

Radishes are used today mostly as an appetizer and in salads, and sometimes the young, tender leaves are boiled and served as greens. Radish varieties are numerous, and they come in many sizes (ranging from cherry- to basketball-size), shapes (round, oval, or oblong), and colors (white, red and white, solid red, or black). But their flavors are very similar. Most common in the United States are small, round, red or white varieties, including 'Cherry Belle' and 'Comet'. The 'White Icicle' is a long and narrow white radish. Oriental radishes are the most spectacular, with some, like the Japanese daikon, reaching several feet in length (Fenton and Kitchen 1956: 69; Carcione and Lucas 1972: 104). Europeans grow large, hot-tasting winter radishes, which they store in cool, dark cellars and eat during cold weather. According to an old description, winter radishes could reach a weight of 100 pounds (Fenton and Kitchen 1956: 69). Methods of serving radishes in the various parts of Asia include pickling them in brine, boiling them like potatoes, eating them raw, and cooking them as fresh vegetables (Fenton and Kitchen 1956: 69–70).

Turnip

Grown since ancient times, the turnip, *B. rapa* or *B. campestris,* has long been prized as a staple winter food, and in some areas it has been the only winter produce available. According to Brothwell and Brothwell, turnip varieties seem to have been indigenous to the region between the Baltic Sea and the Caucasus, later spreading to Europe (Brothwell and Brothwell 1969: 110). Today turnips continue to grow wild in eastern Europe and Siberia. They are almost perfectly round and have white flesh and thin, rough leaves covered by prickly hairs (Fenton and Kitchen 1956: 70). Their cultivation predates recorded history, and excellent storing qualities must have made the vegetable a dependable winter food for livestock as well as people (Brothwell and Brothwell 1969: 110–11).

In antiquity, the name "turnip" also referred to radishes and other root vegetables save leeks and onions (Darby et al. 1977, II: 665). Several varieties of turnips – round, long, and flat – were used by the Romans prior to the Christian Era. Greek and Roman writers indicated that the use was limited largely to "the poorer classes and country folk." Theophrastus wrote that there was disagreement over the number of varieties; he also provided some instructions for their cultivation. He stated that like the radish, the turnip's root grew best and sweetest in wintertime (Theophrastus 1977, 2: 83). Columella pointed out that turnips should not be overlooked as an important crop because they were a filling food for country people and a valuable source of fodder for livestock. In addition, Columella provided his readers with a recipe for pickling turnips in a mustard and vinegar liquid (Columella 1960, 1: 171, 3: 331–3). Apicius recommended mixing them with myrtle berries in vinegar and honey as a preservative. Pliny considered them the third most important agricultural product north of the Po River, and wrote that the leaves were also eaten. Especially interesting was his opinion that turnip tops were even better tasting when they were yellow and half dead (Pliny 1938, 5: 269–71; Brothwell and Brothwell 1969: 111).

The medieval chronicle *The Four Seasons* noted that if soaked in vinegar or brine, turnips could be preserved for up to a year. Sweet-tasting and thin-skinned types were considered the best. Medicinally, the turnip was believed good for the stomach, capable of relieving constipation, and effective as a diuretic. In preparing turnips, the advice was for prolonged cooking, even cooking them twice, to avoid indigestion, flatulence, and swelling. If these problems did occur, however, an emetic of vinegar and salt was recommended as a remedy (Spencer 1984: 109).

Like cabbage and radishes, turnips were a part of vegetable gardens in Roman Britain. By A.D. 1400, they were common in France, Holland, and Belgium, and at that date were among a quite small number of vegetables that had been known and available in northern Europe for centuries (Fenton and Kitchen 1956: 70; Carcione and Lucas 1972: 123). Explorers and colonists brought turnips to North America in the late sixteenth and early seventeenth centuries, where, because they flourish in cool weather, they became a summer crop in the north and a winter crop in the south. Modern varieties are generally less than 5 inches thick, but a turnip weighing 100 pounds was once grown in California, and during the 1500s, most European turnips weighed 30 to 40 pounds (Fenton and Kitchen 1956: 71). Commercially, there are many varieties grown today, and although shape and skin color may differ, like radishes the taste remains the same. The 'Purple-Top White Globe' and the 'Purple-Top Milan' are grown for their roots, and *'Shogoin',* an Oriental variety, is harvested for its tender greens (Carcione and Lucas 1972: 123–4).

Rutabaga

Rutabagas are occasionally referred to as "Swede turnips" or just "Swedes" because they were developed and grown in Sweden before A.D. 1400. According to Carcione and Lucas (1972: 123), rutabagas appear to be "the result of a meeting of a swinging Swedish turnip and an equally willing cabbage." Although closely related to the turnip, the rutabaga, *B. napobrassica,* is a relatively modern vegetable that is larger and longer than the turnip, with a milder taste and flesh that is yellow-colored rather than white. In addition, its leaves are smooth and thick, whereas turnip leaves are thin, rough, and prickly (Fenton and Kitchen 1956: 70). Cattle and pigs feed on raw rutabagas, but people eat the roots boiled and buttered (Fenton and Kitchen 1956: 71; Drummond and Wilbraham 1991: 180).

Rutabagas spread from Sweden to central Europe and the northern regions of Italy, where in medieval times they were called "Swedes" and housewives were advised to accept only those that were garden-fresh. Although "Swedes" reputedly bloated the stomach, they were delicious when prepared with meat broth. Moreover, they were thought to "activate the bladder," and "if eaten with herbs and abundant pepper, they arouse young men to heights of sexual adventurousness" (Spencer 1984: 58).

Rutabagas were cultivated prior to 1650 in Bohemia, and in 1755 they were introduced to England and Scotland from Holland, where they were initially referred to as "turnip-rooted cabbage," "Swedes," or "Swedish turnips." American gardeners were growing rutabagas by 1806, and today, Canada – along with the states of Washington and Oregon – supplies the United States with rutabagas, which explains their often being called "Canadian turnips" by Americans. Two of the best-known rutabaga types are the 'Laurentian' and the 'Purple-Top Yellow' (Carcione and Lucas 1972: 123–4).

Watercress

Native to Asia Minor and the Mediterranean region, watercress *(Nasturtium officinale)* grows wild wherever shallow moving water is found. It is characterized by long stems and small thick leaves (Carcione and Lucas 1972: 126). According to Brothwell and Brothwell, the Romans consumed watercress with vinegar to help cure unspecified mental problems, and both Xenophon, the ancient Greek general, and the Persian King Xerxes required their soldiers to eat the plant in order to maintain their health (Brothwell and Brothwell 1969: 122; Carcione and Lucas 1972: 126). Ancient cress seeds found in Egypt probably arrived from Greece and Syria, where cress is found among a list of Assyrian plants. Dioscorides maintained that watercress came from Babylon (Brothwell and Brothwell 1969: 122–3).

Stronger-flavored kinds of watercress were preferred in medieval Italy, where they allegedly provided a variety of medicinal benefits. Although watercress was blamed for headaches, it supposedly strengthened the blood, aroused desire, cured children's coughs, whitened scars, and lightened freckles. Additionally, three leaves "picked with the left hand and eaten immediately will cure an overflow of bile" (Spencer 1984: 19).

Cultivation of watercress for sale in markets dates to about 1800 in England, although wild watercress was doubtless gathered by humans for many millennia. Brought to the United States by early settlers, watercress can now be found throughout the country. Soil-cultivated relatives of watercress include peppergrass (also called curly cress), upland cress, lamb's cress, cuckoo flower, lady's smock, mayflower, pennycress, and nasturtiums (Carcione and Lucas 1972: 126).

Nutrition, Disease Prevention, and Cruciferous Vegetables

Cruciferous vegetables have substantial nutritional value. They contain significant amounts of beta-carotene (the precursor of vitamin A), vitamin C (ascorbic acid), and "nonnutritive chemicals" such as indoles, flavones, and isothiocyanates, which contribute to the prevention of diet-related diseases and disorders such as blindness and scurvy. In addition, recent investigations have shown them to be effective in warding off several types of cancer. Studies have linked diets high in vitamin A to cancer prevention, and research also indicates that chemicals like indoles inhibit the effects of carcinogens. Vitamin C is recognized as an effective antioxidant, which is thought to be preventive against the development of some cancers and an inhibitor of the progress of the human immunodeficiency virus (HIV).

Moreover, the substances known as antioxidants are critical in the maintenance of homeostasis, a state of physiological equilibrium among the body's functions and its chemical components. Molecules that form the human body are typically held together by the magnetic attraction between their electrons. Occasionally, however, these molecules exist in an oxidized state, meaning that they have unpaired electrons and are seeking out "molecular partners," often with potentially harmful effects. In this condition, these molecules are known as "free radicals," and because they can react more freely with their surrounding environment, they are capable of disrupting many finely tuned processes essential in maintaining good health. In some cases, free radicals serve no particular function and are simply the waste products of bodily processes, but in others, the body's immune system uses them to fight diseases. Yet even when useful, free radicals can damage nearby tissue and impair bodily functions. To control such damage, the human body uses antioxidants to neutralize the effects of free radicals. Unfortunately, there are often inadequate amounts of antioxidants to eliminate all of the free radicals, and there are also periods or conditions during which the number of free radicals increases along with the damage they inflict. This is particularly true when people are infected with HIV or have developed cancer (Romeyn 1995: 42–3).

In the cases of both HIV and cancer, vitamin C reacts with and neutralizes free radicals. This vitamin also helps increase the overall antioxidant ability of vitamin E by preventing certain functions of vitamin E that can actually inhibit the effects of its antioxidant characteristics. Specifically with regard to cancer prevention, vitamin C, of which cruciferous vegetables have high levels, appears to significantly reduce the risk of contracting stomach or esophageal cancers. Other, less conclusive studies suggest that vitamin C may also inhibit the development of bladder and colon cancer. In addition to its role as an antioxidant, vitamin C acts to inhibit the formation of cancer-causing nitrosamines, which are created by cooking or by digesting nitrites found in food.

In citing over a dozen studies worldwide, Patricia Hausman (1983: 24–5) noted that diets rich in vitamin A provide a surprising amount of protection from cancer in eight different organs. The strongest evidence links vitamin A to the prevention of lung, stomach, and esophageal cancer. Although less conclusive, other studies have recognized the potential of vitamin A to protect against cancer of the mouth, colon, rectum, prostate, and bladder.

The term, "vitamin A", encompasses many substances that can fulfill the body's requirements for this nutrient. Retinol is the form found in foods derived from animal products. Beta-carotene and carotenoids are found in fruits and vegetables; however, carotenoids are only a minor source. For most bodily functions that require vitamin A, any one of these forms will suffice, but it is beta-carotene that is tied most closely to cancer prevention (Hausman 1983: 24–5).

Although it is unclear how beta-carotene aids in the prevention of cancer, some chemists have suggested that it might act as an antioxidant. However, Eileen Jennings has noted that there is little doubt concerning the significance of vitamin A as it relates to gene regulation: "The gene regulator and antiproliferation effects of vitamin A may be the entire explanation for the anticancer effect of vitamin A" (1993: 149). Although the final determination of beta-carotene's antioxidant qualities awaits further study, its ability to act as a cancer preventive has been demonstrated, and thus, it is recommended that the cruciferous vegetables containing high levels of this substance be eaten frequently.

Scientific studies also have demonstrated that cruciferous vegetables further limit cancerous growth because they contain small quantities of indoles, flavones, and isothiocyanates. According to Jennings, these nonnutritive chemicals have been shown "to either stimulate production of enzymes that convert toxic chemicals to less toxic forms or interfere with the reaction of carcinogens with DNA" (1993: 223). Hausman (1983: 82–3) wrote that the enzyme system that produces these cancer inhibitors is recognized as the "mixed function oxidase system." Because the family of cruciferous vegetables contains such high levels of these inhibitors, particularly indoles as well as high levels of beta-carotene and vitamin C, the Committee on Diet, Nutrition, and Cancer of the National Academy of Sciences in 1982 emphasized eating these vegetables often. Broccoli, cauliflower, Brussels sprouts, and cabbage have all been linked to lowering the risk of developing stomach and colon cancer, and some studies indicated a possible connection to a reduced risk of rectal cancer.

The absence of beta-carotene and vitamin C in the diet is also linked to the development of deficiency diseases such as "night blindness" and scurvy. Because of the unavailability of fruits or cruciferous vegetables and other foods containing these nutrients, in many parts of the developing world deficiency diseases remain common. Extended vitamin A deficiency results in a severe defect called xerophthalmia, which affects the cornea of the eye. More often this deficiency causes "night blindness," or nyctalopia, which is the inability to see in a dim light. This problem has been very common in the East for several centuries, and according to Magnus Pyke (1970: 104, 127), at least until the past two or three decades, vitamin A deficiency annually caused thousands of cases of blindness in India.

The earliest prescribed treatment of an eye disorder thought to be night blindness is found in the Ebers Papyrus, an Egyptian medical treatise dating from around 1600 B.C. Rather than prescribing the regular consumption of cruciferous vegetables, however, it suggested using ox liver, itself high in vitamin A, which it claimed was "very effective and quick-acting." Hippocrates and Galen were also familiar with night blindness, the former recommending the consumption of ox liver (in honey) as a remedy. Later Roman medical writings gave similar advice, and Chinese literature contained descriptions of this eye condition by A.D. 610 (Brothwell and Brothwell 1969: 179–80). As already noted, the work on foods in medieval Italy, *The Four Seasons,* contended that the cooked juice of cabbage mixed with honey and used sparingly as an eyedrop improved vision (Spencer 1984: 102).

Like night blindness, scurvy, a disease caused by an insufficient intake of vitamin C, continues to be a serious deficiency disease of the developing world. One of the primary functions of vitamin C is the production of collagen, which helps to build new tissue, in a sense maintaining the very structure of the human body. It can reduce lung tissue damage caused by the activation of the body's immune system and is important to the production of hormones, steroids, and neurotransmitters. It is also required for the "conversion of folate into its active form" and aids in iron absorption (Pyke 1970: 114; Hausman 1983: 43; Romeyn 1995: 44–5). A prolonged lack of vitamin C causes the weakening and breakdown of the body's cell structure and tissue, with scurvy the visible symptom of this phenomenon.

Interestingly, humans are susceptible to scurvy only because of an unfortunate biochemical shortcoming in their genetic makeup. Unlike most animals, humans and four other species are unable to synthesize vitamin C and therefore will suffer from scurvy if the vitamin C intake from their food is insufficient for a long enough period of time (Pyke 1970: 115).

Brothwell and Brothwell suggest that deficiencies in vitamin C were rare prior to the appearance of urban development (beginning in the Neolithic era) because hunter-gatherers had more diversity in their diet. Hippocrates has been credited with the earliest mention of scurvy when he described an unpleasant condition characterized by "frequent haemorrhages" and "repulsive ulceration of the gums" – both features of the disease. Pliny also acknowledged the presence of this condition (which he called *stomacace*) in Roman troops stationed in the Rhine region. Writings from the Middle Ages contain many references to scurvy as well, implying that it was prevalent in the Europe of that era (Brothwell and Brothwell 1969: 181).

Before the introduction of the white potato, the disease was common in the spring in the northern countries of Europe. It has also ravaged sailors during long sea voyages, as well as arctic explorers whose provisions consisted mostly of easily preserved food and lacked fresh fruits and vegetables (Pyke 1970: 113–14). But although the disease is of "considerable antiquity," scurvy occurs infrequently today despite the large numbers of underfed and malnourished people in the world because it is a disease that requires an unusual state of deprivation (Pyke 1970: 112). However, scurvy in children has been reported in recent years in Toronto, Canada, in many communities in India, and in Glasgow, Scotland, and "bachelor scurvy" can occur in instances where older men who live alone fail to consume meals with adequate quantities of vegetables (Pyke 1970: 115).

In order to improve nutritional levels in humans and thus prevent deficiency diseases, as well as improve overall health, Henry M. Munger (1988) has suggested that instead of breeding crops to increase nutrient levels, a more effective, and less expensive, solution is to increase consumption of plants already high in nutritional value. He offered broccoli as an example. Relatively unknown in the United States 50 years ago, broccoli has experienced a dramatic increase in its production, from approximately 200 million pounds in the 1950s to over a billion pounds in 1985. In a 1974 study by M. Allen Stevens on *Nutritional Qualities of Fresh Fruits and Vegetables* that compares the nutritional values of common fruits and vegetables, broccoli was ranked highest in nutritional value because of its substantial content of vitamins A and C, niacin, riboflavin, and nearly every mineral. Additionally, "based on dry weight, broccoli contains protein levels similar to soybean" (Stevens 1974: 89). In an earlier study by Stevens, however, broccoli was ranked twenty-first in contribution to nutrition, based on a formula derived from its production as well as its nutrient content. But by 1981, that ranking had risen to seventh, a direct result of its increased production and consumption levels (Stevens 1974: 89–90; Munger 1988: 179–80).

Munger has maintained that improved nutrition in tropical developing countries can be achieved by adapting nutritious, temperate crops to tropical conditions or by expanding the use of less familiar, highly nutritious tropical vegetables. Two of his primary illustrations involve cruciferous vegetables. In the first case he cited an adaptation of Japanese cabbage hybrids for cultivation in the more tropical lowlands of the Philippines. This move lowered production costs and made cabbage more accessible and affordable to the general population. A second example, *choi-sum* or Flowering White Cabbage, a variety of *B. campestris,* is similar to broccoli and grown near Canton, China. Nearly all parts of this highly nutritious plant are edible. It can be planted and harvested year-round, and its production yield is comparable to that of potatoes and corn in the United States. Because of its efficient production and high nutrient concentration, *choi-sum* also seems to Munger a good candidate for promotion in tropical developing nations (Munger 1988: 180–1, 183).

Summary

The cruciferous family of vegetables includes some of the most nutritionally significant foods produced today. Predominantly European and Asian in origin, these vegetables have a history of cultivation and use that spans many centuries. The ancient Greeks and Romans employed some of them not only as foodstuffs but also for medicinal purposes. They believed that cabbage, for example, could cure a wide range of ailments, from healing wounds to correcting problems with internal organs. In medieval and Renaissance Europe as well as in Russia and China, cruciferous vegetables were found in kitchen gardens and composed an important part of the daily diet. Gradually they were transformed from garden produce into commercial crops and today are abundantly available for sustenance and for good health. Contemporary research suggests a link between cruciferous vegetables and disease prevention. Because of their high levels of vitamin C, beta-carotene, and other disease inhibitors, these food plants help avoid deficiency diseases, prevent some cancers, and retard the development of HIV in the human body. Such findings suggest that the consumption of cruciferous vegetables has a positive effect on health, and consequently they should have a prominent place in the human diet.

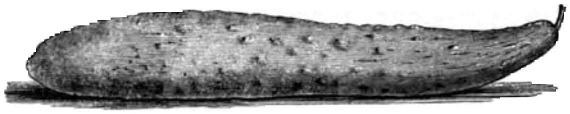
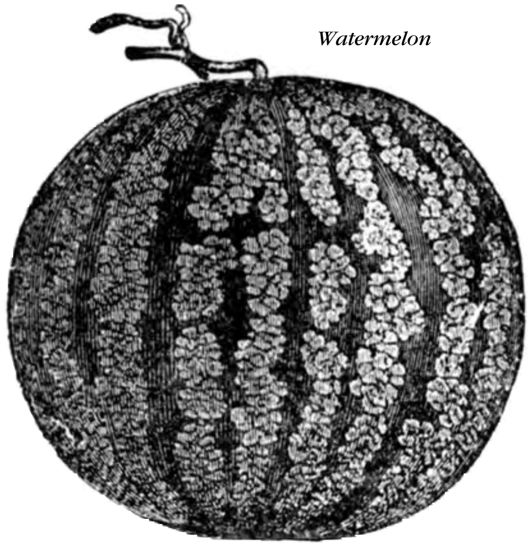
II.C.6 Cucumbers, Melons, and Watermelons

Our focus here is on three important cucurbits – cucumber, melon, and watermelon – although cucurbits of less significance such as the citron, bur (or West India gherkin), and some lesser-known melons are also briefly discussed. These plants, together with all the sundry squashes and pumpkins, constitute a taxonomic group of diverse origin and genetic composition with considerable impact on human nutrition. The term "cucurbit" denotes all species within the Cucurbitaceae family.



Cucumber



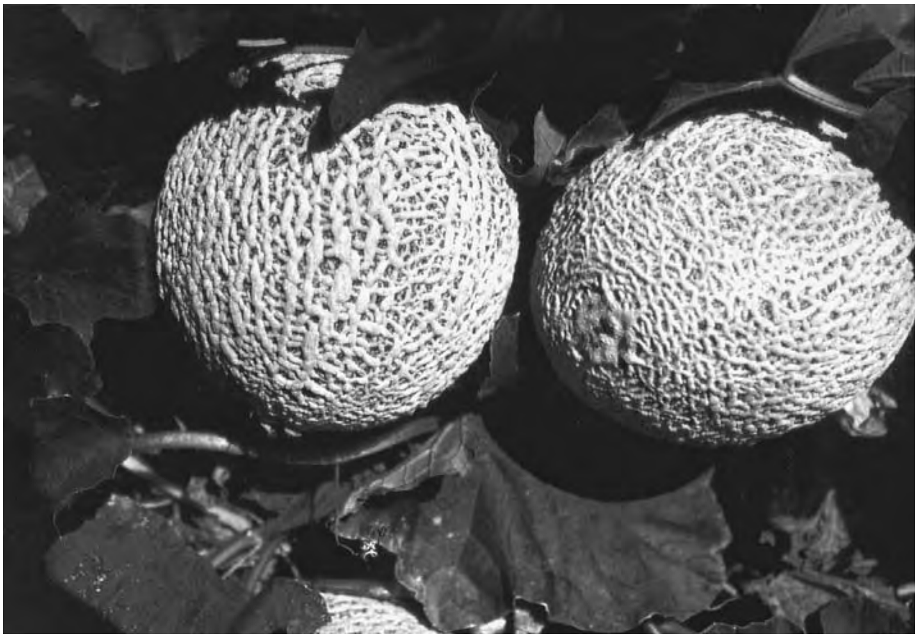
Cucurbits are found throughout the tropics and subtropics of Africa, southeastern Asia, and the Americas. Some are adapted to humid conditions and others are found in arid areas. Most are frost-intolerant so they are grown with protection in temperate areas or to coincide with the warm portion of the annual cycle. Cucurbits are mostly annual, herbaceous, tendril-bearing vines.

The significance of cucurbits in human affairs is illustrated by the abundance of literature devoted to them, albeit much less than that produced on the grains and pulses. Two full-length books have cucurbits as the title (Whitaker and Davis 1962; Robinson and Decker-Walters 1997), and at least four significant publications have been derived from recent conferences on these plants (Thomas 1989; Bates, Robinson and Jeffrey 1990; Lester and Dunlap 1994; Gómez-Guillamón et al. 1996). Moreover, a recent reference book provides an inclusive chapter on cucurbits (Rubatzky and Yamaguchi 1997) and an annual publication is dedicated to their genetics (Ng 1996).

Taxonomy

The Cucurbitaceae family is well defined but taxonomically isolated from other plant families. Two subfamilies – Zanonioideae and Cucurbitoideae – are well characterized: the former by small, striate pollen grains and the latter by having the styles united into a single column. The food plants all fall within the subfamily Cucurbitoideae. Further definition finds cucumber *(Cucumis sativus L.)* and melon *(Cucumis melo L.)* to be within the subtribe Cucumerinae, tribe Melothrieae, and watermelon (*Citrullus lanatus* [Thunb.] Matsum. and Nakai.) is assigned to the tribe Benincaseae, subtribe Benincasinae. The taxonomic sites of West India gherkin (*Cucumis anguria* L.) and citron (*Citrullus lanatus* var. *citroides* [L.H. Bailey] Mansf.) are, as with those just listed, in the same genus. There are about 118 genera and over 800 species in the Cucurbitaceae (Jeffrey 1990a). The melons *(C. melo)* are further subdivided into groups that do not have taxonomic standing but have proved useful horticulturally (Munger and Robinson 1991):

Figure II.C.6.1. Netted cantaloupe fruit.



The Cantalupensis group includes cantaloupe, muskmelon (Figure II.C.6.1), and Persian melon. The fruit are oval or round; sutured or smooth; mostly netted, some slightly netted or nonnetted; and abscise from the peduncle when mature. The flesh is usually salmon or orange colored, but may be green and is aromatic. In the United States, the term "muskmelon" and "cantaloupe" may be used interchangeably, but some horticultural scientists (Maynard and Elmstrom 1991: 229) suggest that they be used to distinguish between types of *C. melo* Cantalupensis group. This group includes the previously recognized Reticulatus group.

The Inodorus group consists of winter melon, casaba (Figure II.C.6.2), crenshaw, honeydew, Juan Canary (Figure II.C.6.3), and Santa Claus (Figure II.C.6.4). The fruit are round or irregular, smooth or wrinkled, but not netted; nor do they abscise from the peduncle at maturity. The flesh is mostly green or white, occasionally orange, and not aromatic.

The Flexuosus group is made up of the snake or serpent melon and the Armenian cucumber. The fruit are quite long, thin, ribbed, and often curled irregularly.

The Conomon group comprises the oriental pickling melon. This fruit is smooth, cylindrical, and may be green, white, or striped. The flesh is white and can taste either sweet or bland.

The Dudaim group includes mango melon, pomegranate melon, and Queen Anne's melon. The fruit are small, round to oval, and light green, yellow, or striped. The flesh is firm and yellowish-white in color.

The Mormordica group is made up of the phoot and snap melon. The fruit are oval or cylindrical with smooth skin that cracks as the fruit matures.

Plant and Fruit Morphology

Cucumber, melon, and watermelon plants share many characteristics but also differ in important ways. As a group they are frost-sensitive annuals with trailing, tendril-bearing vines. The plants are mostly monoecious, the flowers are insect-pollinated, and the fruits are variously shaped, many-seeded berries.

Cucumber

Cucumber plants are annual and may be monoecious, andromonoecious, or gynoecious. They have indeterminate trailing vines with angled, hairy stems bearing triangular-ovate, acute three-lobed leaves. Determinate types with compact plants have been developed for gardens. In monoecious types, staminate flowers appear first and are several times more abundant than pistillate flowers. Flowers occur at the nodes, staminate in clusters or singly close to the plant crown with only one flower of the cluster opening on a single day; pistillate flowers are borne singly on the main stem and lateral branches in monoecious types (Figure II.C.6.5) and singly or in clusters on the main stem and lateral branches on gynoecious types. Pistillate flowers are identified easily by the large inferior ovary that is a miniature cucumber fruit. Both staminate and pistillate flowers are large (2 to 3 centimeters [cm] in diameter) with a yellow, showy five-parted corolla. Fruits of commercial types are

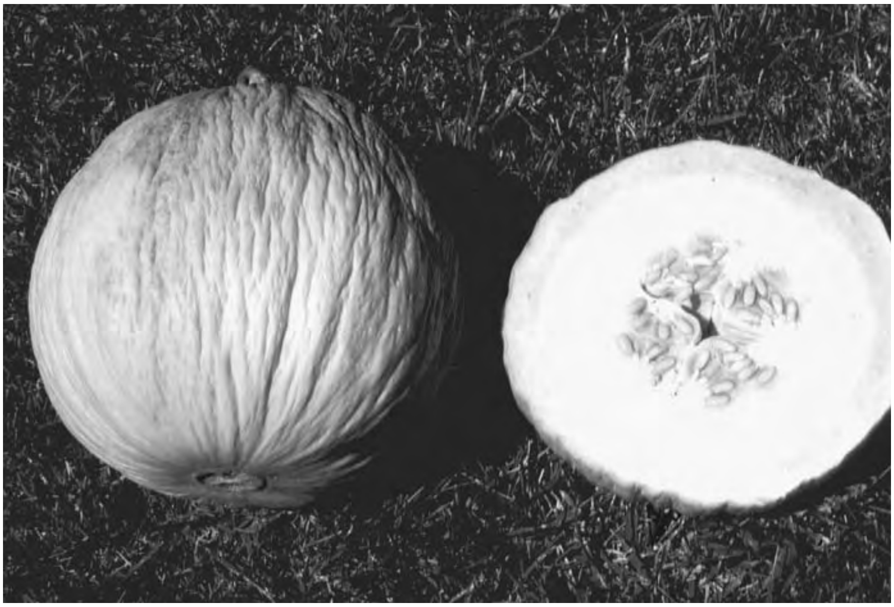


Figure II.C.6.2. Casaba melon.

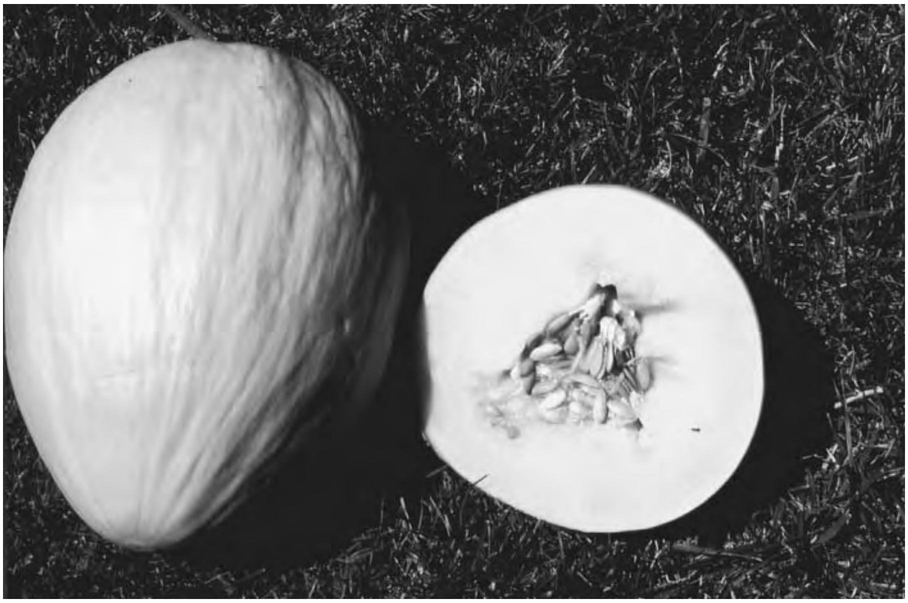

Figure II.C.6.3. Juan Canary melon.

cylindrical and green when consumed at the immature, edible stage (Figure II.C.6.6). The fruit surface is interrupted with tubercle-bearing white or black spines. White spines are typical of fruit used for fresh consumption that, if allowed to attain maturity, will be yellow, whereas black-spined fruit is often used for processing (pickles) and is orange at maturity.

Seedless or parthenocarpic cucumbers are another distinctive type. The plants are gynoecious with a fruit borne at each axil (Figure II.C.6.7). They are grown on a trellis in protected, screened culture to prevent bees from introducing foreign pollen, which would cause seeds to develop. Fruits are long, straight, smooth, thin-skinned, and medium to dark-green in color. A slightly restricted "neck" at the stem end of the fruit serves to readily identify this unique type. Cucumber fruit destined for fresh markets has a length/diameter ratio of about 4:1; that used for pickle production has a ratio of about 2:5, whereas parthenocarpic fruit have a ratio of about 6:1. Seeds are about 8 millimeters (mm) long, oval, and white (Lower and Edwards 1986: 173–81).

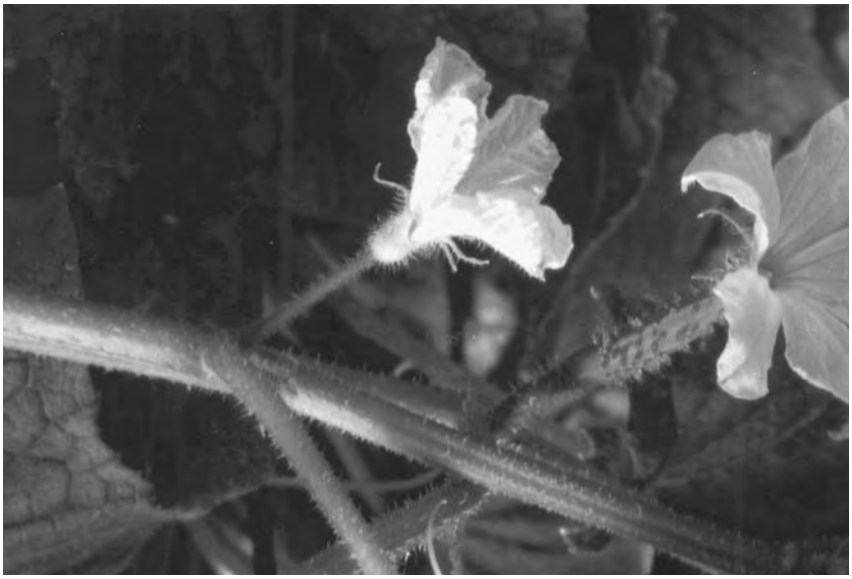

Figure II.C.6.5. Pistillate and staminate cucumber flowers (Courtesy of National Garden Bureau, Downers Grove, Ill.)

West India Gherkin

These plants are annual, monoecious climbing vines with flowers, leaves, tendrils, and fruit smaller than those of cucumber. Fruits, which are spiny, yellow, oval, and about 5 cm long, are eaten fresh, cooked, or pickled. The plant may self-seed, escape from cultivation, and become an aggressive weed.

Melon

Melons are mostly andromonoecious and have annual trailing vines with nearly round stems bearing tendrils and circular to oval leaves with shallow lobes. Staminate flowers are borne in axillary clusters on the main stem, and perfect flowers are borne at the first node of lateral branches. Fruits vary in size, shape, rind characteristics, and flesh color depending on variety. Fruit quality is related to external appearance, thick, well-colored interior flesh with high (>10 percent) soluble solids, and a pleasant aroma and taste (Maynard and Elmstrom 1991: 229). It is a common misconception that poor-quality melon fruit results from cross-pollination with cucumber because these species are incompatible. Rather, the poor-quality melon fruit sometimes encountered is due to unfavorable weather or grow-

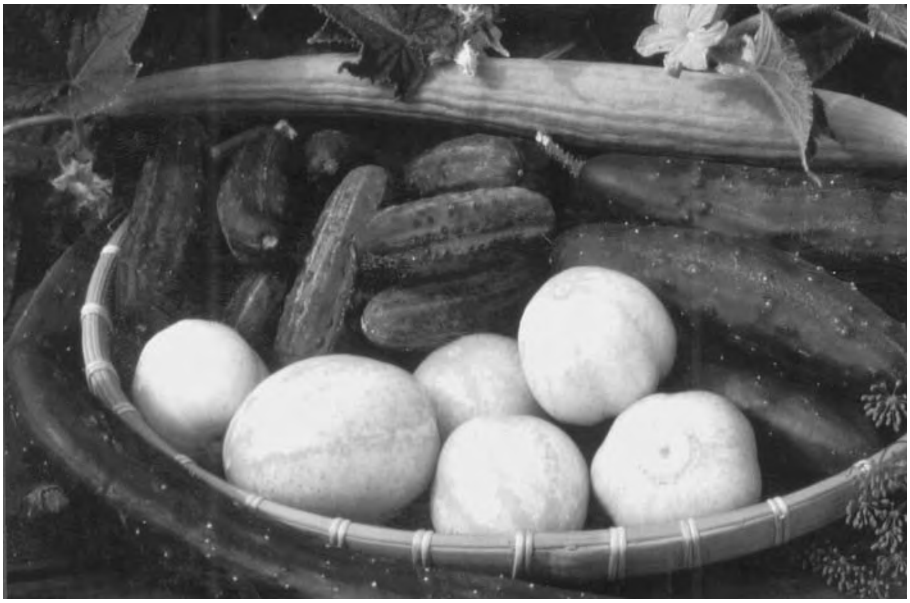

Figure II.C.6.6. Cucumbers: commercial fresh-market type (right), pickling type (left), lemon cucumber (foreground), Armenian cucumber, which is a melon, *C. melo* (background). (Courtesy of National Garden Bureau, Downers Grove, Ill.)

ing conditions that restrict photosynthetic activity and, thereby, sugar content of the fruit. Seeds are cream-colored, oval, and on average 10 mm long.

Watermelon

These plants are monoecious, annual, and have trailing thin and angular vines that bear pinnatifide leaves. Flowers are solitary in leaf axils. Staminate flowers appear first and greatly outnumber pistillate flowers. The flowers are pollinated mostly by honeybees. Fruit may range in size from about 1 kilogram (kg) to as much as 100 kg, but ordinary cultivated types are 3 to 13 kg. Shape varies from round to oval to elongated. Coloration of the rind may be light green, often termed gray, to very dark green, appearing to be almost black (Figure II.C.6.8). In addition, the rind may have stripes of various designs that are typical of a variety or type; thus the terms "Jubilee-type stripe" or "Allsweet-type stripe" are used to identify various patterns. Seed color and size is variable. The tendency in varietal development is to strive for seeds that are small (but vigorous enough for germination under unfavorable conditions) and that are dark-colored rather than white – the latter are associated with immaturity. Flesh may be white, green, yellow, orange, pink, or red. Consumers in developed countries demand red- or deep pink–fleshed watermelons, although yellow-fleshed ones are grown in home gardens and, to a limited extent, commercially (Mohr 1986).

Seedless watermelon. Each fruit of standard-seeded watermelon varieties may contain as many as 1,000 seeds (Figure II.C.6.9) and their presence throughout the flesh makes removal difficult.

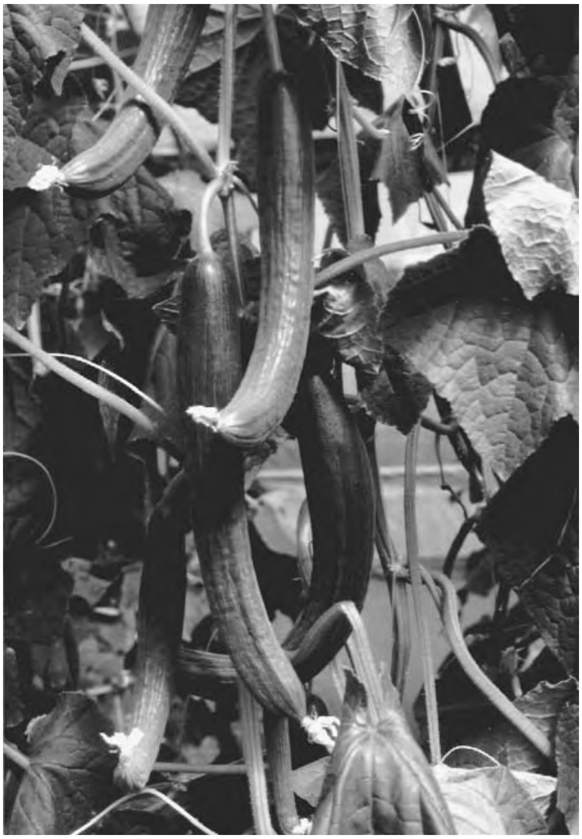

Figure II.C.6.7. Gynoecious, parthenocarpic greenhouse cucumbers.

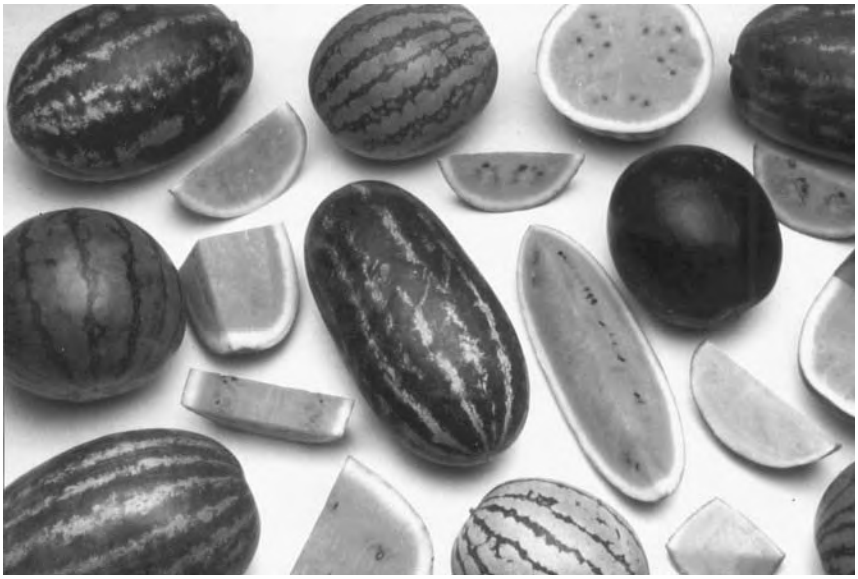

Figure II.C.6.8. Variation in watermelon fruit size, shape, and color and flesh color. (Courtesy of National Garden Bureau, Downers Grove, Ill.)

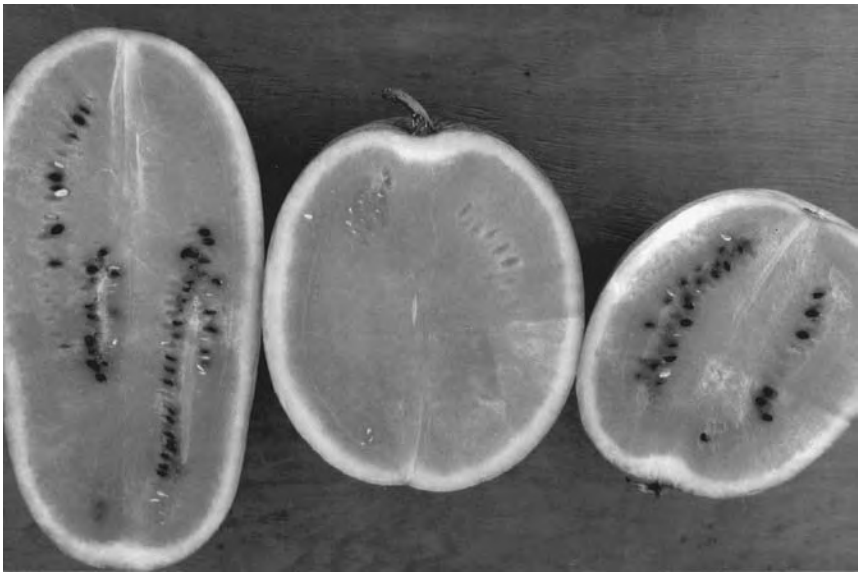

Figure II.C.6.9. Seedless watermelon (center) with seeded watermelon (left and right).

Hybrid seedless (triploid) watermelons have been grown for over 40 years in the United States. However, only recently have improved varieties, aggressive marketing, and increased consumer demand created a rapidly expanding market for them. The seedless condition is actually sterility resulting from a cross between two plants of incompatible chromosome complements. The normal chromosome number in most living organisms is referred to as $2n$. Seedless watermelons are produced on highly sterile triploid ($3n$) plants, which result from crossing a normal diploid ($2n$) plant with a tetraploid ($4n$). The tetraploid is used as the female or seed parent and the diploid is the male or pollen parent. Since the tetraploid seed parent produces only 5 to 10 percent as many seeds as a normal diploid plant, seed cost is 10 to 100 times more than that of standard, open-pollinated varieties and 5 to 10 times that of hybrid diploid watermelon varieties.

Tetraploid lines, usually developed by treating diploid plants with a chemical called colchicine, normally have a light, medium, or dark-green rind without stripes. By contrast, the diploid pollen parent almost always has a fruit with a striped rind. The resulting hybrid triploid seedless melon will inherit the striped pattern, though growers may occasionally find a nonstriped fruit in fields of striped seedless watermelons, the result of accidental self-pollination of the tetraploid seed parent during triploid seed production. The amount of tetraploid contamination depends upon the methods and care employed in triploid seed production. Sterile triploid plants normally do not produce viable seed. However, small, white rudimentary seeds or seed coats, which are eaten along with the fruits as in cucumber, develop within the fruit. The number and size of these rudimentary seeds vary with the variety. An occasional dark, hard, viable seed is found in triploid melons. Seedless watermelons can be grown successfully in areas where conventional seeded varieties are produced, although they require some very unique cultural practices for successful production (Maynard 1996: 1–2). With proper care, such watermelons have a longer shelf life than seeded counterparts. This may be due to the fact that flesh breakdown occurs in the vicinity of seeds, which are absent in seedless melons.

Citron

The citron plants resemble those of watermelon except that their leaves are broader and less pinnate. The fruits also resemble watermelon externally, but the rind is quite hard and the flesh is white to light green and may be quite bitter. Because fruit rinds are used to make pickles and are also candied, the citron is also called a "preserving melon." Plants escaped from cultivation may prove to be aggressive weeds in crop fields.

History and Ethnography of Production and Consumption

Relatively little research literature in cultural anthropology, archaeology, or social history focuses specifically on the species of cultivated cucurbits under consideration here. Indeed, some classic as well as recent important texts on the origins of agriculture make no mention of them (Reed 1977; Smith 1995). There are at least four reasons for this lacuna. First, these cultigens are not part of the complex carbohydrate "cores" of the diets found in centers of state formation (see Mintz 1996) and thus have not received the same attention as other staple food crops. Second, the primary centers of domestication for both melon and watermelon are in sub-Saharan Africa, where the exact timing, locations, and processes of domestication are still poorly understood (see Cowan and Watson 1992). Third, some researchers suggest that "cucurbits are usually poorly preserved among archaeological remains. The features considered most indicative of domestication are characteristics of the peduncle (stem), which is rarely preserved. The earliest remains are seed specimens, which often occur in extremely low frequencies because they are likely to have been consumed" (McClung de Tapia 1992: 153). Finally, the ethnographic record contains limited data on the production and consumption of these crops (with a few notable exceptions), reflecting their secondary significance both materially and symbolically in most human societies.

Cucumber

Cucumbers are generally believed to have originated in India, and archaeological and linguistic evidence suggests that they have been cultivated throughout western Asia for at least 3,000 years (Hedrick 1919: 208; Whitaker and Davis 1962: 2–3; Sauer 1993: 45; Robinson and Decker-Walters 1997: 62). From India, the cucumber spread to Greece and Italy – where the crop was significant in the Roman Empire – and slightly later to China and southern Russia. In classical Rome, Pliny reported greenhouse production of cucumbers by the first century, and the Emperor Tiberius was said to have had them at his table throughout the year (Sauer 1993: 46). Cucumbers probably were diffused into the rest of Europe by the Romans and later throughout the New World via colonialism and indigenous trade networks. The earliest records of their cultivation appear in France by the ninth century, Great Britain by the fourteenth century, the Caribbean at the end of the fifteenth century, and North America by the middle of the sixteenth century (Hedrick 1919: 208).

Colonial encounters between Europeans and Native Americans resulted in the rapid diffusion of cucumbers throughout North America. The Spanish began growing them in Hispaniola by 1494, and less than a century later European explorers were noting that a wide range of Native American peoples from Montreal to New York, Virginia, and Florida were cultivating them, along with a large variety of other crops including maize, beans, squash, pumpkins, and gourds. By the seventeenth century, Native American groups on the Great Plains were also cultivating cucumbers – this in a region where the Spanish had been particularly significant in the diffusion of horses and guns, as well as Old World cultigens such as watermelons and cucumbers (see Wolf 1982).

Like other cucurbits, cucumbers have a wide range of consumption uses cross-culturally. They are generally eaten fresh or pickled and are particularly important in the diets of people living in Russia and East, South, and Southeast Asia, where they may also be served as a fresh or cooked vegetable. In India, the fruits are used in the preparation of chutney and curries. Cucumber seeds, young leaves, and cooked stems are also consumed in some parts of Asia.

In addition, since at least the nineteenth century, cucumbers have been used in the production of a large variety of cosmetics, including fragrances, body lotions, shampoos, and soaps (Robinson and Decker-Walters 1997: 63; Rubatzky and Yamaguchi 1997: 585).

Melon

Melon is generally thought to have originated in western Africa (Zeven and Zhukovsky 1975: 30; Bailey 1976: 342; Purseglove 1976: 294; Whitaker and Bemis 1976: 67), with China or India as possible secondary centers of diversity. Wild melons growing in natural habitats have been reported in desert and savanna zones of Africa, Arabia, southwestern Asia, and Australia. As Jonathan Sauer notes, it is unclear where melon was domesticated and "it is conceivable that it was independently domesticated from different wild populations in Africa and southwestern Asia" (Sauer 1993: 44). Melon was an important food crop in ancient China, where archaeological data suggest that it has been cultivated for over 5,000 years (Robinson and Decker-Walters 1997: 23). Archaeological evidence also suggests that melon was cultivated in Iran some 5,000 years ago and in Greece and Egypt about 4,000 years ago (Zohary and Hopf 1988). Given the fruit's probable African origin, this evidence points to a very early date for the first domestication of melon. Tropical forest swidden systems in Africa typically have yams or manioc as dominant staple food crops with melons among the numerous and multiple secondary crops (Harris 1976: 318).

As with cucumbers, melons were cultivated in the Roman Empire and diffused throughout Europe by the Middle Ages where the "variety and quality of melon cultivars were evidently greatly increased by selection in Medieval gardens" (Sauer 1993: 44). As with cucumbers and watermelons, melons were introduced to the New World by Spanish colonial settlers in the late fifteenth and early sixteenth centuries and subsequently spread very rapidly among Native American horticultural groups. Later during the eighteenth century they reached the Pacific Islanders via British explorers.

Ralf Norrman and Jon Haarberg (1980) explore the semiotic role of cucurbits in Western literature and culture and extend this analysis to selected non-Western cultural contexts. Focusing on melons, watermelons, and cucumbers (as well as other domesticated cucurbits), these authors note that cucurbits generally have deep, profound, and complex multivocal symbolic associations with sex and sexuality, fertility, vitality, moisture, abundance, opulence, luxury, gluttony, creative power, rapid growth, and sudden death. More specifically, they note that melons are highly associated with status in colder climate European societies because historically they were "seasonal, expensive and scarce, with all the symbolic development that a commodity with such characteristics usually goes through" (Norrman and Haarberg 1980: 16). Cucurbits also appear frequently in non-Western cosmologies, for example, "in Burmese and Laotian mythology, the creation of man started from a cucurbit" (Norrman and Haarberg 1980: 26). As with other key symbols marked by binary oppositions, symbolic meanings attached to cucurbits can also be employed to convey a broad variety of negative symbolic associations along race, class, and gender lines.

Melon has a large number of different cultivars and a range of cross-cultural consumption uses parallel to the other species of cucurbits discussed in this chapter. Fruits are typically eaten uncooked, although they may also be cooked or pickled in some Asian cuisines. The seeds of some cultivars are roasted and consumed in parts of India. Dried and ground melon seeds are used as food in some African societies. Melon fruits, roots, leaves, and seeds play important roles in the treatment of a wide range of health problems in Chinese traditional medicine (Robinson and Decker-Walters 1997: 69–70).

Watermelon

Watermelons, which were originally domesticated in central and southern Africa (Whitaker and Davis 1962: 2; Robinson and Decker-Walters 1997: 85), are an important part of the "most widespread and characteristic African agricultural complex adapted to savanna zones" in that they are not only a food plant but also a vital source of water in arid regions (Harlan, de Wet, and Stemler 1976; Harlan 1992: 64). Indeed, V. R. Rubatzky and M. Yamaguchi (1997: 603) refer to watermelons as "botanical canteens." In a number of traditional African cuisines, the seeds (rich in edible oils and protein) and flesh are used in cooking. Watermelon emerged as an important cultigen in northern Africa and southwestern Asia prior to 6,000 years ago (Robinson and Decker-Walters 1997: 24). Archaeological data suggest that they were cultivated in ancient Egypt more than 5,000 years ago, where representations of watermelons appeared on wall paintings and watermelon seeds and leaves were deposited in Egyptian tombs (Ficklen 1984: 8).

From their African origins, watermelons spread via trade routes throughout much of the world, reaching India by 800 and China by 1100. In both of these countries, as in Africa, the seeds are eaten and crushed for their edible oils. Watermelons became widely distributed along Mediterranean trade routes and were introduced into southern Europe by the Moorish conquerors of Spain, who left evidence of watermelon cultivation at Cordoba in 961 and Seville in 1158 (Watson 1983). Sauer notes that "watermelons spread slowly into other parts of Europe, perhaps largely because the summers are not generally hot enough for good yields. However, they began appearing in European herbals before 1600, and by 1625, the species was widely planted in Europe as a minor garden crop" (Sauer 1993: 42). Their first recorded appearance in Great Britain dates to 1597.

Watermelons reached the New World with European colonists and African slaves. Spanish settlers were producing watermelons in Florida by 1576, and by 1650 they were common in Panama, Peru, and Brazil, as well as in British and Dutch colonies throughout the New World (Sauer 1993: 43). The first recorded cultivation in British colonial North America dates to 1629 in Massachusetts (Hedrick 1919: 172).

Like cucumbers and melons, watermelons spread very rapidly among Native American groups. Prior to the beginning of the seventeenth century, they were being grown by tribes in the Ocmulgee region of Georgia, the Conchos nation of the Rio Grande valley, the Zuni and other Pueblo peoples of the Southwest, as well as by the Huron of eastern Canada and groups from the Great Lakes region (Blake 1981). By the mid-seventeenth century, Native Americans were cultivating them in Florida and the Mississippi valley, and in the eighteenth and early nineteenth centuries the western Apache of east-central and southeastern Arizona were producing maize and European-introduced crops including watermelons as they combined small-scale horticulture with hunting and gathering in a low rainfall environment (Minnis 1992: 130–1). This fact is ethnographically significant because other transitional foraging–farming groups, such as the San people of the Kalahari Desert of southern Africa, have parallel subsistence practices involving watermelons. Watermelons and melons were also rapidly adopted by Pacific Islanders in Hawaii and elsewhere as soon as the seeds were introduced by Captain James Cook (1778) and other European explorers (Neal 1965).

In the cultural history of the United States, Thomas Jefferson was an enthusiastic grower of watermelons at his Monticello estate, Henry David Thoreau proudly grew large and juicy watermelons in Concord, Massachusetts, and Mark Twain wrote in *Puddn'head Wilson:* "The true southern watermelon is a boon apart and not to be mentioned with commoner things. It is chief of this world's luxuries, king by the grace of God over all the fruits of the earth. When one has tasted it, he knows what the angels eat." Ellen Ficklen has documented the important role of watermelons in American popular culture in numerous areas including folk art, literature, advertising and merchandising, and the large number of annual summer watermelon festivals throughout the country with "parades, watermelon-eating contests, seed spitting contests, watermelon queens, sports events, and plenty of food and music" (1984: 25).

Growing and exhibiting large watermelons is an active pastime in some rural areas of the southern United States. Closely guarded family "secrets" for producing large watermelons and seeds from previous large fruit are carefully maintained. According to *The Guinness Book of Records,* the largest recorded watermelon in the United States was grown by B. Carson of Arrington, Tennessee, in 1990 and weighed a phenomenal 119 kg (Young 1997: 413).

African slaves also widely dispersed watermelon seeds in eastern North America, the circum-Caribbean, and Brazil. In the southern United States – where soil and climate conditions were optimal for watermelon cultivation – this crop ultimately became stereotypically, and often negatively, associated with rural African-Americans (see Norrman and Haarberg 1980: 67–70). Watermelons have subsequently figured as key symbols in the iconography of racism in the United States as seen during African-American protest marches in Bensonhurst, Brooklyn, in 1989, where marchers were greeted by Italian-American community residents shouting racial slurs and holding up watermelons.

In the ethnographic record of cultural anthropology, watermelons have perhaps figured most extensively in discussions of foragers and agro-pastoralists of the Kalahari Desert in southern Africa. As early as the 1850s, explorer David Livingstone described vast tracts of watermelons growing in the region. The anthropologist Richard Lee notes that watermelons, in domestic, wild, and feral varieties, constitute one of the most widespread and abundant plant species growing in the central Kalahari Desert. They are easily collected by foraging peoples and "the whole melon is brought back to camp and may be cut into slices for distribution. The melon itself may be halved and used as a cup, while the pulp is pulverized with the blunt end of a digging stick. The seeds may be roasted and eaten as well" (Lee 1979: 488).

Watermelons are among the most popular cultigens for forager-farmers in the Kalahari for the following reasons: "First, they provide a source of water; second, they are relatively drought-resistant, especially when compared to seed crops like sorghum and maize; and third, dried melons are an article of food for both humans and livestock and, after they have been cut into strips and hung on thorn trees to dry, they are easy to store" (Hitchcock and Ebert 1984: 343).

Elizabeth Cashdan emphasizes the point that "normally, when one thinks of agriculture one thinks of food resources, but . . . where the dominant factor governing mobility is the availability of moisture, it is appropriate that agriculture should be used to produce a storable form of moisture" (Cashdan 1984: 316). This cultivated water supply allows some Kalahari Desert groups to remain sedentary during both rainy and dry seasons, and watermelons are often stored in large quantities by these societies (Cashdan 1984: 321).

The collection of watermelons by foragers and their incipient domestication by such groups yields insights into probable scenarios for domestication. R. W. Robinson and D. S. Decker-Walters suggest a general process for cucurbits that has a plausible fit with the history and ethnography of watermelons in the Kalahari Desert:

> Aboriginal plant gatherers were probably attracted to some of these products, particularly the relatively large, long-keeping and sometime showy fruits. After fruits were taken back to camp, seeds that were purposely discarded, accidently dropped or partially digested found new life on rubbish heaps, settlement edges or other disturbed areas within the camp. Eventually, recognition of the value of the resident cucurbits led to their tolerance, horticultural care and further exploitation. Finally seeds . . . were carried by and exchanged among migrating bands of these incipient cultivators, gradually turning the earliest cultivated cucurbits into domesticated crops. (Robinson and Decker-Walters 1997: 23)

Such a process of domestication is somewhat different from those analyzed for cereal grains, where early transitional forager-farmers exploited densely concentrated stands of the wild ancestors of later domesticated varieties.

Cross-cultural uses of watermelon are quite varied. They are primarily consumed fresh for their sweet and juicy fruits and are often eaten as desserts. In some African cuisines, however, they are served as a cooked vegetable. The rind may be consumed in pickled or candied form. In parts of the former Soviet Union and elsewhere watermelon juice is fermented into an alcoholic beverage. Roasted seeds of this crop are eaten throughout Asia and the Middle East, and watermelon seeds are ground into flour and baked as bread in some parts of India. In addition, watermelons are also sometimes used as feed for livestock (Robinson and Decker-Walters 1997: 24–7, 85; Rubatzky and Yamaguchi 1997: 603).

Variety Improvement

Cucumber

Early cucumber varieties used in the United States were selections of those originally brought from Europe. American-originated varieties such as 'Arlington White Spine', 'Boston Pickling', and 'Chicago Pickling' were developed in the late nineteenth century. Cucumber is prone to a large number of potentially devastating diseases, and its rapid trailing growth makes chemical control of foliar and fruit diseases quite difficult. As a result, interest in the development of genetic disease tolerance has long been the focus of plant breeding efforts and has met with great success:

Tolerance to at least nine diseases has been incorporated into a single genotype. The first monoecious hybrid, 'Burpee Hybrid', was made available in 1945. Although seed costs were higher, multiple advantages of hybrids were soon recognized. Commercial companies built large research staffs to develop hybrids that provided proprietary exclusivity in those species where appropriate. Gynoecious hybrids made their appearance in 1962 when 'Spartan Dawn' was introduced. This all-female characteristic has since been exploited in both pickling and fresh-market types (Wehner and Robinson 1991: 1–3).

Melon

An 1806 catalog lists 13 distinct melon sorts derived from European sources (Tapley, Enzie, and Van Eseltine 1937: 60). Management of plant diseases in melon presents the same difficulties as with cucumbers. Accordingly, incorporation of disease tolerance into commercial types has been a major objective of plant breeders. One type, 'PMR 45', developed by the U.S. Department of Agriculture and the University of California in 1937, represented an enormous contribution because it provided resistance to powdery mildew *(Erisiphe cichoracearum),* which was the most devastating disease of melons in the arid western United States. This variety and its descendants dominated the U.S. market for about 40 years (Whitaker and Davis 1962: 57–9). Hybrids, which now predominate in the Cantalupensis group, began to appear in the mid-1950s with the introduction of 'Burpee Hybrid', 'Harper Hybrid', and others (Minges 1972: 69, 71).

Watermelon

Tolerance to fusarium wilt *(Fusarium oxysporum* f. sp. *niveum)* and anthracnose *(Colletotrichum orbiculare),* which was a prime objective of watermelon breeding programs, was achieved with the development of three varieties that dominated commercial production for almost four decades. 'Charleston Gray' was developed by C. F. Andrus of the U.S. Department of Agriculture in 1954, 'Crimson Sweet' by C. V. Hall of Kansas State University in 1964, and 'Jubilee' by J. M. Crall at the University of Florida in 1963 (Figure II.C.6.10). These varieties are no longer used to any extent, having been replaced by hybrids of the Allsweet and blocky Crimson Sweet types because of superior quality, high yields, and an attractive rind pattern. In Japan and other parts of Asia, watermelon varieties in use are susceptible to fusarium wilt, so they are grafted (Figure II.C.6.11) onto resistant root stocks (Lee 1994). In addition to diploid hybrids, triploid (seedless) hybrids are expected to dominate the watermelon market in the near future.

Production, Consumption, and Nutritional Composition

Production

Cucumber. As Table II.C.6.1 indicates, well over half of world cucumber and gherkin production occurs in Asia (the term "gherkin" is used here to denote small cucumber, rather than bur or West India gherkin). Though significant production also occurs in Europe and in North and Central

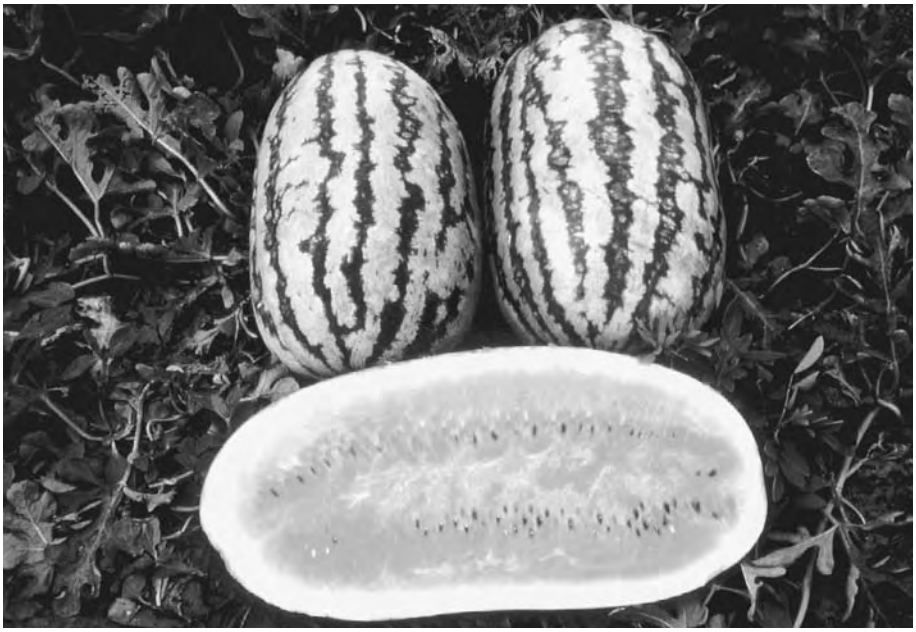

Figure II.C.6.10. 'Jubilee' watermelon developed by J. M. Crall, University of Florida, in 1963.

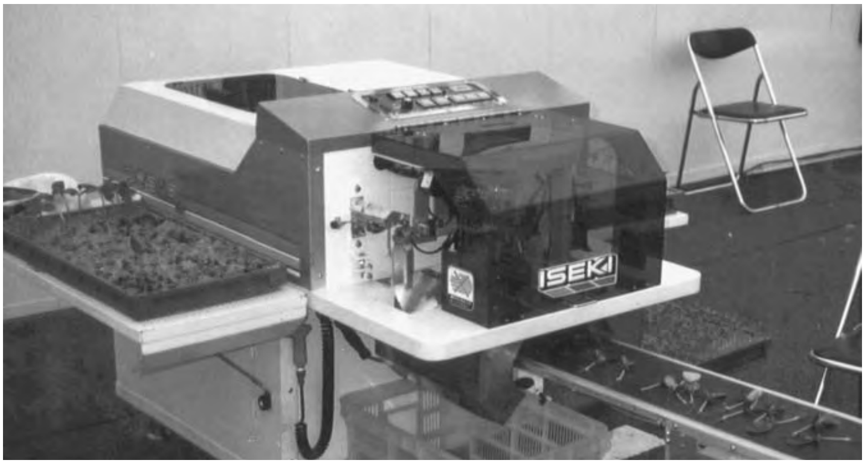

Figure II.C.6.11. In Japan, watermelon seedlings are grafted by machine onto Fusarium-resistant rootstocks.

America, China accounts for about 40 percent of world production. Other Asian countries with high cucumber production are Iran, Turkey, Japan, Uzbekistan, and Iraq. Only the United States, Ukraine, the Netherlands, and Poland are world leaders outside of Asia in cucumber production. Yields in the leading producing countries range from 8.6 tons per hectare (ha) in Iraq to 500 tons/ha in the Netherlands. The extraordinary yields in the Netherlands are because of protected culture of parthenocarpic types (United Nations 1996: 134–5).

Melon. As with cucumber, Asia produces more than half of the world's melon crop (Table II.C.6.2). Whereas Europe, North and Central America, and Africa are important world production centers, China produces about 25 percent of the world's crop. Turkey and Iran are also leading melon-producing countries. Yields in the leading countries range from 13.0 tons/ha in Mexico to 26.9 tons/ha in China (United Nations 1996: 122–3). In Japan, melons are usually grown in greenhouses. The very best ones are sold to be used as special gifts. Prices shown (Figure II.C.6.12) are roughly U.S. $50, $60, and $70 each.

Watermelon. Asia produces about 60 percent of the world's watermelons with major production in China (23 percent), Turkey (12 percent), Iran (9 percent), Korea Republic (3 percent), Georgia (3 percent), Uzbekistan (2 percent), and Japan (2 percent) (Table II.C.6.3). Yields in the major producing countries range from 11.3 tons/ha in Uzbekistan to 30.4 tons/ha in Japan (Figure II.C.6.13), where much of the production is in protected culture (United Nations 1996: 146–7).

Consumption and Nutritional Composition

Cucurbits, as previously discussed in this chapter, are an important part of the diet in the United States (Table II.C.6.4), where the annual consumption of watermelon, melon, and cucumber amounts to just over 17 kg per person (USDA 1996). Cucurbit fruits are high in moisture and low in fat, which makes them popular with consumers interested in healthy diets (Table II.C.6.5). Those with orange flesh like muskmelon and winter squash are excellent sources of vitamin A. Orange-fleshed cucumbers have been developed recently from crosses between United States pickling cucumber varieties and the orange-fruited "Xishuangbanna" cucumber from the People's Republic of China. The provitamin A carotene content of these cucumbers is equivalent to other orange-fleshed cucurbits (Simon and Navazio 1997). Moderate amounts of essential inorganic elements and other vitamins are provided by the cucurbit fruit. Aside from the low fat content and high vitamin A content of some cucurbit fruits, their principal value in the diet of people living in developed countries is in their unique colors, shapes, flavors, and adaptability to various cuisines.

Table II.C.6.4. *Per capita consumption of cucumbers, melons, and watermelons in the United States, 1996*

Vegetable	Consumption (kg)
Cucumber – fresh	2.54
Cucumber – processed	2.18
Honeydew melon	1.13
Muskmelon	4.26
Watermelon	7.26
All vegetables – fresh	90.81
All vegetables – processed	106.86

Source: USDA (1996), VGS-269.

The internal quality of watermelon fruit is a function of flesh color and texture, freedom from defects, sweetness, and optimum maturity. Unfortunately, these criteria cannot, as a rule, be assessed without cutting the melon. So many watermelons of inferior or marginal quality have been marketed that consumers have increasingly lost confidence in the product. The current supermarket practice of preparing cut and sectioned watermelon provides at least partial assurance of quality to the purchaser, but no indication of sweetness. In Japan, the quality of whole watermelon fruit is assessed by nuclear magnetic resonance (NMR) before marketing. Soluble solids and flesh integrity can be determined nondestructively in seconds (Figure II.C.6.14). As mentioned, because of their exceptional quality, such watermelons can be sold locally for the equivalent of about U.S. $50–$70 (Figure II.C.6.15).

In contrast to the composition of the pulp, watermelon seeds, which are used for food in various parts of the world, are low in moisture and high in carbohydrates, fats, and protein. Varieties with very large seeds have been developed especially for use as food in China, where more than 200,000 tons are produced annually on 140,000 ha land (Zhang 1996).

II.C.7 ~ Fungi

Definitions

Fungi are uninucleate or multinucleate, eukaryotic organisms with nuclei scattered in a walled and often septate mycelium (the vegetative part of a fungus). Nutrition is heterotrophic (at least one or more organic molecules required), and fungi usually obtain their nutrients by way of diffusion or active transport.

They lack chlorophyll but may have other pigments such as carotenoids, flavonoids, and so forth.

The true fungi, Eumycota, are grouped into five divisions:

1. Mastigomycotina (aquatic or zoospore-producing fungi) – unicellular or mycelial (coenocytic, no intercellular walls); motile, uni- or biflagellate zoospores during life cycle.
2. Zygomycotina – coenocytic mycelium; sexual state (teleomorph) spores are zygospores which may be absent; asexual state (anamorph) is predominant stage consisting of uni- or multispored sporangia.
3. Ascomycotina – mycelium unicellular to multicellular; regularly septate; asexual state often present; sexual state spores are ascospores formed inside an ascus (sac); no motile state.
4. Basidiomycotina – mycelium unicellular to multicellular, regularly septate; conidial asexual state common; sexual state and motile cells absent.
5. Deuteromycotina – unicellular to multicellular mycelia; regularly septate; conidial asexual state common; no sexual state; no motile cells (O'Donnell and Peterson 1992).

D. L. Hawksworth, B. C. Sutton, and G. A. Ainsworth (1983) have estimated that there are about 250,000 species of fungi, of which Mastigomycotina composes 1.8 percent, Zygomycotina 1.2 percent, Ascomycotina about 45 percent, Basidiomycotina about 25.2 percent, and Deuteromycotina about 26.8 percent.

Most edible fungi belong to divisions 2 to 5, just listed. Yeasts are single-celled fungi that reproduce asexually by budding or fission, or sexually through ascospore formation. The term "mushroom" refers to those macrofungi (visible to the naked eye) with edible fruiting bodies (sporophores), whereas "toadstool" refers to macrofungi with toxic fruiting bodies; both mushrooms and toadstools are found in more than one of the fungal divisions (Hawksworth et al. 1983; Koivikko and Savolainen 1988).

Historical Background

Fungi have been associated with humans since prehistoric times and must have been collected and eaten along with other plants by hunter-gatherers prior to the development of agriculture (Oakley 1962; Monthoux and Lündstrom-Baudois 1979; Pöder, Peintner, and Pümpel 1992). Although their prehistoric use remains uncertain, they may have been employed as food, in the preparation of beverages, and as medicine.

There is, however, no specific evidence for the use of fungi prior to the Neolithic period, when fungi consumption would have been associated with the drinking of mead (yeast-fermented diluted honey) and yeast-fermented beer or wine, and, somewhat later, the eating of yeast-fermented (leavened) bread.

Mesopotamia

Beer was the preferred fermented drink of the Sumerians of the Late Uruk period dating to the late fourth millennium B.C. R. H. Michel, P. E. McGovern, and V. R. Badler (1992) have noted the similarity of the grooves on a Late Uruk jar at Godin Tepe (in the Zagros Mountains of Iran) with the Sumerian sign for beer, ***kas***. The grooves contained a pale yellow residue, which the authors thought was an oxalate salt – oxalate salts are the principal molecules in "beerstone," a material found on barley beer fermentation containers. The Sumerians were very fond of beer and brewed at least 19 different kinds. They also used beer in some of their medical prescriptions (Majno 1975). Date and grape wine were known in Babylonia by 2900 B.C. (Saggs 1962).

Egypt

Fungi were eaten or drunk, perhaps unwittingly, in Egypt thousands of years ago, in beer and, later, in wine and bread. Yeasts were discovered in a vase of the Late Predynastic period (3650–3300 B.C.) (Saffirio 1972). J. R. Geller (1992) identified a brewery at Hierakonpolis by examining the chemistry of the black residue found in the brewery vats dating from roughly the same time. Similar beer vat sites have been discovered in Egypt from the Amratian (about 3800–3500 B.C.) through the Early Dynastic period (about 3100–2686 B.C.) (Geller 1989).

A yeast, resembling modern *Saccharomyces* spp. and named *Saccharomyces winlocki*, was found in an undisturbed Theban tomb of the Eleventh Dynasty (2135–2000 B.C.) (Gruss 1928). *S. winlocki* was also found in an amphora containing beer in the tomb of

Field mushroom

Queen Meryet-Amun of the Eighteenth Dynasty (1570–1305 B.C.) at Thebes (Winlock 1973).

The bag press, used to press grapes in the manufacture of wine, is shown on the walls of Egyptian tombs from around 3000 B.C. (Forbes 1967). Wine was drunk by upper-class Egyptians and beer was the beverage of the lower classes. Leavened bread was also a common food, as is illustrated by paintings in the tomb of Ramses III (Goody 1982).

Sudan

According to H. A. Dirar (1993), date wine, beer, bread, and cake may have been made in the Sudanese Kingdom of Yam (2800–2200 B.C.). Two men drinking beer or wine through a bamboo straw are shown in a drawing at Mussawarat es Sufra, a site dating to Meroitic times (from between 1500 and 690 B.C. to A.D. 323). Strabo (7 B.C.) mentioned that the Meroites (Ethiopians) knew how to brew the sorghum beer that is called *merissa* today. Wine, which dated from between 1570 and 1080 B.C., was introduced into the Sudan by Egyptian colonists of the New Kingdom (Dirar 1993).

China

In Chinese folklore, Shen Nung, the "Divine Ploughman," a mythical ruler, taught the people how to use plant medicines and, presumably, taught them about fungi as well. Y. C. Wang (1985) has suggested that the Chinese knew about fungi some 6,000 to 7,000 years ago but offered no specific evidence for their use as food. K. Sakaguchi (1972), who wrote that mold fermentation was traceable to about 1000 B.C. in China, has been supported by T. Yokotsuka (1985).

B. Liu (1958) claimed that in China, mushrooms were first eaten in the Chou Dynasty about 900 B.C. Lui Shi Chuen Zhou, in his *Spring and Autumn of Lui's Family,* recorded the eating of *ling gi* (*Ganoderma* sp.) about 300 B.C. (Liu 1991). The *Book of Songs,* printed in the Han Dynasty (26 B.C. to A.D. 220), mentioned over 200 useful plants, including a number of common edible mushrooms (Wang 1985). Similarly, the *Book of Rites,* written about A.D. 300, mentions several edible fungi (Wang 1985).

Auricularia auricula and *Auricularia polytrica* ("wood ear") were described by Hsiang Liu (about 300–200 B.C.) and by Hung Wing T'ao (between A.D. 452 and 536). The *T'ang Pen Ts'ao* of the Tang Dynasty (seventh century) described five kinds of *mu-erh,* which grew on various trees. The cultivation of the mushrooms (*Auricularia* spp.) was begun in the Tang Dynasty (A.D. 618–907) (Chang and Miles 1987), although they were probably eaten at least 1,400 years ago (Lou 1982).

The mushroom *Lentinus edodes (shiitake)* was recognized as the "elixir of life" by a famous Chinese physician, Wu Shui, during the Ming Dynasty (1368–1644). This was testimony to a primitive form of *shiitake* cultivation, called *hoang-ko,* that had been developed about 800 years ago (Ito 1978). According to R. Singer (1961), Japanese Emperor Chuai was offered the singular mushroom by the natives of Kyushu in A.D. 199, from which we may infer that they were gathered for consumption much earlier in China.

The Chinese method of producing alcoholic beverages required that *Rhizopus, Mucor,* or *Saccharomyces* spp. be grown spontaneously on compact bricks of wheat flour or other materials called *kyokushi.* This process was said to have been introduced into Japan at the beginning of the fifth century A.D. and, hence, must have been used appreciably earlier in China (Kodama and Yoshizowa 1977).

A pigment from a fungus was mentioned in *Jih Yang Pen Chaio* (Daily Herb), written by Jui Wu in A.D. 1329. The organism producing the pigment was the yeast *Monascus* sp. (Wang 1985), which grows on rice and has been widely used in the Orient. It is the source of a red pigment employed to color such things as wine and soybean cheese (Lin and Iizuka 1982).

The Mongolian conquests introduced another source of fungal foods – cheese – to the Chinese people, who generally shunned dairy products. Su Hui, royal dietician during the reign of Wen Zong (Tuq. Temur) from A.D. 1328 to 1332, wrote *Yenishan Zhengyao* (The True Principles of Eating and Drinking). In it he included dairy products such as fermented mare's milk, butter, and two cheeses (Sabban 1986). Another dietician of the Yuan Dynasty, Jia Ming (A.D. 1268–1374), also discussed the use of cheese over vegetables or pasta and mentioned fungi as food (Sabban 1986).

As previously hinted, cultivation (rather than gathering from the wild) of mushrooms for human food on a large scale may first have begun in China as early as the Han Dynasty (206 B.C. to A.D. 9). In the first century A.D., Wang Chung's *Lun Heng* stated that the cultivation of *chih* (fungus) was as easy as the cultivation of beans. In 1313, procedures for mushroom cultivation were described in Wong Ching's *Book of Agriculture* (Chao Ken 1980).

Fermented protein foods have an ancient history in China (Yokotsuka 1985). According to the *Shu-Ching,* written about 3,000 years ago, *chu* (yeast or fungus) was essential for the manufacture of alcoholic beverages from wheat, barley, millet, and rice as early as the Chou Dynasty, 1121–256 B.C. By the Han Dynasty, *chu* was made in the form of a cake called *ping-chu.* A sixth-century text on agricultural technology, *Chi-Min-Yao Shu,* detailed the preparation of several kinds of *chu* and other fermented foods such as *chiang* (fermented animal, bird, or fish flesh with millet). *Chu* was a common flavoring in the China of the Chou Dynasty (1121–256 B.C.), and *chiang* was mentioned in the *Analects of Confucius,* written some 600 years after that period. S. Yoshida (1985) wrote that fermented soybeans originated in China in the Han Dynasty and were known as *shi.*

Greece and Rome

That the ancient Greeks used fungi as food seems clear, because accidental mushroom poisoning was mentioned in the fifth century B.C. by both Euripides and Hippocrates (Buller 1914–16). Theophrastus (d. 287 B.C.) apparently knew and named truffles, puffballs, and fungi (Sharples and Minter 1983).

The Romans enjoyed *boleti* (the *Agaricus* of today) and even had special vessels, called *boletari,* to cook the fungi (Grieve 1925). Presumably, a dish of *boleti* concealed the poisonous mushrooms that Agrippina administered to her husband, the Emperor Claudius, so that her son, Nero, could become emperor of Rome (Grieve 1925).

According to J. André (1985), the Romans ate *Amanita caesarea, Boletus purpureus,* and *Boletus suillus,* as well as truffles, puffballs, and morels (Rolfe and Rolfe 1925). Fungi must have been prized by wealthy Romans, for they are mentioned as special delicacies by Horace (65–8 B.C.), Ovid (43 B.C. to A.D. 19), Pliny (A.D. 46–120), Cicero (A.D. 106–143), and Plutarch (A.D. 46–120) (Rolfe and Rolfe 1925; Watling and Seaward 1976). The oldest cookbook presently known was written by Caelius Apicius in the third century A.D. and includes several recipes for cooking fungi (Findlay 1982).

Japan

The earliest reference to mushrooms in Japanese texts is in the *Nihongi* (Book of Chronicles), completed in A.D. 720, which recorded that mushrooms were presented to the Emperor Ojin in A.D. 288 by the local chieftains in Yamato (Wasson 1975). But according to Singer (1961), the earliest consumption of fungi in Japan was in A.D. 199, when the Emperor Chuai was offered *shiitake* by the natives of Kyushu. Mushrooms are rarely mentioned in the early poetry of Japan, but *Manyoshu,* the first anthology of poetry (compiled in the latter half of the eighth century), refers to the pine mushroom, and the *Shui Wakashu* (from about A.D. 1008) mentions it twice. In the *Bunrui Haiku Zenshu,* written by Masaoka Shiki sometime around the beginning of the sixteenth century, there were 250 verses about mushrooms and mushroom gathering (Blyth 1973).

Mexico

The Spanish conquerors of Mexico reported in the sixteenth century that the Aztecs used a mushroom called *teonanacatl* ("god's flesh"), and sacred mushrooms were pictured in the few Mayan manuscripts that survived the Spanish destruction of "idols and pagan writings." The Mayan *Codex Badianus,* written in 1552 by Martin de la Cruz, an Indian herbalist, mentioned the use of *teonanacatl* for painful ailments. The *Codex Magliabecchi* (c. 1565) includes an illustration depicting an Aztec eating mushrooms, and Franciscan friar Bernardino de Sahagun (1499–1590) discussed, in his *General History of the Things of New Spain,* the use of *teonanacatl* to induce hallucinations (Guerra 1967). The Aztecs were familiar enough with fungi to give them names: *nanacatl* (mushroom), *teonanacatl* (sacred mushroom), and *quauhtlanamacatl* (wild mushroom). Indeed, the Mazatecs of Oaxaca and the Chinantecs of Mexico still use hallucinogenic mushrooms for divination, medical diagnosis, and religious purposes (Singer 1978).

The Near East

Al-Biruni, an Arab physician of about 1,000 years ago, described the eating of several fungi, including truffles (Said, Elahie, and Hamarneh 1973). *Terfazia urenaria* is the truffle of classical antiquity, and it is prized in the Islamic countries of North Africa and the Near East as *terfaz.* The best truffles were reputed to come from the areas of Damascus in Syria and Olympus in Greece (Maciarello and Tucker 1994).

Europe

Truffles were already a part of Roman cuisine by the first century A.D., when the Roman poet and satirist Decimus Junius Juvenalis wrote: "[T]he Truffles will be handed round if it is Spring, and if the longed-for thunders have produced the precious dainties." At that time, fungi were thought to originate when lightning struck the earth during thunderstorms. Truffles were a part of French cuisine by the time of the Renaissance and were exported to England by the beginning of the eighteenth century (Maciarello and Tucker 1994).

In France, mushrooms were cultivated on manure from horse stables during the reign of Louis XIV (Tounefort 1707), and F. Abercrombie (1779) described an English method of composting such manure for the growth of mushrooms by stacking it, a method still in use today. Mushrooms are still highly prized as food in Europe. Many wild fungi are gathered and eaten, and many more are cultivated or imported (Mau, Beelman, and Ziegler 1994).

Fungi Eaten Now and in the Past by Humans

Fungi have been a prized food of peoples past and present around the world. Many examples of these fungi are listed in Table II.C.7.1, which is meant to be indicative rather than exhaustive.

Fungi are mostly eaten cooked, although some ethnic groups and individuals eat them raw. Today, the people of Asia appear to be the most eclectic consumers of fungi. The Chinese eat perhaps as many as 700 wild and domesticated species. The Japanese use well over 80 species (Imai 1938); the people of India may consume more than 50 species; and the French, not to be outdone, enjoy well over 200 species from one area alone – that of Haute-Savoie (Ramain 1981). Similarly, North Americans eat more than 200 wild and cultivated fungal species (Lincoff 1984).

The reader should be aware that many mushroom genera include both edible and toxic species, and that some mushroom varieties can be edible, whereas others of the same species are not. In the case of some mushrooms, boiling in water before eating will remove toxic or unpleasant secondary metabolites.

Relatively barren areas of the Near East, including parts of Africa and Asia, support thriving populations of truffles, genus *Tirmania,* which are eaten from Morocco and Egypt in North Africa to Israel, Saudi Arabia, and Iraq (Said et al. 1973; Alsheikh, Trappe, and Trappe 1983). Truffles called *fuga* are prized in Kuwait and eaten with rice and meat (Dickson 1971). In some areas of the Arabian Gulf, the truffle crop may be appropriated by the local royal families (Alsheikh et al. 1983).

Today, edible fungi are cultivated or collected in the wild in huge numbers and shipped by air from the source country to consumer countries around the world; fungi may also be canned or dried for long-term storage and later consumption.

[a] *ndiwa* (Chichewa) or *mboga* (Yao) is a relish or side dish of mushrooms fried in oil with onions, tomatoes, and ground nut flour.

Gross Chemical Composition of Fungi

The gross chemistry of edible fungi (Table II.C.7.2) varies with the stage of the life cycle in which they are eaten; for example, the mycelium of *Agaricus campestris,* a common white mushroom, contains 49 percent protein (Humfeld 1948), whereas the sporophore of the same species is 36 percent protein (McConnell and Esselen 1947).

Even the stage in the life cycle of the sporophore may significantly affect the gross chemistry of the fungus (Table II.C.7.3). The sporophore is the fungal part usually eaten, although the mycelium predominates in fermented foods (Purkayastha and Chandra 1976).

Most of the biomass of fungi is water, although there are wide variations in the amount of water in different species (Table II.C.7.2). The dry biomass is mainly carbohydrates, followed by proteins, lipids, and ash, in that order; again, there is wide variation in the amounts of the major components (Table II.C.7.2). In general, dried fungi contain 2 to 46 percent protein, 5 to 83 percent carbohydrates, 1 to 26 percent lipids, 1 to 10 percent RNA, 0.15 to 0.3 percent DNA, and 1 to 29 percent ash (Griffin 1981). Fungal strains with unusually high lipid content have been selected for this trait and are grown under conditions where lipid synthesis is enhanced. These fungi serve as valuable sources of lipids that are required in large quantities for industrial purposes.

The nutritional value of many edible fungi compares well with other common foods. In essential amino acid content, where meat rates 100 and milk 99, mushrooms are rated at 98. Measuring by amino acid "score," meat scores 100, milk scores 91, and mushrooms score 89, whereas, by nutritional index, meat can score between 59 and 35, soybeans score 31, and mushrooms score 28. Indeed, by any of these criteria, some mushrooms have more nutritional value than all other plants except soybeans; at the same time, however, some edible fungi score much lower by the same criteria (Crisan and Sands 1978). One hundred grams of dried fungal biomass has an energy equivalent of from 268 to 412 kilocalories (Griffin 1981).

Table II.C.7.2 indicates that fungi provide significant amounts of protein. There is, however, some question as to how much of fungal protein is digestible (Crisan and Sands 1978). Fungi also contain sufficient quantities of the essential amino acids required by humans and other animals and have a variety of other nitrogen-containing molecules.

Table II.C.7.2. *Gross chemical composition of fungi as a percentage of fungal dry weight*

Species	No. of samples	Protein	Total carbohydrate plus fiber	Total lipids	Total nucleic acids	Ash	H_2O[a]	Ref.

Soluble carbohydrates in fresh fungi range from 37 to 83 percent of the dry weight. In addition, there are fiber carbohydrates that make up from 4 to 32 percent (Griffin 1981).

The lipid content of fungi ranges from 0.2 percent of the cell or tissue dry weight to as high as 56 percent – more specifically, 0.2 to 47 percent for Basidiomycotina, and 2 to 56 percent for Deuteromycotina (Weete 1974; Wassef 1977). Sporophores' contents of lipids tend to be relatively low, but among them are triglycerides, phospholipids, fatty acids, carotenoids, and steroids, as well as smaller amounts of rarer lipids.

Carotenoids may accumulate in some fungi; in fact, some pigmented fungi have been grown in bulk precisely for carotenoids, which are fed to carp or to chickens to color their eggs and make them more acceptable to the consumer (Klaui 1982). Some of these carotenoids may be converted to vitamin A in humans (Tee 1992).

In addition, some fungi are sufficiently good producers of the B vitamins to make them viable commercial sources of these nutrients. *Saccharomyces* spp., for example, are good sources of B vitamins generally (Umezawa and Kishi 1989), and riboflavin is obtained in goodly amounts from *Ashbya gossppii* fermentations (Kutsal and Ozbas 1989). The water-soluble vitamin content of several fungi are shown in Table II.C.7.4.

Fungal Flavors and Volatiles

The nonvolatile meaty flavors of edible fungi come primarily from the amino acids (glutamic acid is one of the most common), purine bases, nucleotides (such as the shiitake mushroom's guanosine-5′-monophosphate)

Table II.C.7.4. *Vitamin content of edible fungi*

(Nakajima et al. 1961), and the products of the enzymatic breakdown of unsaturated fatty acids. The volatile flavors include C8 compounds, such as benzyl alcohol, benzaldehyde, and other compounds (Mau et al. 1994). Many fungi contain monoterpenes, which produce a variety of flavors and odors; *Trametes odorata, Phellinus* spp., and *Kluyveromyces lactis,* for example, produce linalool (sweet, rose-like), geraniol (rose-like), nerool (sweet, rose-like) and citronellol (bitter, rose-like).

Fungi also produce flavors and odors that are buttery; nutlike; mushroomlike; coconut-like (*Trichoderma* spp.); peachlike (*Fusarium poae, Pityrosporium* spp., *Sporobolomyces odorus, Trichoderma* spp.); flowery and woody *(Lentinus lepideus);* earthy *(Chaetomium globosum);* sweet, aromatic, and vanilla-like *(Bjerkandera adusta);* coconut- and pineapple-like *(Polyporus durus);* sweet and fruity *(Poria aurea);* and passion-fruit-like *(Tyromyces sambuceus)* (Kempler 1983; Schreier 1992).

The flavor of truffles, as in other fungi, is partly caused by nonvolatile organic molecules such as those mentioned previously and by over 40 volatile organic molecules. The aroma of white truffles comes mainly from one of the latter, whereas the Perigord (black) truffle's aroma is the result of a combination of molecules. Species of *Russula,* when dried, have an odor that has been attributed to amines (Romagnesi 1967).

Some fungi produce volatile molecules that attract animals – including humans – or emit distinct flavors (Schreier 1992). Truffles, which are among the most valuable of edible fungi, grow underground on plant roots and produce odors that can only be recognized by dogs, pigs, and a few other mammals. Humans cannot smell them, but those with experience can detect the presence of truffles below the ground by cracks that appear in the soil surface over the plant roots.

The major species of truffles are *Tuber melanosporum* – the black truffle or so-called Perigord truffle – found most frequently in France, Italy, and Spain; *Tuber brumale,* also of Europe; *Tuber indicum* of Asia; and *Tuber aestivum* – the summer truffle or "cook's truffle" – which is the most widespread of all the truffles and the only one found in Britain (Pacioni, Bellina-Agostinone, and D'Antonio 1990).

Fungi and Decay

Along with bacteria, fungi hold primary responsibility for the biological process known as decay, in which complex organic molecules are progressively broken down to smaller molecules by microbial enzymes. The decay process destroys toxic molecules and regenerates small molecules used by microbial or plant life. Examples include carbon as carbon dioxide and nitrogen as amino acids, nitrates, or ammonia. Dead plants and animals are broken down to humus and simpler organic molecules that fertilize the soil and increase its water-holding capacity. These same processes have been used by humans in fermentation and in the production of bacterial and fungal single-cell protein (SCP) from waste or cheap raw materials.

Fungal Fermentation

The process of fermentation or microbial processing of plant or animal foods has served many functions, both now and in the distant past, especially in warm and humid climates where food spoils quickly. Fermentation preserves perishable food at low cost, salvages unusable or waste materials as human or animal food, reduces cooking time and use of fuel, and enhances the nutritional value of food by predigestion into smaller molecules that are more easily assimilated. Sometimes, but not always, fermentation increases the concentration of B vitamins (Goldberg and Thorp 1946) and protein in food (Cravioto et al. 1955; Holter 1988) and destroys toxic, undesirable, or antidigestive components of raw food. Moreover, fermentation can add positive antibiotic compounds that destroy harmful organisms, and the acids and alcohol produced by fermentation protect against microbial reinfection and improve the appearance, texture, consistency, and flavor of food. In addition, fermented foods often stimulate the appetite (Stanton 1985).

In ancient times, preservation of foods (such as milk, cheese, and meat) and beverages (like beer, mead, and wine) by fermentation made it possible for humans to travel long distances on land or water without the need to stop frequently for water or food. As described by Dirar (1993), over 80 fermented foods and beverages are presently used by the people of the Sudan, including 10 different breads, 10 different porridges, 9 special foods, 13 different beers, 5 different wines, 1 mead, 7 dairy sauces, 4 different meat sauces, 5 different fish sauces, 5 flavors and substitutes of animal sauces, and 10 flavors and substitutes of plant origin.

Today a wide variety of mainly carbohydrate-rich substrates, like cereals, are preserved, but protein-rich legumes and fish can also be processed by fungi. The combination of fungi, yeast, and bacteria is often controlled by antibacterials, fatty acids that act as trypsin inhibitory factors, and phytases, which destroy soybean phytates that bind essential metals (Hesseltine 1985). Table II.C.7.5 lists some of the foods that depend on fungal processing before they may be eaten (Beuchat 1983; Reddy, Person, and Salunkhe 1986).

Fungal fermentation of cereals does not lead to a marked increase in the protein content of the grain, but it does contribute to a significant increase in amino acids, especially those considered essential to humans. There is a decrease in carbohydrates during fungal fermentation, and lipids are hydrolyzed to fatty acids. Fungal fermentation may lead to an increase in B-vitamin content, although B_{12} will appear only if bacteria are involved in the fermentation.

Table II.C.7.5. *Foods and beverages that require fungal processing*

Product	Substrate	Geographic area	Fungal species
Alcoholic beverages	Cereals, carbohydrates, fruit	Worldwide	*Saccharomyces* sp.
Ang-kak	Rice	Asia, Syria	*Monascus*
Banku	Maize, cassava	Ghana	Yeast, bacteria
Bonkrek	Coconut press cake	Indonesia	*Rhizopus oligosporus*
Burukutu	Sorghum, cassava	Nigeria	*Candida* spp.
Burung hyphon	Shrimp, fish	Philippines	Yeast
Chee-fan	Soybean whey curd	China	*Mucor* sp., *Aspergillus glaucus*
Cheeses			
Brie	Milk curd	France	*Penicillium camemberti*
Camembert	Milk curd	France	*Penicillium camemberti*
Gorgonzola	Milk curd	France	*Penicillium roqueforti*
Roquefort	Milk curd	France	*Penicillium roqueforti*
Stilton	Milk curd	France	*Penicillium roqueforti*
Chicha	Maize	Peru	Yeast, bacteria
Colonche	Prickly pears	Mexico	*Torulopsis* sp.
Dawadawa	Millet	West Africa	Yeast, bacteria
	African locust bean	Nigeria	Yeast, bacteria
Dhoka	Wheat and/or pulses	India	Yeast, bacteria
Dosai	Black gram	India	Yeast, bacteria
Enjera	Teff	Ethiopia	*Candida guillermondii*
Fermented manioc	Manioc	Zaire	Yeast, fungi, bacteria
Gari	Cassava	West Africa	*Candida* spp.
Hamanatto	Soybean and wheat flour	Japan	*Aspergillus oryzae* and bacteria
Hopper	Rice	Sri Lanka	Yeast, bacteria
Idli	Rice and black gram	India	Yeast, bacteria
Injera	Teff, maize, wheat, barley	Ethiopia	*Candida guilliermundii*
Jalabies	Wheat flour	India, Nepal, Pakistan	?
Jamin-bang	Maize	Brazil	Yeast and bacteria
Kaanga-kopuwai	Maize	New Zealand	Yeast and bacteria
Kanji	Rice, carrots	India	*Hansenuka anomala*
Kaoling liquor	Sweet fruit or juice	China	*Monascus* sp.
Oncom	Peanut press cake	Indonesia	*Neurospor intermedia, Rhizopus oligosporus*
Papadam	Black gram	India	*Saccaromyces* spp.
Poi	Taro	Hawaii	Fungi and bacteria
Pozol	Maize	Mexico	Fungi and bacteria
Puto	Rice	Philippines	Fungi and bacteria
Sake	Rice, steamed	Japan	*Aspergillus oryzae* and *Sacchasomyces cerevisiae*
Shoyu	Soy and wheat	Malaysia	*Aspergillus oryzae* and yeast and bacteria
Sierra rice	Unhusked rice	Ecuador	*Aspergillus* spp. and bacteria
Sorghum beer	Sorghum, maize	South Africa	Yeast and bacteria
Soy sauce	Soybeans, wheat	Orient	*Aspergillus* spp., yeast, bacteria
Sufu	Soybean whey curd	China, Taiwan	*Actinomucor elegans, Mucor* spp.
Tao-si	Soybeans and wheat flour	Philippines	*Aspergillus oryzae*
Taotjo	Soybeans and wheat or rice	East India	*Aspergillus oryzae*
Taupe	Cassava or rice	Indonesia	Fungi
Tauco	Soybeans, cereal	West Java	*Rhizopus oligosporus, Aspergillus oryzae*
Tempeh	Soybeans	Indonesia	*Rhizopus* spp.
Katsuobushi	Fish	Japan	*Aspergillus glaucus*
Kecap	Soybeans, wheat	Indonesia	*Aspergillus* spp., bacteria, yeast
Kenkey	Maize	Africa	Yeast, bacteria, fungi
Khaman	Bengal gram	India	Yeast, bacteria
Kochujang	Hot pepper bean paste	Korea	Yeast, bacteria, fungi
Koji	Rice	China, Japan	*Aspergillus oryzae*
Lao-cho	Rice	Indonesia, China	*Rhizopus* spp., other fungi
Meitanza	Soybean cake	China, Taiwan	*Actinomucor elegans*
Meju	Soybeans	Korea	*Rhizopus* spp., *Aspergillus oryzae*
Merissa	Sorghum	Sudan	*Saccharomyces* spp.
Minchin	Wheat gluten	China	Fungi
Miso	Rice and soybeans, rice and cereals	China, Japan	Fungi
Nan	Wheat	India	Yeast
Nyufu	Fermented dry tofu	East Asia	*Actinomucor repens*
Ogi	Maize	Nigeria, West Africa	Fungi and bacteria
Torani	Rice	India	*Candida* spp., *Hansenula anomale,* other fungi
Waries	Black gram	India	Yeasts
Tuba	Coconut palm sap	Mexico	Yeasts
Kaoliang liquor	Sweet fruit or juice	China	*Monascus* sp.
Manioc, fermented	Manioc	Zaire	Yeast, bacteria, fungi

Sources: Steinkraus (1983); Jay (1986); Paredes-Lopez and Harry (1988); and Chavan and Kadam (1989).

Soybeans constitute a good example. Normally they contain B vitamins, but neither vitamin B_{12} nor significant amounts of proteins. When fermented, however, the B vitamins (except for thiamine) increase, and proteins are completely hydrolyzed to amino acids (Murata 1985). Vitamin B_{12} has been found in all commercial samples of fermented tempe, indicating that bacteria were involved in the fermentation as well (Steinkraus 1985).

In Fiji, carbohydrate-rich crops such as breadfruit *(Artocarpus utilis),* cassava *(Manihot dulcis),* taro *(Colocasia esculenta),* plaintain *(Musa paradisiaca* subsp. *normalis),* banana *(Musa* subsp. *sapientum),* and giant swamp taro *(Alocasia indica)* are preserved for future use by pit-mixed fermentation. This process was probably brought to Tonga during the Lapita period some 2,000 to 3,000 years ago and subsequently spread to Fiji (Aalbersberg, Lovelace Madhaji, and Parekenson 1988).

Single-Cell Protein for Human and Animal Food

Fungi have been employed to produce single-cell protein (SCP) from a variety of waste materials that might otherwise be useless, such as crop straw, bagasse, starchy plant materials, and whey, among others. *Candida* alkane yeasts have been examined for their ability to produce protein-rich biomass and edible calories for pigs and other animals, whereas *Chaetoceros* and *Sporotrichum* spp. have been utilized to enrich the protein content of lignocellulose wastes – like straw – for animal feed. *Rhizopus oligosporus* NRRL 270 has been used to increase the protein content of starchy residues (cassava, potato, and banana), and yeasts have been exploited to produce food and alcohol from whey. Treating manioc with *R. oligosporus* by any of three different fermentation methods has resulted in a marked increase in protein content, seemingly at the expense of the carbohydrate content of the manioc (Ferrante and Fiechter 1983).

Alcoholic Fermentation

In Europe, the Near East, and South and Central America, saccharification of the starch in cereals – such as barley, corn, or wheat – has long been done by malting the grain. This procedure is followed by the production of alcoholic beverages and food through the action of *Saccharomyces* spp. In the Orient, *Aspergillus* spp. and *Rhizopus* spp. remain in use to make alcoholic beverages and foods, and the same two fungal species are also employed to hydrolyze the proteins of fish, meat, beans, pulses, and some cereals.

Other Fungally Fermented Foods

Some cheeses are made flavorful – following the formation of the curd and its processing – through the action of enzymes of the fungi *Penicillium camembert* (Camembert and Brie) and *Penicillium roqueforti* (Bleu, Gorgonzola, Roquefort, and Stilton). Country-cured hams are produced through fermentation by *Aspergillus* and *Penicillium* spp.; tuna is fermented by *Aspergillus glaucus,* cocoa by *Candida krusei* and *Geotrichum* spp., and peanut presscake by *Neurospora sitophila* (Jay 1986).

Fungal Secondary Metabolites

Fungi produce a large variety of secondary metabolites, but often only when the fungal cells cease active growth. Some of these secondary metabolites are beneficial to humans, whereas others are toxic, and still others may have useful medical effects.

Fungi supply organic acids for industrial uses: citric acid for the food, beverage, pharmaceutical, cosmetic, and detergent industries; itaconic acid for the plastic, paint, and printer's-ink industries; fumaric acid for the paper, resin, fruit juice, and dessert industries (Bigelis and Arora 1992; Zidwick 1992); gluconic acid for the food, beverage, cleaning, and metal-finishing industries; and malic and lactic acids for the food and beverage industries. In addition, several fungi produce rennets for the dairy industry; among these are *Byssochlamys fulva, Candida lipolytica, Chlamydomucor oryzae, Flammulina velutipes, Rhizopus* spp., and *Trametes ostreiformis* (Sternberg 1978).

Certain fungi (especially *Streptomyces* spp.) have proven to be useful as sources of a host of antibiotics that act as inhibitors of bacterial cell-wall synthesis (Oiwa 1992), as antifungal agents (Tanaka 1992), as antiviral agents (Takeshima 1992), and as antiprotozoal and anthelminthic agents (Otoguro and Tanaka 1992). Some also produce antitumor compounds (Komiyama and Funayama 1992), cell-differentiation inducers (Yamada 1992), enzyme inhibitors (Tanaka et al. 1992), immunomodulation agents (Yamada 1992), and vasoactive substances (Nakagawa 1992). In addition, fungi have been used to produce herbicides (Okuda 1992), fungicides, and bactericides of plants (Okuda and Tanaka 1992).

A number of secondary metabolites of fungi, however, are toxic to humans and their domestic animals. Aflatoxins are hepatotoxic and carcinogenic; deoxynivalenol is emetic; ergot alkaloids are vasoconstrictive, gangrenous, hemorrhagic, and neurotoxic; zearalenone causes vulvovaginitis in swine; trichothecenes produce vomiting, oral necrosis, and hemorrhage; ochratoxin causes nephrotoxicity; and macrocyclic trichothecenes cause mucosal necrosis (Marasas and Nelson 1987).

Those species of the fungal genus *Claviceps* that grow on cereals (as for example, *Claviceps purpurea*) produce a variety of pharmacologically active compounds with positive and negative effects on humans. Among these are the alkaloids lysergic acid diethylamide (LSD), ergometrine, ergotrienine, ergotamine, ergosinine, ergocristine, ergocornine, ergocristinene, ergocryptine, and ergocryptinine. Some of these alkaloids are responsible for the disease ergotism, but others are used beneficially – in childbirth, or to treat migraines (Johannsson 1962).

Still other fungi associated with cereals and legumes produce a wide variety of toxins. These have been implicated in aflatoxin and liver cancer in Africa, in esophageal cancer in Africa and Asia, and in endemic nephritis in the Balkans (Stoloff 1987).

A number of fungi (i.e., *Fusarium* and *Gibberella* spp.) produce zearalanol, which exhibits estrogen activity. These estrogen-like compounds are frequent contaminants in cereals and may be responsible for carcinogenesis and precocious sexual development if present in quantity (Schoental 1985).

Aspergillus flavus, which grows on peanuts, soybeans, cereals, and other plants, may produce the hepatocarcinogen aflatoxin and can cause Reye's syndrome in children. *Fusarium* spp., also growing on cereals, can produce trichothecen toxins that cause toxic aleukia (ATA) and *akakabi-byo* ("red mold disease") in Japan.

The commonly cultivated mushroom, *Agaricus bisporus,* may contain phenylhydrazine derivatives that have been found to be weakly mutagenic. Many other edible fungi have shown mutagenic activity (Chauhan et al. 1985); among them is the false morel, *Gyrimitra esculenta,* which has been found to contain 11 hydrazines, including gyromitrin – and 3 of these hydrazines are known mutagens and carcinogens (Toth, Nagel, and Ross 1982; Ames 1983; Meier-Bratschi et al. 1983).

In addition, a number of wild fungi contain poisonous molecules that can cause serious illness or death. The amount of poison varies from species to species and from strain to strain within individual species (Benedict and Brady 1966). Also, humans vary in their tolerance of fungal poisons (Simmons 1971).

Fungal toxins produce a variety of biological effects: Amanitin, phallotoxins, and gyromitrin cause kidney and liver damage; coprine and muscarine affect the autonomic nervous system; ibotenic acid, muscimol, psilocybin, and psilocin affect the central nervous system and cause gastrointestinal irritation; indeed, many of these substances and other unknown compounds found in fungi are gastrointestinal irritants (Diaz 1979; Fuller and McClintock 1986).

Several edible fungi, such as *Coprinus atramentarius, Coprinus quadrifidus, Coprinus variegatus, Coprinus insignis, Boletus luridus, Clitocybe clavipes,* and *Verpa bohemica,* may contain coprine (Hatfield and Schaumburg 1978). Indeed, European *C. atramentarius* may have as much as 160 mg of coprine per kg of fresh fungi. In the human body, coprine is hydrolyzed to l-aminocyclopropanol hydrochloride (ACP), which acts like disulfuram, a synthetic compound known as antabuse and used to treat chronic alcoholics. Antabuse and ACP irreversibly inhibit acetaldehyde dehydrogenase and prevent the catabolism of ethanol. Thus, coprine plus ethanol leads to severe intoxication when alcoholic beverages are drunk after eating coprine-containing fungi (Hatfield and Schaumberg 1978; Hatfield 1979).

In addition, many mushrooms contain the enzyme thiaminase, which may destroy the vitamin thiamine, leading to thiamine deficiency (Wakita 1976) – especially when the mushrooms are eaten in quantity (Rattanapanone 1979). Several *Russula* spp. may contain indophenolase, which can also be harmful to humans if eaten in large amounts (Romagnesi 1967).

Humans can become allergic to fungi (Koivikko and Savolainen 1988). Moreover, eating fava beans with mushrooms that are rich in tyrosinase may enhance the medical effect of the fava beans – known as favism – because the tyrosinase catalyzes the conversion of L-DOPA to L-DOPA-quinone (Katz and Schall 1986).

Magico-Religious Use of Fungi

As early as the eighteenth century, according to travelers' reports, *Amanita muscaria,* known as the "fly agaric," was eaten by several tribal groups (Chukchi, Koryak, Kamchadal, Ostyak, and Vogul) in eastern Siberia as an intoxicant and for religious purposes. Species of *Panaeolus, Psilocybe,* and *Stropharia* also contain hallucinogens. These fungi were eaten by the Aztecs and the Maya – and are still consumed by *curanderos* in some Mexican tribes – to produce hallucinations for religious purposes, to derive information for medical treatment, and to locate lost objects (Diaz 1979).

II.C.8 Squash

Definition

Wild and domesticated members of the New World genus *Cucurbita* L. (Cucurbitaceae) are typically referred to as "gourds," "pumpkins," and "squashes." The mature fruit of wild plants, technically called a pepo, has gourdlike qualities like a tough rind and dry flesh. These same qualities have led to the term "ornamental gourds" for various cultivars of *Cururbita pepo* L. that are grown for their decorative but inedible fruits. However, the common name for the domesticated *Cucurbita ficifolia* Bouché is "fig-leaf gourd," even though the fleshy fruits are cultivated for human consumption. Because another genus of the Cucurbitaceae, *Lagenaria* L., is considered the true gourd, it is preferable to refer to members of *Cucurbita* differentially, which leads us to the terms "pumpkin" and "squash."

Pumpkin comes from the Old English word "pompion," which is itself derived from the Greek *pepon* and the Latin *pepo* that together mean a large, ripe, round melon or gourd. Traditionally, "pumpkin" has been used to describe those cultivars of *Cururbita argyrosperma* Huber, *Cururbita maxima* Lam., *Cururbita moschata* (Lam.) Poir., and *C. pepo* that produce rotund mature fruits used in baking and for feeding livestock.

"Squash," by contrast, is a term derived from the New England aboriginal word "askutasquash," meaning vegetables eaten green. It was used during the seventeenth century to designate cultivars, usually of *C. pepo,* grown for their edible immature fruits, and by the nineteenth century, called "summer squashes." "Winter squashes," in contrast, are the mature fruits of *C. argyrosperma, C. maxima, C. moschata,* and *C. pepo* that store well and are not usually round; they are prepared as vegetables, baked into pies, or used as forage. Although "winter squashes" are supposed to differ from "pumpkins" in having a milder taste and flesh of a finer grain, the truth is that these culinary categories overlap, adding to the confusion in nomenclature. For the purposes of this discussion, the generic "squash" will refer to all wild and domesticated members of *Cucurbita.*

Squash Growers and Researchers

The story of squash is a story of Native Americans and New World archaeologists, gold-seeking explorers and European colonizers, herbalists and horticulturists, breeders and botanists. Squashes fascinate us all, but none more than the people who have dedicated their careers to squash research. Such research, as we know it, was under way in Europe by the 1800s. Intrigued by the diversity of fruits illustrated in the herbals of the sixteenth and seventeenth centuries (see Whitaker 1947; Eisendrath 1962; Paris 1989), the French horticulturist Charles Naudin (1856) took great pleasure in describing, breeding, and classifying these newcomers to the Old World. By the twentieth century, comprehensive breeding programs were well established in Europe, North America, and Asia. In an attempt to keep pace with the burgeoning of new strains, William Tapley, Walter Enzie, and Glen Van Eseltine (1937) combed the horticultural literature to provide the most detailed descriptions ever of 132 cultivars.

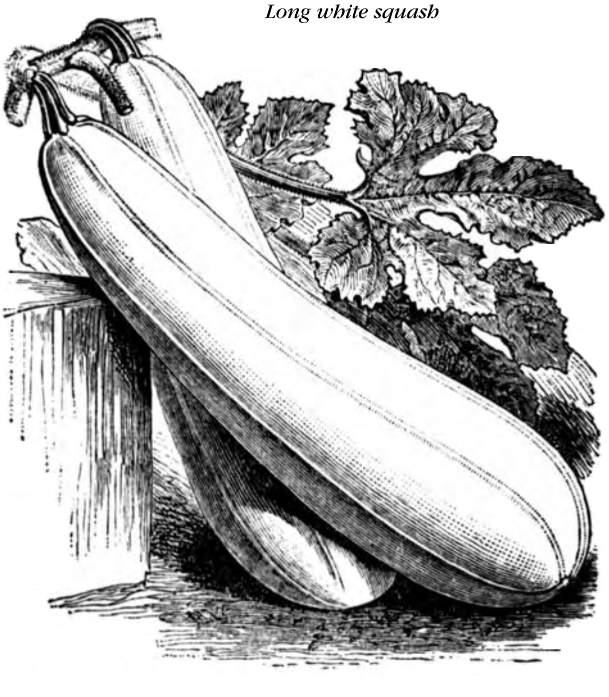
From Russia, organized plant-collecting expeditions were launched to search Middle and South America, eastern Africa, India, and Asia Minor for new landraces. These explorations provided the bases for new classifications (e.g., Bukasov 1930; Pangalo 1930; Zhiteneva 1930; Filov 1966). Other scientists also contributed to the systematics of squash, with Igor Grebenščikov (1955, 1958, 1969) updating an earlier (Alefeld 1866) classification of infraspecific varieties. The Americans E. F. Castetter and A. T. Erwin took a different approach, placing cultivars into horticultural groups as opposed to botanical classes (Castetter 1925; Castetter and Erwin 1927).

During the middle of the twentieth century, archaeological discoveries of ancient squash in the New World (Whitaker and Bird 1949; Whitaker, Cutler, and MacNeish 1957; Cutler and Whitaker 1961; Whitaker and Cutler 1971) provided an added perspective on the history and evolution of these species. In recent decades, some of the most ancient and most accurately dated and identified squash remains (e.g., Kay, King, and Robinson 1980; Conrad et al. 1984; Simmons 1986; Decker and Newsom 1988) have served to highlight the importance of *C. pepo* in the origins and character of North American horticulture (Heiser 1979; Minnis 1992; Smith 1992). Moreover, archaeological studies in South America have also blossomed recently (see Pearsall 1992 and refs. therein), giving us more detailed histories of *C. ficifolia* and *C. maxima.*

Domesticated squashes, with their diversity in fruit characteristics, have long been of interest to horticultural geneticists (e.g., Sinnott 1922; Shifriss 1955; Wall 1961; Robinson et al. 1976). Liberty Hyde Bailey, who explored North America in search of wild species, spent countless hours in his gardens performing breeding and inheritance experiments and making observations on the domesticates (Bailey 1902, 1929, 1937, 1943, 1948).

Thomas Whitaker, a prolific researcher with the United States Department of Agriculture, has been the closest human ally of the cucurbits. He examined relationships among wild and domesticated squashes using all available sources of data, including archaeological remains, hybridization experiments, anatomical

Long white squash



and morphological studies, and various genetic analysis (e.g., Whitaker 1931, 1951, 1956, 1968; Whitaker and Bohn 1950; Cutler and Whitaker 1956; Whitaker and Bemis 1964; Whitaker and Cutler 1965). Other devoted squash enthusiasts of the twentieth century include Hugh Cutler and W. P. Bemis, who often worked and published with Whitaker.

In recent years, individual domesticated squash species have been scrutinized to determine their evolutionary histories from wild progenitor(s) through domestication to diversification and geographic spread. As an additional source of phylogenetic data, isozyme analyses aided Deena Decker-Walters and Hugh Wilson in their examination of *C. pepo* (Decker 1985, 1988; Decker and Wilson 1987), Laura Merrick (1990) in the study of *C. argyrosperma,* and Thomas Andres (1990) in his evaluation of *C. ficifolia.* Similar modern and detailed research is lacking for *C. maxima* and *C. moschata.*

Two very different but nonetheless comprehensive books have been written on members of the Cucurbitaceae. One by Whitaker and Glen Davis (1962) reviews past research to provide the most up-to-date (at that time) coverage on the description, history, genetics, physiology, culture, uses, and chemistry of economically important cucurbits, including squashes. The other, *Biology and Utilization of the Cucurbitaceae,* edited by David Bates, Richard Robinson, and Charles Jeffrey (1990), includes 36 distinct articles written by leading experts of the day and covering the systematics, evolution, morphology, sex expression, utilization, crop breeding, and culture of squashes and other cucurbits.

Plant and Fruit Descriptions

Five domesticated and about 20 wild squash species grow in dry or somewhat humid regions of the tropics, subtropics, and mild temperate zones. Their native turf ranges from the central United States south to central Argentina, with species diversity being greatest in Mexico. The herbaceous vines are not frost-tolerant. However, some of the xerophytic perennials have large storage roots that can survive a snowy winter. Among the mesophytic annuals, which include the domesticates, quick germination, early flowering, and rapid growth have enabled some to adapt to the more extreme latitudes.

Squash plants are monoecious, tendriliferous vines with leaves ranging from entire to lobed and large, yellow to yellow-orange, campanulate flowers. The ephemeral blossoms, opening only once in the morning, are pollinated primarily by specially adapted solitary bees. The inferior ovary of the female flower develops into a gourdlike fruit called a pepo. Pepos of wild plants are usually round with a tough rind and bitter flesh, whereas domesticated fruits generally lack bitterness and are multifarious in their characteristics.

Although primarily outcrossers, individual plants are self-compatible. Hybridization can also occur between some species. In fact, all squash species have 20 pairs of chromosomes and are incompletely isolated from one another by genetic barriers. This ability to cross species boundaries has been important for plant breeders, allowing them to transfer genes controlling favorable qualities from one species to another. In this way, resistance to the cucumber mosaic virus was transferred from a distantly related wild species to cultivated *C. pepo,* using *C. moschata* as the intermediary.

Archaeological remains, hybridization studies, and genetic data suggest that the domesticated species were independently selected from genetically distinct wild progenitors. In spite of their separate origins, *C. argyrosperma* and *C. moschata* are closely related. In fact, *C. argyrosperma* was not recognized as a distinct species until the Russian geneticist K. I. Pangalo (1930) described it as *Cucurbita mixta* Pang. following extensive collecting expeditions to Mexico and Central America. Even so, it can be difficult to correctly identify some plants and fruits. Generally, fruits of *C. argyrosperma* have enlarged corky peduncles, whereas those of *C. moschata* are hard and thin but distinctly flared at the fruit end. Also, the green and/or white fruits of *C. argyrosperma,* which sometimes mature to yellow, rarely display the orange rind coloring that is common among cultivars of *C. moschata.* Foliaceous sepals are largely unique to but not ubiquitous in *C. moschata.* Leaf mottling is more common in *C. moschata* and leaf lobes deeper in *C. argyrosperma.*

Both species have large flowers with long slender androecia, relatively soft pubescence on the foliage, and distinctly colored seed margins. Among the domesticated species, these squashes best survive the hot, humid, low-elevation (usually under 1,500 meters [m] above sea level) climes of the mid-latitudes, often failing to flower when daylengths are too long. But relative to the wide pre-Columbian distribution and diversity in *C. moschata* (Figure II.C.8.1), *C. argyrosperma* has remained limited in its geography and genetic variability.

There are three domesticated varieties of *C. argyrosperma* subspecies (ssp.) *argyrosperma* – variety (var.) *argyrosperma,* var. *callicarpa* Merrick and Bates, var. *stenosperma* (Pang.) Merrick and Bates – and a weedy variety, var. *palmeri* (Bailey) Merrick and Bates (see Table II.C.8.1). Most of the diversity in this squash can still be found in the endemic landraces of the southwestern United States, Mexico, and Central America. The moderately sized, unfurrowed fruits range from globose to pyriform to long-necked; in the latter, the necks may be straight or curved. Rinds are generally decorated with splotchy, irregular green and white stripes, though in var. *callicarpa,* solid white or green fruits are common and the green coloration is often lacy. Commercial cultivars are few, as culinary quality of the pale yellow to orange flesh is relatively poor in this species. Most of the cultivars and landraces in commercial trade today represent var. *callicarpa.*

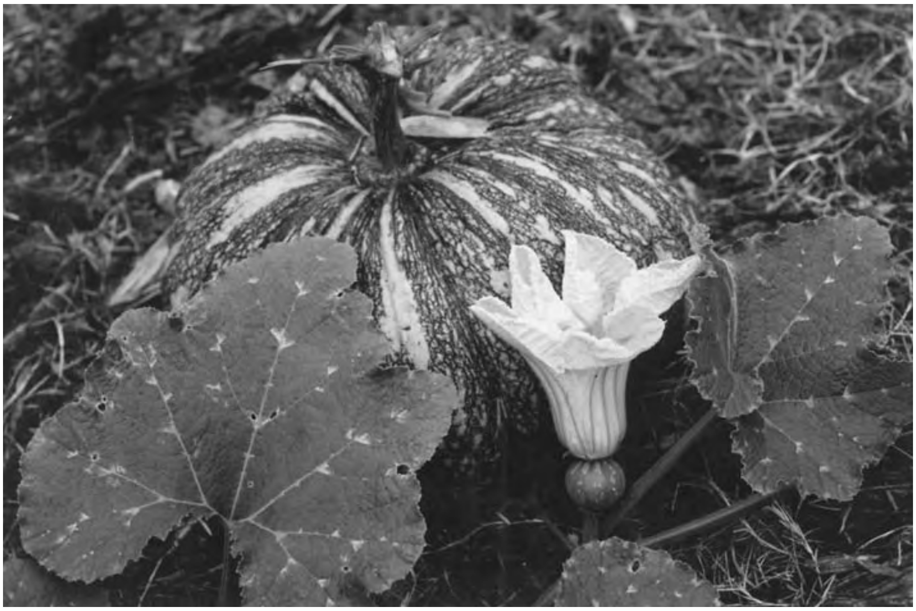


Figure II.C.8.1. The white-splotched leaves, yellow-orange female flower, and immature green-and-white-striped fruit of *Cucurbita moschata.* The swelling of the peduncle where it is attached to the fruit is characteristic of this species.

Fruits of *C. moschata,* weighing up to 15 kilograms (kg) apiece, range from squatty to round to turbinate, pyriform, or oblong to necked. Furrows, sometimes deep, are common and wartiness occasional. The rinds are solid, splotchy, or striped in dark to light greens, whites, creams, yellows, and oranges. Fruit flesh is usually deep yellow or orange.

In North America, cultivars of *C. moschata* have been placed into three horticultural groups – "cheese pumpkins," "crooknecks," and "bell squashes" (see Table II.C.8.2). However, these groups do not satisfactorily accommodate the diversity of landraces that have evolved in tropical regions around the globe. For example, *C. moschata* is widely cultivated in Asia, and several unusual cultivars with names like 'Chirimen', 'Kikuza', 'Saikyo', and 'Yokohama' originated in Japan. Fruit characteristics resembling those of *C. argyrosperma* ssp. *argyrosperma* indicate that the Japanese cultivars may have arisen from interspecific crossings. Genetic diversity in some northwestern Mexican landraces of *C. moschata* also may be the result of introgression from wild and/or cultivated *C. argyrosperma.*

A. I. Filov (1966) expanded earlier classifications of *C. moschata* to include over 20 varieties in several geographical subspecies. Unfortunately, modern systematic and genetic studies that would confirm the natural relationships among cultivars within and among regions are lacking. Nevertheless, these geographical subspecies do reveal centers of diversification that include Colombia, where the seeds are darker and the plants and fruits small; Mexico, Central America, and the West Indies, where landraces

Table II.C.8.1 *Domesticated varieties of* Cucurbita argyrosperma *ssp.* argyrosperma

Variety	Description	Distribution in North America	Cultivars and comments
var. *argyrosperma*	Fruits mostly striped; peduncle relatively thin; seeds broad, smooth-surfaced, white with gray margins	Eastern and southern Mexico, Central America	'Silverseed Gourd' is grown for its seeds, which are the largest in the genus
var. *callicarpa*	Fruits solid in color, striped or blotchy; peduncle thick; seeds white or golden tan with tan margins, surfaces smooth or etched	Central and northwestern Mexico, southwestern U.S.	'Green Striped Cushaw', 'Japanese Pie', 'Puritan', 'Tennessee Sweet Potato', 'White Cushaw', and various landraces; good-quality fruit flesh
var. *stenosperma*	Fruits mostly striped; dark green tint to the placental tissue; peduncle thick; seeds narrow, smooth-surfaced, white with gray or tan margins	South-central Mexico	'Elfrida Taos'; distribution and characteristics overlap with those of the other varieties; grown mostly for the edible seeds

Table II.C.8.2. *Horticultural groups of* Cucurbita moschata

Horticultural group	Description	Representative cultivars	Comments
Cheese pumpkins	Fruits variable but usually oblate with a buff-colored rind	'Calhoun', 'Kentucky Field', 'Large Cheese', 'Quaker Pie'	Plants are hardy and productive under various growing conditions
Crooknecks	Fruits round at blossom end with long straight or curved necks	'Bugle Gramma', 'Canada Crookneck', 'Golden Cushaw', 'Winter Crookneck'	Very popular in colonial America for pies and stock
Bell squashes	Fruits bell-shaped to almost cylindrical	'African Bell', 'Butternut', 'Carpet Bag', 'Ponca', 'Tahitian'	These cultivars, which are the most popular today, were probably selected from "crookneck" types

are genetically variable and fruits of many shapes and colors can be found in a single field; Florida, which is home to the small-fruited, aboriginal 'Seminole Pumpkin'; Japan with its warty and wrinkled fruits; India, where large soft-skinned fruits abound; and Asia Minor, where fruits again are variable but long barbell-shaped pepos predominate.

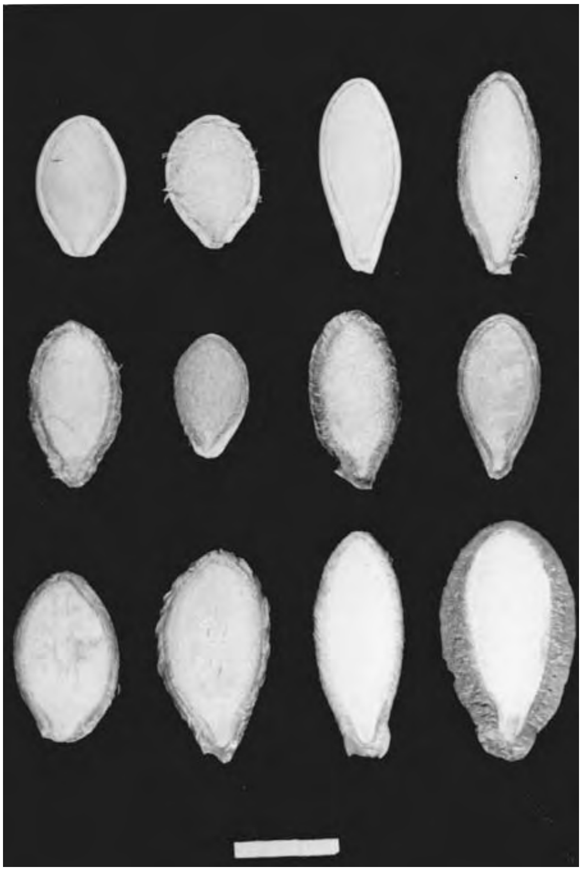

Figure II.C.8.2. Seeds of *Cucurbita pepo* (top), *C. moschata* (center), and *C. argyrosperma* (bottom). At the lower right is a seed of 'Silverseed Gourd,' the largest of all squash seeds. Scale equals 1 cm.

Although *C. moschata* is the most widely cultivated squash in underdeveloped tropical countries, as with *C. argyrosperma,* relatively few cultivars have entered the commercial trade of Europe and North America. "Cheese pumpkins" and "crooknecks" were popular in nineteenth-century New England. Today, only various selections from the "bell squashes" are commonly sold by seed suppliers (Figure II.C.8.3).

Cucurbita pepo is characterized by uniformly colored tan seeds, lobed leaves with prickly pubescence, hard roughly angled peduncles, and short, thick, conical androecia (Figures II.C.8.2 and II.C.8.4). Flowers range from small to large, though they are rarely as grand as those of *C. argyrosperma* ssp. *argyrosperma.* Genetic diversity, expressed in the plethora of differing fruit forms, is greatest in this squash. Orange flesh color is not as common in *C. pepo* as it is in *C. maxima* or *C. moschata.*

Cucurbita pepo appears to have shared a Mexican or Central American ancestor with *C. argyrosperma* and *C. moschata.* From those origins, wild populations – ssp. *ovifera* (L.) Decker var. *ozarkana* Decker-Walters, ssp. *ovifera* var. *texana* (Scheele) Decker, ssp. *fraterna* (Bailey) Andres, ssp. *pepo* – spread over North America before at least two domestications of *C. pepo* took place to produce ssp. *ovifera* var. *ovifera* (L.) Decker and cultivars of ssp. *pepo.* Because *C. pepo* can tolerate cooler temperatures than can *C. argyrosperma* and *C. moschata,* this squash flourishes at more extreme latitudes and higher elevations (1,600 to 2,100 m above sea level) to the delight of farmers from southern Canada to the highlands of Central America. Some wild populations and cultivars are well adapted to the northern United States, with seeds that are quick to germinate and early flowering that is responsive to changes in daylength.

Encompassing many hundreds of cultivars, six horticultural groups of *C. pepo* were recognized during the twentieth century (see Table II.C.8.3). "Acorn squashes," "crooknecks," "scallop squashes," and most "ornamental gourds" belong to ssp. *ovifera* var. *ovifera.* Horticulturists have traditionally classified all small, hard-shelled, bitter fruits grown

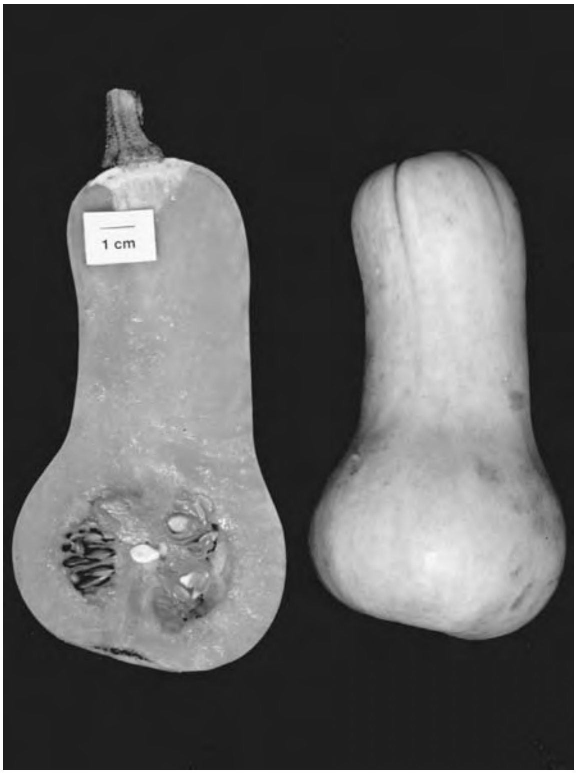

Figure II.C.8.3. 'Butternut', a "bell squash" cultivar of *Cucurbita moschata,* has a cream-colored rind and dark orange flesh rich in carotenes.

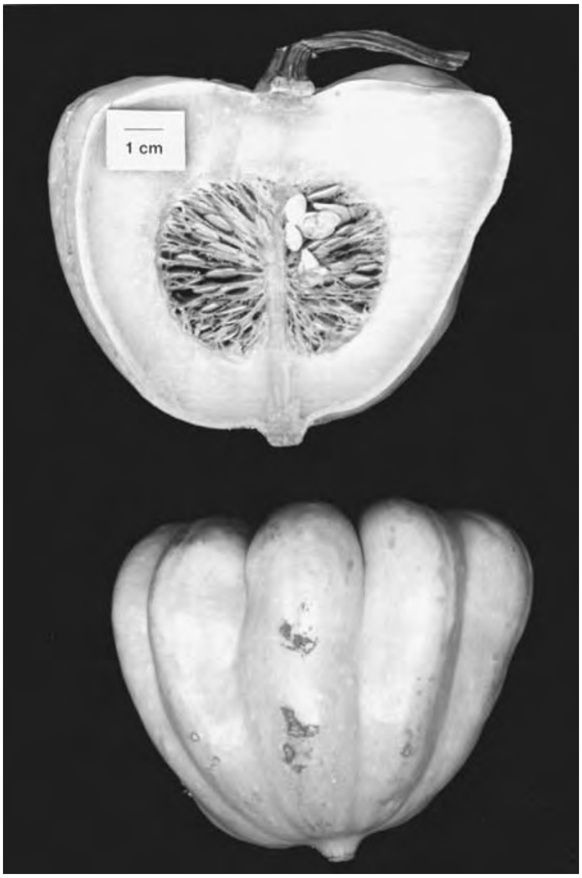

Figure II.C.8.4. An unusual "acorn squash" of *Cucurbita pepo* purchased in Ontario, Canada; cultivar unknown. Flesh and rind are tan colored.

for autumn decorations as ornamental gourds. However, this classification does not reflect the fact that these gourds have various genealogies that include wild populations of ssp. *ovifera,* ssp. *pepo,* and probably ssp. *fraterna.* Pumpkins, such as those grown in temperate to tropical gardens around the globe, and marrows belong to ssp. *pepo.* The former, like acorn squashes, are eaten when mature, whereas the latter, like the crooknecks and scallop squashes, are summer squashes picked during the first week of fruit development. Bushy plants with relatively short internodes have been developed for most of the summer squashes as well as for some of the acorn squashes (Figures II.C.8.5 and II.C.8.6).

Cucurbita maxima is distantly related to the trio just discussed. This squash, whose origins are in South America, exhibits closer genetic affinities to other wild South American species. Like *C. pepo,* some cultivars and landraces of *C. maxima* can tolerate the relatively cool temperatures of the highlands (up to 2,000 m above sea level). Today, this species is grown in tropical to temperate regions around the globe, particularly in South America, southeastern Asia, India, and Africa.

Cucurbita maxima is distinguished by its soft round stems, entire or shallowly lobed unpointed leaves, and spongy, enlarged, terete peduncles. Compared to the other domesticates, the white or brown seeds of this squash are thick, particularly in relationship to their margins. The androecium is short, thick, and columnar. The yellow or orange fruit flesh is fine-grained and of the highest quality (tasty and relatively rich in vitamins) among all squashes. Fruits are quite variable in size, shape, and coloration, with the latter including many shades of gray, green, blue, pink, red, and orange in striped, mottled, or blotchy patterns.

A distinct fruit form characterizes cultivars classified as "turban squashes" (Figures II.C.8.7 and II.C.8.8). The immature ovary protrudes upward from the receptacle, swelling into a turban-shaped fruit with a crown (the part of the fruit not enveloped by the receptacle) upon maturity. Table II.C.8.4 lists some turban squash cultivars and describes five other traditionally recognized horticultural groups – "banana squashes," "delicious squashes," "hubbard squashes" (Figure II.C.8.9)"marrows," and "show pumpkins."

Table II.C.8.3. *Horticultural groups of* Cucurbita pepo

Horticultural group	Description	Representative cultivars	Comments
Acorn squashes	Fruits usually small, of various shapes and colors but always grooved	'Acorn', 'Delicata', 'Fordhook', 'Mandan', 'Sweet Dumpling', 'Table Queen'	A heterogeneous group of uncertain origins but closely related to "scallop squashes"; mature fruits baked as vegetable
Crooknecks	Fruits long, club-shaped with straight or curved neck; rind very hard, yellow to orange, warted	'Giant Crookneck', 'Straightneck', 'Summer Crookneck', 'Yankee Hybrid'	Probably an ancient group of summer squashes although 'Straightneck' cultivars are more recent in origin
Marrows	Fruits long, club-shaped to cylindrical, mildly ridged; rind usually with lacy green pattern	'Cocozelle', 'Moore's Cream', 'Vegetable Marrow', 'Zucchini'	Selected from pumpkins and diversified in Europe; fruits eaten immature
Ornamental gourds	Fruits small of various shapes and colors; rind hard; flesh usually bitter; seeds small	'Crown of Thorns', 'Flat Striped', 'Miniature Ball', 'Nest Egg,' 'Orange Warted', 'Spoon', 'Striped Pear'	A heterogeneous group of multiple origins; some cultivars primitive, others fairly new; fruits not eaten
Pumpkins	Fruits typically large, round or oblong, shallowly to deeply grooved or ribbed; rind relatively soft; seeds large	'Connecticut Field', 'Jack O'Lantern', 'Sandwich Island', 'Small Sugar', 'Vegetable Spaghetti'	Mature fruits used as a vegetable or for pies, jack-o'-lanterns, and forage; grown for edible seeds also
Scallop squashes	Fruits flattened at both ends with edges scalloped around middle; rind hard	'Benning's Green Tint', 'Golden Custard', 'Patty-pan', 'White Bush Scallop'	An ancient group of summer squashes

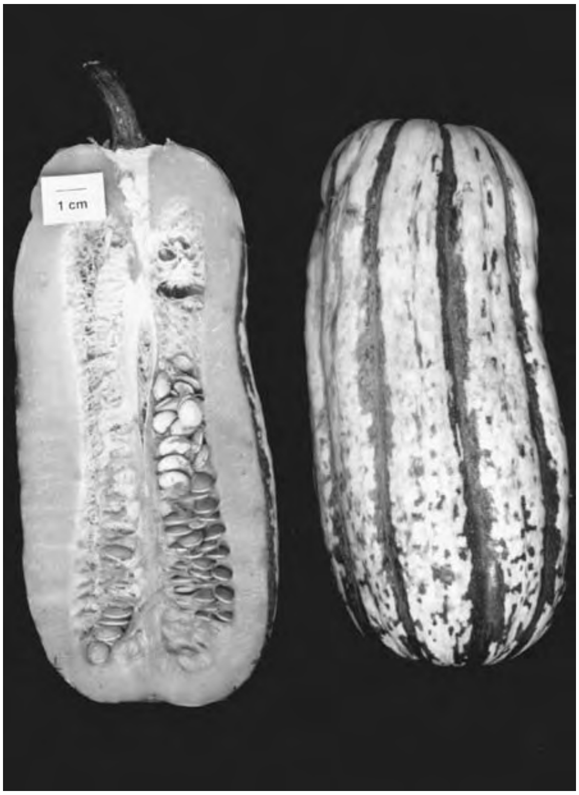

Figure II.C.8.5. 'Delicata' (*Cucurbita pepo*) has a green-and-white-striped rind that turns orange and pale yellow with age. The orange flesh of these long-keeping fruits intensifies in color with storage.

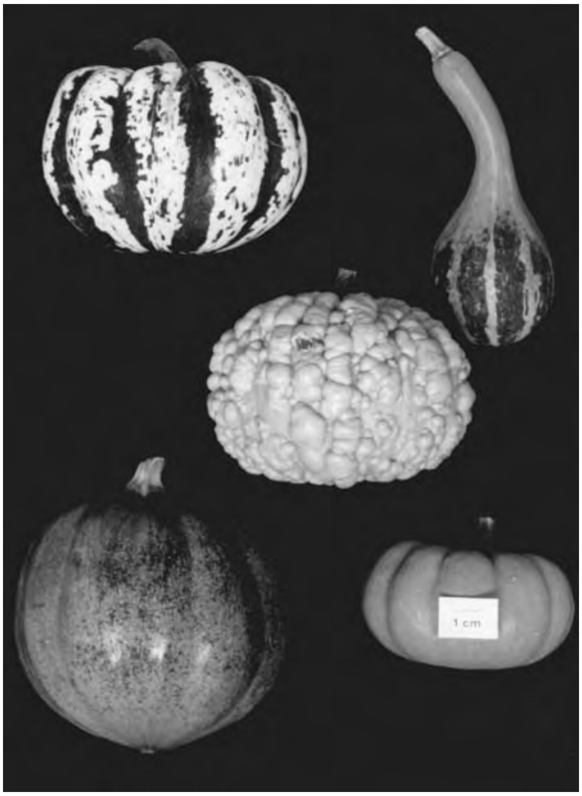

Figure II.C.8.6. Various small-fruited cultivars of *Cucurbita pepo*, including 'Sweet Dumpling' (top left), 'Bicolor Spoon' (top right), 'Orange Warted' (center), 'Table Queen' (bottom left), and 'Jack-Be-Little Pumpkin' (bottom right).

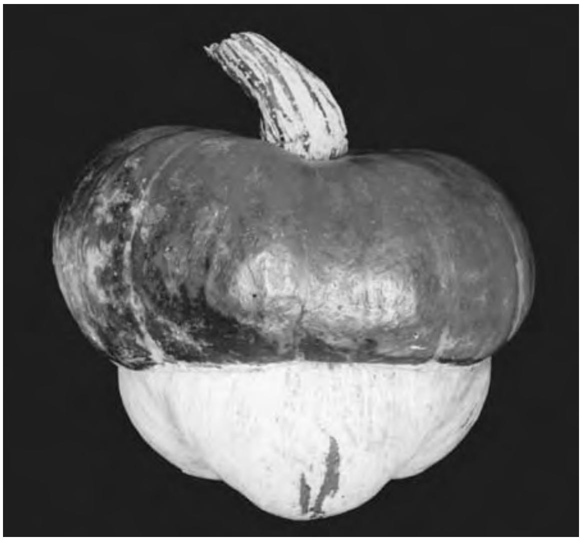

Figure II.C.8.7. 'Turk's Turban' (*Cucurbita maxima*) is often grown as an ornamental because of the deep red rind color. The crown of this fruit has a much paler pattern of green and red splotches.

Over 50 cultivars of *C. maxima* had been commercially traded by the early twentieth century; today, this number has reached over 200. Not all landraces and cultivars can be assigned to the horticultural groups in Table II.C.8.4. Some cultivars, such as the warty 'Victor', were derived from hybridizations between horticultural groups. Local landraces that never entered into, or played only minor roles in, American and European commercial trade often have fruit traits that do not match those characterizing the groups. And although several varieties of *C. maxima* have been proposed over the years, as of yet no one has performed an intensive systematic study of this species to clarify evolutionary relationships among cultivars and groups of cultivars.

Cucurbita ficifolia is not closely related to the other domesticated squashes or to any known wild populations. Distinguishing characteristics include relatively wide, minutely pitted, solid-colored seeds, ranging from tan to black; white, coarsely fibrous flesh; an androecium shaped like that of *C. maxima* but with hairs on the filaments; and rounded lobed leaves. Genetic uniformity in this species is evidenced by the lack of variation in fruit characteristics. The large oblong fruits, measuring 15 to 50 centimeters (cm) long, exhibit only three basic rind coloration patterns: solid white, a reticulated pattern of green on white that may include white stripes, and mostly green with or without white stripes. No distinct landraces or cultivars of *C. ficifolia* have been recognized.

In Latin America today, this cool-tolerant, short-day squash is grown for food in small, high-altitude (1,000 to 2,800 m above sea level) gardens from northern Mexico through Central America and the Andes to central Chile. Usually the mature fruits are candied, but the seeds and immature fruits are eaten as well. *Cucurbita ficifolia* is also cultivated as an ornamental

Table II.C.8.4. *Horticultural groups of* Cucurbita maxima

Horticultural group	Description	Representative cultivars	Comments
Banana squashes	Fruits long, pointed at both ends; rind soft; seeds brown	'Banana', 'Pink Banana', 'Plymouth Rock'	Introduced to the U.S. from Mexico; plants can tolerate high temperatures
Delicious squashes	Fruits turbinate, shallowly ribbed; rind hard; seeds white	'Delicious', 'Faxon', 'Quality'	High-quality flesh; original stock came from Brazil in the late 1800s; similar types occur in Bolivia
Hubbard squashes	Fruits oval, tapering curved necks at both ends; rind very hard; seeds white	'Arikara', 'Blue Hubbard', 'Brighton', 'Hubbard', 'Kitchenette', 'Marblehead'	Inbreeding and hybridization have produced many cultivars
Marrows	Fruits oval to pyriform, tapering quickly at the apex and gradually toward the base; seeds white	'Boston Marrow', 'Golden Bronze', 'Ohio', 'Valparaiso', 'Wilder'	Fruits mature early; original stock probably came from Chile
Show pumpkins	Fruits large, orange; rind soft; seeds white	'Atlantic Giant', 'Big Max', 'Big Moon', 'Etampes', 'Mammoth'	Produces the largest pepos in the genus; grown for show and forage; a lot of diversity in India
Turban squashes	Fruits turban-shaped	'Acorn', 'Buttercup','Crown', 'Essex', 'Red China', 'Sweetmeat', 'Turban', 'Warren', 'Sapallito del Tronco'	Many cultivars were selected in Africa, Asia, and Australia from South American stock; some are more bushy than viny

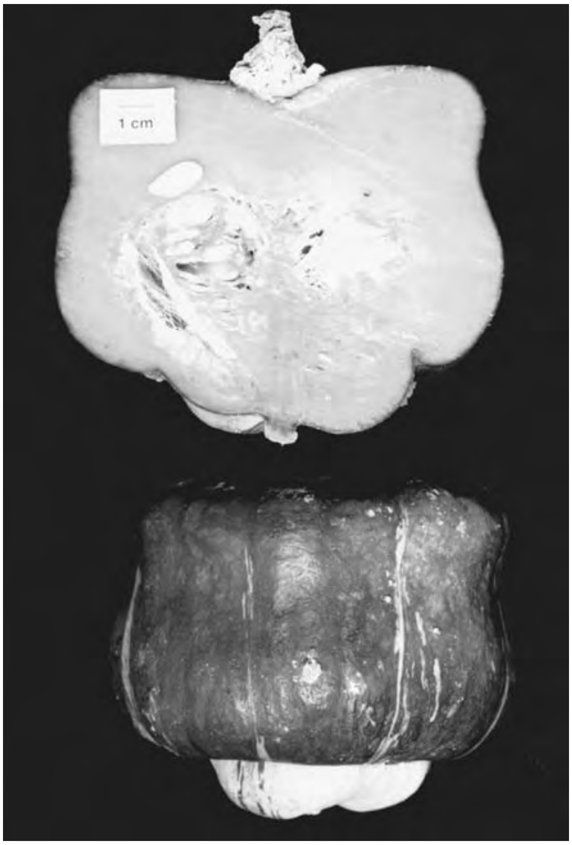

Figure II.C.8.8. 'Buttercup' is a "turban squash" of *Cucurbita maxima*. This fruit has a dark green rind, except for the small crown, which is a pale blue-green. Seeds are white and the flesh dark orange.

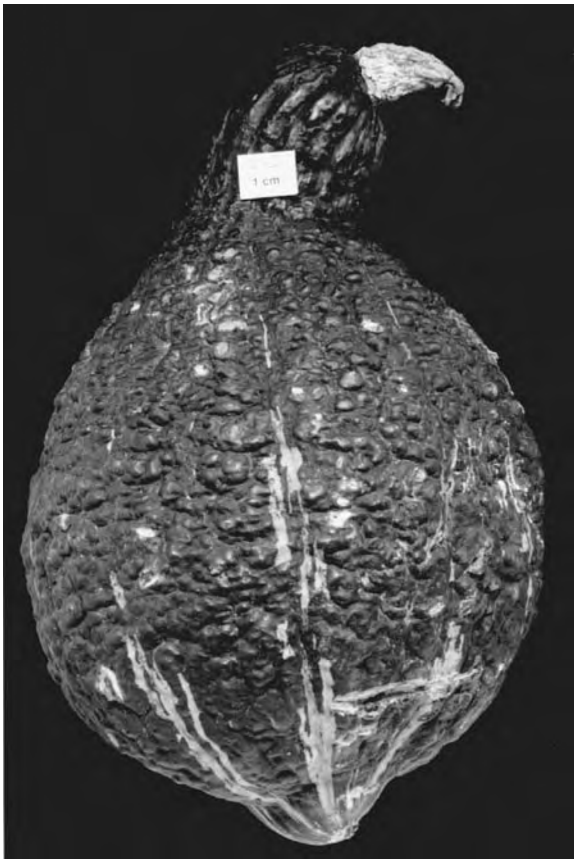

Figure II.C.8.9. This "hubbard squash" of *Cucurbita maxima* has a warted, dark blue-green rind with a few pale stripes. Note the swollen peduncle.

in Europe and the United States and for forage in underdeveloped countries of the Old World.

The Evolution and History of Squashes

The five domesticated squash species were brought under cultivation 5,000 to 15,000 years ago. Native Americans transformed the small green and white gourdlike pepos of wild plants into a cornucopia of colorful and shapely pumpkins and squashes. But long before they were domesticated, wild squash plants made their presence known to human populations. These fast-growing, tenacious vines are prolific opportunists, boldly invading disturbed sites of natural or human origin. Initial human interest in wild squash may have manifested itself in the use of the tough fruit rinds for containers. Additionally, the seeds are a tasty and nutritious source of food. The flesh of wild pepos is too bitter to eat raw. Toxic oxygenated tetracyclic triterpenes, called cucurbitacins, permeate the leaves, roots, and fruits as deterrents to herbivory. Nevertheless, the frequency of immature peduncles among archaeological remains suggests that the young tender fruits were consumed, probably after leaching out the cucurbitacins through multiple boilings.

The development of nonbitter pepos came about as a result of domestication. Indiscriminate harvesting of fruits from wild or tolerated weedy vines eventually led to the planting of seeds from selected genetic strains. In the process of selecting for larger fruits for containers or larger seeds for consumption, thicker, nonbitter, and less fibrous flesh was discovered and selected for as well. Other changes included the loss of seed dormancy, softer and more colorful fruit rinds, adaptation to shorter growing seasons, and generally larger plant parts. In this way, squash became a major component of diets for the ancient farmers of the New World.

Squash domestication took place at least five times to yield the cultivated members of *C. argyrosperma, C. ficifolia, C. maxima, C. moschata,* and *C. pepo.*

These domestications involved genetically distinct wild populations and at least three different cultural groups inhabiting the eastern United States, Middle America, and South America. A discussion of the evolution of these cultivated squashes along with their history and spread follows.

Cucurbita argyrosperma

Cultivars of *C. argyrosperma* ssp. *argyrosperma* are genetically similar to wild populations of *C. argyrosperma* ssp. *sororia,* a native of low-elevation, mostly coastal habitats in Mexico and Central America. Sufficient evidence exists to support the theory that ssp. *sororia* gave rise to domesticated ssp. *argyrosperma.* Domestication probably took place in southern Mexico, where the earliest remains of ssp. *argyrosperma* date around 5000 B.C. Most of these archaeological specimens belong to var. *stenosperma;* landraces of this variety are still grown in southern Mexico today. With a current distribution ranging from northeastern Mexico south to the Yucatan and into Central America, var. *argyrosperma* is the most widespread variety of ssp. *argyrosperma* (Figure II.C.8.10). Remains of var. *argyrosperma* first appear in the archaeological record in northeastern Mexico at about A.D. 200. A little later (c. A.D. 400), var. *callicarpa* shows up at archaeological sites in the southwestern United States. The earliest pre-Columbian evidence of *C. argyrosperma* in eastern North America is fifteenth-century remains from northwestern Arkansas. Although the three varieties of ssp. *argyrosperma* could have been selected separately from wild populations of ssp. *sororia,* Merrick's (1990) interpretation of the morphological evidence suggests that var. *stenosperma* and var. *callicarpa* evolved from southern and northern landraces of var. *argyrosperma,* respectively.

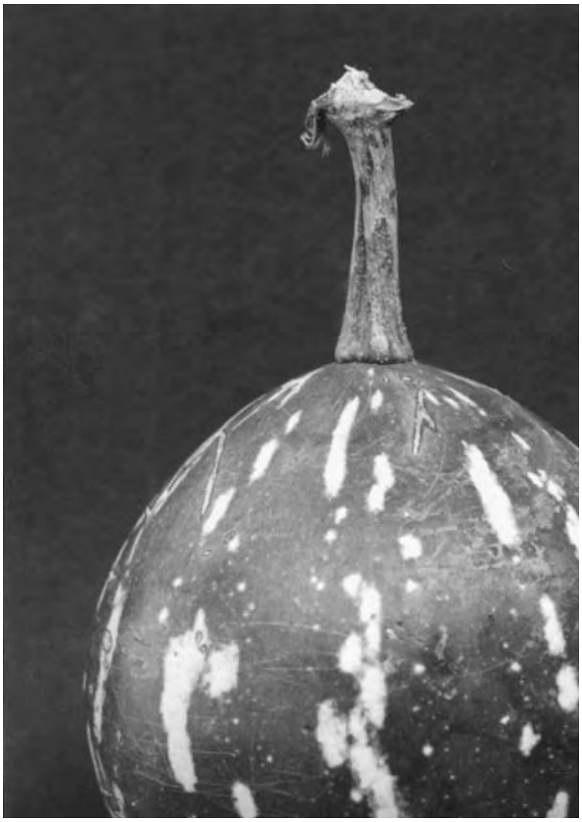

Figure II.C.8.10. This mature fruit of *Cucurbita argyrosperma* ssp. *sororia*, measuring about 7 cm. in diameter, was collected from a wild population in Veracruz, Mexico.

The fourth and final variety of spp. *argyrosperma,* var. *palmeri,* is weedy, possessing a mixture of characteristics otherwise representing wild spp. *sororia* and cultivated var. *callicarpa.* It grows unaided in disturbed areas, including cultivated fields, in northwestern Mexico beyond the range of ssp. *sororia. Cucurbita argyrosperma* ssp. *argyrosperma* var. *palmeri* may represent escapes of var. *callicarpa* that have persisted in the wild by gaining through mutation and/or hybridization with ssp. *sororia* those characteristics (such as bitter fruits) that are necessary for independent survival.

Current uses of wild and weedy fruits in Mexico include eating the seeds, using seeds and the bitter flesh medicinally, washing clothes with the saponin-rich flesh, and fashioning containers from the dried rinds. Although the antiquity of these uses is uncertain, selection for edible seeds has remained the dominant theme in cultivation. In southern Mexico and Guatemala, var. *argyrosperma* and var. *stenosperma* are grown for their large edible seeds, with the fruit flesh serving as forage. In southern Central America, indigenous cultures have produced landraces that yield a necked fruit eaten as a vegetable while immature and tender. Selection pressures in northern Mexico have created several landraces of var. *argyrosperma* and var. *callicarpa;* some produce mature pepos with quality flesh for human consumption as well as edible seeds, whereas others are grown for their immature fruits. At twelfth- and thirteenth-century sites in southern Utah, fruits of var. *callicarpa* were employed as containers, a use that persists among some tribes of the Southwest today. The greatest diversity of fruits in the species, represented primarily by var. *callicarpa,* occurs in northwestern Mexico and the southwestern United States

Relative to the post-Columbian changes incurred by other squashes, the spread and further diversification of *C. argyrosperma* cultivars has been limited. A few commercial cultivars such as 'Green Striped Cushaw' were selected from North American stock and grown in New England soon after colonization. A similar type of squash was illustrated in European herbals of the sixteenth century, and additional types were developed in South America and Asia. As a result of the recent trend to identify, save, and distribute native landraces of New World crops, a large number of landraces of *C. argyrosperma* indigenous to North America have entered the U.S. commercial trade under such names as 'Chompa', 'Green Hopi Squash', 'Mayo Arrote', 'Montezuma Giant', and 'Pepinas'.

Cucurbita moschata

The earliest archaeological remains indicative of domestication of *C. moschata* were discovered in southern Mexico (5000 B.C.) and in coastal Peru (3000 B.C.). Ancient Peruvian specimens differ from those of Mexico by having a warty rind and a pronounced fringe along the seed margins. Although Mexico appears to be the more ancient site of domestication, the Peruvian remains and the diversity of Colombian landraces point to South America as a secondary site of early diversification or an independent center of domestication. Unfortunately, wild progenitor populations have not yet been identified for this species. It is possible that they are extinct; however, a few tantalizing finds of wild squash in Bolivia suggest that South American populations of *C. moschata* may be awaiting rediscovery. Among wild squashes known today in Middle America, those of *C. argyrosperma* ssp. *sororia* express the greatest genetic affinity to Mexican landraces of *C. moschata.*

Even though the centers of landrace diversity for *C. moschata* lie in Central America and northern South America, archaeological remains indicate that this species spread to northeastern Mexico by about 1400 B.C. and to the southwestern United States by A.D. 900. The spread of *C. moschata* to the Gulf coastal area and the Caribbean may have been facilitated by early Spanish explorers and missionaries; a distinctive Florida landrace called 'Seminole Pumpkin' (Figure II.C.8.11) is still grown by the Miccusokees of the Everglades. Among tribes of the Northern Plains, *C. moschata* was definitely a post-Columbian introduction.

The crooknecks and cheese pumpkins, which probably have their origins in North America, were known to colonists and Europeans as early as the 1600s. Variations on the cheese pumpkin theme can be found in the large furrowed pumpkins of India and southeastern Asia. Additional diversification of *C. moschata* took place in Asia Minor, where various fruit types resemble the bell squashes, and in Japan, where selection was for heavily warted rinds. Completing its worldwide travels, this species was well established as a food crop in northern Africa by the nineteenth century.

Cucurbita pepo

The squash represented by the earliest archaeological remains is *C. pepo.* Its seeds and rinds of wild or cultivated material appear in Florida around 10,000 B.C., in southern Mexico around 8000 B.C., and in Illinois at around 5000 B.C. Enlarged seeds and peduncles as well as thicker fruit rinds suggest that this species was definitely under cultivation in southern and northeastern Mexico between 7500 and 5500 B.C. and in the Mississippi Valley between 3000 and 1000 B.C. Cultivation had spread from Mexico to the southwestern United States by around 1000 B.C., and by A.D. 1500, *C. pepo* landraces were being grown throughout the United States and Mexico.

Ancestral North Americans independently domesticated at least two genetically distinct and geographically disjunct subspecies of *C. pepo* to produce the two major lineages of cultivars known today. Although wild populations of ssp. *pepo* (Figures II.C.8.12 and II.C.8.13) are currently unknown

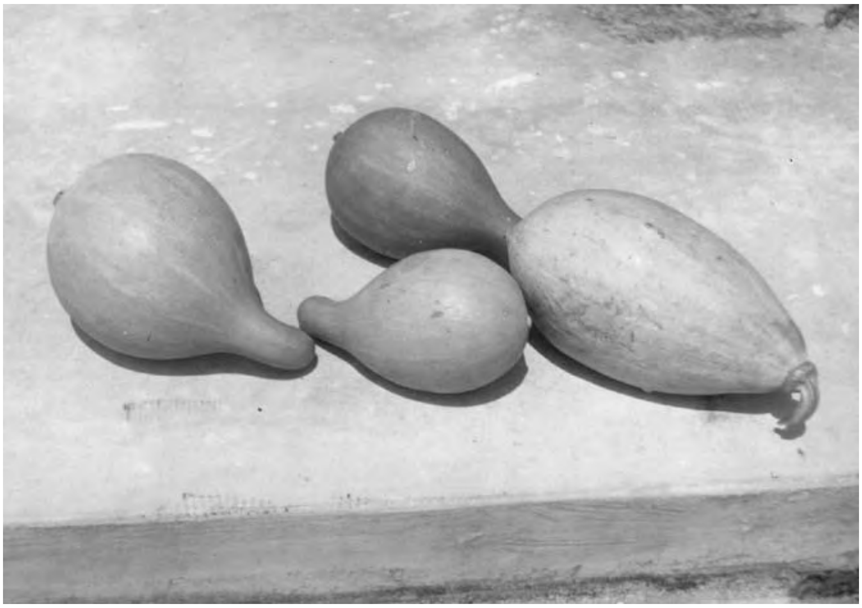

Figure II.C.8.11. Fruit shape in the tan-colored fruits of the 'Seminole Pumpkin' (*Cucurbita moschata*) ranges from round or oblate to oval, oblong, or pear shaped. (Photograph by John Popenoe.)

and possibly extinct, they were probably subjected to the selection pressures of the natives of southern Mexico, giving rise to the majority of Mexican and southwestern U.S. landraces, as well as to "pumpkin" and "marrow" cultivars of this species. As with *C. argyrosperma* and *C. moschata,* human selection with *C. pepo* landraces in southern Mexico focused on producing large seeds within a sturdy round fruit.

Today, wild populations of *C. pepo* range from northeastern Mexico (ssp. *fraterna*) to Texas (ssp. *ovifera* var. *texana*), and north through the Mississippi Valley to southern Illinois (ssp. *ovifera* var. *ozarkana*).

As recently as 250 years ago, wild populations of ssp. *ovifera* may have occurred throughout the Gulf coastal region and certainly in Florida. A whole different lineage of cultivars, classified as ssp. *ovifera* var. *ovifera,* evolved from eastern U.S. populations of var. *ozarkana.* Aborigines of the Mississippi Valley apparently were not as interested as the Mexicans in quickly selecting for large seeds or fleshy fruits. Instead, a variety of small, odd-shaped, hard, and often warty cultivars were used as containers or grown for other nonsubsistence purposes. And although the seeds of early cultivars were probably eaten, in selecting for food, natives of the eastern United States developed several cultivars, such as the precursors of the scallop squashes and crooknecks, that produced tasty immature fruits.

Gilbert Wilson's (1917) treatise on agriculture among the Hidatsa indigenes of the Northern Plains gives us a more detailed account of the aboriginal use of *C. pepo.* These Native Americans cultivated squashes of various shapes, sizes, and colors together, picking them when four days old.

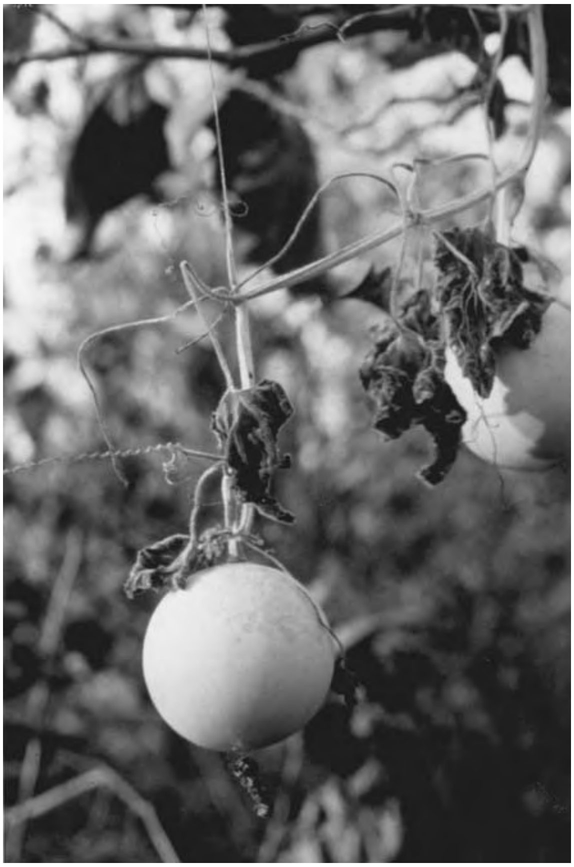

Figure II.C.8.12. The white fruit of this wild *Cucurbita pepo* ssp. *ovifera* var. *ozarkana* plant still clings to the dead vine at a riparian site in the Mississippi Valley. (Photograph by Wes Cowan and Bruce Smith.)

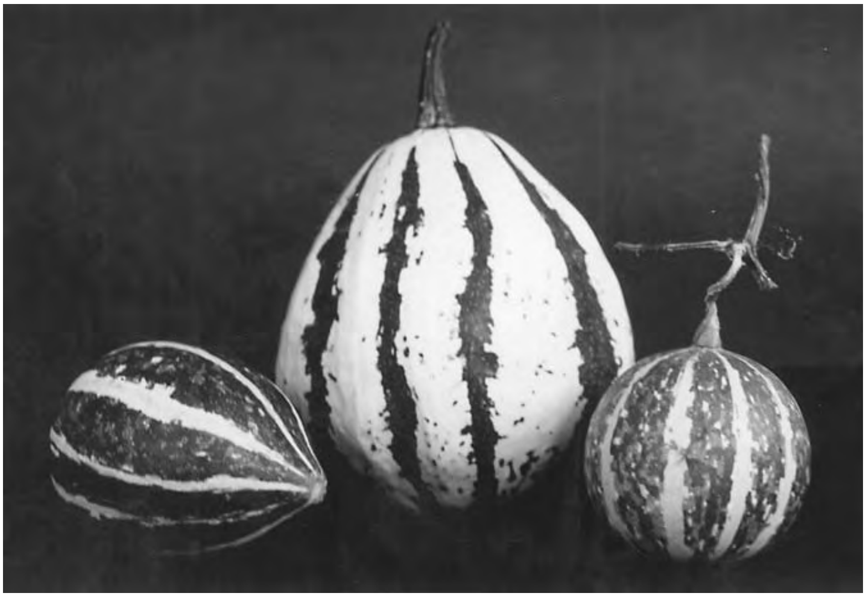

Figure II.C.8.13. From left to right, these green-and-white-striped fruits of *Curcurbita pepo* represent wild spp. *ovifera* var. *texana,* 'Mandan' (a cultivar of var. *ovifera*), and wild ssp. *fraterna.*

The young fruits were eaten fresh or sliced and dried for the winter. The flesh, and sometimes the seeds, of these mature fruits were boiled and eaten. Male squash blossoms did not go to waste either; they were picked when fresh and boiled with fat or dried for later use in mush. One fruit per plant was allowed to mature so as to provide seed for the next planting.

In addition to the two primary centers of domestication of *C. pepo,* a few landraces and cultivars may have been domesticated from wild populations of ssp. *fraterna* in northeastern Mexico. These landraces and those from southern Mexico probably spread to the eastern United States between A.D. 1000 and 1500, if not earlier. The intermingling of cultivars undoubtedly gave rise to new genetic combinations, which accounts for the diversity of fruits encountered by the earliest European visitors. The "acorn squashes," which include the Northern Plains landrace 'Mandan', may have originated in this way when Mexican "pumpkins" met "scallop squashes" in the United States. Similarly, 'Fort Berthold' and 'Omaha' are northern-adapted "pumpkin" landraces that were being grown by Sioux tribes in the early twentieth century.

Fruits representing all of the major horticultural groups are pictured in the herbals of the sixteenth century. More than any other squash, *C. pepo* was enthusiastically embraced by European horticulturists; hundreds of new cultivars, particularly the "marrows," have been developed in Europe and in the United States over the past 400 years. Selection practices emphasized earliness in flowering, compactness or bushiness in growth, and uniformity within a cultivar for fruit characteristics.

Although *C. pepo* was carried to other parts of the globe during the seventeenth century, diversification of landraces was limited primarily to the "pumpkins" of Asia Minor. Nevertheless, unique cultivars did develop elsewhere, such as 'Alexandria' from Egypt, 'Der Wing' from China, 'Nantucket' from the Azores, and 'Pineapple' from South America.

Cucurbita maxima

Numerous landraces of *C. maxima* with differing fruit characteristics can be found throughout South America today. However, archaeological remains are less widespread. Most are from coastal Peru, where the earliest evidence of domestication appears between 2500 and 1500 B.C. Later pre-Columbian remains have been found in Argentina (500 B.C.) and northern Chile (A.D. 600). Early Spaniards noted that landraces of *C. maxima* were being grown by the Guarani indigenes of northeastern Argentina and Paraguay.

The wild progenitor of domesticated *C. maxima* ssp. *maxima* is *C. maxima* ssp. *andreana* (Naud.) Filov, a weedy native of warm temperate regions in northern Argentina, Uruguay, Bolivia, and possibly Paraguay. Hybridization between cultivars and wild populations has contributed to genetic variability in ssp. *andreana,* producing wild fruits that vary from pear-shaped to oblong to round. Some landraces may have been selected from these introgressed populations.

South American aborigines apparently selected for large fruits of ssp. *maxima* with high-quality flesh and good storage capabilities. The largest South American fruits, weighing 20 to 40 kg, are found in landraces from central Chile. Fruits with a woody skin suitable for long storage were noted in Bolivia by Russian explorers in the 1920s. Warty fruits also evolved in South America, and in the twentieth century are found in Bolivia and Peru. Other native landraces yield tasty immature fruits.

Cultivation of *C. maxima* did not spread to northern South America, Central America, and North America until after the European invasion of the sixteenth century. Yankee sailors were supposedly responsible for introducing various cultivars, including 'Acorn', or 'French Turban', 'Cocoa-Nut', and 'Valparaiso', to New England early in the nineteenth century. Although all of the horticultural groups probably have their origins in South America, the spread of *C. maxima* throughout North America yielded some new landraces and cultivars. For example, 'Arikara' and 'Winnebago' are landraces that were grown by aboriginal tribes in North Dakota and Nebraska, respectively, during the beginning of the twentieth century. The "banana squashes" proliferated in Mexico, and "Hubbard squashes," like 'Marblehead', came to the eastern United States from the West Indies during the 1800s.

Visitors took several types of *C. maxima* back to Europe during the sixteenth through nineteenth centuries. Some, like the turban squash called 'Zapallito del Tronco' or 'Tree Squash', came directly from South America. Most cultivars were introduced from colonial North America, but others reached Europe via Asia, Australia, and Africa, where local landraces evolved. For example, 'Red China' is a small turban squash that was brought to Europe from China in 1885. India also became a secondary center of cultivar diversity, particularly for the large "show pumpkin" types. Today, Indian fruits, weighing up to 130 kg, range from spherical to oblong to turban-shaped. Unusually shaped squashes with brown seeds such as 'Crown', 'Triangle', and 'Queensland Blue' are late-maturing Australian cultivars. And in Africa, *C. maxima* was so widespread by the nineteenth century that some botanists mistakenly concluded that Africa was the ancestral home of this squash.

In addition to collecting cultivars from around the globe, the Europeans succeeded in producing their own new strains, particularly in nineteenth-century France. For example, 'Etampes' and 'Gray Boulogne' entered the commercial trade in the 1880s. Selections within the "turban squashes" at this time focused on producing smaller nonprotruding crowns.

Cucurbita ficifolia

Pre-Columbian remnants of domesticated *C. ficifolia* have been found only in Peru, with the earliest seeds, peduncles, and rind fragments dating between 3000 and 6000 B.C. An archaeological seed from southern Mexico that was originally identified as *C. ficifolia* apparently belongs to *C. pepo* instead (cf. Andres 1990). Assuming domestication in northern South America, it is not known when this squash reached Mexico; however, it was being cultivated there in the twelfth century.

No wild species of squash exhibits the type of relationship with *C. ficifolia* that is expected in the pairing of a crop with its wild progenitor. Although definitively wild populations of *C. ficifolia* have not been identified, reports of weedy, self-sustaining plants in Guatemala and Bolivia are intriguing and need to be explored further.

As with the other domesticates, human selection produced relatively large, fleshy, nonbitter fruits with large seeds. However, the overall lack of genetic diversity in *C. ficifolia* relative to the other domesticated squashes suggests that human selection pressures on the former have been limited in their duration, their intensity, their diversity, and their effects.

This cool-tolerant but short-day squash did not reach Europe until the early 1800s, coming by way of southern Asia, where the long-keeping fruits were mainly used to feed livestock, especially during lengthy sea voyages. Although some accessions of *C. ficifolia* have been successfully grown as far north as Norway, the general failure of this species to flower beyond the torrid zone may account in part for its lack of popularity in Europe.

Squash Preparation and Consumption

In rural gardens around the globe, squash is typically planted among other crops, particularly corn, and the vines are allowed to scramble over poles, fences, walls, and other nearby structures. The plants like fertile aerated soil that drains well and lots of space, water, and sunshine. Extremes in temperature or high humidity increase vulnerability to disease. During wet weather, placing a stone or fibrous mat under a fruit lying on the ground prevents the fruit from rotting.

The immature and mature fruits, seeds, flowers, buds, and tender shoot tips and leaves of all of the domesticated squashes can be and have been eaten. Harvest of the one- to seven-day-old fruits of the summer squashes begins seven to eight weeks after planting and continues throughout the growing season. Pumpkin and winter squash fruits take three to four months to mature and are harvested only once, usually along with or later than other field crops. The best seeds are taken from the oldest fruits. Once flowering begins, open male blossoms can be collected almost daily. Leaves and growing tips are picked when needed, but only from healthy, vigorous plants.

Even though immature squashes can be eaten raw, usually they are boiled first and then seasoned to taste. In various cultures, the fresh fruits are sliced, battered, and fried; stuffed with cooked meat and vegetables; boiled and then mashed like potatoes; or added to curries or soups. The Sioux of the Northern Plains sliced fresh four-day-old fruits of *C. pepo,* skewered the slices on willow spits, and placed the spits on open wooden stages for drying. In Mexico and Bolivia, young fruits and seeds of *C. ficifolia* are sometimes blended into a mildly sweetened, alcoholic beverage made from corn mush.

The precursor of the colonial pumpkin pie was a mature pumpkin, probably *C. pepo,* filled with fruit, sugar, spices, and milk. Seeds were removed and ingredients added through a hole cut in the top of the pumpkin. The stuffed fruit was then baked among the coals of an open fire. In a simpler version of this recipe, prepared by aborigines as well as settlers, the fruits were baked first and then sliced and garnished with animal fat and/or honey or syrup. Pumpkin pudding, pancakes, bread, butter, dried chips, and beer have long histories rooted in colonial New England.

In other countries, mature pumpkins and winter squashes are stewed or steamed as vegetables, added to soups, candied, or stored whole or in slices for later use. A presumably ancient aboriginal use of mature fruits of *C. ficifolia* is in making various types of candy. Chunks of flesh are boiled with the seeds in alkali and then saturated with liquid sugar. In Indonesia, the local inhabitants create a delicacy by adding grated coconut to the boiled flesh of *C. moschata.* Of course, the most popular nonfood usage of pumpkin fruits (usually *C. pepo* or *C. maxima*) is for carving jack-o'-lanterns, a nineteenth-century tradition from Ireland and Great Britain.

Although the fruits of all domesticated squashes can be prepared similarly, there are culinary differences among the species with respect to the flavor, consistency, and appearance of the edible flesh. *Cucurbita moschata* and *C. maxima* produce the strongest tasting (mildly sweet and somewhat musky) and deepest colored mature fruits; consequently, these species are favored for canning. Because fruits of *C. maxima* are also the richest in vitamins and finest in texture, they are mashed into baby food. Among the squashes, flesh quality in *C. maxima* generally holds up best when dehydrated and then reconstituted. The elongated fruits of summer squashes make *C. pepo* the foremost producer of easy-to-slice young fruits. Although this species dominates the commercial market, the fuller flavor of the immature pepos of *C. moschata* make *C. moschata* the preferred vegetable in rural China, the Canary Islands, and Central America.

Landraces of *C. argyrosperma* yield the largest edible seeds in a fruit that is otherwise unremarkable. Mature fruits of *C. ficifolia* are the most bland and fibrous of all squashes. However, they store longer than the fruits of the other species (two to three years versus one year) and sweeten with age. The flesh contains a proteolytic enzyme that may be of future commercial value to the food industry. Because of the stringiness of the flesh of *C. ficifolia,* a special Aztec confection called "Angel's Hair" can be prepared from the boiled flesh fibers. Comparable texture in the *C. pepo* cultivar 'Vegetable Spaghetti' allows preparation of the baked or boiled fibrous flesh into a dish resembling the namesake pasta.

For commercial canning, growers have selected high-yielding cultivars like 'Kentucky Field' that have mature fruit flesh of the proper color and consistency. Flavor is less important as it can be controlled with spices. Consistency, which refers to the stiffness or relative viscosity of the processed flesh, is enhanced by using fruits that are barely ripe and by adding the product of a high-consistency cultivar to that of a low-consistency cultivar. Starch, as well as soluble solids, greatly influences consistency. Because fruit storage results in the loss of carbohydrates and in the conversion of starch to sugars, freshly harvested fruits are preferred for the canning process.

Squash seeds, which have a nutty flavor, are eaten worldwide. They are consumed raw, boiled, or roasted, usually with the testa or shell removed. Mexicans grind the roasted shelled seeds into a meal, which is used to make special sauces. In China and India as well as in the New World, rural peoples make pastries from the seeds, often by covering them with syrup and then baking the mass into a type of peanut brittle. Some Chinese cultivars of *C. moschata* and *C. maxima* are grown specifically for their seeds. Similarly, various landraces of *C. argyrosperma* contribute heavily to the commercial production of edible seeds in Mexico.

A "naked seed" cultivar of *C. pepo,* called 'Lady Godiva', produces a seed lacking a testa. These hull-less seeds are popular snacks in the United States. In addition to food, New World aborigines have used squash seeds for a variety of medicinal purposes. A decoction serves as a diuretic and an antipyretic, the seed oil is applied to persistent ulcers, and the seeds are eaten to expel gastrointestinal parasites. Although rural communities use the seed oil for cooking as well as for medicine, the possibility of commercial extraction of the edible unsaturated oil has yet to be explored.

Aboriginal Americans, including the Aztecs, have a long tradition of eating male squash flowers and floral buds. The large orange blossoms lend seasoning and color to stews, soups, and salads and can be stuffed or battered and fried. Young leaves and shoots, which have relatively low concentrations of the bitter cucurbitacins, are also important potherbs in Mexican cooking. In India, squash leaves and growing tips are eaten as salad greens or added to vegetable curries. Nineteenth-century Indonesians prepared a dish in which fish and young leaves of *C. moschata* were wrapped in banana leaves and roasted under live coals.

Nutritional Content

Sixty to 85 percent of a mature fresh squash fruit is edible, as compared to over 95 percent edibility in immature fruits. The edible portion of a pepo, which is 85 to 95 percent water by weight, is lacking in most nutrients, particularly protein (0.5 to 2.0 percent) and fat (less than 0.5 percent). Carbohydrates are more concentrated in mature fruits (up to 15 percent of the fresh edible portion) than in the tender fruits of the summer squashes (less than 5 percent). Likewise, calories per 100 grams of edible fresh-weight flesh range from 10 to 25 in summer squashes versus 20 to 45 in the mature fruits known as pumpkins and winter squashes.

The most significant dietary contribution of the pepo is the relatively high concentration of carotenes, the precursors of vitamin A, in cultivars with deep yellow to orange flesh (see Table II.C.8.5).

Table II.C.8.5. *Mineral and vitamin content of young fruits (represented by the summer squashes of* Cucurbita pepo*), mature fruits, leaves, and growing tips (including* C. maxima, C. moschata, *and* C. pepo*), and ground seed meal (a mixture of* C. pepo *and* C. maxima*); values are per 100 grams`of dry seed meal or, in the case of the other structures, of the fresh-weight edible portion*

[a]Whitaker and Davis (1962); [b]Tindall (1983); [c]Martin (1984); [d]Oomen and Grubben (1978); [e]Lazos (1986).

Particularly well studied and rich in these and other nutrients are the 'Butternut' and 'Golden Cushaw' cultivars of *C. moschata* and various "hubbard" and "delicious" squashes of *C. maxima.* As a source of vitamin A, these winter squashes compare with sweet potatoes and apricots. Although the raw flesh is higher in vitamins, a half cup of cooked mashed winter squash provides 91 percent of the U.S. Recommended Dietary Allowance (RDA) of vitamin A, 16 percent of the recommended vitamin C, 12 percent of the recommended potassium, 1.7 grams of dietary fiber, low sodium, and only 40 calories. In addition to the carotenoids, squashes are good sources of other compounds with cancer-fighting potential, including flavonoids, monoterpenes, and sterols.

For some nutrients the best source is not the fruit but other parts of the squash plant (see Table II.C.8.5). Leaves are richer in calcium, growing tips provide more iron as well as higher levels of vitamin C and the B vitamins, and seeds contain various minerals including potassium, magnesium, copper, and zinc. Although the nutritional content of flowers has not been studied, the orange petals are undoubtedly rich in carotenes.

Seeds are the most nutritious part of the plant, containing 35 to 55 percent oil and 30 to 35 percent protein by weight. In fact, the naked seeds of 'Lady Godiva' are very similar in agricultural yield and nutritional content to shelled peanuts.

The edible semidrying oil of squash seeds is dark brown with a green tint and a nutty odor. About 80 percent of the oil consists of unsaturated linoleic (40 to 50 percent) and oleic (30 to 40 percent) acids. The dominant saturated fatty acid, palmitic acid, accounts for about 13 percent of oil composition. As with other oilseeds, proteins in squash seeds are rich in nitrogen-containing amino acids such as arginine but lacking in lysine and sulfur-containing amino acids. These proteins are packaged primarily in globulins called cucurbitins. Whereas the testa is highly fibrous, carbohydrates in the decorticated seeds are limited to cell wall cellulose, phytic acid, and a minimal amount of free sugars; starch is absent. Ground seeds (including the testas) are good sources of minerals, particularly potassium, phosphorus, and magnesium (see Table II.C.8.5).

II.C.9 ~ Tomatoes

The tomato is a perennial plant, generally cultivated as an annual crop. It can be grown in open fields, weather permitting, or in protective structures when temperatures are extreme. In commercial operations, tomatoes are usually planted as a row crop and harvested mechanically when they are still in the green stage. They can also be trained on trellises and harvested throughout most of the year by hand. Tomatoes adapt well and easily to a wide diversity of soils and climates, but they produce best in well-drained soil and temperate climate, with at least a few hours of sunlight each day.

The tomato contains significant amounts of the vitamins A and C, although probably less than the general public has been led to believe. Its importance as a provider of these vitamins depends more on the quantity consumed than on the amount of the vitamins in each fruit. Its vivid color, the fact that it can be used as both a raw and cooked vegetable, and its ability to blend easily with other ingredients has made the tomato a popular international food item and one of the most important vegetables on the world market.

Enormous changes have taken place in the use and distribution of the tomato since the time of its prehistoric origins as a wild, weedy plant. A multidisciplinary research strategy, using archaeological, taxonomical, historical, and linguistic sources is employed in this chapter to trace this remarkable transformation. And finally, special attention is given to the tomatoes of Mexico because that region is believed to have been the center of the domestication of the species and because it is there that

Tomato

tomatoes have the longest history of use, beginning with the indigenous population.

Taxonomy

The commercial tomato belongs to the genus *Lycopersicon.* It is a relatively small genus within the large and diverse family Solanaceae. The genus is currently thought to consist of the cultivated tomato, *Lycopersicon esculentum,* and seven closely related wild *Lycopersicon* species (Rick 1976: 268; Taylor 1991: 2), all of which are native to northwestern South America. The wild relatives of the cultivated tomato are confined to a narrow coastal area extending from Ecuador to northern Chile and the Galapagos Islands. Some of the wild species contain valuable genes for disease and pest resistance that can be useful for plant breeders in developing new types of cultivated tomatoes when crossed with *L. esculentum.* All of the cultivated tomatoes are derived from the species *L. esculentum.*

The cherry tomato, *L. esculentum* var. *cerasiforme,* is believed to be the direct ancestor of modern cultivated tomatoes and is the only wild tomato found outside South America (Rick 1976: 269). It can also be found in Mexico, Central America, and the subtropics of the Old World (Rick 1976: 269). It bears greater genetic resemblance to the cultivated tomato than other wild species, and the two groups can be freely intercrossed (Taylor 1991: 3).

Lycopersicon esculentum and its close relatives are self-pollinating and exclusively inbreeding due to the position of the stigma inside the anther tube. Wild species may have a slightly exserted stigma, which permits outcrossing, usually with the help of bees or the wind. The modification in the position of the stigma is one of the changes brought about by the domestication process. It is easier to produce a homogeneous product from a self-fertilized plant than one that may cross with a related species.

Although the genus *Lycopersicon* is native to the northwestern coast of South America, there is no archaeological evidence that tomatoes were used by ancient Andean cultures. No plant remains have appeared in site excavations, no clay vessels in the shape of tomatoes have been discovered, and there is no word for the tomato in Quechua or other ancient Andean languages. Such a lack of evidence may indicate that although the tomato existed as a wild species in the Andean region, it was never utilized by pre-Hispanic populations. The commercial tomato in use there at the present time is believed to have been a *post-Columbian* introduction from Mexico after the Americas were unified under Spanish rule. In Mexico the tomato is known by the Spanish name *tomate,* derived from the Nahuatl or Aztec *tomatl.*

As Charles Heiser pointed out some years ago, the theory of the origin of the tomato is strikingly parallel in many ways to that of the chilli pepper, *Capsicum* spp. (1969: 39). The wild species of both are South American in origin. They reached Mesoamerica[1] at an early date, probably by natural means, and there found a favorable ecological niche, were domesticated, and eventually gave rise, respectively, to the cultivated plants *L. esculentum* and *Capsicum annuum.*

Mexican Tomatoes

The most likely region where the tomato was first domesticated is the Puebla–Veracruz area of Mexico, where according to James Jenkins, the greatest varietal diversity of the cultivated form can be found today. It is thought to have reached this area as a weedy cherry tomato, var. *cerasiforme,* and, upon domestication, to have become the larger-fruited *L. esculentum* (1948: 391, 386). The cherry tomato frequently grows wild as a weed in cultivated fields and is better adapted to wet tropical conditions than any of the other species. It is also used as a cultivated plant and is a popular item in the diet of indigenous peoples. Both wild and cultivated tomatoes have a distinct and independent nomenclature in several Indian languages, indicating an ancient introduction.

We will probably never know how the cherry tomato traveled from the Andean region of the hemisphere to Mesoamerica. Winds or water could have transported the seeds, as could birds who consumed the seeds, then eliminated them at some distant point. Perhaps all of these means of transportation were involved in a kind of stepping-stone journey, with stops along the way where the seeds became plants that reproduced, and new seeds were picked up and moved again and again by such vectors.

Alternatively, humans may have had a hand in the diffusion of the wild ancestor of the tomato. Perhaps it was carried by migrating populations who, in spite of the great distance and geographical barriers between Mexico and South America, were able to move from one area to another. Or again, its introduction to Mexico may have resulted from contact between the two areas that some archaeologists believe was established by seafaring traders as early as 1600 B.C. (Green and Lowe 1967: 56–7).

Still other questions have to do with the extent to which indigenous peoples of Mexico came to accept the tomato and incorporate it into their diets. The plant may have caught the attention of food gatherers because of its general similarity to the green husk tomato, *Physalis* (Jenkins 1948: 392). Unlike the plant we just tracked from South America, this plant is native to central Mexico, where it has a significantly longer tradition of dietary usage than the red tomato. Indeed, there is archaeological evidence of its consumption from 900 B.C. in the excavation in the Tehuacan Valley, Puebla, and from 5090 B.C. in the Valley of Mexico (Smith 1967: 248; Flannery 1985: 266). Basalt grater bowls *(molcajetes),* with incised interiors for grinding vegetal matter, appear in the earliest stratigraphic levels of the excavation in Tehuacan, and clay bowls began to appear around 1500 B.C. (MacNeish 1967: 290–309). The word *molcajete* comes from the Nahuatl term *molcaxitl,* composed of *molli* (sauce) and *caxitl* (bowl), or "sauce bowl." One can say with some degree of certainty that they were employed for making salsas of chilli peppers and green (and maybe red) tomatoes, as they are still used in Mexico today.

As in the Andean region, no archaeological evidence of plant remains of the red tomato have been reported from Mesoamerican excavations. In part, this may be because the red tomato is an extremely perishable fruit. However, carbonized seeds are almost indestructible and last indefinitely when they are not mashed or ground up. They can be recuperated from desiccated coprolites (fecal material), which can be reconstituted and returned to their original state in order to be examined. Since coprolites contain the actual materials consumed, analysis of them can provide some important insights into the diet of ancient peoples.

One possible explanation for the absence of tomato seeds in coprolites is that the principal method of preparing tomatoes was by grinding or mashing them in grater bowls or on grinding stones for use in salsas and stews, making the disintegrated seeds impossible to identify in coprolites and other refuse material.

Several changes have taken place in the tomato during the process of domestication. Generally speaking, wild plants have smaller seeds and fruits than the domesticated species. This differentiation can be noted when comparing wild and cultivated tomatoes. Wild tomatoes have two locules, whereas most domesticated fruits are multiloculates, because of an increase in size. Upon domestication, the position of the stigma was established deeper inside the anther tube to insure self-fertilization. Doubt about the extent of such a transformation of the tomato in pre-Columbian times has led some Latin American botanists to view it as a semidomesticated, rather than a fully domesticated plant prior to the arrival of the Europeans. J. León has gone so far as to suggest that it was unimportant as a food crop and considered just another weed in the fields, even though its fruit was the size of some modern varieties (1992: 41–2).

Linguistic evidence is also inconclusive. As previously mentioned, the generic term for the husk tomato in Nahuatl is *tomatl,* with different prefixes or descriptive adjectives used to identify the particular type. The red tomato is known in Mexico by the Spanish term *jitomate* from the Nahuatl *xitomatl,* which may mean "peeled or skinned tomato." The Nahuatl prefix *xi* is possibly derived from the verb *xipehua,* which denotes "to peel, skin, or flay." This could be a reference to the calyx that covers the fruit of the husk tomato and is lacking in the red variety. When ancient Mexicans came across the red-fruited tomato they may have noted its general similarity to the husk tomato and referred to it by a similar name such as *xitomatl,* or "peeled tomato," to differentiate it from the former fruit.

Unfortunately, sixteenth-century Spanish writers did not distinguish between the *tomatl* and the *xitomatl;* they translated both as *tomate.* Thus, it is impossible to determine which tomato they are referring to unless the Nahuatl text is available. In Bernardino de Sahagún's *The General History of the Things of New Spain,* written in both Nahuatl and Spanish, there are more references to green tomatoes than red, indicating a more frequent use of the former at the time of the European conquest (Sahagún 1951–69).

Nonetheless, all kinds and colors of tomatoes could be bought in the great Tlatelolco market when the Spaniards arrived in Tenochtitlan in 1519. Tomato sellers offered large tomatoes, small tomatoes, green tomatoes, leaf tomatoes, thin tomatoes, sweet tomatoes, large serpent tomatoes, nipple-shaped tomatoes, coyote tomatoes, sand tomatoes, and "those which are yellow, very yellow, quite yellow, red, very red, quite ruddy, bright red, reddish, rosy dawn colored" (Sahagún 1951–69, Book 10: 79). The bad tomato seller was described as one who sold spoiled tomatoes, bruised tomatoes, and those that caused diarrhea (Sahagún 1951–69, Book 10: 68). Clearly, a large variety of tomatoes was for sale in early sixteenth-century Mexico – such a variety that it is impossible to identify some of the types with those on the market today.

Bernal Díaz, who participated in the conquest of Mexico in 1519, related that when the *conquistadors* went through Cholula on their way from Veracruz to Tenochtitlan, the Indians "wanted to kill us and eat our meat" and that "they had their cooking pots ready, prepared with chile peppers, tomatoes and salt . . ." (1980: 148). He also mentioned that the Aztecs ate the arms and legs of their sacrificial victims with a *chimole* sauce, made with chilli peppers, tomatoes, wild onions *(xonacatl),* and salt (1980: 564). The ingredients were nearly the same as that of *salsa mexicana,* in use in most Mexican homes today.

Similarly, stews and salsas, sold on the street or in the markets in sixteenth-century Mexico, were made with red or green tomatoes, chilli peppers, and squash seeds as common ingredients (Sahagún 1951–69, Book 10: 70). Another early visitor to Mexico noted that tomatoes were added to salsas to temper the heat of the chilli peppers (Cervantes de Salazar 1914: 118–11).

The sixteenth-century Jesuit priest José de Acosta, who traveled in Mexico and South America, was no doubt referring to red tomatoes when he described them as fresh and healthy, some being large and juicy, and said they made a tasty sauce and were also good for eating by themselves (1940: 178).

Clearly visitors appreciated the tomato, but it was not until the latter half of the sixteenth century that it became the subject of scientific study. Francisco

Hernandez, the personal physician of Philip II, was commissioned by the king to catalog and describe the medicinal plants being used in New Spain. Hernandez spent the years between 1570 and 1577 traveling throughout the country, preparing a list of the local plants and illustrating them. Unfortunately, his description of the tomato plant gives us little reliable information, because he confused the husk tomato and the red tomato. For example, his chapter on tomatoes is illustrated with a drawing of the former.

Hernandez did note, however, that the tomato was used for medical purposes. The fruit and its juice were used to soothe throat irritations, to treat the discomfort caused by headaches, earaches, and stomachaches, and to ease the pain of mumps (Hernandez 1946, III: 699–715).

There are many references to the production of both species of tomatoes during the colonial period in Mexico. The two were generally planted together, along with chilli peppers, in house gardens, on *chinampas*[2] in small plots, and in open fields.

Tomatoes were probably geographically limited to Mesoamerica, as no mention of them was made by early Spanish chroniclers who visited the Caribbean. Gonzalo Fernandez de Oviedo, for example, who left the most complete description of New World flora, and whose travels took him to the Caribbean and to parts of South America, but not New Spain, did not mention the tomato.

American Plants Reach Europe

The migration of domesticated plants is closely related to human migration because these plants need human intervention and care to survive. Among other things, many lose their dispersal mechanisms after domestication and cannot be diffused without human help. Unfortunately, plant movements have seldom been considered important enough to warrant registration upon arrival in a new country, which can make the study of plant migration an exercise in frustration for the plant historian.

Many American plants arrived in Iberia in the sixteenth and seventeenth centuries, along with the supposedly more precious cargoes of gold and silver. Some seeds were carried on purpose, perhaps by returning Spaniards, who had become accustomed to the taste of New World foods and flavors; others arrived accidentally, hidden in the nooks and crannies of ships.

Not all of the new plants were well received when they first appeared in Europe. This was especially the case with solanaceous ones such as the tomato, the chilli pepper, and the potato, which were regarded with suspicion and fear by Europeans already familiar with other plants of the same family.

Certainly tomatoes were not an easy ingredient to incorporate, even into the Italian diet where they were later to become a mainstay. They neither looked nor tasted like any other vegetable known and used by the Italians, and they had a strange texture and consistency. They were too acid to be eaten while green and looked spoiled when they were soft and ripe. They disintegrated upon cooking and were suspected of being poisonous. Thus, it was only after the passage of some considerable length of time that tomatoes were accepted by the Mediterranean peoples to become as much a part of the local food tradition as are wheat, olives, and wine.

But although culinary acceptance of American foods was delayed, European plant specialists, from the very beginning, displayed great interest in any medicinal qualities they might possess. Old diseases, such as plague, were still affecting parts of Europe in the sixteenth century and had been joined by new diseases, like syphilis, to punish populations. Thus, doctors were in constant search of new remedies to treat these ills. They initially had great hopes for the pharmacologic possibilities of New World organisms but soon realized that the new cultivars offered little relief for European illnesses.

However, the American plants did find a place in botanical gardens, popular among scientists of the time, who also established networks through which they exchanged new and exotic plants as well as information about them. In addition, some became popular as ornamentals and could be found in university gardens and on the estates of the nobility. But the tomato had little to offer as an ornamental. Its flowers are a pale yellowish color, not particularly unusual or attractive, and both its leaves and fruit emit a strong, acrid smell that many plant lovers of the time thought offensive.

Herbals with woodcut engravings became popular in the sixteenth and seventeenth centuries, and scientists used them in an effort to establish some order in the plant world. The New World cultivars were quickly fitted in, and much valuable information about them can be gleaned from these publications. In the case of the tomato, the plants appears as a small, heavily ridged and compressed fruit, but large enough to have gone through the domestication process.

American plants in Europe spread out along two different routes after their arrival in Iberia. One led north via Flanders, the other into the Mediterranean via Italy – with all of the former and significant portions of the latter then under Spanish domination, which facilitated communication between these areas.

The moderate climate and loose soil of the Mediterranean countries proved ideal for the adaptation of the tomato as well as other New World plants. They arrived, not as competition for the local cultigens already in production, but as complementary crops whose planting and harvesting schedules did not coincide nor interfere with those of the traditional Mediterranean crops.

Tomatoes in Spain

Spain was doubtless the first stop for the tomato on its migration throughout Europe because Castile held a monopoly on the transport of its New World products to the Continent. Unfortunately, although officials of the Casa de la Contratación[3] kept a watchful eye on all cargo unloaded in Seville so as to ensure the collection of royal import taxes, they seldom recorded the arrival of new plants. Thus, there is no record of the arrival of the tomato in Seville – the only port for Spanish ships returning from the New World.

In fact, there are few historical references to the use of tomatoes in sixteenth-century Spain. They may have been adopted first by rural people, who ate them fresh with a little salt like their eighteenth-century peasant descendants in southern Spain (McCue 1952: 327). No Spanish cookbooks were published at this time, however, and there is no mention of tomatoes having been a part of the diet in the early years.

Nor were tomatoes included in sixteenth-century Spanish herbals, although several described and illustrated New World plants. The husk tomato, for example, arrived in the sixteenth century and is known to have been cultivated in botanical gardens in southern Spain. It was listed as an exchange plant from the garden of Dr. Juan Castañeda, a physician at the Flamenco Hospital in Seville, to the Belgian botanist Clusius (Charles de l'Ecluse) at the end of the century (Alvarez Lopez 1945: 276). Castañeda appears to have been Clusius's principal supplier of American and Iberian plants. Clusius made several trips to Spain to obtain information and specimens of new plants, but he did not mention having encountered the tomato on his travels.

The first written reference to the cultivation of the tomato in Spain was penned around the turn of the seventeenth century. It appeared in a small book by Gregorio de Rios, a priest who worked in the botanical garden of Aranjuéz, which was supported by the King, Philip II. This book, *Agricultura de jardines, que trata de la manera que se han de criar, governar y conservar las plantas,* mentions several American plants. Rudolf Grewe has translated his comments on the tomato as follows: "Tomatoes [*pomates* in the original]: There are two or three kinds. It is a plant that bears some segmented fruits *[pomas aquarteronadas]* that turn red and do not smell. It is said that they are good for sauces. They have seeds, last for two or three years, and require a lot of water. There is a kind said to be from Cairo" (Grewe 1988: 73). By this time at least some Spaniards had apparently adopted the Aztec method of preparing tomatoes in a sauce.

Tomatoes appeared on the list of purchases of the Hospital de la Sangre in Seville in the early seventeenth century. Four pounds were purchased on July 20, and another 2 pounds on August 17, 1608 (Hamilton 1976: 859). The same account lists the purchase of cucumbers "for making salads," and it is possible that tomatoes were used for the same purpose. This appears to have been the only attempt of the hospital to introduce the tomato into its diet as there seem to have been no further purchases.

In addition to such rather scanty seventeenth-century historical information on the tomato there can be added information from indirect sources. Sixteenth- and seventeenth-century Spanish writers had a fascination with all things from the New World and delighted in borrowing vocabulary from Hispanic Indian languages in their works. Among the words most frequently used were those of fruits and vegetables. Spanish variations of Nahuatl, Quechua, and Caribbean plant names appear in the works of Lope de Vega, Tirso de Molino, Miguel de Cervantes y Saavedra, and Francisco de Quevedo (Morínigo 1946). The new names, including those for the tomato, were used as metaphors, in analogies, or merely for the exotic sounds of the words in poetry and drama.

Painters also found the new fruits and vegetables colorful subjects for still-life paintings that became popular in the sixteenth and seventeenth centuries. Bartolomé Murillo's "The Kitchen of Angels," painted for the Franciscan Convent in Seville, depicts the preparation of a dish using tomatoes and squash, a combination that was to become typically Mediterranean. The seventeenth century witnessed severe economic problems throughout the Mediterranean. In Spain the expulsion of the Moriscos, who had contributed so much to the agriculture of that country, brought a sharp decline in crop production. The resulting famine was joined by the return of the plague, which added to the general misery by considerably reducing the workforce. All of these factors contributed to a severe scarcity of food, which may have encouraged desperate rural peoples to put aside their fear of being poisoned and experiment with tomatoes in their diets.

One suspects this was the case because in the following century it was noted that tomatoes were a common ingredient in the diet of the rich, who ate them because they liked them, and of the poor, who ate them because they had no choice (McCue 1952: 327). Tomatoes were produced in abundance on truck farms and irrigated fields throughout the country, especially in southern Spain, where they could be harvested year-round. Indeed, farmers were eating tomatoes for breakfast, and a plate of fried red tomatoes and peppers constituted the main meal of the day for many (McCue 1952: 327).

Several American plants were fully adopted into the Mediterranean diet in the eighteenth century, and the more abundant and nutritious diet they allowed has been credited by some with bringing about a mid-century increase in the population.

Under the influence of a new and burgeoning merchant class in the eighteenth century, a greater emphasis was placed on simple, regional food and the use of local ingredients by everyone, not just the peasants. American vegetables fit well into this new culinary style and were included in the diet, not as new and exotic dishes, but as ingredients that added new flavors to traditional dishes such as thick soups, stews, ragouts, and goulash. In Spain, for example, tomatoes were incorporated into gazpacho (an ancient bread soup, probably dating from Roman times), the rice dish, paella, and *bacalao* (salted codfish). In the process, such dishes acquired new appearances as well as new flavors. The Spanish food historian Nestor Lujan has written that some would like to believe that Spanish and Italian cuisines only began with the introduction of the tomato, because so many dishes cannot be made without it (Lujan 1989: 126).

Clearly, then, tomatoes were well established in Spain by the nineteenth century. In that century, reports from Spain described an abundant production of tomatoes on truck farms and gardens in that country. It was noted that tomatoes were eaten raw with salt, formed the base of sauces, and were cooked in various other ways (McCue 1952: 328).

Tomatoes in Italy

Italy was probably the first country to receive the tomato after Spain, since, as already mentioned, there was a strong Spanish cultural influence apparent during the sixteenth century in those parts of Italy under Spanish domination.

Italy proved to be an ideal country for the adaptation of American plants. The climate and soil were similar to that of central Mexico, and the new plants adjusted easily to the area. Initially, however, tomatoes were grown only in pots and kitchen gardens because they needed a well-managed water supply during the setting of the fruit in summer, usually a dry season in the Mediterranean.

Unlike other parts of Europe, where fresh vegetables were considered food for the poor, Italians had (and have) a singular appreciation for them. This may have been a heritage of the Roman Empire, when men preferred light, easily digestible foods that could be eaten in a supine position. The pressure of growing populations during the second half of the sixteenth century was probably also an incentive to try the new foods.

The tomato in Italy was first mentioned by Petrus Andreas Matthiolus. In the first edition of his herbal *Della historia e materia medicinale,* published in Venice in 1544, it was not referred to by name, but in his 1554 edition he gave it the name of *pomi d'oro.* Unfortunately, Matthiolus mistakenly referred to the tomato as a member of the mandrake family, which focused suspicion upon the plant for centuries to come, as many botanists and writers repeated his description of the plant time and time again. In the 1544 edition he described the unnamed fruit as segmented, green at first, and then acquiring a golden color upon ripening, and he noted that it was eaten like the eggplant, fried in oil with salt and pepper. From his description, it seems apparent that the first tomatoes to reach Italy were yellow, although in the 1554 edition, he added that they also ripened in tones of red (McCue 1952: 292).

At about the same time as the second edition of Matthiolus appeared, a Flemish botanist, Rembert Dodoens, published his herbal, *Cruydt-Boeck,* in Antwerp. He was apparently the first to assign to the tomato the name *poma amoris* or "love apple," which was adopted in translation by the French and English. This name gave the tomato a certain reputation as an aphrodisiac, which probably did nothing to discourage its use. The engraving that accompanied his work shows the tomato as a small, irregular, flat fruit with prominent segments and the name *Gulden-Appel,* translated from the Italian *pomi d'oro* (McCue 1952: 299).

Interestingly, the name *poma peruviana* was given the tomato by Piero Antonio Michel in his herbal, *I cinque libri di plante,* published in 1575 (Jenkins 1948: 382). This must have been nothing more than a remarkable coincidence because he surely could not have been aware that Peru was, in fact, the center of origin of the tomato. Like other European botanists of the time, he was not well informed about New World geography and may actually have considered it as just one general area.

In 1572, another sixteenth-century Italian herbalist, Guilandini de Padua, called the tomato the "tumatle from Themistitan." It has been pointed out that this designation probably represents a corrupt spelling of Tenochtitlan, the capital city of Mexico, referred to as Temistitan by Hernando Cortés in two of his letters to the Spanish king, written shortly after the Conquest (Jenkins 1948: 382).

We mentioned that in 1554 Matthiolus observed that tomatoes were fried in oil with salt and pepper, like the eggplant. This may be the first recorded description of Italian tomato sauce. However, its first authentic recipe only appeared in 1692 in one of the early Italian cookbooks, *Lo scalco alla moderna,* written by Antonio Latini that was published in Naples (Grewe 1988: 74). Apparently the Spaniards had introduced the Aztec method of preparing the tomato in a sauce into Italy, along with the tomato, because a tomato sauce recipe "in the Spanish style" is included in the book. It called for tomatoes, chilli peppers, onion, salt, oil, and vinegar. However, other recipes for tomato sauce were also published that did not ask for peppers, indicating a separation of these two foods in Europe that were so closely linked in Mesoamerican cooking. The tomato, of course, which combined easily with European ingredients and found multiple uses in the diet, became far more important in Mediterranean cooking than peppers.

The careful hands of Italian gardeners improved the tomato through selective pressures, turning it into a large, smooth, and thicker-skinned fruit than that which had arrived in the sixteenth century. In addition, they developed a manner of prolonging the use of this perishable vegetable by drying it in the sun, which permitted its reconstitution and use throughout the winter. Much later, tomatoes were canned in southern Italy and became an important item of export. Italian emigrants to the United States and Argentina took their food traditions with them and established a demand for the tomato and tomato sauce in the Americas (Casanova and Bellingeri 1988: 165).

Eastern Mediterranean Tomatoes

The botanist Edgar Anderson has credited the Turks with the diffusion of the tomato into the Levant and the Balkan countries. The Turks probably diffused American plants to eastern Mediterranean countries in the sixteenth century when the Ottoman Empire was dominant in the area. They would have become acquainted with the plants in Italian or Spanish ports and taken them to other countries, much as they did when they took the chilli pepper into Hungary in 1526 (Long-Solis 1988: 62). Peppers and maize also became popular items in the diet of Balkan countries, and Fernand Braudel wrote that it was the Turks who introduced rice, sesame seeds, cotton, and maize into the area in the fifteenth and sixteenth centuries (Braudel 1976, II: 779). In addition, Anderson has noted that there is a wide and apparently coherent area, encompassing the Balkans and Turkey and running along the edge of Iran toward Arabia and Ethiopia, where the tomato has been used for centuries in the everyday diet of common people (Anderson, in McCue 1952: 289–348). The culinary legacy of the Turks is still evident in Mediterranean cuisine from Yugoslavia in the east to Algeria in the west. The popular salads made with tomatoes and peppers, known as *peperonata* in Italy, can be found in the diet of every Mediterranean country, with only slight variations.

Tomatoes in the Far East

Tomatoes became an important part of the Chinese diet only during this century, although they were probably carried to China from the Philippines much earlier. The Spaniards arrived in the Philippines from Mexico in 1564, and after establishing their dominion, introduced many Mesoamerican plants.

From there the tomato reached southern China, perhaps as early as the 1500s, where it was given the name *fan chieh* (barbarian eggplant). The name itself suggests an early introduction. Anderson has pointed out that several crops are known in South China by names that combine the adjective *fan* (southern barbarian) with the name of a long-established Chinese crop (Anderson 1988: 80). Crops with these names were early introductions; New World crops arriving later are known by the more complimentary adjective *hsi,* meaning Western, or *yang,* meaning ocean (Anderson 1988: 94).

African Tomatoes

Tomatoes are an important food product in Africa today, but the question arises as to how long this has been the case and when they first arrived. The most likely answer is that invaders, explorers, missionaries, and traders all played a role in the tomato's introduction.

The food habits of a region often reflect the influence of such outsiders, and certainly, Portuguese explorers and slave traders would have had an early opportunity to participate in such a cultural transfusion. Probably, Arab traders, active in the ports of Mozambique and Angola, were also instrumental in introducing new crops into Africa.

Another common route for plant diffusion in the early centuries was by way of a well-connected network of monasteries and convents in which seeds and plants were exchanged to help feed the personnel of these institutions. In addition, European botanical gardens had a hand in introducing new plants and crops into English, French, and Dutch colonies of Africa and Asia.

Thus, by at least the seventeenth century, the tomato was in cultivation in North Africa, with an English traveler reporting in 1671 that Spanish *tomates* were grown in the common fields in West Barbary (McCue 1952: 330). Several reports of similar cultivation plots were made in the eighteenth century; by the end of the nineteenth century, tomatoes appear to have been widespread throughout the continent.

Tomatoes in the United States

Despite their being native to the Americas, tomatoes had to be introduced into North America from Europe. Although this introduction occurred in the eighteenth century, tomatoes were slow to gain much of a place in the diet until relatively recently. Today, however, tomatoes rank second only to potatoes as the most important vegetable on the U.S. market. They are also the basic ingredient in that most American of sauces, tomato catsup. In recent years, however, Mexican salsa, composed of tomatoes, chilli peppers, onions, and seasoning has become even more popular on the market than catsup.

The main contribution of the United States to the history of the tomato has been the important role it has played in genetic research programs that have contributed to its improvement. The tomato has many characteristics that make it an ideal subject for plant research. It has an ability to produce and prosper in a diversity of climates and a short life cycle so that it can produce three generations per year under a well-managed program. Tomatoes produce high seed yields. A self-pollinating mechanism practically eliminates outcrossing, although plants can be crossed under controlled conditions. All of these qualities have enabled rapid progress in the improvement of the tomato in the past decades (Rick 1976: 272).

Genetic resources from wild South American species have helped in the development of cultivars that are tolerant to drought, extreme temperatures, and high-salt content in soils and have increased resistance to the diseases and insects that plague tomatoes.

Other improvements are increased crop yields through larger fruit size and an increase in the number of fruits. Improved fruit quality is evident in the shape, texture, color, and flavor of the product. Postharvest handling has been improved and storage durability increased. The restricted growth gene has been exploited, making mechanical harvesting easier because of the uniformity of the height of tomato plants. Harvesters have become more elaborate and larger, allowing them to harvest at a faster rate.

In addition, the tomato has been an ideal subject for research in genetic engineering, where the majority of such research is carried out on plants, such as the tomato, that are important as staple foods in basic diets around the world. Resistance to certain diseases that have proved difficult to treat and an improvement in the control of fruit ripening and color are some of the aspects being investigated. Important changes in the quality of tomatoes can be expected through genetic engineering in coming years.

Janet Long

Notes

1. The term "Mesoamerica" refers approximately to the area between the state of Sinaloa in northwestern Mexico and Costa Rica, which at the time of the Spanish conquest contained peoples sharing a number of cultural traits.
2. *Chinampas* are highly productive farm plots surrounded on at least three sides by water.
3. The Casa de Contratación, or House of Trade, was founded by royal order in 1503 and located in Seville. The Casa served as an administrative focal point for commercial traffic involving Spanish colonies in the New World.

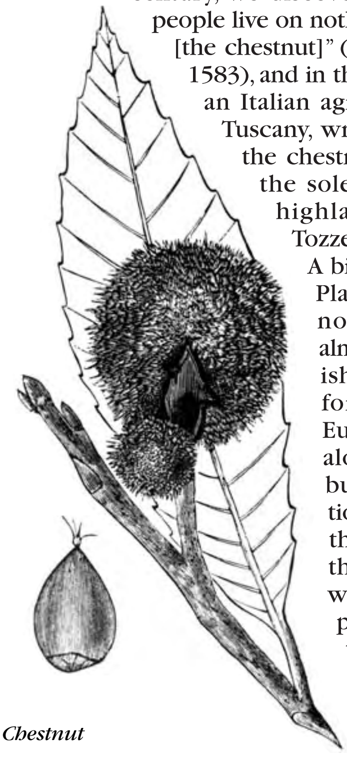
II.D

Staple Nuts

II.D.1 Chestnuts

In the mountainous areas of the Mediterranean where cereals would not grow well, if at all, the chestnut *(Castanea sativa)* has been a staple food for thousands of years (Jalut 1976). Ancient Greeks and Romans, such as Dioscorides and Galen, wrote of the flatulence produced by a diet that centered too closely on chestnuts and commented on the nuts' medicinal properties, which supposedly protected against such health hazards as poisons, the bite of a mad dog, and dysentery.

Moving forward in time to the sixteenth century, we discover that "an infinity of people live on nothing else but this fruit [the chestnut]" (Estienne and Liébault 1583), and in the nineteenth century an Italian agronomist, describing Tuscany, wrote that "the fruit of the chestnut tree is practically the sole subsistence of our highlanders" (Targioni-Tozzetti 1802, Vol. 3: 154). A bit later on, Frédéric Le Play (1879, Vol. 1: 310) noted that "chestnuts almost exclusively nourish entire populations for half a year; in the European system they alone are a temporary but complete substitution for cereals." And in the twentieth century, the Italian author of a well-known book of plant-alimentation history mentioned that chestnuts not only were collected to be eaten as nuts but could also be ground into flour for bread making (Maurizio 1932). He was referring to the "wooden bread" that was consumed daily in Corsica until well into the twentieth century (Bruneton-Governatori 1984). Clearly, then, chestnuts have played an important role in sustaining large numbers of people over the millennia of recorded history (Bourdeau 1894).



Chestnut

The Tree

Geographic location has had much to do historically with those who have found a significant part of their diet at the foot of the chestnut tree. The tree tends to stop bearing fruit north of the fifty-second parallel, and its yield in Eurasia satisfies the growers' wishes only south of a hypothetical line drawn from Brittany to Belgrade and farther east to Trabezon, Turkey – the line ending up somewhere in Iran. In Africa, chestnuts grow only in the Maghreb. In North America, there were many chestnut trees before the first decades of the twentieth century, at which time some three billion were destroyed by a blight. Another species of chestnut exists in China, and Japan is on its way to becoming the world's leading chestnut producer.

Chestnuts grow somewhat haphazardly within these geographic limitations. For example, because they dislike chalky soils, they are rare in Greece, except on some sedimentary or siliceous outcrops, where they can become so abundant that they determine place names, such as "Kastania." In addition, the roots of chestnuts tend to decay in badly drained soils, which helps to explain why the trees thrive on hills and mountainsides. Such exacting requirements also help us pinpoint those regions of Portugal, Spain, France, and Italy where populations were long nourished by chestnuts.

It is true that chestnuts are found beyond the geographic limits just outlined. But these are grown for their wood and not for their fruit (chestnut wood is as strong as oak but significantly lighter) – an entirely different method of cultivation. Fruit-producing chestnut trees must be pruned into low broad shapes, whereas trees for lumber are encouraged to grow tall. In addition, fruit-producing trees require grafting (such as the marrying of hardy to fruit-bearing species) – an activity deemed vital in historical documents (Serre 1600) because the ungrafted tree produces two or three small chestnuts in one prickly pericarp or husk (called a bur) whose only use is for animal feed. Even in our own times, grafting remains necessary as it is practically the only way to avoid the disease enemies of chestnuts that have so menaced the trees since about 1850.

The Nut

After performing the not-so-easy operations of extracting the chestnut from its bur, hard-peel cover, and adhering tannic skin, one has a nourishing nut that is 40 to 60 percent water, 30 to 50 percent glucids, 1 to 3 percent lipids, and 3 to 7 percent protids. In addition, the nut has significant amounts of trace minerals which vary, depending on the soil; and chestnuts are the only nuts to contain a significant amount of vitamin C.

Dried, the chestnut loses most of its water as its caloric value increases. According to the usual conversion table, 100 grams of fresh chestnuts provide 199 calories; dried, they provide almost twice (371 calories) that amount. (For comparative purposes, 100 grams of potatoes = 86 calories; 100 grams of whole grain wheat bread = 240 calories; 100 grams of walnuts = 660 calories.) (Randoin and de Gallic 1976).

When we pause to consider that our sources place the daily consumption of chestnuts by an individual at between 1 and 2 kilograms, we can quickly understand why the chestnut qualifies as a staple food. And like such staples as wheat or potatoes, chestnuts can be prepared in countless ways. Corsican tradition, for example, calls for 22 different types of dishes made from chestnut flour to be served on a wedding day (Robiquet 1835). When fresh, chestnuts can be eaten raw, boiled, baked, and roasted (roasted chestnuts were sold on the streets of Rome in the sixteenth century and are still sold on the streets of European towns in the wintertime).

Chestnuts also become jam and vanilla-chestnut cream, and they are candied. When dried, they can also be eaten raw, but they are usually ground into flour or made into a porridge, soup, or mash (*polenta* in Italy) and mixed with vegetables, meat, and lard. As flour, chestnuts become bread or pancakes and thickeners for stews. Indeed, speaking of the versatility of chestnuts, they very nearly became the raw material for the production of sugar. Antoine Parmentier (that same great apothecary who granted the potato the dignity of human food) extracted sugar from the nuts and sent a chestnut sugarloaf weighing several pounds to the Academy in Lyon (Parmentier 1780). Research on the possibility of placing chestnuts at the center of the French sugar industry was intensified a few years later during the Continental blockade of the early nineteenth century. Napoleon's choice, however, was to make sugar from beets.

A Chestnut Civilization

That the geographical areas favorable to chestnut trees and their fruits were precisely the areas in which populations adopted chestnuts as a staple food seems obvious enough. But in order to make full use of the opportunity, populations had to create what might be called a "chestnut civilization," meaning that they had to fashion their lives around the trees, from planting the trees to processing the fruits.

Planting

Chestnut trees seldom grow spontaneously. Moreover, pollination rarely occurs wherever the trees grow in relative isolation from one another, and fructification is poor when the tree is not regularly attended. For all these reasons, it is generally the case that the presence of a chestnut tree is the result of human activity, in contrast to a random act of nature. This is clearly so in the case of plantations, or trees whose alignment marks the borders of fields and pathways. But it is also the case with the countless clusters of two or three trees that cast their shadows upon the small hilly parcels of poor tenants.

It is important to note, however, that people do not plant chestnut trees for themselves. Rather, they do it for generations to come because the trees do not begin to bear fruit until they are at least 15 years old, and their yield is not optimal until they are 50 years old: "Olive tree of your forefather, chestnut tree of your father, only the mulberry tree is yours," as the saying goes in the Cévennes (Bruneton-Governatori 1984: 116).

Cultivation

Most of the operations connected with chestnut cultivation involve looking after the trees. This means clearing the brush beneath them and, when possible, loosening the soil; giving water when really necessary; fertilizing with fallen leaves; repairing enclosures to keep away stray animals whose presence could be catastrophic and whose taste for chestnuts is well known; and above all, trimming branches so that they will bear a maximum amount of fruit. Yet, tree care is hardly an exacting task, requiring only 3 to 8 days a year per hectare of trees (Bruneton-Governatori 1984). The trees, of course, would survive without even this minimal care, important only for improving the yield of nuts, which prompted some critics in the nineteenth century to compare chestnuts to manna falling directly from heaven into the hands of lazy onlookers (Gasparin 1863, Vol. 4: 742).

Yet, when all of the exacting and repetitive tasks involved in growing and preparing chestnuts are contemplated, with an absence of mechanization the common characteristic, chestnutting suddenly seems like very hard work indeed.

Collecting

Efficient collection required that the area under and around the trees be clean so that few chestnuts would be overlooked. Collecting was a manual job, lasting at least three weeks (chestnuts do not fall all at once), and required the efforts of all members of the family. Perhaps half of the burs – the prickly polycarps – open on the tree or when they hit the soil. The other half had to be shelled, often with the bare and calloused hands of those viewed as tough "chestnutters" by fellow workers. Next the fruits were sorted. The very best nuts were sent to market, about 20 percent were judged "throw-outs" for the pigs, and the rest were set aside for domestic consumption.

Chestnut collection was tedious and hard on the back, requiring about 10 hours of labor for an average collection of between 50 and 150 kg per person. An estimate was made that 110 working days were required (100 women-children/days; 10 men/days) to gather the chestnuts from 2 hectares, which would amount to about 5½ tons of fruit (Hombres-Firmas 1838).

Peeling

Fresh chestnuts constituted the bulk of the diet for those who harvested them until about mid-January – about as long as they could safely be kept. But before they could be eaten, the nuts had to be extracted from their rigid shell and stripped of their bitter and astringent skin. This is a relatively easy procedure when chestnuts are roasted, but generally they were boiled. Peeling chestnuts was usually done by men in front of the fire during the long evenings of autumn and winter. To peel 2 kg of raw chestnuts (the average daily consumption per adult in the first part of the nineteenth century) required about 40 minutes. Therefore, some three hours, or more, of chestnut peeling was required for the average rural family of five. The next morning around 6 A.M. the chestnuts, along with some vegetables, were put into a pot to begin boiling for the day's main meal.

Drying

The only way to preserve chestnuts for longer periods was to dry them. The method was to spread out the fruit on wattled hurdles high over the heat and smoke of a permanent fire for about two weeks, often in wooden smoking sheds built specifically for this purpose. Following this step, the dried chestnuts – from 5 to 10 kg at a time – were wrapped in a cloth and rhythmically thrashed against a hard surface to separate the nuts from shells and skins that the drying process had loosened.

Dried chestnuts had the effect of liberating peasants from the irksome chore of daily peeling, and the drying procedure had important social consequences as well. Diego Moreno and S. de Maestri (1975) have noted that the expanding cultivation of chestnut trees in the sixteenth-century Apennines gave birth to hamlets that sprang up around the smoking sheds.

Grinding and Flour

After the chestnuts were dried, they could be ground into flour that would keep for two or three years, provided it was not subjected to moisture. From this flour pancakes and bread were made, although because chestnut flour does not rise, many commentators refused to call the loaves bread. There were also others who had harsh words for other chestnut products, making fun of "this kind of mortar which is called a soup" (Thouin 1841: 173) or that bread which "gives a sallow complexion" (Buc'hoz 1787: 126).

Chestnut Consumers

Chestnuts were mostly the food of rural peasants in mountainous regions that stretched in a belt from Portugal to Turkey. But they were a well-appreciated food by many accounts, such as those of regionalist connoisseurs who praised the "sweet mucilage" (Roques 1837) and the following 1763 text published in *Calendriers . . . du Limousin:*

> All the goods nature and art lavish on the table of the rich do not offer him anything which leaves him as content as our villagers, when they find their helping of chestnuts after attending their rustic occupations. As soon as they set eyes on them, joy breaks out in their cottages. Only mindful of the pleasure they then taste, they are forgetful of the fatigues they endured: they are no more envious of those of the towns, of their abundance and sumptuousness (Calendriers . . . du Limousin 1763, reprinted in Bruneton-Governatori 1984: 462).

This is not to say, however, that only peasants ate chestnuts, and, in fact, numerous sources indicate that this foodstuff could be a prized dish at higher levels of society. For example, a French nobleman (Michel de Montaigne 1774) recorded that on October 22, 1580, while on his way to Italy, he ordered raw chestnuts. And, in fact, a Spanish nobleman wrote in his account of a campaign against the Moriscos that the whole company, nobility included, consumed 97.4 tons of bread, 33,582 liters of wine, and 240 tons of chestnuts, as against only 19.3 tons of biscuit and 759 kg of chickpeas (Vincent 1975).

We know that chestnuts were served in Utrecht in 1546 at the royal Golden Fleece banquet, and we have the delightful Marie Marquise de Sévigné (1861, Vol. 2: 133–4) playing the woman farmer who claimed to be "beset with three or four baskets" (of chestnuts): "I put them to boil; I roasted them; I put them in my pocket; they appear in dishes; one steps on them."

This and other quotations tend to obscure the fact that, for the rich in particular, there were chestnuts and then again, there were chestnuts. The French (and the Italians) have two words for chestnut. The ordinary chestnut is called *châtaigne,* whereas the best (and sweetest) chestnut is called a *marron* (which in English is known as the Spanish chestnut). The difference lies in size and form. Usually the husk holds only one *marron* with no dividing skin (the kernel is whole), whereas there may be three or more *châtaignes* in a husk divided by partitions. *Marrons* are the material of commercial candied chestnuts and have historically commanded a price three or four times greater than their common, flawed counterparts. One of the reasons is that the yield of *marrons* is less. Thus, in times past, those who grew them were usually located on a commercial artery and did not depend on chestnuts alone to feed families and pigs.

From the Renaissance on, there were three major commercial roads for chestnuts in Europe. One ran from the Portuguese provinces of Minho and Tras-os-Montes to the harbors of northern Portugal and Galicia where chestnuts were loaded aboard ships, usually bound for Bordeaux. In that port the Iberian chestnuts were combined with chestnuts bought on the Périgueux market and then sent on to Great Britain and the Netherlands. A British author writing of this trade route said that the choicest chestnuts were those grown in Spain or Portugal (Miller 1785).

The French, by contrast, thought the best chestnut was the so-called Lyon chestnut, which was actually an Italian chestnut traveling the second of the three European chestnut arteries. Lyon monopolized the importation of Italian chestnuts, transshipping them to Paris and points farther north. The third route, which also originated in Italy, ran from Milan and Bergamo north to the Germanic countries.

Fresh chestnuts, as we have seen, are perishable, staying fresh for only about three months. And weeks of travel in wagons and the holds of ships did them no good. Thus, transporting chestnuts in bulk was a risky business, and wholesalers fixed their prices accordingly. Only the best chestnuts were shipped, and they went mostly into sweetmeats. In markets they were so costly that only the well-off could purchase them for a tidbit at the table. Consequently, the chestnut trade never did involve large quantities, and most of the chestnuts sold for consumption went through local markets and merchants. In 1872, for example, Paris received barely 6,000 tons of an estimated national crop of 500,000 tons.

The bulk of any chestnut crop, of course, reached no market but was consumed by the peasant families that grew them, along with their poultry and two or three hogs. The British agronomist Arthur Young, who traveled in Limousin, France, during the years 1787–89, calculated that an acre with 70 chestnut trees would feed one man for 420 days or 14 months (Young 1792). This seems a substantial overestimation of the average number of trees per acre. It was generally the case that between 35 and 100 trees grew on 1 hectare (about 2½ acres). If, however, one assumes that a family living on a hilly and not particularly productive hectare of land could harvest about 2,800 kg of chestnuts, then certainly the chestnuts alone could feed a family for more than half a year. With an average daily consumption of 2 kg per person or 10 kg for a family of five, the 2,800 kg of chestnuts would have fed the family for close to 7 months and a pig or two (350 kg are required to fatten a pig from 100 to 200 kg). The pigs, in turn, might be sold or slaughtered, and one suspects that several pigs on a chestnut farm were a food index of chestnut surpluses.

Chestnuts in Decline

A very good question is why such a useful and valuable foodstuff as chestnuts has today been virtually forgotten. The "golden age" of the chestnut, which seems, in retrospect, to have begun with the Renaissance, had all but vanished by the middle of the nineteenth century (Pitte 1979). It is difficult to quantify the decline because the statistics do not reflect domestic production for self-sufficiency. Nonetheless, a series of events that had a considerable impact on chestnutting can be identified.

One of the first blows dealt to chestnut production (especially in France) was the very hard winter of 1709. According to observers, tree loss was considerable, even to the point of discouraging replanting (*Journal Économique* 1758). The *Intendant* in Limoges reported in 1738 that owners there had not replanted even a twentieth of the trees that had frozen 29 years earlier. And in 1758, a chestnut plantation around the Pau castle was uprooted. Unquestionably, the winter of 1709 caused considerable concern for the future of chestnut cultivation, as did the similarly devastating winters in 1789 and 1870.

A second factor was the substitution of mulberry trees for chestnuts around the Rhone valley, where Lyon and its silk industry exerted considerable influence. Silkworms are fond of mulberry leaves, and the mulberry tree (unlike the chestnut) grows fast and produces quickly. Its cultivation, therefore, encouraged a cash economy as opposed to self-sufficiency.

A third reason for the decline of the chestnut, at least in France, may have been free trade in wheat. In 1664, fear of food shortages had prompted Colbert to take the severe measures of controlling wheat production and prohibiting its exportation. At the same time, the exportation of chestnuts was encouraged. Such regulations lasted about a century before the free traders triumphed over regional monopolists and wheat became a cheap and widely available foodstuff, even competing with chestnuts in regions that had traditionally grown them.

Chestnuts also came under fire beginning in the eighteenth century as a foodstuff deficient in nutrients. A well-off society that tasted a *marron* occasionally pitied the unfortunate peasants who were condemned to gulping down a pigfood – the *châtaigne.* Such a diet represented "The International of Misery and Chestnut," according to Leroy Ladurie (1966).

But this was the time of the Physiocrats, who thought the soil was the only source of wealth and aimed at improving the productivity of farming by questioning all traditional rural economic processes. That chestnuts suffered at their hands is undisputable. In a query sent to provincial learned societies, François Quesnay and Victor Riqueti Mirabeau, both initiators of the Physiocratic school, asked the following questions: "Are there acorns or chestnuts used as foodstuff for pigs? Do chestnuts give a good income? Or are said chestnuts used as food for the peasants, inducing them to laziness?" (Quesnay 1888: 276). And in an agricultural text of a few decades later, the question of laziness was pursued: "To my knowledge, inhabitants of chestnut countries are nowhere friendly with work" (Bosc and Baudrillard 1821: 272). It went on to suggest that they refused to replace their trees with more productive plants because of their fear of taxation and concluded that they were not worthy citizens of the modern state.

Interestingly, the voice of François Arouet Voltaire (1785: 106) was one of the few who defended the chestnut:

> [W]heat surely does not nourish the greatest part of the world. . . . There are in our country, whole provinces where peasants eat chestnut bread only; this bread is more nourishing and tastier than the barley or rye bread which feeds so many people and is much better for sure than the bread ration given to soldiers.

More than two hundred years later we find A. Bruneton-Governatori (1984) agreeing with Voltaire, noting that chestnuts provide a balanced diet and around 4,000 calories of energy. The condemnation the chestnut received in the eighteenth and nineteenth centuries might "raise doubts about the pertinence of contemporary evidence concerning the nutrition of non-elite people."

The half century from 1800 to 1850 was one of slow decline for the European chestnut as fewer and fewer people were interested in cultivating it, eating it, or defending it. One notes 43,000 trees uprooted in the Italian Piedmont between 1823 and 1832, and public surveyors here and there reported that chestnut-planted lands were diminishing. But following the midpoint of the nineteenth century, we have statistics in France that demonstrate vividly the magnitude of the decline. In 1852, there were 578,224 hectares of land given to chestnut cultivation; in 1892, 309,412; in 1929, 167,940; and in 1975, only 32,000 (Bruneton-Governatori 1984).

A final factor in the decline of chestnuts was doubtless the so-called ink disease, which officially began in Italy in 1842, had spread to Portugal by 1853, and reached France by 1860. The disease could kill chestnut trees in two or three years, and entire hectares of dried-up trees discouraged any notions of replanting. And, as mentioned, another disease appeared in North America to kill practically all the chestnuts there.

Thus, chestnuts went the way of so many other foods of the past as, for example, salted codfish. Once popular and cheap foods that fed many, they have now become expensive delicacies for a few.

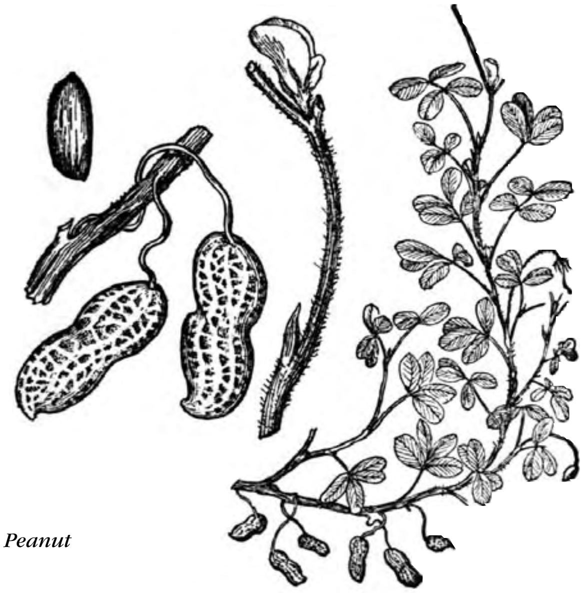
II.D.2 ~ Peanuts

Peanut or groundnut (*Arachis hypogaea* L.) is a major world crop and member of the Leguminosae family, subfamily Papilionoidae. *Arachis* is Greek for "legume," and *hypogaea* means "below ground." *Arachis,* as a genus of wild plants, is South American in origin, and the domesticated *Arachis hypogaea* was diffused from there to other parts of the world. The origin of *Arachis hypogea* var. *hypogaea* was in Bolivia, possibly as an evolutionary adaptation to drought (Krapovickas 1969). Certainly the archaeological evidence of the South American origins is secure. However, the debate about the pre-Columbian presence of New World plants in Asia (especially India) remains unresolved. The other species of *Arachis* that was domesticated prehistorically by South American Indians was *A. villosulicarpa,* yet the latter has never been cultivated widely.

As the peanut's nutritional and economic importance became recognized, it was widely cultivated in India, China, the United States, Africa, and Europe. Thus, the peanut is another of the New World food crops that are now consumed worldwide. The peanut is popular as a food in Africa and in North America, especially in the United States; peanut-fed pigs produce the famous Smithfield ham of Virginia, and peanut butter is extremely popular. There is also much interest in peanut cultivation in the United States.

Botanically, the varieties of peanuts are distinguished by branching order, growth patterns, and number of seeds per pod. The two main types of peanuts, in terms of plant growth, are "bunch or erect," which grow upright, and "runners or prostrate," which spread out on or near the ground. Commercially, peanuts are grouped into four market varieties: Virginia, Runner, Spanish, and Valencia. The former two include both bunch and runner plants, and the latter two are bunch plants. Details on the life cycle and growth of the peanut and its harvesting are provided later in this chapter (Lapidis 1977). Table II.D.2.1 shows the various characteristics of the four varieties.

Peanuts are also called "groundnuts" because they are not true tree nuts. Peanuts are seeds of tropical legumes with pods that grow underground to protect the plant's seeds from seasonal drought and from being eaten by animals. Peanuts consumed by humans are dried seeds of the Leguminosae family, as are kidney, pinto, lima, and soy beans, as well as peas and lentils. The dried shell of the peanut corresponds to bean and pea pods. The names "peanut" and "ground pea" (as the food was called when it was first eaten in North America) became popular because the dried seed had a nutlike shell and texture, and it looked like a pea. Peanuts are also named "goobers," "earth almonds," "earth nuts," "Manila nuts," "monkey nuts," "pinda," and *pistache de terre.* But these terms sometimes also apply to other plants of similar character, such as *Voandzeia subterranea,* found in West Africa, Madagascar, and South America, and the "hog peanut" *(Amphicarpaea menoica),* found in North America.



Peanut

Table II.D.2.1 *Characteristics of peanut varieties*

Variety	Origin	Season (days)	Nut
Virginia (*Arachis hypogea* var. *hypogaea*)	Probably originated in Amazon	140–160	Large; long; slender; 1–2/pod
Runner	A cross between Virginia and Spanish	140–160	Small to large; stubby; 2–3/pod
Spanish (*Arachis hypogaea* var. *vulgaris*)	Originated in Brazil	90–120	Small; round; 2–3/pod
Valencia (*Arachis hypogaea* var. *fastigiata*)	Originated in Brazil and Paraguay	90–120	Small; 3–6/pod

Source: Adapted from Ockerman (1991), p. 546.

Structure

The peanut plant roots at its nodes and is self-pollinating, with flowers that open and die after fertilization. It is unique in that it flowers above the ground, but after fertilization the fruit develops below ground in the soil.

The peanut consists of the germ (heart), two cotyledons (halves of the peanut), the skin, and the shell. The pod is tough and stays closed as the seeds ripen, but the seeds themselves have soft, digestible coats. They have been eaten by humans ever since South American Indians first domesticated them during prehistoric times.

Origins and History

Evidence exists of peanuts having been grown in Peru as early as 2000 B.C. (Sauer 1993). As mentioned, they are believed to have originated in South America, and many wild species of the genus *Arachis* are found there. Spanish explorers spread the peanut to Europe and the Philippines, and Portuguese explorers took it to East Africa. It reached North America circuitously via the slave trade from Africa, although in pre-Columbian times it probably came to Mexico from South or Central America. The stocks developed in Africa provided the basis for many varieties now grown in the United States. Initially, peanuts were cultivated in the United States for livestock feed to fatten farm animals, especially pigs, turkeys, and chickens. But they gained commercial importance after the Civil War, with much of the credit due to George Washington Carver at the Tuskegee Institute. One of America's most distinguished African Americans of the nineteenth century, Carver spent his life developing various uses for peanut products, and they became important as a food and as an oil source.

In addition, commercial mills that crushed peanuts for oil were developed independently in Asia and Europe. Europe's inability to meet a demand for olive oil led to a market for peanut oil there, with the peanuts coming mainly from West Africa, and then from India after the opening of the Suez canal. Peanuts subsequently were cultivated in all tropical and subtropical parts of the world.

Unique Characteristics

Unlike most legumes, peanuts store oil instead of starch. During the early growth of the cotyledon storage cells (up to about 30 days after the peg or gynophore strikes the soil), starch granules predominate, and lipid and protein bodies are few. After this stage, however, to about 45 days, both lipid and protein bodies increase rapidly, and from 45 to 68 days, protein bodies and especially lipid bodies continue to expand. The plant's protein and fat come from these bodies in the peanut cotyledon. In the final stage, there is little further growth of the cotyledon (Short 1990; Weijian, Shiyao, and Mushon 1991). Most peanuts require 140 to 150 frost-free days to mature, but such factors as growing season, location, and time of fruit set also influence the time required to reach maturity (Cole and Dorner 1992). Table II.D.2.1 gives characteristics of peanut varieties.

Peanut Pathogens and Pests

Approximately a quarter of the peanut fruit and vine crop is lost because of plant disorders wrought by insects, bacteria, fungi, nematodes, and viruses. *Sclerotina minor,* the cause of sclerotina blight, and *Cercospora arachidicola,* the cause of early leaf spot, are two important peanut pathogens. These are controlled by herbicides. Unfortunately, resistance to one is often associated with high susceptibility to the other, and resistance to *S. minor* is also associated with small seed size and an undesirable shade of tan color for the Virginia peanut type (Porter et al. 1992). Bacterial wilt is caused by *Pseudomonas solanacearum.* Fungal species, including *Aspergillus, Rhizopus, Fusarium,* and others, cause various diseases.

The peanut root-knot nematode (*Meloidogyne arenaria* [Neal] Chitwood race 1) is a major pest in the peanut-producing areas in the southern United States. These microscopic worms greatly reduce yields but can be controlled with fumigants and nematicides. Efforts are now moving forward to select *M. arenaria*–resistant species of peanuts, because chemical controls of the pest are becoming more limited (Holbrook and Noe 1992).

Tomato spotted wilt virus (TSWV) decreases seed number and weight. Other viruses cause such diseases as spotted wilt and chlorotic rosettes. Insects that attack peanuts include the corn rootworm, which causes rot, and the potato leafhopper, which secretes a toxic substance, damaging the leaves.

Staphylococcus aureus brings about microbial degradation of fat in peanuts, but the major pathogen with relevance to human health is a fungal aflatoxin. It is a carcinogenic metabolite of *Aspergillus flavus* and *Aspergillus parasiticus,* which may cause or promote liver cancer in humans, especially when infected nuts are eaten in large quantities.

Although neither pathogen nor pest, drought is another major limiting factor in peanut production, and efforts are now progressing to develop drought resistance in some varieties (Branch and Kvien 1992).

Horticulture

Production

The six leading peanut-producing countries of the world are India, China, the United States, Nigeria, Indonesia, and Senegal. World production of peanuts in the shell for 1992 was 23 million metric tons, with Asia and Africa producing 90 percent of the total (FAO 1993).

In the United States, the state of Georgia leads the nation in peanut production, followed by Texas, Alabama, and North Carolina (United States Department of Agriculture 1992). The most famous peanut producer in the United States is former President Jimmy Carter.

Cultivation

Peanuts need hot climates with alternating wet and dry seasons and sandy soils. Ideally, rainfall or moisture from irrigation should total at least an inch a week during the wet season. Peanuts are planted after the danger of frost is gone, when soil temperatures are above 65° F. The soil is usually treated with herbicides, limed, fertilized, and plowed before planting. Insecticides may then be applied, and herbicides are applied between preemergence and cracking time (postemergence). Postemergence practices involve cultivation, insecticides if needed, and herbicides for weed control. Calcium sulfate is provided to maximize peanut fruit development. This addition of calcium is important in peanut fertilization, because insufficient levels can lead to empty pods with aborted or shriveled fruit (Cole and Dorner 1992). Peanuts are usually rotated with grass crops such as corn, or with small grains, every three years. This rotation reduces disease and soil depletion. Efforts have been made to intercrop peanuts with other plants, such as the pigeon pea or cotton, but these have not been successful.

Harvesting

Only about 15 percent of peanut flowers produce fruit. The harvest includes both mature and immature varieties, as all fruits do not mature at the same time, and about 30 percent is immature at harvesting. Maturity can be estimated in a variety of ways. The "shell-out method" for recognition of maturity has to do with the darkening of the skin (testa) and the inside of the hull. The "hull scrape method" is done by scraping the outer shell layer (exocarp) to reveal the color of the middle shell (mesocarp), which is black in the mature peanut. Peanut harvesting involves removing plants from the soil with the peanuts attached (the upright plant is better suited to mechanical harvesting). A peanut combine is used to remove the pods from the plant.

Storage

After harvesting, the peanuts are cleaned by removing stones, sticks, and other foreign material with a series of screens and blowers. For safe storage the peanuts are dried with forced, heated air to 10 percent moisture.

Cleaned, unshelled peanuts can be stored in silos for up to six months. Shelled peanuts are stored for a lesser time in refrigerated warehouses at 32–36° F and 60 percent relative humidity, which protects against insects. A high fat content makes peanuts susceptible to rancidity, and because fat oxidation is encouraged by light, heat, and metal ions, the fruit is best stored in cool, dry places (McGee 1988). On the whole, however, unshelled peanuts keep better than shelled.

Processing

Peanuts may be processed shelled or unshelled, depending on the desired end product. Those left unshelled are mainly of the Virginia and the Valencia types. They are separated according to pod size by screening; discolored or defective seeds are removed by electronic color sorting, and the stems and immature pods are removed by specific gravity (Cole and Dorner 1992). Peanuts that are to be salted and roasted in the shell are soaked in a brine solution under pressure, and then dried and roasted.

Peanuts to be shelled are passed between a series of rollers, after which the broken shells and any foreign materials are removed by screens and blowers. Next, the shelled peanuts are sorted by size. Any remaining foreign materials and defective or moldy seeds are removed by an electronic eye, which inspects individual seeds. Ultraviolet light is useful for detecting aflatoxin contamination.

Peanuts are frequently blanched to remove the skins and hearts. This can be done by roasting (259–293° F for 5 to 20 minutes), or by boiling, after which they are rubbed to remove the skins. Then the kernels are dried to 7 percent moisture and stored, or converted into various peanut products.

Another method – dry roasting – is popular because it develops a desirable color, texture, and flavor for peanut butter, candies, and bakery products. In this case, unblanched peanuts are heated to 399° F for 20 to 30 minutes, then cooled and blanched.

Shelled peanuts are usually dry roasted in a gas-fired rotary roaster at 399° F, then cooled to 86° F, after which they are cleaned and the skins removed for making peanut butter. Oil-roasted peanuts are placed in coconut oil or partially hydrogenated vegetable oil at 300° F for 15 to 18 minutes until the desired color is achieved, whereupon a fine salt is added. Roasting makes the tissue more crisp by drying and also enhances flavor because of the browning reaction. Relatively low temperatures are used to avoid scorching the outside before the inside is cooked through. The roasting of peanuts also reduces aflatoxin content. For example, roasting for a half hour at 302° F may reduce aflatoxin B_1 content by as much as 80 percent (Scott 1969).

And finally, peanut oil is extracted by one of three different methods: hydraulic pressing, expeller pressing, or solvent extraction.

Food Uses

Traditionally, peanuts were used as a source of oil and, even now, most of the world's peanut production goes into cooking oils, margarines, and shortenings, as well as into the manufacture of soap and other industrial processes. Also called "arachis oil," "nut oil," or "groundnut oil," peanut oil is a colorless, brilliant oil, high in monounsaturates. Virgin oil is mechanically extracted (expeller pressed at low temperature [80–160° F]), and lightly filtered. This method provides the lowest yield but the highest-quality edible oil.

Refined oil is typically produced by solvent extraction. It is made from crushed and cooked peanut pulp, which is then chemically treated in order to deodorize, bleach, and neutralize the flavor of the oil. In the United States, only low-grade nuts are used for oil production. The fatty acid composition is quite variable for a number of reasons, such as genotype, geography, and seasonal weather (Holaday and Pearson 1974). When refined oil is stored at low temperature, a deposit is formed, and hence it cannot be used in salad oils and dressings.

Only peanuts that are free from visible mold and subject to less than 2 percent damage are used for edible purposes. In the United States and Western Europe, most peanuts to be eaten go into the "cleaned and shelled" trade and are consumed as roasted and/or salted nuts, as peanut butter, or as a component of confections.

Because of its high protein and low carbohydrate content, peanut butter was first developed in 1890 as a health food for people who were ill. It is a soft paste made from Virginia, Spanish, or other types of peanuts. The skin and germ are removed, and the kernels are dry roasted and ground. Salt, antioxidants, flavors, and sugars (dextrose or corn syrup) may be added after grinding. Hydrogenation and/or the addition of emulsifiers prevents separation. "Crunchy style" peanut butter has bits of roasted nuts mixed into it.

Peanut butter is approximately 27 percent protein, 49 percent fat, 17 percent carbohydrate, 2 percent fiber, and 4 percent ash. Its sodium content is approximately 500 mg per 100 g. Peanut butter has good stability even after two years of light-free storage at 80 degrees Fahrenheit (Willich, Morris, and Freeman 1954), and keeps longer if refrigerated. But sooner or later, it becomes stale and rancid.

Peanuts are frequently employed in the cuisines of China, Southeast Asia, and Africa. The residual high-protein cake from oil extraction is used as an ingredient in cooked foods and, in Chinese cooking, is also fermented by microbes.

In recent years, peanuts have been added to a variety of cereal- and legume-based foods to alleviate the problem of malnutrition. Moreover, peanuts in the form of flour, protein isolate, and meal in a mixed product have desirable sensory qualities (Singh and Singh 1991). Peanut flour is made by crushing the shelled, skinned nuts, extracting the oil, and grinding the crushed nuts. In India, the flour is used in supplementary foods, weaning foods, and protein-rich biscuits (Achaya 1980).

In addition, the peanut plant itself has a high nutritional value and can be used for livestock feed or plowed back into the soil to aid in fertilization of future crops (Cole and Dorner 1992). Nonedible nuts are processed into oil, with the cake used for animal feed. Peanut shells, which accumulate in abundance, can be used as fuel for boilers (Woodroof 1966).

Nutritional Value

Protein

Having a higher percentage of protein by weight than animal foods and beans (ranging from 22 to 30 percent), peanuts provide an excellent, inexpensive source of vegetable protein for humans. A 1 ounce serving of oil- or dry-roasted peanuts provides 7 to 8 grams of protein, or 11 to 12 percent of the U. S. Recommended Dietary Allowance (RDA).

The protein quality of the peanut also is high, with liberal amounts of most of the essential and nonessential amino acids (the limiting amino acids in roasted peanuts and peanut butter are lysine, threonine, methionine, and cystine). For this reason, U. S. government nutritional guidelines include peanuts along with other high-quality protein foods, such as meat, poultry, fish, dry beans, and eggs. In the last few decades, cereal- and legume-based plant food mixtures using peanuts have grown in popularity, especially in developing countries, because of the excellent nutritional value of peanut proteins and their low cost. Table II.D.2.2 presents some chemical indices of protein quality for peanuts and other high-protein foods.

New methods for determining free amino acids in whole peanuts are now available (Marshall, Shaffer,

Table II.D.2.2. *Comparison of various indexes of protein quality for peanuts and other protein-rich foods*

Protein source	Essential amino acid index	Observed biological value	PER	NPU
Peanuts	69	57	1.65	42.7
Egg, whole	100	96	3.92	93.5
Beef	84	76	2.30	66.9
Fish	80	85	3.55	79.5

Note: The essential amino acid index rates protein quality with respect to all of the 11 essential amino acids. The PER (protein efficiency ratio) is an animal bioassay that measures the efficiency of a protein in producing weight gain in rats. The NPU (net protein utilization) is a similar method that adjusts with a control fed no protein whatsoever, and measures the changes in body nitrogen between the two dietary groups and a group of animals sacrificed at the beginning of each feeding period. BV (biological value) uses estimates of retained nitrogen from the difference between ingested nitrogen and that accounted for in urine and feces.

and Conkerkin 1989); Table II.D.2.3 shows that peanuts have an amino pattern similar to that of high-quality proteins, and Table II.D.2.4 indicates that peanuts are much higher in protein than other staple plants, save for legumes.

Peanut proteins include the large saline-soluble globulins, arachin and conarachin, and the water-soluble albumins. The relative protein content of peanuts may vary with variety, strain, growing area, and climate. Arachin constitutes about 63 percent, and conarachin 33 percent, of the total protein in peanuts. The remaining 4 percent consists of other proteins, including glycoproteins, peanut lectin (agglutinin), alpha beta amylase inhibitor, protease inhibitors, and phospholipase D.

Fat

Depending on the cultivar, the fat content of peanuts ranges from 44 to 56 percent. Over 85 percent of the fat in peanuts is unsaturated; an ounce of peanuts contains 14 grams of fat, of which about a third is polyunsaturated and over half is monounsaturated. More precisely, peanuts have a polyunsaturated to saturated fat ratio of 2:3; a high proportion of their total fat is monounsaturated (49 to 54 percent), and a low percentage (14 to 15 percent) is saturated (McCarthy and Matthews 1984).

Monounsaturated fats help to lower LDL (low density lipoprotein) cholesterol when they replace saturated fats in the diet, and thus can help reduce risks of coronary artery disease that are associated with hyperlipidemia.

Calories, Carbohydrates, and Cholesterol

Well over three-quarters of the calories in peanuts are from fat, with the remainder from protein and carbohydrate, although the content of the latter varies with variety and growing conditions. Peanuts usually have about 20 percent carbohydrates, most of which are sucrose (4 to 7 percent) and starch (0.5 to 7 percent). Peanuts have no cholesterol.

Table II.D.2.3. *Comparison of the amino acids in peanuts compared to high-quality proteins*

	Mg/g protein

Fiber

The dietary fiber content of peanuts is approximately 7 percent by weight. The percentage of edible fiber is 3.3 (Ockerman 1991a), and of water-soluble fiber 0.77. The latter two percentages were determined by enzymatic figures (Deutsche Forschungsanstalt für Lebensmittelchemie 1991).

Sodium

In their raw state, peanuts are very low in sodium. Unsalted dry-roasted nuts, and "cocktail" nuts, contain no sodium in a 1-ounce serving. However, whole peanuts are usually served salted. A 1-ounce serving of lightly salted peanuts contains less than 140 milligrams of sodium, which is the U. S. Food and Drug Administration's current definition of a low sodium food. But other peanut products, such as "regular salted" nuts, contain higher amounts of sodium.

Vitamins and Minerals

Peanuts are good sources of riboflavin, thiamine, and niacin, and fair sources of vitamins E and K. They are also relatively high in magnesium, phosphorous, sulfur, copper, and potassium.

In the case of niacin, peanuts are rich sources of tryptophan (an essential amino acid that can be converted into niacin) and, in addition, are relatively rich sources of preformed niacin itself, a 1-ounce serving providing 20 percent of the U.S. RDA.

Nutrients and Processing

Under processing conditions in developing countries, dry roasting preserves both the storage stability of peanuts and their nutritional value to a greater extent than oil roasting (DaGrame, Chaven, and Kadam 1990). With roasting, the thiamine content decreases and the color darkens; hence color gives an indication of the extent of thiamine loss. The proteins, vitamins (except thiamine), and minerals are very stable during processing. But blanching or mechanical removal of skin further reduces thiamine content because thiamine is concentrated in the skins (Woodroof 1966). Table II.D.2.5 shows the nutritional composition of *Arachis hypogaea L.*

Table II.D.2.5. *Nutritional value of* Arachis Hypogaea L.

Health-Related Issues

Enhancing Protein Quality

Plant proteins, like those in peanuts, which are rich in essential amino acids and nitrogen and low in only a few amino acids, help improve the overall quality of diets, especially diets based on plant proteins. Protein supplementation involves adding to the diet small amounts of a protein that is a rich source of those amino acids that would otherwise be lacking. Protein complementation involves combining protein sources so that they mutually balance each other's excesses or deficiencies (Bressani 1977).

These principles have been used to produce cereal–legume multimixes for humans (Bressani and Elias 1968), and the cuisines of several countries that have traditionally relied on plant protein foods as staples also employ these same principles to good effect, so that protein quality is rarely a problem.

A Weaning Food in Cereal Multimixes

Infants and young children, as weanlings, are growing rapidly and require plenty of high-quality protein. Yet, for cultural and economic reasons, protein–rich animal foods are frequently not readily available in many developing countries. A quarter of a century ago, cereal and cereal–legume multimixes (including peanuts) began to be used to provide a high-protein and high-calorie weaning food for children in this age group. These multimixes can be produced at the local level, are economical, and have excellent results in supporting child growth.

Similarly, many protein-rich cereal- and legume-based foods containing peanuts are now in widespread use in developing countries for alleviating problems associated with protein calorie malnutrition. Peanuts, which are rich in oil and in protein, and are also tasty, are particularly valuable for these purposes (Singh and Singh 1991).

Allergenicity

It is unfortunate that peanuts are not for everyone. The cotyledons, axial germ tissue (hearts), and skin of peanuts contain allergens, and some, but not all, of these are still present after roasting. Because the allergens do not have a characteristic odor or flavor, they cannot easily be detected by peanut-sensitive individuals; thus, labeling of peanut-containing products is essential, save for pure peanut oil, which is not allergenic.

The many different peanut allergens that exist all contain protein. These allergens have been demonstrated by the use of radioallergenabsorbent test (RAST) inhibition, and by immunologic techniques, such as crossed radioimmunoelectrophoresis (CRIE), two-dimensional electrophoresis, and immunoblotting to isolate and characterize the peanut allergens. Then sera from peanut-sensitive individuals is used to determine if specific IgE binding to the various isolated subfractions exists. Since the isolation and characterization methods may affect the physical structure of the protein or its subfractions, different techniques may give different results. Nonetheless, at present, it is clear that multiple allergens exist in peanuts.

A well-characterized peanut allergen recently identified in patients with atopic dermatitis and positive peanut challenges is called Ara h I *(Arachis hypogaea I)* in the official nomenclature (Burks et al. 1991). Highly atopic infants and children appear to be particularly likely to form IgE antibodies that respond to peanuts, as well as to other food proteins (Zimmerman, Forsyth, and Gold 1989). Such children begin producing IgE antibodies to respond to inhalant allergens during their first and second years of life; they are defined as highly atopic because their serum IgE levels are 10 times those of normal infants, and their RAST tests are positive on multiple occasions.

Diagnosis. Diagnosis of peanut allergy is difficult because standardized peanut extracts do not yet exist. A RAST can be used on the sera of already sensitive persons for whom a skin test would be dangerous. Double-blind placebo-controlled challenges are definitive but are not often needed. If such double-blind challenges are done, provisions need to be made to cope with emergencies that may arise if an anaphylactic reaction occurs. The allergenicity of hydrolyzed peanut protein must be further studied. It is not clear at what level of hydrolysis allergenicity is lost.

Prevalence of peanut sensitivity. Peanut sensitivity is less prevalent among humans than are, for example, sensitivities to milk and eggs, but peanuts are especially dangerous for a number of reasons. One important reason is that peanuts occur in small amounts in so many different foods and recipes, ranging from satay sauce and "vegeburgers" to main dishes and spreads, making it difficult for those who have the allergy to avoid them (Smith 1990).

The allergy occurs in vegetarians as well as omnivores (Donovan and Peters 1990), and cross-reactivity with other legumes appears to exist. In addition, individuals who are allergic to other foods besides legumes are sometimes allergic to peanuts. Finally, highly atopic individuals, such as asthmatics, and those who suffer from atopic dermatitis or from multiple other food allergies, are likely to be at particular risk.

Signs of peanut allergy. The signs of peanut sensitivity range from urticaria (hives) to angioedema and asthma, and occasionally even to anaphylaxis and death (Lemanske and Taylor 1987; Boyd 1989). Crude extracts of proteins in both raw and roasted peanuts, as well as purified peanut proteins, such as arachin, conarachin, and concanavalin A reactive glycoprotein, are all allergenic in some persons (Barnett, Baldo, and Howden 1983).

Natural history of peanut allergy. Allergic reactions to peanuts usually begin early in life and persist. Studies over a period of several years have now been completed on individuals who exhibited symptoms of peanut allergy in childhood after a double-blind, placebo-controlled challenge, and reacted positively to puncture skin tests at the same time. Most such individuals had avoided peanuts since diagnosis, but those who inadvertently ingested peanuts 2 to 14 years later had reactions. This, coupled with a continued skin reactivity to peanut extract in puncture tests, suggests that peanut-sensitive individuals rarely lose their sensitivity with time (Bock and Atkins 1989). Fatal reactions to peanuts can also occur after many years of abstinence (Fries 1982). Fortunately, peanut oil, at least the usual grade sold in the United States and Europe, which contains no detectable protein, is not allergenic (Taylor et al. 1982). Unfortunately, in other countries the oil may contain enough of the protein to cause allergic reaction.

Allergy treatment. Avoidance of products containing peanut protein is the surest way to avoid peanut allergy. But certain foods may be accidentally contaminated with peanut protein, so that even products supposedly peanut free may be dangerous. Because the prevalence of peanut allergy is high, both labeling and label reading are important. Treatment of peanut sensitivity with immunotherapy has not proved helpful. If a sensitive person does ingest peanuts, self-administered epinephrine may help.

Peanut anaphylaxis is a medical emergency (Sampson 1990). One common cause is consumption of a product containing deflavored and colored peanut protein reformulated to resemble other nuts (Yunginger et al. 1989). In one case, an "almond" icing that was actually made from peanuts led to a fatal reaction (Evans, Skea, and Dolovich 1988). Other possible hidden sources of peanuts are egg rolls, cookies, candy, pastries, and vegetable burgers. Chinese food and dried-food dressings that contain peanuts have also been causes of anaphylactic shock (Assem et al. 1990).

Peanut allergy is probably the major cause of food-related anaphylaxis in the United States. Only a few milligrams will cause reactions in some persons. Those who are at risk of anaphylactic reactions to peanuts should wear medic-alert bracelets and carry preloaded epinephrine syringes and antihistamines. If treatment is needed, repeated doses of epinephrine, antihistamines, corticosteroids, mechanical methods to open airways, oxygen, vasopressors, and intravenous fluids may be necessary to prevent a fatal reaction (Settipane 1989).

Cross-reactivity in allergenicity. Peanuts cross-react in vitro with other members of the Leguminosae family, especially with garden peas, chickpeas, and soybeans, although clinical sensitivity is not always observed (Toorenenbergen and Dieges 1984; Barnett, Bonham, and Howden 1987). Reactions to nonlegume nuts, however, are relatively rare among those allergic to peanuts.

Aflatoxin

Aflatoxins are naturally occurring environmental contaminants that often infest peanuts. These carcinogenic mycotoxins arise from a fungus *(Aspergillus flavus)* that colonizes peanuts under certain environmental conditions or improper storage conditions that permit fungal growth. The aflatoxins B_1 and B_2 are most common in peanuts.

Aflatoxin-contaminated food has been shown to be associated with liver cancer in both humans and several experimental animals. The problem appears to be most severe in Africa and other parts of the world where environmental and storage conditions favor the mold's growth and where processing methods that could identify and eliminate contaminated seeds are still not in place. But it is also a problem in the Orient, where people prefer the flavor of crude peanut oil. This form of the oil is high in aflatoxins.

In highly industrialized countries, aflatoxin contamination generally occurs before the harvest; in developing countries, contamination during storage is an additional and seemingly greater problem. In the former case, insect damage to the pods and roots permits seed contamination by the mold, especially during growing seasons where there is a late-season drought, which increases stress on the plant and also helps to exclude competition by other fungi. In a three-year study it was found that pods are more susceptible to contamination than roots (Sanders et al. 1993). Shriveled peanuts have the highest content of aflatoxin B_1 (Sashidhar 1993).

Under favorable environmental conditions, *Aspergillus flavus* produces millions of spores, which can be carried by the wind for miles (Cleveland and Bhatnagar 1992). Insect damage promotes *Aspergillus flavus* growth when the spores land at a site of insect injury and when the moisture content exceeds 9 percent in peanuts, or 16 percent in peanut meal, and temperatures are 30 to 35° C. Therefore, the only sure method to avoid aflatoxins is to prevent their formation by careful harvesting and quick drying and storage. Food additives, such as sodium bisulfite, sorbate, proprionate, and nitrite, reduce aflatoxin production. Also, certain food components and spices, such as peppers, mustard, cinnamon, and cloves, may inhibit mycotoxin production (Jones 1992).

Visual screening of peanuts will reveal the conidial heads of the *Aspergillus flavus* fungus. Another technique is to screen unshelled nuts for the presence of bright greenish yellow fluorescence (BGYF) under ultraviolet light, using electronic color-sorting techniques. However, neither of these techniques screens out all aflatoxin contamination. For greater precision, chemical tests are used that include thin layer chromatography (TLC) and high performance liquid chromatography (HPLC) (Beaver 1989).

Immunological methods, such as ELISA or affinity column methods, are also useful, although precautions must be taken in performing the analysis since aflatoxins are highly carcinogenic (Wilson 1989). Much research is now in progress on the development of standardized methods for determining aflatoxin in peanut products. Other research concentrates on eliminating the contamination or inactivating it.

Chlorine gas can inactivate one aflatoxin, aflatoxin B_1, and the resulting compounds do not appear to be mutagenic (Samarajeewa et al. 1991). Ammonia and ozone treatments of peanuts also appear to work. As yet, however, these methods are still experimental.

The liver cancer in question is thought to be caused by hepatitis B, with other factors, such as aflatoxin, acting as promoters or as less-potent initiators. In most case-control studies, primary hepatocellular carcinoma is highly associated with antibodies to hepatitis B and C virus; other risk factors, such as peanut consumption (presumably with aflatoxin contamination), smoking, and drinking, are less highly associated (Yu et al. 1991). A recent large study in mainland China showed high correlations of liver cancer with hepatitis B surface antigen (HBsAg+) carrier status, whereas lesser associations were seen with alcohol use and cadmium of plant origin, but none with the measure of aflatoxin exposure that was used (Campbell et al. 1990). However, smaller studies, especially of peanut oils contaminated with aflatoxin, continue to suggest that aflatoxin may be involved in hepatobilliary cancers (Guo 1991).

Aflatoxin: Food safety. In recent years, the European Community has increasingly collaborated on food safety tests, and a great deal of effort has been devoted to developing more sensitive, rapid, and standardized methods for detecting aflatoxin levels in peanut products (Van Egmond and Wagstaffe 1989; Patey, Sherman, and Gilbert 1990; Gilbert et al. 1991). Thanks to this collaboration, standardized methods and materials are now available for assuring valid and reliable food safety testing. Current guidelines are that no more than 20 parts per billion of aflatoxin are permitted.

Developing countries and the aflatoxin problem. As we have mentioned, the problem of aflatoxin contamination is particularly serious in developing countries because of storage and processing problems. Thus, by way of example, aflatoxin levels in Pacific countries such as Fiji and Tonga are high, and so are liver cancer rates. Therefore, in addition to improving inspection methods, techniques must be developed for decreasing the carcinogenicity of aflatoxin-contaminated foods for humans and for animals. One technique that has been helpful in reducing the carcinogenicity of aflatoxin-contaminated groundnut cakes is ammoniation (Frayssinet and Lafarge-Frayssinet 1990). However, more such solutions are needed.

Table II.D.2.6. *Nutritive value of common peanut foods (g/100g)*

	Nut, roasted (Spanish or Virginia, salted)	Peanut butter	Peanut oil
Water, g	1.6	1.7	0

Protein, g	26	25	0
Carbohydrate, g	19	19	0
Fat	50	51	100

Miscellaneous

Because peanuts are a low-acid food, incorrect commercial canning of peanuts can cause botulism, as a recent case in China showed (Tsai et al. 1990). On a more positive note, peanuts are often used by dentists as foods for masticatory tests for jaw and muscle function (Kapur, Garrett, and Fischer 1990), because they are easy to standardize and familiar to patients (Wang and Stohler 1991). Moreover, roasted peanuts are among the least likely of popular snack foods to cause dental caries (Grenby 1990). Peanuts remain available dry, oil roasted, unsalted, lightly salted, or salted, as well as in a variety of flavors today in the United States (Nabisco Foods Group, Planters Division 1990). And finally, the not fully mature (or green) peanuts can be used as a vegetable that is much appreciated in the southern United States. Green peanuts are boiled in a weak brine solution and usually consumed immediately. If refrigerated, they will last for five days. They can also be frozen or canned.

Table II.D.2.6 shows the nutritive value of various peanut foods.

II.E

Animal, Marine, and Vegetable Oils

II.E.1 An Overview of Oils and Fats, with a Special Emphasis on Olive Oil

Oils from vegetable sources are playing an increasingly important role in human nutrition, and they, along with foods incorporating them, currently compose 30 percent of the calories in a typical Western diet. In the past, however, vegetable oil utilization was limited, and animal and marine fats were far more important. This chapter discusses the nutritional value of fats and oils widely used in the world today.

Fatty Acid Nomenclature

Most oils consist primarily of triacylglycerols, which are composed of 3 fatty acids esterified to a glycerol molecule. The "essential" fatty acids are a major consideration in assessing the nutritional value of fats and oils. G. O. Burr and M. M. Burr first discovered that fats and oils contained substances that were essential for normal growth and reproduction (Holman 1992), and in the 1970s, convincing evidence was presented to show that the omega-3 fatty acids were also essential in humans. In addition to fatty acids, other components present in fats and oils include fat-soluble vitamins (A, D, and E) and sterols, and as few other compounds in fats and oils are of nutritional importance, only fatty acids, fat-soluble vitamins, and sterols are discussed in this chapter.

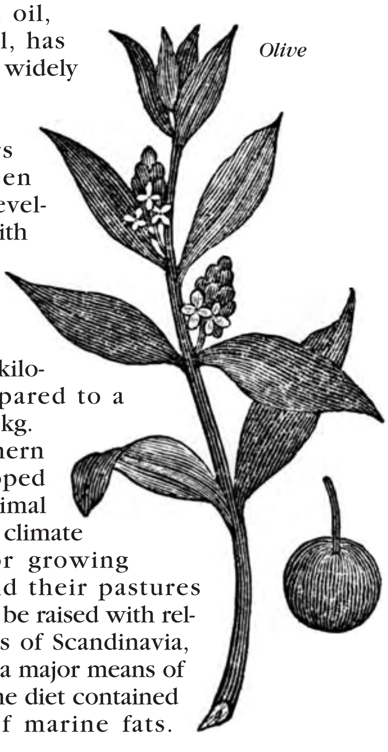
The sterols of importance to nutrition include cholesterol and the plant sterols. The structures of common sterols are shown in Figure II.E.1.1. Recently, there has been a great deal of interest in cholesterol oxides, which are formed in cholesterol-containing foods and oils after heating or oxidation and which have been implicated in the development of atherosclerosis (Smith 1987; Nawar et al. 1991).

Fatty acid composition is often presented as an average value representing a middle point in the composition of an oil. There are many factors that affect the fatty acid composition of oilseeds, marine oils, and animal fats. Thus, it is preferable to present a range of fatty acid compositions that are common, rather than to present one value.

World Fat and Oil Production

Current production estimates for important fats and oils are shown in Figure II.E.1.2. Soybean oil is by far the leader, followed by palm, sunflower, and rapeseed oil, with others trailing far behind. The current levels of production of the various vegetable oils reflect relatively recent changes. Palm oil production has increased dramatically in the last few decades, as Malaysia and other Asian countries have promoted it, and in the past half century, soybean oil, once a minor oil, has become the most widely used of all.

Today, fat and oil usage differs markedly between developed and developing countries, with the per capita consumption of fats and oils in industrialized nations about 26 kilograms (kg), compared to a world average of 7 kg. Historically, northern Europeans developed diets based on animal fats because their climate was unsuited for growing oilseed crops and their pastures allowed animals to be raised with relative ease. In areas of Scandinavia, where fishing was a major means of food production, the diet contained large amounts of marine fats.



In Africa, Asia, and the Mediterranean, however, because the raising of large numbers of animals was impractical and fish were not dietary mainstays, fats were derived primarily from plants, such as oil palms and olive trees. Thus, historical differences in patterns of fat consumption largely resulted from environmental conditions that fostered the various agricultural practices of the different areas of the world.

Yet, over the past 100 years, there has been a decreased consumption of animal fats and an increase in that of vegetable oils. When vegetable oils were first produced in commercially important quantities, they could not be used to displace animal fats because the latter (for example, butter, lard, and tallow) were solid at room temperature and had specific applications that required solidity. But the process of hydrogenation, developed early in the twentieth century, permitted the manufacture of plastic fats (such as shortening and margarine) based on vegetable oils, and lard and butter were subsequently displaced in the diets of many peoples.

The twentieth-century industrialization of oilseed production, as well as vegetable oil extraction and refining, has been the primary factor leading to large-scale changes in the fat composition of diets around the world, although genetic engineering, breeding, and mutation have also brought significant changes in the fatty acid composition of a number of oilseeds. Moreover, the fatty acid composition of animal fats and aquacultured fish can be altered by dietary manipulation. Such changes complicate discussion of the nutritional benefits obtained from oils.

Oil Extraction and Processing

A knowledge of the ways in which oils are obtained (extracted) and processed is important to an understanding of the nutritional value of the oils. Fats and oils are extracted from animal and vegetable materials by the three main processes of rendering, using the screw press, and solvent extraction.

The first method humans employed to extract oils was undoubtedly rendering, which is still used today to remove fat from animal and fish tissues. In this process, the material to be rendered is heated (either dry or in water), which disrupts the tissues and allows separation of the oil. The quality of the oil yielded by early rendering operations must have been poor, but later developments in processing (such as steam heating) have permitted the rendering of high-quality products. The conventional wet-rendering process includes an initial cooking step, in which the tissue is heated with direct or indirect steam, or is heated as it passes through a conveyer. The cooked material is pressed in continuous or batch presses, and the liquid ("press liquor") is centrifuged to separate the water and oil. The oil obtained may be dried further before storage.

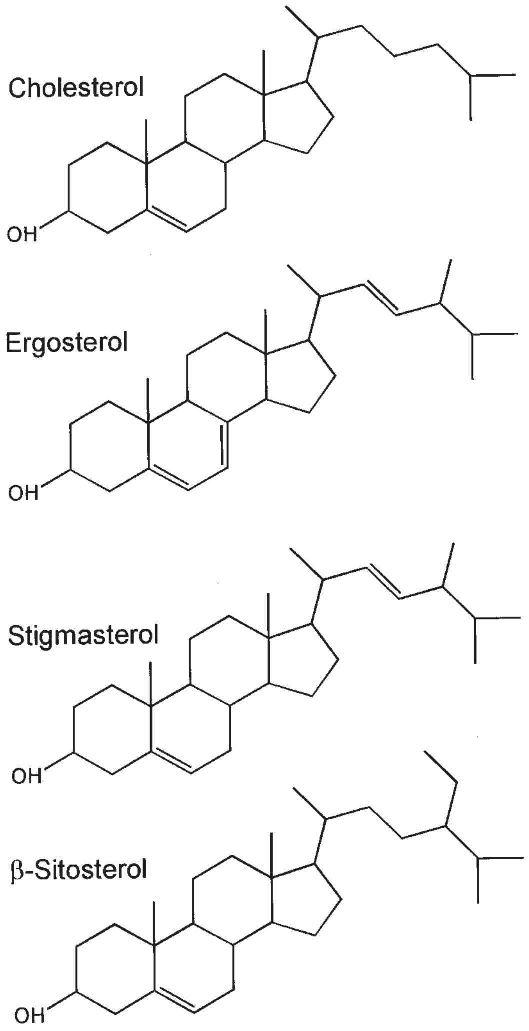


Figure II.E.1.1. The structure of common sterols.

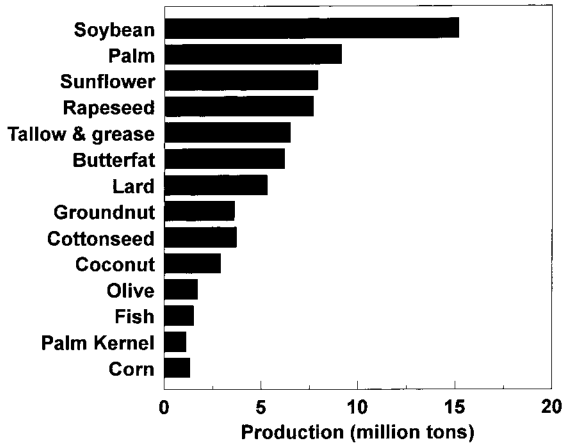

Figure II.E.1.2. Production estimates for important fats and oils.

Table II.E.1.1. *Average oil content of plant sources of oil*

Material	Oil percent
Soy	18–20
Palm fruit	45–50
Sunflower	25–45
Rapeseed (canola)	35–60
Peanut	45–55
Cottonseed	18–20
Coconut (copra)	63–68
Olive	25–30

In the second method, an expeller, or screw press, removes oil from vegetable materials by mechanical pressure. The pressure creates heat, disrupting the tissue and causing the oil to separate, after which it flows out through holes in the press. Such presses have been documented in early Hindu medical texts; the first of these devices, however, doubtless had low output, and the extracted oil was probably used for illumination or for medicine. These were batch presses, which had to be filled with oilseed and then emptied in each extraction step. By contrast, modern screw presses operate continuously and have much greater capabilities than batch presses. Screw-press extraction of oil is most feasible when the oil content of the material to be pressed is high. The oil content of some vegetable sources of oil is shown in Table II.E.1.1 (Sonntag 1979a).

The third method of oil recovery, solvent extraction, was only possible after supplies of solvents with appropriate characteristics became available. The solvent-extraction process for soybeans is outlined in Figure II.E.1.3. The refining steps include alkali neutralization, which results in the removal of phospholipids and free fatty acids; bleaching, which removes pigments, metals, and free fatty acids; and deodorization, which removes odorous compounds, some sterols, and tocopherols.

W. Normann's discovery of liquid phase hydrogenation (which results in loss of polyunsaturated fatty acids and production of monounsaturated "trans" acids) led to the development of plastic fats derived from vegetable sources. Crisco, the first shortening to be sold (1911), was based on hydrogenated cottonseed oil. By the mid-1940s, 65 percent of the cottonseed oil produced in the United States was used to make shortening.

Vegetable Oils

Olive Oil

Olive oil is derived from the fruit of the evergreen tree *Olea europaea,* which grows in temperate climates with warm and dry summers. Around 5,000 or 6,000 years ago, at the eastern end of the Mediterranean, the tough, spiny, wild olive trees dominating the countrysides of Palestine, Syria, and other areas of the Middle East were first brought under cultivation (Chandler 1950). The trees became gnarled with domestication, and less bushy, and their fruit (green that ripens to brown or to blue-purple-black) was laden with oil. That oil – technically a fruit oil rather than a vegetable oil, as it is classified – doubtless was used to fuel lamps, and it found its way into medicines and cosmetics as well as cooking. The many uses for oil created much demand in the ancient world, which was satisfied by oils made from walnuts, almonds, and the seeds of sesame, flax, and radishes, as well as from olives (Tannahill 1988). The latter, however, were the most productive source of oil from the Bronze Age onward, and their cultivation spread throughout the Mediterranean region, so that the waning centuries of that age found the people of the island of Crete cultivating great numbers of olive trees and growing rich on the export of oil (Trager 1995).

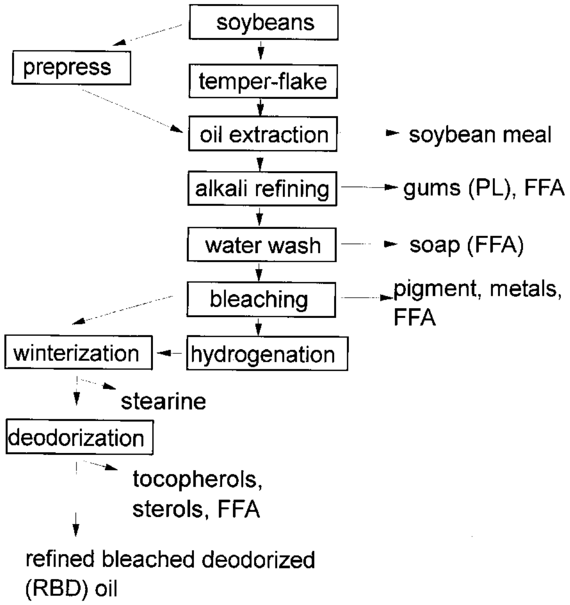

Figure II.E.1.3. Operations in soybean oil extraction and refining.

Shortly after the dawn of the Iron Age, the Greek landscape reflected a similar dedication to olive production, spurred in the early sixth century B.C. by the prohibition of Solon (the Greek statesman and legal reformer) of the export of any agricultural produce except olive oil. Greece (like Crete, two millennia earlier) would learn how devastating the effects of monoculture could be when war made trade impossible (Tannahill 1988).

Nevertheless, as a relatively precious product requiring special climate and skills, yet easy to store and ship in jars, olive oil lent itself well to this kind of specialization. Barbarians in contact with the Greeks became good customers, although any possibility of

Greek monopoly ended when Etruscans carried the techniques of olive cultivation into Italy, and Phoenicians did the same for North Africa and the Iberian peninsula.

Because many years are required for olive trees to become productive after planting, olive cultivation in these new areas probably required the passing of a generation or two before its possibilities were appreciated. But certainly one thing worth appreciating was that olive trees seemed to live forever. In Spain, for example, it is said that there are trees some 1,000 years old, which meant that in the absence of some catastrophe, such as disease or fire, the task of planting olive trees and then waiting for them to become productive seldom troubled grove owners more than once, if that (Chandler 1950).

In the first century A.D., Pliny noted a dozen varieties of olives grown as far away from Rome as Gaul (France) and Spain, and certainly it was the case that by the time of the Romans, olive-tree cultivation had caught on in Iberia in a big way. With olive oil a staple in the Roman diet, Spanish oil was a commodity sought throughout the Empire, and henceforth olive oil would be established as the most important dietary oil in southern Europe. In the north – where livestock did well and olive trees did not – cooking was done with butter and lard. Obviously, the cuisines these cooking mediums helped to shape were often strikingly dissimilar.

Within fourteenth-century Spain, olive oil was exported from south to north, and wool and hides from north to south, in a kind of microcosm of greater Europe, and, following the conquest of the New World, American demand continued to stimulate Spain's olive oil industry. As the colonists began to make their own oil, however, the flow of Spanish olive oil across the Atlantic diminished. In North America, Thomas Jefferson tried to grow olives at Monticello, but the cuttings he used would not take root (Trager 1995). At about the same time as this failed experiment in the east of the continent, olive cultivation was successfully launched in California by Spanish missionaries, and by the beginning of the twentieth century, that western state had joined Provence in France and the Lucca district in Italy – in the eyes of at least one American writer – as a producer of some of the world's best olive oils (Ward 1911).

Today, 90 percent of the world's olives go into oil, and only 2 percent of the acreage given over to olive production is outside of the Mediterran-ean region (McGee 1984). In terms of volume, Spain, Italy, Greece, and Portugal are the largest producers, although much of their olive oil is not reflected in production figures because there are many people – with just a few trees – who pick their own olives and take them to local cooperatives to be pressed.

Olives are sometimes picked by hand because they, and the twigs they grow upon, are fragile. However, because the fruit should be all of the same size and degree of ripeness, the same tree might be picked several times, all of which significantly increases the price of the oil (Toussaint-Samat 1992). To avoid picking several times, the fruits are generally treated less elegantly and are knocked off the trees, either from ground level with long poles or with small rakes by harvesters who climb the trees to shower the olives down. The fruits are caught on cloths spread on the ground or (more frequently today) on sheets of plastic.

Olives to be eaten are usually picked green and unripe. But, as Harold McGee (1984: 204) has remarked, anyone who has ever bitten into one knows instantly that something more must be done to render it edible. This something more is generally pickling, which has been practiced since the days of ancient Rome by soaking olives in a solution of lye to remove the bitter glucoside called oleuropein (from *Olea europea*).

Black olives – those that ripen at the time of the first frosts – are the kind made into oil. After they are gathered, they are permitted to stand and get warm, but not to ferment. Then they are washed and crushed. The oldest known technique for extracting oil was that of crushing the fruit underfoot; later, crushing was done by hand, using a pestle, and later still with millstones. In fact, many of the old-style Roman oil mills, with their large millstones operated by donkeys or mules (or by slaves in Roman times) continued in use throughout the Mediterranean area until well into the twentieth century (Toussaint-Samat 1992).

The crushing results in a paste that is pressed to secure the 25 to 30 percent of the olive that is oil. Extra virgin oil, also called "cold-pressed," comes from the first and lightest pressing and is unrefined; moreover, no heat is used to extract further oil. Virgin oil is produced in the same manner but has slightly greater acidity. Cold-pressed olive oil, although it has a wonderful flavor, will not keep as well as refined olive oil and, consequently, must be shielded from the light in cans or dark bottles.

The oil produced by succeeding pressings (usually with heat or hot water added) generally contains substances that give it a bad flavor, whereupon it is refined. Light and extra light oils are olive oils (not virgin) that have been filtered, producing a light scent, color, and taste. Oil labeled "pure" is a combination of virgin oil and that derived from the second pressing. Production of olive pomace oil – the cheapest grade of olive oil – requires hot water, which is added to the residue of olive oil cake, then poured off. This oil, typically not very good, has traditionally been exported to countries where a taste for olive oil has not been highly developed, although it is sometimes consumed by its own producers, who in turn sell their virgin oils for income (Toussaint-Samat 1992).

Table II.E.1.2. *Fatty acid composition ranges (weight percentage) of natural populations of vegetable oils*

	Soybean	Palm	Sunflower	Rapeseed	Peanut	Cottonseed	Coconut	Olive
6:0	0	0	0	0	0	0	<1.2	0

18:0	2–5.5	1.5–14.7	1–6.5	0.5–4	2–6.5	1–4	1–4.7	0.5–3.5
18:1	20–50	27–52	14–70	9–58	40–72	13–44	3.4–12	56–86
18:2ω6	35–60	5–16	20–75	8–27	13–38	33–58	0.9–3.7	3.5–20
18:2ω3	2–13	0.5–5	<0.5	3–21	<0.5	<0.5	0	01.5
20:0	<1	<1	<1	<1.5	1–2	<0.5	<0.2	<0.1
20:1	<1	0	<0.5	5–18	0.5–1.5	<0.5	<0.2	<0.1
22:0	<0.5	0	<1	<1.5	2–4	0	0	<0.1
22:1	0	0	0	30–60	0	0	0	0
24:0	0	0	<0.2	<2	1–2	0	0	<0.1

A more complicated (and technical) grading system for olive oils is based primarily on the free fatty acid levels: Extra virgin oil, which comes from the first pressing, has an acidity of less than 1 percent and perfect flavor and odor. Virgin oil, from the same pressing, contains less than 3 percent free fatty acids. Extra virgin and virgin olive oils may be processed only by washing, decantation centrifugation, and filtration. Refined olive oils are obtained by refining virgin or extra virgin olive oils, using the same alkali neutralization, bleaching, and deodorization steps employed in refining other oilseeds. Olive pomace oil is produced by solvent extraction from the cake remaining after pressing. It was sometimes called sulfur olive oil in the past, when carbon disulfide was used as an extraction solvent.

To maintain low free fatty acid levels and produce oil of the highest quality, olives must be processed within three days of harvest. This is primarily because ripe olives contain a high amount of water, allowing lipase enzyme activity and a resulting increase in free fatty acid levels. Consequently, in some areas that are not equipped to press olives as fast as they are harvested, either the fruit is left on the trees until it can be processed, or it is stored, which can be a risky procedure.

Olive oil is characterized by a very high oleic acid content averaging around 75 percent (Table II.E.1.2). Palmitic acid is the second most prevalent fatty acid, followed by linoleic and linolenic. There has been a great deal of interest in olive oil as a promoter of human health since the development of the hypothesis that a "Mediterranean diet" is protective against heart disease, perhaps because for centuries, olive oil has been the only oil readily obtainable for human use that has a high oleic characteristic.

Recent developments in oilseed breeding and genetics, however, have produced high-oleic safflower, sunflower, peanut, canola, and soybean oils. Yet, it is unlikely that these will take over the applications of olive oil, which is enjoyed as much for its flavor as for any nutritional advantages it may have. As already noted, because they are not refined, virgin olive oils have a pleasant and characteristic flavor, and of all the major vegetable oils, only olive oil is sold unrefined. The deodorization process undergone by other oils removes compounds that would otherwise produce flavors unsuitable for many applications. In addition, some oils have flavors that can only be characterized as unpleasant.

Olive oil has a moderate amount of tocopherols, primarily alpha-tocopherol. Despite a low level of gamma-tocopherol, olive oil is remarkably stable, which is attributable to its low levels of linoleic and linolenic acids, as well as phenolic compounds that are present. Minor components in olive oil are not removed because the oil is not refined; the levels of some of these compounds are shown in Table II.E.1.3. Finally, it should be noted that olive oil contains very low levels of phospholipids and waxes, which permits the production of a clear oil without refining.

Table II.E.1.3. *Levels of minor components in olive oil*

Component	Mg percentage
Squalene	125–750
Sterols	125–250
Triterpene alcohols	50
Chlorophyll	0.06–0.22
Carotenoids	0.06–0.95

Soybean Oil

The soybean *(Glycine max* L., formerly *Soja max),* of the family Leguminosae, is grown worldwide for its high-protein content and its oil. There are wild *(Glycine ussuriensis)* and intermediate *(Glycine gracilis)* as well as cultivated *(G. max)* soybean varieties. Although soybeans have been used as food in China for thousands of years, their development as the world's primary oilseed has only taken place since the mid-1940s.

As mentioned (and as shown in Figure II.E.1.2), the production of soybean oil today overshadows all others. The soybean contains 40 to 50 percent protein and an average of 18 to 20 percent lipids (Table II.E.1.1). Its oil is a byproduct of the production of soybean meal, which is primarily used as animal feed. The oil obtained directly from soybeans contains about 88 percent neutral lipid (triacylglycerols and sterols), 10 percent phospholipid, and 2 percent glycolipid. Refined oil contains more than 99 percent triacylglycerols, and it is necessary to remove the phospholipids to produce a stable, clear oil. Like other vegetable oils, save that from olives, soybean oil is usually refined, bleached, and deodorized before use.

Soybeans contain a number of antinutritional compounds, including protease inhibitors, hemagglutinins, saponins, goitrogens, allergens, phytic acid, and oligosaccharides (raffinose, stachyose), as well as isoflavones (phytoesterogens). However, because these compounds are not transferred to the lipid, the oil is essentially devoid of them.

Soybean oil is one of the two common oils that contain appreciable levels of omega-3 fatty acids, and it is ironic that at the same time that some investigators were discovering the important roles played by omega-3 fatty acids in the human diet, other researchers were working to reduce the levels of these fatty acids in soybean oil (Hammond 1992). The reason for the interest in lowering linolenic acid in soybean oil (which ranges from 5.5 to 10 percent) is that it oxidizes at a rate some 2 or more times greater than linoleic acid, which, in turn, oxidizes at a rate about 10 times lower than oleic acid (Hammond 1994). Lowering linolenic acid levels results in a more stable oil; the more unsaturated the oil, the less stable it will be. In the past, soybean oils have been lightly hydrogenated (brush hydrogenation) to reduce the linolenic acid content to less than 3 percent. This is uncommon today because of health interests in oils with no trans acids and also because of problems with cloudiness at refrigeration temperatures.

Recently, there has also been a great deal of interest in reducing the amount of palmitic acid in soybean oil, which is a major dietary source of it. This is because palmitic acid is thought to be one of the three saturated fatty acids most responsible for raising plasma cholesterol in humans (the other two are myristic acid and lauric acid). Varieties of soybeans with modified fatty acid composition have been developed, including low-linolenic, high-stearic, high-oleic, high-palmitic/low-linolenic, high-palmitic, and low-saturate/low-linolenic.

The low-saturate/low-linolenate composition, shown in Table II.E.1.4, has much lower palmitic acid levels than traditional soybean varieties; the other fatty acids are relatively constant. The linolenic and oleic acids are at the high end of the fatty acid ranges in normal soybeans. Lowering the palmitic acid content of soybeans has been a major improvement in terms of nutritional value, and more varieties of oilseeds with tailor-made fatty acid compositions for specific purposes should be seen in the future.

The tocopherol composition of soybean oil is shown in Table II.E.1.5. It should be noted that, in some reported analyses of vitamin E compounds, the beta and gamma isomers are combined, whereas other analyses do not report these isomers. The beta and gamma tocopherols are very similar in structure (Figure II.E.1.4). For most vegetable oils, the alpha and gamma isomers predominate. The alpha isomer is by far the most bioactive of the tocopherol isomers (Table II.E.1.6), but the antioxidant effect appears to be greater for the gamma isomer. Tocopherols are reduced during the refining process at the deodorization stage. Roughly 30 percent of the total tocopherols are removed. The data presented in Table II.E.1.6 are for refined, bleached, and deodorized (RBD) oils.

Table II.E.1.4. *Fatty acid compositions (weight percentage) of modified fatty acid vegetable oils*
