Fourteen thousand years ago, human populations throughout this region were mobile hunter-gatherers who relied on wild plants and animals for sustenance (Table V.A.1). Little is known of the full range of foods eaten by these people. There is scant evidence of the plant foods consumed even though nuts, starchy seeds, and tubers were probably important contributors to the diet (Colledge 1991). But the skeletal remains of forest and steppe animals attest to a variety of game that was eaten, including several types of deer and gazelle, wild cattle, pigs, sheep, goats, and onagers (Hesse 1995).

Table V.A.1. *Chronology of the Near East and Egypt*

Near East			Egypt	
Calibrated date B.C.		Uncalibrated date B.C.		Calibrated date B.C.
Literate civilizations of Mesopotamia			**Pharaonic state**	
3,100	-	2,600	-	3,100
	Early states		Predynastic	
3,500	-	2,800	Later villages & towns	
	Later villages & proto-urban societies	3,000	-	3,750
			Early predynastic villages	
		3,700	-	4,500
			Semisedentary farmers/foragers	
		6,300	-	5,200
	Pottery Neolithic			
6,900	-	6,000	-	
Aceramic Neolithic			**Mobile foragers**	
10,200	-	8,300	-	
	Sendentary and semisedentary foragers			
12,000	-	10,000	-	
	Mobile foragers			

Source: Adapted from Evin (1995) for the Near East and Hassan (1985) for Egypt. Calibrated dates interpreted from Stuiver et al. (1986, fig. 7) and uncalibrated dates based on Libby half-life (5,568 years).

Note on Chronology: Scientists have developed ways to calibrate radiocarbon dates so that they more accurately reflect calendar years. Most of the reports and papers cited here, however, use uncalibrated radiocarbon dates for periods before the early states. In order to be consistent, we have decided to use calibrated and historical dates throughout (cf. Evin 1995). We hope this does not cause confusion for readers who investigate some of our source material.

By 12,000 B.C., seeds and nuts had become an important part of the diet (Flannery 1973). At this time, foraging populations in the more favorable areas became less mobile and began to stay in settlements for extended periods. People living in the steppe and steppe forest began to concentrate on a few main species of animals and plants. The faunal evidence is fairly straightforward; at sites from the Levant to the Syrian steppe, gazelle appears to have been the primary source of animal protein (Garrard 1984). At Abu Hureyra, for example, gazelle constitutes about 80 percent of the animal bone (Legge 1975). Depending on local availability, the meat diet in other areas also seemed to focus on only one or two wild ungulates, like sheep, goat, pig, and onager (Hesse 1995).

As the climate changed during this period, the habitat of wild grasses expanded. Analysis of isotopes in human bone from archaeological sites suggests that people were now eating more plant foods. The most extensive collection of archaeological plant remains comes from the site of Abu Hureyra. Though Gordon C. Hillman, Susan M. Colledge, and David R. Harris (1989) suggest that the Abu Hureyrans consumed a wide array of plants, some of the plant remains they have turned up as evidence may have derived from animal dung burned as fuel, and so may not fairly represent human food choices (Miller 1996). Slightly later samples from nearby Mureybit (Zeist and Bakker-Heeres 1984) have a few concentrations of seeds that are more likely to be human food remains, especially those of wild einkorn.

Accompanying the shift to a settled lifestyle were advances in food technology that probably contributed to a more stable food supply and population growth. In addition to cooking, which probably had been practiced for about a million years, archaeological evidence points to improvements in grinding and storage technology. Without grinding and cooking, the digestibility of wild cereals and pulses would have been low, but with such techniques, even pulses that are toxic when fresh could be nutritious, and, consequently, the amount of food available from a given tract of land would have been increased. Moreover, storing food in pits reduced both intra- and interannual variation in food availability.

These technological changes encouraged an increase in sedentism as well as in population during the early village period. Food, a welcome addition to most social interactions, probably also became important for greasing the wheels of human relations. Feasting, practiced on a grand scale in later periods, was doubtless begun for a variety of reasons, ranging from the cementing of alliances to the attracting of labor. Such activities would have encouraged sedentary foragers to accumulate surplus beyond bare subsistence needs (Bender 1978).

Farmers

Sometime after 12,000 B.C., sedentary hunter-gatherer communities in the Levant, followed slightly later by inhabitants of Anatolia and parts of the Zagros Mountains, embarked on a path that led to the domestication of plants and animals and, ultimately, food production. This shift in subsistence that archaeologists refer to as the "Neolithic Revolution" was the most profound change in human history and one that still has a far-reaching impact on the planet.

Current consensus is that plant domestication in the Near East began in the Jordan Valley around 9500 B.C. (Zeist 1988), and animal husbandry started about the same time or a little later in the Zagros Mountains and, possibly, North Africa (Hole 1984; Rosenberg et al. 1995). By the middle of the ninth millennium B.C., domesticated plants could also be found in Anatolia and the Zagros. Even with advances in agriculture, however, wild plant gathering and hunting continued to play an important role in the economy. In fact, it is probable that the ancestors of the first domesticated plants in the Near East – emmer, einkorn, and barley – had been important food plants for local foraging populations.

Domesticated plants entered the archaeological record at different times and places. For example, emmer wheat originated in the Jordan Valley, but bitter vetch is probably Anatolian. The earliest farming villages did not use pottery or domestic animals and, like their forebears, stored grain in pits. As early as the ninth and eighth millennia B.C., the ability to store surplus food enabled small, undifferentiated settlements of farmers to develop into larger communities of more complex social and economic organization. Changes are evidenced by public architecture (shrines), differences in wealth as reflected in the goods accompanying burials, specialized occupations for a few, and elaborate mortuary cults (see Voigt 1990). Some of the communities were also vastly larger than the earliest villages and may have housed a thousand or more inhabitants.

Nomadic foragers who followed herds of goat and sheep in the mountains of Iran began managing wild herds about 12,000 years ago, and pigs may have been domesticated at about that time as well (Rosenberg et al. 1995). Cattle were domesticated in Anatolia about 7000 B.C. By determining the age and sex of the animals slaughtered, faunal analysts can infer herd management strategies. For example, if the bone assemblage includes both adult males and females, it is unlikely that milk production was the goal; whether hunted or herded, the primary product supplied by the animals of the early herders was meat.

By 6700 B.C., a fully agricultural economy that relied almost entirely on farming and herding was established over much of the Near East. The staple crops grown over a broad area were cereals (emmer, einkorn, durum wheat, bread wheat, and two- and six-row barley) and pulses (lentil, bitter vetch, and chickpea). It is likely that these crops were eaten, even toxic ones (like bitter vetch) because they are sometimes found in concentrations in roasting pits. Whereas cereals satisfied much of the caloric needs of the early villagers, the addition of domesticated pulses and livestock helped satisfy protein needs. A variety of wild plants, including such nuts as pistachio, almond, and acorn, continued to enhance the diet as well (see, for example, Mason 1995).

Farming spread to the hot, dry lowlands of Mesopotamia where techniques for water management developed. Late in the sixth millennium B.C., the Near Eastern complex of crops and livestock also spread to the Nile Valley, where still other irrigation techniques emerged to take advantage of the Nile floods. Farming villages proliferated as the new subsistence systems proved to be highly productive and capable of supporting a burgeoning population. After the initial phase of domestication, such fruits as grape, olive, fig, and date were domesticated. Their dietary and economic potential, however, was not fully realized until relatively late.

The Near Eastern agro-pastoral subsistence system proved very productive, initially supporting ever-increasing populations. Although one might think the domesticated pulses would be the perfect dietary complement to the cereals, the inclusion of domestic animals in a mixed economy had several advantages lacking in a purely plant-based system. First, animals provided ready access to dietary fat; aside from wild nut trees (especially pistachio and almond), oil plants (olive, flax, and sesame) do not appear to have been utilized at this early date. Second, land marginal for agriculture could have been used productively for pasture. Third, animals convert inedible pasture plants into tasty meat, which would have increased the food supply. Finally, domestic animals may have been traded with other groups to "set up reciprocal obligations and maximize sharing during lean years" (Flannery 1969: 87).

In the short run, the new farming methods seem to have been successful in evening out seasonal and year-to-year fluctuations in the food supply. On a theoretical level, the combined effect of plant and animal husbandry should have been a more stable food supply for growing populations (Raish 1992; Redding 1993). Yet the land could not continue to support expanding populations without some change in management (Köhler-Rollefson 1988). In fact, the first half of the sixth millennium B.C. saw a fairly widespread abandonment of settlements and the reestablishment of smaller communities on other sites, and faunal assemblages from Iran to Syria show a renewed emphasis on hunted animals (Buitenhuis 1990, Zeder 1994). Overgrazing and inadequate fallowing may have exacerbated a long-term impact of fuel cutting by village farmers, with inevitable results.

It was the development of new techniques of chemically transforming food that allowed the theoretical advantages of the agro-pastoral system to be realized. Pottery, widespread by 6000 B.C., permitted new forms of storage and cooking possibilities (though stone boiling in animal skins would have been possible even in prepottery days) (Moore 1995). Fermentation allowed farmers to transform grain and fruits into psychotropic substances; though alcohol is itself not digested, the fermentation process makes many nutrients more available.

Fermented grapes could also have yielded vinegar, a pickling agent. In the Near East, the earliest evidence for fermentation comes from Iran – wine residues at Hajji Firuz, around 5500 B.C., and beer (and wine) residues at Godin Tepe, around 3500 B.C. (Michel, McGovern, and Badler 1993; McGovern et al. 1996); it did not take long for people to appreciate the added value of fermentation. Beer became a convenient and pleasant way to consume grain's carbohydrates and vitamins. It is probably no accident that olives, which must be cured before eating, were domesticated in this era, and olive oil would have been a welcome addition to the diet.

Early Near Eastern farmers did not just experiment with plants. Although we do not know when adults in these populations lost at least some of their inability to absorb lactose (Simoons 1979), at some point they probably began to consume milk from their herds. Cheese, ghee, yoghurt, and other cultured milk products were most likely innovations of the later village societies. Based on the age of slaughter, the zooarchaeologist Simon Davis (1984) suggests that dairy products were not emphasized until relatively late, around 4500 to 4000 B.C. in western Iran. In the Levant, ceramic vessels considered to be churns date to this time (Kaplan 1954). And in the earliest archaic texts from Mesopotamia (before 3000 B.C.), mention of an elaborate array of storable dairy products that were produced in institutional quantities suggest strongly that these items had long been part of the culinary repertoire (Nissen, Damerow, and Englund 1993).

Finally, the period of the later villages seems to have been the time when people began to use salt as a food preservative, although the mineral may have been used for animal hide preparation as early as the seventh millennium B.C. Archaeological evidence for the production and procurement of salt at this time is not available (Potts 1984), but it is difficult to imagine that the large quantities of fish placed as offerings in the fifth millennium B.C. temple at Eridu were fresh! Certainly by the third millennium, drying and salting were well-known techniques of food preservation (see Reiner 1980). In summary, it seems that the major food-transforming technologies developed and spread between about 5500 and 3500 B.C.

By about 3500 B.C., orchard crops began to make a noticeable contribution to the diet. Grape and olive in the Mediterranean region and date in Mesopotamia, so important to the earliest civilizations, had been domesticated. Such fruits as fig, pomegranate, and apple came under cultivation, too. By this time domesticated livestock had almost completely replaced their wild relatives and other hunted animals. The ability to preserve large quantities of varied foods permitted surplus accumulation that, in turn, provided an impetus toward the developments we associate with civilization: urbanization, a high degree of economic specialization, and social inequality (Sherratt 1981; Redding 1993).

The First States

Productive surplus-generating agriculture may not have caused the changes set in motion, but it certainly permitted them to occur. Towns began to appear across Mesopotamia and the northern plains, which individually, as well as collectively, had all the trappings of a society more complex than any previously seen in the Near East. Among them were monuments and temples, full-time craft specialists, social stratification, and large populations.

Specialized nomadic pastoralists who began to share the landscape with settled agricultural populations joined in feeding the growing urban populations, and by 3500 B.C. the trend toward larger and more complex communities culminated in the emergence of the literate civilizations of Mesopotamia and, around 3100 B.C., in the appearance of a state in Egypt. Such social and cultural changes accompanying the rise of complex societies also had profound implications for foodways.

In earlier times, differences in consumption patterns had resulted from seasonal and local resource availability. But these early civilizations were now composed of people divided by wealth, class, occupation, and ethnicity, and their diets varied accordingly. Social status, in other words, had become an additional factor in determining who ate what.

Moreover, the basic Near Eastern crop complex was joined by a few new plants, as indicated by the archaeological record of the third and second millennia B.C. (see Miller 1991). For example, a grave offering included dried apples at Ur (Ellison et al. 1978), and coriander, fruits, and garlic cloves have been uncovered at Tell ed-Der (Zeist 1984). Plants originally domesticated beyond the borders of the Near East also began to appear, including millets, sesame, and rice (Zohary and Hopf 1993). Wild plants continued to add variety to the diet, as evidenced by occasional finds in food-related contexts: a jar of caper buds and fruits at Sweyhat (Zeist and Bakker-Heeres 1985), *Prosopis* seeds at Nimrud (Helbaek 1966), and *Chenopodium* at Shahr-i Sokhta (Costantini n.d.).

Deposits in cesspits provide direct evidence of diet, but they are not commonly found. A mineralized cess deposit from the third millennium B.C. city of Malyan, however, produced dozens of grape seeds and incompletely digested seeds of wheat and barley (Miller 1984). Most plant remains found are charred, however, so they do not directly represent food remains. Rather, they reflect fuel use, trash disposal, and cooking accidents. Archaeobotanical analysis is, therefore, not the primary means of understanding class or ethnic distinctions in human food consumption, but the situation is different for faunal remains.

As in earlier times, the major food animals were sheep, goat, cattle, and pig. Such domesticates as donkey, horse, and camel became more common, but they do not appear to have been eaten to any great extent. A variety of wild animals, such as gazelle, small game, birds, turtles, and fish, are frequent but minor contributors to faunal assemblages (Hesse 1995).

Several studies of the pattern of animal bone disposal on urban sites demonstrate the strategies employed to ensure a steady access to animal products, as well as social differences among the inhabitants. On most Near Eastern sites, the bulk of the bone is from sheep or goat, yet a fluctuating percentage of pig bone consistently appears. Pigs do well in forest and thickets, and can only survive harsh summers with shade and water. Generally then, pork-consuming regions are ecologically suited to the pig (Hesse 1995: 215).

The distribution of pigs in the later periods probably reflects the economics of pig production; they are a fine animal for town dwellers because they reproduce quickly and eat garbage. Thus, in Mesopotamia, the town residents of al-Hiba ate more pork than their rural counterparts in the community of Sakheri Sughir (Mudar 1982: 33). The difficulty in managing large numbers of pigs was another variable in pork consumption. At Lahav, in Israel, their numbers increased when the site was occupied by relatively isolated independent households. But when the settlement was integrated into a regional economy and, presumably, pig raising was more strictly regulated, production declined (Zeder 1995a). Faunal studies have not yet detected specific evidence for the Jewish prohibition on pork consumption because it is difficult to segregate ecological and economic from symbolic values reflected in archaeological bone remains (Hesse 1995: 215).

The dietary impact of wealth is exhibited at al-Hiba, a site where residents of the temple precinct had greater access to domestic animals, and residents of the lower town ate relatively more wild animals, along with pork (Mudar 1982). At Leilan, too, the lower town residences of poorer people had relatively large quantities of pig bones (Zeder 1995b). At Malyan, differential distribution of species and of meat-bearing elements across the site suggests that some residents had more direct access to the herds of sheep and goat than others, and some higher-status households appear to have had greater access to choicer cuts than did lower-status ones (Zeder 1991: 199).

Our sources of evidence for food multiply after the advent of complex society. Visual representations of food and texts concerning its production, distribution, preparation, and consumption fill out a picture constructed with more ubiquitous archaeological remains like seeds and bones. Writing, glyptic, and monumental art are associated with the upper strata of society and comprise evidence that begins to overshadow the archaeological plant remains among the literate societies. Animal bones, however, continue to be the primary source of information about meat consumption.

Among the earliest written signs in Mesopotamia is the one for beer, a necked jar (Green and Nissen 1987: 229). Even after the pictograph was transformed into a more abstract cuneiform sign, the image of two people sitting opposite each other and drinking (beer) with reed straws out of a necked vessel became one of the major elements in banquet scenes on seals (Selz 1983). Bread baking, beer brewing, and other food procurement and preparation scenes give some idea of the vast establishment that was necessary to support the major palace and temple institutions (Strommenger n.d.).

Plants of any sort are rarely depicted in the art of the ancient Near East, as either landscape elements or food. In contrast, images of animals are relatively common. There is no reason to suppose, however, that they are literal symbols of food sources, even when the subject is a food animal. Stylized animal representations in clay figurines are a normal part of assemblages from the aceramic Neolithic on. Although they frequently show important food species (bovids, caprids, and dogs), the animal taxa do not occur in proportion to bone refuse. The famous installations and wall paintings of Çatal Hüyük (eighth to seventh millennium B.C.) depict cattle, but they also depict vultures (Mellaart 1967). The pottery of some late farming cultures includes stylized birds and caprids, but again, there is no direct correlation with the faunal remains.

Depictions of animals in the art of the early civilization of Mesopotamia include many different life forms: scorpions, fish, turtles, birds, and wild and domestic mammals, along with imaginary creatures (Strommenger n.d.). Files of animals on cylinder seals and wall art seem to show sheep, goat, and cattle heading toward byres and are probably depictions of offerings to temple or palace. Haunches of meat and other comestibles are also elements in offering scenes. Portrayals of capture, such as men fishing with nets, sometimes suggest food procurement, but at other times, sport, as with the Assyrian royal lion hunts. A victory stela, showing human captives caught in a net, illustrates a new use for an old technology (Strommenger n.d.: 67), further demonstrating that pictorial evidence cannot be taken at face value. Moreover, scenes directly reflecting diet or dining only refer to a small segment of society. Their symbolic message is more significant than their documentary value.

Mesopotamians began keeping records on clay toward the end of the fourth millennium B.C. In the third millennium, the Sumerians developed writing for a variety of additional purposes. Hundreds of plant and animal names, many of which were used as foods and medicines, occur in ancient Sumerian and Akkadian texts from Mesopotamia (see, for example, Powell 1984; Stol 1985, 1987; Waetzoldt 1985, 1987; Postgate 1987). Economic and literary texts from Mesopotamia point to the importance of wheat, barley (and beer), date (and date wine), cattle, goat, sheep, dairy products, fish, and some fowl. Onion, garlic, and leek were the most important condiments. Different types of food preparation, such as roasting, brewing, and baking, are mentioned, as are names for many types of beer, cheese, and the like (Civil 1964; Ellison 1984; Bottéro 1985).

With textual evidence, it becomes easier to assess geographical, cultural, and social dietary variations. For example, although the staple plant foods of the Near East continued over a wide area, they had overlapping distributions. Cultural preference within the irrigation civilizations of southern Mesopotamia favored barley and beer, as well as date and date wine, whereas wheat and grape wine prevailed in the hilly regions and were joined by olive oil around the Mediterranean (see Powell 1995). Many regional differences are a function of ecology – grapes are more suited to a Mediterranean regime, and dates cannot be grown in the cooler climes. But these "natural" explanations for food preferences do not exclude cultural differences in attitudes toward various kinds of food. Wine, for example, came to have a religious significance in the Mediterranean civilizations that carries through to this day.

Distribution of food in the urban societies of lower Mesopotamia reflected social distinctions. It would seem that in the stratified societies of the ancient Near East, meat was a less important part of the diet for those of the lower classes. Economic texts from some of the major third millennium institutions show that careful track was kept of food provided to workers. Barley comprised the bulk of the rations for people working for the state or temple, although oil, malt products, meat, and other animal products were also distributed. Amounts varied according to the age and sex of the recipients, but scholars still disagree about whether daily ration for a worker constituted his or her whole diet or just a part of it (Gelb 1965; Ellison 1981).

Palace and temple archives also give a glimpse of herd management and production, but they deal exclusively with the large institutional herds of cattle, sheep, and goats. It has long been recognized that such archives tell only part of the story. Illustrative is sheep milk. Textual evidence suggests that only cattle and goats were milk producers, and sheep were grown for their wool and meat (Stol 1993). Yet sheep milk is high in fat and protein and would hardly have been wasted. Perhaps shepherds were allowed to milk the herds directly, or, as is ethnographically attested, sheep milk was mixed with cow's milk, but not recorded separately. Similarly, although quantities of fish were frequently deposited in temple and palace storehouses, no mention is made of fish preservation; because large quantities of fresh fish spoil rapidly, it seems likely that fish preservation and processing (for oil) was carried out by the private sector (Potts 1984).

Textual evidence of food preparation is slender. Perhaps best known is a hymn to the Mesopotamian beer goddess, which describes how *bappir,* an aromatic-flavored dough, is mixed with barley malt and fermented with herbs and other flavorings to make beer (Civil 1964). Three culinary texts from the second millennium B.C. (Bottéro 1985, 1995) contain recipes of sorts, although they are by no means step-by-step cooking instructions. Jean Bottéro, the Assyriologist who has studied them, considers them to be a codification of court cuisine that sets down general guidelines. Although the texts do not contain materials representative of the entire range of foods eaten by the upper stratum of society, let alone ordinary people, a few things are worth noting. The recipes include words for a variety of birds. They also contain words for meats and a method of cooking that included repeated washing of meat at different stages of food preparation. The number of plant types mentioned is relatively low, and those that have been identified appear to have been cultivated (with the possible exception of the potherbs). Finally, Mesopotamian cuisine was based on the use of sauces, which, as Bottéro points out, permitted the blending of subtle flavors unavailable with less elaborate forms of food preparation.

In earliest times, subsistence depended on wild resources available locally. The advent of agriculture brought together plants and animals from different regions and led to the creation of the Near Eastern agricultural complex of wheat and barley, pulses, sheep, goat, cattle, and pig. People of the Near East came to depend on domesticates, but wild plants and animals always constituted at least a minor portion of the diet. Advances in food preparation and storage technologies transformed agriculture into a highly productive and reasonably stable food procurement system, and effective food preservation techniques, in turn, permitted dense populations in towns and cities. Allowing for differences rooted in geography and culture, the diet and cuisine of Egyptian civilization developed along a similar path.

Egypt and North Africa

Beginning some 11,000 to 12,000 years ago, North Africa experienced a moist phase that lasted until historic times, although it was broken by several brief arid spells. During this period, summer rains produced seasonal lakes and dry grasslands, and the boundary of the Sahel shifted hundreds of kilometers north of its present location (Grove 1993). Hunter-gatherers who had been living on the margins of the Sahara began moving out onto what had been desert to subsist on wild plants, such fauna as gazelle and hare, and, in some cases, even fish (Muzzolini 1993).

By the seventh millennium B.C., these groups were growing larger and becoming more settled, as in the Near East. At Nabta Playa in southwestern Egypt, there were seasonal settlements that included storage pits, wells, and oval huts arranged in rows. Archaeological remains of plant foods indicate that the inhabitants gathered wild grasses, especially sorghum *(Sorghum)* and millet *(Pennisetum),* as well as Christ's-thorn fruits *(Zizyphus spina-christi)* and other wild fruits and seeds.

They cooked the plant foods in vessels, possibly made of hide, set in the sand of the hut floors (Wasylikowa et al. 1993). They may have also used the grinding stones that have been found in abundance at these sites to process grain. By the sixth millennium B.C., the Nabta Playa folk herded domestic cattle, sheep, and goats. The cattle were probably kept mainly for milk and blood, rather than meat (Wendorf and Schild 1984, 1994). Some scholars believe they were herded as early as 8000 B.C., but others reject this very early date (Gautier 1987; Muzzolini 1993; Wendorf and Schild 1994).

Livestock raising was gradually adopted by various groups of hunter-gathers in the Sahara and surrounding regions. Eventually pastoralism, combined with the gathering of wild plants, became a common pattern across North Africa, persisting in some areas until Roman conquerors introduced farming (Muzzolini 1993). In fact, in some regions of the desert, pastoralism and plant gathering are still practiced, although by 3,000 to 4,000 years ago, much of the Sahara had become far too arid to support any life (Grove 1993). It is believed that the African cereals, such as millet and sorghum, were domesticated in the Sahel, but little archaeological evidence of these plants has been collected (Harlan 1992). In contrast, the Egyptian Nile Valley has yielded a rich archaeological record of food and diet.

Nile Valley Hunter-Gatherers

Just off the Nile Valley in Wadi Kubbaniya, investigation of a series of 18,000-year-old camps has revealed one of the most detailed records of a hunting and gathering diet in the Old World (Wendorf and Schild 1989). Root foods from wetland plants, such as tubers, rhizomes, corms of sedges, rushes, and cattails, were dietary staples. The most important of these was purple nutgrass *(Cyperus rotundus)* (Hillman, Madeyska, and Hather 1989), which grows abundantly in wet ground and can be easily harvested with a digging stick. Young tubers are simply prepared by rubbing off the outer skin and roasting. Although older nutgrass tubers become woody and bitter with toxic alkaloids, grinding and washing renders them palatable. All of the archaeological specimens were found charred, suggesting roasting as the method for preparing young tubers. Aging tubers were probably prepared with the grinding stones found scattered across the Kubbaniyan sites (Hillman et al. 1989). Root foods were abundant through the fall and winter but became woody and eventually inedible by summer. Seeds of wetland plants helped fill the gap, but during the summer, the Nile's annual inundation restricted plant foods to wild dates and dom (or doom) palm fruits (Hillman et al. 1989).

The flood also brought catfish, the main source of animal protein for the Kubbaniyans. Catfish would have been exceptionally easy to catch at the onset of the inundation, when they spawned (Gautier and van Neer 1989). As the Nile waters moved across the floodplain, catfish would move to shallow water, where they congregated in dense masses and where they were doubtless readily taken with baskets, nets, spears, clubs, and even by hand. At the Kubbaniyan campsites, catfish were prepared for storage by drying or smoking after their heads had been removed. The vast quantities of catfish bones that littered the campsites suggest that they may have been eaten for some months after having been caught. Fish were supplemented with migratory waterfowl and small quantities of gazelle, hartebeest, and aurochs (Gautier and van Neer 1989).

The Nilotic adaptation, focused on root foods and catfish, appears to have persisted up until the beginnings of agriculture in Egypt, though the scant record of diet throughout these millennia does not provide incontrovertible evidence for either stability or change (Wetterstrom 1993). There are clues, however. Fishing gear and catfish bones are common at late hunter–gatherer sites. Fishing may have become even more important in the diet as fishing techniques apparently improved. Three fish of the deep Nile channel (Nile perch, *Bagrid,* and *Synodontes*) became common at sites after about 9,000 to 10,000 years ago (Neer 1989). The bones of aurochs, hartebeest, and gazelle indicate that they were the most abundant mammals. Occasional finds of other animals, such as hippopotamus or wild sheep, suggest rare catches.

Evidence of plant use for this period in the Nile Valley has not been collected systematically except at one site – a camp in the Fayum. Here, seeds of wetland plants were recovered, but no root foods were found, probably because preservation was poor (Wetterstrom 1993). The only other clue to the use of root foods is the fact that many sites during this period were located in ideal situations for collecting wetland tubers – next to embayments where the marshlike conditions necessary for wetland plants would have prevailed.

The Early Farmers of Egypt

The earliest traces of domestic plants and animals in Egypt are dated to roughly 5000 B.C. at a series of campsites in the Fayum Depression and in the oldest level of Merimde, a site on the western edge of the delta (Wetterstrom 1993). The Fayum data suggest that local forager groups adopted a few domestic crops and livestock but continued subsisting on wild plants and animals (Caton-Thompson and Gardiner 1934). Merimde, slightly younger than the early Fayum sites, may have been farther along in this transition. Although the settlement was probably only used seasonally, livestock bones found there are far more abundant than those of wild fauna (Driesch and Boessneck 1985). At this point, however, crops may not have supplied the bulk of the plant foods, as the facilities necessary for storing harvests were very limited (Wetterstrom 1993).

It is not clear when ancient Egyptians finally crossed the threshold from foraging to farming, shifting the balance in their diet from wild products to crops and livestock, but this appears to have occurred within a few centuries after domesticates were taken into the economy. Before 4400 B.C., Merimde had become a substantial village with abundant settlement debris and capacious storage facilities, while similar sites began to appear elsewhere, first in the north and later in the south. By 4000 to 3800 B.C., full-time farmers lived in permanent villages in the south as well as the north (Wetterstrom 1993).

The Near Eastern crop complex was the source of Egypt's first domesticates, and it formed the core of the agricultural economy through later periods (emmer wheat, six-row barley, lentils, peas, and flax, along with sheep, goats, cattle, and pigs). All of these, except perhaps cattle, probably came to Egypt from the Levant by way of the Sinai. As noted, cattle could have been independently domesticated in North Africa. The Near Eastern crops, all adapted to the Mediterranean climate, were planted in the fall after the annual flood had receded. As in the Near East, domesticated crops and livestock probably evened out the large seasonal fluctuations in the diet. Stored food may also have reduced the impact of year-to-year variations in Nile floods.

After Egyptians had become dependent on farming, they doubtless continued to supplement their diet with wild foods (Wetterstrom 1993). Fish were an important resource in many communities year-round, as were migratory waterfowl in the winter months. Larger animals, like gazelle, hippopotamus, and crocodile, occasionally show up among archaeological remains. But hunting was probably a rare adventure by this time. Where bone remains have been collected, wild fauna are extremely uncommon, as is hunting gear.

The archaeological evidence for wild plant foods is also unfortunately very limited. A small number of types have been recovered from archaeological sites, including the fruits of Christ's-thorn *(Zizyphus spina-christi),* sycamore fig *(Ficus sycamorus),* dom palm *(Hyphaene thebiaca),* and balanites *(Balanites aegyptiaca),* which has an edible oil in its seed. The small nutlike tubers of nutgrass *(Cyperus esculentus)* have been recovered from a variety of contexts: burials, inside a pot at a settlement, and from the stomach of a body mummified by the desert sands. This sedge, related to the *Cyperus* eaten at Wadi Kubbaniya, has been cultivated for its tubers since pharaonic times (Täckholm and Drar 1950). Seeds of grasses, sedges, vetches, and other wild plants have also been found at pre-Dynastic sites, although it is not clear if these were all used as foods. A variety of wild plants that do not preserve very well, if at all, were probably also gathered, including leafy vegetables and the stalk and rhizome of papyrus that we know were eaten in later periods (Täckholm and Drar 1950).

How prehistoric Egyptians prepared these foods and combined them into meals is very difficult to determine. Without the texts or representations of foods, so abundant in later periods, pre-Dynastic foodways must be inferred from a meager archaeological record. Cuts of meat – ribs, blades, legs – found in pre-Dynastic burial pots (Brunton 1928, 1937) hint at simple cooking techniques: boiling in pots or roasting over a fire. Headless remains of fish found in pots at settlements (Brunton 1928) suggest that fish were boiled after beheading. Fish may have also been smoked for storage as in earlier times, but there is no clear evidence of this.

Perhaps the easiest way to use cereals is in porridge, and this dish was probably on the early Egyptian farmer's menu. Bread is another simple way to turn grain into food. There is abundant documentation of bread in the Pharaonic Period, but for prehistoric periods, the evidence is limited to coarse loaves found in graves and settlement sites. At one site, a charred piece of bread was made of flour described as "more crushed than ground grain" (Debono 1948: 568). Though the pre-Dynastic breads seem crude, some may have been leavened with yeast, as they are porous (Brunton 1928). This would not necessarily have required any sophisticated understanding of baking techniques; a simple sourdough can easily be produced if flour and water are left to sit and collect wild yeast from the air. Fermentation could also have been readily discovered when grain and water or fruit juices were allowed to sit for a while. Egyptians certainly realized early the potential of fermentation, as attested to by traces of beer dregs found in the bottoms of vessels (Lucas and Harris 1962; Helck 1975a). Beginning around 3500 to 3400 B.C., formal brewery installations appeared at a number of sites (Geller 1989), associated with increasing economic specialization in Egypt.

Like Mesopotamia before it, Egypt, after the mid–fourth millennium B.C., was transformed from a society of simple autonomous villages into an organized, hierarchical state. In southern Egypt, burials showed marked differences in wealth and status among different groups, as well as individuals (Trigger 1983, Bard 1994). Large centers with temple and palace complexes and industrial and residential areas began to appear in southern Egypt. By around 3100 B.C., a centralized state had emerged with domain over the whole Nile Valley from the delta south to the First Cataract near Aswan (Bard 1994).

Pharaonic Egypt

The Pharaonic Period in Egypt, which spanned nearly 3,000 years, was an extraordinarily stable, conservative era (Map V.A.1.). From the beginning, a strong centralized government ruled Egypt as a single polity. The reign of the pharaohs was disrupted only three times when the power of that government broke down as a result of civil war or foreign invasion. Following these three so-called "intermediate" periods between the Old, Middle, and New Kingdoms and the Late Period, the central government was reestablished (Table V.A.2).

Like early Mesopotamian civilization, pharaonic Egypt had a complex economic and social organization. People were divided by wealth, class, and occupation. Whereas the pharaoh, a divine king, presided at the top of the hierarchy, most of the people belonged to the lowest classes, working in myriad trades and as farmers and laborers (O'Connor 1983). In theory, the pharaoh owned all of Egypt; in practice, much of the land was held by the crown, but there were also large private estates. Crown-land harvests and taxes in kind from private lands supported the state bureaucracy, the military, and the conscripted laborers. Some land was also held as trusts, which supplied food to mortuary cults and temples (O'Connor 1983; Trigger 1983).

Pharaonic foods and diet are documented by a wealth of sources. These include artistic depictions in tombs, food offerings and offering lists in tombs and temples, tomb models, texts, and archaeological remains (Helck 1975b). Artistic depictions of everyday life, including food preparation, are common in Old and Middle Kingdom tombs, but less common in those of the New Kingdom. They are a rich source of information but can be difficult to interpret, as Egyptians tended to use a highly standardized iconography (Weeks 1979; Samuel 1989, 1993a, 1993b, 1994). Tomb models, most frequent in Middle Kingdom contexts, pose some of the same problems. Offerings and offering lists present a selective set of foods, the significance of which may elude present-day observers (Weeks 1979). Texts dealing with economic matters are abundant for the New Kingdom but less common for earlier periods. In addition, many words in the texts, including names of foods, are not yet understood (Janssen 1975).

Popular tales from the Middle and New Kingdoms offer clues to diet, but they are limited in scope. Archaeological data provide actual evidence of foods, allowing proper taxonomic identification in many cases, and may be useful in refining insights gained from textual sources and representations in tombs. Unfortunately, for the Pharaonic Period most archaeological material comes from tomb and temple contexts, with very little recovered from settlements. Other kinds of archaeological evidence, such as ovens, bakeries, and hearths, indicate something of food processing and preparation, but the precise ways in which they were used is not always apparent. Recently, archaeologists have tried to test insights and theories gained from tomb depictions and other evidence by experimenting with baking, milling, and brewing techniques (Samuel 1989, 1993a, 1993b, 1994; Lehner 1994, 1997).

What emerges from the assorted lines of evidence is that all members of Egyptian society shared the same basic foods, with the upper strata having access to larger quantities and greater variety. At the core of the ancient Egyptian diet were bread and beer, consumed as staples by pharaoh and peasant alike throughout pharaonic history. Indeed, bread and beer were the basic wages, along with oils, grain, and clothing, paid to workmen on public and private projects (Eyre 1987). They were also the foods mentioned most often in popular tales, such as in the Middle Kingdom "Tale of the Eloquent Peasant" (Darby, Ghalioungui, and Grivetti 1977). As the hero set out on a trip, he commanded his wife, "[Y]ou shall make for me the six measures of barley into bread and beer for every day on which [I shall be traveling]" (Simpson 1973: 31).

Bread and beer were also fit for a king, however. An economic text from the Thirteenth Dynasty recorded a daily delivery of 1,630 loaves and 130 jugs of beer to the king's court (Scharff 1922). Bread and beer were also delivered to the temples every day and were viewed as essentials for the afterlife. The elite placed offerings of bread and beer in their tombs and enumerated them on offering lists. For example, Pharaoh Tutankhamen's tomb was stocked with bread (Hepper 1990).

Bread was produced in modest village kitchens (Janssen 1975) and in the large "commissaries" of elite households, the court, temples, and civic projects (Helck 1975b; Samuel 1993a, 1993b). Whereas the village breads that have been recovered are simple round loaves baked in an oven (Darby et al. 1977), professional bakers used a variety of techniques. Ceramic molds, which first appeared in late pre-Dynastic times, were commonly employed in the Old and Middle Kingdoms to bake offering breads and probably also rations for workmen (Jacquet-Gordon 1981; Lehner 1994). These coarse, thick-walled molds, shaped like flowerpots, were used as a kind of portable oven for baking in open pits (Lehner 1994). By the time of the New Kingdom, molded breads appear to have been made for special purposes and were baked in ovens in long, narrow, cylindrical molds (Samuel 1989, 1993b).

In addition to the mold-made loaves, a wide assortment of other breads and cakes were prepared for the temple and for the elite, employing a variety of techniques, temperatures, and grains (Drenkhahn 1975; Wild 1975; Samuel 1994). This was especially true during the New Kingdom, when loaf shapes proliferated; tomb art depicts spirals, cows, human figures, and other fanciful forms (Wreszinski 1926). Forty different kinds of breads and cakes were known at this time, compared to about a dozen in the Old Kingdom (Wild 1975). Emmer flour appears to have been the main ingredient in Egyptian bread, but other ingredients were also used (Grüss 1932; Täckholm, Täckholm, and Drar 1941), such as barley flour, ground nutgrass *(Cyperus esculentus)* tubers (Wilson 1988b), and sprouted wheat, which gave bread a slightly sweet flavor (Samuel 1994). Bakers sometimes added honey, dates, figs, and other fruits (Wilson 1988a; Samuel 1993a). For example, bread found in Tutankhamen's tomb was flavored with Christ's-thorn fruits (Hepper 1990).

Like bread, beer was brewed in modest households and in commissaries. Little is known of home-brewed beer, but breweries are frequently depicted in tomb scenes and models (Montet 1925). Archaeological traces of them have been found at a number of sites, as have vats and jars with beer residues (Lutz 1922; Lucas and Harris 1962; Helck 1975a; Geller 1992a, 1992b). The brewing process carried on at these ancient breweries, however, has not been well understood (Nims 1958; Geller 1992a; Samuel 1993a). The depictions are often ambiguous and the texts accompanying them subject to various interpretations because of difficulties in translating the language.

Delwen Samuel (1996) sidestepped these problems by turning to the direct evidence of brewing – ancient beer dregs and brewing by-products from the New Kingdom. Using scanning electron microscopy, she examined the microscopic structure of the starch granules in the residues and determined the processes they were subject to while being transformed into beer. It appears that Egyptians prepared grains intended for brewing in several different ways. After the grain was malted, or sprouted, some of the moist malt was heated while the rest was dried gently. The latter would have provided active enzymes for breaking down starch granules into simple sugars, which would support the yeast or lactic acid that is essential for producing alcohol. The roasted malted grains would have imparted a pleasant flavor and yielded a gelatinized starch that would be particularly susceptible to enzymatic attack. In addition, unsprouted, cooked grains may also have been used to make some beers. A large variety of named beers may have been produced by using different kilning and cooking techniques to prepare malted or unsprouted grains prior to brewing (Samuel 1996).

Both emmer and barley were used for beer in institutional breweries (Samuel 1996). In modest households, though, barley seems to have been the choice for brewing; as suggested in the "Tale of the Eloquent Peasant" and the evidence at Deir el-Medineh, a New Kingdom artisans' village, beer was brewed from barley rations (Lucas and Harris 1962; Janssen 1975). Bread, which has long been regarded as an essential ingredient of Egyptian brewing (Faltings 1991), played no role in these beers, according to the evidence that Samuel examined. As for flavorings in ancient Egyptian beer, there is little substantial evidence (Samuel 1996), although dates have often been propounded as a basic ingredient (Faltings 1991). As for Old Kingdom brewing techniques, Samuel's findings for the New Kingdom may well apply. No comparable studies have been conducted on beer dregs of the former period, and the archaeological evidence poses the ambiguities noted.

While bread and beer were basic subsistence to ancient Egyptians, vegetables and fruits were apparently regarded as above the level of basic needs. They were sometimes distributed as wages but were also depicted in market scenes, indicating that they could have been acquired through barter (Eyre 1994). The lower classes probably saw only the most common fruits and vegetables. The high labor costs of watering fruits and vegetables would have put many of them out of the reach of the poor (Eyre 1994). For the elite, on the other hand, "a variety and abundance of fresh produce was the mark of a luxury diet, emphasized by the elaboration of the fruits and vegetables recorded as offerings on the walls of tombs and temples" (Eyre 1994: 73).

Common vegetables in ancient Egypt included lettuce, leeks, onions, garlic, cucumbers, and radishes (Helck 1975b). Other names are listed in texts, but they have not yet been translated (Janssen 1975). How vegetables were prepared is not clear; they are shown as fresh produce in temple and tomb depictions. For lower classes, vegetables probably served mainly as condiments, as suggested by a New Kingdom tomb scene in which a workmen eats a lunch of bread, cucumber, and onion (Wilson 1988a).

The lower classes may have also supplemented their diet with wild plants. A host of weedy plants found in the fields and gardens, such as amaranth, chenopod, knotweed, sheep's sorrel, and wild grasses, could have been used as potherbs and grains. Their seeds have been found in settlement sites, such as Kom el-Hisn, an Old Kingdom community in the delta (Moens and Wetterstrom 1988), and Kom Rabi'a, a Middle and New Kingdom artisans' village at Memphis (Murray 1993), but it is not known for certain that these were actually consumed; many probably arrived at settlements as contaminants of cereal harvests. Still, many of these herbs have edible greens and/or seeds, which, ethnographic accounts indicate, have been used by others as foods (Fernald and Kinsey 1958; Nicolaisen 1963; Goodman and Hobbs 1988; Harlan 1989; Facciola 1990).

A number of fruits were known in ancient Egypt. Starting in the Old Kingdom with a short list – sycamore fig, dom palm, balanites, date, Christ's-thorn, and grape – the assortment grew as new types were introduced. Early additions were the true fig *(Ficus carica),* melon *(Cucumis melo),* persea, and a small watermelon *(Citrullus lunatus)* cultivated for its seeds (Germer 1985). Later, cordia *(Cordia myxa),* pomegranate, and olive were adopted. During the

New Kingdom, exotic tropical fruits, such as grewia *(Grewia tenex),* were imported, as were pinenuts and almonds (Hepper 1990).

For peasants, the most important fruits were probably those that grew in Egypt with little or no care, such as Christ's-thorn, sycamore fig, and dom palm, as they would have been relatively cheap. Pomegranate, grape, and olive, on the other hand, all require tending and watering and were probably the prerogative of the elite. In tomb paintings and reliefs, fruits were usually displayed in large, overflowing baskets, perhaps to be consumed fresh, but fruits were also enjoyed dried, or cooked, and used as ingredients in other dishes. At Saqqara, a funerary meal laid out in a Second Dynasty tomb belonging to an elderly woman included plain Christ's-thorn berries placed on a plate and figs (probably *Ficus sycamorus*) prepared as a stew (Emery 1962). Fruits, particularly grapes, were also used to prepare wines imbibed by the elite (Janssen 1975). Wine production, which required substantial labor and skill, took place primarily in the delta and oases. But wine was also imported from Palestine, starting, perhaps, as early as pre-Dynastic times (Stager 1992). Often listed as an offering, wine was frequently depicted in New Kingdom funerary banquet scenes and was included in the funerary meal at Saqqara just discussed (Emery 1962).

Animal products were highly valued in the ancient Egyptian diet and together constituted the third most frequently mentioned food item in popular tales, after bread and beer (Darby et al. 1977). But they were not considered basic for subsistence, as indicated by the fact that meat was not given as rations. Market scenes in tombs show peasants buying pieces of meat through barter (Harpur 1987). For the well-to-do, meat figures prominently in tomb scenes, offering lists, and actual food offerings in tombs. The Saqqara funerary meal included four plates of meat out of a total of twelve dishes (Emery 1962).

Cattle were the most highly valued livestock in ancient Egypt, serving as draft animals and sacrificial beasts, as well as a source of food. Associated with the bovine deity Hathor (a mother goddess), they were considered sacred. Costly to raise, cattle were the premier choice for sacrifice at temples and tombs. Countless tomb paintings and reliefs show scenes of cattle husbandry, sacrificial processions, and the sacrifice of young, well-fed oxen. Beef consumption was almost certainly a prerogative of the elite, and the priests who butchered the cattle may have eaten the largest share (Darby et al. 1977). At the pyramid complex of Giza, for example, cattle bones from animals under two years of age predominate among the faunal remains (Redding 1992). The "middle classes," however, were not entirely excluded from enjoying beef. At Deir el-Medineh, cattle were delivered for feast days and periodically at other times for butchering, providing an occasional, but not rare, treat for the king's artisans (Janssen 1975).

For the lowest classes, beef was probably an extremely rare luxury. At Kom el-Hisn, for example, there is almost no bovine bone among the abundant faunal remains, although cattle were raised there (Moens and Wetterstrom 1988; Wenke 1990; Redding 1992). Kom el-Hisn peasants consumed only the occasional elderly or very young animal that died of natural causes, although they raised cattle destined for sacrifice at major ceremonial centers, such as the pyramid complex at Giza (Redding 1992).

Small livestock (sheep, goat, and pig) were more important sources of protein for lower classes. Bones of sheep and goats are common at settlement sites (Redding 1992). At Kom el-Hisn, peasants may have maintained their own small flocks while raising sacrificial cattle (Redding 1992). Pig remains are even more abundant at Kom el-Hisn and other settlement sites, such as the workmen's village at Amarna (Hecker 1982). Richard W. Redding (1991) proposes that peasants in rural areas raised small numbers of pigs for their own consumption, particularly in marginal regions where grain agriculture was not important.

Small livestock apparently played a minor role in the diet of the well-to-do. Large herds of sheep and goat were kept primarily for wool, hair, and milk. They were seldom depicted as sacrificial animals or placed in tombs as offerings. On the other hand, the Saqqara funerary repast did include a pair of kidneys from a small domestic animal (Emery 1962), and texts indicate that goats were occasionally sacrificed for certain festivals (Darby et al. 1977).

Relatively little is known about how meat was prepared, but food offerings placed in tombs during the Old Kingdom provide clues. Ribs and legs of beef found in the Saqqara funerary meal were most likely boiled or roasted. A dish that could not be identified (perhaps a stew) included ribs of beef among its ingredients (Emery 1962). A kitchen scene from a Fifth Dynasty tomb shows a cook cutting chunks of ox meat into pieces that were placed in a large cauldron. The hieroglyphic label underneath reads "cooking meat" (Hayes 1953: 97). Texts and a few tomb scenes indicate that beef was roasted as well (Darby et al. 1977).

While domestic livestock played an important role in ancient Egyptian life, the major sources of animal protein for rich and poor appear to have been fish and wild fowl. Both were abundant, and because little investment was required to produce them, they were probably inexpensive, compared with domestic animals. Texts from Deir el-Medineh indicate that they were very cheap at the time (Nineteenth Dynasty), with fish nearly as cheap as bread and beer (Janssen 1975). Fish are often shown in market scenes being purchased by barter (Eyre 1987). At Deir el-Medineh, fish were apparently a major source of protein, because they were distributed as rations (Janssen 1975). At Kom Rabi'a, abundant fish bones suggest that fish were an important source of food there as well (Ghaleb 1993).

As virtually the entire population lived close to the Nile waters, nearly everyone would have had some access to fish, at least during the flood season.

Poor Egyptians would, likewise, have had access to waterfowl during the winter migration. Fish and fowl were also common foods of the elite, who included them in tomb offerings and, particularly during the Old Kingdom, depicted fishing and fowling on their tomb walls (Montet 1925; Harpur 1987). Tomb scenes of food preparation indicate that fish were usually sun dried, pickled, or salted, whereas fowl was commonly roasted on a spit (Montet 1925). Wild fowl were also kept and fattened for consumption. The funerary meal from the Saqqara tomb included a cooked fish, cleaned, dressed, and beheaded, as well as a pigeon "stew" (Emery 1962).

Wild mammals were another potential source of meat, but hunting, already on the decline during the pre-Dynastic Period, had become an insignificant source of food by Old Kingdom times. At settlement sites, bones of wild mammals are rare; at Kom el-Hisn, for example, gazelle and hartebeest accounted for only 3 percent of the total faunal remains (Wenke 1990).

The traditional "poor man's meat" – pulses – were probably eaten by most of the people of ancient Egypt, although there is scant documentation. Pulses do not appear as tomb offerings or art, nor are they mentioned with any frequency in texts. But there are scattered archaeological finds, hinting at their importance. Lentils, for example, occur frequently in Tutankhamen's tomb as a contaminant of baskets of food offerings, suggesting that they were a common crop in ancient Egypt (Vartavan 1990, 1993). At Giza, lentils were found in trash left by workmen (Wetterstrom unpublished data). In Zoser's Third Dynasty tomb at Saqqara, lentils occurred in straw fill (Lauer, Täckholm, and Åberg 1950). They are also common in Middle and New Kingdom deposits at Kom Rabi'a (Murray 1993).

Records of other pulses in Egypt are few (scattered reports of lupine and fava beans [see, for example, Germer 1988]). Peas occasionally appear in archaeological contexts, such as Kom el-Hisn (Moens and Wetterstrom 1988). Chickpeas were apparently introduced in New Kingdom times; a few occurred in Tutankhamen's tomb as contaminants (Vartavan 1990, 1993). They are mentioned in texts from the Eighteenth Dynasty on but do not occur as offerings.

Dietary oil was considered an essential food, as indicated by the fact that it was among the rations allotted. Flaxseeds, castor beans, moringa nuts *(Moringa aptera),* olives, and, in later periods, sesame and safflower were all sources of oil (Germer 1985). Sesame seeds occur as offerings in Tutankhamen's tomb (Vartavan 1990), but they were not restricted to the elite; at Deir el-Medineh, artisans were given rations of sesame oil (Janssen 1975). In contrast, olive oil, most of which was imported from Palestine beginning in pre-Dynastic times (Stager 1992), was food for the elite.

The first cultivated spice found in Egypt is fenugreek, dated to 3000 B.C. (Renfrew 1973). From the New Kingdom on, and perhaps earlier, a wider range of seasonings was available in Egypt. In Tutankhamen's tomb, black cumin *(Nigella sativa)* and coriander occurred frequently as contaminants among baskets of foods, suggesting that they were grown widely and, therefore, were popular condiments (Vartavan 1990). Dill and cumin were also known in New Kingdom Egypt (Germer 1985). How these seasonings were used is not known, as recipe texts from ancient Egypt have yet to be found.

Honey and fruits were the only sweeteners known in ancient Egypt. In the Old Kingdom, honey, a scarce and costly resource, was under Pharaoh's control. Still expensive by the Middle Kingdom, honey was a frequent offering in private tombs and was employed extensively in temple rituals (Kueny 1950). It is unlikely that lower classes ever saw honey, relying instead on fruits and fruit juices as sweeteners. Sweetened breads and flavored beers, however, were probably a rare treat among the poorest classes.

During the 3,000 years of pharaonic history, it appears that the diet changed slowly, showing great conservatism and stability, like other aspects of Egyptian culture. The most visible changes relate to the introduction of new crops, new technologies, and new imports. Although the core of the agricultural system remained unchanged, with emmer wheat and barley the dominant crops, improvements in water management made it possible to grow fruits and vegetables in orchards and plantations (Eyre 1994) and, probably, to raise many of the new introductions, such as olives. While bread and beer retained their place as staples, baking and brewing technologies became more sophisticated.

Changes in the diet and the rewards of new technologies were probably not universally experienced. Initially, the diets of rich and poor were likely not vastly different. The elite would have had access to greater quantities of food, particularly meat, and sole access to a few costly goods, such as wine and olive oil. The elite may also have eschewed some low-status foods, such as pulses. But by New Kingdom times, and perhaps earlier, the gulf between rich and poor diets may have expanded into a chasm. The upper classes, undoubtedly, had greater access, and in some cases exclusive access, to new crops and imports, such as pine nuts, almonds, and pomegranates. In addition, tomb art and textual evidence suggest an elaboration of cooking techniques among the well-to-do during the New Kingdom.

Conclusion

In this chapter we have traced the history of food and diet over a heterogeneous territory and through a long time period that extended from the end of the Stone Age to the first civilizations. This era saw what are arguably the most significant changes ever to occur in the human diet, establishing the food patterns that still sustain people today.

With the adoption of farming and herding, peoples in the Near East and Egypt abandoned their diverse hunting-gathering diet and came to rely on the Near Eastern complex of domesticated plants and animals. After the shift to agriculture, both areas followed similar cultural trajectories, which involved the development of larger and more complex communities and, eventually, the emergence of civilizations. In both regions, improvements in food production and food storage technologies led to surplus accumulation and permitted the growth of large, dense populations and urban centers.

With the advent of complex society, people no longer had equal access to all types of food. An elite class ultimately controlled the production and distribution of much of the food supply. Some foods even became their sole prerogative, particularly exotic imports and those requiring extensive labor to produce. Most of the population, however, subsisted mainly on grain and grain products as earned wages in kind. In both Egypt and the Near East, the diet was based on plants, primarily cereal products like bread and beer, supplemented with vegetables, fish, and meat. For the lower classes, meat was probably a rare commodity except for the pigs that households could raise without interference from state authorities. Yet, although Egypt and the Near East followed similar social trajectories and shared the same core diet, they developed their own distinctive cuisines. Today much of the world shares that same core diet based on the Near Eastern domesticates, and variations on it are still developing.

The History and Culture of Food and Drink in Asia

V.B.1 ∾ The Middle East and South Asia

Although the regions we call the Middle East and South Asia constitute a very wide area, their collective culture has been shaped by a shared history from the conquest of Alexander the Great to the Islamic empires. The precepts of Islam have been adopted in most of the countries in the area under scrutiny, if not always by the majority, as in India. There are, therefore, many similarities in their cultures and especially in their preparation of foods. Each country, region, and town has its own cooking traditions, but it is easy to spy the similarities behind the differences.

This region of the world is socially traditional; therefore, women stay at home most of the time and are in charge of the kitchen. Food is often prepared in the company of other women in Muslim houses, which makes it a time for socializing. Professional cooks (always male) are employed for special occasions in wealthier homes.

The cooking is done mostly on a stove. The process is very long and slow, resulting in a very tender meat or vegetable, literally ready to disintegrate. The people of the Middle East and South Asia have no liking for red meat (even pieces of meat or kebabs for roasting are cooked previously or at least marinated).

Food is almost never cooked in water alone. Rather, it is first fried, then simmered or boiled, and finally enriched with fat. There is also a wide consumption of street food, fried or grilled. Savory pastries, such as *borek, samossa,* and *brik,* are popular.

Meat is an important item of the diet for those (except for the vegetarians) who can afford it, and it is used as often as possible, even as part of a stuffing or in a broth. Lamb is the favorite meat, although the less expensive chicken dominates in poorer houses. Because of the Islamic influence, pork is avoided, except by minorities, such as the Goanese Christians, for example.

The cookery is also characterized by the use of many pulses, clarified butter (*samn* or *ghee,* mainly from buffalo's milk), and fresh yoghurt (as a drink and a cooking liquid). Unlike in the Far East, milk, milk products, and milk sweets are important here, and all the people of the region rely on a basic cereal, mostly rice or wheat. Food is very colorful as well as flavorful because of the use of such spices as saffron and turmeric. Spices are used extensively, even if only in small quantities. There is a spice street in every bazaar in the Middle East and South Asia. All the countries of the region are on the same spice route, which begins in Asia, with the Middle East a conduit for spices on the way to Africa and Europe.

Scents are also typical of this exotic cookery: Rose, amber, musk, camphor, santal, orange blossom, jasmine, and orchid are used in many a sherbet and dish. People share a fondness for sour things: Lemon or lime, vinegar, tamarind, sumac, pomegranate juice, and sour cherries add zest to meat dishes.

Spices are also used for their assumed medicinal properties, and the composition and preparation of foods is often explained in terms of health needs created by climatic conditions. In fact, another similarity between the cultures of South Asia and the Middle East is a belief in medico-magic properties of food. This, in turn, encourages secrecy in cooking, and the preparation of aphrodisiacs and other potions at times tends to blur the tasks of cook and alchemist.

The History and Culture of Food in the Middle East

The Middle East encompasses a large area stretching from the Arabian Peninsula to Afghanistan and includes the border states of the eastern Mediterranean. It is divided into many countries: Turkey, Syria, Lebanon, Jordan, Israel, Egypt, Saudi Arabia, Iraq, and Iran. The people of the Middle East are of several racial types and have embraced different religions. Geographic and climatic conditions are extremely diverse in the region. Nonetheless, the Middle East can be described as a single cultural entity. Islam has played a unifying role in the area through the building of vast "Islamic" empires that rule over most of these people and the conversion of a vast majority of the population.

There is, therefore, a Middle Eastern civilization with a collection of several culinary traditions, each of which will be given due attention (although the food of the minorities of the region, Coptic, for example, or the cosmopolitan cuisine of Israel will be ignored for the sake of coherence). Overriding similarities in tastes and manners, however, will also be pointed out.

Before the Arrival of Islam

Long before dwellers in Europe could imagine the possibilities of fire, the civilizations of the Middle East had invented agriculture, cattle breeding, and numerous ways of preparing and enjoying foods.

Pre-Islamic Arabia. The diet of pre-Islamic Arabia was the typical diet of a pastoral people in a desert region. It was simple and monotonous, with the most important roles played by dairy foods. According to ancient poems and the *Koran,* milk, milk products, and dates were the main items of the diet. Camel milk was most frequently used, but goat and sheep milk were also available. The milk could be diluted with water and was used in the preparation of a sort of cheese and of clarified butter *(samn)* for cooking.

The oases provided the nomads with dates, which were sometimes the only food available. Dates supplied energy, were easy to carry, and, over time, acquired a symbolic value. They were served at festivals, and the Prophet Mohammed later stressed their importance by making them one of his favorite foods, especially for the breaking of fasts.

Meat was seldom eaten, except for festive occasions, when sheep were frequently consumed and especially appreciated for their fatty tails. Camels, sometimes slaughtered and their coagulated blood shaped into sausages to be cooked, were another source of animal protein. Beef, pork, or fowl were quite unknown. Hare, bustard, large lizards, and grasshoppers could become food in harsh environments.

Cereals were scarce. The Prophet ate cakes of coarse barley with a little vinegar, oil, and perhaps a few dates. Dried barley was also made into a meal that was easily cooked into a gruel with the addition of water and fat. Another type of gruel *(harira)* was prepared from flour cooked in milk. A richer gruel could be made with bran and meat.

A number of vegetables were also available throughout the settled communities of the desert. Cucumbers, vegetable marrows, beets, chicory, and olives were common, as well as leeks, onions, and garlic. Lemons, pomegranates, and grapes or raisins were the main fruits, although figs and apples are mentioned in some texts. By combining all these products, the Arabs could prepare a few elaborate dishes. *Tharid* was one: bread pieces soaked in a meat and vegetable broth. *Hayes* was another. Made of milk, butter, and dates, it is said to have been another favorite of the Prophet. These dishes and the more common broths were quite bland. The nomads preferred to sell the spices they had rather than use them themselves. Imported wine was a luxury, but the Arabs were familiar with fermented drinks, prepared from dates, barley, honey, or raisins.

Pharaonic Egypt. Thanks to numerous archeological remains, it is possible to imagine how the kings and people of ancient Egypt would dine. Cattle and sheep were slaughtered in the palace and then might be roasted whole or grilled in pieces. Lamb chops were a delicacy, and fowl was also served, as were different types of bread and pastries. The food was seasoned with cream and, perhaps, imported olives from Greece. Lentils and fish constituted a simpler diet, and beverages consisted of beer, milk, and wine. Beer was prepared from the fermentation of barley, wheat, and dates. The country was so rich in wheat that during its Roman period (30 B.C. to A.D. 395) it became the empire's granary.

Ancient Mesopotamia. It was in ancient Mesopotamia that agriculture and cattle breeding were invented, and we can infer much about the diet of these early inventors from that of the people living in the region today. The staple food for this population of agriculturists was bread made of barley rather than wheat. Barley was often eaten in the form of gruel as well.

The banks of the Mediterranean are famous for their olives and grapes. The whole of the region that was once ancient Mesopotamia is very fertile: Cucumbers, turnips, onions, leeks, fennels, herbs, lentils, and chickpeas are among the vegetables grown. Many types of fruit can also be found, most importantly, dates, figs, and pomegranates. Fish is sometimes served, but meat is scarce. In the past, a sheep or goat was occasionally slaughtered for sacrifice or in honor of a guest. But as a rule, beef and pork, along with fowls and pigeons, were rarely eaten. Apart from pulses, most of the protein came from eggs, milk, and milk products, which included curd and cheese. Honey was and is a common treat. Olive and sesame oils are abundant. The common beverages were water, milk, or beer. The rich, however, enjoyed palm or grape wine.

Cooking was done on a stove. For the poor this consisted (and still consists) of a simple cavity, dug in the ground of a house or courtyard, and coated with clay in which embers were piled. These hearths are sometimes built in raised fashion along a wall, and some are ovens entirely of clay.

The arrangement of ovens designed for the baking of the bread is quite complex. They are built in the shape of beehives, with a side opening to introduce the embers. The bread cakes are placed against the hot walls inside and cook very quickly. These ovens are located in a courtyard or in empty ground between houses, where the meal is usually prepared by grinding grain with hand millstones made out of a long, flat stone and a pestle, or by pounding meal in three-legged stone mortars.

General Features of Food in the Middle East

The Imprint of Islam

In pre-Islamic Arabia, there were few prohibitions on food, although certain holy families did not eat meat, and each tribe had customs that might prohibit the eating of a certain part of an animal. Wine was drunk quite often and sometimes ritually. But, even before the time of the Prophet, certain Arabs had been influenced by Judaism and Christianity. Thus, they abstained from eating animals not ritually slaughtered or those sacrificed to idols and, perhaps, refrained from drinking alcohol. The Prophet, however, established what was lawful *(halal)* and unlawful *(haram)* to eat. Prohibitions in some instances included blood, the flesh of an animal that had died, or that of an animal not properly slaughtered. In addition, pork was proscribed, along with a few marginal animals that were snakelike in appearance or wild.

Mohammed insisted that the restrictions for his people were not as excessive as they were for Jews. He also stressed that food should be regarded as a divine blessing and, therefore, thoroughly appreciated. The Koran at first praised the virtue of wine but soon showed reservations about it and, finally, forbade it. In addition to these rules, Islam decreed a periodic general fast during the month of Ramadan.

Middle Eastern Table Manners

Food is traditionally eaten with three fingers of the right hand, from dishes or trays that can be shared by four to eight people. The thumb, index and middle fingers are used to pick up the food. It is polite to take the piece of food nearest to you in the serving dish. Pieces of meat or vegetables are usually taken with the help of a piece of bread, and fingers are licked after the meal.

The "table" is laid in a simple manner: Cloth is spread on the floor, or a large tray is placed on a low stool to form a table. Today, people sit cross-legged around these arrangements, although Pierre Belon, a sixteenth-century observer, noted that Arabs rested on their heels while eating and Turks sat on the floor. Dishes for those dining are displayed in front of them, usually all at the same time. If there is dessert, it is brought after the meal, and coffee follows in many Middle Eastern countries. Hands are washed with the help of a basin and a flask and dried on towels before and after meals.

The meals are inaugurated in Islam with an invocation of God. Islam dislikes the mixing of the sexes, and so in traditional homes, women and men usually eat apart. Everyone stops eating at the same time, and it is polite to nibble until your neighbors are finished. The choicest parts are offered to special guests. A host can also honor a guest by offering him a good morsel from his hand. There is a strong sense of hospitality, and the expected, or unexpected, guest will always be offered something to drink and eat.

Basic Ingredients and Cooking Techniques

Much of the Middle East is desert, with only about 10 percent of the land useful for cultivation. As a consequence, the common diet can be quite monotonous. Chickpeas and lentils have been part of Middle Eastern cuisine for thousands of years, along with a number of vegetables and fruits. The aubergine (eggplant), for example, is omnipresent on Middle Eastern tables. The Turks claim they know more than 40 ways of preparing this vegetable. It can be smoked, roasted, fried, or mashed for a "poor man's caviar." According to a Middle Eastern saying, to dream of three aubergines is a sign of happiness.

Because of the shortage of pasture land, sheep, goats, and chickens are the main animals raised. Pork is not eaten by Muslims and, generally, beef is not much appreciated. Animals are slaughtered by Muslim ritual; the throat is slit quickly, cutting through the trachea and the esophagus. Thus, the animal does not suffer. At the moment of cutting, the name of God is invoked. Ideally, the animal will have its left side facing Mecca at the moment of death.

Barley has become increasingly neglected in favor of wheat and rice. Wheat is used as flour in many leavened and unleavened breads. So too is ***burghul*** or cracked wheat, a preparation in which the whole grains are partially cooked, then dried and cracked. Three sizes of burghul are available, medium and large grains found in pilafs and stuffings, and a fine variety that is preferred for salads and ***kibbeh.*** Medium and large grains must be soaked before use.

Rice arrived in the Middle East later than wheat and is used mainly by urban populations, whereas wheat is the staple food of the countryside. Many types of rice are available, with the best and longest grains coming from Iran. It is prepared differently in every region, although rice is soaked everywhere. In Syria, it is boiled for 2 minutes in the same water it was soaked in, then simmered for 20 minutes until the water is absorbed. Melted butter is poured on it and the rice left to stand for a few minutes before eating. In Lebanon, water and butter are boiled together. In Egypt, the rice is fried in fat, then simmered. Iranians claim to have the best method of cooking rice: They parboil for 6 to 8 minutes, then steam with butter in a sealed dish. The rice is fluffy and flavorful, with a golden crust at the bottom of the pan.

Milk is widely used, especially in the form of thin or thick yoghurt. It is also churned into clarified butter *(samn).* Other cooking oils are derived from olives, cottonseeds, nuts, corn and sesame seeds. Olive oil is often associated with fish and salad dishes. A very sought-after delicacy is the rendered fat of sheep tails.

Because the region has long been involved in spice trading, some spices, mostly of Indian origin, are part of the diet. These include turmeric, cumin, coriander, and cinnamon. If they can be afforded, nuts are widely used in cooking (walnuts in Iran and pine nuts in Lebanon, for example). A few exotic items in a Middle Eastern pantry are *sumac,* a red spice with a sour lemony flavor that is the powder of dried, round berries and gives color and taste to many dishes (in Iran it is sprinkled on rice or kebabs); *tahina,* which is sesame seed paste; and *mahlab,* the powder of black cherry stones. Rose and orange blossom water, mastic, and powdered orchid root are also used, but more rarely.

Traditional cooking is done on a stove or *fatayel,* with bread usually baked by a professional. Moreover, in the past, the baker's oven also served as a public oven. Families sent their pans or dishes to be placed in the oven for very slow cooking. Today domestic ovens play this role most of the time. Middle Eastern cooking is a painstaking and slow process, made possible on an everyday basis because most women of the Middle East spend the day at home. For this reason, these women are able to carry on cooking traditions and people remain very much attached to the dishes of the past.

There is a considerable pride of craftsmanship that goes into Middle Eastern cookery. Miniature foods (like miniature paintings) are favorites, stuffings can be incredibly elaborate, and mock dishes are sometimes invented to puzzle the guests. Pastries are elaborate and reflect craftsmanship, as do the numerous finger foods, such as small pizzas, stuffed grape leaves, fried meat balls with delicate moist fillings, and confections that are jewel-like.

Coffee was first popular in Yemen and Saudi Arabia, then spread throughout the region. There is no ceremony, no bargaining, nor any counseling session without coffee. Cups are small and made of different materials, which vary from country to country. The sugar is usually boiled together with the coffee in water (although Egyptians like their coffee unsweetened). When the water boils, sugar and coffee are thrown into the pot. The beverage is stirred, simmered briefly, then poured, still frothy, into cups. In Lebanon, coffee is often flavored with orange blossom water.

Other Middle Eastern favorites are pickled vegetables or fruit (raw or lightly cooked and soaked in a salt-and-vinegar marinade) and fruit syrups (sherbet) of many kinds: orange, rose water, quince, apricot, and tamarind (in Egypt). A meat and wheat soup is usually served, especially for celebrations. Meat is often minced or hand pounded before cooking. If not, it is cubed, or at least cooked so as to be easily torn to pieces, because it is eaten with the fingers. A typical salad dressing in the Middle East is a simple mixture of olive oil and lemon juice, seasoned with salt, pepper, garlic, and herbs.

The dietary similarities of Middle Eastern countries reflect the long unification and acculturation process under Arab, "Islamic," and Ottoman domination. Under the Abbassids, for example (ninth to twelfth century), during the Golden Age of Islam, there was one single empire from Afghanistan to Spain and the North of Arabia. The size of the empire allowed many foods to spread throughout the Middle East. From India, rice went to Syria, Iraq, and Iran, and eventually, it became known and cultivated all the way to Spain. The use of sugar was common among wealthy people, along with spices from Asia, coffee from Arabia, olive oil from Syria, cheese from Crete, saffron from Tuscany, and even wine from the south of France. Dried and salted fish, honey, and hazelnuts also reached the Middle East from Russia and the Slavic countries.

To keep the products from deteriorating in transit, different techniques were used. Melons from Transoxiana were packed in ice inside lead boxes before they were sent to Baghdad. Nuts and desert truffles were dried. The crystallizing of fruit in honey or sugar, an old process developed in ancient Rome, was also employed, and milk was often preserved in the form of cheese.

Cooks also traveled; those from Egypt and Bolu, in Turkey, were the most famous and in the most demand. In addition, recipes spread, making Iranian and, later on, Turkish dishes fashionable. The culinary arts were considerably elevated early on under the Caliph Hârûn-al-Rashîd (786–801). The gastronomy of the time is depicted in poetry, as well as in medical treatises on food hygiene. The caliphs of Baghdad were renowned for their lavish and sophisticated tables. The rulers liked to converse about food and encouraged people to write about it and experiment with it. Manuals on good manners stressed that the well-bred man of the time could not ignore the culinary arts.

Palace food was characterized by its expense (plenty of meat, spices, sugar, rice), complexity (elaborate combinations of flavors, as well as stuffings), beauty (rich colors), and mock dishes. Palace doctors offered advice in the choice and preparation of food, as dietetics was important for the elite.

Many dishes of that period are still prepared today with ingredients available to the common people. Some of these are vinegar preserves, roasted meat, and cooked livers, which could be bought in the streets, eaten in the shops, or taken home. Such dishes considerably influenced medieval European and Indian cookery; for example, *paella,* which evolved from *pulao,* and pilaf and meat patties that started out as *samosa* or *sambusak.*

Despite the rich and relatively coherent cultural area created by the Muslim conquest, three main types of Middle Eastern cookery can subsequently be distinguished. One is that of Iran, another that of the Fertile Crescent, and the last that of Turkey. Each of these will be examined in turn.

Iranian Cookery

General Features

Iran is a vast land of varied climatic conditions. The coast of the Caspian Sea is known for its heavy rainfall and a verdant vegetation. But such a climate precludes the growing of long-grain rice and citrus fruits, such as oranges, tangerines, lemons, and limes. The region along the Persian Gulf is one of extreme heat, suitable for palm trees and the production of dates. Wheat is grown everywhere except on the Caspian coast, and the whole of the country produces tea, olives, peaches, apricots, pomegranates, pistachios, and walnuts. The famous red and white Damask roses, cultivated in Iran, yield an excellent rose water. The melons and grapes of Iran are also renowned. Although alcohol is prohibited in the Islamic religion, Iran was known in the past for good wines, especially those from Shiraz.

Sheep and goats are raised in large areas of Iran, with the main breed of sheep having fat tails and lean meat (fat is concentrated in the tail). These animals also provide milk from which large quantities of yoghurt are made.

Iranian dishes have changed little over the centuries, and many of them are somewhat unique in the Middle East because sweet and savory ingredients are often cooked together. A lamb stew with spinach and prunes is one example and duck in a sour cherry or pomegranate sauce is another.

Another feature of Iranian dishes is the wide use of fresh herbs, such as parsley, dill, coriander, mint, and cress, and a bowl of fresh herbs can play the role of a salad. Herbs mixed with rice flavor the green *sabzi pollo.* Iranian dishes are very subtly and lightly spiced. Saffron and cinnamon are among the most commonly used spices, dill and coriander seeds among the herbs most frequently employed.

Rice is an Iranian specialty, with many different kinds available, ranging from the longest and most flavorful to the quite ordinary. Rice is used in various ways: as *chilau* (white) or as *pollos* (with different meats and vegetables), and as a dessert (a *shol-e-zard* or saffron rice pudding served, among other occasions, for the annual observance of the martyrdom of Imam Hassan).

There is an Iranian legend explaining the high value of rice. When the Prophet Mohammed was accidentally conveyed into paradise, he sweated with terror at the idea of facing the throne of the Almighty. Six drops of his precious sweat came to earth from paradise. The second of these became a grain of rice.

As noted, Iranians have a unique method of preparing rice. This method is designed to leave the grains separate and tasty, making the rice fluffy and very flavorful. After soaking, parboiling, and draining, the rice is poured into a dish smeared with melted butter. The lid is then sealed tightly with a cloth and a paste of flour and water. The last stage is to steam it on low heat for about half an hour, after which the rice is removed and fluffed. The golden crust on the bottom of the pan, or *tah-dig,* is crumbled on top or served separately.

In addition to *pollo,* other typical Iranian preparations are *koresht* (stews of meat or fowl to be served with rice, such as chicken in walnut-lemon sauce or lamb in pomegranate sauce); *khorak* (eggplant casserole); and kebabs (pieces of roasted meat or game).

Iran is also famous for its soups, which include meat broth with chickpeas, typical rice and spinach soup, and hot yoghurt soup. Spinach originated in Iran and is used in many dishes. In a *kookoo,* or Iranian omelette, for example, the eggs are beaten and sometimes enhanced with a little baking soda so that the result is a very thick souffle, quite unlike an ordinary omelette. This versatile preparation comes in many variations, as does yoghurt, which when combined with fruit, herbs, and nuts is a common side dish, called *borani.* Their *dolmehs,* or stuffed vegetables, the Iranians borrowed from Turkey. Bread, in the past, served as a plate to hold food but today is employed in the Western way, on the side.

Historical Background

The early Persian empire (500 B.C.) was influenced by the Macedonians, Greeks, Romans, and Parthians. At the time of the Achaemenids, the king and the 1,500 individuals who generally dined with him had a great assortment of animal flesh from which to choose, including camels and ostriches. The satraps, or governors, also had to feed many guests. The satrap in Jerusalem, Nehemiah, often fed up to 150 notables at each meal. Food was prepared by a number of specialists, including chefs, bakers, pastry makers, drink mixers, and wine attendants. Tablecloths spread on the floor were of costly fabrics, and gold and silver vessels were in use among the nobility. Indeed, the Persians had such a passion for gold cups that Darius III once lost three or four tons of them, made of gold and encrusted with gems, to an enemy.

Like Nebuchadnezzar and the Assyrian kings before him, the Persian monarch enjoyed the special Helbon wine, from the vineyards on the slopes above Damascus, as well as wheat from Assos, salt from the oases of Ammon, oil from Karmanice, and water from the Nile and Danube.

With Alexander the Great (330 B.C.), links were established between India and Persia, that created common features in their cooking traditions. Under the Sassanids (third to seventh century), Persians seem to have become masters in the art of fine living. A Pahlavi text notes that the study of gastronomy was part of the education of a well-bred boy at the time of the Khusraus (end of sixth and early seventh century). Many of the words used in Middle Eastern cooking are of Persian origin and were popularized during this period. The cookery book of the Roman Apicius gives two recipes "in the Parthian manner." Both include *asafoetida,* a resin, appreciated as a condiment in spite of its unpleasant smell, which used to be important in Persian cooking. One of these recipes is a chicken dish; another uses kid or lamb, flavored with ground pepper, rue, onion, and stoned damson plums. Clearly, Iranian taste for sweet and sour combinations was already apparent at this early date.

During the reign of Khusrau II (early seventh century), a very lavish and sumptuous cookery was invented to satisfy the appetites of the monarch who had conquered Antioch, Damascus, Jerusalem, and Alexandria. It consisted of hot (grilled on a spit or fried) and cold meats, stuffed grape leaves, and marinated chicken. Other foods included mutton in pomegranate juice and rice pudding rich with honey, butter, and eggs. Young kid was popular, as was beef cooked with spinach and vinegar. Meat was marinated in spiced yoghurt, as it is today. Jams of quince, almond pastries, and dates stuffed with almonds and walnuts were served for dessert. *Rishta,* a kind of pasta similar to tagliatelle, was also known in ancient Persia.

In his twelfth-century writings, Marco Polo was impressed with the region and its wealth of foodstuffs: pomegranates, peaches, quince, and big fat sheep. But he noted that whereas the people of the countryside ate meat and wheat bread, those of Ormuz dined on dates, salted fish, and onions. Some 600 years later, John Bell, a visitor to Ispahan, took part in a big dinner:

> The entertainment consisted mostly of different kinds of rice boiled with butter, fowls, mutton, boiled and roasted lamb. The whole was served in large gold or china dishes and placed in the baskets, which stood on a long cloth spread above the carpets. The dishes were interspaced with saucers filled with aromatic herbs, sugar, and vinegar. [In addition to] the common bread, [there were] some very large thin cakes, which were used instead of napkins to wipe our fingers. They were made of wheat flour. (Bell 1965)

Sherbet was served cooled with ice, the latter from water frozen in the winter, then kept in cellars.

Food in the Arab Countries

General Features

In contrast to the Iranians, the Arabs have subsisted on a fairly rustic diet. Its origin is in the simple food of the Bedouins, which has not evolved much. The wealthy prefer rice; bread is the staple food of the common people. Bread of millet is made in the Aden protectorate; elsewhere, it is more generally of wheat, with sour or sweet fresh dough. It can be baked or fried on a griddle. Porridge and wheat gruel are still popular, as they were in ancient Arabia.

Fresh dates are a staple food in the poorest houses and are common everywhere. Individuals who consume *meshwi,* or meat grilled or roasted on a spit, betray tribal origins. Those who cannot afford lamb eat chicken or eggs often baked in an *eggah* or thick omelette. This is a versatile preparation that can be flavored with all kinds of vegetables, herbs, or meat. It is very close to the Spanish *tortilla* or the Iranian *kookoo.* Arab dishes of bread broken in pieces and soaked in stock, with various toppings, are reminiscent of *tharid,* the Prophet's favorite.

In coastal areas, fresh and dried fish are pounded and cooked with clarified butter and onions, or broken into pieces for easy consumption. Milk products are somewhat rare, with sour milk a common drink among the wealthy but not the common people. The mixture of milk, butter, and dates that Mohammed enjoyed is still prepared today. Spices and condiments, such as salt, pepper, chillies, tamarind, coriander, cloves, and cinnamon, are sometimes used.

A *mansaf,* or normal dinner, in a Bedouin family is simple, but served in a festive manner. Women cook huge wheat "pancakes" *(shrak)* on an iron plate. Several of these are piled on top of each other on a tray, then covered with rice and lamb, with butter poured over the top. A more elaborate meal for special occasions is a whole roasted lamb stuffed with rice, onions, nuts, and spices, and surrounded with mounds of rice, with hard-boiled eggs as a decoration. This meal is considered magnificent if the lamb is stuffed with a chicken, which, in turn, is stuffed with eggs and rice.

Meat balls *(kofte)* are another typical way of serving meat in Arab countries. They can be stewed in a soup, simmered in their own juice, or fried, and rice and spinach can be added to stretch the meat if it is scarce.

A meal is usually followed by one to three cups of boiling hot coffee. In the Aden protectorate, a kind of coffee prepared from the husks of the bean is a popular drink. It is not sweetened but flavored with ginger. A raisin tea made with boiled raisins and cinnamon is a specialty in Saudi Arabia.

Historical Background

Some travelers have left vivid written images of the foods and table manners of seventeenth-century Arabia. Among other things, their writings show how food was served. A large skin or woolen cloth was spread on the floor and dishes were placed on top. On great occasions, more than 10 dishes were offered and served six or seven times. In the middle of the table was placed the spectacular whole lamb or sheep with its trimmings. Arabs of rank ate at a small table 1 foot high with a large plate of tinned copper on it. Their food was served in copper dishes, tinned within and without. Instead of napkins, they used long linen cloths placed on their knees.

Western observers stressed the fraternity around these "tables." Sir Thomas Roe noted that Arabs make no great differences among table guests – the king and common soldiers, masters, and slaves, sat together and took food from dish (Roe 1926). Such fraternity is a value in Islam and still a tradition in Arabia. Travelers remarked, however, that women ate apart.

They also stressed the simplicity of the meals. Arabs had only a few cooking utensils of copper and big wooden bowls to use as large dishes or for kneading bread dough. They were reported to be fond of fresh bread and said to have baked it in a number of ways. Three examples of baking techniques are the use of an earthen pot in which a fire of charcoal was kindled (the bread was cooked on the sides of the pot), the placing of the dough on a heated plate of iron, and baking directly on charcoal.

In the desert, however, even the "more eminent schiechs *[sic],*" wrote Carsten Niebuhr, "eat of nothing but pilau or boiled rice. It is served up in a very large wooden plate" (Pinkerton 1811). A little mutton was consumed on occasion, but pastries were rare.

Most Arabs in poorer circumstances dined on bread and onions, sometimes with a little sour milk, salt, cheese, or oil. "But the most plenty and useful of all their fruits are their dates, which support and sustain many millions of people," wrote Roe (1926). Travelers, such as Roe, were also impressed by the use of coffee: "As soon as everyone is seated a servant brings a pot of coffee. It is very hot and poured in tiny cups. They are filled two, even three times, then a pipe of tobacco is presented" (Roe 1926).

Even though Islamic regulations were strictly observed and prayers said before and after meals, some inquisitive foreigners remarked that Muslims sometimes drank alcohol privately at night. Notwithstanding these "mistakes," the travelers gave the picture of a very traditional and modest food consumed by the Arabs, the same food that the Prophet himself had eaten.

Food in Egypt

General Features

Dishes served in Egypt constitute another type of old and simple tradition that goes back to pharaonic times, like the *melokhia* soup, a broth with the leaves of *corchorus olitorius,* (Tussa jute) which imparts a glutinous texture. Also old is the *batarekh,* or salted dried roe of the gray mullet, served sliced with bread. Pulses play an important role in the diet. Lentil soup is common, and the national dish is *ful medames,* brown Egyptian beans boiled and seasoned with olive oil, lemon juice, and parsley. To eat *ful medames* according to custom, one must first eat some of the beans whole, then mash some in the juice, and finally crush the rest with a hard-boiled egg placed on top of the dish. Cooked white broad beans, shaped into patties *(falafel),* spiced, and fried, are another favorite of the Egyptians, especially when eaten in a pita, or hollow flat bread.

Egypt is not a country where people consume animal protein in large amounts, but *hamud,* a chicken soup with lemon, is very popular. It is traditionally served with rice, cooked in the Egyptian way, fried then boiled. A kind of *kibbeh* (pounded meat and cereal) is prepared in Egypt, with ground rice instead of cracked wheat as in the Fertile Crescent. Fish kebabs are also quite common, and pigeons are frequently consumed. Couscous, a North African dish of a sort of semolina prepared with meat and vegetables, is served in Egypt as a dessert, topped with butter and fried raisins.

Nonetheless, the diet of the *fellahs,* or peasants, is mostly vegetarian. They usually have three meals a day, *futour* at sunrise, *ghada* taken while working in the fields, and a hot meal in the evening called *acha.* All of these meals consist mainly of raw or stewed vegetables.

Historical Background

In a fifteenth century Egyptian market, all kinds of foodstuffs could be purchased. Among them were wheat, barley, rice, beans, peas, chickpeas, carrots, cucumbers, lemons, watermelons, beef, mutton, chicken, goose, camel flesh, sugar, olive oil, sesame oil, clarified butter, and white cheese.

Pierre Belon du Mans, visiting in the sixteenth century, noted that Egyptians knew how to preserve foodstuffs. Lamb, for example, was cubed and boiled, cut in very small pieces, and boiled again in fat with cooked onions. Then the preparation was salted, spiced, and stored in barrels for up to two weeks. The French traveler also mentioned other preservation techniques, such as olives in brine, dried sea bream, salted gray mullet roe, and dried cheese (Belon 1557). These are not particularly sophisticated techniques, but they do show that Egyptians were able to make good and prolonged use of the products of their land.

Food in the Fertile Crescent

Syria, Jordan, and Lebanon have similar culinary traditions because all three were influenced by early Greek and Roman civilizations. In addition, Lebanon has recently been the recipient of a strong French influence, which is said to have enhanced the quality of its cookery.

This region is marked by the use of *burghul,* or cracked wheat, which is often consumed in the form of the traditional *tabouleh,* an herb salad with burghul and lemon juice. Burghul also plays an important role in another specialty of the area, *kibbeh,* which is said to have been mentioned in ancient Assyrian and Sumerian writings. Certainly, archeological evidence indicates that all the utensils and products necessary for this dish were on hand in the region long before Islam put its imprint upon it.

Kibbeh is made by pounding lamb with burghul, onions, and a little cinnamon; it is a mixture that can be eaten raw *(kibbeh naye),* grilled, or fried. Stuffed kibbeh is a variation that has become an art in Syria. A kibbeh shell is shaped around the finger of the cook as evenly and thinly as possible. It is then filled with meat, nuts, and herbs and sealed. Once fried, it becomes crisp with a moist inside. Kibbeh is one of the many possible items one can choose as a typical snack *(mezze),* along with a variety of olives, nuts, small pizzas, and pies. In Syria, a favorite is *muhamara,* a mixture of chopped nuts with hot pepper sauce. In Lebanon, another favorite is *mankoush,* a spicy herb flat bread. Lebanese people can spend hours nibbling these sorts of snacks while enjoying a drink of *arak,* an anise-flavored liquor. Local specialties include rice with almond sauce (Damascus), brown lentils and rice (Lebanon), bean salad (Lebanon), and lamb with yoghurt (Jordan). *Fattoush,* or bread salad, with a dressing of olive oil, onions, and lemon juice is common throughout the region.

Turkish Food

General Features

In Turkish food, one encounters the same differences between country food and the palace cookery that we have seen in other countries and regions once parts of the Ottoman empire. A classic Turkish meal starts with hot or cold yoghurt soup. In some villages the soup is made on baking day in a pit oven. A Turkish menu also offers *mezzes* (appetizers), such as sausage, vegetables in oil, cheese, *pastirma* (dried pressed meat cured with garlic and spices), or *borek* (flaky pastries with different fillings). A classic Turkish menu will feature soup, a meat dish, a borek, a vegetable dish, and a dessert.

Meat is a very important item in Turkish cookery. It comes in dozens of varieties of kebabs. Mutton and lamb are favorites, especially minced or pounded. Meat is even used in fruit dishes and puddings; examples include stewed apricots or quinces with lamb and a pudding of chicken breast. For big parties, a whole kid is roasted on a spit. Minced meat is the filling for the numerous *dolmasi,* or stuffed vegetables, such as peppers, tomatoes, vegetable marrow, and grape leaves.

Eggs are an important item of food, and many Turks raise chickens in their backyard. There are more than 130 varieties of fish available in the Bosporus Straits, with mackerel the most popular. A kind of unleavened flat bread made at home is the Turk's staple food. The baker offers many varieties of white bread, the most famous of which is the ring-shaped *simit.*

Turkey is well known for its pilafs, or rice dishes, made from long-grain rice, pounded ripe wheat *(dogme),* toasted unripe wheat *(firik),* and bulgur, or couscous. They are enriched with meat, dried fruit, vegetables, spices, and yoghurt.

Yoghurt is used in two forms in Turkey, one semiliquid and the other firm. The latter is often eaten with jam or used for cooking, while the former, as a yoghurt drink *(ayran),* is often served with meals.

A very special Turkish drink is *salep,* which is made with the infusion of a powder from the root of the salep orchid in milk and served hot. Coffee has been prepared and served in coffeehouses in Turkey since the fifteenth century. It is offered black and strong, usually with confections. Turks are very proud of their sweets, and a confectionery in Istanbul can feature more than 100 sorts of halvah (sweetmeats), such as plain and rose *lokum* and almond and pistachio marzipan.

In the past, vendors made and sold all kinds of foods on the streets. Today, these individuals are not so numerous, but sesame-sprinkled *simits* are still sold everywhere, the water or juice seller is still seen, and the streets of Istanbul still often smell of grilled fresh mackerel or roasted lamb.

Regional differences are important in Turkish food. The Aegean region is renowned for its fish and seafood. The Mediterranean region is rich in vegetables, with aubergines, peppers, tomatoes, and garlic featured in many stews. People of the Black Sea region enjoy cabbage soup and anchovies in many dishes, including a pilaf. Anatolia is the home of the best Turkish roast meat. Bursa is the town that gave birth to the world-famous *doner kebab,* meat roasted on a vertical revolving spit.

Historical Background

The nomadic period (before the eleventh century). In the Turkish city of Konya, people ate bulgur and lentils and knew how to use the pit oven, or tandor, 7,000 to 8,000 years ago. Turks in central Asia probably drank soups of *tarhana* (dried curd and cereals) and, when still nomads, they relied on mutton and horse meat, unleavened bread, milk, and milk products. *Manti* (a kind of ravioli) and *corek* (ring-shaped buns) were probably also known.

The Seljuk sultans and principalities period (1038–1299). During these centuries, the nomads were drawn from their steppes into the armies of the caliphate. They began to settle down, ruled a number of local dynasties, and as they did so, acquired more refined manners and tastes. Dishes of the period reveal that cooking was becoming an art. In an eleventh-century dictionary, for example, there is mention of a layered pastry, of noodle soup, grape syrup, and a corn-flour halvah.

Mowlavi Jalâl-al-Dîn Rumi, founder of the order of Whirling Dervishes, was a philosopher who, nonetheless, showed great interest in the subject of food. Thus, it is possible to infer from his writings the types of comestibles consumed in the thirteenth century. A few examples include saffron rice, homemade noodles with meat, *kadayif* (layered nut filled pastry), all kinds of halvah, wine, and fruit syrups. Within the order, strict rules were established concerning the organization of the kitchen and tables manners. Among other things, such rules show that social distinctions were made among those involved in food preparation, from sherbet makers to coffee masters to waiters, dishwashers, and cooks.

The Ottoman period (1299–1923). One group of nomads, the Osmanlis, or Ottomans, came to control the Islamic empire. Their rulers were cosmopolitan, having previously been slaves (or descendants of slaves) in all parts of the known world as far north as Russia and western Europe. These new rulers first took Persia as a model for their court life, then developed their own, including the culinary arts, borrowing from all over their empire.

The first Turkish cooks employed in the palace came from Bolu, the region where the sultans did their hunting. The men of Bolu were accustomed to leaving their land to learn this craft at the palace. Food was so important to the sultans that the insignia of their renowned janissary force was a pot and a spoon, symbols of their higher standard of living. The titles of janissary officers were drawn from the camp kitchen, such as "first maker of soup" and "first cook." The sacred object of the regiment was the stew pot around which the soldiers gathered to eat and take counsel.

When Sultan Mehmet II, the Conqueror, captured Constantinople (1453), he laid down the rules for food preparation, to be followed at the court for a long time to come. The palace kitchen was divided into four main areas: the king's kitchen; the sovereign's kitchen (responsible for food for his mother, the princes, and privileged members of the harem); the harem kitchen; and a kitchen for the palace household. That there was a movement toward culinary specialization seems clear in that the kitchen staff included bakers, confection and pastry makers, a yoghurt maker, and a pickle maker.

Ottaviano Bon (1653) has provided us with a good account of the kitchen in the seraglio in the seventeenth century, which shows how complex the organization had become. Food was prepared by the *Ajomoglans* (Christian renegades) and 200 cooks and scullions who began their work before daybreak.

The sultan would eat three or four times a day, commonly dining at 10 in the morning and 6 in the evening, with snacks in between. He ate cross-legged, with an expensive towel upon his knees and another hanging on his left arm. Three or four kinds of white bread and two wooden spoons were placed before him (one for soup, one for dessert) upon a piece of Bulgar leather. The sultan's ordinary diet consisted of roasted pigeons, geese, lamb, hens, chickens, mutton and sometimes wild fowl. He would eat fish only when he was at the seaside. Preserves and syrups were always on the "table," though pies were "after their fashion, made of flesh" (Bon 1653). Sherbet followed the meal, since the ruler had adopted Islam and could not take wine.

When he finished, the leftover food was given to high officers. Lesser officers ate from a different kitchen where the food was of lesser quality. Odah youths (young Christians or Turks raised to become officers of the sultan) were fed on two loaves of bread a day, boiled mutton, and a thin pudding of rice with butter and honey. Queens had the same food as the sultan but consumed more sweets and fruit, reflective of their sweet and delicate nature. They drank their sherbet mixed with snow in the summer.

The hierarchy in the palace may be seen in many ways. Four kinds of bread were baked, the best for the sultan (with flour from Bursa), middle-quality loaves for ordinary officers, and a black and coarse bread for the servants; sailors received only sea biscuits.

Reaching the sultan's kitchen were luxury items from all over the empire. Alexandria sent rice, lentils, spices, pickled meats, and sugar, as well as prunes and dates. The latter were used in the dressing of roasted or boiled meats. Although few spices were used in Turkish cooking, an incredible amount of sugar was invested in pies, sherbets, and confections. Even common people offered each other sweets.

In addition, Valachia, Transylvania, and Moldavia sent honey to be used in broth, sherbets, and meat stews. Olive oil arrived from Greece and butter from the Black Sea region.

Bon noted that Turks used the flesh of calves in the same way that Christians used pork in puddings, pies, and sausages. They also dried the meat to make *basturma.* The serai kitchen was lavish in its use of meat, with 200 sheep, 100 kids, 10 calves, 50 geese, 200 hens, 100 chickens, and 200 pigeons slaughtered daily.

This aristocratic tradition of opulent dining that Bon depicted in the seventeenth century would continue into twentieth-century Turkey. Every meal of wealthy families would feature seven courses: fish, egg or *borek,* meat or fowl, cold vegetables in oil, hot vegetables with butter, pilaf, and pastry or pudding. Such meals were certainly not the democratic and rustic affairs of the Arabs.

The History and Culture of Food in the Indian Subcontinent

The Indian subcontinent is a huge triangle extending from the Himalayas to Cape Comorin and from the Baluchistan deserts to the rice fields of Bengal. It is divided into the countries of India, Bangladesh, Pakistan, Sri Lanka, and the Himalayan states. A diversity of physical environment in this area explains the diversity of the various agrarian civilizations and, in turn, the diversity of cookery traditions. The obvious contrast between the wheat eaters of the North and the rice eaters of the South is but one of numerous possible means of classification. Opposition is also found in the vegetarian ideal of Hinduism and the Muslims' fondness for meat. But it is interesting to note that the art of cooking unites, rather than divides, the people of the peninsula. This is an art that has evolved into a very rich and complex affair called "Indian cookery."

Indian Cookery: A Kaleidoscope

Three Cereals

As noted, we can divide the subcontinent into agricultural zones in which either wheat, rice, or millets are predominant. Although cereals are supplemented by various plants and pulses, they nonetheless constitute the staple food in each zone.

Rice is eaten everywhere in the Indian world, but it is the staple food only of the South and of Bengal, where it is boiled and served with a *dahl* (made from one of the many pulses of the peninsula), or perhaps with different curries and fresh yoghurt. When rice is ground and parboiled with split peas *(urad dahl),* it becomes a batter that the cooks of Tamil Nadu leave to ferment and to steam in molds to make the spongy *idlis.* The same batter can be shaped into small doughnuts and fried, or spread on the griddle to make a crispy pancake called *dosa.* All these preparations are served with chutney, a spicy vegetable curry, or a souplike *sambar.*

Millets like *jowar* (sorghum), *bajra,* or *ragi* are cultivated on the poorest soils and are found mainly in the Dekkan, Western Ghats, Gujerat, and Rajputana. They have been the staple food of the peasants, although "richer" cereals are increasingly becoming more preferred.

Wheat is mainly cultivated in the northern provinces. Most of the time it is used as bleached and unbleached flour. When mixed with water and salt (and for richer loaves, with milk, butter, or oil), it is the basis for the numerous Indian breads.

Roti or *chapati,* a thin whole-wheat griddle bread, is the daily accompaniment of *dahl.* With butter in the dough or on the pan, it becomes a golden *paratha.* Deep fried, it turns into a puffy *puri.* But thanks to the Muslim influence, northern India and Pakistan also know oven bread in its various forms. The most commonly found are the unleavened oblong *nan* or the round and soft *shirmal,* which is smeared with saffron milk. Lucknow and Hyderabad are also famous for their sourdough square breads or *kulchas.* All these oven breads are made of white flour and traditionally baked on the sides of the tandoor, the central Asian clay oven.

Such bread goes well, and is best associated, with the nonvegetarian cookery of the North, which includes kebabs and rich stews *(kormas)* of lamb or chicken.

North and South

Like the differing architecture of their temples and linguistic features, the North and South of the subcontinent have separate staple foods, and there are many differences between their cookeries.

With the curries, for example, the *masalas* (spice mixtures) that give each dish its character are not the same. In the North, the spices are dried, ground, and then dry-roasted or fried before being added to a dish. The dishes themselves are often nonvegetarian, due to a stronger Muslim influence, and tend to be dry so that food can be scooped up with bread. In the South, fresh spices are pounded with a liquid into a paste. The dishes these pastes flavor are mostly vegetarian, and rather liquid, to moisten the plain rice that generally is an important part of the meal.

Northern cooks will, therefore, have many dry spices on hand, such as cardamom, ginger, turmeric, black pepper, chillies, coriander, cumin, and, sometimes, dried vegetables or fruits that could not endure in the humid climate of the South. They use *ghee* (clarified butter) to cook the meat and oil (mustard oil, if possible) for the vegetables. Among the many pulses employed is the chickpea, which is a favorite in the North. Green tea in Kashmir and black tea, elsewhere, is boiled with water and sugar, spiced with ginger and cardamom, and whitened with rich buffalo milk.

By contrast, southerners use few dried spices and no dried vegetables. Rather, the latter are bought fresh on a day-to-day basis. Fruit and vegetables are preserved, however, in oil and chillies *(achar)* and in vinegar (pickles). In addition to jars of these relishes, a good kitchen will have different varieties of rice, some for everyday use, others for festivals and desserts, and still others for the servants. Rice flour will be present, as well as many types of pulses. In the vegetarian South, pulses are a major source of protein. Ghee is seldom used, but sesame and coconut oils are common.

The South, in tropical Asia, is also a land of coconuts and many other exotic products, such as mangoes, limes, bananas, "drumsticks," *moringa oleifera,* and jackfruit, all of which are often part of the diet. Coffee, introduced by the Arabs, is preferred to tea in the South, where it is prepared with milk and sugar. Now it is also found everywhere in its instant form.

Cooking utensils differ from north to south, although the *chula* (square hearth), the *tawa* (griddle), and the *karkhai* (deep frying pan) are common to the entire peninsula. In the North, the dry spices are ground on a grindstone *(chakki),* and in the South, the fresh ingredients are pounded with a mortar and pestle. The coconut grater is also typical of the South. Food is served on individual metal trays *(thali)* in the North, but on a clean banana leaf in the South. Finally, although all people of the subcontinent eat with their right hand, northerners tend to use the tips of the fingers, whereas southerners will dip their whole hand into the food.

More Regional Variations

The diversity of the culture of food and drink in the Indian world is much more complex, however, than simply differences between north and south. There are many interesting variations within the vast regions.

For example, the valley of Kashmir in the northernmost part of India has a somewhat cold climate, which is perfect for growing fruits, walnuts, and cumin, and for breeding sheep. Thus, as one might expect, the cookery is more closely related to that of central Asia. The tea there is made in a samovar and is a green tea, as in Tibet. The bread is closer to that made in Afghanistan than to Indian *chapatis* and is generally baked in clay ovens by professionals.

In Rajasthan, culture has dictated other food habits. Historically, their men have been warriors and, thus, have long been accustomed to outdoor cooking. For this reason, many of their dishes include marinated and grilled meats (including game), often prepared by males.

In contrast to this rugged fare, a Maharashtran meal starts with a sweet, eaten with a *puri* or *chapati.* Maharashtra is rich in seafood and coconuts, and both are often blended together. Every morning the ladies of many houses begin their day by grinding coconut and spices on a grinding stone. The milk of the coconut is also present in practically every dish, even in *pulao* (flavored rice, the Indian rendition of the Turkish pilaf).

Bengali food is reputed to be quite plain, but the sweets of the region (*sandesh, rasmalai, gulab jamen,* and all-milk sweets soaked in syrup) are famous. The waters of the Bay of Bengal yield hundreds of varieties of fish and shellfish. In fact, the "vegetarian" Brahmans of the region, who theoretically should avoid seafood, eat it nonetheless, calling it "vegetables of the sea."

The Portuguese, in their quest for empire, settled in Goa as well as in other places. Thus, personal names, architecture, and festivals, along with the foods of the region, reveal this influence. Indeed, Goanese food is Portuguese food, save for the lavish inclusion of red chillies and coconut milk. The use of onions and tomatoes in many soups is very Portuguese, and the Goanese consumption of pork is unique in India. Vinegar gives many dishes a typical sour-hot taste. Sweets include a lot of egg yolks and almonds. Thus, dishes such as *caldine, bife, souraca,* and *assada* are all reminders of the colonial past.

Malabar Muslim cookery constitutes another example of a blending of local and foreign traditions in India. Kerala Muslims are supposed to have descended from intermarriage between local Kerala women and Arab traders who settled there. Malabar food has a great deal in common with food elsewhere in Kerala in that it testifies to an extensive employment of coconuts, coconut oil, and rice. But the Arab influence is evident in dishes such as *alisa* (a wheat and meat porridge), or stuffed chicken. Another dish *(byriani)* shows the linkage with the Muslims of northern India, although it contains coconut and prawns. A Muslim love for bread is reflected in the Moplah specialty called *pathiri,* which is a rice *chapati.*

Cultural Background

The four major religions of India are Hinduism, Buddhism, Jainism, and Islam. The Islamic influence, which arrived in the eighth century, placed great emphasis on the enjoyment of food because it was considered a reward from God to the believer. Yet food is not a petty matter in the view of other dominant religions either. "All doings come from food" is an Indian saying. For the traditional Hindu, cooking and eating are not just matters of survival but moral investments and rituals as well. The *Mahabharata,* one of the sacred books, refers to the necessity of ensuring purity in food and drink as one of the ten essential disciplines of life; and even in the big cities, a majority of Indians still live according to such age-old customs.

Vegetarianism is a precept of the three Indian religions although, of course, the people of India were not always vegetarian. The first humans who appeared near the basin of the river Indus around 15,000 B.C. ate meat along with rice, molasses, spices, and betel leaves. It was not before the Vedic era (1500–800 B.C.) that an aversion toward meat consumption appeared in ancient texts. At this time, milk acquired a symbolic value and the cow was described as a "gift." Little by little, animals were replaced by clay or flour figurines for sacrifices, and instead of consuming the cows that constituted much of their wealth, the people of India began revering them.

It was the new religions of Buddha and Mahavira Jina (sixth century B.C.), however, which provided the decisive impulse to the vegetarian doctrine. Both prescribed nonviolence *(ahimsa)* and the abstinence from meat. This ideal is still subscribed to by the orthodox Hindus, whereas Jains go so far as not to touch foods that resemble meat, such as tomatoes, beet roots, and so forth.

However, there has always been an ambivalence in the Hindu attitude toward meat consumption. If Brahmans avoided it, it was recommended to the *Kshatriyas* (kings and warriors) and was not forbidden to the castes of merchants, agriculturists, and servants. All this suggests that the Hindu concepts on food were elaborated for a whole society, in which everyone had duties and a diet suited to those duties. Those who lived close to the world and its violence were urged to eat meat to gain energy. By contrast, the Hindu priests and Brahmans embraced vegetarianism; indeed, those who prayed were enjoined to avoid everything exciting to the senses, even onions.

Each individual can follow many diets. Hindus believe that a perfect life is lived in the four stages of student, householder, hermit, and ascetic. A man, therefore, might be vegetarian while single, then be nonvegetarian, and finish his life in abstinence and fasts.

The cow is still held sacred, its products considered excellent for health, as well as religious purposes. Pure *ghee* (clarified butter) is highly esteemed, and many Indians still feed the newborn baby with a spoonful of ghee after the Brahman ritual. They also give ghee to sick individuals and, although very expensive, it is still considered the best cooking medium.

While vegetarian doctrine was being elaborated, concepts of pure and impure foods were being developed as well. A ritual is organized around the meal to ensure its purity, which includes bathing and the wearing of clean clothes for both the cook and those who dine. The kitchen must be as clean as a temple and separated by a little wall from the rest of the house, far from the refuse area and near the prayer room. It is often swept and washed, and, traditionally, the floors are covered with cow dung, a sacred substance and one regarded as an antiseptic.

Purity also shapes the whole Hindu society as a hierarchical structure with the Brahmans at the top. An exchange of food is traditionally prohibited among the segments or castes of this society, especially from the lowest (most impure) to the highest (Brahmins). Even in the same family, it is considered "unclean" to touch food that has been touched by someone else, which is why the food is served directly from the cooking vessels onto the *thalis* (leaves). This also explains why there is no tradition of dining out in India. The quest for purity is too strong.

These age-old principles are still professed by most Hindus, but orthodoxy is sometimes sacrificed for the sake of health (diets low in fat, sugar, and spices), diversity (new recipes), status (for example, the Western habit of going to restaurants), and convenience (ready-made food).

As we have noted, Islam also strongly imposed itself on the cookery of the subcontinent for religious, as well as for purely gastronomic, reasons. Although a late cultural and religious arrival, Islam came to India via many channels. Arab traders, Afghan and Turk soldiers, along with Iranian administrators, all settled down there and made converts to their religion, as well as to portions of their culture.

If Hinduism has given a high spiritual content to the meal, it has paid little attention to the art of cooking. Boiled cereals and griddle bread, stewed vegetables, and pulses had been the usual diet since the beginning of Indian civilization. Islam gave to Indian cookery its masterpiece dishes from the Middle East. These include *pilau* (from Iranian pollo and Turkish pilaf), *samossa* (Turkish *sambussak*), *shir kurma* (dates and milk), kebabs, sherbet, stuffed vegetables, oven bread, and confections (halvah). Such dishes became so well acclimated in India that vegetarian versions of them were elaborated. It is this cross-cultural art that is now acclaimed all around the world.

V.B.2 Southeast Asia

Southeast Asia, geographically and culturally diverse, stretches from Burma (Myanmar), through Thailand and the Indochinese and Malay peninsulas, to islanded Indonesia. Some would include the Philippines and Indonesian New Guinea as parts of Southeast Asia, but this study adds only the Philippines. European scholars called the region "Farther India" for its location "beyond the Ganges" (Coedes 1968). It is separated from China by the Himalayas and their eastern extension. Each country in the region has other mountain chains, channeling rivers to the South China, Java, Celebes, and other Indonesian seas, and to the Indian Ocean. Lowland plains south of the highest ranges of the mainland are home to most of the populations of Burma, Thailand, Malaysia, Cambodia (Kampuchea), Laos, and Vietnam. The region is also insular: Indonesia has over 13,000 islands, spreading some 5,400 kilometers (3,300 miles). Most people live on or near oceans or river deltas.

Southeast Asia is in the tropical belt along the equator, with little temperature variation – about 15.5 to 24 degrees Celsius (60 to 75 degrees Fahrenheit) in winter to 29 to 32 degrees Celsius (85 to 90 degrees Fahrenheit) in the dry summer months (Hanks 1972).

This is monsoon Asia, and annual rainfall amounts to several hundred millimeters (over 100 inches). North Pacific winds bring rain from the northeast down the South China Sea from October until March, and there is a southwesterly monsoon in summer from May to September (Jin-Bee 1963). Rain is not constant, but brief showers or thunderstorms are always imminent. Temperatures and precipitation are noticeably lower in higher parts of the region. Europeans early recognized the comfort of the foothills and built hill-station retreats where their accustomed temperate plants – fruits, flowers, trees, and vegetables – all flourished.

The mountains, rivers, plains, seas, climate, and laterite, "red-earth" soil have combined to influence what foods are grown or have been available for the choosing since human beings first dwelt there. But despite northern mountain barriers and north–south mountain chains that hinder passage within and beyond the region and keep hill-tribe people (with their different agricultures and religions) apart from lowland dwellers, outside influences have managed to modify behavior and material objects, including what there is to eat. In other words, historically, political, economic, and social factors have frequently resulted in new technologies, products, foodstuffs, and behaviors.

European exploitation of Southeast Asia began with the Portuguese during the Western Age of Exploration in the sixteenth century. But Indians had ventured there much earlier, perhaps in prehistoric times (Jin-Bee 1963; Burling 1965), and had founded kingdoms and introduced Buddhism (Coedes 1968). China has also had a long history and influential relationship with Southeast Asia. Northern Vietnam was part of the Chinese empire for a thousand years until the tenth century A.D. (Burling 1965). Malacca, commanding the waterway through which ships passed from the west to China or the Spice Islands, came under Chinese control in the fifteenth century as a hub of trade. But by the fourteenth century, Islam had been introduced to Southeast Asia by Gujarat Indians, Arabian merchants, or both.

Later colonizers included the Portuguese, Dutch, British, Germans, French, and, in the Philippines, Spaniards and North Americans. All of these cultures influenced foods and the implements for producing and eating them, as indicated among other things by Romanized names for both foods and implements in the languages of the region. It is interesting to note, however, that the World War II occupation of much of the area by Japan had little effect on food practices.

And finally, increased air travel, tourism, commercial marketing, television, advertising, and imported foodstuffs have certainly made the diets of indigenous people more complex, although not necessarily more nutritionally or culturally worthy (Wilson 1994).

Obviously, then, from the foregoing, much of the history of food and drink in Southeast Asia is the history of introductions, some of which can only be guessed at. Written records of the movements of peoples and their political and religious struggles were first made by early Chinese regimes (Coedes 1968). Pre-Aryanized, preliterate kingdoms (Cambodia and Burma) are known to have had complex material cultures, irrigated rice, domesticated cattle and plants, ancient belief systems, temples, and art objects, and also to have bestowed important roles on women. Archaeological records are intermittent, with imprecise dating (Burling 1965; Coedes 1968), so the written Chinese records provide most of our knowledge of early history. But other clues come from linguistic changes, plant distributions, local lore and myth, and, for recent centuries, reports of administrators, travelers, and ethnographers.

Despite the region's diversity, a basic eating pattern common throughout Southeast Asia is a heavy reliance on white rice, consumed with smaller quantities of an accompanying side dish, most often fish, prepared with a sauce from grated coconut meat and a variety of spices, many of which originated in the region (Wilson 1975).

Staples

Rice

Rice *(Oryza sativa)* belongs to the family of grasses, Gramineae. The cultivated species is chiefly *O. sativa,* which, some authorities believe, originated from wild rices native to southeastern Asia (Burkill 1966). *Oryza sativa* is polymorphic, responding with changes in structure to altered environmental growth conditions. This trait earlier led to reports of many different genuses and species until plant genetic studies showed which species were fertile when crossed and which were sterile. Botanists reduced the number of distinct species to 25, but hundreds or thousands of varieties (also termed races) of *O. sativa* exist, having different growing seasons, or responding with inflorescence to less sunlight or drier soils (Burkill 1966; Hanks 1972).

Rice will grow on dry uplands, which may have been the site of its first cultivation in late Mesolithic or early Neolithic times (Coedes 1968; Hanks 1972). The early cultivators could also have accidentally created new species by tying awns of different varieties together to prevent lodging. However, present species and races could also have developed in nature because they grow under similar conditions in the same places and readily interbreed. Quite likely, the process goes on at present when different races are planted for specific characteristics, as suggested by Douglas E. Yen (cited in Crawford 1992).

Rice is a plant of warm, damp areas and, hence, is climate-dependent. It grows satisfactorily in the tropical and subtropical belt from Asia through Africa to warm, moist parts of North and South America. Recognition of its reliability must have been gradual, and the initial understanding of its potential for dependable growth again and again in the same locale (initiated by inserting seeds in the ground) was probably fortuitous suggested when ungathered seeds germinated in a rain-fed field. A liking for the taste of this intermittent crop probably led to efforts to husband its growth, though when and how rice cultivation dawned as a regular agricultural pursuit can only be guessed at (Hanks 1972).

Based on archaeological finds (shards and tools) made in this century (Coedes 1968), together with recent techniques of carbon dating and ethnobotanical research, it has been estimated that the "first" crops of rice appeared some 10,000 to 15,000 years before the present. But "primitive" rice culture continues in some remote areas today, and its ecological and economic consequences that have been recorded also provide insights into early rice cultivation (Conklin 1957).

Rice requires moisture, warmth, and soil with organic matter. The soils of Southeast Asia, like those of much of the tropics, are lateritic, from iron compounds above underlying clay that oxidize upon exposure to air. For plants to grow, a top layer of organic matter, humus, is needed. This may be deposited naturally as fallen detritus in forests or as silt brought by rivers to the deltas. Many of Asia's rice bowls are located between inland forests and coastal mangrove swamps that hold these deposits.

But "dry" rice, which preceded irrigated rice, is still grown in Southeast Asia's upland forest areas, as well as in small dooryard plots (Wilson 1970). Most dryland rice involves shifting cultivation, for the plant removes much of the soil's nutrients, and considerable fallow time must be allowed before a new crop can be nourished (Hanks 1972).

Early growers had to be keenly aware of and attuned to the rhythms of the seasons and plants before regularizing their planting activities. These began by cutting forest growth well ahead of the onset of the rainy season, then drying and burning it. The latter tended to destroy competing plants, and the ash provided phosphates and potassium otherwise lacking in the soil. Still before the rains, seeds were planted through the ash. Such soil could produce crops for two years; after this, the agriculturists would either select another nearby area to plant or move on. Overpopulation and continued land use could lead to erosion and incursion of hardy weeds, and with prolonged soil use, trees would not be able to regenerate to restore the forest.

The other principal method of rice culture is wet-rice cultivation, with its use of shallow water to kill off competing plants. In all countries where rice constitutes the "bulk of consumption" (Wilson 1985), each step in rice raising, from selecting grains for the next year's crop to harvest, storage, and husking for cooking, is accompanied by rituals of worship. People from Burma to the Philippines have long felt that this paramount food is the homesite of a potent god and have made it central to civil and religious rites. Indeed, beliefs regarding the efficacy and supernatural or curative properties of rice antedate the introduction of organized religions to the region (Geertz 1960; Rosemary Firth 1966; Wilson 1970).

Varieties in which the endosperm starch is partially replaced by soluble starch and dextrin produce glutinous, "sticky" rice that is sweeter, but less easily digested, than ordinary rice (Burkill 1966). Dyed yellow with turmeric (formerly saffron, which is the color of royalty in Southeast Asia), glutinous rice is served for ceremonial occasions as part of the meal or made into sweetmeats exchanged at religious holidays (Geertz 1960; Rosemary Firth 1966; Wilson 1985). One of the most popular of these "cakes" is Malay-Indonesian *ketupat,* usually made of steamed glutinous rice (white, red, or black) mixed with coconut cream and recooked in a woven or folded leaf (Wilson 1985). In Sumatra this mixture is called *lemang* and may be served with fruits or with festival meats such as *sate* or *rendang.* The rice sometimes is made into a fermented liquidlike toddy.

Despite the widespread visibility of wet-rice paddy fields, they are a relatively recent phenomenon. Wet rice was not extensively cultivated in Indonesia, the Philippines, Thailand, or Burma until the latter part of the nineteenth century. Its cultivation coincided with the opening of the Suez Canal and a greatly expanded trade to the area, at a time when colonial powers were encouraging increased food production for growing populations (J. N. Anderson, personal communication).

A continuous need for water and its control has increased sensitivity to seasonal fluctuations in the rains and has also encouraged an elaborate technology to harness and store it – all accompanied by rituals similar to those used for the rice that grows in the water. Where hillside erosion prevented regular upland cropping, terracing was introduced and is still used. Terraces require substantial investments of time and energy because effective structures can be realized only gradually. Notable examples of terracing are to be found in Java and Bali. It has been suggested that the terraces of the northern Philippines were constructed for earlier propagation of taro and other root crops, which may have preceded rice planting (Pollock 1992).

Dry-rice growers practice various means to delay fallowing and maintain soil fertility, including intercropping, a common technique among shifting cultivators. Indonesians, for example, have recently introduced peanuts *(Arachis hypogaea)* in some areas. Moreover, at the International Rice Research Institute in the Philippines, and elsewhere, high-yielding, fast-growing, more highly nutritious strains of rice have been bred to meet increasing demand.

This "Green Revolution" was technically successful, but preexisting races cultivated by small growers were often preferred for taste or for aroma, and when hand-hulled by pounding in a mortar, they retained much of the germ removed by machine hulling. The new strains that replaced them, however, required greater input in terms of time, technology, fertilizers, and water control, and have, therefore, proven too expensive for many small cultivators. Because of these developments, some compromises have ensued, and gene banks for rice now recognize the value of older varieties.

Root Crops

In addition to rice, or as a substitute, Southeast Asians have eaten a variety of other starchy staples (chiefly root vegetables) that are indigenous as well as introduced. Notable among them are yams of the *Dioscorea* species, chiefly *Dioscorea alata,* the greater yam, and *Dioscorea esculenta,* the lesser yam, both of which are ancient plants thought to have been domesticated several thousand years ago in Southeast Asia (Burkill 1966; Pollock 1992). *Dioscorea alata,* is a cultigen unknown in the wild, whereas *D. esculenta,* still has wild varieties. Robert Dentan (1968) notes that the Semai (Malaysian aborigines) tend wild yam patches, which may give us a glimpse of how agriculture began. The plants have climbing vines and starchy tubers that can be stored in the ground. Now chiefly famine foods, these roots, propagated by cuttings, contain alkaloids and other toxins not yet identified, among them acrid substances used by indigenous peoples as fish poisons (Heiser 1990). Consequently, those who rely upon wild yams are careful to boil or roast them before eating.

Another root that may have preceded rice as a staple is *Colocasia esculenta,* together with other members of this family, *Alocasia macrorrhiza, Cyrtosperma chamissonis,* and *Xanthosoma sagittifolium,* that are collectively known as taro. Except for *Xanthosoma,* which is American in origin, taros are Asian or Pacific plants. *Alocasia* and *Colocasia* have been cultivated "from remote times" throughout Southeast Asia (Burkill 1966). *Colocasia,* unknown as a wild plant (Herklots 1972), probably originated in northern India. Its common names are *dasheen, eddo, cocoyam,* or *keladi* (Malay). Taros have not been relied on as a starch food in much of Southeast Asia for many years. They contain crystals of calcium oxalate that must be leached out before the corms are cooked. Occasionally, however, the stems and leaves are boiled or fried in coconut oil.

Two other starchy roots, introduced to Southeast Asia, are the white potato *(Solanum tuberosum)* and manioc (cassava, yuca) *(Manihot utilissima),* both of South American origin. The potato was probably brought by the Spaniards to the Philippines in the sixteenth century and by the Dutch to Java in the following century (Burkill 1966). A taste for it has been slow to develop, but the same cannot be said of manioc. Of the family that includes figs *(Ficus)* and other latex-producing species, manioc was widespread in tropical America (Jones 1959). It was noted by voyagers who followed Christopher Columbus and was taken early to Africa; it reached Asia much later, however, and although the date of its arrival in Southeast Asia is not certain (Burkill 1966), it may have been as late as the eighteenth century.

According to Robert Hefner (1990), in the nineteenth century the Dutch colonial government introduced manioc to Java, where rural people resisted its cultivation until a serious food crisis was experienced in the 1880s. Although a comparative latecomer, manioc is now ubiquitous throughout the region. The roots may be left in the ground for long periods, and because manioc produces more food per unit of land than any other crop, it is increasingly relied upon as a famine food. Yet manioc is nutritionally inferior to most other foods, and it drains soils of nutrients without contributing any. Moreover, most races contain hydrogen cyanide (prussic acid), and South American techniques for removing this poison by boiling or roasting did not accompany manioc to Africa and the East. In Java (Burkill 1966), Malaysia, and other parts of the region, sun-dried strips of manioc are sold and consumed as snacks. In both countries, parboiled tubers are fermented several days with locally produced yeast to make an inexpensive *tapai* (Burkill 1966; Wilson 1986). In addition, the young leaves are sometimes used as a vegetable.

Grain Staples

Another New World staple, maize *(Zea mays),* caught on considerably more swiftly in Southeast Asia than did manioc and the potato. Lucien Hanks (1972) quotes the European traveler Nicholas Gervaise, who wrote, in 1688, that the grain had first been sown just 12 to 15 years earlier in Siam, yet it already covered the upland plains. Maize was also relied upon as a staple by upland dwellers in precolonial Java (Hefner 1990) – before Dutch rule in the nineteenth century. Although the Semai adopted it (together with manioc) as a staple food (Dentan 1968), it has tended to be a substitute grain in the region, and despite introduction of newer varieties, it is used primarily as feed for animals or as a snack, roasted or boiled, for humans.

Some staple grains of importance elsewhere also grow in Southeast Asia. Foxtail, or Italian millet *(Setaria italica),* and some other races have been food sources for tribal peoples (Burkill 1966). Wheat *(Triticum vulgare)* flour is of some importance in bread, biscuits, crackers, and cookies. Wheat was introduced following European settlement and used to make, among other things, noodles, which came to Southeast Asia from China (Chang 1977). Noodles are made and eaten in all the countries of the region, often as snack foods (Wilson 1986). Bread is of some importance in Vietnam and is increasingly common in other parts of the region. Bakeries in major urban centers produce bread and rolls that are sold in shops and markets and by itinerant salespeople. Such baked goods are usually consumed as morning snacks but are considered inferior to rice in relieving hunger.

Palm Staples

The sago palms *(Metroxylon sagu* or *Metroxylon rumphii)* yield a starch from the inner parts of the trunk after they are grated and soaked. This starch is a fallback food, consumed when rice supplies are short in the region. The trees are cut at maturity, about 9 to 15 years after planting, when the starch is at its peak (Burkill 1966). Sago flour is also used in making snack foods.

Another palm, the lontar (*Borassus flabellifer,* also known as the palmyra), grows from India eastward to the Celebes and yields sugar and toddy (wine) in the juices of its trunk. The time required for the lontar to reach maturity is similar to that of the sago (Burkill 1966). The tip of the tree is cut, and the juice collects in a vessel. It may be tapped for several months with daily cuts. J. J. Fox (1977) studied an Indonesian group on the island of Roti, Lesser Sundas, who subsist largely on this juice. Vinegar is made from overfermented lontar toddy (Burkill 1966), and the leaves have long been used in Indonesia for writing; books of leaves fastened together are known as *lontar.*

Staple Qualities

Southeast Asians believe that foods have inherent qualities that affect the body. Such beliefs stem from the humoral systems of Ayurvedic (Indian), Chinese, and Islamic medicine, all of which have influenced these populations over the last millennium (Hart, Rajadhon, and Coughlin 1965; Hart 1969; Lindenbaum 1977; Laderman 1983). Although with ethnic and individual differences, objects, physiological states (including disease), weather, and behaviors are categorized as having degrees of "hot," "cold," and "neutral." Most staple foods are defined as "neutral" among these populations. Manioc, however, is "hot," and eating it is thought to make the body hot, a situation also brought about by consuming animal protein, salt, and some anomalous fruits and seeds. The definition of manioc as "hot" may indicate recognition of the toxic chemical in the raw tuber.

Fish, Meat, and Fowl

Fish

There is little disagreement among experts (Raymond Firth 1966; Hanks 1972) that the dietary staples of Southeast Asians during the historical era have been primarily rice and fish. But the archaeological record is less clear regarding the presence of fish in diets of prehistoric hunter-gatherers, in large part because archaeological research in the area is far from complete. Finds in northern Vietnam of middens of mollusk shells in Hoabhinian-era levels (Burling 1965) indicate an early reliance on foods from the sea, and E. N. Anderson (1988) writes of rich sources of fish and game for central and southern China in Neolithic times. For later periods, Ying-Shi Yu (1977) has noted the finding of several species of fish in the tomb of a Han aristocrat who died in the first century before the present era in Hunan Province (southern China).

The bony fishes antedate mammals by several hundred million years. When the continents reached their present-day positions, land masses blocked fish migration through the tropical seas, but species found in Southeast Asia range throughout these latitudes as far as Africa or Australia. Relatively few comprehensive listings have been compiled, yet Raymond Firth (1966) cites C. N. Maxwell, who described 250 species of marine food fishes for Malaya, and J. S. Scott (1959) lists 294, including the skate, shark, and ray family, and the dolphin, *Coryphaena hippurus,* as sea fishes of Malaya. Though many are edible, the list of favored marine fish is shorter. Raymond Firth (1966) notes that over 20 types were landed at a Malay village in amounts greater than 1,000 tons. Most were of the mackerel family, *Scombroidii,* including herring (*Clupea* spp.) and small horse mackerel (*Scomberomerus* spp.) (Scott 1959). Of deepwater fish feeding near the surface Firth notes dorab or wolf herring *(Chirocentrus dorab),* shad *(Clupea kanagurta),* sprat or whitebait (*Stolephorus* spp.), and anchovies (*Anchoviella* and *Thrissocles* spp.). Bottom feeders taken in quantity during Firth's research included jewfish (among which are numbered croaker, *Umbrina dussumierii, Corvina* spp., *Otolithes ruber,* and several types of *Johnius*), sea bream (*Synagris* spp.), sea perch *(Lates calcarifer),* snapper (*Lutianus* spp.), gray mullet (*Mugil* spp.), and flatfish (including sole, flounder, *Pseudorhombus,* and *Synaptura* spp.) (Scott 1959; Raymond Firth 1966). This list is echoed by Thomas Fraser (1960), Carol Laderman (1983), and Christine S. Wilson (1983).

Other fish common to the region and mentioned by Raymond Firth include pomfret (*Stromateus* spp., generally prized in Southeast Asia), catfish (*Chilinus* spp., not a popular food), sardines (*Sardinella* spp.), bluefish *(Pomatomus salatrix)*, grouper (*Epinephelus* spp.), pike (*Sphyraena* spp.), and scad *(Caranx leptolepis).* Fish have been caught with indigenous methods developed over time, chiefly by nets from shore or small boats, or by handline. Before the existence of motorized transport, these activities were local and subsistent, but commercial trade of sea products seems to have begun with Chinese embassies early in the first millennium (Fraser 1960).

Additional sea animals eaten by Southeast Asians include squid or cuttlefish (*Loligo* and *Sepia* spp.) (Burkill 1966), crabs (*Charybdis* spp.), prawns and crayfish (*Penaeus, Penaeopsis, Parapenaeopsis* spp. and *Peneus semisulcatus;* the spiny lobsters *Panulirus*), and the lobsterlike *Squilla.* Shrimp *(Acetes erythraeus)* (Burkill 1966) and other crustaceans caught in tidal nets are the source of a fermented paste eaten as a side relish with rice meals (Wilson 1970).

A fish of continuing commercial value, used in dishes such as cooked vegetables, is the small whitebait or anchovy (*Stolephorus* spp.). The green sea turtle *(Chelonia mydas)* (Burkill 1966) provides meat occasionally and widely prized eggs seasonally. Mollusks – cockles *(Cardium),* clams, mussels (*Mytilus* spp.), and oysters *(Ostrea edulis* and *Ostrea rivularis)* – are collected along shorelines, often by women and children (Burkill 1966).

Sharks and rays, the Elasmobranchs, are widely found in tropical seas. The gelatinous skeletons are prized by the Chinese, and members of the Carcharidae and Dasybatidae families provide income to fishermen who sell the valued fins (Burkill 1966). The dogfish *(Scoliodon sorrakowah C.),* and other members of this class, are usually eaten by poorer people (Scott 1959; Burkill 1966). Salting (curing in brine) and drying fish have long been practiced. Before ice machines and mechanical refrigeration, these preservation methods permitted the sale of surplus fish at a distance and storage for monsoon months when fishing was unsafe.

Animal Meats

Meat – the flesh of mammals – is chiefly reserved for feasts and special occasions (Geertz 1960; Kirsch 1973; Volkman 1985). Often the flesh is that of the water buffalo *(Bubalus bubalis)* (Burkill 1966), that ancient ricefield plough-laborer. A native of Asia, the water buffalo is said to have been domesticated in many locales, but at present the best evidence points to southern China some time around 5000 B.C. (Hoffpauir, this work). Buffalo milk is higher in fat than that of most cattle, about 7 percent (Heiser 1990), but is little used in Southeast Asia because the populations exhibit high incidences of primary adult lactose intolerance (Simoons 1970).

Other *Bos* species have been domesticated in the region, such as the *seladang (Bos gaurus)* of Malaysia, the *mithan (Bos frontalis)* of Indochina, and the *banteng (Bos sondaicus)* of Java. Some cattle *(Bos taurus),* the species common in the West, are found in the region – mainly in Java and the Philippines (Burkill 1966). *Zebu,* Indian cattle, though well adapted to the climate are relatively rare.

Another ruminant of the bovine family, the goat *(Capra hiracus),* is widespread throughout the region, where it has substituted for more expensive meat species despite its strong flavor. Its Malay name, *kambing,* is well known throughout the region and is applied locally to sheep – *kambing biri-biri* – as well. Rural people neutralize goats' destructive grazing with fences or by staking. Archaeological remains of domesticated sheep have been dated from 9000 B.C.; goat domestication probably was almost that early (Heiser 1990). K. C. Chang (1977) indicates that goats were introduced to China from western Asia in prehistoric times.

The pig *(Sus scrofa)* is said to have been domesticated in the Near East (Anderson 1988; Heiser 1990) around 7000 to 5000 B.C., when villages developed, although Frederick Simoons (1994) suggests that pigs were first domesticated in Southeast Asia. When Islam came to Southeast Asia, its prohibition against eating pork stopped pig raising among many peoples, although others who were not converted continued the practice. Wild pigs are native to Asia as they are to Europe, and it has been suggested that in rural Asian Muslim countries, the animals may be called something other than "pigs" by the natives and, thus, may be hunted and eaten.

Although many wild mammals and birds are protected by legislation (Medway 1969), some are still hunted for meat, particularly by aboriginal peoples. Well liked by all inhabitants of Southeast Asia is another local ruminant, the deer *(Cervus unicolor)* (Medway 1969), along with the mouse deer or chevrotain *(Tragulus javanicus* and *Tragulus napu).* The flesh of this smallest of hoofed mammals is said to be excellent and is salted, dried, and smoked (jerked) throughout Malaysia. Other wild animals that have acted as occasional food sources include the large fruit-eating flying fox or fruit bat *(Pteropus edulis* or *Pteropus vampyrus)* (Burkill 1966; Medway 1969). In addition, jungle tribes may hunt birds, monkeys, and other small animal species for food.

Poultry or Fowl

Chickens *(Gallus gallus)* are generally the most important domestic fowl in Southeast Asia and may have been domesticated there. The archaeological record is not clear, and experts differ as to whether this Asian jungle bird was first domesticated in India or Southeast Asia (Heiser 1990). Yet there is general agreement with I. H. Burkill (1966) that the chicken was early selected for gaming as well as divination, in which both entrails and thigh bones were and still are used (Heiser 1990). Chickens are kept for meat and eggs in rural areas, with the meat often prepared for feasts (Geertz 1960), along with other animal meats. Clifford Geertz and other anthropologists (e.g., Fraser 1960) have noted the frequency of *kenduri* or *slametan,* special feasts of a familial or community nature, with curried chicken dishes to accompany the glutinous rice. Chicken is generally liked and is sometimes a meal-saver during monsoon months when fresh fish is not obtainable.

Fowl eggs have also been valued for use in divination. Simoons (1994), for example, has commented on their use in this capacity by hill-tribe peoples from Assam eastward, while also noting their avoidance (along with fowl meat) because of beliefs associating them with fertility. Others (Rosemary Firth 1966; Strange 1981) have noted the symbolic use of eggs as fertility symbols that are given to female guests at weddings and as spirit offerings to launch a boat or enter a new house.

Simoons (1994) notes a particular preference in this region for brooded eggs, with the embryo well developed – these are especially relished in the

Philippines. He hypothesizes that the practice may have originated, before domestication, in the gathering of wild fowl eggs, which, if they contained half-hatched chicks as recognizable forms of life, were judged as not dangerous to eat. Other poultry kept by Southeast Asians include ducks (the *Anas* species, related to the mallard), which were domesticated independently in both Europe and China (Burkill 1966). In Indonesia, ducks are part of an ecological system that includes rice fields and irrigation ditches containing fish. The ducks subsist on the rice (after threshing) as well as on the fish, while providing eggs and meat for their caretakers. Geese (*Anser anser,* the European domestic species, or an Indian hybrid, *Anser cygnoides*) (Burkill 1966) sometimes play similar roles in rural Southeast Asia. The goose probably reached the region via India.

Nonstaple Plant Foods

Vegetables

Although Western visitors to Southeast Asia have noted native plants sometimes used as food (for example, Burbidge 1989; Wallace 1989), and have commented on "curries" for main meals without always specifying their components (Lewis 1991), nutritionists and anthropologists have been those most concerned with the importance of vegetable foods in Southeast Asian diets. Rosemary Firth (1966), for example, has noted that for Malay fishing people, vegetables are a marginal need. The sandy soil near the sea is not conducive to vegetable propagation, and the people who might have time for such an effort, and who play significant roles in rice raising, have no tradition of gardening. Before the advent of motorized transport, the attitude toward vegetables seemed to be that they made a nice addition to a meal but were not essential to it (Wilson 1988).

Traditionally, the growers of vegetables for market in Southeast Asia have been the Chinese. But others living in rural areas long ago learned of wild plants growing on empty lands and in the forests, including wild ferns, and well into this century, older women made gathering trips to bring these wild plants back for consumption (Wilson 1970). Burkill (1966) lists a number of edible ferns, such as *Diplazium esculentum* and *Stenochlaena palustris,* although most of the species cited are used for making woven objects or for medicinal purposes.

During colonial times, Europeans introduced a number of Western vegetables to the hill stations at higher altitudes. The carrot – *Daucus carota sativus* – is an example: It was carried from Persia to India and then China in the thirteenth century (Herklots 1972). (The Dutch introduced quick-maturing cultivars in Indonesia during the nineteenth century, but roots such as carrots do best at higher elevations.)

Laderman (1983) lists three dozen vegetables that she identified as collected or purchased in an East Coast Malay village. Among those eaten occasionally that are grown locally are many types of spinach, gucil *(Antidesma ghaesembilla),* sweet shoot *(Sauropus androgynus),* and bamboo shoots (*Bambusa* spp.) (Burkill 1966). Several species of amaranths *(Amaranthus gangeticus)* (Herklots 1972) are ancient potherbs here, native to the region and eaten like spinach. Another local spinach abundant in the region is *kangkung (Ipomoea reptans)* (Burkill 1966; Herklots 1972). It grows on or near water, has a peppery taste like watercress, and is also called swamp cabbage.

The Western view that Southeast Asians have little interest in eating vegetables probably results from the climatically difficult enterprise of raising temperate species. Those that are grown are often natives of China or India, such as *Brassica chinensis,* Chinese cabbage, and *Brassica juncea* (Burkill 1966). Among the leguminous plants that are found is the long bean *(Vigna sinensis),* which became a cultigen during ancient times in Asia or Africa and has pods that may measure 1 meter in length (Burkill 1966). Another legume, *Psophocarpus tetragonolobus,* the winged or four-angled bean, was noted in the seventeenth century in the Moluccas as introduced from elsewhere. On the basis of its Malay name, *kachang botor* (*botor* means lobe in Arabic), Burkill (1966) infers that it was brought by Arabs from the African side of the Indian Ocean. The pods and beans are eaten raw or cooked, as is the root. This plant has received international attention in recent decades thanks to its high protein content, along with some derogatory comments because of preparation difficulties (National Academy of Sciences 1975; Henry, Donachie, and Rivers 1985; Sri Kantha and Erdman 1986).

Another legume is the yam bean *(Pachyrhizus erosus).* A native of tropical America, this bean was brought by the Spaniards to the Philippines in the sixteenth century. From there it quickly spread as far as Indochina and Thailand and soon grew wild (Burkill 1966; Herklots 1972). Both young pods and the starchy root are eaten.

Several other leguminous seed pods that originated in Africa or Asia have added protein and variety to Southeast Asian diets. Examples are the gram beans: red *(Cajanus indicus),* the Indian *dhal* (sometimes known as the pigeon pea), green or mung *(Phaseolus aureus),* and black, also known as mung or *dhal* (*Phaseolus mungo* L.) (Burkill 1966; Herklots 1972). Sprouts as well as vegetable cheese have been prepared from both *dhal* beans.

The other bean-cheese source for the region is the soybean, *Glycine max,* which has been cultivated by the Chinese for at least 4,500 years (Herklots 1972). In addition to sprouts and oil, the beans have been fermented to produce *tempe* or tofu and soy sauce, a fermented product soaked in brine and exposed to the sun (Burkill 1966).

The South American groundnut or peanut *(Arachis* *hypogaea)* may have reached Asia early by western as well as eastern routes (Burkill 1966). A variety of races have developed over the last two centuries, some of which have been selected for oil content. Peanut oil production has been a Southeast Asian industry for over a century, with the oil (chemically similar to olive oil) sold in the region. Nuts, ground into paste, cooked with onions, peppers, and other spices, are served with curries, roasted meat, and in fresh fruit and vegetable salads in several Southeast Asian countries.

Two leguminous trees of the *Parkia* and *Pithecolobium* genera provide seeds that are eaten with meals as a relish and also used as diuretics (Burkill 1966). *Parkia biglobosa* is also found in Africa, where the seeds are eaten after roasting, but the preferred species in Southeast Asia is *Parkia speciosa,* the *petai. Pithecolobium* species are found in Asia and America. *Pithecolobium jiringa,* the *jering,* is the seed of choice for both medicinal and food purposes. It may be boiled or roasted. Both seeds smell and taste like garlic, and the odor lingers on the eater's breath.

One vegetable seemingly native to the region is eggplant (also called *brinjal* and *aubergine,* or *terong* in Malay). *Solanum melongena,* related to the potato and tomato, reached India, Africa, and Europe via Spain (Burkill 1966). Charles Heiser (1990) and G.A. C. Herklots (1972) believe it originated in India, reaching Spain and Africa via the Arabs and Persians. The latter authority notes its mention in a Chinese work on agriculture of the fifth century. The plant produces large, egg-shaped fruits, ranging in color from white through golden to green and blackish purple.

Another vegetable – this one has been cultivated in the region for at least two millennia and may, indeed, have originated there – is the climbing snake gourd *(Trichosanthes anguina* or *Trichosanthes cucumerina)* (Burkill 1966; Herklots 1972). The Chinese obtained it from the south, presumably Malaysia, suggesting that it was cultivated there at least from the early Christian era. Another native gourd is the wax gourd *(Benincasa cerifera)* (Burkill 1966; Herklots 1972). Bitter melon or cucumber (*Momordica charantia* L.), a long, green, warty-looking gourd (Herklots 1972) with seeds inside bright red arils, has long been an ingredient in curries (Burkill 1966). It is probably African in origin. The bottle gourd *(Lagenaria leucantha)* may also have originated in Africa; known to the Egyptians, it reached China sometime during the past 2,000 years (Burkill 1966). Other gourds of ancient origin, such as the *Luffah* species, have also served as vegetables (Herklots 1972).

The Chinese or Japanese radish *(Raphanus sativus),* a cultigen of eastern Asia with a long white root, has origins similar to the European radish (Burkill 1966; Herklots 1972). Okra, or "lady's fingers" *(Hibiscus esculentus),* a vegetable assumed to be of African origin (Burkill 1966), is sometimes named a bean in local languages; the Malay term *bendi* is from Hindi (Burkill 1966; Herklots 1972).

The tomato *(Lycopersicum esculentum)* (Burkill 1966) was brought from America to Europe and thence to Asia more than 300 years ago. Eaten raw or cooked, it is also the source of bottled sauces called in many lands *kichap* – the name usually given in Malay to soy sauce. (A Malay calls catsup *sos tematu.*)

Edible toadstools or mushrooms *(Volvariella volvacea)* are grown and eaten in some countries of Southeast Asia (Burkill 1966). With the advent of refrigeration and tinned foods in the twentieth century, a variety of Western vegetable foods became available to people in money economies, particularly in urban locales.

Fruits

Southeast Asia has a wealth of native fruits, as well as some introduced from other regions. Best known is the banana (*Musa* species). Heiser (1990) believes that *Musa acuminata,* the wild banana of Malaysia, was the progenitor of all other banana species. In fact, Heiser feels that Southeast Asia was the original home of all bananas, although Betty Allen (1967) suggests that the place of origin may have been India.

Cultivated bananas may be small or large, red- as well as yellow-skinned, and sweet or tart. Plantains have always been eaten cooked; some other races, cultivated for centuries, are dipped in batter and fried. Flowers from banana plants of a Philippine race are served as a vegetable. For millennia the leaves have been used as wrappings for food and as temporary rain cover.

Citrus fruits are also of Asian origin, although grapefruit may be an exception (Burkill 1966; Heiser 1990). Species have been cultivated in subtropical climes from before the time of Alexander the Great. *Citrus microcarpa* (Burkill 1966) is a small, round, green ball of a fruit (sometimes called the music lime) long used in cooking and making drinks, as is *Citrus aurantifolia* (much like the West Indian lime). *Citrus nobilis* (Burkill 1966) is the Mandarin orange or sweet lime, not to be confused with *Citrus sinensis,* the sweet or Chinese orange familiar to Western palates, though both may have originated in China. The rind of the Mandarin orange, green to orange in color, peels easily like that of a tangerine, and the segments are readily removed. Native to Southeast Asia is *Citrus maxima* or *Citrus grandis* (Burkill 1966; Allen 1967), the sweet pomelo, as large as a grapefruit. It reached Europe in the twelfth century (Eiseman and Eiseman 1988) and is now sold in U.S. markets. It is highly valued in Southeast Asia, where it is associated with the Chinese New Year.

Garcinia is a genus of trees of the rubber family in the Old World tropics (Burkill 1966). A number of species have edible fruits, and several yield dyes, ink, or watercolor paint. *Garcinia mangostana,* the mangosteen, is a favorite throughout Southeast Asia and has been known elsewhere since the voyages of exploration; it is also famous for having earned the admiration of Queen Victoria. The small, round fruit has a ¼-inch (0.635 centimeter), dark red to purple rind, and five or more white, fleshy segments of edible matter with a delicate, slightly tart flavor. F. W. Burbidge (1989) was enthusiastic about the mangosteen when he wrote in 1880, as was Alfred Wallace (1989: 148), who commented in his mid-1850s report on the Malay Archipelago that "those celebrated fruits, the mangosteen and . . . durion . . . will hardly grow" elsewhere. *Garcinia atroviridis,* a bright yellow-orange, acid-astringent, fluted fruit about 3 to 4 inches (8 to 9 centimeters) in diameter, and eaten as a relish (Burkill 1966), is native to Malaysia and Burma and common in Thailand (Allen 1967).

Several members of the Sapindaceae family have a tart-sweet pulp, with the best known, *rambutan (Nephelium lappaceum),* named for the hairlike cilia extending from its red or yellow rind. Native to the region, it is widely cultivated, but wild forest specimens are also found (Burkill 1966). Also native is *Nephelium malaiense* ("cat's eyes"), which is small with a buff skin (Allen 1967). The litchi (lychee) from southern China *(Litchi chinensis)* is cultivated as well (Burkill 1966).

Other fruits with refreshing pulp include the langsat *(Lansium domesticum)* – an indigenous fruit that is now cultivated. It was noted by the Chinese in Java in the fifteenth century (Burkill 1966). *Salak (Zalacca edulis)* is a similar fruit from a palm that grows throughout Southeast Asia. Its thin, brown skin looks like that of a lizard (Burkill 1966; Eiseman and Eiseman 1988).

Two members of the rubber and castor oil family produce pleasant fruits. One, *Cicca acida* (Burkill 1966; Allen 1967), known in English and Malay as *chermai,* the Malay or Otaheite gooseberry, is a very tart tree fruit. Although it has been cultivated for centuries, its place of origin is not known. The other fruit, *rambai (Baccaurea motleyana),* is a Southeast Asian native and has long been cultivated there (Allen 1967).

Perhaps the most famed Southeast Asian fruit is durian *(Durio zibethinus)* (Burkill 1966), which grows on trees too tall to climb (70 to 80 meters or more). Ovoid or round, variable in size, each fruit may weigh several kilograms. The thick, green rind has sharp spines that cushion its fall. Inside are four or five arils of soft pulp surrounding seeds. Durian smells and tastes like onion, garlic, or cheese. The fruit is edible for only a few days after dehiscing, after which it undergoes rapid chemical change (Wilson 1970). Most Southeast Asians and some Europeans relish this seasonal fruit, and the seeds are roasted and eaten as well. Durian conserves, sweet or salty, have been made by local people, and in recent decades durian ice cream has been developed.

The mango *(Mangifera indica)* is the most famous member of its family, which originated in India (Burkill 1966). Other species grow throughout Southeast Asia. It has been known for more than 4,000 years (Allen 1967) and was one of the earliest tree fruits to be cultivated (Eiseman and Eiseman 1988). Fruits may be 17 centimeters (7 inches) long, and about 7 centimeters (3 inches) in diameter. When ripe, the flesh is yellow to reddish, sweet, aromatic, and much prized. *Mangifera odorata,* called *kuini* in Malay, is also sweet when ripe, with a resinous smell. The horse mango, *Mangifera foetida,* is inedible until ripe. Both *M. odorata* and *M. foetida* are fibrous and are sometimes eaten to help remove intestinal parasites.

A New World member of this family, *Anacardium occidentale* – the cashew – was brought by the Portuguese in the sixteenth century to become one of the first American trees cultivated in Southeast Asia (Burkill 1966; Allen 1967). The tart fruit, a greenish pedicel the size of an apple, which is rich in ascorbic acid, and its appended nut are both well liked. The nut must be boiled or roasted to remove an irritant chemical, cardol. In rural areas, monkeys and fruit bats vie with human consumers for the fruit, which otherwise serves as a cooked relish with a rice meal.

Two members of the Urticaceae family, *Artocarpus integra* and *Artocarpus champeden* (jackfruit and *chempedak*), are native to Asia, the jackfruit coming from India (Burkill 1966). Both have large fruits as long as 30 centimeters (1 foot), with mottled green, bumpy rinds and yellowish, creamy flesh surrounding seeds that are boiled before eating. The fruits are used to make sweetmeats. Historically very popular, they were known to Pliny. *Artocarpus communis* (breadfruit), a member of this family, is less common and not much consumed.

Two small trees native to Malaysia produce acid fruits that are cooked and used as tart, refreshing relishes, *Averrhoa bilimbi* and *Averrhoa carambola* (Burkill 1966). The latter, brought to the West by early explorers, is known in Western countries as starfruit because of its shape when cut horizontally. In Asia, both are called *belimbing.* Four tropical American fruits, *Annona muricata* (soursop, or "Dutch durian"), *Annona reticulata* (custard apple or bullock's heart), *Annona cherimola* (cherimoya), and *Annona squamosa* (sweetsop), were brought very early to Southeast Asia (Burkill 1966).

Eugenia, found throughout the tropics, has more than two dozen species in south India and Southeast Asia that have grown wild and been cultivated for centuries for their valued fruits. One, *Eugenia aromatica,* produces cloves. Others have pearlike, rosy or pink-tinted fruits, about 5 to 7 or more centimeters long (2 to 3 inches), that are called *jambu* in Malay, and "apples" by English speakers: *Eugenia aquea* (or *Eugenia jambos*) are water or rose apples, *Eugenia malaccensis* is the Malay apple, and *Eugenia javanica* is the Java apple (Burkill 1966). Also of this Myrtaceae family is the guava, *Psidium guajava,* an American native brought by the Spanish across both the Atlantic and Pacific at an early date (Burkill 1966). The thin, green skin becomes yellow and soft at maturity;

the pulp is white, greenish, or rose, with many small seeds. They are good eaten raw and make excellent juice drinks.

Other well-liked, early introductions from the Americas are papaya *(Carica papaya),* pineapple *(Ananas comosus),* and passion fruit *(Passiflora laurifolia).* Papaya reached Southeast Asia via the West Indies before the sixteenth century (Burkill 1966; Allen 1967). A large herb, it is fast-growing, producing fruit in six months. Ever-bearing, the papaya is a useful dooryard plant, rich in nutrients, green-skinned until ripe, with yellow to red flesh, and 15 to 35 centimeters (6 to 14 inches) in length.

Pineapple was cultivated in America from remote times, and the Europeans brought it around the world to all parts of Asia before the seventeenth century (Burkill 1966). A pineapple plantation industry was developed during the nineteenth century in Malaysia, Indonesia, and the Philippines, when canning was introduced (Allen 1967). Passion fruit, a climbing herb of tropical America, was also introduced to India and other Asian countries in the nineteenth century (Burkill 1966).

Fruits of purple *Passiflora edulis* and yellow *Passiflora laurifolia* are sweet in smell and taste and suitable for both eating or juice. *Passiflora quadrangularis,* the grenadilla, is popular in Indonesia. Unripe it serves as a vegetable and is also preserved in sugar. Not a fruit but a similar snack is sugarcane *(Saccharum officinarum),* a grass eaten by chewing the cane, or drunk as pressed juice (Burkill 1966). It was domesticated in New Guinea or Indonesia during remote times (Heiser 1990). Burkill (1966) has documented its spread through Asia, and Sidney Mintz (1985) has provided its later history. Early Indian references to the crystallized form of sugar date from several hundred years B.C., and Alexander the Great noted it during his voyages (Burkill 1966). The watermelon *(Citrullus vulgaris),* an African plant known to the Egyptians (Burkill 1966), reached China via India in the tenth century and is grown in some Southeast Asian countries. The fruits resemble North American varieties in color and character.

Fruits native to the region but less well known because they are seldom marketed are cultivated in dooryards for local consumption. Among these are *Sandoricum indicum* (the *sentul*) (Burkill 1966) and *Erioglossum rubiginosum (mertajam),* a tree with small red to black astringent fruits, called *kerian* by Malays. The *kundungan (Bouea macrophylla)* is a small tree related to the cashew that is cultivated in villages (Burkill 1966). It is native to Malaysia and much of Indonesia, with a sour-to-sweet taste. Further north, it is called *setar* for the capital of Kedah, Alor Star (Allen 1967).

Kemuntung, or rose myrtle, a shrub of the Myrtaceae family *(Rhodomyrtus tomentosa),* produces small, wild fruits prized by children. Still other fruits have been available since refrigerated shipping began; pears, grapes, and oranges are enjoyed by rural people who can afford market prices. Some grow in hill stations or at high altitudes. A few wild species of *Prunus,* relatives of the peach *(Prunus persica),* as well as species of *Pyrus,* related to the pear *(Pyrus communis)* and the apple *(Pyrus malus),* are grown, but most are of European origin (Burkill 1966).

Spices and Seasonings

Southeast Asia encompasses the Spice Islands, whose lure motivated the fifteenth- and sixteenth-century European voyages of discovery. Most sought after were pepper *(Piper nigrum),* cloves *(Eugenia aromatica),* and nutmeg *(Myristica fragrans)* (Reid 1993). Although clove and nutmeg trees are Southeast Asian natives and have been cultivated for centuries, their early history is dim (Burkill 1966). Clove was known to the Chinese by 300 B.C.; it was in Egypt by the first century A.D. and reached the Mediterranean by the fourth century. Arabs brought nutmeg to Europe in the sixth century. Nutmeg, which is also the source of mace, is made into a sweet by boiling to remove tannin before adding sugar (Burkill 1966). Before the twentieth century, it was candied for sale in Europe.

Piper is a genus of many species that grow in moist, warm parts of the world (Burkill 1966). *Piper nigrum,* with both black and white berries, was apparently first cultivated in India; its name in countries to which it subsequently spread are cognates of the Sanskrit *pippah.* By the sixteenth century, it became an export plantation crop in Dutch-controlled Sumatra and in other countries (Andaya 1993). Supplanting the Portuguese, the Dutch assured their profit by allowing cultivation only in areas they controlled by treaty with local rulers. All these spices remain important cuisine condiments and, thus, important commercial crops (Steinberg 1970).

Cinnamon *(Cinnamomum zeylanicum),* the bark of a tree of eastern and southeastern Asia, is another aromatic spice of ancient origin (Burkill 1966). The genus was once common in Europe and was known to the Egyptians, Hebrews, and Aryans. *Cinnamomum cassia,* a Chinese tree known over the last two millennia, provides cassia, an alternate form of cinnamon in Southeast Asia. *Cinnamomum zeylanicum* grows wild at high elevations in western India and Sri Lanka (Ceylon) and still produces the best cinnamon (Burkill 1966). Both cassia and cinnamon are known in Malay as *kayu manis* ("sweet wood") and are used medicinally as well as for seasoning.

Ginger (*Zingiber* species) is an herb native to tropical Asia and the Pacific (Burkill 1966), where several species and races grow wild. *Zingiber officinale* was cultivated in India and China before the Christian era (Yu 1977). The fresh rhizomes are used medicinally and as flavoring and are also dried and candied. Another family member, galangal *(Zingiber galanga)*

(Burkill 1966), is also native to tropical Asia and India and has been extensively used in Malaysia and Java. Its history and use compare to that of ginger.

Turmeric *(Curcuma domestica),* from the same family, is a Southeast Asian native as well and was used as a condiment (a substitute for saffron) and dye long before the Aryans reached India (Burkill 1966). Its color was the same as the royal color of India and the Indianized states of Southeast Asia, and turmeric was used in weddings and to tint ceremonial rice (Rosemary Firth 1966). Cardamom *(Amomum kepulaga)* (Burkill 1966), still one more herb of the ginger family, grows wild in Java and is cultivated as a breath sweetener and for use in curries.

Other important seasonings in general use have reached Southeast Asia from the outside world. Chief among these are members of the lily family (*Allium* species, such as onions, garlic, shallots, leeks, and chives) and chilli peppers (*Capsicum* species, which are natives of the Americas). Alliums are northern plants, mainly from the Mideast, where they have been grown since ancient times (Burkill 1966). But garlic *(Allium sativum)* and others were also cultivated long ago in India, spreading east from there. Bulbs of the *Allium* species (for example, shallot – *Allium ascalonicum*) are grown for market in hilly parts of Indonesia and the Philippines; most, however, are imported from India. All are ingredients in curries and used as seasonings, and most have also been employed medicinally for generations (Skeat 1967; Gimlette and Thomson 1971). Shallots are eaten raw individually or in salads along with other vegetables and are pickled in brine. Garlic is more prominent in areas closer to China. *Allium cepa,* the white or red onion, may be shredded and deep-fried as a condiment for other foods, as may shallots.

Columbus brought *Capsicum* (the chilli pepper) to Europe, whereupon writers of the time commented on its introduction (Burkill 1966). But less than 50 years later it was termed the "pepper of Calicut," a misnomer that ignored its New World origin. Chilli peppers have long been cultivated in Central and South America, and their European names reflect Spanish versions of the Mexican term *aji* as well as the desire of Dutch black pepper traders to save their own product from confusion by means of another Spanish translation, "*chilli.*" Early on, naturalists distinguished over a dozen races, but the main species remain *Capsicum frutescens,* the sweeter, less pungent type represented by bell peppers, and *Capsicum annuum,* the very hot, small perennial known as bird pepper, which is the source of tabasco.

A number of races of both grow in Southeast Asia. *Capsicum baccatum* var. *baccatum,* the source of cayenne (Herklots 1972), has been used medicinally and for arrow poisons in Asia as it was in South America (Burkill 1966). Certainly the chillies are much appreciated in Southeast Asia. Burkill has noted that Malays prefer *Capsicum* to "black" pepper in cookery, and Westerners have long commented on the fiery nature of Thai cuisine (Steinberg 1970). The active principle in peppers is capsaicin, an alkaloid known to irritate skin and mucous membranes (Burkill 1966). It is also said to be addicting (Pangborn 1975), which may explain its lengthy history of use in Southeast Asia as well as in America (Rozin and Schiller 1980). Chillies have long been dried for market sale throughout Southeast Asia.

Tamarind, a leguminous tree with pulp-filled pods, was known to Greeks in the fourth century B.C. Although it probably originated in Africa or India, it was early cultivated in Southeast Asia (Burkill 1966). The pulp of *Tamarindus indica,* which is sweet to tart, looks in its marketable form like dates, which prompted Arabs and Persians to call it *tamar,* the Indian date (Burkill 1966). It is used as a relish and in cooking, and the flowers are sometimes eaten as well. In Java, the pulp is salted and made into balls that are steamed for preservation. Tamarind has also been used for medicinal purposes, to fix dyes, and to clean metal.

A grass native to the region, *Cymbopogon citratus* – lemon or citronella grass – has been cultivated as a food flavoring, a liquor spice, and a tea (Burkill 1966). In Java it is part of a spicy sherbet drink, and in Malay it plays a role in medicine and magic. The Portuguese took it to Madras in the seventeenth century, and it subsequently spread to all the tropics (Skeat 1967).

Three herbs of the temperate Old World or Levant, caraway, coriander, and cumin *(Carum carvi, Coriandrum sativum, Cuminum cyminum),* have been seasonings in Southeast Asia since their introduction at about the beginning of the Christian era. Because they have a past prior to written records (Burkill 1966), they are sometimes thought of as interchangeable, and anise *(Pimpinella anisum),* another family member, has been associated with them because of its odor and flavor. Anise was known to the Egyptians and, within the past thousand years, was carried by Arabs or Persians to China and India. In Malay, anise, caraway, and cumin are all called *jintan* (Winstedt 1966). Fresh coriander leaves (cilantro, or Chinese parsley) are used to flavor soups, meat, and fish dishes; the Thais, in particular, have a passion for them uncooked in many dishes.

Basil *(Ocimum basilicum* and *Ocimum canum),* an herb of the warmer parts of the world, has religious or symbolic roles as well as seasoning and medicinal ones in Southeast Asia (Burkill 1966). The Hindus, to whom it is sacred, may have introduced *Ocimum* species to Southeast Asia during "Indianization" (Coedes 1968). Mint (*Mentha arvensis* and other species), a similarly fragrant herb, is cultivated at higher elevations and used for flavoring and for medicines (Burkill 1966).

Salt has been a substance of physical as well as economic need (to produce dried seafoods) in Southeast Asia and, therefore, has been an item of commerce as well (Kathirithamby-Wells 1993). The salt trade probably antedates written records. Seacoast areas have long been local sources, and sea salt from solar evaporation has been produced in Thailand, Indonesia, and Vietnam for export as well as domestic use (ICNND 1960, 1962; Raymond Firth 1966); in addition, Thailand has salt deposits in the northeast (ICNND 1962).

Unfortunately, the local salt is not iodized, and iodine-deficiency diseases are a health problem in several of these countries (ICNND 1962) despite reliance on seafood, which is a good source of the mineral. The incidence of goiter on Bali, for example, may result from the Balinese preference for pork instead of seafood.

Although honey was undoubtedly the earliest sweetener, the boiling of the inflorescence of the nipa palm *(Nipa fruticans)* to make sugar has been an enduring cottage industry (Burkill 1966; Winstedt 1966). Refined white cane sugar has been much prized for hot drinks, but although refining was done in Java and other locales from early colonial times (Burkill 1966), it has proved too expensive for rural people, even in recent decades (Rosemary Firth 1966). Perhaps unfortunately, however, it has become a dietary essential (Wilson 1970, 1988).

Vinegar has been made from both palm and cane sugar, as well as from rice and fruit pulp (Burkill 1966). It occurs naturally if palm or fruit syrup is allowed to ferment more than 40 days. It is used in food preparation, and much of it has been imported from China in recent decades.

Soy sauce and the fish soy of Vietnam, *nuoc mam,* have already been briefly discussed. *Nam pla* or *pla-ra* (ICNND 1962) is the Thai version. Malay coastal villagers make *budu* by salting small fish, such as anchovies, in vats until the mixture ferments (Wilson 1986). A Philippine version is called *patis* (Steinberg 1970). A similar product, *gnapi,* is made in Burma by allowing fish to decay in the open (Lewis 1991). Shrimp paste is similarly made in most of these countries. The Malay version is *belacan,* the Indonesian *terasi,* and the Philippine *bagung.* These products are relishes or side dishes, often enlivened with fresh raw chillies; all are excellent sources of calcium and protein (Wilson 1986) and, with the chillies, of vitamin C.

Although not a condiment or a seasoning, yeast for household cooking is locally made (Wilson 1986). Burkill (1966) reports that the Javanese use their word for yeast, *tapai* (of Arabic origin), to include the Malaysian preparation *ragi* (from the Hindu) (Winstedt 1970). To rice flour and several spices, *Aspergillus* fungi as well as *Saccharomyces* spores are added, some adventitiously. This combination results in the fermented glutinous rice cakes, *tapai* (Wilson 1986), and also toddy.

Cooking Fats and Oils

Until the past few decades, the cooking mediums in Southeast Asia have been water, oils, sauces, and coconut milk. To save fuel, most cooking was done over wood fires, as quickly as possible, and long, slow roasting was done over coals. The premium oil has been coconut *(Cocos nucifera).* The nut of this palm is the seed of the fruit, and its grated ripe flesh, squeezed in water, also provides coconut milk (*santan* in Malay), the base for the curries of the region. This "most useful of trees" (Heiser 1990) requires warmth and moisture to grow well, and seacoasts provide the best climate. Southeast Asia produces 90 percent of the world's coconuts.

When the coconut was domesticated is not known (Heiser 1990). Its importance to Southeast Asians can be seen in the Malay names given it at every stage of development (Burkill 1966). It is planted by human effort at house sites, and when the trunk has formed, it will fruit in 4 or 5 years, yielding about 50 fruits a year for decades. The nut reaches full size before the meat forms and is fully ripe in one year. People generally pick coconuts, but the Malays and Thais also train the macaque, or "pig-tailed," monkey *(Macacus nemestrina)* to climb the trees and gather ripe fruits when they are ready to fall (Wilson 1970).

The water inside can be drunk for refreshment before the fruit ripens, but it is astringent. The endosperm of a 10-month fruit is eaten with a spoon as a delicacy, whereas the meat of the ripe endosperm is grated for consumption. It is also sun- or heat-dried to make copra, which is pressed for oil as both a cottage and commercial industry. The oil, milk, and meat of coconuts were used in cooking long before the arrival of Europeans. In addition, the husk provides coir for rope, and the shell is both employed as a utensil and made into charcoal. Different parts of the coconut at different development stages are used in pregnancy, in childbirth, and in magical rites (Burkill 1966). The immature inflorescence of the tree is bound in anticipation of later tapping for toddy production.

The oil palm *(Elaeis guineensis)* (Burkill 1966) was brought to Southeast Asia from West Africa as a plantation crop in the nineteenth century by colonial powers, and new plantations have continued to be planted. Most production goes into oil for commercial export to make soap and margarine as well as cooking oil. Palm oil is chemically similar to coconut oil. Other vegetable oils, such as that of the soybean, are imported from China and India.

Beverages

The most important beverages for early humans in Southeast Asia, as elsewhere, were water from rain, streams, ponds, and lakes, and liquids that could be obtained from fresh fruits (Robson 1978). All other drinkables are introductions, although tea *(Camellia sinensis)* is grown in the region. Anderson (1988) indicates that tea probably originated somewhere in the Burma–India border country and was taken to China by Buddhist monks, to become a passion there before the middle of the first millennium A.D. Burkill (1966), however, relying on earlier writers, suggests that tea did not reach western Asia before the thirteenth century. The Dutch and British independently established a sea trade in green tea, and in the eighteenth and nineteenth centuries, the plant was introduced to India and to various locales in Southeast Asia. Basic tea flavors come from postharvest processing of the leaves. Green tea is dried and rolled; black tea is fermented before drying (Burkill 1966).

Coffee originated around the Red Sea (Heiser 1990), where it still grows wild (Burkill 1966). As its Latin name, *Coffea arabica,* suggests, the Arabs were the first to use it as a drink (in the thirteenth century), but whether this was done before or after the technique of roasting (to enhance the flavor and aroma) was developed is unclear. Coffee beans (like some tea leaves) are fermented before roasting. Use of the beverage spread, with the drink reaching Europe in the seventeenth century. The first planting of coffee outside Arabia was in Java in 1696, under Dutch direction. In the next century, the plant radiated to all parts of the world's tropics and had become an industry in Java by the 1800s. Early in that century, Dutch administrators enforced greater cultivation of the shrub, particularly at higher elevations in Java, and entire forest ecosystems were replaced in the process (Hefner 1990).

Smaller plantations in other countries of the region were begun at about this time. A number of species have been cultivated in Southeast Asia, with some, including *C. arabica,* susceptible to the fungus *Hemileia vastatrix,* which spread from Ceylon in the mid-nineteenth century (Burkill 1966). The fungus drove some planters to Malaya, and one resistant species, *Coffea liberica,* was introduced at that time. Coffee (like tea) has generally been drunk hot, often with sugar and sweetened condensed milk.

Adoption of both tea and coffee no doubt owes much to their stimulating effects (Heiser 1990), but how this became recognized is not known, for processing is needed to make their action noticeable. The alkaloids causing the effects are caffeine and similar compounds. Cocoa, another beverage containing a related substance, theobromine, is much less used in Southeast Asia, although the tree, *Theobroma cacao,* was introduced in several locales by planters as a replacement for coffee destroyed by the fungus. Originating in the New World, cacoa trees were in the Philippines by the seventeenth century and in Malacca during the following century. Thus, Spaniards, Portuguese, and Dutch all took part in its dissemination. The cocoa bean is fermented and roasted (like coffee) to produce the powdered material from which the drink is made.

Commercial bottled or tinned beverages are recent introductions. Rosemary Firth (1966) has commented that soft drinks and sweetened condensed milk were considered luxuries in Kelantan, Malaya, in 1963, and prior to World War II were largely unknown. By the late 1960s, however, colas and other carbonated beverages had reached remote villages and, by the mid-1980s, advertisements for well-known brands were common. Local or regional industries produced bottled soy milk for adult consumption. By then, bovine milk processed to remain fresh without refrigeration, and packaged in cardboard containers, had reached village shops, as had similarly processed and packaged fruit drinks. Instant coffee and juice powders, for reconstitution with water, also became available.

Alcoholic Beverages

Muslims are forbidden alcohol-containing beverages, but non-Islamic Southeast Asians have produced local beers and wines as well as toddy. Early dwellers probably sampled sap and other fermentable products and learned how to encourage the process (Burkill 1966). Toddy, the most common of old Southeast Asian drinks, is made from palm sap. Fermented glutinous rice *(tapai)* produces wine during processing that is 3 percent alcohol (ICNND 1964). Spirits had become familiar in Southeast Asia before the end of the sixteenth century, when the Chinese began distilling alcohol in Java (Burkill 1966).

Nonnutritive Ingestants and Inhalants

Oral activity may take place for behavioral or physiological reasons not related to nutrition (Oswald, Merrington, and Lewis 1970). Southeast Asians' most common nonnourishing oral activities involve the substances betel nut and tobacco, which are often chewed together (Burkill 1966; Reid 1985).

Areca nut *(Areca catechu)* is the seed of a native Malaysian palm (called the betel palm) that spread to India and East Africa between A.D. 1000 and 1400. Betel is also the name of the leaf of the pepper *(Piper betel),* also Malaysian, in which the quid is wrapped (Burkill 1966). The nuts are sun- or heat-dried, split, and cut into pieces for the chew. The active principles are alkaloids affecting the nervous system, as does nicotine (Burkill 1966). The quid usually includes lime (calcium carbonate from seashells) that helps to release the stimulants. When these substances came into use in Southeast Asia is unclear, but their oral use was known in southern China by the fourth century A.D. (Anderson 1988). Ash of the nut has been used as tooth powder, and the nut itself is used medicinally, magically, and ceremonially (Wilson 1970).

V.B.3 China

Legend has it that when Emperor Tang, the founder of the Shang dynasty (sixteenth to eleventh centuries B.C.), appointed his prime minister, he chose Yi Yin, a cook widely renowned for his great professional ability. Indeed, in the Chinese classics (the oldest of which date from the eighth and seventh centuries B.C.) the art of proper seasoning and the mastery of cooking techniques are customary metaphors for good government (Chang 1977: 51; Knechtges 1986). Moreover, in certain contexts the expression *tiaogeng,* literally "seasoning the soup," must be translated as "to be minister of state"!

That government should be likened to the cooking process is not really surprising, considering that the foremost task of the emperor was to feed his subjects.[1] Seeing the sovereign, the intermediary between heaven and earth, in the role of provider of food is in keeping with a mythical vision of primeval times. According to legend, the first humans, clad in animal skins, lived in caves or straw huts and fed on raw animals, indiscriminately devouring meat, fur, and feathers in the same mouthful. Shennong, the Divine Farmer, one of the mythical Three August Sovereigns and founders of civilization, taught men to cultivate the five cereals and acquainted them with the blessings of agriculture (Zheng 1989: 39) after Suiren had taught them to make fire for cooking their foods. In mythology, cooking is associated with the process of civilization that put an end to the disorder of the earliest ages and led to a distinction between savagery and civilized human behavior.

Throughout Chinese history, the cooking of foodstuffs and the cultivation and consumption of cereals were considered the first signs of the passage from barbarity to culture. Thus the Chinese of the Han ethnic group set themselves apart from surrounding nationalities who, they said, had no knowledge of agriculture or did not know about the cooking of food (Legge 1885: 223; Couvreur 1950, 1: 295; Chang 1977).

Cooking and food, then, were assigned a major role in ancient China. This is very clear in the *Zhou Ritual,* a compendium describing the idealized administration of the Zhou dynasty (1066–771 B.C.). Written in the fifth century B.C., this compendium indicates that half of the personnel of the imperial palace were occupied in the preparation of food, meaning that more than 2,000 persons were involved in handling the food of the sovereign and his family (Knechtges 1986: 49).

In the third century B.C., the authors of the *Lüshi chunqiu,* a compendium of the cosmological and philosophical knowledge of the time, credited cook and prime minister Yi Yin with inventing a theory of cuisine and gastronomy that became a major point of reference for posterity. The culinary principles of Emperor Tang's minister (in fact a set of rules of good government) were to remain the implicit standard adopted by all the subsequent authors of culinary works. Yi Yin classifies all foodstuffs according to their origin, categorizes flavors, indicates the best sources of supply and the best products, and stresses the importance of the mastery of cooking techniques and the harmony of flavors. He points out that raw foods, whether they belong to the vegetable, animal, or aquatic kingdom, have a naturally disagreeable odor, which can be corrected or intensified by the combination of the five flavors and the mastery of the three elements, water, fire, and wood. These techniques make it possible to create, at will, balanced sweetness, sourness with acidity, saltiness without an excess of brine, sharp flavor that does not burn, and delicate but not insipid tastes (Chen Qiyou 1984; Knechtges 1986).

To this day, cuisine in China is implicitly defined as the art of using cooking and seasoning to transform ingredients steeped in savagery – as their unique smells indicate – into edible dishes fit for human beings living in society. Dishes cooked in this manner are not only edible but healthful. In ancient China, all foodstuffs were considered both nutriment and medicine. In principle, the dietary regime was supposed to provide all that was needed to maintain the body's vital energy. It was – and still is – believed that the first step in treating an illness must be a change of diet and that medications should be brought to bear only if diet proves ineffectual. Foodstuffs were, therefore, classified by their "nature" (hot, cold, temperate, cool) and their flavor (salty, sour, sweet, bitter, acrid) as part of a humoral medicine founded on matching, contrasting, or combining these qualities with those of the illness to be treated. Although there is some controversy as to where ideas of hot and cold foods originated (with Greece and India leading candidates along with China), it is a credit to the great originality of the Chinese that they invented what one might call a "medicinal gastronomy," which, still in vogue, endeavors to heal by using the pharmacopoeia without sacrificing the aesthetics or the tastes of high-class cuisine.

The Importance of Cereals

Although emperors and the princes enjoyed the privilege of savoring the very finest dishes, they, like everybody else, could not get along without cooked cereals. For in ancient as in modern China, cereals have been assigned the function of nourishing and sustaining life, which has given birth to the model of the Chinese meal, whose antiquity is suggested by the classic texts. When Confucius asserted, for instance, that a little coarse rice washed down with water was enough to make him happy, he meant to indicate that he was humble and modest, but he also was making the point that no one can survive without these two ingredients. In normal times, Confucius liked to eat his rice accompanied by fine dishes and complemented by wine. But he made it clear that the quantity of meat should never exceed that of rice. Underlying this recommendation is the norm that makes cereal the centerpiece of the meal (Legge 1893).

Cereal, or more precisely starch, remains the basic ingredient of the daily meal in China, and despite an increased meat consumption of late in urban areas, a very large majority of the population continues to derive almost 90 percent of its proteins from vegetable foods.

An ordinary meal consists of a starch cooked in water or steamed and a choice of several dishes prepared with meat, fish, eggs, vegetables, and products derived from soybeans. Such a pattern is not peculiar to China. This kind of meal was also the norm in preindustrial Europe and still exists in many countries where foods such as couscous, corn tortillas, polenta, and bread are considered the staff of life. The dishes or sauces that accompany them are more a matter of seasoning and gastronomic pleasure than of dietary bulk.

In China, not all staples have the same status. Two of them, rice and wheat, are the most highly valued, with millet and maize less appreciated. Tuberous plants, such as taros, yams, and white and sweet potatoes, are generally disliked and considered poor substitutes for the prestigious cereals.[2]

From an agricultural point of view, wheat, various millets, and maize are the typical cereals of the north,[3] whereas rice is characteristic of the regions south of the Yangtze River and of western China. But that more wheat buns are eaten in Beijing than in certain poor country places of Guangdong Province is not simply a matter of climate and geography. When in the past the prince and his entourage enjoyed ravioli made of fine wheat flour, the peasant, the soldier in the field, and the hermit made do with gruel, in keeping with their social status (Sabban 1990). Access to "fancy" cereals still depends on a family's economic situation. Sometimes the inequalities are stark. Whereas prosperity and city living attenuate the differences by offering wide food choices to the inhabitants of Beijing, Shanghai, or Canton (Guangzhout), who thus do not experience the constraints of local supply, poorer people and peasants living far from urban centers have access only to the cheapest local products.

It is, therefore, only on festive occasions that ordinary people treat themselves to a good banquet, during which they almost dismiss the tyranny of the daily cereal. On such occasions cooked dishes become the center of the meal, and when rice or steamed buns are served at the end, the guests will casually take only a mouthful or two. For once, they have filled up on dishes that ordinarily only complement the meal. Such short-lived disdain for a foodstuff that is venerated in day-to-day life is a way of expressing one's pleasure and satisfaction.

The Historical Roots of the Different Chinese Cuisines

In an area larger than that of Europe, the territory of China stretches some 5,000 kilometers from the Siberian border in the north to the tropics in the south and a similar distance from the Pamir Mountains in the west to the shores of the Yellow Sea in the east. This climatic and geographical diversity makes for a variety of Chinese cuisines. However, the division of China into gastronomic regions is relatively recent and does not obscure the ancient contrast between North and South China, which is as pertinent as ever.

As already suggested, the production of different cereals as basic staples has made North China and South China two distinct entities with identifiable political, cultural, and economic roots. Throughout Chinese history the location of the capital has moved back and forth between the north and the south, and with it the court and the decision-making bodies. Such shifts also meant that each new capital became the center of innovation in fashions and taste, and on such occasions the other part of the Chinese world was made to adopt the values and views of the capital.

This struggle for preeminence has always been mirrored in the cuisine and food habits of the Chinese. A political exile, for instance, might evoke a specific food to signify his homesickness and indignation about the injustice he is suffering. Or, again, one who has betrayed an unfamiliarity with foods peculiar to the "other" China gives a reason for others to stigmatize his or her ignorance, or naivete, or haughtiness.

The strong allusive value of some foodstuffs that assumed the rank of regional emblems thus made deep or nuanced comparisons unnecessary.[4]

As we have seen, wheat was to the north what rice was to the south. Most characteristically northern, however, were the breads, cakes, and wheat-based noodles, all subsumed under the generic term *bing* until the end of the Tang (A.D. 618–907) (Sabban 1990). These foodstuffs were highly appreciated by the aristocracy and identified those who ate them as "northerners," as did mutton and milk products.

The cuisine of the south, by contrast, was characterized by rice and also by pork, vegetables, and fish. Indeed, as shown by archaeological findings from ancient times and supported by more recent texts, fish have long occupied an important dietary role for the Chinese, who very early developed techniques of pisciculture. But even more important than pond-raised aquatic animals were the freshwater fish and shellfish present in the rice paddies of the lower Yangtze River. In this area, covered with rivers, lakes, and streams, large carp grew naturally along with an abundance of vegetables.

If before the Song (A.D. 960–1279), the northerners with their noodles, butter, and milk tended to elevate their own preferences as the standard of taste, the southerners were occasionally able to defend their indigenous products. King Wu of Jin who reigned from A.D. 266 to 290, for instance, unfavorably compared *lao* – a kind of yoghurt made from the milk of sheep and highly prized for its excellence in the north at the time – with a soup made of young aquatic plants growing in the southern lakes (Xu Zhen'e 1984).

Between the end of the Tang and the beginning of the Song, the center of gravity of Chinese civilization shifted from the north to the south. Subsequently, the Song period marked the rise of a new urban society and of a nationwide economy based on a network of transportation and distribution (Shiba 1970). Kaifeng and Hangzhou, the respective capitals of the northern and southern Song dynasties, were the scenes of an unprecedented mixing of populations, for it was here that inhabitants of north and south, as well as people from Sichuan, met and mingled. In this encounter, each group became conscious of its own food habits. Once they were recognized as distinct, the culinary styles of the north, the south, and Sichuan could be combined and finally become the cuisine of the capital.

In a parallel development, the discourse on cooking and food habits assumed new dimensions. The food of the emperor and his entourage had always been commented upon, and it was understood that the governing class and the well-to-do ate choice dishes (and sometimes too much of them), whereas the rest of the population, in keeping with its rank, consumed coarse cereals and vegetables. Before the Song period, testimonies to these contrasting habits were rare and widely scattered. Only the recipes of the agricultural treatise *Qimin yaoshu,* written in the fourth century by a northern notable, provided a glimpse of the tastes of the contemporary elites (Shi Shenghan 1982).

In the Song period, the discourse on food practices began to take a larger view. Although the opposition between north and south remained at its core, some attention was now paid to other, more remote and even foreign regions, and, at times, value judgments yielded to quasi-ethnological descriptions. In this way, the customs and cuisines of foreign peoples came to be considered as legitimate as those of the Chinese. Thus, the culinary part of a household encyclopedia of the early fifteenth century contains a list of Muslim recipes and another of Jürchet (also Juchen or Jurchen) recipes (Qiu Pangtong 1986).[5] It is true that beginning in the late thirteenth century, the Mongol domination added impetus to the greater openness that had emerged in the Song period. A diet book containing many recipes, visibly influenced by foreign customs practiced in central Asia and India, was written in Chinese by the court dietician and presented to Emperor Tuq Temür in 1330 (Sabban 1986a).

In the sixteenth century, the literati Wang Shixing commented on the proverb "[t]hose who dwell on the mountain live off the mountain, those who haunt the seashore live off the sea" by noting that

> the inhabitants of the southern seashore eat fish and shrimp, whose odor makes the people of the north sick, while the men of the northern frontiers consume milk and yoghurt that southerners find nauseating. North of the Yellow River, people eat onions, garlic, and chives, which do them much good, whereas south of the Yangzi people are chary of spicy foods. (Wang Shixing 1981: 3)

Then he tolerantly and wisely concluded: "These are ways peculiar to different regions, and any attempt to make them uniform by force would be useless."

Beginning with the Qing or Manchu dynasty (A.D. 1644–1912), regional differences of cuisine were no longer perceived as the traceable consequences of geographic and climatic diversity but rather as veritable styles defined by a series of criteria involving the nature of the ingredients, seasonings, and types of preparation. The schema founded on three culinary styles, and supplemented by the cuisine of Sichuan dating from the Song period, gave rise to the notion of a China divided into four major gastronomical regions. But as the country's frontiers expanded as a result of the Manchu domination, what was called the "North" stretched even farther north, reaching as far as Shandong, Beijing, and Tianjin; the "South" came to include Zhejiang and Jiangsu, as well as Anhui, with the region of Canton becoming the country's "Deep South." The West still meant Sichuan but also came to include Guizhou, Yunnan, Hunan, and Hubei.

This division is still recognized today, although the limits of these four regions are often drawn very loosely. For example, the cuisine of Canton is seen as including that of Fujian Province and Taiwan, which may not be altogether justified.[6] Nonetheless, once travelers from Beijing have crossed the Yangtze River, they are in the south, and everything is different for the palate.

A regional cuisine is defined by certain dishes, by the frequent use of certain modes of cooking, by the use of specific ingredients, and especially by its condiments and spices – in short, by the tastes that set the one Chinese cuisine apart from all the others.

North of the Yellow River, garlic and onions have always been in favor, as Wang Shixing said long ago. Peking duck, with its fat and crunchy skin, must absolutely be eaten with a garnish of raw scallions and sweet sauce, *tianmianjiang.* The aroma of mutton blends with that of garlic, and the taste of balsamic vinegar cleanses these strong flavors with its tempered acidity.

Sichuan has the strongest condiments and spices, and the sharpest among them, chilli pepper and fagara, or Sichuan pepper *(Xanthoxylum Piperitum),* are highly prized. Together with sesame oil or puree and fermented broad bean paste *(doubanjiang),* they are used to flavor dishes and produce harmonies of flavors bearing such evocative names as "strange flavor" *(guai wei),* "family flavor" *(jiachang wei),* or "hot-fragrant" flavor *(xiangla wei).*[7]

The inhabitants of the low-lying plains of the Yangtze, a land of fish and rice, produce the most tender vegetables and raise the biggest carp and the fattest crabs. They slowly simmer dishes of light and subtle flavor enlivened by the presence of refreshing ginger and the fillip of Shaoxing wine. This is the only region of China where gentle flavors and sweet-and-sour tastes are truly appreciated and beautifully cooked.

The complexity and richness of Cantonese cuisine cannot be reduced to a few dominant flavors, for the art of the Cantonese cook is characterized by mastery in blending different flavors or, alternatively, permitting each one of them to stand out on its own. Seafood, however, is one of the main features of this cuisine. Its preparation emphasizes freshness by, for instance, simply steaming a fish au naturel. Oyster sauce is used to season poached poultry, fish, and briefly blanched green vegetables. But Canton is also famous for its roasted whole suckling pigs and its lacquered meats hung up as an appetizing curtain in the windows of restaurants.

China's culinary diversity can also be seen in the streets, where itinerant vendors sell small specialties *(xiaochi)* to hungry passersby at all hours of the day. Soups, fritters, skewers, fried, cooked, or steamed ravioli, cakes, crepes, tea, fruit juice – the choices seem infinite, though they depend, of course, on the season and the region. In the streets of Beijing, skewers of caramelized haws are offered in winter, whereas ruby-red slices of watermelon appear on the hottest days of summer.

To this mosaic of practices, habits, and tastes, one must add the cuisines of some 50 ethnic minorities. Among these are those of Turkish origin living in the autonomous region of Xinjiang and the Hui families, who in every other way are indistinguishable from the Han Chinese disseminated throughout the territory. These Islamic communities have developed a "Chinese" cuisine from which pork and all its derivatives are absent but are replaced with mutton and beef, which are consumed after Islamic ritual slaughtering.

Nor must one forget *su* cooking, which goes back very far and was already highly regarded under the Song. Based on the exclusion of all animal foods, this cuisine was adopted by the Buddhists and others who wished to eat a meatless or light diet. In their gastronomic version, *su* dishes bear the names of normal meat-containing dishes, and the cook's art consists of using vegetable ingredients to reproduce the taste, consistency, and shape of the meat normally included in these dishes.

Such diversity might make it appear as if there were no Chinese cuisine but several Chinese cuisines, and it is true that there is no haute cuisine without regional roots or affiliation with a genre (be it *su,* Islamic, or even traditional court cooking) that imparts its rhythm, its style, and its specific flavors to a gourmet meal. Nonetheless, everyday cooking is the same from one end of China to the other in its principles and its results. Throughout the territory, people use the same flavoring agents, namely soy sauce, ginger, scallions, and chilli peppers, supplemented, to be sure, by local condiments. Moreover, certain originally regional dishes, among them "Mother Ma's soy curds," "vinegar carp of the Western Lake," and "sweet-sour pork," have become so widely known that they are on the menu of ordinary restaurants in all parts of the country.

The Principles of Cooking Technique

The Chinese word for "to cook" is *pengtiao,* composed of two morphemes signifying, respectively, "to cook" and "to season." In China, cooking foods and combining their flavors are thus two equally important operations.

Certain condiments, as well as mastery of the techniques of chopping and cooking – which, in turn, are related to the use of specialized tools such as the wok and chopsticks – are indispensable in the practice of Chinese cooking. In other words, there is a close connection between the manners of the eater and the work of the cook. Small pieces and foods that can be broken up without using a knife are better suited to the use of chopsticks than any other food. But it would be naive to attribute the functioning of the Chinese culinary system merely to the way food is served and eaten, for Chinese cooking developed out of the interaction of all its constituent parts.

A clear distinction must be made, however, between day-to-day cooking designed to feed a family as economically as possible and professional cooking by specialists highly trained in every technique. The endeavors of the latter have nothing to do with necessity and are exclusively concerned with providing satisfaction and pleasure to the senses.

Home Cooking

Characteristic of cooking in the home is the chopping of ingredients into uniform small pieces, followed by their rapid cooking, usually sautéing in a semispherical iron skillet or wok.[8] The cooking is done with little fat but with a gamut of seasonings dominated by soy sauce, fresh ginger, scallions, sesame oil, Chinese vinegar, fagara, and chilli peppers. Such preparation of food makes for a remarkable economy of equipment. In addition to a rice cooker,[9] all that is needed to prepare any dish is a chopping board – a simple tree "slice" 5 to 10 centimeters in thickness – a cleaver, the wok, and a cooking spatula.

In the city most people cook on a gas ring; in the countryside they have a brick stove with several holes in the top so that the wok can be placed directly over the flame. Since fuel is scarce and expensive, it is always used sparingly, which has given rise to the widespread practice of quick stir-frying over high heat. Sometimes the cook will make use of the heat generated by cooking the rice to steam one of the dishes of the meal above the rice on the rice cooker. Several different dishes are cooked in the same wok, one right after the other, but this is done so rapidly that they have little time to cool. And even if they do cool, the rice, always served piping hot, will provide a balance.

Professional Cooking

Becoming a professional cook demands long years of apprenticeship under the watchful eye of a great chef, and before the aspiring kitchen boy can himself become a chef, he must pass through all the work stations. If he chooses the specialty of meat and vegetable cooking, he will go to the "red work bench" *(hongan),* where he will learn all about chopping and carving, composing, cooking techniques, and seasoning. If he prefers the white vest of the "pastry cook" he will go to the "white work bench" *(baian)* to learn the meticulous art of preparing little dishes made from flours and cereals, including the proper cooking times for pasta products.

A great chef does not, of course, have to be concerned with economy, for he is called upon to use ingredients to their best advantage and to bring out their quintessential flavor by treating them according to the rules of the subtle and difficult techniques he has mastered. He will, thus, use the hump or the heels of a camel without worrying about the rest of the animal when asked to create two of the great dishes of the haute cuisine of North China. Nor is there any economy in the use of fat, a great deal of which is used for deep frying, a practice generally absent from family cooking. Ovens, which are unknown in private homes, are part of the equipment of professional kitchens, particularly in restaurants located in such culinary regions as Beijing or Canton, where roast meat is a specialty.

Even though the same basic principles inform both the great gastronomy and the home cooking of China, professional practice gives cooking a scope and a complexity that cannot possibly be achieved at home. And so one usually turns to a restaurant if one wants to taste the grand specialties prepared with rare, costly, and such delicate ingredients as shark fins, bird's nests, sea cucumbers, abalones, shark's skin, and mountain mushrooms.

A Rich Repertory of Products and Condiments

Because most Chinese enjoy such a wide variety of foods, it is often asserted that there are no food taboos in China. In fact, the Chinese make the claim themselves,[10] even though they recognize that China's Muslims avoid pork and devout Buddhists reject all flesh as well as garlic and onions. Doubtless, such a claim stems, in part, from the popular understanding that a number of unexpected animal species such as the cat, the dog, the snake, and even the anteater end up as a ragout under the chopsticks of Cantonese food lovers, and from the knowledge that Chinese cooks do not, in principle, shun any edible product as long as they are able to prepare it according to the rules of the art. Indeed, haute cuisine calls for "the precious fruits of sea and mountain," essentially animal by-products whose consumption is limited because they are so rare and costly. If their strangeness strikes the imagination, they are not the only gustatory exotica that speak to the originality and the history of China's culinary repertory.

Such consumption of animal foods has a long history in China despite the frequent assertion that the country was traditionally a kind of "vegetal kingdom." Neither hunting nor pastoral activities were proscribed in ancient China and both classical written sources and archaeological findings testify to the importance of cattle breeding in ancient and medieval China. The first millennium of the Christian era probably paralleled the "golden age" of domestication in China in which the utilization of draft animals and the production of meat products gave rise to increasing leisure (and increasing warfare). It has only been in more recent times that activities leading to meat production and to specialized breeding of animals for hunting have become progressively marginalized (Cartier 1993; Elisseeff 1993).

China also stands out for the exceptional richness of vegetal species grown and eaten there – many times more than the fruits and vegetables known in the West. Moreover, these plants are used in an intensive manner, and roots, stems, leaves, shoots, seeds, and sometimes flowers are all exploited for their respective qualities.

The original stock of plants in China was later supplemented by large numbers of new plants, which were very quickly assimilated. As early as the first century B.C. the Chinese acclimatized plants imported from central Asia (which had mostly reached there from the Near East, India, and Africa) such as cucumbers, coriander, peas, sesame, onions, grapes, and pomegranates. Under the Tang (618–907), spinach was acquired from Persia. This was a time when there was great interest in the exotic, and in North China, fresh fruits that grew in faraway southern countries were highly prized. Thus we know that citrus fruit and litchi were carried from Lingnan (today in the Canton region) by special courier for Empress Yang Guifei.

Finally, in the mid-sixteenth century under the Ming, the "American plants" appeared in the coastal areas of Fujian and Guangdong, with the Portuguese and their ships instrumental in bringing maize, sweet potatoes, and peanuts to China. The tomato did not become known until the following century, and the chilli pepper had to await the eighteenth century. These new arrivals became highly popular in China, and scholars subsequently went so far as to attribute the country's population growth in the eighteenth century to the availability of maize and the sweet potato (Ho Ping-ti 1955). The chilli pepper wrought a deep change in the fundamental taste of the cuisines of Sichuan, Hunan, and Yunnan, which are known today for their highly spiced character.

To these expanding natural resources must be added a large number of "processed" foods made from meat, fish, vegetables, and fruit and subsequently used in the culinary process as basic ingredients or condiments. These processed foods have their own history, for their production is predicated on the availability of the appropriate technologies. The oldest texts (of the fourth and fifth centuries B.C.) mention the names of forcemeats, *coulis,* and seasoning sauces, as well as vinegars, pickled and fermented vegetables, and "smoked and salted meats," all of which shows beyond a doubt that aside from day-to-day cooking there was already a whole food "industry" founded on foresight and the stockpiling or conservation of foodstuffs.

The oldest example of this kind of organization is provided by the description of the ideal functioning of the imperial household of the Zhou in the *Zhou Ritual.* The household administration naturally included brigades of pigtailed officials in charge of preparing the daily meals, along with pork butchers *(laren),* the wine steward *(jiuzheng),* and the employees of the manufactory of spiced preserves *(yanren)* and of vinegar *(xiren)* (Biot 1851; Lin Yin 1985).

For the period before the sixth century of the current era we have no idea what these functions involved or, rather, what items were produced under the supervision of these officials. A weighty agricultural treatise of this period devotes a fourth of its space to food preparation. This section contains as many cooking recipes in the narrow sense as it does recipes pertaining to brewing, pickling, malting, and preserving. All of these recipes testify to great expertise and to the widespread use of preserved foods (Shih Sheng-han 1962). The most remarkable, and probably the oldest, of these recipes are those for making seasoning sauces by fermenting grains and legumes and the more than 20 recipes for different vinegars, which are also obtained by subjecting cooked cereals to acetic fermentation. In addition, this text contains a large number of recipes for pickled vegetables, "smoked and salted meats," and, of course, alcoholic beverages, the role and importance of which in Chinese culture we shall examine next.

Contrary to what one might expect, however, this treatise does not even allude to certain products that are today considered the very emblems of Chinese cooking. An example is soy sauce, which is so universally used in our day. Then it was probably perceived as nothing more than the residual liquid of a spicy paste until the Song period, when it became clearly identified with its own name. Similarly, the clotting of soy milk for a curd called *doufu* (tofu) seems to have been unknown in the written sources until the tenth century, when the first reference to this subject can be found (Hong Guangzhu 1987: 8).[11]

Conversely, some foods that have almost disappeared today seem to have enjoyed a certain vogue in the past. *Lao,* for example, which is a kind of fermented milk, and butter were luxury foods highly prized by the upper classes of society, at least until the end of the Song (Sabban 1986b). The reputation of these products (and the taste for them) lasted until the Qing period, although they were probably difficult to obtain outside of court circles, which had access to cows and ewes as well as to a "dairy" that produced for the emperor and his entourage. Perhaps the popularity of the Beijng yoghurt today and the recent fashion of "dairy cafés" offering traditional sweets made of milkcurd are vestiges of these ancient and prestigious treats.

This entire food "industry" was predicated on a remarkable knowledge of the phenomenon of fermentation, which is still used in the production of popular ready-to-use condiments such as soy sauce *(jiangyou),* salted black beans *(douchi),* sweet-salty sauce *(tianmianjiang),* and fermented broad bean paste *(doubanjiang).*

In addition to these condiments produced by fermentation, the Chinese developed original techniques for turning plant materials into edible substances much sought after for their consistency, their malleability, and their taste. In this category one finds a considerable variety of noodles made with cereal or leguminous plant flours. *Mianjin,* or "gluten," is a kind of firm but elastic dough obtained by rinsing a sponge of wheat flour. Also used are all the secondary products of soy milk, such as fresh or dried curd and its skin and gelatin. The textures of these particular substances have stimulated the imaginations of many cooks; thus, they not only have played a vital role in the development of *su* cooking diffused by Buddhist temples but also have made their mark on home cooking and on the cuisine of great restaurants. In this area the Chinese developed a technical prowess that may well be unmatched by other societies (Sabban 1993).

A Culture of Alcoholic Beverages

China is known as the land of tea, but in fact alcohol has been drunk there longer than the brew of the plant that has conquered the world. Yet tea has come to overshadow the other Chinese beverages called *jiu.* Difficult to translate into Western languages, this word *jiu* designates today all alcoholic liquids, from the lightest beer to the strongest distilled alcohol, with wines made from grapes and rice and sweet liqueurs in the middle.[12]

Before the advent of distillation, which is generally assumed to have occurred around the fourteenth or fifteenth century, *jiu* meant all alcoholic beverages obtained through the fermentation of cereals. But these were not beers whose fermentation was induced by malt, such as are found in several other ancient societies, but rather beverages with alcohol contents of between 10 and 15 percent obtained through a "combined fermentation" that called for the preliminary production of an ad hoc ferment that subsequently started the fermenting process in a mash of cooked cereals (Needham 1980; Sabban 1988). Each of these two processes involved fairly lengthy preparation and maturation. The cereal, the water, and the ferment *(qu)* were so indissolubly associated that the Chinese sometimes compared the *jiu* that had resulted from their transmutation to a body in which the cereal occupied the place of the flesh and muscle, the ferment that of the skeleton, and the water, like blood, irrigated all the veins.

This original technique, which subsequently spread to Japan, Korea, and all of Southeast Asia, has existed in China for a very long time. The first texts that have come down to us allude to the precise fermenting time of the *qu* needed for making *jiu* (Hong Guangzhu 1984). The "invention" of this precious liquid is attributed to Du Kang, a legendary figure venerated as the "immortal of *jiu*" who is the object of a cult in several villages of North China. He is supposed to have lived at the end of the Shang dynasty (1324–1066 B.C.). We do know from the texts and from an abundance of magnificent utensils found in archaeological sites that the Shang aristocrats loved to drink, and there is evidence that some of their predecessors had also succumbed to this passion. In fact, the production of alcoholic beverages in China seems to go all the way back to the end of the Neolithic and perhaps even further. The site of Dawenkou in Shandong (4000 B.C.) has yielded a great variety of earthen vessels used for preserving, storing, and consuming alcoholic beverages.

There is no question that since the presumed time of their appearance alcoholic beverages have enjoyed considerable popularity in China. The sixth-century agricultural treatise *Qimin yaoshu* gives more than 30 recipes, each one for a specific beverage identified by its mode of production, its ingredients, and its flavor, color, strength, and so forth (Shi Shenghan 1982). We also learn from the texts that these beverages played an important role at all levels of society. Their production was controlled by the institution of state monopolies in the course of the first dynasties, and there were times when their consumption was forbidden. Every ritual involved alcoholic beverages as offerings to the gods or the ancestors. But alcohol was regularly used for more mundane purposes, and families were consequently ruined and promising careers cut short. In a word, it is clear that alcoholic beverages were present at every moment of people's lives. In the sixteenth century 70 kinds of *jiu* were counted (Du Shiran et al. 1982), and to this profusion should be added the exotic "grape wines" imported from central Asia, which became very fashionable in court circles under the Han and the Tang.

Alcoholic beverages maintain their importance in the present. No banquet, for example, would be complete without them. Indeed, the ceremony of marriage is referred to by the expression *he xijiu* or "drinking the wine of happiness," and each of the guests is invited to raise a glass in honor of the bride. The latter, as she was already enjoined to do in the ritual books of the third and fourth centuries B.C., must exchange a goblet with the groom. To testify to their mutual commitment, betrothed couples no longer drink out of the two halves of the same gourd but now cross their arms and give to each other the goblet they hold in their hands.

In eastern Zhejiang, a region where the production of a renowned rice wine is a tradition, people would bury several earthenware jars of good wine at the birth of a child and not open them until the day of his or her marriage. A family celebration without alcoholic beverages is unthinkable, and even on the occasion of a funeral it is customary to offer a drink to friends who have come to salute the deceased for the last time. Seasonal and religious festivities as well have always included generous libations, and until the advent of the republic in 1912 the winter solstice was celebrated with libations to heaven performed by the emperor and his ministers, whereas families made offerings of alcohol to their ancestors.

Alcoholic beverages are also items of gastronomy consumed for no particular reason at a drinking party or to accompany a meal. Drinking with friends is a social activity mentioned in the oldest literature. In grave no. 1 of the Mawangdui site dating from the Eastern Han period (about 168 B.C.), where the spouse of the Marquis of Dai is buried, the arrangement of the objects contained in the northernmost funerary chamber is thought to represent the deceased seated at a lacquered table laden with meat dishes and goblets containing two kinds of wine. There is little doubt that this scene depicts either a drinking party or the first part of a banquet devoted, as usual, to the drinking of alcoholic beverages (Pirazzoli-t'-Serstevens 1991).

Although drinking parties sometimes had a political function, for instance when the seating arrangements concretely showed patterns of social hierarchy (Yü Ying-shih 1979), they were mainly moments of joy and exaltation. Almost all the poets have devoted some of their writings to the celebration of wine and the inspiring inebriation it brings. Poets of the Tang and Song period felt that wine was as necessary as paper, brush, and ink, and there was no lack of hardened drinkers among the rhymesters. It is even said that once when the great Li Bai (701–62) was in his cups, he thought that he could catch the moon when he saw its quivering reflection in the river and so perished by drowning. Perhaps it was a befitting end for a poet who, certain of his modern confreres do not hesitate to say, was permanently steeped in alcohol.

Drinking in China is a form of entertainment and a way to shed inhibitions. Sometimes it also gives rise to games and contests that make the losers drink more and more. At popular banquets the game of *morra* marks the time for drinking amid peals of laughter and screams of excitement. The famous eighteenth-century novel *The Dream in the Red Pavilion* furnishes a fine example of the jousts associated with wine drinking in literary circles: Any participant who did not succeed in improvising a song or poem with prearranged constraints within a limited time was made to drain his cup on the spot.

Although getting drunk is the admitted aim of these drinking bouts, drinking without eating is unthinkable. In order to "make the wine go down" *(xiajiu),* one must sip it while nibbling at some tidbits or little dishes that not only fill the stomach but also sharpen one's thirst, although they should never distract the drinker from the appreciation of the wine.

The social standing of the drinker determines how fancy these indispensable accompaniments can be. A small bowl of fennel-toasted beans is all there was for poor Kong Yiji, the hero of a novel of Lu Xun, who occasionally treated himself to a nice bowl of warm wine at the corner tavern (Yang and Yang 1972). By contrast, goose braised in marc, pork of five flavors, fish with crayfish eggs, and the finest specialties of Suzhou carefully selected to go with the drinks were enjoyed by Zhu Ziye, the gourmet of the recent novel by Lu Wenfu (Lu Wenfu 1983). A contemporary of poor Kong Yiji, Zhu Ziye was vastly more wealthy.

The prewar taverns no longer exist, and the wine of Shaoxing is now rarely served warm, but people never fail to drink at a banquet or any other celebration. The choice of beverages has become wider: There are now clear alcohols made of rice or sorghum like the famous *maotai* and wines made of glutinous rice, the best of which is probably the yellow wine of Shaoxing. In addition, there is osmanthus-flavored liqueur, grape wines, which are now produced in China, and also port wine and even cognac.

Beer has been regularly consumed ever since it was introduced by the Europeans early in this century. "Qingdao," the best known and most renowned brand, is manufactured at Qingdao in Shandong, a town and region taken over in 1897 by the Germans, who established a brewery there in 1903 (Wang Shangdian 1987). Today, beer is the first alcoholic beverage people will buy if they are looking for a little treat.

The Art of Making Tea

Appearing much later than alcoholic beverages, tea began to acquire considerable importance in the Tang period, when its use became widespread. At first it was perceived as a serious competitor of wine, which it implicitly is to this day. Certain "weak natures" who could not tolerate alcohol very well actually replaced wine with tea when they attended official drinking parties. A *Discourse on Tea and Wine* (Wang Zhongmin 1984) from the late Tang period pits Tea against Wine in a debate that allows each of them to argue and preach in favor of his own brotherhood. Wine calls himself more precious than his opponent and better able to combat death, whereas Tea accuses Wine of causing the ruin of families and prides himself on being a virtuous drink of beautiful color that clears away confusion. But in the end Wine and Tea make peace when Water reminds them that without her neither of them amounts to much and that they should get along, since tea often helps to dissipate the vapors of drunkenness. And it is true that infusions of tea were first used for medicinal purposes (Sealy 1958; Chen Chuan 1984). Tea, however, very quickly became much more than a mere remedy.

Part of its enormous success can be attributed to its commercial value both within and without the borders of China, in nearby regions, and throughout the world. Of the three stimulating beverages – coffee (from Ethiopia and Yemen), tea (from China), and cocoa (from the New World) – that the Europeans "discovered" in the late Renaissance, tea was the most widely disseminated and is still the most commonly consumed today. China gave us this custom of drinking tea, which also took root in Japan, Korea, and northern India. It should be noted that all of the tea consumed in western Europe was initially imported from China until the

British broke this monopoly by launching their highly successful tea plantations in Ceylon and India toward the end of the nineteenth century.

Sichuan was the cradle of the decoction of a bitter plant thought to be tea, which was probably first used toward the end of the Western Han period (206–23). The names employed at the time are still somewhat doubtful, but the plant was clearly *Camellia sinensis.* At that time tea was not infused but prepared in decoction, perhaps seasoned with salt, onions, ginger, or citrus peels, and its leaves were sometimes simmered in cooked dishes. Clearly this was a far cry from what we call "tea" today. Two factors are thought to have facilitated the spread of tea throughout China to its northernmost frontiers, beginning with the Sui (581–618) and the Tang (618–907). One is that tea soon came to be an item of tribute and, thus, became known and appreciated in court circles. The other has to do with the vigorous growth of Buddhism between the beginning of the Christian era and the Tang period. It is reported that tea was a great help to Buddhist monks, whose religion prohibited the drinking of "intoxicating" beverages like wine and whose practice of meditation demanded fasting and staying awake for many hours at a time. Tea plantations therefore followed the founding of Buddhist temples in the mountains.

Most would agree, however, that it was Lu Yu, author of the famous *Classic of Tea* (Carpenter 1974; Lu Yu 1990), who in the middle of the eighth century provided the Chinese culture of tea with its veritable birth certificate. The Tang period, moreover, marks the beginning of the "tea policy" adopted by the Chinese government. More or less successful, depending on the period, this policy, which lasted until the Qing period, regulated the monopoly, the tribute, and the taxation of tea and monitored an official trade in which tea was exchanged for "barbarian" horses on the country's northern and northeastern frontiers. Doubtless the vast scope of tea consumption and the potential profits of its cultivation played a decisive role in the elaboration of this policy. Lu Yu himself probably only codified and formally described the practices and the techniques peculiar to his time and to the literati. His work in three chapters was devoted to the origins, the cultivation, the processing, and the drinking of tea. It had enormous influence on the rise of the culture of tea, which developed not only in China but in Japan as well.

Lu Yu's work gave rise to an endless number of treatises that either followed in the same vein or provided more elaborate information. It is important to note that in China – unlike Japan, where tea was associated with a Zen discipline – the art of tea was always in the realm of practical "know-how," somewhat ritualized but only done so to encourage a more thorough enjoyment of life. Lu Yu explains the comparative merits of different beverages in perfectly straightforward terms: "To quench one's thirst, one should drink water; to dissipate sadness and anger, one should drink wine; to drive away listlessness and sleepiness, one should drink tea" (Fu Shuqin and Ouyang Xun 1983: 37). But despite such straightforwardness, he insists that the processing, preparation, and drinking of tea must be done according to the rules, and he heaps scorn on those who, believing that they are drinking tea, settle for "stuff that has washed out of the rain spout" (Fu Shuqin and Ouyang Xun 1983: 37).

It goes without saying that although Lu Yu was sometimes worshiped as the "God of Tea," planters, processors, and lovers of the divine brew have gone beyond the master's instructions. As processing techniques evolved, they led to modifications in the preparation of tea and changes in the consumers' tastes. As early as the Tang period, "steam wilting" was discovered, a technique that made it possible to free the brew of its "green taste." Then, under the Song, planters began to wash the leaves before wilting them, and loose-leaf tea replaced the kind that had hitherto been pressed into "cakes" that had to be crumbled before being used in decoctions. In the early Ming period the growing taste for loose-leaf tea spelled the victory of infusions over decoctions. The leaves of *C. sinensis* were now mixed with fragrant flower petals whose scent is imparted to the infusion. Today the best known of these infusions is jasmine tea.

In the Tang period, several local teas had already acquired a great reputation, and by the Song period 41 kinds of tea were considered worthy of serving as tributes. Today there are three major types of Chinese teas: green tea, oolong tea, and black tea. Green tea, which is the kind most frequently consumed in China and Japan, is not made to undergo fermentation, whereas oolong tea, most popular in the southern provinces, is semifermented. Black teas, mainly produced for export, are called "fermented."

Drinking and serving tea today are such commonplace activities that they do not elicit any commentary. Wherever they might be, people can expect to find a thermos of boiling hot water, covered mugs, and tea leaves ready to be steeped. In any waiting or reception area, the visitor is offered tea. Tea is never drunk with the meal.[13] But when invited to share a meal, visitors are always received with a cup of tea. And this little offering is repeated to mark the end of the meal. On all such occasions this gesture must be made, whether or not the tea is actually drunk.

Every Chinese worker – blue or white collar – and every traveler carries a glass receptacle whose lid is tightly closed over some hot water in which a small handful of tea is steeping. In the course of the day more water is added and the liquid becomes paler and paler. This type of consumption, which in Taiwan is facilitated by automatic dispensers, is suited to the normal use of tea conceived as a mildly stimulating internal lubricant that will aid the digestion. The tea used throughout the day is usually of rather poor quality and in principle affordable for everyone. In lean times, the habit continues even without tea and people drink hot water, calling it "tea."

Along with such routine tea drinking in all parts of the country, the southern provinces have developed a veritable culture of tea. Every town or village has its "tea house," which can be quite modest, where people go to relax, to talk to their friends, and to share and comment on the latest news. These "tea parlors" have a long history in China. Indeed, those of the capitals of the northern and southern Song have become legendary thanks to the authors of the *Descriptions of the Capital* (Gernet 1962), who vaunted their lively and refined character.

In Canton and its region, however, and in Hong Kong, too, tea drinking is a more serious matter, as is everything that involves food. In Canton, the gastronomic capital of China, there are vast numbers of establishments that from morning until midafternoon offer tea lovers the opportunity to order a large pot of their favorite tea along with, if they choose, an incredible variety of "little dishes" – ravioli, fritters, dumplings, tartlets, pâtés, noodles, and so forth – all of them especially designed to accompany tea without overpowering its taste.

Françoise Sabban
(translated by Elborg Forster)

Notes

1. This assertion is according to the hallowed expression taken from the *History of the Han* (compiled in the first century of our era): *Wangzhe yi min wei tian, er min yi shi wei tian,* "The most important thing(s) in the world for the prince are his subjects, for whom nothing is more important than food."
2. In the food trade, a distinction is made between "fine cereals," *xiliang,* that is to say, rice and wheat, and "coarse cereals," *culiang,* meaning all the others. Counted among the latter are the tuberous vegetables, which are the mainstay of the diet in the poorest regions and in times of shortage.
3. To this list should be added sorghum, which can also be consumed as the mainstay of the diet when nothing else is available but which is generally used for the production of alcoholic beverages.
4. Until the Tang (618–907), North China, the cradle of Chinese civilization, imposed its values on the rest of the territory and hot and humid South China remained a neglected part of the huge empire, to cite Jacques Gernet (1962). But as a result of the continuous onslaught of nomadic barbarians from central Asia, who made increasing inroads on the great northern plain, the Yangtze Basin assumed ever greater importance. Under the Song, when South China had become conscious of its strength, it developed a refined urban civilization, which in turn gave birth to a genuine national cuisine based on the recognition of three major regional cuisines.
5. The Jürchet were a Tungusic tribe of the present Heilongjian Province in northeastern China who adopted the dynastic name of Jin in 1115. They were neighbors of the northern Song, with whom they concluded an alliance to attack the Liao empire. But they eventually turned on the Song, whom they finally annexed when they conquered their capital of Kaifeng in 1126.
6. The present literature on Chinese cuisine contains a great many typologies of regional cuisines, but all of them are based on the historical division into four major zones. Certain specialists assign different culinary schools to eight geographic regions. In reality, each province lays claim to its own cuisine and every provincial publishing house has published works devoted to the cooking of its own provincial cuisine.
7. Here are two of the most typical flavor combinations of Sichuan: One is *yuxiang wei,* literally "fish flavor," which does not contain a single fish-based ingredient but consists of a mixture of chilli pepper, fermented broad bean paste, soy sauce, scallions, and so forth. The other is *mala wei,* literally "numbing hot flavor," which, consisting essentially of chilli pepper and fagara, or Sichuan pepper, is said to produce in the mouth a blended sensation of numbness, relaxation, and heat.
8. "Wok" is the Cantonese pronunciation of the word for this utensil, pronounced *huo* in standard Chinese. In North China this type of skillet is given another word, pronounced *guo.*
9. Today, this is often an automatic electric cooker.
10. This assertion holds except with respect to certain combinations of foods whose consumption during the same meal is not recommended for reasons of health. Works on diet, but also peasant calendars, contain lists of pernicious, that is, poisonous, "combinations" of foodstuffs, although not without indicating the corresponding antidotes. Their presence in calendars makes it seem likely that in addition to medical reasons, considerations of a magic and religious nature are also involved here.
11. See also the arguments of Chen Wenhau (1991), who advances the hypothesis that tofu was a much earlier invention dating back to the end of the Eastern Han period (25–220).
12. Although fully aware of the inadequacy of this choice, I shall here translate *jiu* as "wine" or "alcoholic beverage," as a matter of convenience. But it does seem better than the word "beer," which today designates a product that has nothing to do with the Chinese *jiu,* since it has always involved the use of malt. This is not the case for various Chinese *jiu,* which are produced by "combined fermentation" with ferments from cereal mashes. (In this connection see the essay by Ankei Takao 1986.) The few available recipes from the sixth century actually indicate that malt, though well known in China, was by that time used only to make "cereal sugars" or "maltoses."
13. One must be clear about what is called a "meal." An implicit classification defines the standard meal by its composition, namely, a staple cereal accompanied by its cooked dishes and often a light soup, and by the time at which it is eaten, essentially at noon and in the evening. If, in Guangdong, tea sometimes appears as part of a "snack" that might be considered a meal – for the "Cantonese breakfast" can be eaten any time between the morning and early afternoon – such a snack is really a matter of drinking tea and eating some accompanying dishes, even though it might take the place of a meal by virtue of the quantity of food and even the time when it is eaten.

V.B.4 ~ Japan

Rice and Staple Food

Rice has long been the main staple of the traditional Japanese diet. It is not only consumed daily as a staple food but also used to brew sake, a traditional alcoholic drink. Japanese cuisine has developed the art of providing side dishes to complement consumption of the staple food. Table manners were also established in the quest for more refined ways of eating rice and drinking sake at formal ceremonial feasts. The history of the Japanese diet, which is inseparable from rice, started therefore with the introduction of rice cultivation.

Subsistence during the Neolithic period in Japan (known as the Jōmon era, beginning about 12,000 years ago) was provided by hunting and gathering. Agriculture did not reach the Japanese archipelago until the very end of the Neolithic period. Collecting nuts (especially acorns and chestnuts) and hunting game were common activities, and a large variety of marine resources was intensively exploited throughout the period. The Jōmon era, however, ended with a shift from hunting and gathering to sedentary agriculture.

The Yangtze delta in China is considered to be the original source for the practice of rice cultivation in Japan. Continuous waves of migrants bearing knowledge of the technique reached Japan from the continent around 2,400 years ago via two major routes. One was through the Korean peninsula and the other was a direct sea route from China. Rice production techniques were accompanied by the use of metal tools, which provided high productivity and a stable supply. Population increased rapidly, and localized communities appeared in the following Yayoi era (1,700 to 2,400 years ago). Paddy-field rice cultivation was then under way except in the northern Ainu-dominated region of Hokkaido and in the southern Okinawa islands, an island chain between Kyūmshū (the southernmost main island of Japan) and Taiwan.

From the beginning of cultivation, only short-grain rice was known in Japan. Although long-grain rice was common in Southeast Asia and India, its absence from Japan caused the Japanese to develop prejudices about rice that persist until today. For them, rice means exclusively the short-grain variety; the long-grain type is regarded as inferior and unpalatable.

Traditionally, a meal consists of boiled plain rice, called *gohan* or *meshi,* and seasoned side dishes, called *okazu.* Cooked rice has always been the staple of a meal, so much so that the words *gohan* and *meshi* are used colloquially as synonyms for the word "meal." Side dishes complement rice consumption with their seasoned flavors, and as a rule, the sophistication and variety of such dishes has betokened the affluence of those who served them.

Peasants living in mountain areas with low rice productivity, along with poor people in general, formerly mixed millet with rice. The sweet potato, introduced in the eighteenth century, also became popular as a staple in the south of Japan, where it supplemented a low yield of rice. However, even the poor cooked pure boiled rice and pounded rice cake from pure glutinous rice for important meals. Pounded rice cakes *(mochi),* prepared by pounding steamed glutinous rice with a mortar and pestle, have been indispensable food items for Japanese ceremonial feasts. People thought that the essence – the sacred power of rice – was made purer by pounding, and *mochi* was believed to contain the "spirit of rice." Naturally this was and is the most celebrated form of rice and therefore the most appropriate food for feasts. Thus, New Year's day, the principal annual feast in Japan, sees *mochi* always consumed as a ceremonial food.

In a census record of 1873, nutritional information for the Hida Region (Gife Prefecture, Central Honsyū) shows that rice was the most important food, notwithstanding the general unsuitability of the area for the crop's cultivation (Koyama et al. 1981: 548–51). The same data reveal a typical daily intake of nutriments for premodern Japanese people. The recorded population of this mountainous region was about 90,000, and these people are thought to have maintained the highest dependency in Japan on millet as a rice substitute. The average daily energy intake per capita was 1,850 kilocalories (kcal) (in 1980 it was 2,600 kcal), of which 55 percent was supplied by rice, which also supplied 39 percent of the protein.

Both rice and millet, when served as a staple, have always been either boiled or steamed. Milling, however, was not developed generally, and processed powder was used only for cakes or snacks and not for bread. Later, noodle products made from the powder became popular. The oldest form of the noodles, *sakubei,* produced by adding rice powder to flour, was introduced from China in the eighth century.

Noodles made from flour as a light lunch or snack became popular during the fourteenth and fifteenth centuries, and consumption increased considerably after the seventeenth century, when a processing technique for buckwheat noodles *(soba)* was developed in Edo, now Tokyo. Since then, *soba* has become popular mainly in eastern Japan, where Tokyo is located, whereas *udon* noodles (made from flour) have always been popular in western Japan (Ishige 1991a).

Meat and Fish

A unique feature of Japanese dietary history has been the country's various taboos on meat eating. The first recorded decree prohibiting the eating of cattle, horses, dogs, monkeys, and chickens was issued by Emperor Temmu in A.D. 675. Similar decrees, based on the Buddhist prohibition of killing, were issued repeatedly by emperors during the eighth and ninth centuries. The number of regulated meats increased to the point that all mammals were included except whales, which, given their marine habitat, were categorized as fish.

The taboo against the consumption of animal flesh developed further when the Japanese aboriginal religion, Shintō, adopted a philosophy similar to that of the Buddhists. This did not mean, however, that meat eating was totally banned in Japan. Professional hunters in mountain regions ate game (especially deer and wild boar), and it was not uncommon for hunted bird meat to be consumed. However, a lack of animal breeding for meat kept its consumption very low. Indeed, it was only during the fifteenth century and its aftermath that the tradition of eating both the meat and eggs of domestic fowl was revived. Fowls, until then, had been regarded in Shintō as God's sacred messengers and were reared to announce the dawn rather than as a mere food resource.

Milk and other dairy products failed to become popular in Japan, China, and Korea. In fact, the only Japanese dairy product known to history was *so,* produced between the eighth and fourteenth centuries. Milk was boiled down to yield this semisolid product. But even this food, consumed at the court and among the noble class, disappeared as a result of the demise of the aristocracy. Cattle were raised only for drawing carts or plowing fields. To utilize them for meat or even for milk was, until relatively recently, a long-forgotten practice.

Lack of meat and dairy products in the Japanese diet produced an aversion to oily tastes, so that even vegetable oil was not commonly used for cooking. Tempura, fish or vegetables fried in a vegetable oil, is one of the best-known Japanese dishes today, but it became popular only after the mid-eighteenth century.

The lack of meat products also minimized spice utilization. Pepper and cloves were known from the eighth century and were imported either via China or directly from Southeast Asia, and garlic was also grown on a small scale. But these spices were used mainly to make medicines and cosmetics.

In the coastal seas of Japan, warm and cold currents mix to provide bountiful fishing grounds. This favorable natural environment and the traditional exclusion of fish from the meat taboo meant an extensive exploitation of marine resources. The Japanese developed a special liking for fish, and most people enjoyed a variety, although consumption was still largely forbidden for Buddhist monks.

Fish dishes, with a higher status as well as a more attractive taste than vegetable dishes, were formerly considered indispensable at feasts. However, before the introduction of modern delivery systems, the difficulty of preserving and transporting fresh marine fish minimized consumption in inland areas where freshwater fish were commonly eaten instead.

The basic concept of fish preparation in Japan is suggested by the following proverb: "Eat it raw first of all, then grill it, and boil it as the last resort." To amplify, it is felt that the taste and texture of fish is best appreciated when it is very fresh and eaten raw. If the fish is a little less than fresh then its best taste will be produced by sprinkling it with salt and grilling it. If the fish is not fresh, then it is better boiled with seasonings, such as soy sauce *(shoyu)* or soybean paste (miso).

The consumption of fish raw has been traditional since ancient times. *Namasu,* or the eating of thinly sliced raw fish dipped in a sauce with a vinegar base, is a typical example. However, the better-known sashimi has been popular only since the seventeenth century – its popularity increasing as the general consumption of soy sauce increased. Delicately sliced raw fish of the utmost freshness and quality is eaten after being dipped in soy sauce flavored with a small amount of grated wasabi *(Wasabia japonica),* which is similar to horseradish.

As a rule, the philosophy of cooking aims at the creation of new tastes that do not exist naturally – such creation is a result of imposing artificial processes on food materials. But Japanese cooking methods are antithetical to this philosophy. The ideal of Japanese cooking is to retain the natural tastes of food with the minimum of artificial processes. Thus sashimi, for example, can be viewed as a representative product of the Japanese cooking philosophy.

Nigiri-sushi, prepared by putting a slice of raw fish onto a bite-size portion of hand-rolled, vinegar-flavored rice, has recently become internationally popular. But sushi originated as a means of preserving fish by fermenting it in boiled rice. Fish that are salted and placed in rice are preserved by lactic acid fermentation, which prevents proliferation of the bacteria that bring about putrefaction. A souring of flavor occurs during the process, and the fish is eaten only after the sticky decomposed rice has been cleaned off.

This older type of sushi is still produced in the areas surrounding Lake Biwa in western Japan, and similar types are also known in Korea, southwestern China, and Southeast Asia. In fact, the technique first originated in a preservation process developed for freshwater fish caught in the Mekong River and is thought to have diffused to Japan along with the rice cultivation.

A unique fifteenth-century development shortened the fermentation period of sushi to one or two weeks and made both the fish and the rice edible. As a result, sushi became a popular snack food, combining fish with the traditional staple food, rice. Sushi without fermentation appeared during the Edo period (1600–1867), and sushi was finally united with sashimi at the end of the eighteenth century, when the hand-rolled type, *nigiri-sushi,* was devised. Various styles of hand-rolled sushi were developed, such as *norimaki,* in which vinegar-flavored rice and seasoned boiled vegetables are rolled in paper-thin layers. In addition, sushi restaurants became popular during this era. They offered ready-made rice prepared with vinegar and other seasonings and rolled with different toppings according to the taste of the guests. In this manner, sushi has changed from its original character as a preserved food to that of a fast food (Ishige and Ruddle 1990: 21–94).

Vegetable Food

In daily meals, vegetables have generally constituted the main ingredients of side dishes and soups accompanying rice. Among these vegetables are a variety of sea plants that have been utilized since ancient times and remain a unique feature of Japanese cooking even today. Sea plants are usually dried and soaked in water before cooking. Sea tangle has been the most important of all. It is commonly used to prepare broth, and owing to its rich content of glutamic acid, it enhances the original taste of the foodstuffs with which it is boiled.

Traditionally, salted vegetables have been an indispensable part of the daily diet of even the poorest classes of people. Some several hundred varieties of salted vegetables are known in Japan; however, the method of pickling common in the West, using vinegar, has not developed there.

Of all beans, the soybean is the most significant. It is a good source of vegetable protein, and its importance in the Japanese diet is surpassed only by that of rice. Varieties of soya in a processed state, such as tofu and *nattō,* have played an extremely prominent dietary role over the ages. Tofu, or soybean curd, which diffused from China and is first mentioned in Japan in an eleventh-century document, has been one of the most widespread of the processed foods. A cookbook providing 100 different recipes for tofu cooking was published in 1782 and became so popular that a second volume, containing another 138 recipes, was issued the following year. Many of these recipes were devised by Buddhist monks, who abstained from eating meat for doctrinal reasons and relied heavily on tofu as a source of protein.

Bacillus subtilis bacteria, which grow on rice straw, are cultivated on boiled soybeans to produce *nattō. Nattō* has a unique sticky consistency and is usually seasoned with soy sauce and mustard before eating; minced *nattō* is used as an ingredient of soybean-paste soup. *Nattō* contains abundant protein and vitamin B_2 and has been popular as a breakfast food because it is easily digestible.

Vegetarian diets, or *shōjin-ryōri,* rely on a variety of foods processed from soybeans. These include tofu, *abura-age* (fried tofu), *kōri-dōfu* (freeze-dried tofu), and *yuba* (paper-thin processed tofu), as well as mushrooms, sea plants, sesame, walnuts, and, of course, vegetables. *Fu,* which is produced by condensing wheat gluten, has also been a popular foodstuff. *Shōjin-ryōri* has generally been served during periods of mourning, for Buddhist rituals, and on the anniversary of the death of close kin.

From a dietetic point of view, the Japanese vegetarian diet is both well balanced and quite rational. It supplies protein from tofu and similar products, fat from sesame, walnuts, and vegetable oil, vitamins from vegetables, and minerals from sea plants. Such a diet not only is nutritious but also offers many palatable recipes, which have been refined by such techniques as employing a broth made from dried sea tangle and mushrooms as a base for cooking. Vegetable oils, which are extensively used, were especially developed by those Zen Buddhist monks who had maintained contacts with China.

Seasonings and Flavorings

Because of an absence of rock salt in Japan, salt made from seawater has been prevalent since the Neolithic era. But a salty residue fermented from soybeans has traditionally been used as a basic and versatile seasoning in Japan (as well as in China and Korea). Miso (soybean paste) and *shōyu* (soy sauce), the two major products of this residue, have been used to season boiled dishes and as ingredients in the preparation of various sauces.

Of the *kōji* fungi that are employed as starters for soybean fermentation, *Aspergillus oryzae,* which grows on rice grains, is the most common. The fermented products of soybeans were first recorded in a law book called the *Taihō-ritsuryō,* compiled in A.D. 702. But it is known that by that time a type of miso was already being produced, using a technique thought to have been introduced from Korea. The indigenous Japanese processing method, which employs artificially cultivated starters like *kōji* and combines soybeans with rice and barley, was devised later. It differs from the Korean method, which relies on natural bacteria in the air to ferment pure soybeans, to which salt is added.

The traditional Japanese method of processing miso is to mash boiled or steamed beans while the *kōji* fungus is cultured on boiled or steamed rice or barley. All these ingredients are then mixed together with salt and placed in a container. After a maturation period of more than a year, the mixture changes into miso, a pastelike substance. The liquid that oozes out in the maturation container is sometimes used as a type of soy sauce. Other types of miso are also made; these all vary by region in processing techniques.

Similarly, the general method of processing *shōyu* (soy sauce) is to culture *kōji* fungus on pounded, preparched wheat grains and then to mix this with boiled beans and a large amount of salt water in a maturation container. The mixture is stirred occasionally, and fermentation is completed within three or four months. During the maturation period following fermentation, the contents intensify in color and flavor, owing to chemical reactions among the ingredients. After one year of maturation, the liquid obtained by squeezing the contents is pasteurized and becomes *shōyu.* As with miso, *shōyu* also has many regional varieties.

The use of the liquid by-product of miso processing as a seasoning has been known for a long time, but commercial production of *shōyu* dates only from the sixteenth century. Propagation of recipes from major cities where *shōyu* was employed extensively during the Edo period gave *shōyu* national status as a seasoning, and more than 70 percent of present-day Japanese recipes employ it in some way. In contrast to *shōyu,* miso has decreased in importance as a seasoning for both boiled dishes and sauces, and its daily use has generally been restricted to soup.

Rice is employed to make the traditional Japanese vinegar. In addition, a type of sake with a strong sweet taste, called *mirin* (which is processed in a slightly different way from the usual brew), serves as a cooking wine.

Another unique feature of Japanese food culture is the extensive development of dried foods for the preparation of soup stock (broth), or *dashi.* Dried sea tangle *(konbu),* dried bonito *(katsuo-bushi),* and dried brown mushrooms *(shiitake)* are some examples. They are not only used for *dashi* but also often added to boiling vegetables.

Katsuo-bushi, or dried bonito, is produced by boiling the fish, after which it is heat-dried and cooled. This process is repeated more than 10 times until the water content of the fish is reduced to less than 20 percent and the surface is covered by "tar." The covering of "tar" and fat is scraped off and the remaining meat is placed in a wooden box and left for two weeks to propagate an artificially planted fungus of the genus *Aspergillus.* After two weeks the surface is cleaned, and the fungus-planting process is repeated four more times.

At completion, a majority of the remaining contents are protein and flavor essence. Water content is reduced to 15 percent of the original, and the final product, *katsuo-bushi,* appears dry and hard like a block of wood. The fungus-planting process, which yields a better flavor and helps extract the water, was invented in the seventeenth century, although the rest of the process has been known since ancient times.

When used, small amounts of very thin flakes of *katsuo-bushi* are shaved from the block with a specially designed plane, then placed in boiling water to extract their flavor. When the water is strained it becomes a pure soup stock, and the flakes are usually discarded except in rare cases when they are combined with soy sauce to prepare a salty side dish. *Konbu* and *shiitake* are similarly boiled to prepare soup stocks yielding their particular flavors.

Dried foods for making *dashi* were developed essentially to add subtle and enhancing flavors to traditional dishes that consisted mainly of vegetables with little intrinsic taste. But the traditional interest in such products led Japanese scientists to conduct chemical analyses of their flavors. The analyses found that inosinic acid from *katsuo-bushi,* monosodium glutamate from *konbu,* and guanylic acid from *shiitake* were the sources of their natural tasty flavors. This research was the forerunner of Japan's modern natural and artificial flavor research industry.

Table Manners and Tableware

As is the case in China and Korea, Japanese food is usually served in sizes suitable for picking up by chopsticks, the use of which is thought to have been introduced from China in the seventh century. That the Japanese ate with the fingers prior to the introduction of chopsticks was recorded by a Chinese mission in the early third century. Spoons, however, although common in China and Korea, did not catch on in Japan, perhaps because the habit of sipping soup from handheld wooden bowls made the use of spoons superfluous. Japan's abundant forest resources meant that wooden tableware was more readily available than ceramic ware, and a wooden bowl can be more comfortably held than a ceramic or metal one.

Traditionally, only lacquered wooden ware was used for formal feasts. Chinaware remained unpopular until the seventeenth century, when mass production became possible as a result of new manufacturing techniques learned from Korea. The more widespread use of china caused a functional division between wooden and chinaware to evolve for daily use. Chinaware was used for rice and side dishes, whereas boiling hot soup was served in wooden lacquered bowls.

As a rule, every individual has his or her own chopsticks and a set of tableware. An extra set of chopsticks is used to serve food from a communal food vessel to each individual vessel. If extra chopsticks are not provided with the communal food vessel, then individuals reverse their own chopsticks and use them to transfer food to their own vessels. This practice, however, reflects more a psychological cleanliness derived from Shintoism (in order to prevent one's spoiled spirit from passing to others through shared foods) than it does practical sanitary concerns.

No chairs were used in Japan before the general adoption of dining tables in the latter half of the twentieth century. Diners sat either on tatami (straw mats) or on the wooden floor. Vessels containing food were served on a small, low, portable table called a *zen.* Usually, each dish was set on a *zen* in the kitchen and then brought to and placed in front of the diner. Several *zen* tables were used for each person at a formal feast, as the numerous separate dishes could not all be placed on just one. The number of small tables at a feast consequently became a standard for evaluating the event as well as the host. One unique feature of a Japanese meal is that all the dishes are served simultaneously. The only exceptions are meals served as part of a tea ceremony, in which dishes arrive in an orderly manner one after the other.

As a diner's personal table is very low, vessels containing food are handheld and lifted close to the mouth, to which the food is delivered with chopsticks. When sipping soup it is not considered bad manners to make a slurping sound. Modern Japanese table manners, for the most part, originated at the formal feasts of the samurai warrior class during the sixteenth and seventeenth centuries. From these feasts evolved the rituals and complicated manners for using tableware and chopsticks that are still commonly practiced today.

A big change, however, has occurred in the traditional table setting during the twentieth century. During the first half of the century, a larger portable table called *cyabu-dai,* on which there is space enough to place all the diners' dishes, gradually replaced the traditional personal table. Family members sat on tatami mats and surrounded the dining table for their daily meals. But the biggest change has been the increasing use of Western-style tables and chairs in ordinary households during the last few decades. This has drastically westernized Japanese dining settings: About 70 percent of all households now use a table and chairs for meals (Ishige 1991b).

Tea and Liquor

The first record of tea in Japan mentions an offering of prepared tea to the Emperor Saga, in A.D. 815, by a Buddhist monk who had studied in China. This particular tea was prepared by pounding a roasted block of compacted tea leaves into powder and then boiling it in water. The emperor became fond of it and ordered the planting of tea trees. Tea drinking quickly became fashionable among the aristocracy but, for some unknown reason, lost popularity in the tenth century. The taste and flavor may have been too strong for the Japanese palate at that time.

In the thirteenth century, tea drinking again became a popular custom as a result of the reintroduction of the tree, on the one hand, and on the other a new method of tea preparation, brought from China by a Buddhist monk called Yōsai. Yōsai's book, which recommended tea as healthful, caused a strong revival of interest in tea drinking among aristocrats and monks, and the popularity of tea has continued undiminished until the present. After its reintroduction, steamed tea sprouts were dried and then ground to produce powder, which was mixed with boiling water in a tea bowl, a method basically the same as that which continues today as the tea ceremony.

The tea ceremony, or *cha-dou,* was established in the sixteenth century by Rikyu, who refined the custom to an aesthetic form based on Zen philosophy. It was an attempt to create an aesthetic whole, unifying architecture, gardening, fine arts, crafts, religion, philosophy, literature, food preparation, and presentation. The meal that accompanies the ceremony, called *kaiseki-ryōri,* has come to be regarded as the most refined form of cuisine and is still served in the best Japanese restaurants today.

The drinking of powdered tea, however, did not achieve general popularity owing to the intricate preparation and drinking etiquette required. Even today it is limited to the tea ceremony or other special occasions. The popular green tea is a leaf-type tea, or *sen-cha,* which is prepared by pouring boiling water on dried tea leaves in a teapot. Neither milk nor sugar are added. Drinking of this type of tea started in China during the Ming dynasty, and in the seventeenth century was introduced to Japan, where it became a custom widespread throughout the population and, thus, was incorporated into the Japanese way of life. People who had drunk only hot water prior to the introduction of tea now finished meals with it, had tea breaks, and served tea to welcome guests. That this tradition has survived is evident in the free tea service still offered in virtually every Japanese restaurant.

Only in recent times have alcoholic drinks such as wine or beer (produced by the saccharification of cereal germination) existed in Japan. The oldest-known such beverage, mentioned in eighth-century literature, utilized the starch saccharification potential of saliva. Raw or boiled rice was chewed and expectorated into a container where it mixed with saliva. This primitive technique survived until the beginning of the twentieth century in Okinawa. By tradition, virgins prepared this type of liquor for special religious ceremonies. Another practice – that of applying *kōji* fungus to rice as an initiator of fermentation (introduced from China) – has also been in general use since ancient times.

Rice wine or sake, which was homemade by farmers, is a result of the alcoholic fermentation of a simple mixture of steamed rice, *kōji,* and water. Professional brewers would prepare sake by adding low-alcohol sake to newly mixed steamed rice and *kōji* without previous filtering. This process causes saccharification and alcoholic fermentation at the same time and increases the alcoholic strength of the mixture. In contemporary commercial production, such a process is repeated three times to increase the amount of alcohol to nearly 20 percent. The mixture is then placed in a cloth bag and squeezed with a press. The pasteurization of the clear liquid from the press is the last part of the process.

The latter technique was first mentioned in A.D. 1568, in the *Tamonin-nikki,* the diary of a Buddhist monk, indicating its practice in Japan some 300 years before Louis Pasteur. In China, the first country in East Asia to develop the technique, the earliest record of the process dates from A.D. 1117 (Yoshida 1991).

Today, sake is normally served by warming it to nearly 50 degrees centigrade in a china bottle immersed in boiling water, after which it is poured into a small ceramic cup. This popular procedure began in the seventeenth century, although at that time hot sake was regarded as appropriate only in autumn and winter.

Shōchū, a traditional distilled liquor first mentioned in a sixteenth-century record, uses rice, sake lees, or sweet potatoes as a base material. A similar distillate from Okinawa, *awamori,* employs rice exclusively. In this case, the production technique is thought to have been diffused from Thailand in the fifteenth century, but the true forerunner of Japanese *shōchū* has yet to be firmly identified. One theory regards Okinawa and its *awamori* as the origin, whereas another insists that China was the source. We do know that *shōchū* was produced mainly in southern Kyūshū and Okinawa, where the hot climate made the brewing of good-quality sake difficult, and the liquor has been consistently consumed there since the Edo period. In other regions, *shōchū* has been regarded as a drink for the lower classes, who wanted a stronger (and cheaper) beverage than the more expensive sake.

Establishing Traditional Food Culture

As already mentioned, since the introduction of rice cultivation, various foods and their processing or cooking techniques have reached Japan from both China and Korea. In addition, European foods, brought by Portuguese traders and missionaries, started to flow into Japan between the late fifteenth and the early seventeenth centuries. But European styles of cooking, which mainly used meat, were not accepted by the mostly Buddhist Japanese, who were banned from eating meat by religious decree. Nonetheless, Western desserts and sweet snacks were welcomed, and some of the techniques of preparing these were adopted locally and still survive today. A typical example is a sponge cake called *kasutera* that derived from the Portuguese *bolo de Castelo,* a cake from the Castelo region of Portugal (Etchū 1982: 78–9).

Fearing that the propagation of Christianity by Western missionaries was merely a pretext to disguise Western attempts to colonize Japan, the Tokugawa Shogunate banned Christianity and closed the country to outsiders in 1639. The resulting near-total isolation from the rest of the world, lasting until 1854, brought domestic peace during the Edo period (named for the Shogunate's city). Domestic social stability, combined with isolation, tended to lend an unchanging quality to Japanese culture, including the culture of food. Indeed, most traditional dishes served in homes and restaurants today had their origins in the Edo period.

During the Edo period, Japanese food culture was developed and refined among wealthy urban middle-class merchants and artisans. This was a situation much different from that of many other countries, the food cultures of which, including styles of cooking, preparation techniques, table settings, and manners, were first developed and refined in the social life of the court and aristocracy before they diffused to the general society. But the Imperial Court in Kyoto had only a symbolic status at that time, with little political, economic, or social influence. The warrior class that supported the shogunate administration adopted the ritualized court cuisine of former times, which placed great emphasis on an intricate etiquette of food consumption, rather than on the food itself. The ruling class that regulated its members through ascetic morals had little interest in developing better or different flavors and tastes in their cuisine, whereas the majority of the peasants lived in poverty and were scarcely able to sustain themselves on the meanest of foods.

Wealthy merchants controlled (at least economically) Edo society, and Japanese haute cuisine restaurants came into being about the middle of the eighteenth century to cater to them. These restaurants were mostly located in the three major cities of Edo, Osaka, and Kyoto, and were similar to those established in Paris for the French bourgeoisie. With their superb interior decorations and ornamental gardens, such restaurants made every effort to serve refined, palatable dishes that were utterly different from those offered at the formal banquets of the court and the warrior class. The new and innovative recipes and food preparation techniques gradually spread to influence eating habits nationwide and ultimately became the core of today's traditional Japanese cuisine.

The emphasis on aesthetic food presentation in contemporary Japanese cuisine also originated in these restaurants with presentation devices of *kaiseki-ryōri.* The Japanese philosophy of food presentation seeks to reflect the Japanese view of nature in the elimination of anything artificial from the plate. Thus, symmetrical presentation, for example, is the antithesis of this philosophy, which would rather have imbalance and a blank space on a plate. This approach provides an elegant appearance, whereas to cover a whole plate with various foods is considered vulgar, even though it gives an affluent impression at first glance. Conceptually similar to an empty space in an India ink oriental painting, this deliberately proportioned space becomes an integral part of the art of food presentation. The representation of a season of the year in the display of a dish (by utilizing specific materials such as bonito fish in May or the taro potato in August – both lunar months) is also an important dimension of this philosophy.

Along with the haute cuisine restaurants, inexpensive eating houses and pubs for craftsmen and store employees also appeared in big cities. Not only did various noodles, along with sushi and tempura, become popular snacks in these eating houses, but other specialty restaurants and stalls serving only specific items proliferated. One *soba* shop and two sushi shops to a block was a common sight in the center of Edo, even in the eighteenth century, and according to the 1804 census, 6,165 eating houses existed in the city. This meant that there was one eating house for every 170 persons in the population, not counting peddlers' stalls and eating houses in the red-light district, which were excluded from the census. Another record (which again excluded peddlers' stalls) shows that in 1860, representatives of 3,763 *soba* shops from all over Edo held a meeting to discuss raising prices to meet the increased cost of ingredients.

Restaurant guidebooks for urban gourmets and visitors from the country became popular from the late eighteenth century, corresponding to the rapid increase of dining-out facilities in big cities. Indeed, there were urban bourgeoisie who enjoyed restaurant hunting in Japanese cities with help from guidebooks nearly a century before the publication of the *Michelin Guide* in France (Ishige 1990). Cookbook publication was also brisk, with about 130 originals and several hundred later editions of the originals known to have been printed.

Modernization of Foods

The Meiji Restoration, which put an end to the Tokugawa Shogunate in 1868, gave expression to the need for rapid social modernization. The government-led industrial revolution introduced Western technology and culture and developed a capitalistic economy with the ultimate goal of enriching and strengthening the Japanese nation in the world. A change of eating habits, which occurred in accordance with social improvements, can be seen in government encouragement of meat eating and milk drinking so as to make the physique of Japanese people comparable to that of Western people.

The change began with a public report in 1872, which mentioned that Emperor Meiji enjoyed beef dishes. Following this declaration, it became a custom of the court to entertain international guests with formal dinner parties at which French cuisine was served, and the traditional taboo against meat eating disappeared rather quickly. The first popular meat dish was boiled, thinly sliced meat served with tofu and leeks. It was seasoned with soy sauce and sugar and later became known as sukiyaki. Yet Western cuisine in general was reserved for special occasions and was prepared exclusively by professional chefs; thus, although the number of Western restaurants in big cities increased, Western cuisine was not commonly adopted in Japanese homes for a long time to come.

Milk drinking, although introduced by resident Westerners and repeatedly praised as nutritious by the government, met nonetheless with stubborn resistance from a general public unwilling to accept it as part of the normal diet. Indeed, until the mid-twentieth century, milk was regarded as either a medicine or a special health drink for the sick or persons of weak constitution. Except for canned condensed milk, welcomed by nursing mothers as a supplement to breast milk, few people adopted the custom of consuming dairy products (such as butter and cheese) before the general introduction of bread as a breakfast food in the 1960s. Yet even in the present, the limited consumption of dairy products in the home is another of the features that set Japanese eating habits apart from those of other developed countries.

It is interesting to note that although Western cuisine became progressively more popular after the Meiji Restoration, Chinese cuisine was largely ignored, even though it shared with Japanese cuisine a common food element (rice) and eating method (chopsticks) and had long influenced Japanese food culture. Western cuisine was regarded as a symbol of modernization, whereas the late nineteenth century Japanese victory in the Sino-Japanese War over Korea strengthened contempt for the Chinese people and their culture. Such factors delayed the Japanese patronage of Chinese restaurants until the 1920s, though there were many such restaurants in Japan, catering to Chinese merchants and students. The Japanese maintained a similar prejudice against Korean cuisine, arrogantly disregarding the culture of a people whom they had annexed. But also at the time, the spicy flavor of Korean food created by the use of garlic and pepper was contrary to the traditional plain taste of Japanese food. Korean barbecues and pickles have, however, subsequently become common in Japanese homes.

The production of beer and wine began in the early Meiji era. Beer, despite its bitter and unfamiliar taste, soon became popular, while sake drinking also continued. The government tried to promote a wine industry for export, but the project was destroyed by phylloxera, which raged through European vineyards at that time and reached Japan in 1884 via imported vine stock. After the devastation, only artificially sweetened wine, consumed as a nourishment for the sick or by people of weak constitution, was produced – and this on a small scale. However, quite recently a resumption of domestic table wine production has occurred in Japan to meet a demand that has increased since the 1970s. This development has paralleled Japanese economic growth and with it a growth of interest in European and Californian wines. But although wine was unpopular until recently, by the 1920s beer, whiskey, coffee, and black tea were regularly drunk at an increasing number of bars, beerhouses, cafés, and teahouses in the big cities.

The modernization of Japanese food culture after the Meiji Restoration was interrupted by the rise of militarism and World War II. Following the Manchurian incident of 1931, 15 years of war and large-scale mobilizations, along with trade sanctions by Western nations, caused food imports to decline severely and slowed domestic agricultural production as well. Consequently, major food items, including meat and dairy products, were rationed under government control. Even fish was in short supply as war destroyed the fishing industry, and a return to the traditional meal of rice with vegetable side dishes was strongly encouraged by the government.

As the war progressed, even the minimum food ration could not be distributed regularly, and malnutrition became a serious problem. People were forced to supplement their rations by growing sweet potatoes (as a rice substitute) and other vegetables in home gardens; even after the defeat in 1945, it took 10 years for the nation to regain its prewar level of agricultural output. However, as a result of the rapid growth of the Japanese economy since the 1960s, diets previously concentrated on carbohydrates and poor in fat and animal protein have greatly improved. As foreign foods and styles of cooking have been embraced for cooking in the home, with their original tastes altered to conform with Japanese preferences, a large-scale fusion of foreign and traditional cuisines has taken place.

Thus, annual per capita rice consumption, which reached a maximum of 171 kilograms (kg) in 1962, has since declined and has remained at around 70 kg since the late 1980s. The consumption of sweet potatoes and barley as rice substitutes has declined drastically, and only a few people still eat them regularly. Such traditional carbohydrate foods have been largely supplanted by bread, which school-lunch programs made popular. These programs served bread made from American flour to schoolchildren. The flour had been received as food aid during the postwar food shortage.

Today, about 30 percent of the adult population eats bread for breakfast, but very few people eat bread at lunch or dinner. In contrast with the laborious preparation needed for rice, timesaving bread is suitable for the breakfast needs of a developing urban society in which many people commute and so have less time for meals.

Although there has been a rapid increase in the consumption of previously rare foods, such as meat, eggs, dairy products, and fats, the consumption of traditional foods, like fish and vegetables, has also increased. People in Japan no longer maintain the attitude that meals are merely a source of energy for labor and that a staple food is the most efficient source of such energy. Now people enjoy the meal itself through the various tastes of side dishes, and a greater emphasis on side dishes than on staple foods has kept pace with increases in the national income.

A large variety of foreign foods and cuisines are now part of the household menu. But they have become popular only as it was determined that their flavors complement rice, soy sauce, green tea, and so on. Moreover, their tastes and preparation have often been adapted to moderate flavors, and their size or form has been arranged for use with chopsticks. In other words, such modifications should be viewed as part of an expansion of Japanese eating habits and cuisine, rather than a headlong adoption of foreign dietary patterns.

The Japanese intake of the chief nutrients reached an almost ideal level by the end of the 1970s, except for a little too much salt and a lack of calcium. The general physique has improved accordingly and the average life span has become the longest in the world. This ideal situation, however, may not continue long, as the generation now being raised in this affluent society on a high-protein diet may later pay a stiff price in geriatric diseases as a result of overnutrition – a problem that is becoming acute in other developed nations.

V.B.5 ~ Korea

Historical Background

If the history of a dietary culture is, in many ways, the history of a people, then the evolution of Korea's dietary traditions clearly reflects that nation's turbulent history. Geography and environment play a decisive role in determining the foundation of a nation's dietary culture, whereas complex political, economic, and social conditions and interactions with other cultures contribute to further development.

Traditional dietary strategies must balance the need for sufficient calories and specific nutrients with the need to avoid or minimize diseases associated with foods that are contaminated, spoiled, or otherwise unhealthy. An account of traditional diets should, therefore, deal with food- and waterborne diseases as well as with typical foods and cooking methods. Once dietary habits and food preferences have been established, they become a central part of the culture and are highly resistant to change.

It is not uncommon, however, to find that in the course of exchanges between cultures, foreign foods have become so thoroughly adapted to local conditions that their origins are quite forgotten. In a rapidly changing and interdependent world, it is important to understand the historical background of traditional diets and the impact of modernization in order to maintain and develop dietary strategies that balance cherished traditions with new circumstances. An understanding of the traditional foods of Korea, therefore, requires a brief overview of Korean geography and history.

Korea occupies the mountainous peninsula south of Manchuria; the Yellow Sea separates Korea from mainland China to the west. Japan is only 206 kilometers (km) away across the southern Korea Straits. Because of its strategic location, Korea has a history that has been intimately linked to developments in China, Japan, and other Asian countries. The total size of the peninsula is about that of the state of New York. It was artificially divided along the 38th parallel as the result of World War II and the Korean War, with the area of the northern zone about 122,370 square kilometers (sq km) and that of the Republic of Korea about 98,173 sq km. The peninsula is approximately 1,000 km in total north-south length and 216 km wide at its narrowest point, with a rugged coastline about 17,269 km long. Korea has long been a cultural bridge and a mediator between China and Japan and often the target of their territorial ambitions and aggression. Devastated and exhausted by centuries of conflict, the "Hermit Kingdom" during the sixteenth century embarked on a policy of isolationism that kept Korea virtually unknown to the West until the last decades of the nineteenth century.

Only vague outlines of Korea's early history have been reconstructed. Old Choson – the first of the periods of Korean history – is traditionally, but unreliably, dated from 2333 to 562 B.C. Ancient sources recall a period of settled village life in which the people cultivated the five grains, domesticated the six animal species, and harvested foods from the sea.

The Three Kingdoms period encompassed the era of Koguryo (37 B.C. to A.D. 688), Paekche (18 B.C. to A.D. 660), and Silla (57 B.C. to A.D. 935). Since the fourth century A.D., Buddhism has provided a sense of spiritual unity for the peninsula, despite conflicts among the Three Kingdoms.

The period from A.D. 618 to 935 is known as the time of Unified Silla. The Koryo dynasty lasted from 918 to 1392 and was followed by the establishment of Modern Choson under the rule of the Yi dynasty (1392–1910), whose bureaucratic and administrative structures were based on Confucian principles. During the Three Kingdoms period, the adaptation of the Chinese writing system to the Korean language stimulated state-supported compilation of national histories, but none of these annals survive. Extracts from the annals compiled during the Koryo era are the oldest extant Korean historical texts.

Korean Foodways

Staples

As might be predicted from what we know of Korea's long history and the struggles of its people to maintain their independence and their unique culture, Korean dietary patterns, traditions, and customs can be described as deeply rooted and not easily changed. Some modern Korean nutritionists not very modestly proclaim that traditional Korean foods constitute the perfect diet, outstanding in nutrition, taste, appearance, and variety. In sum, Korean cuisine is said to provide a nutritious, well-balanced answer to the weight and cholesterol problems that plague the developed world. Moreover, presenting traditional foods in the proper manner is said to promote a sense of peace and well-being that enhances the stability of the family and the nation.

The Korean diet is about 70 percent carbohydrate, 13 percent fat, and 14 to 17 percent protein. The European diet, in contrast, is usually about 40 percent carbohydrate, 30 to 40 percent fat, 15 to 20 percent protein, and 10 to 15 percent sugar. Scientific studies of traditional Korean foods, however, find both good and bad aspects. On the positive side, by combining and mixing a variety of materials, Korean cooks have been able to balance the nutritional qualities of available foods. On the other hand, traditional foods and seasonings provide a very high salt intake. Rice is regarded as the staple food, and other foods are described as subsidiary. Of course, although rice may satisfy hunger, it is not a complete food, and essential elements must be added to the diet to avoid malnutrition. Korea's famous fermented vegetable preparations, known as kim-chee, almost invariably accompany each meal.

The traditional arts of cooking and presentation are said to be fundamental aspects of Korean culture; the proper preparation of food is considered a noble art as well as a science. Although it is difficult to precisely analyze and describe the special "Korean taste," preserving special dietary traditions and transmitting them to future generations is highly valued. Beyond nostalgia, Korean nutritionists are also concerned with the scientific analysis of the many components of the Korean diet and methods of preparation.

Historically, Korean food components and methods of preparation have been adapted to the four distinct seasons of the year and the different regions. Seasonal and regional adaptations bring out the best tastes in available foods and provide the balance needed to supply the body's nutritional requirements. Food etiquette is inextricably linked to food preparation and presentation, which is expressed in terms of rules for the placement of food on the table and rules for facing the table. Although the original Korean low food table, around which diners sit on the floor, has been largely displaced by Western-type tables and chairs, the etiquette of food presentation has not been forgotten.

Generally, the traditional Korean diet features three meals a day in which the foods are divided into two parts: the main dish or staple food – almost invariably boiled rice – and subsidiary foods or side dishes, such as soup, bean curd, cooked meat or fish, cooked vegetables, and fermented vegetables. Proper meal planning dictates diversity in methods of preparation and ingredients. The simplest meal has three side dishes, whereas more elaborate meals are characterized by an increasing number of side dishes. An ordinary everyday meal might consist of a serving of rice and soup for each person and a series of shared side dishes. The table setting shows a clear distinction between the main and the subsidiary dishes. For rituals and festivals, the table setting becomes more elaborate and includes a variety of appetizers, soups, noodles, vegetables, rice cakes, pastries, and beverages.

The evolution of Korea's traditional grain-based diet required the development of farming techniques as well as tools for hulling and pulverizing the grains. The evolution of the house, the kitchen, and the utensils for cooking, serving, and eating food was also part of this process. Cereals, such as millet and sorghum *(kaoliang),* were cultivated in Korea from about 2000 B.C. Excavations at ancient sites have yielded stone farming tools and the remains of different kinds of millet. Millet is probably the only grain native to the whole peninsula, but rice has long been the most important component of the Korean diet, with short-grain rice ultimately the favorite staple.

Rice was introduced from China, perhaps as early as 2000 B.C., although, according to some accounts, a

Chinese nobleman brought rice to Korea in 1122 B.C. Though small in area, the Korean peninsula has an extremely varied climate, so other cereals predominated in regions not suited to rice farming. In southern areas, rice was the mainstay, whereas millet was the staple grain in the north. Barley was introduced to Korea earlier than wheat, but the exact date is unknown. Barley was grown mainly in the southeastern region, where it was consumed as a staple in combination with rice. Wheat was not cultivated until about the first or second century A.D. It was probably introduced into Korea from China around the first century, but it has never been considered a staple. Even in the 1930s, the area devoted to wheat farming was only about half that occupied by barley.

During the Three Kingdoms era, Koguryo, Paekche, and Silla all engaged in land-reform policies, expanded irrigation systems, and actively encouraged the propagation of improved iron farming implements. Rice became the staple food of Paekche, whereas the people of Silla still depended on barley, and millet remained as important as rice in Koguryo. During the Unified Silla period, further developments in land use and farming techniques led to significant increases in rice production. But other important crops, in addition to barley, millet, and sorghum, were soybeans, red beans, mung beans, and buckwheat. Policies that increased farming productivity and land use were of primary importance to the government of Koryo. Rice reserves were maintained for emergency use, and the price of grain was regulated in order to increase rice production.

The soybean, a legume, is the most widely eaten plant in the world and is used in many forms, especially in China, Korea, and Japan. With only slight exaggeration, the ancients called the soybean a treasurehouse of life, well suited to sustain, restore, and enrich the soil and the human body. The nutritious quality and versatility of the soybean make it an important part of the diet in areas like Korea, where adults do not drink milk and dairy products are not used. Soybeans can be eaten fresh, dried, ground, fermented, sprouted, or processed into bean curd and various pastes and sauces. Both soybeans and mung beans yield bean sprouts, a good source of vitamin C.

The soybean is also an excellent source of oil, although sesame oil is a favorite component in Korean cooking, and both toasted sesame seeds and sesame oil are important flavoring agents. Many different kinds of vegetables, fruits, and nuts have been part of the Korean diet since ancient times, among them radishes, turnips, lotus roots, taro, leeks, lettuce, green onions, garlic, cucumbers, eggplants, pears, peaches, chestnuts, pine nuts, and hazelnuts. In addition, there are wild plants, such as bamboo shoots, ferns, mushrooms, ginseng, and the broad bellflower obtained from the mountains and fields. During the Koryo era, radishes and pears were especially grown for the preparation of kim-chees that were said to be superior in taste to the fermented vegetables of the Three Kingdoms period. Vegetable leaves were also used as wrapping for little packages of rice or meat.

Agricultural techniques developed further during the Choson era, and practical farming manuals, stressing methods appropriate to Korea, were written during this period. The Yi dynasty actively encouraged an expansion of the trade in exotic foreign drugs and foods that had begun during the Koryo era. For example, the great king Sejong (reigned 1418–50) supported attempts to grow orange and grapefruit trees in several provinces in order to determine whether these fruit trees could be established in Korea. These and other experiments made it possible for Korean farmers to cultivate various foreign plants and trees.

New Foods

Somewhat later, important foods from the Americas, including chilli peppers, pumpkins, sweet potatoes, white potatoes, maize, and tomatoes, were introduced. The sweet potato reached Korea from Japan in 1763 with an official returning from a diplomatic mission. Originally regarded as a famine-prevention food, it eventually became a popular part of the diet. The white potato was introduced by way of China about 1840. It proved well suited to cultivation in the northern regions.

Chilli peppers and tobacco were brought to Korea about the time of the devastating war with Japan known as the Hideyoshi Invasion (1592–8). But today it is impossible to imagine Korean food without chilli peppers, which constitute the main seasoning in most Korean dishes, especially in kim-chee and hot soybean paste.

One of the early names for the plant was "Japanese mustard," because the Japanese had acquired knowledge of the chilli pepper, and probably its seeds as well, from Portuguese Catholic priests. King Sonjo (reigned 1567–1608) made numerous requests to Japan and even to China in attempts to obtain the seeds. Unwilling to lose their monopoly, however, the Japanese claimed that the pepper plant could grow only in foreign tropical areas, and that even if seeds could be obtained, they would not necessarily grow in Korea. They also claimed that the foreigners who sold peppers always boiled the seeds so that they would be useless in attempts to grow new plants. The Korean king countered that various other plants and animals that had been brought to Korea from foreign lands had flourished, and after the difficulties in obtaining the seeds had finally been overcome, the pepper plant was easily adapted to Korea.

Some authorities thought that chilli peppers contained a powerful poison, but the new food quickly became widely used as a seasoning and even was sold in winehouses, where drinkers added it to liquor for a sensation of hotness. Presumably, given the eager acceptance of chilli peppers, Korean cuisine had not been bland before their arrival. And, in fact, Koreans had previously used a hot spice from China, which was probably similar to the Sichuan peppercorn. The ancients thought that pepper was valuable in the cure of fever, whereas modern admirers of the chilli pepper claim that its active agent strengthens the stomach, offers protection against dysentery, and prevents the oxidation of fats.

Cooking and Eating

Bowl-shaped earthenware pots were used for cooking in Korea from the beginning of the farming period. But steaming was thought to improve the quality of the food, and earthenware steamers for cooking grains have been found in Bronze Age shell mounds that date from 1000 to 300 B.C. Koguryo wall paintings in third-century tombs depict food cooked in an earthenware steamer. The kinds of food cooked in the steamer apparently included five-grain rice (a mixture of rice, millet, soybeans, red beans, and barley or sorghum), steamed rice cakes, and glutinous rice cakes. Sauteed rice cakes or sorghum pancakes were also consumed. Cast-iron kettles for rice cooking did not become common until the later part of the Three Kingdoms era, and the traditional chinaware and brassware used for serving foods developed during the Choson period. One interesting example is a special large dish with nine compartments that was used to hold an assortment of side dishes placed in the individual compartments. Wealthy people used this dish for outdoor meals and picnics.

Ideas about the ideal configuration of the house reflect the importance of the kitchen and the proper handling of rice. According to custom and classical texts, the house with the most auspicious configuration was one that faced south and had a mountain behind it. The mountain protected the house from the northeasterly winter winds and the sun could shine into the front of the house. The kitchen would be located to the west so that when the rice was scooped out of the pot, the flat wooden spoon faced the inside of the house. If the kitchen faced east, the spoon would face the outside; this was thought likely to bring bad fortune.

A unique aspect of Korean table manners is that Koreans, unlike the other peoples of East Asia, use spoons for soup and rice and came to believe, unlike the Chinese, that it was rude to bring bowls up to their mouths. In the northern parts of the Korean peninsula, where staple foods included millet and barley, it was found that the grains of these cereals (especially when mixed with nonglutinous rice) were not easily managed with chopsticks. Thus, bronze spoons as well as chopsticks have been found in fifth- and sixth-century royal tombs.

Bronze spoons from the Unified Silla Kingdom (618–935) differed in shape from spoons found in China in that they were bent, thin, and long, and were apparently used together with chopsticks in sets (the shape of Korean chopsticks is also different from those of the Chinese and Japanese). Silver spoons were used at court and by the ruling class. In addition to being elegant, silver was supposed to detect poison in food.

The short-grain sticky rice favored in Korea can readily be picked up with chopsticks, but the use of the spoon is essential in dealing with the ubiquitous soups, stews, and porridgelike preparations found at almost every meal. Another important utensil is the *chori,* a bamboo strainer used to separate rice from sand and stones. Because the *chori* sifts good from bad it has been used as a symbol of good fortune.

It was during the Choson period that Confucianism came to exert a profound impact on political and moral standards, family structure, rituals, and ceremonies. Under the influence of Confucian ideals, the rules concerning food for the extended family and for ceremonial occasions became increasingly strict and rigid. Some concept of the most elaborate cuisine of this time period can be obtained through studies of the foods prepared in the palaces of the kings of Choson. Although the rituals and regulations governing royal cuisine were not common knowledge, some aspects of the art of royal cuisine influenced the dietary culture of the ruling class and diffused beyond the palace walls.

By the end of the Choson period, the art of royal cooking was on the verge of disappearing, and in 1970, when only one former palace chef still remained alive, royal cuisine was designated a major cultural property. Chef Han Hi-san, who had served King Kojong, King Sunjong, and Queen Yun, was awarded the title of Human Cultural Property of Royal Cuisine in 1971. After Han died, Professor Hwang Hye-song, who had studied with Chef Han, inherited the title. Hwang published many books on Korean cooking, established a research institute for royal cuisine, and held exhibitions to bring royal cuisine to the attention of the general public.

Traditions

A grain-based diet need not be bland or totally monotonous, even when boiled rice remains the single most important component. Thus, cereals were also made into gruel, noodles, and dumplings. Well-cooked porridge-like dishes, especially those made of millet, are still considered particularly nourishing and appropriate to the needs of the sick. Another simple, nourishing ancient food product called *misu karu* was made by washing, drying, roasting, and pounding cereal grains into a fine powder that could be mixed with water and used as an instant food. The roasted flour of assorted grains was useful for travelers, students, and others who needed a simple, ready-to-eat food.

Noodles and dumplings are such an ancient and popular part of the traditional Korean diet that, like China, Italy, Japan, Germany, and France, Korea also claims to have invented pasta (Korea has not, however, asserted this claim as passionately as Italy).

Dumplings and noodles have been made from rice and barley and prepared by boiling, steaming, or frying. They were usually served as main dishes for lunch or on special occasions. Noodles were considered especially appropriate for birthdays because they are a symbol of long life. Various kinds of noodles were made of wheat, buckwheat, rice, soya, or mung beans. Steamed wheat-flour buns were first brought from China and also became very popular for festive occasions.

Many different kinds of rice cakes and pancakes have been associated with holidays and festivals ever since the Koryo period. Steamed rice cakes were made with regular or glutinous rice and flavored with chestnuts, honey, jujubes, sorghum, and mugwort. Rice cakes, flavored with mugwort leaves or flowers, are a specialty of the southern provinces, and many therapeutic virtues have been attributed to mugwort *(Artemisia vulgaris),* which is also known as *moxa. Moxa* is supposed to increase the user's level of energy and ward off disease. Mugwort is dried and used in making *moxa* for cauterization *(moxibustion)* and other medicines. Rice cakes made with mugwort paste are traditionally served at the *Tano* festival.

Mugwort figures prominently in the foundation myth of Old Choson. According to ancient sources, the King of Heaven, leader of the gods of wind, rain, and clouds, ruler of grains of all kinds, who presided over life, disease, punishment, and goodness and evil, established his Holy City at the summit of Mount Taebaeksan. The god was approached by a bear and a tiger who beseeched him to make them human. The god gave them each a stick of *moxa* and 20 cloves of garlic and told them to eat them and avoid the sun for 100 days. The tiger failed to follow these instructions, but the bear did and became a woman. The god married her and she had a son called Tan-gun, the founder of Old Choson. Thus, both *moxa* and garlic were regarded as powerful drugs and foods in early times.

Among the most treasured traditional Korean foods are those associated with holidays, ceremonies, and seasons. Traditionally, Korean women prepared special dishes for folk holidays according to the lunar calendar. During the Choson period, with the rise of Confucianism, great attention was paid to rituals attached to holidays, including the preparation of foods thought to supply nutrition appropriate to each season. Such foods were a part of the ceremonies that expressed the hope of good harvests and harmony within the family and the village. Special holiday foods are often described as particularly nourishing and are said to encourage harmony between man and nature. Among these are rice cake soup, dumpling soup, cakes made of glutinous rice, rice cakes steamed on a layer of pine needles, five-grain rice, rice gruel prepared with red beans, sweet rice beverages, and seasoned dried vegetables. Cooking methods and ingredients have varied with regional customs, products, and increasing modernization.

The custom of making a red bean porridge with small dumplings of glutinous rice to mark the winter solstice has been practiced since the Koryo era, and sharing this dish with neighbors has also been part of the tradition. Eating certain foods on holidays was said to prevent different kinds of misfortune: For example, consuming red bean porridge on the day of the winter solstice was supposed to ensure good health, prevent colds, and drive away ghosts.

Five-grain rice and nine kinds of vegetables are typical holiday fare for the first full moon of the lunar year; rice cake soup was eaten on New Year's Day; crescent-shaped rice cakes were prepared for the second lunar month; azalea flower pancakes for the third lunar month; and grilled wheat cakes for the sixth lunar month. In the heat of mid-July, holiday foods that included chicken broth with ginseng, red dates and glutinous rice, and croaker stews were thought to revive the appetite and ward off illness. Foods appropriate to the August harvest moon festival have included taro soup, wine, rice cakes, and new fruits such as pears and persimmons.

Food and flower customs expressed the theme of seeking harmony with nature and incorporating its beauty in delicacies. A document from the Choson period describes an especially fragrant delicacy made by boiling together apricot petals, melted snow, and white-rice porridge. It was customary to go on "flower outings" several times a year, and while admiring the beauty of the flowers, participants would eat foods that incorporated them, such as chrysanthemum pancakes, chrysanthemum wines, chestnut balls, and citron tea.

Different kinds of rice cakes still retain symbolic value. For the ceremonial feast on a child's 100th day of life, steamed rice cakes represent purity and cleanliness; glutinous rice cakes, coated with mashed red beans, represent endurance; rice cakes steamed on a layer of pine needles represent generosity; and stuffed rice cakes represent intelligence. Collectively, the ceremonial foods represent longevity, purity, and divinity. At the feast held for a child's first birthday, there are, in addition to rice cakes, cakes made with cinnamon bark, steamed rice balls rolled in colored powders, and even a steamed, layered, rainbow rice cake that represents the parents' hope that the child will enjoy a wide range of accomplishments.

Seafood

Because Korea is surrounded by the sea on three sides and has many large rivers, its supply of seafood has been plentiful and varied. The remains of abalone, clams, oysters, snails, mackerel, pike, shark, and sea urchins have been found in ancient shell mounds. Different kinds of seaweed were also harvested, dried, and prepared in various ways. For example, seaweed can be made into paper-thin sheets, called *laver,* which are usually seasoned with hot sauce and wrapped around small portions of rice, vegetables, and meat. Seaweed soup is still considered essential for women recovering from the birth of a baby. At the ceremonial feast held when the baby is 100 days old, the mother again eats seaweed soup.

By the Three Kingdoms period, shipbuilding skills had been highly developed, so that many kinds of seafoods could be harvested. The challenge of storing highly perishable aquatic animals led to the development of methods for preserving them by fermentation. Fresh shrimp, fish, and other seafoods were salted and allowed to ferment. Pickled fish were often added to winter kim-chee.

During the Choson period, fishing techniques were further developed, fisheries became significant enterprises, and the production of herring, anchovies, pollack, codfish, and croakers increased rapidly. So, too, did the production of seaweed, and particular kinds were cultivated and processed on offshore islands.

All these products of the sea were dried, salted, or fermented and sold throughout the peninsula. Some were regarded in China as valuable medicines and desirable exotics. Chinese physicians were very interested, for example, in the properties of a certain mollusk that was eaten by the people of Silla; the medical men thought that a soup made from this mollusk and seaweed would cure "knotted-up breath."

Meat

Although geographic conditions in Korea were not suitable for livestock farming, cows, pigs, and hens were raised on a small scale, and, thus, some meat also entered the diet. Wild game could be found in the mountains, and the Koguryo people were known as skillful hunters of pheasants, roe deer, and wild boar. The people of Silla kept semiwild livestock on nearby islands. Cattle, hens, pigs, horses, and oxen were raised by the people of Paekche.

During the early Koryo period, when the influence of Buddhism was especially strong, kings and commoners alike generally refrained from eating meat, but pickled fish and shellfish were often served as side dishes. By the middle of the Koryo period, cattle were being raised on Cheju Island, and those whose religion and finances permitted it ate beef, pork, lamb, chicken, pheasant, and swan meat. Wealthy people might have their meats cooked whole, but cooking thinly sliced pieces of meat became popular during this time. Among the favorite meat dishes of the Koryo period were roasted ribs and bone and tripe soup. Significant changes in dietary customs developed during the Choson era, including increased (and perhaps guilt-free) consumption of beef, pork, chicken, and pheasant.

Fermented Food and Drink

Korea's famous pickled cabbage, kim-chee, has probably been an important side dish since agriculture began, but the first appearance of the word "kim-chee" occurred in the collected poems of Lee Kyu-bo (1168–1241), an eminent Koryo poet. Fermented vegetables were essential parts of the diet during the long, harsh Korean winter, when fresh vegetables were not available. Kim-chee is said to retain all the nutrition of almost any fresh vegetable.

Making kim-chee for the winter was a major annual event for each household. Traditionally, relatives and neighbors took turns helping each other, sharing the ingredients and the freshly made kim-chee. Originally, kim-chee contained only simple vegetables, but eventually a large number of regional and seasonal variations evolved, including those flavored with fermented seafoods, such as shrimp, anchovies, cuttlefish, crabs, and oysters. When hot chilli peppers were introduced in the middle of the Yi dynasty, the method of making this traditional food underwent substantial changes and improvements.

Although kim-chee is eaten as an essential side dish throughout the year, different ingredients and methods of preparation are associated with the changing seasons and different regions. Almost all varieties include Chinese cabbage, radishes, red pepper, and garlic. Salted shrimp provides the special flavor characteristic of the kim-chee preferred by residents of Seoul; salted anchovy is used in southern regions, and various kinds of fish are favored in northern regions, but the art of making kim-chee can be applied to an almost endless variety of basic ingredients, spices, and flavorings. Even the stems of the sweet potato vine can be turned into kim-chee.

Today, except for rice, kim-chee is the most important and popular food in the Korean diet. Another interesting fermented food, however, is made from a mixture of chopped fish, rice, radishes, and malt. This preparation is said to ward off indigestion, especially during festivals when overindulgence is likely to occur. Similar health-promoting benefits have been ascribed to kim-chee. There is no doubt that it is a good source of vitamins, including ascorbic acid, which protects against scurvy. Kim-chee is also said to regulate body fluids and intestinal fermentation, prevent constipation, and stimulate the appetite. Certainly, fermented foods add taste, texture, and important nutrients to the bland main dish of rice and other grains. They are said to provide the five different tastes: sweet, salty, hot, sour, and bitter.

In addition, wine and soy sauce are important products of fermentation. The production of alcoholic beverages from fermented grains probably developed during the early stages of farming. Similarly, soy sauce and hot soybean pastes, made by processing soybeans, have long been used as seasonings and condiments that contribute to the characteristic flavor of Korean foods. Techniques for making wine and soy sauces became highly advanced in the Three Kingdoms period, but the art of making soybean paste was revolutionized by the addition of the hot chilli pepper. Soy sauce and hot soybean pastes are still indispensable seasoning agents in Korean cooking. Koreans consider Japanese soybean sauces excessively sweet in comparison to their own, which they characterize as salty, light, simple, and refreshing. Each household traditionally prepared soy sauce and soybean pastes in the spring or autumn and stored them in large earthenware jars on special terraces. Recent health claims have been made for soy sauces: It is suggested that they not only prevent the oxidation of dietary fats but also contain anticancer factors.

Various kinds of rice wine were made during the Koryo period, including several that served for medicinal purposes. Other wines derived from sources as diverse as roots, barks, irises, chrysanthemums, and bamboo leaves. Many of these were made at home – an important task for the housewife. Farmers and laborers traditionally drank rice wine from a gourd before and after meals and with their midmorning snack to wet the throat and clear away the kim-chee aftertaste.

Exactly when techniques for the distillation of hard liquor were imported into Koryo is unknown. However, records of the time of King Kongmin, who reigned from 1351 to 1374, suggest that hard liquor was already being used and misused. During the twentieth-century Japanese occupation (1910–45), Japanese wines, grape wines, and Western liquors gradually became popular. After liberation from Japan in 1945, Western liquor and beer became widely available, and cocktails and mixed drinks were commonly served at social functions, especially in the cities.

Hot Beverages

In Korea, hot beverages have been collectively referred to as *ch'a,* or tea. Green tea, made of dried tea leaves steeped in hot water, was introduced to Korea in the eighth century by a Buddhist monk from China. Ancient Chinese texts associated tea with Taoist philosophy and referred to tea as the elixir of immortality. Tea plants and the seeds of tea bushes arrived from China in the ninth century. At first, tea drinking was associated primarily with Buddhist temples, the court, and the aristocracy. Drinking the beverage was said to soothe the mind and refresh the spirit while cleansing and improving the body. But it soon became popular among the common people as well, and offerings of tea and tea-drinking ceremonies were part of all national rites. Buddhist temples operated large tea plantations and sponsored tea-brewing competitions.

With the establishment of the Yi dynasty, the custom of tea drinking declined among members of the upper class, who were now professing Confucianism. The Choson government denounced Buddhism and levied high taxes on tea plantations. Alcoholic beverages, such as rice wine, generally took the place of tea in official ceremonies. But despite government repression, tea drinking remained popular, and people cultivated small tea gardens near their homes. Buddhist monks and nuns also continued to drink tea, which was always included in offerings to the Buddha, and men of letters associated tea drinking with artistic endeavors and the contemplation of nature.

The opinions of tea-loving scholars, monks, and poets profoundly influenced Korean culture, especially those of the Buddhist monk and scholar Ch'o Ui (1786–1866), who is credited with reviving interest in the rituals and traditions of tea drinking. In his *Eulogy to Oriental Tea* (1837), Ch'o asserted, among other things, that Korean tea was superior to Chinese tea in taste, fragrance, and medicinal virtues.

In addition to green tea, other such drinks, made from barley, corn, rice, sesame seeds, ginseng, ginger, cinnamon bark, citron, quince, dates, pears, strawberries, cherries, watermelon, and peaches, are also popular. Even the pollen of pine tree flowers can be mixed with honey and made into a sweet tea. Sweet beverages based on honey or fruits are often accompanied by rice or barley cakes. Indeed, many pastries were developed as accompaniments for tea, including fried honey cookies, fried cookies made from glutinous rice, small cakes made with green tea, and candied fruits.

Another important traditional beverage is the scorched-rice tea served with everyday family meals. It is made by pouring water over the rice that sticks to the bottom of the pot in which the rice was cooked. Boiling this rice with water creates a fragrant drink, and rice that is not consumed with the meal can also be mixed with this tea. Making such a beverage also has the virtue of making it easier to clean the spoon, rice bowl, and rice kettle.

Since the 1940s, coffee has become very popular in Korea, but King Kojong, who reigned from 1864 to 1906, appears to have been the first Korean king with the coffee-drinking habit. He was introduced to coffee by the Russian consul general in Seoul. In 1898 Kojong's enemies tried to murder him along with the crown prince by putting poison in their morning coffee. Fortunately, Kojong noticed a peculiar odor and did not drink his coffee. The prince was not so observant, but he vomited the tainted brew before it could do him significant harm.

Famine and Food-Related Disease

Famine

Ancient sources refer to famines and epidemics, floods, severe droughts, and grasshoppers that consumed all the grain. Early agricultural societies were very vulnerable to crop failures and famines. The importance of agriculture in the early Three Kingdoms period is reflected in references to Paekche kings punished for crop failures by removal from the throne, or even by death.

Other sources mention the Koryo relief system and the efforts made by these kings to deal with famines and epidemics. Warehouses were established in various provinces and opened as needed to ward off mass starvation. Government officials were charged with aiding and feeding the poor, and they provided a set measure of millet per day per person. During the Choson period, food reserves were maintained for use during natural disasters and for famine relief. To prepare for famine years, farmers were ordered to gather various edible roots, flowers, fruits, and leaves. Texts written in the sixteenth century describe hundreds of different kinds of foods that could be stored for famine relief. In order to disseminate such information to the general population, books on famine relief were written in the Korean alphabet, the script for the people, rather than in scholarly Chinese characters. Other texts provided discussions of the relationship between diet and health.

Food-Related Disease

Thirteenth-century texts dealing with traditional Korean medicine describe food poisoning that was variously attributed to the consumption of domestic animals, fish, crabs, mushrooms, alcohol, medicines, and miscellaneous chemicals. Given the age-old problem of contaminated food and water, it is not surprising that dysentery was historically one of Korea's more common diseases, to which even members of the royal family fell victim.

Despite the many virtues ascribed to kim-chee, including those of preventing everything from scurvy to dysentery, the symptoms of some vitamin deficiency diseases seem to have been described in early Korean medical texts. One recurrent condition suggests the possibility of beriberi. The symptoms described included swelling of the lower limbs, followed by swelling of the heart and stomach, difficulty in urination, weakness in the feet, and dizziness. However, early accounts are vague, and the symptoms of beriberi are not easily differentiated from those of other diseases.

According to Koryo sources, the Chinese apparently believed that beriberi could be cured by wearing shoes made from the skin of a remarkable fish found in Korea. The skin of this fish was said to be similar to that of the cow. Beriberi was probably rare in Korea, when compared to other parts of Asia, because few Koreans subsisted on a thiamine-deficient polished white rice diet. But the disease was noted among Japanese living in Korean cities because the Japanese were more likely to consume polished rice. During World War II, polished rice became more common in Korea, and beriberi was sometimes observed even in villages. Scurvy and pellagra seem to have been rare, but anemia was not uncommon, and symptoms that suggest rickets, including a condition referred to as "turtle chest," appear in the pediatric sections of ancient medical texts. Classic descriptions of "gentle wind" disease probably refer to osteomalacia, a form of adult rickets. In modern Korea, osteomalacia, a gradual deformation of improperly calcified bones, is fairly common among older women.

Parasitic infections are widespread in Asia, and presumably always have been, but ancient texts are too ambiguous to provide specific diagnostic clues as to the agents involved or the specific sources of infection, although various herbal remedies were prescribed to remove parasites. Gastritis seems to have been the major disease in the category of digestive disorders, but symptoms are also described that suggest gastric ulcers, intestinal disorders, and parasitic infestations.

Paragonimiasis (or pulmonary distomiasis) is caused by infection with members of the genus *Paragonimus,* and references to a disorder characterized by rusty-brown mucus are suggestive of this disease, which could have been acquired by eating contaminated raw crabmeat or other seafoods. The developing parasites lodge in the lungs and cause an intense inflammatory reaction that results in the production of the rusty-brown sputum.

Other parasites were still widespread in the early twentieth century. Infestation with flukes was generally caused by eating raw fish and crustaceans contaminated with the lung fluke *(Paragonimus westermani),* the liver fluke *(Clonorchis sinensis),* or the intestinal fluke *(Metagonimus yokogawai).* Until recent times, contaminated food and water were also a constant source of intestinal diseases such as bacillary and amebic dysentery. The custom of drinking tea or water boiled in the rice kettle provided some protection, as did the use of kim-chee instead of fresh vegetables. Noting that Korean patients recovered from dysentery more easily than Japanese patients, early-twentieth-century medical missionaries advised the latter to eat kim-chee.

Nutritional Status Today

The history of disease in twentieth-century Korea illustrates the remarkable impact of improved sanitary conditions, public-health measures, land reform, and economic development. Despite the devastation caused by World War II and the Korean War, and the repatriation of millions of Koreans from Manchuria, China, and Japan, many epidemic and endemic diseases have been virtually eliminated.

Since land reform policies were put in place in 1948, South Korean agricultural policy has encouraged the development of small, intensively worked farms. This policy was vindicated by the achievement of self-sufficiency in rice production and an increased food output that has kept pace with population growth. South Korea, Japan, and Taiwan have among the world's highest per-acre rice yields. Because much of the peninsula is mountainous and unsuitable for farming, agricultural development policy has focused on maximizing yields by means of high-yield crop varieties. Today, genetic engineering is seen as a principal means of increasing crop yields.

In addition, in the 1960s, South Korea embarked on a vigorous and highly successful program of economic development, and since 1962 the Korean economy has grown at one of the fastest rates in the world. In a remarkably short period of time, South Korea's traditionally agrarian society has undergone a major structural transformation, and the country has become one of the key industrialized nations of the Pacific Rim.

Since the late 1940s, numerous studies of the nutritional status of the South Korean people have addressed the question of shortages in the quantity and quality of the food supply. Most of these investigations reached the same general conclusions, despite some relatively minor regional differences. Overall, the traditional South Korean diet is high in carbohydrates and low in protein and fats. Studies of the state of nutrition in Korea undertaken in 1946 found that over 90 percent of foods consumed came from plant sources.

When similar studies were conducted in the 1960s, the proportion of grains consumed had been somewhat reduced. Rice, however, remained the main food, which may reflect a reaction to years of food rationing and shortages during the Japanese occupation. But rice shortages from 1960 to 1975 led the government to establish rice conservation measures, such as the increased production of wheat, the importation of American surplus foods, and attempts to create two "rice-free days" each week, during which, as a patriotic duty, wheat products would be eaten instead of rice. Bread was used in school lunches, restaurants were ordered to use wheat-flour foods, and a nationwide mass communication campaign was launched to encourage the consumption of wheat products. Although resistance to these attempts to change dietary habits was quite strong, at least students and some white-collar workers seem to have adopted the custom of eating bread for breakfast. Nevertheless, Korea remains primarily a rice-eating culture.

Although self-sufficiency in rice production was attained in the 1980s, imports of wheat products and maize were still essential. In fact, increased demand for wheat flour, used in bread and instant noodles, reflects a significant change in South Korean dietary patterns. Beef imports have also increased, whereas the production of traditional cattle has decreased. Fish and other seafoods have become increasingly important sources of protein.

In general, the intake of animal protein has significantly increased since the 1970s, and the growth in the amount of protein consumed was accompanied by a threefold jump in fat intake between 1962 and 1982. Consumption of beef and pork increased about two times; chicken consumption increased almost five times, and the use of milk and other dairy products also increased about five times. Although the intake of some minerals, particularly calcium, increased significantly, that of iron did not, and many Korean women have exhibited symptoms of iron-deficiency anemia. Investigations of infant and child nutrition in different regions during the 1970s led nutritionists to urge mothers to increase the use of eggs, fish, and vegetables as supplemental foods. One problem with the typical Korean diet is a very high intake of salt and hot chilli peppers; these factors appear to be linked to high blood pressure and a high incidence of gastroenteritis and stomach cancer. Researchers report that the use of great amounts of salt becomes habitual for South Koreans prior to reaching 6 years of age.

It is interesting to note that studies of nutritional status and dietary patterns conducted in the 1960s indicated that at that point, despite changes associated with rapid industrialization, many people had maintained traditional food habits. Indeed, the Korean dietary pattern seems to have been remarkably stable from the early beginnings of Korean history to the end of the Yi dynasty and beyond. Researchers have found little evidence of changes in the basic ingredients and cooking methods used by Korean families other than an increase, in urban areas, in the consumption of dairy products such as butter and cheese.

Between 1970 and 1990, however, the combination – already mentioned – of urbanization, modernization, industrialization, socioeconomic development, and the influence of Western culture wrought significant changes in the typical South Korean diet. In addition, factors such as the 1988 Seoul Olympic Games, the expansion of the fast-food industry, and the influence of mass media have helped accelerate such changes. South Korean nutritionists predict that in coming years, the pattern of food consumption in South Korea will involve a continuing decrease in the amount of grains used and an increase in the consumption of foods of animal origin. Consequently, they urge the development of a national health and nutrition policy that will focus on the prevention of the kinds of diseases associated with these new dietary patterns. Since the 1970s, the pattern of major diseases and causes of death in South Korea has become that of the Western world, whereby cardiovascular diseases, circulatory problems, and stroke are the most important killers. Those who value Korea's unique historical culture warn against losing the harmony and balance encapsulated in the traditional dietary culture and etiquette of the table.

V.C

The History and Culture of Food and Drink in Europe

V.C.1 ∾ The Mediterranean (Diets and Disease Prevention)

The basic elements of healthful diets are well established (USDHHS 1988; National Research Council 1989; USDA/USDHHS 1995). They provide adequate amounts of energy and essential nutrients, reduce risks for diet-related chronic diseases, and derive from foods that are available, affordable, safe, and palatable. A very large body of research accumulated since the mid-1950s clearly indicates that healthful diets are based primarily on fruits, vegetables, and grains, with smaller quantities of meat and dairy foods than are typically included in current diets in the United States and other Western countries (James 1988; USDHHS 1988; National Research Council 1989).

Throughout the course of history, societies have developed a great variety of ways to combine the foods that are available to them (as a result of geography, climate, trade, and cultural preferences) into characteristic dietary patterns. In some areas, typical diets have developed patterns so complex, varied, and interesting in taste that they have come to be identified as particular cuisines. Some of these, most notably those of Asia and the Mediterranean, seem to bless the populations that consume them with substantially lower levels of coronary heart disease, certain cancers, diabetes mellitus, and other chronic diseases than those suffered by other peoples. Consequently, such apparent relationships between cuisines and health have created much interest in traditional dietary patterns.

Illustrative is the current interest in Mediterranean diets that has been stimulated by the unusually low levels of chronic diseases and the longer life expectancies enjoyed by adults residing in certain regions bordering the Mediterranean Sea (WHO 1994). Such good health cannot be understood within the context of those factors usually associated with disease prevention in industrialized countries, such as educational levels, financial status, and health-care expenditures. Indeed, the percentages of those who are poor in Mediterranean regions are often quite high relative to those of more developed economies (World Bank 1993). To explain this paradox, researchers have focused on other lifestyle characteristics associated with good health, and especially on the various constituents of the typical Mediterranean diet.

Data from the early 1960s best illustrate the intriguing nature of the paradox. At that time, the overall life expectancy of Greeks at age 45 exceeded that of people in any other nation reporting health statistics to the World Health Organization (WHO/FAO 1993). Subsequently, the ranking of life expectancy in Greece has declined somewhat, at least partly because of undesirable changes in dietary practices that have occurred (Kafatos et al. 1991). But even with such changes, in 1991 life expectancy at age 45 in Greece was an additional 32.5 years, second in rank only to the 33.3 years yet available to Japanese people. By comparison, in the same year, life expectancy at age 45 for adults in the United States, United Kingdom, and Canada was respectively 30.8, 30.9, and 32.1 years (WHO 1994).

Even these brief observations raise interesting historical questions. For example: What, precisely, is a "Mediterranean" diet? When and under what circumstances did it develop? What are the health effects of specific dietary patterns? In what ways do diets change, and what are the health implications of such changes? Should – and could – a Mediterranean-style diet be adopted elsewhere, and if such a diet were to be adopted in, for example, the United States, what would be the impact on agriculture, the food economy, and health patterns? Because such questions address fundamental issues of food and nutrition research and policy, the Mediterranean diet constitutes an especially useful model for studying healthful dietary patterns (Nestle 1994).

Historical Antecedents

Diets of the Ancient Mediterranean

In the absence of written records, knowledge of ancient diets must be inferred from other kinds of evidence. Fortunately, evidence related to Mediterranean diets is extraordinarily abundant, including a vast and extensively documented archaeological record of food debris and a large quantity of food-related art, pottery, tools, and inscribed tablets excavated from prehistoric, Neolithic, Bronze Age, and later sites throughout the region (Fidanza 1979). The evidence also includes information derived from scholarly analyses of the writings of Homer and other classical authors. (The many and varied sources of information about the diets of ancient Egyptians, for example, are summarized in Table V.C.1.1.)

Inferences based on such sources must, however, be tempered by consideration of the difficulties inherent in evaluation: poor preservation of materials, incomplete fragments, errors of oversight, biased opinions, false information, and problems of translation, classification, dating, and interpretation (Darby, Ghalioungui, and Grivetti 1977). Nonetheless, scholars have used these sources over the years to firmly establish the availability in ancient times of an astonishing variety of plant and animal foods, breads, spices, sweets, and beers and wines (Seymour 1907; Vickery 1936; Vermeule 1964).

Discovery of the presence of various foods in a region suggests – but does not prove – that people ate those foods on a routine basis. Reports of actual dietary intake in ancient times are scanty and are especially lacking for the diets of the general population. When classical authors described foods at all, they wrote almost exclusively about those consumed by warriors or noblemen. Such accounts do not seem entirely credible; the writings of Homer, for example, leave the impression that Hellenic heroes consumed nothing but meat, bread, and wine (Seymour 1907). Homeric texts mention vegetables and fruits only rarely, perhaps because such foods were considered inadequate to the dignity of gods and of heroes (Yonge 1909), and olive oil is mentioned only in the context of its use as an unguent (Seymour 1907).

Table V.C.1.1. *Sources of information about diets in ancient Egypt*

- Archaeology (preserved remains of animals and plants)
  - Stomach and intestines of human mummies
  - Tombs (sealed and opened)
  - Mud bricks

- Art (depictions of foods, food preparation, domestic animals)
  - Temple and tomb paintings and reliefs
  - Statues, models, dioramas

- Literature
  - Papyrus, tomb, or temple texts
    - Daily food allowances
    - Lists of food offerings
    - Foods in medical prescriptions
    - Cosmology and mythology texts
  - Greek, Roman, and Arabic texts
  - Religious texts
  - Descriptive accounts by travelers, historians, naturalists

Source: Adapted from Darby, Ghalioungui, and Grivetti (1977), 1:23.

Perhaps as a result of such research, scholars have concluded that the typical diet of the common people in ancient times must have been rather sparse, based mainly on plant foods and bread, with meat and seafood only occasional supplements. In fact, such a diet was characteristic of the Mediterranean region even in the early twentieth century (Seymour 1907; Vickery 1936). However, a second- to third-century A.D. review of the food writings of classical poets and authors has provided a vivid contrast. It described foods and drinks in great detail, classifying them by flavor and aroma, means of preparation, and contribution to meals and banquets, suggesting that people of all classes ate and enjoyed a vast array of foods and ingredients (Yonge 1909).

Modern scholars have related dietary practices to the health of ancient Mediterranean populations through inferences from examinations of prehistoric skeletal remains, analyses of sepulchral inscriptions, and other kinds of evidence, as indicated by the listings in Table V.C.1.1. Some of this evidence provides insights into dental lesions, anemia, and other diseases, and taken together, it all suggests that the average life span in ancient Greece and Rome was probably on the order of 20 to 30 years (Wells 1975). The evidence also indicates, however, that this brief life expectancy had much more to do with infection and civil conflict than with malnutrition and starvation (Darby et al. 1977).

Modern History: The Rockefeller Study

The first systematic attempt to investigate dietary intake in the Mediterranean region took place shortly after the end of World War II. In 1948, the government of Greece, concerned about the need to improve the economic, social, and health status of its citizens, invited the Rockefeller Foundation to conduct an epidemiological study on the island of Crete. The aim was to identify factors that would best contribute to raising the standard of living of the Greek population, and Leland Allbaugh, an epidemiologist, was appointed to oversee the study. Allbaugh and his colleagues designed and conducted an extraordinarily comprehensive survey of the demographic, economic, social, medical, and dietary characteristics of the members of 1 out of each 150 households on the island, a sample chosen through a carefully designed randomization process. The foundation published the results of these investigations as a monograph in the early 1950s (Allbaugh 1953).

The report of the survey was remarkable in several important respects. It was, for example, extraordinarily thorough. It included a 75-page appendix that contained descriptions and critical evaluations of statistical methods and a 50-page compendium of the questionnaires used to obtain information. The survey's numerous dietary components included a review of agricultural data on the Greek food supply; the administration to 128 households of several distinct questionnaires examining cooking practices, daily menus, food expenditures, household food production, and food handling and consumption practices; and three dietary-intake surveys: one of pregnant women and nursing mothers, another of children and adolescents aged 7 to 19 years, and yet another of children aged 1 to 6, with the information in the latter obtained from the parents. These multiple surveys, however, constituted only the most peripheral components of the overall dietary probe.

The core of the survey's dietary sections consisted of 7-day weighed food inventories collected from the 128 households, 7-day dietary-intake records obtained from more than 500 individuals in those households, and food-frequency questionnaires administered to 765 households. These extensive dietary investigations were conducted in the early fall by volunteer nurses from the Greek Red Cross who, after 5 full days of training, went to live in the survey communities for periods of 7 to 10 days and made daily visits to the sample households. The work of these nurses was closely supervised and their data cross-checked in several ways. Given the extent, complexity, and comprehensiveness of these investigations, it is difficult to imagine that anything like a survey of this magnitude could be initiated – or funded – today.

Table V.C.1.2 compares selected data on Cretan dietary practices obtained through the various dietary survey methods. The methods yielded substantial agreement about the daily amount of energy consumed by the population – an average of 2,500 kilocalories per day – and the amounts of meat and dairy foods consumed on an average day. Agricultural food "balance" data, which represented the amounts of food available throughout the entire country of Greece on a per capita daily basis, indicated a higher intake of cereals and sugar and a lower intake of potatoes, pulses, nuts, oils, and fats than did data derived from the Crete surveys. However, as is discussed later in this chapter, these differences can be attributed to sources of random and systematic error inherent in methods of dietary-intake measurement. Data on alcohol consumption best illustrate the nature of such errors. Allbaugh was able to explain the discrepancy between the small amount reported in the dietary-intake records and the much larger amount indicated by food balance or household inventory data as a result of systematic underreporting. This was confirmed by his own observations as well as by "an expressed feeling by the respondents that the visiting Americans might be expected to frown upon heavy wine consumption where food was short" (Allbaugh 1953: 106).

A comparison of the food sources of energy in the diets of people in Crete, Greece, and the United States, as reported in the Rockefeller study, may be found in Table V.C.1.3. It displays data derived from dietary-intake surveys for Crete and reports data taken from food-supply surveys for Greece and the United States, even though these types of data are not truly comparable. The results indicate that plant foods – cereals, pulses, nuts, potatoes, vegetables, and fruits – comprised 61 percent of total calories reported as consumed by people in Crete, whereas plant foods comprised 74 percent of the energy available in the Greek food supply (although not necessarily consumed in the Greek diet) and 37 percent of the energy in the U.S. food supply (again, available but not necessarily consumed).

Table V.C.1.2. *Dietary intake in Crete in 1948 as estimated by three methods*

	Greece	Crete	
	Food balance 1948–9	7-day diet record	Household inventory[a]
Energy, MJ (kcal)/d	10.2 (2,443)	10.7 (2,547)	10.7 (2,554)
Foods, kg/person/y			
Cereals	158.2	127.7	128.2
Potatoes	30.9	59.1	38.6
Sugar, honey	9.1	5.5	5.5
Pulses, nuts	15.0	20.0	23.2
Vegetables, fruits, olives	120.5	175.9	132.3
Meat, fish, eggs	23.2	28.6	27.7
Milk, cheese	35.0	25.5	34.5
Oils, fats	15.0	30.9	30.9
Wine, beer, spirits	37.7	10.0	38.6

Source: Adapted from Allbaugh (1953), p. 107.

[a] Adjusted for information obtained from food-frequency questionnaires.

Table V.C.1.3. *Percentage of total energy contributed by major food groups in the diet of Crete as compared to their availability in the food supplies of Greece and the United States in 1948–9*

	Crete (7-day record)	Greece (food balance)	U.S. (food balance)
Total energy, MJ (kcal)/d	10.7 (2,547)	10.4 (2,477)	13.1 (3,129)
	Energy (%)		
Food group			
Cereals	39	61	25
Pulses, nuts, potatoes	11	8	6
Vegetables, fruits	11	5	6
Meat, fish, eggs	4	3	19
Dairy products	3	4	14
Table oils, fats	29	15	15
Sugar, honey	2	4	15
Wine, beer, spirits	1	–[a]	–[a]

[a] Data not available.

Similarly, foods of animal origin – meat, fish, eggs, and dairy products – comprised only 7 percent of energy in the Cretan diet, in contrast to 19 percent of the energy in the Greek food supply and 29 percent of the energy in the U.S. food supply, but table oils and fats were reported to contribute 29 percent of the energy in the Cretan diet, whereas they constituted only 15 percent of that in the Greek and U.S. food supplies. In Crete, however, 78 percent of the table fats derived from olives and olive oil. The total amount of fat from all sources in the Cretan diet, including that "hidden" in animal foods, was reported as 107 grams per day, or an estimated 38 percent of total energy, a percentage similar to that in the U.S. food supply in the late 1940s (USDA 1968) and considerably higher than that recommended today as a means to reduce chronic disease risk factors (Cannon 1992; USDA 1992; USDA/USDHHS 1995).

The data in Tables V.C.1.2 and V.C.1.3 constitute the basis for the conclusion of the Rockefeller report that "olives, cereal grains, pulses, wild greens and herbs, and fruits, together with limited quantities of goat meat and milk, game, and fish have remained the basic Cretan foods for forty centuries . . . no meal was complete without bread . . . Olives and olive oil contributed heavily to the energy intake . . . food seemed literally to be 'swimming' in oil" (Allbaugh 1953: 100). The Rockefeller survey data also indicated that wine was frequently consumed at all meals – midmorning, noon, and evening.

Whether olive oil made such a contribution to the diet for 40 centuries, however, is doubtful. At least one analysis of tree cultivation in southern Italy suggests that olive oil must have been a scarce commodity until at least the sixteenth century and that its principal use in medieval times was in religious rituals (Grieco 1993).

Thus, in attempting to correlate his current observations of dietary intake with the nutritional and general health of the population, Allbaugh noted certain limitations of his study. Few data were available on the nutrient and energy composition of Cretan foods, and virtually no information was available on the clinical and biochemical status of the Cretan population. Nevertheless, the study reported few serious nutritional problems in Crete; those that existed "were limited to a relatively small number of households, living under conditions of very low income and little home production of food" (Allbaugh 1953: 124). Diets generally were nutritionally adequate as measured against the U.S. Recommended Dietary Allowances of that time (National Research Council 1948). The investigators concluded that the diets and food consumption levels observed for most individuals "were surprisingly good. On the whole, their food pattern and food habits were extremely well adapted to their natural and economic resources as well as their needs" (Allbaugh 1953: 31).

This favorable conclusion, however, was one not necessarily shared by the study subjects. Allbaugh reported that only one out of six of the interviewed families judged the typical diet to be satisfactory. He quoted one family as complaining: "We are hungry most of the time" (Allbaugh 1953: 105). When asked what they would most like to eat to improve their diets, survey respondents listed meat, rice, fish, pasta, butter, and cheese, in order of priority. A large majority of respondents (72 percent) listed meat as the favorite food. On the basis of such views, Allbaugh concluded that the diet of Crete could best be improved by providing more foods of animal origin – meat, fish, cheese, eggs – on a daily basis.

Ancel Keys and the Seven Countries Study

Despite the great wealth of information provided by the Rockefeller report, interest in the health implications of Mediterranean diets is more often thought to have begun with the work of Ancel Keys, an epidemiologist from the University of Minnesota. In 1952, impressed by the low rates of heart disease that he had observed on vacations in the Mediterranean (Keys 1995), Keys initiated a series of investigations of dietary and other coronary risk factors with colleagues in seven countries. Keys and his wife, Margaret, have reported the genesis of these investigations in vivid detail:

> Snowflakes were beginning to fly as we left Strasbourg on the fourth of February. All the way to Switzerland we drove in a snowstorm . . . On the Italian side the air was mild, flowers were gay, birds were singing, and we basked at an outdoor table drinking our first espresso coffee at Domodossola. We felt warm all over. (Keys and Keys 1975: 2)

The two were particularly impressed by the difference between the diet they were eating in Italy and the typical diet consumed by people in the United States. As they described it, the Italian diet included:

> [H]omemade minestrone . . . pasta in endless variety . . . served with tomato sauce and a sprinkle of cheese, only occasionally enriched with some bits of meat, or served with a little local sea food . . . a hearty dish of beans and short lengths of macaroni . . . lots of bread never more than a few hours from the oven and never served with any kind of spread; great quantities of fresh vegetables; a modest portion of meat or fish perhaps twice a week; wine of the type we used to call "Dago red". . . always fresh fruit for dessert. Years later, when called on to devise diets for the possible prevention of coronary heart disease we looked back and concluded it would be hard to do better than imitate the diet of the common folk of Naples in the early 1950s. (Keys and Keys 1975: 4)

Keys and his colleagues published the results of their Neapolitan investigations, which found Italian diets to be remarkably low in fat – 20 percent of energy, or just half the proportion observed in the diets of comparable American groups (Keys et al. 1954). By that time (and long before such ideas became commonplace), Keys had associated the typical American diet, rich in meat and dairy fats, with higher levels of blood cholesterol and, therefore, with increased risk of coronary heart disease.

In 1959, the the principal lines of evidence for these associations were reviewed in a cookbook designed to help the general public reduce risks for coronary heart disease (Keys and Keys 1959). In a foreword to this volume, the eminent cardiologist Paul Dudley White, who had made several expeditions with the authors "to study the health and the ways of life of native populations" in southern Italy and Crete, extolled both the health benefits and the taste of the lowfat foods – and the wine – that they had routinely consumed during their Mediterranean travels.

In this cookbook, perhaps the first of the "healthy heart" genre, the authors summarized their "best advice" for lifestyle practices to reduce coronary risk (Keys and Keys 1959: 40). Table V.C.1.4 lists their precepts in comparison to the 1995 U.S. dietary guidelines for health promotion and disease prevention (USDA/USDHHS 1995). As is evident, the guidelines closely follow the 1959 advice that Ancel and Margaret Keys derived from their observations of diet and coronary risk in southern Italy and Crete. This comparison demonstrates that the Mediterranean diet of the 1950s can be considered to constitute the original prototype for development of current dietary guidance policy in the United States.

Table V.C.1.4. *Ancel and Margaret Keys' 1959 dietary advice for prevention of coronary heart disease compared to the 1995 U.S. dietary guidelines*

The Keyses' "best advice"	1995 dietary guidelines
	Eat a variety of foods.
Do not get fat; if you are fat, reduce. Get plenty of exercise and outdoor recreation.	Balance the food you eat with physical activity – maintain or improve your weight.
Restrict saturated fats, the fats in beef, pork, lamb, sausages, margarine, solid shortenings, fats in dairy products. Prefer vegetable oils to solid fats, but keep total fats under 30 percent of your diet energy.	Choose a diet low in fat, saturated fat, and cholesterol.
Favor fresh vegetables, fruits, and nonfat milk products.	Choose a diet with plenty of grain products, vegetables, and fruits.
Avoid heavy use of salt and refined sugar.	Choose a diet moderate in salt and sodium. Choose a diet moderate in sugars.
Be sensible about cigarettes, alcohol, excitement, business strain.	If you drink alcoholic beverages, do so in moderation.

Sources: Adapted from Keys and Keys (1959) and USDA/USDHHS (1995).

Beginning in the early 1950s, and for more than 20 years thereafter, Keys and his colleagues identified dietary and other risk factors for coronary heart disease through a large-scale study of nearly 13,000 middle-aged men from 7 countries distributed among 16 cohorts (Keys 1970; Keys et al. 1980). The overall results of the Seven Countries Study provided strong epidemiological evidence for the effects of fat and various fatty acids on serum cholesterol levels and on coronary heart disease risk (Kromhout, Menotti, and Blackburn 1994).

Dietary-intake data for foods and food components other than fat, however, were published in English for the first time only in 1989 (Kromhout et al. 1989). That report compared the 16 cohorts in the 7 countries with respect to their intake of bread, cereals, various vegetables, fruit, meat, fish, eggs, dairy foods, table fats, pastries, and alcoholic beverages. These data confirmed that Mediterranean diets in the early 1960s were based primarily on foods from plant sources, but that some versions were higher in fat – mainly olive oil – than might be expected in a population with such good health. The Seven Countries' data, as confirmed by subsequent investigations (Cresta et al. 1969; Kafatos et al. 1991; Trichopoulou et al. 1992), constituted the principal research basis for the proportions of foods from plant and animal sources proposed recently as a Mediterranean diet pyramid (Willett et al. 1995) or a Greek column (Simopoulos 1995).

The EURATOM Study

One additional large-scale study, from a rather unexpected source, yielded comparative information about dietary intake in the Mediterranean and other regions of Europe. From 1963 to 1965, the European Atomic Energy Commission (EURATOM) examined household food consumption among 3,725 families in 11 regions of 6 European countries in an effort to identify the foods among those most commonly consumed that were likely to be sources of radioactive contaminants. Investigators conducted dietary interviews for 7 consecutive days in each of the selected households and weighed all foods present in the households on those days. After applying several correction factors, the researchers converted the data on household food consumption to daily average amounts of food consumed per person. These data were published in 1969 (Cresta et al. 1969).

Of the regions selected by EURATOM for the study, nine were in the north of Europe and two in the south. One of the northern regions was in Italy (Friuli).

Because both of the southern regions also were in Italy (Campania and Basilicata), the data could be used to compare the typical dietary intake of the Italian north – which was quite similar to dietary patterns throughout the rest of northern Europe – with that of the Mediterranean regions. A detailed comparative analysis of these data is now available (Ferro-Luzzi and Branca 1995).

The EURATOM study revealed distinct differences in dietary-intake patterns between the northern and southern Italian regions. Diets in the Mediterranean areas were characterized by a much greater intake of cereals, vegetables, fruit, and fish, but a much smaller intake of potatoes, meat and dairy foods, eggs, and sweets. Although no consistent differences were observed in overall consumption of table fats, the foods contributing to total fat intake were quite different. Consumption of butter and margarine was much higher in the north, whereas in the south, the principal fat was olive oil, and margarine was not consumed at all. Taken together, the results of the EURATOM study provide further evidence that the Mediterranean diet of the mid-1960s was based predominantly on plant foods and included olive oil as the principal fat.

Recent Observations

In the years following these investigations, the Keys' description of the role of diet in coronary risk has become more widely accepted (James 1988; USDHHS 1988; National Research Council 1989). Along with this acceptance has come increasing recognition that the traditional dietary patterns of many cultures meet current dietary guidelines and that the cuisines of these cultures – especially those of Mediterranean and Asian countries – could serve as models for dietary improvement (Nestle 1994). In recent years, reports of investigations of the scientific basis and health implications of Mediterranean diets have been published in at least five edited collections of papers (Helsing and Trichopoulou 1989; Spiller 1991; Giacosa and Hill 1993; Serra-Majem and Helsing 1993; Nestle 1995). Public interest in Mediterranean diets has been stimulated by numerous articles in the popular press (Kummer 1993; Hamlin 1994), and their palatability has been celebrated in cookbooks emphasizing the dual themes of good taste and good health (Shulman 1989; Goldstein 1994; Jenkins 1994; Wolfert 1994).

Historical and Research Issues

As noted previously, studies of Mediterranean dietary patterns raise research issues that are also applicable to a more general understanding of the role of diet in health.

Definition of the Mediterranean Diet

The peoples of the 16 or more countries that border the Mediterranean Sea vary greatly in culture, ethnicity, religion, economic and political status, and other factors that might influence dietary intake, and their food supplies vary widely in the quantity used of every item that has been examined. Thus, the identification of common dietary elements within the region has proved a challenging task to researchers (Ferro-Luzzi and Sette 1989; Giacco and Riccardi 1991; Varela and Moreiras 1991; Giacosa et al. 1993).

Because the studies of Ancel Keys found the typical dietary pattern of the Greek island of Crete in the 1950s and 1960s to be associated with especially good health, this pattern has come to be viewed as the model, and because olive oil was a principal source of fat in the Cretan diet, the model has been extended to include diets consumed in olive-producing Mediterranean regions. In this manner, the generic term "Mediterranean diet" has come to be used, in practice, as referring to dietary patterns similar to those of Crete in the early 1960s and other regions in the Mediterranean where olive oil is the principal source of dietary fat (Willett et al. 1995).

Dietary Epistemology: Research Methods

Knowledge of the content of Mediterranean diets in the early 1960s – or at present – necessarily depends upon the reliability of methods used to determine the typical food intake of the population. National diet surveys, such as those that are conducted regularly in the United States, have not been generally available in Mediterranean countries. The Rockefeller study of Crete was a notable exception, remarkable by any standard of epidemiological investigation (see Table V.C.1.2) in its use of multiple methods, lengthy personal interviews, and critical analysis of results to attempt to define dietary intake (Allbaugh 1953). The Seven Countries Study also used multiple methods. For most of the 16 cohorts, Keys and his colleagues obtained 7-day diet records from small subsamples of each group and corroborated these records by analyzing the energy and nutrient composition of weighed, duplicate meals. For a few cohorts, investigators collected dietary data from 24-hour recalls as verified through food-frequency questionnaires (Keys 1970). Finally, the EURATOM study attempted to corroborate daily reports of household food intake by weighing all foods present in the house on each of the seven consecutive interview days (Cresta et al. 1969).

These investigations were designed to overcome fundamental flaws in each of the methods commonly used to evaluate the dietary intake of individuals and populations; all provide opportunities for random and systematic errors in reporting food intake, estimating serving sizes, and determining nutrient content (Mertz 1992; Buzzard and Willett 1994; Young and Nestle 1995). Such problems are compounded in studies that attempt to compare dietary-intake data from one country to another, or within one country over time. If the methods for determination of dietary intake differ, their results are not strictly comparable – a situation similar to comparing apples to oranges (see Tables V.C.1.2 and V.C.1.3).

For purposes of international comparison, investigators must often rely on food-balance data – agricultural data on specific commodities present in the food supply from one year to the next. As already noted, these data are distinctly different from those that describe dietary intake. They reflect the amounts of specific foods produced in a country during a given year, with imports of foods added and food exports subtracted, expressed on a per capita basis through dividing by the population total on a defined day of the year.

Such data are also known by other names: food supply, food availability, food disappearance, and food consumption. Among these terms, "consumption" is a misnomer, because food-balance data are only an indirect estimate of dietary intake. A food that is produced but then wasted, fed to animals, or used for industrial purposes is not consumed; for many foods, therefore, food-balance data overestimate dietary intake. In the case of foods produced at home, however, food-balance data underestimate consumption. The average annual per capita availability of a food commodity only rarely – and accidentally – is an accurate measure of actual consumption by an individual man, woman, or child. These limitations may explain observed discrepancies in study results, and they emphasize the need for caution in interpreting comparative data such as those presented in Tables V.C.1.2 and V.C.1.3.

Despite such limitations, food-balance data are often the best – or only – data available to estimate time trends in dietary practices, and they are used frequently in comparative descriptions of Mediterranean diets (Ferro-Luzzi and Sette 1989; Helsing 1995). Three agencies of the United Nations (UN) produce such data. The Organization of Economic Cooperation and Development (OECD) has published data for the supply and use in 23 countries of specific food items, such as pork, cheese, or olive oil, from 1979 to 1988 (OECD 1991).

The Food and Agriculture Organization (FAO) publishes individual food-balance sheets for 145 countries that include data for per capita supply of major food groups (e.g., meat, legumes, alcohol); its most recent edition provides data in 3-year averages from 1961–3 through 1986–8 (FAO 1991). The World Health Organization (WHO) Regional Office for Europe has established a comprehensive computerized database that incorporates FAO food-balance data as well as the WHO annual health statistics since 1961 for each of the countries that supply such data to the UN (WHO/FAO 1993). This program makes it possible to generate an immediate display of the relationship between the availability of any food and the disease rates in any country of interest (Ferro-Luzzi and Sette 1989; Helsing 1995).

Health Impact

By the definition used here, the Mediterranean diet can be considered a near-vegetarian diet. As such, it would be expected to produce the well-established health benefits of vegetarian diets and to solve any deficiencies of energy or micronutrients (especially vitamin B_{12}) that are occasionally associated with such diets (Johnston 1994). Vegetarian or near-vegetarian diets are especially plentiful in key nutrients, particularly antioxidant vitamins, fiber, and a variety of phenolic compounds that have been identified as protective against cancer and other chronic diseases (Dwyer 1994; Kushi, Lenart, and Willett 1995a, 1995b). Researchers, however, have yet to establish the relative contribution of any single nutrient or food component, the foods that contain such factors, or physical activity and lifestyle patterns – alone or in combination – to the favorable health indices observed in the Mediterranean region.

In this context, the role of olive oil is of particular interest. The Greek diet, for example, contains a higher proportion of fat than is usually recommended. Yet much of this fat is olive oil, and the diet is associated with very good health. Diets rich in olive oil are associated with exceptionally low rates of coronary heart disease, even when blood cholesterol levels are high (Verschuren et al. 1995). The traditional Greek diet is also associated with an exceptionally low risk for breast cancer (Trichopoulou et al. 1995).

Changing Dietary Patterns

If it is indeed true that Mediterranean diets of the 1960s protected adult populations against premature death, it would seem highly desirable to preserve the protective elements of those diets. Evidence from dietary-intake surveys and from food-balance data indicates, however, that dietary patterns throughout the region are changing rapidly, and generally in an undesirable direction. For example, one dietary-intake study of an urban population on Crete (obtained by 24-hour diet recalls corroborated by food models, photographs, and clinical and biochemical measurements) reported an increase in the intake of meat, fish, and cheese but a decrease in the intake of bread, fruit, potatoes, and olive oil (Kafatos et al. 1991) from levels reported by Keys and his colleagues in the early 1960s (Kromhout, Keys, Aravanis, et al. 1989). Similar changes have been observed in Italy (Ferro-Luzzi and Branca 1995). Food-balance data also document large increases in the availability of meat, dairy foods (FAO 1991), and animal fats (Serra-Majem and Helsing 1993) throughout the region since the early 1960s. Given this situation, the traditional Mediterranean diet may well become a historical artifact.

Increasing evidence suggests that the recent changes in Mediterranean dietary patterns have been accompanied by increases in chronic disease risk factors among the populations. These risk factors include a decline in levels of physical activity, along with higher levels of serum cholesterol (Kafatos et al. 1991), hypertension, and obesity (Spiller 1991). Associated with these changes in risk factors are reports of rising rates of coronary heart disease, diabetes (Spiller 1991), and several types of diet-related cancers (LaVecchia et al. 1993) in several Mediterranean countries. These trends confirm well-established relationships between diet and chronic disease risk (James 1988; USDHHS 1988; National Research Council 1989) and suggest the need to reverse current practices through widespread efforts at preserving and promoting traditional diets within the region (Nestle 1994).

Preservation and Adaptation

Overall dietary patterns in a country are the result of an ongoing interaction between culturally determined food traditions and the assimilation of new foods through economic improvement, foreign contact, or international food marketing. Education also has a role in influencing personal food preferences and dietary change (Heimendinger and Van Duyn 1995). Until recently, Mediterranean dietary patterns were quite resistant to change. Allbaugh and Keys both remarked on the similarity of the foods commonly eaten in Italy and Crete to those produced and consumed in those areas in the ancient past. Despite suggestions that traditional dietary patterns are beginning to be abandoned (Alberti-Fidanza et al. 1994), such foods are still routinely consumed by at least some older population groups (Trichopoulou, Katsouyanni, and Cnardellis 1993).

Issues related to the assimilation of Mediterranean dietary patterns within other countries are best illustrated by the adaptation of southern Italian foods to American tastes (Levenstein and Conlin 1990). Italian immigrants of the late nineteenth and early twentieth centuries retained many of their food traditions despite North American–held views of their diets as insufficiently nutritious, indigestible, unsanitary, and inadequate in amounts of milk and meat. Such views, however, began to change during the economic restrictions of World War I, when Italian pastas became popular as inexpensive, well-balanced alternatives to meat, and since the 1920s, Italian food products have been widely marketed in the United States (Levenstein 1985). But today many Italian-style foods have been "Americanized" to the point that they are far higher in energy, fat, cholesterol, and sodium than the traditional foods from which they were derived (Hurley and Liebman 1994).

Policy Implications

Policies designed to encourage consumption of traditional diets within their country of origin, or to promote the adaptation of traditional models to new locations, will have to address many well-defined cultural, economic, and institutional barriers (Nestle 1994). They will also need to recognize that diet is only one of a great many behavioral factors that influence health and that other determinants may command higher national priorities for action (Jamison and Mosley 1991). Moreover, the transfer of traditional Mediterranean dietary patterns to a country such as the United States would be likely to affect agriculture, the food industry, the overall economy, and the environment in highly complex ways, some of which may be beneficial, but others undesirable (Gussow 1994, 1995; O'Brien 1995).

The role of the Mediterranean diet in U.S. dietary guidance policy is of particular interest. As is demonstrated in Table V.C.1.4, the Mediterranean observations of Keys' led directly to the formulation of dietary guidelines for the prevention of coronary heart disease. In turn, such guidelines eventually encompassed more general advice for health promotion and disease prevention in American statements of dietary guidance policy, as expressed in the Dietary Guidelines for Americans (USDA/USDHHS 1995). Because animal foods are principal sources of fat, saturated fat, and cholesterol in American diets (Gerrior and Zizza 1994), dietary guidelines necessarily should promote predominantly plant-based diets similar to those traditionally consumed in the Mediterranean region or in Asia. That this may not be evident from standard American food guides (USDA 1992) is, at least in part, a result of political pressures from producers of meat and dairy foods to ensure that their products retain a dominant position in the American food supply and diet (Nestle 1993). Such pressures may well have resulted in dietary recommendations that are ambiguous and confusing to the public (Nestle 1995a).

Research Directions

Traditional Mediterranean diets appear to have been based mainly on plant foods, to contain foods from animal sources in very small amounts, to use olive oil as the principal dietary fat, to feature alcohol in moderation, and to balance energy intake with energy expenditure. Substantial research – in quantity and quality – supports the very great health benefits of just such dietary and activity patterns (Willett 1994; Kushi et al. 1995a, 1995b).

Mediterranean diets are consistent with current food guide recommendations for public-health promotion and disease prevention, as well as with recommendations for nutritionally adequate vegetarian diets (Haddad 1994). Because they also are appreciated for their gastronomic qualities, they are well worth further study as a cultural model for dietary improvement. Several areas of historical and applied research related to Mediterranean diets seem especially worthy of additional investigation; these are listed in Table V.C.1.5. While awaiting the results of such studies, immediate efforts should be instituted to preserve the ancient – and healthful – dietary traditions within the Mediterranean region and to encourage greater consumption of plant foods among industrialized populations as a means to improve health.

Table V.C.1.5. *Suggestions for further historical and applied research on the health impact of Mediterranean diets*

Historical research needs

Identification of methods to determine the typical dietary intake of individuals and populations in Mediterranean countries in the past, present, and future.

Identification of methods to determine time trends in Mediterranean dietary patterns.

Determination of the impact of dietary changes on nutritional status and health risks in Mediterranean countries in the past and present.

Identification of cultural, behavioral, economic, and environmental determinants of dietary change in Mediterranean countries in the past and present.

Determination of the impact of dietary changes on the agriculture, food industry, economy, and environment of Mediterranean countries in the past and present.

Determination of the impact of adoption of Mediterranean foods or dietary patterns on the agriculture, food industry, economy, and environment of countries outside the Mediterranean region in the past and present.

Applied research needs

Identification of the roles of specific plant foods characteristic of Mediterranean diets – fruits, vegetables, legumes, cereals, nuts, oils, wine – in health promotion and disease prevention.

Identification of the roles of specific plant-food nutrients – vitamins, minerals, monounsaturated fatty acids, linolenic acid, fiber, alcohol, phytochemicals – in the low rates of chronic diseases observed in Mediterranean countries.

Determination of the proportions of plant and animal foods in Mediterranean diets optimal for reducing disease risk.

Determination of the proportion of energy from fat and specific fatty acids in Mediterranean diets associated with the lowest risk of disease.

Development of dietary recommendations and food guides that best reflect current scientific knowledge of the health benefits of Mediterranean diets.

Identification of effective methods to educate the public in Mediterranean countries about traditional dietary practices that best promote health.

Marion Nestle

V.C.2 Southern Europe

The basic ingredients that have historically comprised the southern European diet are well known and have recently received much attention for their health-promoting benefits: These are bread, wine, olive oil, and a wide variety of fruits and vegetables supplemented by fish, dairy products, and a relatively small amount of animal flesh.

Less known, however, are the historical forces that shaped how southern Europeans think about food. Essentially, three rival systems have influenced the culture of food in southern Europe since late antiquity, and in various combinations these systems have informed eating patterns at all levels of society.

The most pervasive of these food systems might be called "Christian," although its roots are not necessarily found in the teachings of Jesus and his disciples. It encompasses monastic asceticism as well as the calendar of fasts and feasts that have historically regulated food consumption. In all its manifestations, the ideal goal of Christian foodways has been spiritual purity through the control of bodily urges, though this can easily be lost sight of when rules are bent and holidays become occasions for excess.

The second major system is medical in origin and has gained and lost popularity in the past two millennia depending on the state of nutritional science, though it continues to influence common beliefs to this day. The object of this system of "humoral physiology," of course, is the maintenance or recovery of health by means of dietary regimen.

Lastly, the "courtly" or gastronomic food culture has also profoundly influenced southern Europe, radiating from urban centers of power such as Rome, Naples, Venice, and the courts of Aragon, Castile, and Provence. Its goal is ostensibly pleasure, but this is usually mixed with motives of conscious ostentation in order to impress guests.

Whereas religious, medical, and gastronomic considerations shape the foodways of most cultures, it is their unique and often surprising combinations that make those of southern Europe especially fascinating. The gourmand monk, the duke surrounded by swarms of physicians, the parvenu townsman indulging his taste for spices – all reveal glimpses into the dynamics of society and the ways that individuals express themselves through food preferences, which in southern Europe are to a great extent informed by one or more of these fundamental systems.

Christianity

Although "Quadragesima," or Lent, was instituted in remembrance of Christ's 40-day fast in the desert, there is little in the biblical account of Christ and his followers that would warrant either regular fasting or placing restrictions on which foods can be consumed. In fact, the Gospels consciously reject the dietary legalism of the Old Testament and assert that all foods are clean: "Not that which goeth into the mouth defileth a man" (Matt. 15: 11). Furthermore, Christ celebrated numerous feasts – the marriage at Cana, supper at Emmaus, the "Last Supper."

Fasting, or a denial of bodily urges to achieve spiritual purity, seems to be more directly rooted in

Greek and Eastern ideas about the dualism of body and soul. If the body is merely a temporary corruptible prison for the eternal soul, then suppressing its sinful demands will cleanse the spirit in anticipation of its release from bodily constraint. Rejecting the appetites for food, sex, and sleep becomes a path to righteousness.

St. Anthony (c. 250–350) was the most popular of the early ascetics, and the example of his austerities in the Egyptian desert would inspire many future Christians. The church fathers also adopted a favorable stance toward fasting and abstinence. St. Augustine (354–430) recommended abstinence from meat and drink in an epistle to his sister's nunnery, and both St. Ambrose (340?–397) and St. Jerome (340?–420) were influential in advocating an abstemious diet for monastics in Italy.

It was St. Benedict of Nursia (c. 480–547) who would be most influential in framing a rule that would form the foundation for European monasticism. However, before we examine this specific institution, the more general topic of public fasts demands attention.

In the fourth and fifth centuries, the Christian church gradually defined the fast as an abstention from meat and animal products such as milk and eggs and a limitation of meals to one a day. The 40 days between Ash Wednesday and Easter, as well as the 30 days of Advent preceding Christmas, were set aside as the most important fasts. Wednesdays and Fridays, and sometimes a third day of the week, were also designated as fast days, as were the evenings preceding holidays. Although originally proscribed, fish increasingly became the ideal food for these periods.

In principle, fasts were intended to be public expressions of self-denial in atonement for sins. Minor mortifications would presumably quell the passions and turn the mind to spiritual exercise in preparation for major holy celebrations. Depending on their budgets, people could, in practice, consume rare and expensive fish, dried fruits, and spiced confections, so Lent did not necessarily involve a sacrifice of luxury. Rather in wealthy households it could become the occasion for the ingenious invention of meatless dishes incorporating almond milk to replace cream. But for the majority of people a normally meager diet would now be limited to bread, legumes, and the often reviled stockfish.

The cyclical seasons of want were bracketed by festivals of plenty, and numerous saint's days and local celebrations punctuated the medieval calendar. The festival of St. Iago in Spain and that of St. Joseph in Italy are two examples. Many of these feasts originated in pagan agricultural rites that were absorbed into the early church and transformed into holy days. Each town across southern Europe would also celebrate the feast of its own patron saint with specially prepared foods.

The most universal feast was held on the day before Ash Wednesday, Martedi Grasso or Mardi Gras, when all meat and eggs had to be consumed before Lent. This day of meat eating or "Carnevale" often became the occasion for gross indulgence. Drunkenness, flesh eating, violence, and sexual license were all associated with this binge preceding the rigors of abstinence.

By the late Middle Ages, mock battles would be held between personifications of Carnival and Lent, and the natural order of society would be subverted in mock trials, mock weddings, and even mock prayers. Indeed, the world was said to be turned upside down in this brief catharsis of revelry (Burke 1978). Gluttony was still considered among the seven deadly sins, though this rule, too, was momentarily suspended.

The most important "feast" in the Christian calendar, however, was of a more sacred nature. The sacrament of the Eucharist, in which bread or a thin wafer consecrated by a priest is placed in the mouth of each communicant, offers a form of spiritual nourishment. After the Fourth Lateran Council in 1215, the official doctrine of transubstantiation held that the substance of the bread is transformed into the actual body of Christ while its "accidents" or shape still appear to be bread. Through this miracle, and the act of eating the bread, one receives merit, which aids in salvation. Drinking wine is also central to the sacrament, although it was customarily reserved only for priests. The wine becomes the blood of Christ in the same way that the bread becomes the body. Thus, the everyday acts of eating and drinking were transformed into one of the central mysteries of the Christian church.

Also central to the culture of food as influenced by Christianity was the development of monasticism. In his "Rule" for monks at Monte Cassino in the sixth century, St. Benedict laid down specific regulations for food consumption that spread across Europe. Two cooked dishes were to be offered at either the noontime (prandium) or late afternoon (cena) meal and a third dish of fresh fruit or vegetables when available. Each monk was to be given a pound of bread daily as well as a "hemina" of wine, which was roughly two glasses (St. Benedict 1981: chap. 40, n. 40.3).

St. Benedict noted that wine was hardly a proper drink for monks, but few could be convinced of that in his day. Benedict also carefully fit meals into the daily schedule of prayers, though over the years his original provisions were supplemented by snacks such as the "collation," eaten while hearing readings from St. Cassian's Collations. There might also have been extra portions of food, the "pittance" provided by pious benefactors, though this may not have amounted to much, considering what this word has come to mean.

Most important, in addition to the regular cycles of fasting, monks were expected to abstain entirely from meat, except perhaps on rare occasions, as when dining in private with the abbot or when ill. These rules were often observed only in the breach, especially as monasteries grew more wealthy and lax in the tenth and eleventh centuries. Cheese was eventually allowed, following the logic that it is no more flesh than olive oil is wood (Moulin 1978: 87). Other prohibitions were also avoided: St. Benedict cannot have been referring to fowl when demanding that monks abstain from the meat of quadrupeds (St. Benedict 1981: chap. 39).

Rather than models of austerity, many monasteries became gastronomic enclaves, and there is, no doubt, some truth to the complaints of St. Peter Damian and Dante Alighieri about portly Benedictines (Dante 1939: 130). In addition to preserving and spreading viticulture throughout Europe, the monks originated many renowned cheeses, pastries, and confections. From their medicinal gardens they also concocted many celebrated cordials, chartreuse, and vermouth – not to mention champagne (Dom Perignon in the seventeenth century).

It was precisely in reaction to this gastronomic luxury and laxity that many new and more rigorous orders were founded in successive waves of religious revival. In contrast to lavish Cluniac monasteries, Cistercian simplicity began to flourish in the late twelfth century, influenced by St. Bernard of Clairvaux. Later came new austere mendicant orders such as the Franciscans, and following the advent of bubonic plague, a number of intensely penitential and flagellant orders flourished, such as the Gesuati. At any rate, the ascetic attitude toward food remained active in spite of the luxury of wealthier orders.

Many holy men and women so successfully mortified their flesh through abstinence that we can only conclude they deliberately starved themselves to death. This was precisely the goal of some Cathars in the South of France, who believed (heretically) that the world was created by the devil and that everything in it, the body as well as food, was evil. For the Cathars, starvation was a way to attain spiritual perfection. The Carthusians, an entirely different vegetarian order, had to go out of their way to assert the goodness of food to avoid being suspected of the Cathar heresy.

Self-starvation itself, however, was not necessarily considered heretical or demoniacal. St. Catherine of Siena, it has been suggested, suffered from a form of anorexia and subsequently became a model consciously imitated for centuries (Bell 1985). For many young women, conquering the self and hunger may have been the only outlet for expressing their pious urges in an entirely male-dominated society, the ideal of holiness being achieved only with the destruction of appetites and often the body itself.

Following the Counter Reformation, asceticism was gradually supplanted by activism as the ideal fruit of devotion. The Lenten fast, however, remained in force up until Vatican II, and to this day many Catholics continue the practice as an integral part of their food heritage.

Humoral Physiology

Physicians promulgated another theoretical food system, humoral physiology, which had a profound impact on the culture of food in southern Europe. As a legacy of Greek science, nutritional theory survived in more or less threadbare form through the early Middle Ages. Among the Moors of Spain it did undergo a rich development, but its first major revival in the Latin West was within the walls of the earliest universities, most notably at Salerno, Montpellier, Bologna, and, later, at Padua and Valladolid.

Translating Galen and Hippocrates via Arabic sources and commentaries, Gerard of Cremona (1140–1187) and Arnald of Villanova (1235–1312) provided Europe with its first guides to nutrition. The popular *Regimen Sanitatis* (c. 1160) of Salerno was the most widely known of the early diet books, and works continued to be written through the Middle Ages by individuals such as Magninus of Milan and Ugo Benzo.

During the Renaissance, dozens of new works were printed throughout southern Europe, the most popular by Marsilio Ficino, Platina, and Girolamo Savonarola. A second major revival followed in the sixteenth century, as complete and accurate translations of ancient Greek texts became available. Despite extensive scientific research in the seventeenth and eighteenth centuries, the old humoral system was fully abandoned only in the nineteenth century, and it still survives in the popular consciousness, most notably in Latin America.

Humoral physiology is based on the idea that four major fluids dominate the human body: blood, phlegm, choler, and black bile (or melancholy). Each "humor" is composed of two basic elements: Heat and moisture are the elements that make up blood; cold and moisture constitute phlegm; heat and dryness combine to form choler; and cold and dryness make up melancholy. When the body is in a state of health, the four humors were said to be balanced, or in the correct proportion of 16 parts to 4 parts to 1 part to 1/4 part. An imbalance of humors was seen as the origin of sickness and disease. Each individual, however, was also said to have his or her own natural "complexion" or constitution in which one humor dominated, and this distinctive makeup determined the nature of bodily functions, character, and intelligence.

That this system was well known is confirmed by frequent references to it in southern European art and literature from the High Middle Ages onward. But the system was not merely a philosophical abstraction or literary conceit. People did try to judge the state of their bodies' vital signs and tried to correct imbalances through regulation of the "nonnaturals" or external influences, such as sleep, exercise, air quality, sexual activity, and – most important for this discussion – diet.

Essential to this system was the belief that each food also had its own complexion or dominant humor and would thus interact with the humoral balance of the individual who consumed it. Several signs revealed the qualities of a food: color, aroma, and, most notably, taste. Sweetness was evidence of heat and moisture. Spicy, salty, and bitter foods were all considered hot and dry in varying degrees; we still describe foods like chilli peppers as "hot." Cold and dry foods tasted sour, styptic, or tannic (hence a "dry" wine). Lastly, insipid and watery foods were composed of cold and moist elements. Foods in each of these categories also promoted their own specific humor in the body when eaten. Cool and moist cucumbers supposedly converted into phlegm; hot and dry cinnamon became choler; and sugar made good blood.

As a rule, healthy individuals were advised to consume foods similar to their own natural complexions. When "distempered" or ill, one should consume the opposite foods to correct the imbalance. Medicines were prescribed following the same logic. A "cold" or phlegmatic imbalance might be corrected with hot and dry spices, or a more potent medicine if more serious. Tobacco was first taken for such conditions. When a person was overheated, a cold acidic drink was viewed as a good corrective.

By the mid-sixteenth century, physicians most frequently recommended nourishment opposite to the natural complexion, but such advice merely assumed that the patient was usually somewhat distempered, and the recommendation did not constitute a change in theory (Flandrin 1982, 1987: 295–6).

The complexion of each food also determined how it would best combine with other foods. An excessively cold and moist food, such as melon, was best corrected with salt or prosciutto. Fatty phlegmatic meats were more digestible with hot and dry spices. A food whose substance was difficult to "concoct" in the stomach, such as crass and gluey fish, would be improved by a cutting lemon juice or vinegar.

Indeed, humoral physiology is at the very heart of many culinary traditions that persist in southern Europe to this day. Salads are a perfect example. Cold and moist lettuce is combined with hot and dry herbs, both of whose humoral natures are counteracted by hot and dry salt and cold and dry vinegar, given further balance by hot and moist oil. Consider quail with grapes, strawberries with balsamic vinegar, or pork with mustard. All these combinations have their origin in humoral dietary theory.

According to dietary theorists, however, deciding exactly what to eat was a far more complicated affair than simply balancing flavors. Each meal also required consideration of the season, because the body was thought to respond to atmospheric conditions and air quality. The age and gender of the diner was also essential; young people were thought to have hotter systems, as were all males. This is why wine was considered harmful for boys but excellent for the aged *(Vinum lac senum est)*. The amount of physical exercise people performed also helped determine the most healthful diet for them. According to the theory, laborers had hotter stomachs and could digest tougher, denser, and darker foods such as beans, sausages, coarse whole grain breads, and porridge, but the leisured required more subtle and rarefied foods such as chicken, eggs, white bread, light wines, and refined sweets. Clearly, social prejudice was built right into the system.

The amount of sexual activity also had to be taken into account, for this heated and dried the body, using up nutrients as blood was supposedly converted into semen. Hot foods could overheat the sexually active or actually incite lust. Conversely, a less nutritious diet was seen as an aid to celibacy; less blood, and ultimately less semen, would be produced. Cold foods, such as lettuce, became effective anaphrodisiacs recommended for priests and others with a need for them.

Mood was also directly related to diet. A diet of cold and dry foods, such as beef, could lead to depression, as could crass, indigestible foods, which clogged the body and permitted humors to accidentally corrupt. Laziness could be triggered by a debilitating "phlegmatic" humor, just as overly hot foods could provoke wrath. Equally, the emotional state of the individual determined which foods were corrective. Melancholic people, for example, were cheered up with aromatics, borage, hot (and moist) wines, and sweets.

Many popular dietary recommendations, however, appear to have derived from a source other than standard humoral physiology. Frequently, physicians mentioned that the character traits of a particular animal would produce similar traits in the person who ate it. Thus, the flesh of rabbits would make one timid, and it was often described as a melancholic food. But highly strung birds could make one nervous and edgy, even causing insomnia. The same elements that materially caused these characteristics in the animal were transferred into the consumer. In similar fashion, a light and subtle wine was thought to produce, in a process not unlike distillation, light "spirits" that flowed easily through the brain and instilled subtlety of thought. This process of direct transference was also applied to specific animal parts: Testicles promoted virility, brains gave rise to wit, blood (or milk, which was believed to be produced from blood in the mammary glands) fortified the weak and blood-deficient.

Direct transference began to be criticized in the mid-sixteenth century and was eventually banished from nutritional theory along with the doctrine of signatures, which posited that foods good for specific ailments would bear the marks of their potency in their outward form. That is, brain-shaped walnuts were good for the intellect; red wine was an analogue for blood. But by the mid-seventeenth century the entire system of humoral physiology had been called into question, particularly after systematic research had been conducted into the process of digestion. An entirely new system to replace humoral theory appeared in the nineteenth century with Justus von Liebig and the discovery of the role of proteins, carbohydrates, and fats, and in the twentieth century with the discovery of vitamins.

The Courtly Aesthetic

The third major influence on the foodways of southern Europe derives from the social connotations of particular foods and methods of preparation. Historically, it was usually the court that set culinary trends, which then spread to lower ranks of society. But this was not simply a process of invention and imitation. Specific items could be devalued or revived, depending on which social class they were currently associated with.

In southern Europe it is particularly the proliferation of social strata and the specialization of the economy that have generated a wealth of food prejudices (Goody 1982). In a relatively unstratified society, where the majority of the population is involved in food production and eats essentially the same diet, few foods will be associated with particular classes. This was most likely the case in the early Middle Ages. But in many parts of southern Europe, particularly in trading and manufacturing centers, where there always have been both noble and impoverished classes, food prejudices become central, and this has been increasingly true from the High Middle Ages to the present.

Specific foods also rise and fall in popularity. For example, in the Middle Ages and early Renaissance, saffron was a symbol of wealth and privilege because it was expensive and because it lent a dazzling effect to foods. The way to impress a guest was to present a saffron-daubed dish, sparkling like gold. Indeed, saffron became a symbol for gold, and to eat it represented a literal incorporation of wealth. However, enthusiasm for saffron abated during the sixteenth century, when for the first time it was cultivated on a large scale (Toussaint-Samat 1992: 522). As a consequence, it became far more affordable, less potent as a symbol of wealth, and at court it went out of fashion. Sugar had much the same history, beginning when it was first processed in Portuguese and Spanish colonies (Mintz 1985).

Economic factors can also influence the association of a particular food with a certain class. For example, in the sixteenth century, as populations grew and the living standard of the majority dropped, the price of meat rose considerably faster than that of grains. Thus, a greater proportion of expendable income had to be spent on the former, a process described as "depecoration." Poorer people were forced to purchase less fresh meat, and what meat products they could afford would necessarily be long-lasting or preservable. Examples include sausages and smoked meats, as well as herring and salted codfish. As these items became identifiable as peasant food, they were increasingly reviled at court – and, it is interesting to note, condemned by dieticians.

Other foods readily identified with the peasantry – beans and onions and porridges of barley and millet (and later maize, as in polenta) – were stigmatized as southern European society was increasingly stratified. Particular foods became more obvious symbols of class. To consume something beyond one's budget was an act of social climbing, just as eating "common" foods showed a lack of taste and breeding.

Oddly enough, though, peasant foods came back into fashion, particularly during periods of nostalgia for simplicity and earthiness, as in the Romantic movement or in recent decades. The most interesting and subtly malleable food prejudices always have and still do center around bread. Because it has been the staple of the West, bread preferences are almost always an encapsulation of social climate. In fact, at times, the whiteness and texture of bread have been arranged hierarchically and have matched precisely the structure of society.

Illustrative is fifteenth-century Ferrara, where an essentially two-tiered society was reflected in the distinction between fine white bread and all other types (Camporesi 1989). Seventeenth-century works depict each social level with its own proper type of bread, but in other periods, brown, whole wheat, and multigrained breads have gained popularity. When ethnic awareness is valued, rustic, homemade loaves reappear.

If we specifically examine courtly food fashions, a number of interesting patterns emerge. The oldest and most obvious symbols of nobility were large game animals, such as roast boar or venison, presented whole to a large hall of retainers. Such viands would be carved and apportioned according to rank, and naturally the most honored (and favored) guests would be seated closest to the lord (Visser 1991). This type of meal perfectly matched the feudal warrior society in which prowess on the hunt was valued as much as it was in battle.

Gradually, however, this rustic sort of meal was replaced on noble tables with meals of magnificence and sophistication. Perhaps originating in the Burgundian court, dishes including peacocks (resewn into their feathers), swans, baked porpoises, and sturgeons became fashionable and quickly spread to Italy and the rest of southern Europe. Exotic spices and sugar, liberally strewn over each dish, also became requisite symbols of wealth; even pearls, amber, and gold might be incorporated into elaborately prepared confections. Disguised foods and hybrid creations, such as half-pig and half-chicken, also became popular. These new foods signified aesthetically new symbols of power and new values of wealth, as well as new far-flung connections.

An entire literary genre flourished that described the proper way to throw a banquet, and by the time of the Renaissance, precise rules for carving and using newly introduced cutlery were elaborated (Rosselli 1516; Romoli 1560). This new "civilized" behavior at the table reflected a pacification of society as governments claimed a monopoly on violence (Elias 1982). A profusion of tastes and textures became the hallmark of sophistication. Cristophoro di Messisbugo described a Ferrarese banquet for 54 guests held during Lent in 1529. It included over a dozen courses that consisted of 15 to 54 individual servings of 140 separate foods and required over 2,500 plates. It is interesting to note that each course also contained savories, sweets, soups, and salads in no discernible order (Messisbugo 1549).

When lower social classes (such as wealthy merchants) began to imitate such ostentatious meals, however, once again courtly fashion shifted – this time toward simplicity and refinement. New American products made their appearance. Chocolate drinking spread quickly from Spain as the ideal drink for indolent aristocrats (Schivelbusch 1992). Italian chefs were lured to northern courts, and the French entirely transformed haute cuisine in the seventeenth century by increasingly abandoning spices and the juxtaposition of flavor and texture. The new culinary aesthetic became one of simple ingredients, delicacy of preparation, and careful ordering of courses (Revel 1982; Mennell 1985: 71). French classicism in art, absolutism in government, and courtly cuisine thereafter dominated in southern Europe, though regional variations did not disappear. The tomato, for example, caught on in the south much more than elsewhere in Europe.

The influence of the courtly aesthetic declined in nineteenth-century Europe in the wake of popular revolutions, and the democratization of governments ushered in a similarly leveling tendency in taste. A "bourgeois" cuisine introduced a greater simplicity that was, in part, a reaction against aristocratic refinement, and there eventually arose a new awareness and appreciation of folk recipes and traditional foodways, especially with the growth of nationalism.

In the modern era in southern Europe an even greater splintering of society into various groups has resulted in further proliferation of eating styles and a greater need of individuals to be associated with a distinctive group on the basis of taste. Today, vegetarianism, fast food, health food, ethnic food, and nouvelle cuisine all vie for adherents with their own distinctive ideologies and approaches. The modern era in southern Europe can also be sharply contrasted with preceding centuries because of the advance of food technologies in areas such as scientific methods of farming, canning, refrigeration, and factory processing. Food industries are now entirely geared toward a consumer society and are firmly linked to global markets. Not only have subsistence crises and hunger become things of the past for most in the developed world, but they have been replaced with the problem of overeating.

To conclude, three ideologies of food – Christian, dietetic, and courtly – reveal some of the ways southern Europeans have thought about food and indicate the kinds of considerations that entered into their food choices. But little, thus far, has been mentioned of what they actually had to choose from, and thus, in closing, a very brief catalog of the most common ingredients and their particular social or medical associations is offered.

Wheat has always been southern Europe's dominant grain, used primarily in leavened breads. Until recently, the whitest and most finely bolted flour was considered the most prestigious as well as the most healthful; flours containing bran were thought to be crass and fit only for laborers. Various pastries and cookies were praised by physicians for their restorative power and were certainly indulged in at court as well as within monasteries throughout the Middle Ages. Only in the early modern period were they judged to be unhealthy enticements, precisely at the time when sugar and spices became available to ordinary people.

Pasta made its appearance in the late Middle Ages, and from the start was condemned by physicians as difficult to digest. Although pasta was usually associated with common kitchens, courts did not entirely reject it, as is evidenced by Bartolomeo Scappi's references to macaroni (Scappi 1570). Extruded pasta, usually made with semolina flour, has come in dozens of sizes and shapes since the late nineteenth century.

Barley has also been popular since ancient times and was most frequently used in porridges and polenta, as were millets, although these were replaced entirely by maize, introduced in the sixteenth century. Rice had been an expensive luxury, usually served with milk and sweetened. It was first cultivated widely in the fifteenth century in Lombardy, and later in Spain, after which a stout variety (*arborio*) became the basis of risotto and paella.

Legumes, particularly fava beans, peas, and chickpeas, have flourished since Roman times. None were considered suitable for delicate constitutions, and since the late Renaissance were increasingly stigmatized as peasant food. Nonetheless, beans were perhaps the quintessential Lenten fare for those with modest budgets, and new varieties of beans introduced from the Americas have also been popular.

As for vegetables, few were considered especially nutritious, but watery cucumbers, zucchini, and squashes, although frowned upon by physicians, were nonetheless cultivated and enjoyed at all levels of society. The vegetables particularly associated with southern Europe have been salad greens: lettuce, sorrel, endive, purslane, orache, radicchio, dandelion, spinach, and beet and turnip greens. In addition, all varieties of the Brassica family were consumed: cabbages, broccoli, cauliflower, and kale, as well as such others as artichokes, cardoons, asparagus, and fennel. Eggplants were probably introduced by the Arabs, but they were considered very dangerous, along with other members of the Solanaceae. Tomatoes have been a staple of southern European cuisine for only the past few centuries; along with capsicum peppers, they were widely used after their introduction from the New World in the sixteenth century.

Onions and garlic, traditionally, have been indispensable flavorings, though the latter, in the past as now, has strong peasant associations. Truffles, particularly the white variety from Piedmont and the black from Perigord, have always been highly prized luxuries. But as with mushrooms, physicians usually considered them dangerous "excrements of the earth."

The most distinctively southern European herbs are parsley, oregano, rosemary, thyme, sage, fennel, aniseed (the fruit of the anise plant), and mint – all praised as hot and dry "correctives." Also widely used are bay laurel, myrtle, juniper, lovage, lemon balm, saffron, wormwood, borage, rue, savory, lavender, and, finally, basil, which had a mixed reception among physicians. Spices most frequently imported into Venice, Genoa, Marseilles, and, later, Lisbon and Seville include pepper, cinnamon and cassia, cloves, nutmeg and mace, grains of paradise (malagueta pepper), coriander and cumin, ginger, and galanga – although these have all waxed and waned in popularity on aristocratic tables.

Olives and olive oil have been traditional staple commodities, along with grapes, citrus fruits (since late antiquity), figs, and imported dates. Peaches and melons were wildly popular in early modern courts but were strongly denounced by dietary theorists as excessively cold, moist, and corruptible. Cherries, plums, strawberries, pomegranates, quinces, apples, and pears have also been popular – especially in art – as symbols for the Nativity. Among nuts, almonds, pistachios, pine nuts, walnuts, and hazelnuts take first place, and chestnuts, too, have been important, particularly in the Cévennes Mountains and around Rome. Chestnuts, however, were often described as peasant food.

Cheese from Piacenza seems to have been the first cheese to be universally praised in southern Europe. It was superseded, however, by *parmigiano-reggiano* and *pecorino romano. Mozarella di bufala* and *ricotta* are also renowned. The south of France boasts many incomparable cheeses as well, and Spain and Portugal both produce especially good cheeses made from the milk of goats and ewes.

Fowl, both domestic and wild, were credited by physicians with being the most tempered of foods and were lauded at court. They included chickens, pheasants, pigeons and partridges, and later guinea fowl and turkeys, as well as numerous tiny birds or "ucelli" (larks, thrushes, and sparrows). Ducks and geese were quite often associated with Jews, who salted and cured them. Eggs were esteemed as the ideal food for convalescents and as symbols of Christ's resurrection.

With the coming of Lent, fish appeared on most tables, although for the poor it was usually dried cod. Sardines and anchovies, squid and octopus, crustaceans, and shellfish were all consumed, along with a wide variety of fresh fish from the Atlantic, the Mediterranean, the Adriatic, and from lakes and rivers. Among these were tuna, mackerel, mullet, bass, trout, perch, pike, carp, sole, and turbot – to name but a few. At court, mammoth sturgeons, newly born eels, turtles, snails, and even tender young frogs (eaten whole) were all fashionable at one time or another.

Among the meats consumed, veal and kid were considered the most healthful and the easiest to digest. Beef was to be reserved for robust laborers, as were innumerable varieties of pork sausage, blood sausage, organ meats, and other "salume" – though prosciutto was served on wealthy tables as well as poor. Lamb and rabbits generated a good deal of medical controversy, as did those game meats most readily associated with rural nobility.

Lastly, to do justice to the topic of wine would be impossible in this chapter. But in short, it is indispensable to Christianity, has been viewed as essential to a healthful diet in both past and very recent nutritional theories, and remains a principal object of gastronomic snobbery. Perhaps coffee has been its only serious rival in recent times.

V.C.3 ⁂ France

The Dominance of the French *Grande Cuisine*

Many in Western societies as well as upper-class members of non-Western societies consider French cookery to be the world's most refined method of food preparation. This reputation has mainly to do with the *grande cuisine,* a style of cooking offered by high-class restaurants and generally regarded as the national cuisine of France. The *grande cuisine* attained its status because it emphasizes the pleasure of eating rather than its purely nutritional aspects. Whereas all cuisines embody notions of eating for pleasure, it was only in France, specifically in Paris at the beginning of the nineteenth century, that a cuisine that focused on the pleasure of eating became socially institutionalized. Moreover, it was the bourgeois class of the period that used this emphasis on eating for pleasure for their cultural development. Previously, the aristocracy had determined the styles and fashions of the times, including the haute cuisine, but this privilege was temporarily lost with the French Revolution.

The middle class also used the *grande cuisine* to demonstrate a cultural superiority over other social groups with growing economic power and, thus, the potential to rise on the social ladder. At the same time, restaurants – new and special places created for the *grande cuisine* – came into being. Spatially institutionalized, the *grande cuisine* was transformed into a matter of public concern and considerable debate (Aron 1973).

The institutionalization of a cuisine that emphasized the pleasure of eating had many effects, not the least of which was that in France, more than in other European societies, eating and drinking well came to symbolize the "good life" (Zeldin 1973–7). As such, the *grande cuisine* became culturally important for all French classes, not only for the middle class that had created it, with the result that cooking and discussions about food and the qualities of wines came to be of paramount moment. Indeed, this self-conscious stylization of eating and drinking by all classes of France led to the description of the French by other Europeans as pleasure-oriented, and the characterization of the French style of living as *savoir vivre.*

Within French society, the manner of eating became an important indication of an entire lifestyle because eating habits represented a part of culture in which social differences and dissimilarities were expressed more intensely and more subtly than in any other area. Pierre Bourdieu's study, *La Distinction,* impressively showed this phenomenon in relation to French society (1979).

Another effect of the institutionalization of the *grande cuisine* went beyond French society: The *grande cuisine* became the model and the basis for an internationally renowned cuisine and one that is culturally and socially more highly valued than other regional and national cuisines. Prices reflect this valuation most clearly. French restaurants not only are associated with gourmet food but are also the most expensive restaurants in practically any country. This internationalization of the *grande cuisine* has led to the adoption and variation, in other nations, of French recipes, French food decoration, and French ideas of service, such as the order that dinner courses should follow. The international dominance of the *grande cuisine* can be most clearly seen by the fact that the menu, the cooking language, the organization of the kitchen, and the training of the cooks are all to a large extent based on French models.

Outside of France, the *grande cuisine* holds the reputation of being a national cuisine, with people forgetting perhaps that there also exist a number of different French regional cuisines. These are bound to each other not so much by common cooking traditions as by a complicated cultural rating scheme that determines the cultural superiority or inferiority of cuisines of similar regional and social origin. This cultural judgment is also applied to those who cook and eat these regional dishes, which means that foods can be used to establish symbolic boundaries and to produce social inequality (cf. Gusfield 1992).

We can illustrate this social process with the *grande cuisine* and the regional cuisines. The former originated in an urban, aristocratic, and bourgeois environment; the latter represent rural and lower-middle-class cooking. They are not variations, one on the other, but opposites, each with different "cultural capital" (Bourdieu 1979). The *grande cuisine* is considered to be well developed, refined, and luxurious; rural cooking is described as simple, plain, and modest (Bonnain-Moerdyk 1972). Not only do these descriptions standardize the styles of cooking, they also express the meaning and function of eating and drinking in those social classes that have a special cuisine. The cultural meanings that can be derived from the *grande cuisine* suggest that members of the bourgeois and aristocratic classes are elevated beyond the mere physical need of nourishment, whereas characterizations of the styles of cooking of the lower, middle, and rural classes emphasize the physical aspect of eating. It is said that these classes do not possess the "cultural capital" necessary to go beyond the physical need to eat and drink. Thus, different cuisines are used for cultural and social differentiation and establish (as well as reflect) social inequality.

The History of the French Cuisine

One might think that there are no better resources than recipe collections and cookbooks to reconstruct what in former centuries was considered delicious cooking. Such sources, however, are inherently biased because only the wealthy classes could read and write, and there are no written reports about the cooking customs of the majority of the population. Moreover, it is doubtful that we can deduce from those recipe collections and cookbooks we do have what foodstuffs were even eaten by the upper classes. Most of the time recipes were not written by cooks because the majority of them could not read and, consequently, could not always have strictly followed recipes. Most cookbooks, then, presumably served more to idealize the aristocratic style of eating than to give cooking instructions, and we can only hope to learn from them something about the cooking notions of a certain class of literate people at a particular time.

In general, cookbooks and recipe collections are examined historically for two reasons (Barlösius 1992). One of them is to discover tendencies in the regionalization of cookery. In France this is apparent only from the nineteenth century onward because it was then that "the upper classes began to take interest in regional folklore," and of course, this included an interest in regional cookery as well (Flandrin and Hyman 1986: 4). A second reason is to reconstruct long-term changes in cooking customs in order to discern processes of cultivation and civilization (see, for example, the works of Jean-Louis Flandrin [1983, 1984, 1986]).

The Fourteenth to the Eighteenth Century

The earliest known French recipe collection is the "Ménagier de Paris" from the fourteenth century. The oldest known French cookbook is the *Viandier de Taillevant,* published by Pierre Gaudol between 1514 and 1534. In both, we can find only a few clues to the regional origins of the recipes and other instructions (Stouff 1982; Bonnet 1983; Laurioux 1986), and in fact, it can be shown that some recipes were taken from previously published collections. Some were entirely plagiarized, others only partly changed.

Another resource, very famous and popular in Europe at that time, was the cookbook *De Honesta Voluptate* (c. 1475) by Platina (Bartolomeo Sacchi). Taken together these cookbooks give the impression that there was no regional or rural differentiation in cooking in Europe during the Middle Ages. "Cookbooks, regardless of who their readers might have been, diffused culinary models inspired more by aristocratic practices than by those of the common people, and were more cosmopolitan than regional" (Flandrin and Hyman 1986: 4). The European aristocracy had, then, a common culture in eating and drinking that was not restricted by state borders. The later development and proclamation of national cuisines is closely connected to the process of state formation, which was reinforced by the assertion of independent cultures in support of national identities (Barlösius in press).

Common European cooking traditions endured until the seventeenth century, when national cuisines began to develop. It was only when French cookery became culturally stylized and was used to mark social differences that it also became a model for the courtly and aristocratic cuisines of Europe. This conscious cultural creation of cookery and table manners shows itself most clearly in the fact that before the seventeenth century, cookbooks and recipe collections were rarely published. Then, suddenly, in the seventeenth and eighteenth centuries, many cookbooks appeared. The first of this series was *Cuisinier François* by François Pierre de la Varenne, published again and again from 1651 until 1738. Other very influential cookbooks were the 1656 *Le Cuisinier* by Pierre de Lune, the 1674 *L'Art de Bien Traiter* by L. S. R., François Massialot's *Le Cuisinier Royal et Bourgeois* (published 1691–1750), and Menon's *Nouveau Traité de la Cuisine* (1739).

In these books, changes in cooking were described with terms like *ancien* and *moderne,* which were also used to indicate changes in other arts (Barlösius 1988). The cookery of the Middle Ages was criticized as being rude, even ridiculous (whereas the new cookery was considered to be refined and cultivated). Culinary tastes had obviously changed. The cooks of the seventeenth century, especially, complained about the medieval customs of cooking food too long and overseasoning it. One result was that Asian spices, like saffron, ginger, cinnamon, passion fruit seeds, and mace, were hardly used in the new cuisine, although native herbs, such as chervil, tarragon, basil, thyme, bay leaves, and chives, became popular (Flandrin 1986).

The new culinary taste was also apparent in meat choices. During the Middle Ages, the menu of the aristocracy consisted mainly of dishes with chicken and venison (Revel 1979). Beef and pork were scarcely ever eaten, although beef was an ingredient in broths and soups. Other meats that were consumed seem exotic even today, as for example, swans, storks, cranes, peacocks, herons, and large sea mammals.

During the first decades of the seventeenth century, recipes for big birds and sea mammals like whales, dolphins, and seals disappeared from the cookbooks. It was not just that such meats were believed to have no gastronomical value; they were no longer considered edible, and attempts to prepare them marked one as uncultivated, to say the least. In fact, all animals were scratched from the menu that were not especially raised or chased for food. Also out of fashion was the medieval penchant for realistic presentation, in which, for example, cooked birds might be redecorated with their feathers before being served. At this point, then, beef dishes and some pork dishes came into fashion, but only those that used the most valuable and exquisite meat parts, such as fillets, loins, legs, and hams (cf. Flandrin 1986).

Such changes give the impression that cooking was natural and bland in the seventeenth and eighteenth centuries, but this is the case only when measured against medieval cookery. In comparison with today's food preparation, however, the courtly eighteenth-century aristocratic cuisine was heavy, excessive, and complicated. Original flavors were altered, even overwhelmed, with excessive seasoning and the mixing of different kinds of foods. The aristocratic love of splendor demanded as many dishes as possible on the table, and flavor and taste were subordinated to food decoration. Until the nineteenth century, it was common to serve food *à la française,* which signified that many different kinds of dishes were offered at the same time. There were no strict rules concerning the number of dishes, but often, depending on the number of guests, there might be as many different dishes per course as there were guests, and there was a minimum of three courses. Thus, this could mean that a meal with 25 persons in attendance required 25 different dishes per course, meaning that 75 dishes were served altogether (Malortié 1881). It is true that the guests had a much greater choice than today, but inevitably many of the dishes were cold by the time they were finally served and people had the opportunity to eat them.

Table manners also changed with culinary tastes to become standardized and strictly regulated. During the Middle Ages, everybody shared the same plate and cutlery. But in the seventeenth and eighteenth centuries, each person had his or her own plate, glass, cutlery, and napkin. People were embarrassed to eat from the same plate as others or to use the same knife or glass, and with the new regulations, the distance between guests became wider (Elias 1981). Table manners were constantly cultivated and regulated down to the tiniest details. Some of the rules even changed to their opposites. In the sixteenth and seventeenth centuries, for example, it was proper to cut one's bread with a knife, but in the eighteenth century, this was considered bad form. Instead, one broke bread with the hands.

Thus, medieval notions (albeit aristocratic ones) of how to organize eating, drinking, meals, and cooking were culturally devalued, and new (but also aristocratic) ones were put in their place. Most likely much of the reason for this change was that the aristocrats were interested in creating greater social distance between themselves and the growing masses, and contributing to this desire was an increased emphasis on cultural characteristics, such as refined culinary taste and distinguished table manners. Certainly it is the case that social differentiation processes were at work at the dinner table as well as in other areas of everyday life. Thus, the aristocracy developed a lifestyle in which culinary and other cultural attitudes became an important means of establishing as well as reflecting social distances and defining social units. This new development was the haute cuisine.

The Emergence of the **Grande Cuisine** *in the Nineteenth Century*

In the seventeenth and eighteenth centuries, like music, painting, and literature, the haute cuisine served to express courtly aristocratic lifestyles. Only cooking and eating that demonstrated wealth, luxury, and pomp could accomplish this goal and distinguish the aristocracy in no uncertain terms from the rising middle class.

Haute cuisine was institutionalized in the *salle à manger* (dining room) of the aristocracy. Alexandre Dumas once complained that in the salons, commoners like Montesquieu (Charles Louis de Secondat), Voltaire (François-Marie Arouet), and Denis Diderot discussed important social issues in a serious and enlightened fashion, but sophisticated cookery was available only to the aristocrats (Dumas 1873: 30). Middle-class notions about cookery were excluded from the *salle à manger.* It is noteworthy that in the second half of the eighteenth century, haute cuisine was one of the last cultural areas in which the aristocratic taste still dominated (Barlösius 1988).

The aristocratic host (amphitryon) was called, after the verse by Molière [Jean-Baptiste Pocquelin]), *le véritable Amphitryon est l'Amphitryon où on mange.* He invited his guests, selected the menu, and made sure that the *salle à manger* looked splendid. At the beginning of the nineteenth century, Alexandre L. B. Grimod de la Reynière, in his book *Manuel des Amphitryon,* described standards of behavior for aristocratic hosts (Grimod 1808). Indispensable characteristics were wealth, good taste, an innate sensitivity, the desire to eat well, generosity, gracefulness, vividness, and a predilection for order. That money alone was not enough to run an excellent household could be observed again and again among the nouveaux riches (the "new rich") of the French Revolution (Grimod 1808).

The cooks who provided the haute cuisine were craftsmen who had an excellent knowledge of their craft. No aesthetic creativity was needed, however, and because of social position, they could not pursue their artistic inclinations, which were frequently directed toward the simplification of food presentation and spicing as well as a refined design of taste and flavor.

The aristocracy demanded a visible stylization that was in contrast to the cook's focus on the taste of the food rather than its appearance. The *salle à manger* as well as the amphitryon (host) were symbols of the ancien régime, so that the bourgeois *grande cuisine* was, to a great extent, developed in the restaurants. In fact, as already noted, it was at the time of the French Revolution that restaurants were established in Paris in great number (Andrieu 1955; Guy 1971; Mennell 1985). Before 1789, there were fewer than 50 restaurants in Paris; by 1820, the number had climbed to 3,000 (Zeldin 1973–77: Vol. 1, 739). It was in these restaurants that a bourgeois eating culture was established and the *salle à manger* disparaged, although its example was followed in standards of service, tableware, crystal, and cutlery.

The founding of the restaurants was the most important step in the process of changing aristocratic haute cuisine to bourgeois *grande cuisine.* Everybody who had enough money could eat in restaurants, where cookery was no longer the privilege solely of the aristocrats (Aron 1973; Barlösius and Manz 1988), and a cuisine that placed emphasis on the pleasure of eating was no longer influenced by aristocratic taste. In short, restaurants and their cooks succeeded in making cooking an aesthetic, taste-oriented art, which did not focus on a certain class (Barlösius and Manz 1988).

Indeed, the cooks helped to institutionalize the *grande cuisine* (Barlösius 1988). Many who had previously worked for the aristocracy now became cooks in the restaurants. They were responsible for menu planning, food design, and the financial aspects of meal production and began a process of professionalizing themselves as they assumed total responsibility for the design of the cuisine. Not only did they regard their cookery as an art, they defined themselves as artists whose task it was to make cooking equal to already established arts such as music and painting. Like other arts, that of cooking constantly changed because the cooks were competitive and strove for social recognition. But in calling themselves artists, they overlooked the fact that many of them were not working independently, and thus, it is not surprising that their working conditions and wages were often below those of other skilled workers.

Another factor in the institutionalization of the *grande cuisine* was the gourmand. Gourmands, who were supposed to be well informed in food matters and to have well-developed tastes, began to educate the public with an outpouring of gastronomic literature. Important works were Grimod de la Reynière's *Almanach des Gourmands* and Anthèlme Brillat-Savarin's *La Physiologie du Goût* (Grimod 1803–12; Brillat-Savarin 1833).

In fact, the gourmand took the place of the traditional aristocratic amphitryon, who did not fit into the sophisticated bourgeois culture of eating. Whereas an amphitryon was considered to be a gourmand because of his social position, social background was not important for a gourmand, who represented the bourgeois idea of a connoisseur. The following characteristics necessary to a gourmand were listed: a sensitive and well-developed sense of flavor, a distinctive aesthetic taste, and the ability to put the pleasure of eating into words. Finally, the gourmand was supposed to know in theory what the cook knew and did in practice, because only with that knowledge would the gourmand be able to make a sound judgment about food and drink (Brillat-Savarin 1833).

From the gourmand, professional gastronomic critics evolved. They ranked the restaurants according to a rating scheme and also published gastronomic guides. One of the first institutions of gastronomic criticism was the Société des Mercredis, founded in 1781 or 1782 by Grimod de la Reynière and some 17 gourmand friends, with Grimod as its chairman until 1810. This jury examined the quality of restaurants, with the members meeting once a week to jointly determine their expert opinions. Grimod was the first to have the idea of forming a jury whose only task was to taste and rate food. Inevitably, his jury was also the first to be accused of partiality in its judgments and, thus, of jeopardizing those restaurants that got low marks. With only a few exceptions, the jury's judgments were published from 1803 until 1812 in the *Almanach des Gourmands* (Guy 1971; Revel 1979).

The Société des Mercredis and the *Almanach des Gourmands* were forerunners of all those institutions of gastronomic criticism that followed, such as the various restaurant guides. Early in the twentieth century, the most influential gastronomic critic was Curnonsky (pseudonym Maurice-Edmond Sailland), who in 1928 founded the *Académie de Gastronome* on the model of the *Académie Française* (Curnonsky and Rouff 1921–8). In France, the best-known restaurant guides are those by Michelin and Kléber-Colombes.

Journals can also be indirect instruments of gastronomic criticism. For example, they give obligatory descriptions of the kinds of food to eat and how to enjoy eating them, and superficially, one cannot detect any traditional regulations and standardizations in these publications, such as, for example, rules of behavior. But such publications, nevertheless, belong to a genre in which questions of taste and table manners are dealt with, even if in subtle ways and not in the form of regulations. As in the past, today's media that focus on gastronomic criticism and the development of taste constitute a means of potentially producing social distance, as well as other distinctions, and setting a certain standard of cooking and taste.

The Change of the Grande Cuisine

At the beginning of the nineteenth century, the bourgeois *grande cuisine* was still detached from the traditions of the aristocratic haute cuisine, although not completely so, as is shown by recipes and food decoration. During this phase, the *grande cuisine* was influenced by Antonin Carême, said to be its founder, and by Antoine Beauvilliers, one of the first of the restaurant cooks (Beauvilliers 1814–16; Carême 1821, 1843–8). In his three-volume work *L'Art Culinaire de la Cuisine Française au Dix-neuvième Siècle,* first published in 1830, Carême described this cuisine extensively and depicted it in very detailed and exact drawings. He claimed the Italian architect Andrea Palladio (1508–80) as his model and adapted classical architectural forms to food presentation. No wonder the *grande cuisine* of this period, with its preference for regulated forms and symmetrical arrangement, can be called *cuisine classique.*

Carême concentrated on the visual aspect of cookery and not so much on food flavor. He also held to the *service à la française,* viewing as much less elegant the *service à la russe,* which was becoming more and more popular in restaurants. The latter corresponds mainly to today's style of service: The food is put on plates in the kitchen and served immediately to guests instead of being arranged aesthetically on the table beforehand.

Two cookbooks published later in the nineteenth century became very famous: These were Felix Urbain Dubois and Émile Bernard's *La Cuisine Classique* and Jules Gouffé's *Le Livre de la Cuisine.* In these volumes the tension between artful food decoration and the development of flavor and taste was discussed, but no unanimous decision was arrived at (Gouffé 1867; Dubois and Bernard 1874). Dubois and Bernard did not favor the *service à la russe* because, for them, cookery had to appeal to all of the senses. They did, however, simplify food decoration.

The contradiction between style and flavor became a point of dispute among Parisian chefs in the 1880s: Should food presentation be simplified in order to enhance the pleasure of eating? And if so, did that mean that cooks had to give up their claim to be artists? This debate, carried on in the cooks' clubs and journals, was a reaction to the criticisms that cookery was in crisis and had become decadent because it had neither adapted to alterations in taste nor paid attention to social changes in the clientele of the restaurants. The discussion was led by cook Prosper Montagné, who slowly succeeded in establishing that cookery had to focus primarily on food flavor and taste (Montagné and Salles 1900). At this juncture, the *cuisine classique* was developing into a cuisine that was aimed at an integration into new social realities – a *cuisine moderne.*

The cooks of the *cuisine moderne* reacted to alterations in taste as well as to social changes. Among these was the fact that people increasingly had limited time when eating in a restaurant. Another had to do with a change in the mixture of restaurant customers by the late nineteenth and early twentieth centuries. Auguste Escoffier, the most famous cook of that period, recommended that his colleagues study the tastes and habits of their guests and adapt their cookery to them, with special attention to those tastes that had changed over the years (Escoffier 1921). The cooks went into action. They simplified their recipes, shortened cooking times, left out superfluous decoration, and tried to speed up service in order to satisfy their new kinds of customers. Their artistry now focused fully on the composition of the food's flavor and taste (Barlösius 1988).

Yet the *cuisine moderne* was itself soon due for modification. Formerly it was thought that there existed universally valid rules for cooking; these determined which foods went well together and how they were to be prepared and decorated. In other words, people believed that recipes were independent of the cook. Cookery was regarded as an art, but not as an individual art whereby each cook had his own particular style that distinguished him from all others. In the 1930s, however, the obligatory cooking rules of the *cuisine moderne* were relaxed. Now cooks were asked to improvise when cooking. Traditional notions of matching foods were not taught anymore. Cooking came to be treated as an experiment, and this cookery was called *cuisine de liberté,* or the nouvelle cuisine.

Fernand Point, its most famous practitioner, placed emphasis on the arrangement of side dishes while simplifying existing recipes and developing new ones (Point 1969). The *cuisine de liberté* stressed the food's own taste and aimed at the perfection of cookery so as to create the best-quality dishes. In order to achieve this effect, new cooking methods were developed to retain the natural flavors, tastes, and colors of food. Although Point had not yet thought in terms of the nutritional and physiological aspects of his cookery, the nouvelle cuisine did integrate modern knowledge about nutrition that appealed to a new health consciousness.

The *grande cuisine* had scarcely been concerned with the health aspects of food, but now cooks attempted to link the pleasures of eating with foods that were healthful. It became very important to cook foods that were light and easily digestible. Moreover, the cooks of the nouvelle cuisine distanced themselves from industrialized food production. They disapproved of canned and prefabricated foods on the grounds of poor quality and demanded a return to small-farm food production.

The nouvelle cuisine also accepted regional cooking traditions to an unprecedented extent, and with this development, the dominance of Parisian cuisine, which had existed since the emergence of haute cuisine, was diminished. Nonetheless, in restaurants the nouvelle cuisine was expensive, and relatively few were able to afford it. For its part, the *grande cuisine* had begun to influence private cooking. Through television shows and mass-produced cookbooks, chefs were able to introduce their cookery to large segments of the population. Whereas original haute cuisine cookbooks had been written only for aristocratic and bourgeois households, and those in the first phase of the *grande cuisine* had addressed cooks in restaurants, now many cookbooks focused on family and household cooking. Thus, on one hand, the cooks opened up new sources of revenue with their books and shows, and on the other hand, the public became more interested in the art of cooking.

French Regional Cuisines

The term "regional cuisines" refers to the cookery and foodways of specific geographic areas whose borders frequently correspond with ethnic boundaries. The emergence of regional cuisines is often explained in climatic, biological, and geographic terms, and certainly these naturally caused differences help explain the more or less distinct division between northern and southern French cookery. The cuisines of southern France are marked by Mediterranean culture and more resemble Italian and Spanish regional cuisines than those of northern France. The latter are similar to cuisines found in Belgium and in the region of Baden, in Germany. The natural differences between the Mediterranean and northern French cuisines are certainly demonstrated by their use of fats. Southern cookery is based on cooking oils, such as nut and olive oils, whereas northern cookery uses butter and lard. There is also a difference in beverage preference, with those in southern France preferring wine and those in northern France beer or cider (Hémardinquer 1961; Mandrou 1961).

Such differences are not sufficient, however, to explain the emergence of small regional differences in cookery (Flandrin 1983). The concept of regional cookery presupposes that common ways of preparing food are cultural specialties that are further developed to become objects of cultural identity. Through these processes, demarcation from other cuisines occurs because of different methods of food preparation. Cooking, then, is a sociocultural phenomenon, and different recipes and foodways are the products of this phenomenon. And when certain recipes become cultural characteristics, the cuisines are distinguishable and can be regarded as independent cultural products. Therefore, cuisines can establish cultural differences as well as common grounds.

These social contexts explain why cooking traditions, which frequently differ from region to region, are stylized as regional cuisines only if the region as a whole is perceived as a cultural, ethnic, or political unity. Most of the time, the process of regionalization has been a reaction against the centralizing tendencies of the state. Thus, the first explicitly regional cookbooks published in France, appearing during the course of the nineteenth century, can be looked upon as evidence of a conscious cultural upgrading of typically regional ways of cooking (Capatti 1989). But they can also be seen as constituting a reaction against the increasing cultural dominance of the *grande cuisine,* which emanated, of course, from Paris.

Rural traditions, however, were not included in such regional cookbooks. They described urban bourgeois cookery only because the increasing centralizing tendency of Paris meant that the urban bourgeoisie in the rest of the country were not only spatially but also socially and culturally pushed into a peripheral border position. In short, the formation of independent regional cultural identities, even if only in terms of eating and drinking, can be interpreted as cultural self-assertion in the face of the emergence of a "national" cuisine.

The conscious development of regional cuisines led to popular dishes, beverages, and often cheeses that are frequently pointed to as typical and characteristic of particular regions. Wines, dishes featuring sausages with sauerkraut, the now-famous quiche, and Muenster cheese, for example, are culinary features of the Alsace-Lorraine region. Typical of the cuisine of Normandy are seafood, cider, and Calvados and the cheeses Camembert, Brie, and Pont l'Évêque. The cuisine of Provence is based on garlic, tomatoes, and olive oil. Bouillabaisse is often noted as one of its typical dishes; it consists of fish and crustaceans from the Mediterranean. The most famous dishes of the cuisine of Brittany are thin, sweet, or salty pancakes called crepes and galettes. Some areas are more famous for their wines than their cookery, especially Bordeaux, Bourgogne, Touraine, and Champagne. But in these regions, even though the wines are deemed more important than food, they nonetheless symbolize true eating enjoyment (Fischer 1983).

Although certain dishes and beverages have been pointed to as characteristic of specific regional cuisines, it is not always safe to conclude that they are consumed very heavily in their region, and in fact, statistics bear this out. One reason is that many typically regional dishes are traditionally prepared for festive occasions but not for everyday consumption. Another is that these dishes may be quantitatively a small part of the diet when compared to basic foods like bread. The main reason, however, is that regional cuisines tend to reflect the national cuisine in the sense that they assign to some foods a special historical status that is not deserved. To take Provence as an example, it can be demonstrated that foods that are supposed to be native and indispensable to its cuisine do not necessarily originate in that region. Tomatoes, beans, potatoes, and artichokes are the basic elements of the cuisine of Provence. But none of these foods originated there; rather, they reached southern France only following the fifteenth century (cf. Stouff 1982; Flandrin and Hyman 1986).

French Cuisine – Today and the Future

In recent years, it has become apparent that for many in the West, French cookery is no longer seen as the culinary standard, or even as the most refined cuisine. Other cuisines, such as those of Italy or Japan, are regarded as on an equal level, even though, both nationally and internationally, the French government and lobbies for the country's gastronomic arts attempt to forestall this loss of predominance by means of advertising, awards, "taste-training" events, and even great state dinners.

Why is the French style of cuisine (which was, after all, something of a standard for more than 300 years) losing its dominant position now? Two important reasons, among many, are directly connected with each other. One is that the European aristocracy and the established middle classes, for whom France served for so long as the culturally guiding nation, in language and cuisine as well as in civilization generally, no longer hold a culture-forming position, and the new cultural elites have oriented themselves to other lifestyles. The second reason reflects the shifting of political, economic, and cultural positions of power within the global society. Although French cuisine, in particular, maintained a European dominance in the past, the increasing acceptance and popularity of, say, Japanese cuisine illustrates something of the cultural competition internationally at the turn of the twenty-first century. In other words, both within Europe and in other parts of the world, French culture and, therefore, French cuisine have become devalued in terms of prestige.

The future will show if another cuisine will replace that of France in a position of prominence. It is more likely, however, that several different national styles of cookery will achieve acceptance as equally delightful and ideal. One thing is already certain: The French cuisine (and French wines as well) are no longer matchless in quality.

V.C.4 The British Isles

Prehistory (6000 B.C. to 54 B.C.)

Until very recently, all settled communities have eaten the foods that their geographic contexts offered. Once Britain was cut off from the mainland of the Continent (by 6500 B.C.) and fishing was feasible in the clement weather of the summer, fish became as integral a part of the local diet as meat was in the winter. Yet the bulk of the diet (about 85 percent) was made up of plant foods, as it always had been. Humankind has relied on wild foods for 99.8 percent of its time on the planet. There are over 3,000 species of plants that can be eaten for food, but only 150 of these have ever been cultivated, and today the peoples of the world sustain themselves on just 20 main crops. We underestimate the harvest from the wild that humankind gathered and the detailed knowledge, passed on from generation to generation, about which plants were toxic, which were healing, and which were sharp, bitter, sweet, and sour; such knowledge must have been encyclopedic.

The women and children gathered roots, leaves, fungi, berries, nuts, and seeds. Early in the spring the new shoots of sea kale, sea holly, hogweed, bracken, "Good King Henry," and asparagus could be picked. Then there were bulbs to be dug up that had stored their energy during the winter. These included the bulbs of lilies and of the *Alliums* (including wild garlic), the rhizomes of "Solomon's Seal," and the tubers of water plants that were dried and then ground to make a flour. Baby pinecones and the buds of trees were also springtime foods, not to mention the cambium, the inner live skin beneath the outside bark of the tree, which in the spring was full of sweet sap and yielded syrup. The new leaves of wild cabbage, sea spinach, chard, and sea purslane could be picked, as could fat hen, orache, nettle, purslane, mallow, and much else. Other edible leaves were those of yellow rocket, ivy-leaved toadflax, lamb's lettuce, wood sorrel, dandelion, red clover, wild marjoram, and salad burnet (Colin Renfrew, in Black 1993). The flavoring herbs, like wild mustard, coriander, poppies, corn mint, juniper, and tansy, would have been gathered with pleasure. Wild birds' eggs were also eaten in the spring, with a small hole made in an egg's shell and the egg sucked out raw. The bigger eggs, however, would have been cooked in their shells in the warm embers of a fire.

In the autumn, there were fruits to be gathered, like crabapples that were sliced and dried for the winter, along with berries (sloes, elderberries, strawberries, and blackberries), mushrooms, large tree fungi (like *Fistulina hepatica*), and nuts. Hazelnuts, walnuts, sweet chestnuts, pine nuts, beechnuts, acorns, and different kinds of seeds were also stored. In addition, lichens and algae (both very nutritious) were gathered and dried, and cakes were made out of them.

Fishing communities grew up at the mouths of estuaries and along coasts where there were sheltered coves and inlets that could harbor boats and fishing equipment. Dragnets of nettle fiber were held between boats, woven basketlike traps caught crabs and lobsters, and fresh fish (trout, salmon, and pike) were speared with tridents of sharpened bone lashed to a stick. Fish were wind-dried and smoked over peat or wood fires.

Seabirds, killed with clay pellets flung by slings or with arrows having blunt wooden heads, were another source of food (Wilson 1973). Unplucked birds were covered with a thick layer of smeared clay and cooked in the embers of a fire. Large seabirds – oily and strong in flavor – could also have been smoked over a fire and stored for the winter. Smaller game birds in the forest were more difficult to catch, though traps made of nets might have been used. In the late Upper Paleolithic site at Kent's Cavern, Torquay, the bones of grouse, ptarmigan, greylag goose, and whooper swan were found (Renfrew, in Black 1993).

In the winter, red deer, roe deer, elk, wild oxen, and wild boar were hunted, whereas smaller game like wildcats, foxes, otters, beavers, and hares were frequently caught in traps. Nooses, hung from trees, served as one form of trap. Hounding animals into gullies was another method of capture. Deer-antler mattocks were wielded to hack meat off the carcass, whereas flint knives were employed for skinning. Nothing was wasted: The gut and stomach were used as casing for the soft offal, cut up small and mixed with fat and herbs, then slowly roasted.

The first domestic animals were brought to Britain around 3500 B.C. by the islands' first farmers, Neolithic immigrants from the coasts of western and northwestern Europe. Following their introduction, herds of sheep, goats, cattle, and pigs grazed in forest clearings. Unwanted male cattle were poleaxed, and many of the bones were split to extract the marrow. That a large number of calves were killed suggests that there would also have been a generous supply of milk with which to make butter and cheese.

The Celts, who began to settle in Britain from the eighth century B.C., added hens, ducks, and geese to the list of Britain's domesticated animals. They refused to eat the wild horses and instead tamed them for riding and for drawing wagons and chariots. The Celts were the first to recognize that the soil of Britain is more fertile than that of continental Europe, and they cleared forests to plant cereals and to allow pasture to grow for grazing. They preserved meat, fish, and butter in salt and exported British beef to the Continent. The Celts also tilled the soil so successfully that they exported grain to many parts of Europe. In Britain, they built underground grain storage silos.

The Celts processed wheat by setting ears alight, then extinguishing the fire when the husks were burnt. The wheat was then winnowed and baked, and saddle querns were used to grind it into flour. These industrious farmers also began beekeeping, with conical hives made from wickerwork daubed with mud or dung. They employed shallow earthenware pots as drinking vessels, whereas deeper pots were made for cooking pottages (mixtures of meat, grains, leaves, roots, and herbs) slowly over a fire.

Honey and water, left together in a pot, will ferment, and this drink – mead – was often flavored with wild herbs and fruits. Some cow, ewe, and goat milk might have been drunk fresh, but most of it would have been made into cheese and only the whey drunk. The Celts made an unhopped beer from barley and wheat, first allowing the grain to germinate, then stopping this process with heat and allowing it to ferment. Finally, they also imported wine and, later, began to grow vines themselves.

The Roman Period (54 B.C. to A.D. 407)

The Romans raised vines in southern England and grew peaches, apricots, figs, and almonds in sheltered gardens. Beef and mutton were consumed in large quantities by Roman soldiers, as was pork where it was plentiful in the south and east of England.

The Romans introduced animal farming by enclosing large tracts of land, where they kept red, roe, and fallow deer, and wild boar, as well as bears captured in Wales and Scotland. Moreover, their villas had *leporaria* for keeping hares and rabbits in estate gardens, along with pheasants, peacocks, guinea fowl, partridges, and wild pigeons – the latter kept in columbaria (dovecotes). The Romans' pigs were confined in sties in order to fatten them. Snails were confined upon islands, so that they could not escape, and were fattened on milk, wine must, and spelt; when they became so fat that they could not get back into their shells, they were fried in oil. The Romans tamed barnacle geese and mallards and, of course, also raised chickens and capons (castrated male chicks), which (like other food animals) they kept in confinement and fattened.

They considered all kinds of shellfish to be great delicacies, and many of the oyster beds that still exist today were started by the Romans. They also brought into Britain many new spices, as well as the traditions of Greek and Roman cuisine that were as refined and sophisticated as a civilization could demand. Columella (Lucius Junius Moderatus), the Roman poet and agronomist, mentioned the use of lamb or kid rennet for making cheese. Previously, plant rennet – wild thistle, nettle, or lady's bedstraw – may have been used, perhaps discovered by accident when stirring warm milk with a stem or twig of one of these plants.

The Romans also introduced the cultivation of oat and rye, though barley was the predominant crop. They brought their bread ovens and even the *cilabus* (a portable oven) to Britain and used eggs in cooking, a practice unknown to the Celts. Eggs and milk were heated together to make a custard; eggs were fried in oil and eaten with a sauce poured over them; eggs were mixed with pounded meat or fish to make rissoles, sausages, and stuffings. With Roman rule came imported pepper, ginger, cinnamon, cassia, and other spices from the East, and white mustard cultivation was introduced. The grains of the white mustard were pounded and mixed with white vinegar to preserve vegetables. For table use, the mustard was mixed with almonds, honey, and oil.

The Romans were obsessed with two flavorings. One was the powdered root of *silphium,* which no longer exists but is thought to have been a little like asafetida. The other was *liquamen,* a sauce made from rotting small fish, which was a cross between anchovy essence and the clear fish sauce of the Orient. There were *liquamen* factories all over the Roman Empire. Honey was also a favorite flavoring, and several writers devoted pages to the craft of beekeeping in their farming manuals. In addition, cheese was much used in cooking, quite often with fish.

The Romans introduced lentils into Britain and, for the first time, cultivated globe artichokes, asparagus, shallots, and endive. They also popularized wild plants like "Good King Henry," corn salad, nettles, and pennycress. In addition, they brought new herbs to Britain, among them borage, chervil, dill, fennel, lovage, sage, and thyme.

There is an assumption that Roman banquets were an excuse for gluttony and vulgarity, even though many of their writers reveal both fine taste and moderation in their selection of foods. Notorious gluttons like the emperor Vitellius Aulus might eat four huge meals a day, but many others, like Pliny the Younger (Gaius Plinius Caecilius Secundas), would partake only of meals that were simple and informal. Pliny (1748) condemned a dinner of oysters, sow's innards, and sea urchins while listing his own notion of an evening meal: lettuce, snails, eggs, barley cake, and snow-chilled wine with honey. A dinner described by Martial (Marcus Valerius Martialis) (1993) was rather more elaborate, though he called it modest, and it was served in a single course: a kid with meatballs, chicken, ham, beans, lettuce, and leek, flavored with mint and rocket. Such a sense of a modest, well-balanced meal, with plenty of fresh green vegetables and fruits, would not be found in Britain for another 2,000 years.

The Romans encouraged wine making. They had wines flavored with salt water, resinated wines flavored with myrtle or juniper, and medicated wines mixed with herbs and taken for various ailments. Sweet wines were made by adding honey, rose petals, or citron leaves; spiced wine was made by adding wormwood. By contrast, the Britons continued to drink unhopped beer.

The Early Medieval Period (407 to 1066)

After the Romans departed, sheep, pigs, and goats were the main livestock kept, and cattle were raised as plough and draft beasts. Sheep supplied wool and milk; pigs were economical, as they ate waste and foraged in the woodlands. The rabbits escaped from the *leporaria* and died out in the wild, as did the guinea fowl and the peacocks. But hens and geese were still kept by some for their eggs and flesh, although wild birds were the only kinds available to the majority of people. Fowlers hunted birds with nets, snares, birdlime, traps, and hawks, and falconry became the sport of kings.

Germanic tribesmen added ale to the alcoholic beverages of Britain. Ale is a drink made from fermented barley or wheat, and alehouses sprang up in every village and hamlet. The beer of Britain tended to be sweeter and darker, whereas ale could be both light and mild. Mead, however, remained the drink of the elite.

After the rites of the Catholic church had taken hold in Britain (by the sixth century A.D.), fast days numbered half of the year and, later on, even more than half. This encouraged fishing, which had declined under the Germanic settlers, who were mainly farmers. But now fishermen had larger boats and longer lines and could venture farther out to sea. Drift nets grew larger, so that shoals of herrings might be caught, and the herring industry on the east coast of Britain had become important to the economy by the time of the Norman conquest in 1066. Stranded whales belonged to the Crown, but except for the tongue (thought to be a delicacy), they were generally granted to the tenant who owned that piece of shoreline. Whale meat was salted and preserved for Lenten food.

The use of olive oil disappeared with the Romans to be replaced with butter (much of it made from ewes' milk), which found its way into all cooking. The majority of the population lived, as they always had, on daily pottage, which was a stew of cereal grains with green leaves and herbs (generally orache, cabbage, or wild beet) flavored with thyme, rosemary, and onion. The starches in the cereal thickened the stew, but a richer meal was made by adding fat from a carcass or animal bones. Plants with seeds that have a high oil content were particularly treasured, and linseed was eaten extensively in rural communities from prehistory until very recently.

The seasons dramatically influenced what people could eat. Winter was a time of scarcity. From November to April there was no pasture, and the little hay that could be cut had to be saved for the draft animals, the warhorses, and the breeding stock. Thus, most of the animals were slaughtered before the winter began. The slaughter of hogs began in September, whereas cows were killed for the Feast of St. Martin (November 11). On this day all the offal was cooked and eaten, for it could not be preserved (like the carcass meat) by salting, drying, or smoking. Chitterlings, tripe, black puddings, pasties of liver, and dishes of kidneys were all eaten during this feast that was called Yule. Later, the offal was also pickled in spiced ale for a short time to make " 'umble pie" for Christmas.

Beginning in the sixth century, the Slavs introduced a new type of plow in Europe, which made it possible to bring new expanses of land under cultivation. It needed six to eight oxen to pull it, but it cut deeply into the soil and turned the furrow over at the same time. One result was that a three-field system of crop rotation came into being; one field was planted with wheat or rye, the second with peas, lentils, or beans, and the third was left fallow. The countryside fed the towns, where people also kept hens, cows, and pigs. The latter are excellent scavengers. They frequented the dark, narrow alleys where the refuse from the houses was discharged; without pigs, the people of medieval towns would have been practically buried under their own sewage and rubbish, especially after those towns began to grow in population. Certainly, epidemics like the plague would have decimated towns and their peoples long before they did.

The Medieval Period (1066 to 1485)

In the thirteenth century, herrings were gutted, salted, then smoked. The industry grew, and a century later, the fish were also salted and packed into barrels. Smoked and pickled herring became a major source of protein for the poor throughout the winter.

Fish played a large role in medieval banquets as well. They were baked in pies, made into shapes or jellies, and large creatures like the porpoise were cooked whole and carved as if they were big roasts. But because of the great number of fast days, the nobles ate three courses of meat – beef or mutton, fowl, and game – on those days when meat was permitted.

The invading Normans brought with them new varieties of apples and pears and other fruits such as peaches, cherries, gooseberries, plums, medlars, and quinces. Returning Crusaders introduced citrus fruits and pomegranates to Britain from the Middle East, though these remained rare and expensive. Dried fruits were imported from the Mediterranean and were considered medicinally better for the body than fresh fruits.

The medieval garden was well stocked with a great variety of herbs and salad plants that appeared in herbals with instructions on what ailments they would cure. Salads were eaten with oil, vinegar, and salt. The earliest salad recipe, from around 1390, called for such plants as parsley, sage, onions, leek, borage, fennel, cress, rosemary, rue, and purslane to be mixed together. Over a hundred herbs are listed as necessary to the garden in a fifteenth-century list.

The Crusaders also brought back with them a great range of spices, along with many ideas about the dishes that they were used in. Meat and fish dishes were flavored with such things as ginger, cinnamon, nutmeg, cloves, and grains of paradise. Indeed, in the thirteenth century, ginger, cinnamon, cloves, galingale, mace, nutmeg, cubebs, coriander, and cumin were listed as occupants of at least one English cupboard. The old Roman trade routes, which began in southern China, the Moluccas, Malaya, and India, and extended to the ports of the eastern Mediterranean, were flourishing again. The Crusaders had discovered sugarcane growing on the plains of Tripoli, and by the end of the eleventh century, sugar had begun creeping into British recipes. Even then, sugar came in the same hard, pyramid-shaped loaves (which had to be scraped or hacked at) that were still around at the beginning of the nineteenth century.

Cider making was introduced to Britain from Normandy in the middle of the twelfth century and, at first, was confined to Kent and Sussex in the southeast. But it soon spread to East Anglia and Yorkshire. If cider was made from pears, it was called "perry." Whey and buttermilk were drunk by peasants. Sweet wines, which became immensely popular, were imported from southern Europe and the eastern Mediterranean, another result of the Crusades. Wines from Crete, southern Italy, Tuscany, Spain, and Provence were also highly valued. Madeira malmsey was exported by the Portuguese after 1421, following the planting of malvasia grapes from Crete.

Wheat was cultivated for the fine white bread of the nobility, whereas barley was grown for brewing. Oats (that withstood both cold and rain) were raised in northern Britain to be used in pottages, porridges, and thick soups. Rye was grown to make bread for the majority, who lived off their daily pottages, supplemented by curd cheese, eggs, and whey. Poaching was a capital offense, as the forests belonged to the king. Nonetheless, much netting of game birds and trapping of deer and boar continued because, for the people, starvation was never far away. If the weather destroyed a harvest, then famine was likely that winter. Beginning around 1315, at the start of the Little Ice Age (caused by an advance of polar and alpine glaciers that lasted until 1700), Britain suffered years of famine that brought on revolts and rebellion (Tuchman 1978).

Cheese was made from the milk of goats, ewes, and cows, sometimes mixed together, at other times separated to make particular cheeses. Milk was seldom drunk fresh; the nobility thought it was unhealthy as it curdled in the stomach. Besides, the popularity of butter, cheese, whey, curds, cream, and buttermilk was such that fresh milk was thought too valuable to be used simply for drinking. In the summer, strawberries and cream constituted a rural banquet. Drinks called possets were fashioned with milk curdled by ale. Often flavored with fruits and honey, possets could also be drained and made into a dessert to be cut into slices.

Fast days provoked much ingenuity (among the rich) in replacing forbidden foods with alternative concoctions. Almond milk, an expensive substitute for cows' milk, was curdled, pressed, drained, and transformed into cream cheese. Eggs were modeled from fish roe, and ham and bacon were made from salmon masquerading as lean meat, with pike as the fat (Wheaton 1985). St. Thomas Aquinas, at one point, stipulated that chickens were aquatic in origin; therefore, because they counted as fish, they could be eaten on fast days. At rich monasteries, rabbits were bred for their embryos, as these did not count as meat either.

Those who could afford it ate from "trenchers," which were thick slices of coarse rye and wheat bread with a little of the center scooped out. "After the meal, these were collected and given to the poor. During a meal, the nobility used several trenchers, made from a better class of bread. Much of the meat consumed by the rich came from hunting, and so a great variety of fresh game could be eaten throughout the winter. In addition to wild boar and deer, there were also birds, ranging from herons, swans, and peacocks to curlews, partridges, pigeons, quail, snipe, and woodcocks.

Medieval feasts could be as elaborate as those of Roman times. Illustrative is the banquet of three courses given upon the coronation of Henry IV in 1399. The first course had 10 different dishes: slices of meat, cooked in a spiced sweet-and-sour sauce; a puree of rice and mulberries, sweetened with honey and flavored with wine and spices; a boar's head; baby swans; a capon; pheasants; herons; and a pie made from cream, eggs, dates, prunes, and sugar. Then the "subtlety," a highly decorated dish of pastry, jelly, almond paste, and sugar, was brought in to indicate the end of the first course.

A second course, of nine dishes, comprised venison, calf's-foot jelly, stuffed suckling pigs, peacocks, cranes, rabbits, pies, chickens, and fritters. Another subtlety was followed by the third course of 16 dishes, which included a lot of small game birds as well as jellied eggs and custard tarts. What is interesting about medieval menus is the similarity of the courses. There was no sense of a first course being an appetizer to whet the palate or of the last course being something to refresh or pacify the diner. Those ideas were lost with the Romans, and it was many centuries before they returned. Meanwhile, simple gluttony and gorging prevailed.

Pie makers were familiar figures in medieval England. The pie was a development of the Roman idea of using a flour and water paste to seal the cooked juices of a piece of meat. But because in England butter and lard were mixed in with the flour, it was possible to make a free-standing paste container that could be packed full of a mixture of meat, game, fish, and vegetables. In 1378, a special ordinance of Richard II regulated the prices cooks and pie bakers in London could charge for their roasted and baked meats (Wilson 1973).

Except for the peasants, who still gathered much wild food, people did not eat many vegetables, which were believed to be sources of disease, especially when raw. *The Book of Keruynge* (1508), for example, warned its readers to "beware of green sallettes." But onions, leeks, garlic, and cabbage were thought not to be harmful so long as they were cooked thoroughly. This was usually the case after stewing for long hours with meat or carcass bones to make soup.

Craftsmen and workers in the towns enjoyed a better diet than peasants in the countryside. An act passed in 1363 ordered that servants of noblemen, as well as artisans and tradesmen, were to have meat or fish once a day, as well as milk and cheese. Breakfast was bread and ale, with possibly some pickled herrings or cheese. A midday meal bought at a tavern or cookshop could be roast meat, stew or soup, bread, cheese, and ale. Supper was bread and cheese again, perhaps with cold meats, and ale or wine. The law's concern with the welfare of servants was a direct result of the Black Death, which had severely pruned the population, making the survivors substantially more valuable.

In the few decades that came before the onset of the plague, however, a rise in population outpaced agricultural production, which meant overpopulation, undernutrition, and a people more vulnerable to disease. Agricultural methods and tools had not advanced for 800 years; the clearing of productive land had been pushed to its limits, and poor soils could not be made more productive nor crop yields raised. When the plague appeared, in 1348, people starved by the thousands, and the peasantry bore the brunt. The chronicler Henry Knighton, canon of Leicester Abbey, reported 5,000 dead in one field alone, "their bodies so corrupted by the plague that neither beast nor bird would touch them" (Tuchman 1978: 103). Fields went uncultivated, seeds were unsown, dikes crumbled, and salt water soured the land. "So few servants and labourers were left," wrote Knighton, "that no one knew where to turn for help."

The plague killed 40 percent of Europe's population by 1380 and halved it by the end of the century. Yet as with servants, the catastrophic event improved the lives of those peasants who survived. Landowners reduced rents and sometimes even forgave them altogether. The acreage sowed in grain 30 years after the onset of the plague was only half what it had been before the calamity. But the plague did mean that some peasants became tenant farmers, and the size of their holdings continued to grow in ensuing centuries.

Tudor, Elizabethan, and Stuart England (1485 to 1688)

Many of the foods and dishes eaten during the Middle Ages remained popular into the sixteenth and seventeenth centuries. Although new and exotic American foodstuffs could be obtained, many of these took centuries to become part of the diet. An exception was the turkey, which had found its place upon English tables by the 1540s. However, potatoes, tomatoes, peppers, and haricot beans took 200 years or more before they were ever eaten, except as rare, exotic ingredients on the tables of the wealthy.

As Iberian sugar production on islands off Africa and in the Americas increased, the national consumption of sugar rose. Queen Elizabeth was inordinately fond of sweetmeats, and the wealthy all suffered from tooth decay. Sugar was used to make the most intricate shapes and sculptures for banquets. Birds, beasts, and fruits were contrived from spun sugar, placed in baskets of marzipan, and sometimes made even more lifelike by painting and gilding.

Hunting – still the most popular pastime of the nobility – also provided occasions for ornate al fresco breakfast banquets. The gentry ate dinner at 11:00 in the morning and supper between 5:00 and 6:00 in the evening. Meals were now served on plates, and trenchers were unknown, although they lived on in the practice of serving cubes of bread beneath boiled or stewed meats. Potteries producing tin-glazed earthenware were established in Norwich and London at the end of the sixteenth century by Andries and Jacob Jansen from Antwerp (Peter Brears, in Black 1993), and glass became fashionable for drinking vessels, although silver and gold cups remained popular with the nobility.

An act of Parliament in 1548 made Saturday a fish day so as to encourage both shipbuilding and fishing. The English fishing fleet on the east coast was in constant competition with the Dutch, who fished openly in England's coastal waters and sold their catch in English ports. Salted fish was never very popular in Britain, and more effort was made to bring in fresh fish for sale. Shellfish remained the most popular seafoods; lobsters, crabs, shrimps, and prawns were boiled and eaten cold, and sometimes lobsters were boiled, then wrapped in brine-soaked rags and kept for a few months buried in sand. Oysters were eaten both fresh and pickled in vinegar. Anchovies from the Mediterranean became increasingly popular; pickled in brine, they served as appetizers before meals and were added to meat and fish dishes for flavor. Fish pies were a common dish in Lenten fare. These were filled with a mixture of herrings, salmon, eels, and sturgeon and made with butter, egg yolks, spices, and dried fruits. There were various recipes for an Elizabethan fish-day salad that usually included herbs and periwinkles, along with white endive and alexander buds, with whelks to garnish the whole.

Local cheeses became widely known through the popularity of cheese fairs that were visited by merchants, factors, and peddlers, who bought cheeses for resale elsewhere. The best were selected for the rich. Highly thought of were Banbury and Cheshire cheeses, in which, it was said, neither the rennet nor the salt could be tasted. Cheeses were also imported from abroad; Parmesan was the most popular, although Dutch cheeses were also appreciated.

In the seventeenth century, a much greater range of salad plants were grown in the walled gardens of the great estates. John Evelyn (1620–1706), in his *Acetaria, a Discourse on Sallets,* enthused over the health-giving properties of the "Herby-Diet." Yet vegetables were still frowned upon by the majority of people, with the lack of fresh vegetables in the diet evidenced by the prominence of scurvy. Gideon Harvey, physician to Charles II, spoke of it in 1675 as the "Disease of London" (Spencer 1993: 214).

Distillation of plant juices became a public activity following the dissolution of the monasteries, as monks found new vocations as apothecaries and distillers, and English soldiers, returning from the Dutch wars, spread the popularity of strong liquors. Nonetheless, beer and ale remained the most popular beverages.

Early Modern England: The Agricultural Revolution (1688–1750)

Farming technology had progressed little between the sixth and eighteenth centuries. Because there was no winter pasture, the animals were still killed at the beginning of winter. But new ways of feeding cattle began to change this situation. It was discovered that cattle could be fattened very nicely on turnips, and a manual, *The Practical Farmer* by William Ellis (1732), advised giving cattle rapeseed cakes and turnips for winter provision, as was done in Holland. There, it had been discovered that cattle would thrive on the residue left after the oil (used for lighting) had been pressed from crushed rapeseed. Later, other vegetables, such as swedes, mangelwurzels, clover, and cabbages, were also used for winter cattle feeding.

At the same time, more efficient farm tools were being invented. Jethro Tull devised the first horse-drawn hoe and field drill, which wasted less seed and allowed more grain to be harvested. Farm tools were now made of cast iron and could be mass produced; the Rotherham plow was invented, and the first threshing machine appeared before 1800. Other machines were designed that could prepare animal feed, chop turnips, and cut chaff. Because animals could at last be maintained throughout the winter, those with the most valuable traits could be retained and used to breed in the spring. Robert Blackwell (1725–95), a Derbyshire breeder, introduced the longhorn, a cow that gave a high milk yield, and John Ellman (1755–1832) introduced a new breed of sheep, the Southdown, that fattened in half the time of other breeds. The growing size of animals not only increased yields of carcass meat and milk but also ensured finer-quality fleece from sheep and more hide from cows.

At the end of the seventeenth century came the creation of the Norfolk four-course system, whereby wheat was grown in the first year, turnips in the second, then barley with clover and ryegrass undersown in the third. In the fourth year the clover and ryegrass were either cut or used for grazing.

With this new farming technology came a need for larger fields, unimpeded by hedges. Gradually, the common land, where farmworkers traditionally had kept a cow, a pig, and a few hens, and where they gathered wood for cooking fires, was removed from public use by a series of Enclosures Acts. In the reign of George III (1760–1820) alone, 3 million acres of common land were added to private farming estates, hindering the ability of thousands of farmworkers to feed their families. Many emigrated to America, whereas others went into the factories in the new and burgeoning industrial cities.

The effect of the Enclosures Acts was far-reaching. Rural life was radically altered and partially destroyed, and whole villages were abandoned. Within a generation, cooking skills and traditional recipes were lost forever, as the creative interrelationship between soil and table (the source of all good cuisine) had been severed.

From then on, the diet of the workers rapidly declined, although in the north of England the potato had, at last, been accepted. In the south, wheat, the source of fashionable white bread, had taken over the land. A farm laborer with a wife and four children averaged £46 in annual earnings, but the cost of the same family's food amounted to £52 a year. Each week, such a family typically consumed 8 loaves of bread, 2 pounds of cheese, 2 pounds of butter, 2 ounces of tea, a half-pound of boiled bacon, and 2 pints of milk. By contrast, dinner for a late-eighteenth-century middle-class family of six has been depicted as consisting of three boiled chickens, a haunch of venison, a ham, a flour-and-suet pudding, and beans, followed by gooseberries and apricots (Drummond and Wilbraham 1959). Jonas Hanway, the reformer, said of the poor in Stevenage in 1767: "The food of the poor is good bread, cheese, pease and turnips in winter with a little pork or other meat, when they can afford it; but from the high price of meat, it has not lately been within their reach. As to milk, they have hardly sufficient for their use" (Drummond and Wilbraham 1959: 208).

The eighteenth century, however, was one in which vast amounts of meat were eaten by those who could afford it. Sydney Smith, canon of St. Paul's Cathedral, calculated that during his 77 years, he had consumed 44 wagonloads of meat and drink, which had starved to death fully 100 persons. In Smith's letters, and in Parson James Woodforde's diaries, accounts of meals are laden with meats: game, fowl, cold tongue and hams, roasted sweetbreads, giblet soup, pigeons, veal, and marrow sauces. Obesity was caricatured by artists like William Hogarth and Thomas Rowlandson, and huge weights, up to 40 stone (about 560 pounds), were attained by some people. Among meat eaters, meat consumption averaged about 147 pounds per person annually, about the per capita amount eaten today in the United States.

Throughout the century, market gardens had been started around growing cities and towns. London had gardens at Lewisham, Blackheath, Wanstead, and Ilford. A vegetable market at Liverpool arose because an influx of French Canadians wanted cheap vegetables for their soups. Most vegetables, however, were of poor quality and little variety (cabbages, carrots, spinach, sprouts, and turnips), although special vegetables were still grown in the walled gardens of great estates. Unfortunately, eighteenth-century practices of hygiene were not very advanced, and many of the barges that brought fruit and vegetables to the city of London took away the contents of the city's cesspits on their return journey.

Not only did overeating typify the times, so did an excess of fats used in cooking. Hannah Glasse (1971: 5) commented in her cookery book: "I have heard of a cook that used six pounds of butter to fry twelve eggs, when everybody knows (that understands cooking) that half a pound is full enough." Fashionable food centered around huge pies made from turkey and swan, or mixtures of game with veal, sweetbreads, mushrooms, and potatoes. Dr. Samuel Johnson's favorite dinner was "a leg of pork boiled till it dropped from the bone, a veal pie with plums and sugar and the outside cut of a salt buttock of beef" (Pullar 1970: 170).

Beer and ale remained the most popular drinks in Britain until the beginning of the eighteenth century, when home-brewed distilled spirits took over. Dutch *genever,* or gin, had begun to appear in England as early as Stuart times, and ginlike liquors, flavored with juniper berries, were made from beer dregs, lees of wine or cider, and soaked dried fruits. With the addition of extra yeast, large quantities of spirit could be distilled from any of these mixtures. Molasses fermented with barm (the yeasty froth on fermenting malt liquors) made a crude rum, and "grains of paradise" made the spirits hot and fiery in the mouth. British brandy was a spirit drawn from newly fermented barley malt.

Dutch-cultivated coffee beans spread from East Indian colonies to the West Indies and then to England. Coffeehouses became fashionable places to meet and gossip, and coffee was taken up by the nobility. It grew in popularity until the Georgian era, when tea began to compete with it. Drinking chocolate was perhaps not quite as popular, as the manner of making it was a chore. Cocoa beans were exported to England, where they were dried, peeled, and powdered. Next, sugar, cinnamon, vanilla, nutmeg, and ambergris were added, and then the mixture was rolled, made into cakes, and cast into molds. It was these cakes that had to be scraped and grated for use in drinks and puddings.

The foods eaten by the majority (the working and lower-middle classes) were all either grown locally or preserved by pickling and smoking. Jane Austen's father – a modest country clergyman – farmed a smallholding where he kept cows, pigs, and sheep and grew wheat for making bread. His wife kept fowl and looked after the vegetables, herb garden, and orchard. She taught her daughters how to supervise the making of butter, cheese, preserves, pickles, and homemade wines, as well as how to brew beer and cure bacon and hams (Black 1993). But such a life and its lessons were lost as the century grew older, the towns larger, and the world smaller.

Later Modern England: The Industrial Revolution (1700 to 1900)

As more and more factories were built for the mass production of goods, so towns and cities grew to serve the factories. The population of London quadrupled in the nineteenth century. In 1800, Manchester had 75,000 inhabitants; some 50 years later, there were 400,000. Social reformers were astonished that although riches grew and a new bourgeoisie of affluence appeared, the most abject poverty afflicted the majority of workers. Potatoes, bread, and tea constituted the main diet of the poor; about once a week there was some milk and sugar and, perhaps once a year, a piece of bacon. Almost half of the children born in towns died before they were 5 years old, whereas those who survived were severely undernourished, low in stature, physically weak, and frequently grew up deformed by rickets.

Nearly all food was adulterated with illegal additions to make it stretch further. Alum was added to bleach flour for white bread; various drugs and flavorings, even sulfuric acid, were put into hops. The leaves of ash, sloe, and elder were mixed into tea. Copper was used to color pickles green, red lead colored the rind of Gloucester cheese, and coffee contained roasted corn and red ocher.

The growing, well-off middle class in the towns and cities did not possess large estates, as the old landed gentry still did, which meant that the middle classes owned no source of natural foods. Thus, the nineteenth century produced the modern grocer, and railroads made it possible for milk and produce from the country to be delivered to the center of any great metropolis. Steam trawlers replaced sailing boats, and the railways also carried fresh fish, well-chilled in ice, to inland areas. Cod became commonplace, and the first fish-and-chips shops opened. The invention of bottling and canning methods of food preservation put many cheaper items onto grocers' shelves, where bottled sauces, along with canned foods – vegetables, meats, fish, and fruits – were now essential provisions. Aberdeen, although 515 miles away, became the abattoir of London because of the ability to send carcasses overnight by rail. The world had become one huge food market. After 1880, Australian beef could be sent by sea in refrigerated ships. Tea from India was no longer expensive, nor was wheat from America; hence, not only was a greater range of cheaper food now available, but much of it was packaged beguilingly, with certain brand names becoming household words.

The middle-class Victorian housewife had most of her fresh foods delivered. The baker, muffin man, and milkman made their rounds daily. The fishmonger brought cod, hake, salmon, skate, eels, herring, and shellfish; the greengrocer called with a wide range of seasonal vegetables delivered to him early from the market gardens. If a housewife left her basement kitchen to shop, it was only to buy from the butcher and the poulterer. Veal was the cheapest meat; calf's-feet jelly and a pig's-head brawn would both be appreciated by the family. Capons and pheasants were thought of as party dishes, and small game birds were kept to be served as savories (Black 1993).

A German chemist, Justus von Liebig, helped increase food production with his advocacy of artificial fertilizers at the same time that his research in nutrition attempted to classify foods scientifically. His main discovery in this endeavor was that of the food chain – the interdependence of plants and animals – and his research into plant nutrients led to his identification of protein, which resulted, during the next century, in fundamental changes in the ways that food was thought of, grown, and eaten.

The diet of the poor, however, did not improve; their wages were still low and malnutrition was widespread. In 1847, the Vegetarian Society was founded in the midst of industrial Britain. It was very much a social reforming movement, dedicated to temperance and the improvement of the working classes. Vegetarianism also flourished for a time among members of the affluent middle classes, who saw themselves as social reformers. They were shocked at the inadequacy of the diets of working people. Bread and jam (with the jam made from colored, sweetened fruit or vegetable pulp) was all that some children ate throughout the day. This scandal was at last drawn to the government's attention when cannon fodder was needed; in the enlistment for the Boer War (1899–1902), it was discovered that 37 percent of the volunteers were so unfit for service that they had to be invalided out.

The Twentieth Century

British society and its food did not change until after the end of World War I (1914–18). The postwar period was one of intense trading and competition in the world market. For the first time, people could eat tropical fruits (imported from the East) in winter; shipments of chilled apples and pears came all the way from New Zealand. Canada, Australia, and the Argentine grew wheat and exported it to Britain, and in addition to fruits, butter and lamb from New Zealand competed with Danish butter, eggs, and bacon. But the British farmer, too, had to compete with these cheaper imports.

More foods were now packaged under brand names that soon became familiar, and consumers grew to expect an improved quality of service from retailers and food producers. Many of the household cooking chores had already been eliminated, as much of the food – custard, blancmange, jellies, gravy, and porridge – now came out of packages. Breakfast revolved around corn flakes or other cereal products, and the range of canned foods included not only soups but salmon, corned beef, vegetables, fruits like pineapple, and even game birds and condensed milk. Many of the favorite dishes for special occasions might come from a variety of containers, which was a boon for many, as servants were rapidly becoming nonexistent, except in extremely wealthy households. Food retailing in Britain in the 1930s absorbed nearly one-third of the national income.

What consumers failed to realize was that many additives entered these new foods. Food manufacturers added preservatives and improvers – anticaking agents to stop flour, milk, salt, and sugar from forming lumps; emulsifying agents, to blend substances that tended to separate; sequestrants, to keep fats from going rancid – none of which were disclosed on the labels.

Evidence of vitamins and how they contribute to health was published in 1911, and the subject, from then on, was never far from the public eye. It was gradually realized that afflictions like pellagra, rickets, scurvy, and beriberi, once believed to be contagious, were actually the result of deficiencies in vital elements of the diet. Of course, some of the new knowledge required generations to take hold. For example, the idea that brown flour, which contained all the bran and minerals, was more healthful than white flour was first mooted in the last quarter of the nineteenth century but required a full hundred years to be accepted.

In 1914, as in the Boer War, it was once more noted that volunteers for the armed services were grossly undernourished, and at last, the government took action by stressing the importance of the health of munitions workers and the importance of adequate nutrition to the workforce as a whole. By the end of World War I, a thousand industrial canteens were supplying a million meals a day, and workers in British industry, now for the first time had hot, well-cooked meals at reasonable prices (Burnett 1966).

By the time of World War II (1939–45), the government was far better prepared than before to ration food while increasing its production. A Food (Defence Plans) Department had been set up in 1936, but in 1939 Britain was only 30 percent self-sufficient in food compared with 86 percent for Germany. Rationing, however, was begun immediately because all the details had been worked out and the ration books printed. The science of nutrition was now so advanced that the nation's diet could be planned informatively and wisely. Food technology, it was also seen, could play a vital part in economizing on shipping space by dehydrating vegetables, drying eggs and bananas, importing boneless meat, and compressing carcasses. A good example is "Spam" – the bane of the wartime kitchen. A Food Advice Division was set up to give nutrition information to the public through radio and newspapers.

Britain rationed meat, bacon, cheese, fats, sugar, and preserves on a per person basis. Bread was brown, and vitamins A and D were added to margarine. Additional proteins, vitamins, and minerals were given to small children and to pregnant or nursing mothers. Communal feeding grew in importance; firms employing more than 250 people were required to provide a canteen service, and school canteens began to ensure that all children had at least one well-balanced meal a day. British restaurants in the blitzed areas provided hot, cheap, nutritious meals to the general public and grew to number 2,000 in 1943.

Millions of people "dug for victory." Flower beds and lawns gave way to vegetable gardens. A great amount of potatoes was eaten, and the consumption of green vegetables and fresh fruit also increased. Throughout the war, there was a decline in infant mortality, and the general health of children improved. On average, they were taller and heavier, and for the first time in British history, the poorest third of the population was eating an adequate and balanced diet. In fact, the British diet has never been more healthful, before or since the war, however much the people complained. They were then consuming a great deal more fiber, much less sugar and refined flours, little meat, and more fresh fruit and vegetables. The war encouraged people to go into the woods and hedgerows to harvest wild foods, to make jams out of sloes and rose hips, and to gather fungi, wild herbs, and greens for flavoring.

Rationing continued until 1953, and for a time there was even less food available than during the war. Women had tasted independence during the war years, and they were not always prepared to return to full-time domesticity. There was a move for women to go out to work, and to encourage this, there was a growth in domestic technology. From the mid-1950s onward, certain trends are noticeable. Less food was bought for home consumption, meals were smaller and lighter, and there was a growing demand for "convenience foods." This was a new concept: processed foods that are labor-saving because they can be prepared and brought to the table in only a few minutes. In this category, the greatest rise in consumption has been in quick-frozen foods (Burnett 1966), followed by precooked chilled dishes and microwave meals.

Such a change in diet would not have been possible had it not been for a postwar revolution in farming methods throughout the world, occurring on a scale far greater than that of the previous agricultural revolution in the eighteenth century. Intensive factory farming was an idea explored because of the rigors of wartime rationing and the fear that there would not be enough protein for a growing world population. Various factors coming together in the 1950s allowed for new methods. First, there was research in cellular growth and DNA, so that natural hormones could be extracted from livestock, then used to stimulate desired characteristics. Second, the ability was enhanced for chemical companies to research and produce a varied range of drugs, including antibiotics, that allowed farmers to keep greater numbers of animals than ever envisioned before. And third, new building technology could provide cheap housing units for animals, with concrete stalls and automatic feeders and timers that made controlled feeding, watering, and lighting feasible. One result was that fewer and fewer stockmen were needed on the farm to watch over and care for the animals.

Also in the 1950s, agriculture began to spawn a vast number of different but interdependent industries engaged in the development of new equipment, fertilizers, and seeds, as well as new techniques and products for the storage, processing, and preservation of foods. As a consequence, heavily mechanized farms with computer technology made farmers more and more dependent on a host of suppliers. A farmer might often be unable to make a choice on the way he reared his livestock because of the rules laid down by a particular supplier. Large companies, such as those of the pharmaceutical industry, were financing farming with millions of pounds of capital, which meant that the farmer was controlled from a remote city office. Agriculture had become a highly sophisticated energy-intensive system for transforming one series of industrial products into another series of industrial products that just happened to be edible (George 1986).

Selective breeding of livestock also became a new skill, and improvements in the control of selective breeding are certain to continue in the future. But this development also means that we lose genetic diversity (21 British cattle breeds have become extinct since the beginning of the twentieth century). When one bull can sire over a quarter of a million offspring, it allows for enormous inbreeding, which can reveal hitherto unsuspected defects (Johnson 1991). One of the drawbacks for the consumer with these new methods of rearing livestock is that a lack of exercise, combined with a rich protein diet, produces a carcass high in saturated fats. There is also a wide belief that food produced in such a way has less flavor than when natural rearing and feeding is employed. Fully 63 percent of housewives in Britain in the 1980s felt that food had less flavor than it did 20 years earlier (Johnson 1991).

This sense that basic English foods have become blander (Johnson 1991) may partly explain the great popularity of ethnic foods and restaurants. Since the 1950s, Chinese, Indian, Cypriot, Thai, and Mexican restaurants have grown up throughout the towns and cities of Britain. No doubt, the willingness to try new foods was encouraged by postwar travel, although packaged holidays in the popular cheaper resorts of Europe now cater to the most conservative of British tastes with fish and chips, roast beef, and Yorkshire pudding. Popular food is also controlled by American companies that produce hamburgers, fried chicken, and the like. This is poor food nutritionally, with a high amount of saturated fat; nonetheless, it symbolizes the American way of life, and by consuming fast food, the eater becomes a part of that way of life. Indeed, this demonstrates how atavistic food consumption still is and how little it has changed from the days of prehistory, when to eat the meat of an ox meant that one was hoping to attain the strength of oxen.

In reaction to factory farming, to the widespread exploitation of animals, and to the high amount of saturated fat in the British diet, the vegetarian movement has grown in the last 40 years. In 1945, there were 100,000 vegetarians in Britain; by the 1990s there were 3 million, the number having doubled during the 1980s. Moreover, 40 percent of British people have reduced their consumption of red meat or entirely eliminated it from their diets (Spencer 1993).

Because of the worldwide market, there is now a far greater range of food available to more people than ever before in history. Yet the diet of the majority tends to be high in refined carbohydrates, sugars, and salt and relies on convenience foods, which lack the fiber and essential vitamins and minerals provided by fresh vegetables and fruits. Food has become blander and more stereotyped over the last 30 years, and the divide between rich and poor has not gotten any smaller. In fact, with a doubling of the population predicted within the next 40 years, it can only grow wider.

V.C.5 Northern Europe – Germany and Surrounding Regions

The majority of foods found in modern northern Europe – which includes the lands around the North Sea and the Baltic Sea and those of northern Alpine region – are not indigenous to the area. It is here, however, that one of the most stable of humankind's agricultural systems was established, and one that has proved capable of providing densely populated areas with a high standard of living. Such an agricultural bounty has helped northern Europe to become one of the most prosperous areas of the world.

The Paleolithic Period

The northern European environment underwent drastic change several times during the Pleistocene. Glaciers coming from Scandinavia and the Alps covered a large part of the landscape with glacigenic sediment several times during the Ice Age. Forests retreated from northern Europe and were replaced by a type of vegetation that can be regarded as a mixture of those of tundra and steppe. In this environment, forest-adapted herbivores were replaced by large grazing species such as caribou *(Rangifer tarandus),* wild horse (*Equus* sp.), and mammoth *(Mammonteus primigenius).* These species, associated in small or bigger herds, migrated from the north to the south and vice versa in a yearly cycle. In summer they fled north from the multitude of biting insects (to Jutland, for example), and in winter they were attracted by the somewhat higher temperatures in areas of the south, such as that just north of the Alps.

Reindeer herds proved to be a very good source of food for Paleolithic reindeer hunters, whose widespread presence in northern Europe is well established by excavations. The hunters migrated with the herds from the south to the north and back again. Prehistoric humans located their temporary dwelling places so as to achieve a maximum vantage point – usually so they could hunt downhill using their lances and bows or a kind of harpoon made of stone and bone material (Bandi 1968: 107–12; Kuhn-Schnyder 1968: 43–68; Rust 1972: 19–20, 65–9).

Although the archaeological evidence for hunting is very clear, hunters doubtless also gathered wild plants. The latter, however, is very difficult to demonstrate, as it is rarely possible to find plant material, such as fruits and seeds, preserved in the layers of Paleolithic camp excavations.

During the late glacial period, trees from the south colonized northern Europe so thoroughly that the landscape was nearly totally forested. Unfortunately, we know little about human nutrition following the return of forested conditions to northern Europe. Reindeer and other steppe-tundra fauna became locally extinct in the newly forested regions.

The Mesolithic Period

There is clearer evidence for human nutrition at the beginning of the postglacial period (the interglacial hiatus in which we live), approximately 11,000 years ago. Following the retreat of the Würmian glaciers, forests again established themselves in most parts of northern Europe to the extent that these landscapes became unsuitable for reindeer and other large herd herbivores. The reindeer herds retreated to those parts where tundra was established: northern Scandinavia, northern Finland, and northern Russia. It is only in these regions that a "Paleolithic way of life" has remained possible up to the present day, because the relationship between reindeer herds and hunters has remained as in millennia before. In the unforested region of the extreme north it is also still possible to practice Paleolithic hunting methods, as exemplified by the Laplanders and Inuit.

In most landscapes of northern Europe, however, hunting methods and nutrition changed, reflecting the changing environment. The forests were invaded by smaller and less frequent solitary woodland fauna, such as red deer *(Cervus elaphus),* boar *(Sus scrofa),* and badger *(Meles).* These species are difficult to hunt in dense forests, and they do not provide a large meat yield. Changes in the vegetational environment were reflected in the hunter's tool kit. Long-range projectile weapons, for example, cannot be used in a wooded landscape. Smaller hunting tools constructed from "microliths" (typical archaeological remnants of the Mesolithic period) were better suited to the vegetation and woodland prey (Wyss 1968–71, 3: 123–44).

Life during the Mesolithic was perhaps harder than during the Paleolithic. It was more difficult to hunt an animal in a wooded landscape, and thus meat was certainly not available all the time. Possibly the plant component of the diet became more important during the Mesolithic. For example, at the very few Mesolithic dwelling places that have been examined by environmental archaeologists, there is evidence of the use of hazelnuts *(Corylus avellana)* (Vaughan 1987: 233–8).

During the Mesolithic, hazelnut bushes spread rapidly to many parts of Europe, as evidenced by pollen diagrams. This is in contrast to the vegetation development of the earlier interglacials. Hazelnuts are heavy, with low dispersal rates, so that it is very unlikely that the plant diffused unaided to all parts of northern Europe at the same time. Instead, it has often been assumed that hazelnuts were culturally dispersed by Mesolithic peoples (Firbas 1949: 149; Smith 1970: 81–96). Indeed, the distribution of these nuts is recorded by pollen analysis in the Mesolithic layer of Hohen Viecheln at the border of Lake Schwerin in northern Germany (Schmitz 1961: 29).

Most likely the expansion of hazelnut distribution was due to the nuts' chance spread during the preparation of "hazelnut meals" by migratory Mesolithic people. Most of the other wild fruits available in the present-day northern European woodlands are not archaeologically recorded for the Mesolithic, nor for the Neolithic period, which has been much more intensively examined by environmental archaeologists. Thus, it is unlikely that strawberries, wild apples, and pears, for example, contributed to human nutrition during the Mesolithic (Küster 1986: 437).

The Neolithic Period

The transition from the Mesolithic to the Neolithic has often been regarded as a revolution by northern European archaeologists (Childe 1956: 66–104). But the Mesolithic–Neolithic transition, with its change from a hunter–gatherer community to a sedentary food-producing farming community, was not a revolution in other parts of the world such as the Near East. In these areas a gradual evolution can be traced from the one stage to the other. In contrast, the transition from hunting and gathering to farming in northern Europe seems to have indeed been a revolutionary process, in which none of the nutritional mainstays of the Mesolithic was incorporated into the Neolithic food-production system.

Rather, all wild elements of the new farming system had been previously cultivated or domesticated elsewhere, mainly in the Near East. Both domesticated animals and cultivated crops were introduced into northern Europe, primarily from the Near East, and were, therefore, exotic elements at the beginning of the Neolithic. Near East domesticates, such as cattle *(Bos primigenius f. taurus),* goats *(Capra aegagrus f. hircus),* sheep *(Ovis ammon f. aries),* and pigs *(Sus scrofa f. domestica)* were introduced into many parts of northern Europe during the Neolithic.

Although most had been introduced in the Balkans, only some of the ancient Near Eastern crops became important in Neolithic northern Europe. It is very likely, however, that each component of a well-balanced vegetarian regime (starch from cereal crops, proteins from pulses, and fat from oil plants) was available to all Neolithic settlements in the region.

In most parts of northern Europe, einkorn *(Triticum monococcum)* and emmer *(Triticum dicoccon)* were the predominant cereals during the Neolithic. Both traveled upstream on the Danube River and downstream on the Rhine River from the Balkans to northern Europe. The same expansion route can be traced for peas *(Pisum sativum)* and lentils *(Lens culinaris),* the major pulses of the Neolithic, although at that time lentils had a more extensive distribution. Today, lentil production is restricted by climatic conditions in many parts of northern Europe. Linseed *(Linum usitatissimum)* was the major oil (and also fiber) crop (Knörzer 1991: 190–3; Küster 1991: 180–2). Only in the extreme west – in southwestern Germany, along the Rhine, in the Netherlands, and in some parts of Scandinavia – were different crops apparently grown. Wheat *(Triticum aestivum* and/or *Triticum durum)* and naked barley *(Hordeum vulgare)* cultivation is evidenced in southwestern Germany and Switzerland (Jacomet and Schlichtherle 1984: 153–76; Küster 1991: 180–2), in the Netherlands, and in southwestern Scandinavia. These plants had their origins in the Near East but likely expanded via the Mediterranean and western Europe (Bakels 1982: 11–3). The only crop not of Near Eastern origin found in the Neolithic of northern Europe, the opium poppy *(Papaver somniferum),* most likely arrived from the western Mediterranean. Inside northern Europe, regional differences in agriculture and nutrition are traceable from the early Neolithic onward, making clear the borders between "economic provinces." For example, barley was important from the very beginning in southwestern Germany and the Netherlands but not in Bavaria and the Rhineland. Yet barley did become important later on in areas where it had not been grown during the early Neolithic.

Through agriculture, the northern European landscape was totally changed by humans. The clearing of the earlier wooded landscape caused environmental changes that are not completely understood today. Hunting, fishing, and the gathering of plants were activities still practiced by the early farmers, but the bulk of human nutrition was certainly derived from agricultural products.

Yet the variety of nutriments available in the Neolithic was severely limited. Because there were very few crops, no herbs and spices, and no cultivated fruits, all meals must have tasted very nearly the same, day in and day out, save on those rare occasions when a meat dish was available.

Toward the end of the Neolithic, some Mediterranean flavorings were introduced in northern Europe, but only in those parts that had cultural and economic contacts with Mediterranean areas. Among the imports were parsley *(Petroselinum crispum),* celery *(Apium graveolens* var. *juice),* and dill *(Anethum graveolens),* which reached some areas of southwestern Germany and northern Switzerland to enliven drab fare (Küster 1985; Jacomet 1988). Other spices were employed in the preservation and storage of meats. This importation of Mediterranean spices is the earliest indication we have of some sophistication in food preparation, as well as a gardening culture, in the southern parts of northern Europe. Following the end of the Neolithic, herbs and spices disappear from the record, and there are no remains of such plants in northern Europe in Bronze Age and even Iron Age settlements.

The Bronze Age and Iron Age

After the Neolithic Revolution, the development of northern European agriculture was influenced more by evolutionary than revolutionary processes. Although the people still did not personally participate in the process of domesticating animals and plants, they did continue to import new cultigens and domesticates. The basic diet, however, does not seem to have undergone any dramatic shifts.

Through trial and error, Bronze Age and Iron Age farmers discovered those crops that were best adapted to the environmental conditions of northern Europe. As they did so, einkorn, which provides only a small yield, became less common, whereas emmer, barley, and (from the early Bronze Age onward) spelt *(Triticum spelta)* were increasingly cultivated. Spelt, however, was common only in some regions: at the northern border of the Alps, in Jutland, and in southern Sweden, where it possibly was grown as a winter crop.

As a rule, only two different crops were grown in a settlement, which left such agricultural communities susceptible to crises when one or the other cereal had poor yields. Indeed, it seems likely that at times famine may have been the result of the ecological instability that a farming community relying on the cultivation of just two different crop species can create. And, of course, the crops were not just for human consumption; they also helped to feed the livestock.

During the Bronze Age, the horse *(Equus przewalskii f. caballus)* was domesticated. This probably took place in eastern Europe, but horses were subsequently introduced into northern Europe, where they not only were used for riding, transport, and agriculture but also became an important component of the human diet (Wyss 1971). Unlike other livestock, horses cannot subsist solely on leaf hay; they require special supplemental feed. Thus, it is striking that the introduction of domesticated horses coincided with the expansion of the millets *(Panicum miliaceum* and *Setaria italica)* and the horsebean *(Vicia faba)* into northern Europe. But whereas the impetus for the adoption of these plants may have been the feeding of horses, during the late Bronze and Iron Ages millets and beans doubtless also contributed to human nutrition.

Over time, agricultural methods became more sophisticated, with better ploughs (as metals were increasingly available), bigger fields, the use of better-adapted plants, and concomitant greater yields. But the basic elements of human nutrition remained more or less the same. Cereal crops, pulses, and oil plants still provided the bulk of the daily fare, and milk was plentiful. But meat was eaten only on special occasions, as reflected in hoary rules concerning the consumption of meat that have persisted until today.

Since animals were not hunted every day and only seasonally slaughtered, meat, as a scarce item, became regarded as an important component of banquets. In fact, from ancient times onward a good reason for inviting numerous guests to a banquet was so that the bulk of any meat served was consumed before it became rancid. Because slaughtering was commonly done in autumn, banquets were (and often still are) given in late autumn and around the time of Christmas. By contrast, meat was normally not consumed during the winter and spring months, when people maintained only as many cattle as were necessary for breeding. This period corresponds to the fasting season (Lent) of the Catholic church between Shrove Tuesday and Easter. Lamb was and remains a traditional dish at an Easter banquet, for this was the time of year when an abundance of newborn sheep could be culled from the flock.

The Roman Age

Around the time of the birth of Christ, parts of northern Europe situated southwest of the Rhine and south of the Danube became colonies of the Roman Empire. Within this area, foodstuffs took on an increasingly important role in Roman commerce, with the Rhine serving as an important trading route. Wheat, rice *(Oryza sativa),* and exotic spices were transported downstream to Roman garrisons and to towns in northwestern Germany and the Netherlands. However, colonies not situated near the Rhine, although involved in the trade of spices and wine, did not trade in bulky items such as grain. Thus, in these regions, the Romans had to force the subdued peoples to deliver crops to the towns and settlements where their soldiers and civilians lived.

There were great efforts during Roman times to increase crop yields, which can be seen in the construction of the villa system. Sophisticated agricultural methods were practiced. But ultimately, difficulties in transporting enough food to the Roman soldiers in those parts of the Imperium not accessible by river routes may be one of the reasons for the decline of the Roman Empire in the Danube provinces. By contrast, the area between Cologne and the Netherlands was one of the economically most powerful parts of the Imperium even in the late Roman age.

Outside of the Roman Empire, some improvement of agricultural methods also took place. Rye *(Secale cereale)* and oats *(Avena sativa)* were grown as additional crops, certainly enlarging and stabilizing of the food supply and possibly enabling the local farmers to export crops to Roman towns. Yet despite the influence of Roman commerce and the presence of trade routes in the area, the peasant diet, at least, seems to have been similar to that of prehistoric times.

The inhabitants of towns and garrisons, by contrast, enjoyed considerably more variety in viands. Those who had the ability bought many different spices at market, and cultivated fruits became available. In fact, the oldest fruit-tree groves and vineyards in northern Europe date from the Roman Age. The basic requirement for these was the stability that Roman rule brought to settlements. Prehistoric settlements had lasted for only a few decades at the most – not long enough for the fruits of groves and vines to appear in any abundance.

The Middle Ages

Many of the Roman trade routes were still used after the Romans departed. For example, the trade route along the Rhine remained important, and its commerce was extended by Viking merchants to the coasts, to northwestern Germany, and to the islands and peninsulas around the North Sea: England, Ireland, Iceland, Norway, and Jutland. Artifacts that represent importations into Viking settlements, such as wine and wine vessels in Haithabu (Behre 1983), serve to document the existence and extensiveness of these routes.

The Hanse merchants added the areas around the Baltic Sea to their economic empire, bringing exotic food to the towns along the Baltic coast. Indeed, at times there was more imported food inside the towns than local products. As an example, during a period of grain shortage in Lubeck, marzipan, a bread that is baked not of ordinary flour but of almond "flour" and sugar, is said to have been invented (Küster 1987).

The food trade in northern Europe experienced yet another shift when the exchange began of meat (or livestock) and crops between the agricultural and grassland areas. In the Netherlands, oxen were taken from Frisia westward to the big towns, whereas crops were transported from the dry, sandy areas to the fen landscapes where cattle farms came into existence (Bieleman 1989). The trade of oxen, in turn, led to the development of "oxen routes" inside northern Europe. In the late Middle Ages, as food transport and trade became more important, these activities were no longer confined to waterways but were also carried out over such overland routes.

All parts of northern Europe that were distant from the trade routes had remained rural, and the diets of their residents continued to be restricted to the few elements of food (cereals, pulses, oil plants) that had been exploited since prehistoric times. Only the species of plants had changed. Rye, oats, and, in some areas, wheat had become more important, whereas emmer was only rarely cultivated.

Urban growth meant a continuing demand for as much food as possible, which led to intensive agricultural production. Nearly all woods were cleared, and a sophisticated rotation system – winter crop, summer crop, and fallow – came into existence. The settlements became stable and were usually arranged around a church. As during Roman times, such stability (in towns, monasteries, and castles) promoted the cultivation of fruit trees and vines, the produce of which was available in the markets. Yet the demands of rapidly growing urban populations frequently led to shortages in basic foodstuffs like flour, which in turn led to conflict and even civil war between city peoples and peasants. The *Bauernkrieg* ("Peasants' War") of 1525 was perhaps the most famous of these conflicts, signaling the end of the Middle Ages and its accompanying social system in northern Europe.

Modern Times

During the following centuries, it became even more difficult for rural farmers to supply enough food for urban populations that continued to swell (Abel 1978). There was one crisis after another, which brought periods of famine in northern Europe and periods of migration to North America. But at the same time, American food plants were taking root in Europe.

In the period of mercantilism, just prior to the Age of Industrialization, factories were founded in many parts of northern Europe. People began working for wages, and thus many more became dependent on the food market, which had difficulty meeting demand, especially in years with low crop yields. In response, northern European landowners forced peasants to cultivate the American potato *(Solanum tuberosum),* which delivered a high yield of food per unit of land cultivated.

In principle, such cultivation made it possible for ordinary workers to buy sufficient food in the form of potatoes to sustain themselves. But the expanded food supply caused rapid population growth and a concomitant growth of towns. Indeed, the industrialization of northern Europe would not have been possible without the introduction of the potato (Küster 1992a).

It was not, however, until the nineteenth and twentieth centuries that the peasants' diet began to include imported food items, such as spices, long enjoyed by town dwellers. This change was precipitated by an extensive construction of railways that linked the countryside with the cities. With the new foodstuffs came grocers to the villages. They were called "Kolonialwarenhändler" in the German language, which means "colonial produce merchants." Yet only exotic food imports were sold in the grocery shops, whereas the most important constituents of the diet were provided by the farmers themselves.

During the nineteenth and twentieth centuries, the construction of railways has also led to further spatial concentration of cattle raising and crop production. With the invention of mineral fertilizers that were transported by rail, crop production was abandoned in mountainous areas but intensified in the plains. In addition, the great increase in yield on fertilized fields led to the abandonment of remote acres where spruce forests could be planted.

Another agrarian and nutritional revolution was caused by the beginning of extensive maize *(Zea mays)* cultivation during the past few decades. Maize silage provides enough food for large cattle and chicken producers, causing meat and eggs to become relatively cheap to northern European consumers. Since World War II there has been a marked shift toward increased meat consumption. The protein-rich diet causes health problems, and dietitians recommend eating more grains and vegetables and less meat and eggs. In northern Europe today, food shortages are not a problem, and the price of food plays less of a role in determining an individual's nutrition than it did in the past. It is interesting that despite the great variety of foods available on the shelves in the supermarket, dietitians are recommending a return to the dietary staples of prehistoric times (Haenel 1986).

Nonetheless, a huge variety of foods is now produced in northern Europe, and other foods produced outside of that region can be purchased by almost everyone. Some of the crops produced, such as wheat, barley, oats, and rye, have been grown and consumed for millennia. Others, such as potatoes and maize from the Americas, are relatively new but very important. Also important are certain foods brought in from abroad. Rice, which is imported in large quantities from South Asia, is one of these. Coffee and tea are others. The northern Europeans have long been fond of hot beverages, and today Dutch and Saxonian coffees are famous the world over.

In a remarkable turnaround compared with the past, today more crops and meat are produced in northern Europe than can be consumed by the people of the region, and such abundance has created great political and economic problems. Oversupply of such items as pork, butter, wine, and apples has prompted the common market of the European Union to insist on less production, and farmers have been forced to destroy a portion of their harvests and cut back on the amount of meat produced. Because areas where long-established crops can be cultivated have become increasingly restricted, farmers are turning to alternative crops such as spelt, flax, and sunflowers. Many products from these new crops are available in health-food stores as well as supermarkets, as northern Europeans, like people in other developed countries, are giving more thought to improving their nutrition.

Another important nutritional development in the region began in the 1950s, when labor shortages there opened the way for southern European workers to move north. With them came their national cuisines and specialty restaurants; Italian and Greek foods are very popular in northern Europe today. Pizza restaurants can be found even in small villages, and frozen pizza is one of the most common fast-food dishes in the home.

In addition to the influence of southern Europeans, there has been a substantial culinary contribution made by the people of now-independent overseas colonies to their former mother countries. Just as Indian food and restaurants are common in England, and North African cookery is widespread in France, there are many Indonesian restaurants in the Netherlands.

As the northern European countries have become more prosperous, they have also attracted the peoples (and thus the foods) of most of the rest of the world. Chinese restaurants, for example, are ubiquitous, and spring rolls and other Chinese dishes are available in all the supermarkets.

Indeed, because of prosperity on the one hand and all of these culinary choices on the other, cooking at home has come to an end in many households. It is easy and inexpensive to purchase already prepared dishes from the supermarket in cans, or frozen, or dried. Moreover, it has become very common to eat in what might be termed "neighborhood" restaurants where one encounters friends and can relax. Fast-food restaurants from America have been introduced but are still not all that popular because they are too hurried.

Clearly, then, the history of food and drink in northern Europe has entered into a unique chapter. There is an abundant variety of both native and exotic foods available, and famine is unknown. More and more customers are demanding higher-quality foodstuffs, and it has become fashionable, for example, to use the very best olive oils and spiced vinegars in the preparation of salads. Factories that turn out convenience foods, such as mashed potato powder and instant soups and sauces, are supplemented by a market network that supplies frozen and fresh fruits, vegetables, meats, and fish, all of which combine to supply a high – perhaps too high – level of nutrition for the northern European.

This situation stands in stark contrast to nutritional levels in the poorer regions of the world. For economic and political as well as logistical reasons, it is a complicated matter to ship foods from northern European countries to the underdeveloped nations. But some, especially the Scandinavians, have done much to help improve the standard of living, including the level of nutrition, of developing-world peoples. Moreover, there are regular airlifts from northern Europe to famine-ravaged regions of the world, although, of course, balanced diets are hardly provided in such bulk shipments.

In conclusion, it is worth stressing that the sheer amount of nutrients available to northern Europeans today also stands in stark contrast to their own long past of undernutrition and even famine. One hopes that one day soon, like the northern Europeans, the people in today's developing countries will be confronting the problem of overnutrition.

V.C.6 ~ The Low Countries

The term "Low Countries" is used here to mean the Netherlands. Belgium, known in the past as the southern Netherlands, has been independent since the 1830s. Situated between France to the south and the Netherlands to the north, Belgium has had a different history and has developed different cultural characteristics since the seventeenth century. Thus, in this chapter, Belgian culinary culture is employed for comparative purposes only.

A general overview of the history and culinary culture of the Netherlands should, perhaps, start with the observation that the Dutch have never succeeded in being proud of their cuisine. This seems to be a reflection of a lack of national pride that sometimes borders on indifference. If asked, most would probably not be able to identify important, genuinely national, dishes. Moreover, if such a dish were named, it might well be *rijsttafel,* which is not Dutch in origin but Indonesian and is a product of the Dutch East Indian colonies. Such a lack of concern with indigenous culinary culture forms a more or less sharp contrast to the attitudes of the inhabitants of neighboring Western European countries like Belgium, France, and, to some degree, Germany.

Over the centuries, foreign visitors have repeatedly expressed amazement at the Dutch lack of exaltation of the table. But since the late Middle Ages, daily food has always been prepared according to the general rule that it must be simple, nourishing, and cheap. Only after World War II did this undemanding attitude begin to change.

Contrasts and Similarities: The Late Middle Ages (1300 to 1500)

Little evidence is available about food and drink in the late medieval Low Countries. Cookery books in this era were exclusively aimed at the secular and ecclesiastical upper classes. The recipes, nevertheless, give some indication of the extremely wide range of possible dishes at the tables of the elite. The first Dutch-language cookbook, printed in Brussels by Thomas van der Noot in 1510 and titled *Een notabel boecxken van cokeryen* ("A notable book of cookery"), offers medieval recipes for festivities such as weddings and banquets that deal with the preparation of sauces, jellies, fish, meat, fowl and game, pies, tarts and other pastries, eggs, dairy products, various sugars, wine, and, finally, candied quinces and ginger.

The recipes come from various sources, many of them French, which underlines the observations of Stephen Mennell (1985) about the essential similarity of the tables of the medieval rich everywhere in western Europe, with the elite following culinary standards that were mostly Italian and French. It was especially at such festivals that princes, nobles, and church dignitaries ate and drank lavishly. The festive banquets of the Burgundian dukes, at that time rulers in northern France and the southern Netherlands (Flanders), initiated a luxurious and flamboyant civilization that served as a model all over Europe, as did the ceremonies of their peripatetic courts.

Prodigious consumption at the courts, particularly of meat (from pigs, calves, sheep, various fowl, and game) and wine, contributed to the maintenance of the high social position of the nobility. So, too, did the lavish use of precious spices and sugar in the preparation of a large number of dishes to be presented all at once. A refined taste, however, still had to be acquired, and social standards in eating, appetite, and table manners evolved only over the course of a lengthy civilizing process (Elias 1994). In the Middle Ages, quantity prevailed over quality, in no small part because of the irregularity of the food supply. It was a time when harvests failed, diseases killed domestic animals, and life was made even more insecure by pestilence and war (Mennell 1985: 20–39).

Religious restrictions on the consumption of meat and dairy produce also exerted a profound influence on cooking and eating. Prescribed days of abstinence were not confined to the period of Lent but (in addition to special days of fasting) were in force twice each week, which made for a total of about 150 days of food proscriptions every year. These religious rules of abstinence and fasting raised impediments to, and at the same time opened possibilities for, the culinary creativity of the cooks at the courts as well as those in ordinary kitchens. Fish – a preferred Lenten food – was abundantly available from the sea as well as from the many rivers and lakes in the Low Countries. Thus, meals at the court of the Bishop of Utrecht in the fourteenth century included about 20 different fish dishes, such as haddock, plaice, whiting, eel, herring (in various preparations), sturgeon, pike, perch, and carp. But Lenten abstinence may also have hindered the use of certain cooking methods – such as frying in northern Europe, where butter was the principal edible fat – and in such areas hampered the development of culinary variety in general. By contrast, in southern Europe, where olive oil – not proscribed during Lent – was the major fat, the days of abstinence may have encouraged the inventiveness of cooks, especially in the competition for prestige at noble and royal courts (Jobse-van Putten 1995).

Thus, sharp contrasts existed between festive and daily eating, between feasting and fasting, and between years of plenty and those of scarcity. Other contrasts and variations were related to the rhythm of the seasons, to the church calendar, to the regional agricultural produce, and, above all, to the social strata. To this might be added the contrast between fresh and preserved foods. Except for the short periods during harvest and slaughter, no possibility existed of eating one's fill of fresh vegetables and meat. Rather, because of the rapid deterioration of foodstuffs, they were generally consumed as salted and dried products.

The ecological and geographic conditions typical of a northwestern European delta, with its rivers, lakes, sea inlets, and clay soils, applied especially to the western and northern parts of the Netherlands – Holland, Zeeland, and Friesland – that were to assume a dominant position in the Dutch Republic. The eastern and southern parts of the territory were higher and more sandy, with vegetation different from the lower regions. Such a division between the northwest and the southeast was for centuries an important factor in the economic and agricultural structure, influencing the products available for consumption. The cultivation of grains, for instance, was a matter largely defined by climate and soil.

In fourteenth-century Europe, famines and epidemics, most notably the Black Death, caused a considerable reduction of the population that in turn led to a transformation in the production and distribution of food. The grazing of cattle increased relative to the growing of crops, and for a time, meat was available in larger quantities, even for the poor. Later on, however, the cultivation of grains increased in the Low Countries as elsewhere in Europe, transforming them into staple foods.

A moderate maritime climate in the Low Countries allowed the growing of several types of cereals, including barley, oats, and rye. At least initially, wheat could be cultivated only in the southwest, and rye became the prominent grain in the Netherlands, even though wheat was the more appreciated of the two (Jobse-van Putten 1995: 83). Unfortunately, the quantity of grain produced was not sufficient for the population and had to be supplemented by imports from eastern Europe. In the thirteenth and fourteenth centuries, this took place within the flourishing trade network of the Hanse – towns of the Hanseatic League – through which substantial parts of northern Europe were commercially interrelated, forming a line from the Baltic Sea and the river Danube in the east to Bruges (Flanders) and London in the west. In the fifteenth century, the position of the Hanse deteriorated, and the grain trade shifted to Amsterdam, which became the most important grain center, not only for the Low Countries but for Europe as a whole.

From the fourteenth century onward (although in Flanders much earlier), economic differentiation began to take place. The importance of money and trade increased; means of transport were improved; and cities came into being. Consequently, some farmers began to produce for the market. Butter and cheese, for example, were made in the low-lying grasslands of Holland and Friesland (where animal husbandry was important) and later became very famous delicacies. Despite such surplus production, however, subsistence agriculture remained the dominant economic pattern, especially on the small and isolated mixed farms in the eastern and southern parts of the Low Countries (Burema 1953: 29).

This type of economy substantially influenced attitudes toward preserving, cooking, and eating home-produced foods, an influence that endured, in part at least, until the second half of the twentieth century (Jobse-van Putten 1995: 379–84). Meals everywhere in the Low Countries were prepared in roughly similar fashion, although local and regional differences in agricultural products and technical conditions of cookery caused variations from place to place in the composition and taste of dishes and drinks. Grain was cooked as porridge (often the poorer qualities), baked as pancakes or bread, and brewed for beer. Porridge could be made in a pot over an open fire, but bread required an oven and, thus, tended to be found in the households of those in more fortunate circumstances. Beer was the common drink, as water was of poor quality and milk was mainly used for making butter and cheese. Vegetables and fruits – thought to be unhealthy – were not much appreciated. Nonetheless, tubers, beetroots, turnips, and peas were often daily foods by necessity. Green leafy vegetables were little known and eaten only among the upper strata. The number of meals per day depended on social position. The elite preferred two meals, but those performing physical labor often ate three or more times daily. In rural areas, frequent hot meals were common.

The ordinary medieval hot meal among country people and townsfolk consisted of a half-liquid pottage, which was a mush made of water, milk, or beer, root vegetables, and pulses (various types of peas) or grain, sometimes enriched with a piece of meat or lard. This dish, prepared over an open fire, like porridge, underwent changes as different ingredients became available throughout the seasons. If an oven was available, bread went with each of the day's hot and cold meals.

In the consumption of pottage, the Low Countries were not very different from other western European countries during the Middle Ages. The records of two hospitals in the cities of Leiden and Utrecht between 1367 and 1500 indicate that pottages were an important dish in both institutions. Meat and fish (salted herring was a preferred Lenten food) were served with bread once or twice a day, and smaller meals consisted of bread, butter, cheese, eggs, and milk, buttermilk, or beer (Jobse-van Putten 1995: 145–50). Every part of an animal (head, brain, eyes, and entrails) was utilized in meat dishes, and the frequency with which such dishes were served by the two hospitals in question is an indication of both the relative prosperity of the cities and the abundance of meat in this period.

Is it possible to discern some traits of an emerging national cuisine in the Low Countries during the late Middle Ages? And is there any indication of a continuity with later developments in Dutch foodways? The little available evidence suggests a negative answer to both questions. The similarities in foodways with other western European countries seem to have been substantially greater than the differences. National states were later inventions, and local and regional networks were dominant in determining the production, distribution, and preparation of foods. The contrasts between common and festive fare, and between meal preparation among the elite, on one hand, and the masses, on the other, were everywhere alike.

There were, of course, some contrasts. One was the Dutch dependency on butter and meat fat for cooking instead of olive oil. That Dutch butter and cheese were famous products at an early stage, and continued to be so for centuries, was another. A final difference was the Dutch expertise in horticulture, which had gained a widespread reputation.

Gardening was initially practiced in the monasteries, but castles and country houses also began to develop cabbage patches and orchards for pears and apples. In addition, commercial gardens were cultivated near cities. Like butter and cheese, horticultural produce was later promoted for export. Foreigners came to regard it as "typically Dutch," and it also achieved fame. Catherine of Aragon, for example, had salad vegetables brought to the English court from Holland by a special courier (Burema 1953: 16).

Rise and Fall of the Dutch Republic (1500 to 1800)

As already noted, strangers visiting the Netherlands over the centuries have often noted a simplicity in cuisine and lack of refinement in the eating and drinking habits of its citizens. The latter were frequently portrayed as people with little discrimination but fond of large quantities of food, which they swallowed quickly. By the late Middle Ages, the Dutch were also well known for their exorbitant drinking habits (Burema 1953: 53). Seventeenth-century paintings by Rembrandt and others show overloaded tables and bacchanalian parties of guilds and fraternities. Yet other paintings show families praying before a simple meal of nothing but bread and cheese. Although some of the latter may carry moral and religious messages, the same simplicity is also mentioned in foreigners' descriptions (Schama 1987: 159–75). Together, these images give an impression of both the exception and the rule in Dutch eating and drinking in the sixteenth and seventeenth centuries. Feasting was characterized by excessive indulgence, reminiscent of the late medieval Burgundian court. Yet daily meals were frugal and consisted, more often than not, of only one or two courses, even among the well-to-do and the aristocracy. As both types of meals lack refinement, how does one interpret the combination of excess and simplicity that has become a distinguishing mark of Dutch culinary culture?

Popular wisdom has it that Dutch culinary mediocrity was caused by Calvinism, which frowned on mundane pleasures. Indeed, the economic and social influence of religion, especially of Calvinism, has been a much-discussed topic among historians and sociologists, who have pondered, among other things, the extent to which it was a force in the sociogenesis of the Dutch Republic and in subsequent public and private spheres of life. Culinary attitudes and preferences, of course, belong to both spheres and are part of the lifestyles and mentalities of the social groups in power. Thus, to understand the culinary culture of the Netherlands, a look at the process of state formation and related economic development is indispensable.

Certainly, the shift of the commercial and industrial center of gravity in Europe from the south to the northwest was an important marker in the beginning of the modern age, and the Low Countries were at the heart of this process. But the forces that led to the flourishing economic position of the Republic of the Seven United Provinces from 1588 to 1795 had already been set in motion by the end of the fifteenth century. At that time, the Low Countries were under the rule of the Habsburg monarchs, who were able, through fortuitous marriages, to enlarge their domains to include Austrian, Burgundian, and Spanish territories.

Situated as they were around the estuaries of the rivers Scheldt, Maas, and Rhine, the inhabitants of the Low Countries knew how to take advantage of the new economic opportunities this expansion provided. The development of new technologies to master floodwaters, the reclamation of land, and the construction of an early infrastructure of navigable canals and windmills were an important Dutch contribution to modern European economic growth. In addition, there were well-known Dutch advances in shipping and commerce, and development also occurred in other important fields such as agriculture, fisheries (especially herring), and industry (principally textiles and timber). It is important to note that all of this economic upsurge had already taken place before the Reformation, with its various brands of Protestantism (especially Calvinism), could have had any influence (De Vries and Van der Woude 1995: 23–67, 205–13).

Moreover, even the Calvinist influence was often moderated by a liberal and humanistic Christian faith in the tradition of Desiderius Erasmus. Consequently, Calvinism never succeeded in achieving a religious monopoly; indeed, many citizens clung to the old Roman Catholic church. This is not to say, however, that Calvinism was not an important force in Dutch history. It helped sustain the country during its revolt against the Spanish Habsburgs, and the great merchants who emerged as the Dutch Republic came into existence were supporters of the Reformation. These men found their rising influence in the affairs of the state legitimized by the new Protestant faith, and they, along with the patricians, did impress a cultural style on the public and private spheres of daily life that was typical of the urban bourgeois from Holland and Zeeland.

This meant that the exceptionally broad, but differentiated, middle classes in the cities were at the heart of the republican society (Huizinga 1984: 39–59; Van Deursen 1992) – a situation that was fundamentally different from other European countries such as England and France. In England, both the royal court and the rural gentry left their mark on cultural life, whereas in France, new cultural models, in foodways as in other areas, were pioneered at the urban court where the king and nobility resided (Mennell 1985: 102–34). But in the Netherlands, during the sixteenth and seventeenth centuries, the dominance of bourgeois influence, legitimized by the characteristic Christian lay religiosity of either the orthodox Calvinist or the liberal humanist, resulted in a frugal and simple culinary style.

This simplicity was not the case on festive occasions, however, despite the complaints of some Calvinist ministers about the collapse of tables under the weight of too many dishes, and despite the decrees issued by Doctor Nicolaas Tulp (the mayor of Amsterdam around 1660) against excessive expenditures for eating and drinking at weddings, christenings, and funerals. Indeed, such festivals were occasions when considerations of social status and competition overcame the ever-present virtue of thriftiness (Van Otterloo 1986: 39–43).

From 1500 to 1800, as in the late Middle Ages, the main foods remained grain, tubers, meat, lard, fish, cheese, and butter. The central importance of the grain market in Amsterdam meant an increasing abundance of wheat, and wheat bread became the most popular farinaceous food among the urban well-to-do, as well as among the patricians in their country houses. In addition, spices, for those who could afford them, were increasingly available from 1602 onward because of the trading efforts of the Dutch East India Company.

The diets of artisans and farmers centered mainly on a daily porridge, sometimes interchanged with or complemented by pancakes and rye bread. Bread might be accompanied by butter or cheese, but not both. The two together were viewed as a needless luxury, even as "devil's work." If possible, bread was eaten at breakfast with fish, porridge, or another hot dish, and perhaps at a third or even fourth meal in the early evening with a pottage. Many varieties of bread were used, depending on social position and the type, rhythm, and place of work.

In distinguished circles, the salad, an invention diffused from the south, often accompanied the early evening meal or was used as an entrée at the beginning of a hot meal. Initially, beer was the beverage of choice at meals, but later on it was largely replaced by milk, buttermilk, or whey, although the poor generally drank water. After 1680, coffee began to be used; in the eighteenth century, it became a popular drink, and there were many coffeehouses in the cities and towns. Tea – called "women's tobacco" – also came into use and long remained a high-status beverage, partly because of the costly tea set required by social custom. Tea was drunk by the wives of patricians and bourgeois regents and diffused very slowly among the lower social strata during the eighteenth and nineteenth centuries (Jobse-van Putten 1995: 151–226).

For many, the day's two hot meals generally consisted of one to three courses: a starter, a main course, and possibly a dessert. The starter might have been a salad or a *sop* (pottage) from groats or bread soaked in milk or broth. Other possibilities were a dish of pulses with butter and onions, braised root vegetables, or cabbage. Dessert was usually buttermilk porridge in rural areas; among the urban merchants, however, pastry (for example, "shoemaker's tart," made from apples, bread, and eggs) and fruits were common. The main course was a dish of fish or meat, served, if possible, with green herbs, prunes, or currants. In wealthy households, this course might be followed by oysters or lobster with sweet sauces (Burema 1953: 96).

The relative simplicity of the bourgeois kitchen was reflected in the unique cookbook of Dutch origin *De verstandige Kock of Sorghvuldige Huyshoudster* ("The Prudent Cook or Careful Housekeeper"), published in Amsterdam in 1667. This frequently reprinted book was intended for wealthy merchants who owned country houses and had access to produce from their own gardens (gardening was a relatively new pursuit of the urban elite). The book opens with instructions for building a kitchen range that permitted the simultaneous preparation of separate dishes. Next, the book deals with the preparation of salads (both cooked and raw); vegetables (braised in sauces thickened with bread crumbs); meat, game, and fowl; salted fish, fish from the sea, and freshwater fish (the three separate chapters on fish indicate the importance of this food); and cakes, tarts, and pastry. The traditional Dutch pottage of meat and vegetables is present in the cookbook as a "Spanish hodgepodge," and a few recipes are given for a festive mixed-meat dish, *olipodrigo,* that was widely known in Europe (Van't Veer: 1966: 69–93).

In the eighteenth century, there was a growing French cultural influence among the elite, and a modest refinement can be discerned in cookery, table manners, table coverings, and tableware. The fork increasingly became an obligatory instrument after the 1750s, and pewter and silver, as decorative materials, were now preferred over copper or iron. For the upper classes, ambivalence about luxury at the table now belonged to the past. But at the same time, the gulf between rich and poor increased considerably, and the potato would soon become crucial to the survival of the latter.

That gulf was also manifested in poems and plays that ridiculed bourgeois virtues, such as, for example, the preference of aristocrats and their bourgeois imitators for game and white bread (*Heerenbroot* or "lord's bread") instead of rye bread and cheese (Schama 1987: 172; Zahn 1989: 48–52, 272). Indeed, a widespread contempt for the upper classes and their ostentation helped bring about a society without a steep social hierarchy or an influential central court. This situation, however, as suggested by Jack Goody (1982: 97–134) and Stephen Mennell (1985: 103–34), may have discouraged the rise of a uniquely Dutch haute cuisine.

Modernization and Industrialization: The Modern World (1800 to 1960)

In 1795, the Low Countries became a part of Napoleonic France. The administration by regents and merchants came to an end, and Amsterdam's trade monopoly shifted to England. These developments increased the general impoverishment of many in the population that had already begun with economic deterioration during the late eighteenth century. Following the period of French control, the Low Countries became a kingdom ruled by the princes of Orange. William I (1813–40), the "king-merchant," tried to restore the old Dutch commercial position and to give the country new economic life by the founding of trading companies, the construction of roads and canals, the reclamation of land, and other modernizing measures. But his efforts were more or less unsuccessful. Moreover, during his reign, there was the 1830 separation of Flanders and the Walloon provinces in the south from the rest of the nation; these united to become the country of Belgium.

The 1840s are well known in western European history as a decade of turbulence and revolution, caused in part by recurring shortages of food. This was certainly the case in the Netherlands, where the decade represents a low point in Dutch history. A dearth of grain put even bread and porridge out of reach of both the masses in the cities and many in the countryside. Meat and lard virtually disappeared from the diet, and countless people ate potatoes, carrots, and turnips, or perhaps only potatoes, morning, noon, and evening.

Indeed, from the end of the eighteenth century onward, potatoes increasingly became a staple food for the nation and a substitute for unaffordable bread. In 1847 and 1848 this near-exclusive dependence on potatoes had disastrous consequences, as the potato blight during these years triggered crop failures and famine. Food shortages were joined by epidemics – as was often the case in the preindustrial period – to produce high death rates, primarily in the strongly urbanized province of North Holland. Fortunately, many of the urban poor were helped by local administrations or by charitable institutions. Soup kitchens and eatinghouses provided portions of cheap or free food, and the thin soup (invented by Count Benjamin Rumford and composed of bone-jelly, beans, potatoes, and sometimes turnips or carrots) that became famous all over Europe was also popular in the Netherlands.

Slight improvements in the food supply were made intermittently during the decades that followed, but in the 1880s, a deep agricultural crisis, caused by a sudden profusion of overseas grain, again brought widespread shortages and misery, this time mainly in the countryside, as local grain prices tumbled. After 1890, however, substantial economic growth took place in the Netherlands, and industrialization, improved transportation, and an ensuing rise in income brought an expansion of the distribution and affordability of foodstuffs.

In the twentieth century, two World Wars and the economic crisis of the 1930s again caused shortages, but after the 1950s, food scarcity and hunger became things of the past, and a new age of plenty was under way. Paralleling these developments was the modernization of Dutch foodways that took place between 1880 and 1960. This modernization involved the diffusion of food and drink innovations, new dishes, and new sequences of meals that passed, in general, from the upper to the lower classes, from town to country, and from the western market-oriented regions to the eastern and southern provinces, hitherto geared to subsistence agriculture. At the start of this period, contrasts were sharp, but by the end, similarities were the norm, brought about by increasing education, democratization, and uniformity (Van Otterloo 1990: 127–84; Jobse-van Putten 1995: 499–506).

These were long-term processes that involved, among other things, what might be called the replacement of foods of necessity with foods of luxury, as qualitatively better and more expensive foods gradually became more accessible to more people. In other words, potatoes, pulses, root vegetables, and grains such as buckwheat and rye were little by little replaced by wheat, meat, butter, cheese, other dairy produce, and sugar. The change began with the replacement of rye (cheaper but nutritious) with wheat, most preferred but more expensive. The next phase, after World War II, saw a decline in the consumption of wheat (bread) but steep increases in the per capita intake of meat, cheese, and sugar. The position of potatoes as a staple food, strong during the entire nineteenth century, began to deteriorate after 1900, and after 1920, potato consumption declined at an accelerated pace (Van Otterloo 1990: 45–8).

Industrialization also had revolutionizing effects on food and meals in the production of foodstuffs and in the organization of work and the family. The shifting of food production to the factory was made possible by rapidly increasing scientific knowledge in relation to the mechanization and "chemicalization" of food. Industrially processed ingredients, like corn flour, *fécule* (custard powder), "Oxo" (bouilion cubes), margarine, canned vegetables, meat, and fish, had become available at the end of the nineteenth century and were readily so during the interwar years. The food industry promoted its products through advertisements and educational campaigns, sometimes enlisting cookery teachers, even doctors, to inspire public trust in the new time- and energy-saving processed foods.

As elsewhere, the level of education in the Low Countries increased considerably after 1900. Women benefited from cooking classes and schools of home economics that taught the principles of hygiene and nutrition and, not incidentally, how to prepare tasty and healthy meals. (Although similar institutions were known elsewhere in western Europe, cookery books used in Dutch schools were distinguished by meticulous calculations of the prices of ingredients.) After 1930, radio and women's magazines helped to diffuse such knowledge, and in this way, the culinary cultures of Europe, especially that of France, trickled down to the middle and lower classes in the cities and, finally, to the country people in the eastern and southern provinces of the Netherlands. Also crucial to such a democratization of taste was the metamorphosis of the kitchen range, along with an increasing ease of securing water, gas, and electricity.

The modern industrial organization of work and the family also brought about several important changes in the dishes of Dutch people and in their meal system as a whole. The number, type, and composition of meals one consumed had for centuries reflected social, regional, and rural–urban differences. But now there was a movement toward uniformity (Jobse-van Putten 1995: 275–498). The number of meals in a day became three – generally a cold breakfast, a cold lunch, and a hot dinner at about 6:00 in the evening. Coffee and tea, popular among the urban middle classes since the end of the eighteenth century, now diffused (coffee in particular) to the whole Dutch populace and were drunk throughout the day, both with and between meals; these drinks replaced to a great extent other beverages like beer, milk, and buttermilk. Tea, at first a prestigious middle-class beverage drunk in the afternoon with a biscuit or a sweet, began somewhat later than coffee to accompany breakfast or lunch.

At breakfast, potatoes, porridge, and pancakes gave way to just bread and tea or coffee. A cold lunch around noon was an invention of the industrial age, suited to the new rhythm of work. Initially, hot potato meals were taken to the factory, but these were soon replaced with packets of bread brought from home. Much later, canteens supplied foods for employees, as they did elsewhere in Europe. Dinner in the Netherlands evolved into a three-course hot meal, ideally with a starter, preferably (vegetable) soup based on a meat stock, a French custom that between 1900 and 1940 was gradually adopted in the Low Countries (where pork or chicken was used as a stock instead of beef). The main course (again ideally) consisted of potatoes and gravy, cooked vegetables with a sauce, and a meat dish. Following this was a sweet dessert of (partly industrially processed) pudding, custard, or fresh or preserved fruits.

At first, this highly prestigious bourgeois meal was consumed exclusively on Sundays and festive occasions in the countryside, but it was later adopted in the cities as well. Thus, the centuries-old regional diversity of meals, comprising pancakes, porridges, stews, and thick soups based on pulses, grain, rice, and turnips, largely disappeared.

We might pause to ask and answer the question of whether any aspect of culinary culture in the Netherlands during this period was typically Dutch and thus unique in Europe. This was certainly not the case with breakfast, which seems to have followed the common Continental evolutionary path. At most, it was different only because of particular bread fillings, like chocolate sprinkles. The singular addiction of the Dutch to coffee and tea breaks at work is perhaps a national sin, not elsewhere indulged to the same extent.

Lunch took on a very simple form; it was mainly served cold and without frills. Except for an occasional salad, it continued the Dutch tradition of simplicity and frugality. This was also generally true of dinner, which had a simple and straightforward character, in which quantity (but also nutritiousness) continued to be preferred above quality and refinement. Another illustration of simplicity and frugality was the late development of habitually eating out in the Netherlands. In Belgium, restaurants had become popular as early as 1840, but restaurants in the Netherlands were only hesitantly visited beginning in about the 1890s, and eating out did not become a socially acceptable habit until the 1960s and later (Scholliers 1993: 71).

Globalization and Civilization: The Low Countries since the 1960s

World War II shook the Netherlands much more violently than World War I, and the populace experienced the distress of occupation and a scarcity of goods, even the pangs of hunger. Following the war, reconstruction of the economy and the country's infrastructure were priorities for the government and goals that required the utmost efforts of the entire population. Consumption was therefore postponed, and frugality continued.

The eating and drinking habits in the Netherlands were also patterned on the prewar model. No fundamental developments occurred except for a limited upsurge of interest in Indonesian food. This arose because of the tens of thousands of soldiers and people of mixed Dutch-Indonesian descent who flooded into the Netherlands during the years following the independence of this former Dutch colony.

Dutch postwar industriousness ultimately resulted in economic prosperity, and with it came a climate of widespread opposition to old ways and established authority. This was, of course, not unique to the Netherlands. In other Western countries, such as the United States, France, and Germany, similar developments took place, particularly at universities, where forces of change were aimed at questions of power and dependency in relationships between authorities and citizens, younger and older generations, and men and women. Institutional practices in the spheres of government, education, work, family life, and leisure were fundamentally altered by a cultural revolution in which the young formed the vanguard.

Frugality and hard work yielded to the drive for enjoyment, and pleasures such as popular music, sports, and travel became paramount. Consumption in the private sphere arose as a respected goal; certain brands of clothes became status symbols; homes were equipped with new furniture, televisions, washing machines, refrigerators, and other appliances. With Saturday as well as Sunday decreed days of leisure, weekends underwent a complete metamorphosis in family activities that encouraged the more convenient preparation of foods. As incomes rose and leisure hours increased, sociability became more important. Visits and parties were – as always – accompanied by food and drink, and traveling abroad led to exposure to the foodways of other cultures. Mediterranean countries such as France, Spain, Italy, and the former Yugoslavia became preferred holiday destinations for wide segments of the population.

At the same time, migrant workers came from areas of southern Europe to take jobs in the Netherlands. In the 1970s and 1980s, many foreigners, along with nonwhite citizens of the Caribbean, especially Suriname, were attracted by the high levels of welfare and social security, all of which transformed the Netherlands into a multicultural and, in some respects, a multiethnic society.

Other important transformations took place in the private sphere. These had to do with changing relationships among family members, now that people increasingly worked outside of the home. A growing divorce rate, an earlier independence of the young, and a rise in the number of old people combined to stimulate a substantial growth in the number of one- and two-person households. Such new and distinct conditions of life in the Netherlands led, among other things, to a fundamental alteration of the Dutch attitude toward food, which started among the middle classes but reached into innovative groups in the lower strata.

As elsewhere in the West, eating became less associated with a physical need to fill the stomach and more with a fashion of dining well, even elegantly, and the status that this conveyed. A flood of cookbooks, glossy cookery magazines, even serious treatises on culinary culture, swept into the bookshops and newsstands; cooking classes and culinary demonstrations on television became popular, and the media increasingly devoted columns and programs to the pleasures of the table.

Exotic herbs, spices, and other ingredients became available, and the figure of the gourmet was no longer one likely to be scorned or ridiculed. This does not mean that a genuine high culinary culture developed in the Netherlands, as it did in Belgium (Scholliers 1993), but it was the case that a "civilizing" of eating and taste spread throughout the various social strata. Eating out in restaurants and inviting nonfamilial guests for dinner at home – practices that formerly had never been common – gradually became the norm, and the per capita use of alcoholic beverages and soft drinks rose to heights never seen before. Between 1965 and 1990, the consumption of beer multiplied by two and a half times, wine by four, and soft drinks by slightly more than two and a half (CBS 1994).

The new and discriminating Dutch taste was not characterized by uniformity. Rather, there were various (and sometimes contradictory) trends, as international foodstuffs were increasingly distributed across the globe. A demand for exotic food was first apparent in the success of Chinese and Indonesian restaurants, which appealed to the Dutch because the food was cheap and large quantities were provided. Asian food was followed by Mediterranean cuisine from the various countries visited by vacationing Dutch, and from this point, culinary inquisitiveness spread to include foods from more distant parts of the world, like Mexico and Japan.

Indeed, the Dutch developed a world cuisine of their own, although the exotic dishes that comprised it were often not relished in their original forms and strong flavors but were shaped and moderated to meet the Dutch preference for bland tastes. Another international eating trend was adopted in the form of fast food from the United States, which had, in many respects, replaced France as a postwar cultural model for the Netherlands.

Like others in the West, the Dutch have embraced the tendency to make cooking in the home as easy as possible, which has meant a greater use of convenience food in preparing meals, and the use of snack foods has become marked. Many working housewives and mothers (whose numbers have increased substantially) now regularly escape their previously important duty of cooking for the family, and in fact, the rhythms of work and leisure of individual household members no longer coincide, which has changed the pattern of meals. Nowadays, the hot family meal in the evening might be the only one shared; yet even then, individual members of the household frequently have other commitments that oblige them to use the microwave to heat their share of the meal at a later time.

The consumption of snacks (described as grazing) in between, instead of, or in combination with regular meals has increased considerably. In addition, many restaurants, ranging from very exclusive to very simple, have come into existence to meet the new needs of the different strata of the population. Between 1965 and 1990, the number of restaurants multiplied five times (CBS 1994). Typically, these establishments borrow from cuisines the world over: snack bars and take-out restaurants feature American hamburgers, Indonesian *nasi,* Belgian *patates frites,* and Italian pizza.

As elsewhere, such changes in eating habits have brought anxiety about extremely processed food and concomitant concerns about obesity, food allergies, eating disorders, and food additives and contaminants. Vegetarianism and other movements supporting specific dietary principles have grown in popularity and in acceptance. In short, various trends and countertrends emphasizing the enjoyment, but also the dangers, inherent in food developed in contradiction with one another. This is, indeed, a remarkable change in a country that has never been characterized by a pronounced culinary culture! Both developments may be interpreted as aspects of the globalization of eating and drinking in the Netherlands (Elias 1994).

Summary

In this chapter, it has been suggested that the development of Dutch eating habits over the centuries has been influenced by a complex set of interrelated economic, political, and sociocultural forces. Processes of state formation and nation building, civilization, and democratization have marked the culinary culture of the Low Countries since the Middle Ages.

Until the last few decades, the Dutch maintained a preference for cheap, simple, and nourishing food, even though their cooks had obtained ideas and inspiration from foreigners, particularly the French, since the Middle Ages. That a high culinary culture was never created in the Netherlands differs greatly from the experience of Belgium, where, in the last 150 years, one has developed that is much appreciated abroad as well as at home.

The lack, however, of a haute cuisine in the Netherlands does not mean that the Dutch retained their seventeenth-century habits of binge eating and drinking at festivals. Rather, the French influence on daily life among the elite increased substantially in the eighteenth century, with Dutch patricians losing their bourgeois mentality and coming to resemble aristocrats in the usual sense. This change increasingly shaped their preferences and manners according to French (courtly) ways, particularly in dress and in the choice of dishes and recipes. The growing "civilizing of appetite" (Mennell 1985: 20–40) impeded immoderate "guzzling" among broader strata of the urban middle classes and encouraged them at the same time to permit themselves the luxury of refinement in eating, tableware, and table manners. Later rounds of democratization and civilization took place during the nineteenth and twentieth centuries and ultimately reached farmers and other country people and urban workers.

In the aftermath of World War II, new culinary models from America, the Mediterranean, and the (postcolonial) Far East became available. Subsequently, a decrease in the consumption of bread and potatoes, backbones of the earlier Dutch meal, bore witness to fundamental changes at the Dutch table. The movement from potatoes to pasta has meant a fading both of the traditional composition of meals and of national boundaries. To eat in a typically Dutch way seems to mean "going global" in the Netherlands at the turn of the twenty-first century.

Anneke H. van Otterloo

Many thanks to Dr. Jozien Jobse-van Putten and to Prof. Dr. Stephen Mennell for their fruitful comments on an earlier version of this chapter.

V.C.7 ◆ Russia

Dietary patterns in Russia display marked continuities over most of the past millennium or so. Staple foodstuffs have remained remarkably constant, and despite the introduction of new foods and beverages in later centuries and the gradual eclipse of a few items, the diets of the vast majority of the population underwent little qualitative change until well into the nineteenth century. Russia, relatively isolated from the West until the reigns of Peter I and Catherine in the eighteenth century, was as conservative in its cuisine as it was in politics and society, and the sharp gap between rich and poor was reflected in what they ate and drank.

Russia is defined for the purposes of this study as the lands inhabited by the modern eastern Slavic peoples, the Belorussians in the west, the Ukrainians in the south, and the Russians in the north and center of "European Russia." Brief mention is made of the Baltic, Transcaucasian, Siberian, and central Asian peoples, primarily as their foods influenced the diets of their Slavic rulers in the Russian Empire and the Soviet Union. Imperial Russia also controlled Finland and much of Poland during the nineteenth century, but these areas are not considered here.

Peoples ancestral to the modern eastern Slavs apparently began spreading out from their homeland in the territory near the modern borders of Poland, Belarus, and Ukraine around the seventh century. They moved into the forests of central and northern Russia at the expense of scattered Finnic peoples, most of whom were eventually absorbed or displaced. Expansion into the grasslands of the Ukraine and beyond was much slower because the steppes were dominated by pastoral peoples of Turkic and Mongol stock. The medieval Kievan state was able to hold the horsemen at bay for a while, but by the twelfth century the Slavs began to retreat northward under nomad pressure. Not until the sixteenth century was the new Muscovite state strong enough to begin the reconquest of the Ukraine and extend Russian power down the Volga. Traditional Russian cuisine developed in the forest zone but was profoundly influenced by expansion into the grasslands and along trade routes.

Early Russian Diets

Archaeological evidence indicates that the early Slavic inhabitants of the forest, like their Finnic neighbors, were farmers who used slash-and-burn techniques to make clearings for their villages and farms. Their primary grain was rye; oats, buckwheat, and barley played secondary roles, and wheat was always uncommon in the north. Grain was consumed primarily as bread, including the famous Russian black rye bread, but gruels (kasha) and porridges were common as well. Noodles were borrowed from the Tatars in the thirteenth or fourteenth century. Grain was also converted into beverages ranging from the virtually nonalcoholic *kvas* to light beer *(braga)* and beer.

A variety of fruits and vegetables were also grown. Turnips, hardy enough to thrive in the harsh northern climate, were an important root crop; carrots, beets, and radishes were also significant. Garlic and onions were common seasonings. Cabbages and cucumbers were important in diets, both fresh or preserved by pickling or in salt. Such preparations provided the main supply of vegetables during the long winter and were essential as antiscorbutics. Cabbage soup *(shchi)* was and remains a dietary staple. There was at least limited cultivation of apple and cherry orchards from very early times.

The long winters created severe forage problems that precluded large-scale stock raising, but limited numbers of cows, horses, pigs, chickens, and ducks were kept. Possession of livestock was a measure of family wealth. Slaughtering was usually done in the fall. Milk, meat, and eggs were scarce and expensive and generally appeared in meals on feast days and festivals. Hard cheeses were not important, but cottage cheese was fairly common.

The forests also supplied many foods. Game animals provided welcome meat, especially in areas with sparse populations. Ducks, geese, and other birds were widely hunted and traded. Fish, fresh from local streams and ponds, or traded in salted or dried form, were the major source of animal protein. Wild nuts and berries provided seasonal variety, and mushroom gathering was and remains a popular activity. The forest was also a habitat for bees, whose hives were raided for wax and honey. The latter was a prized sweetener and was often fermented into mead. Beekeeping eventually became a lucrative sideline for some farmers.

Salt, crucial for preserving fish, meat, and vegetables, was mined in rock form in a few places and was later obtained from the sea in the Crimea and salt lakes near Astrakhan at the mouth of the Volga. The major sources of salt, however, were well north of Moscow. Boiling seawater to crystalline salt was being done on the White Sea by the twelfth century, and salt production developed into an important industry in this remote region. By the fourteenth century wells were being drilled to tap underground brine pools at many sites between Moscow and the White Sea. Salt was an essential commodity and its production and trade were lucrative and heavily taxed enterprises.

In the tundra zone of the far north, from the Lapps (Saami) of the Kola Peninsula to the Chuckchi in extreme northeastern Siberia, Russian fur traders and pioneers encountered peoples who survived by hunting land and sea mammals, fishing, and herding reindeer. Further south, in the Siberian taiga forest, aboriginal peoples like the Yakuts supplemented hunting and fishing with stock raising. Russians venturing into such environments had, of course, to adapt to local conditions, but they traded with their countrymen for grain and introduced bread and other grain products, including fermented and distilled beverages, to their northern neighbors.

Daily diets were strongly influenced by religious requirements and the seasons. Conversion to Christianity, traditionally dated to 988, had a profound impact on food consumption patterns. The Orthodox calendar included a large number of feast and fast days which, to the amazement of some foreign observers, were widely observed. Church fasts included Lent, the 40 days before Christmas, and the Saints Peter and Paul fast. This fast, which ended on June 28 and could last from one to six weeks, depending on when Easter fell, came at a time when stored food was running low and caloric demands for agricultural work were very high.

Meat was forbidden during all fasts; fish and all foods of animal origin were forbidden during Lent. Wealthy Russians, however, frequently enjoyed elaborate fish dishes and fine wines during fast periods. Feast days, including Christmas, Easter, weddings, harvest celebrations, and, sometimes, funerals, were the major occasions for eating meat, pastries, and other rarities and for hearty drinking bouts. Binge drinking, and to some extent, binge eating, were regular features of Russian life, reflecting both the agricultural cycle and religious observances.

Peasants ate best in the fall, when the new harvest was gathered and animals were slaughtered. Mushrooms were hunted all over Russia and the Ukraine. They were both a prized food and an excuse for convivial excursions. The autumn was a common time for weddings and associated feasts. Fresh fruits and vegetables were available during the warmer months, but stored grain, pickled cabbage, and salted cucumbers were the winter staples. Food supplies often ran low in the spring; diminished stores and religious fasts meant lean meals during plowing and planting time in the late spring.

The conquest of the entire Volga River to its mouth on the Caspian Sea, completed by 1569, placed Russia in an advantageous position to trade for spices, notably pepper, saffron, and cinnamon. Melons and fruits from central Asia became more accessible, and the empire gained new sources of salt. The Volga and its tributaries provided a rich variety of fish, including sturgeon and its caviar and the sterlets, a variety of small sturgeon that delighted both Russian and visiting foreign gourmands. Fish were sold dried or salted and even transported live in special boats for the tables of the Tsar and other notables. Frozen fish were widely distributed during the winter. *Pirogi* (sing. *pirog*), pastries filled with meat, fish, or other delicacies, and *pel'meni,* small Siberian dumplings, probably entered the Russian diet during the sixteenth century. They may have been borrowed from Finnic or Tatar peoples of the Volga valley.

Russia slowly and erratically expanded into the Ukraine and southern Russia during the sixteenth, seventeenth, and eighteenth centuries. The conquest of these rich black-earth grasslands provided the basis for extensive wheat cultivation and a growing export of grain. Ukrainians and Russian colonists were able to raise more fruit and vegetables in these milder climes and to keep more livestock. Meat, though not milk, played a larger role in diets. Beets were a popular crop, and beet soup *(borshch)* held the place of cabbage soup *(shchi)* in the Ukrainian cuisine. Beets were also made into *kvas,* which was not only a beverage but a common stock for Ukrainian soups and stews. Large quantities of watermelons and eggplants were grown in some districts for local consumption and for trade.

The Eighteenth Century

The eighteenth century was a period of change in Russian diets, particularly among the elite, as many new foodstuffs were introduced. Peter the Great's opening to the West, symbolized by his construction of a new capital on the recently conquered shores of the Baltic, and complemented by the modernizing policies of Catherine at the end of the century, exposed the growing Russian Empire to an array of new foods and drinks from Europe, Asia, and the Americas. European, especially French, chefs appeared in many noble homes, and gourmet cooking spread among courtiers and other members of the elite. The first Russian cookbook appeared in 1779; it was followed by many translations of German and French cookbooks, sometimes adapted to local ingredients and tastes.

A few Russians learned to eat salads, an innovation dismissed by others as the equivalent of eating grass. The Dutch had introduced asparagus in the 1600s; at the end of the century a French visitor was treated to "dates from Egypt" by a clergyman in the far north. Tea, coffee, sugar, and the tomato were introduced among the upper classes. Elegant finger foods for hors d'oeuvres *(zakuski)* provided refreshment at receptions.

Wine had always been imported in small quantities by the church for communion and had occasionally graced the tables of the elite, but in the eighteenth century wines from Europe, and later from Armenia, Georgia, and parts of the southern Ukraine, gained popularity in gentry homes. Distilled spirits, first introduced from the Baltic and Poland in the 1500s, began to displace mead and beer, even in some poor households. Tea, known as a curiosity from the seventeenth century, was brewed in ornate samovars in the homes of the rich and in new urban cafés during the 1700s, and tea drinking began to percolate down the social scale. Tea was often served with cane sugar from the West Indies. Sugar, a major import by the late 1700s, gradually replaced honey as a sweetener, first in the homes of the wealthy, and then, like tea and vodka, it spread to more humble abodes.

Two other New World cultigens reached Russia during the eighteenth century. The potato, as in Ireland and Hungary (and like cassava in western Africa), was introduced to prevent famines. Catherine issued an edict recommending its cultivation after a dearth in food production in 1765, but this directive garnered little response except in the Baltic provinces dominated by German nobles, who took more interest in the tuber and made sure that their Baltic peasants did, too. For decades, however, the potato was scorned by the Slavic peasantry, remaining only a curiosity on the tables of sophisticates. Maize, introduced into eastern Europe in the eighteenth century and a staple crop in Hungary, Serbia, and Romania by the nineteenth century, remained insignificant in Russia, except in Bessarabia (Moldova) in the far southwest.

The tradition of keeping foreign dignitaries busy with lengthy banquets, featuring numerous rich dishes served in a seemingly endless sequence and even more numerous alcoholic toasts, reached a high stage of development during this period. Such ostentatious hospitality, already given mixed notice by sixteenth-century English and Dutch visitors, has continued until the present. The foreigners were well treated, kept in a haze during their visit, and distracted from seeing or hearing things that their hosts preferred they not know about.

The Nineteenth Century

Dietary innovations began to reach the peasantry, the vast majority of the population, only in the nineteenth century. The gradual spread of sugar beets and tomatoes in the Ukraine and southern Russia, and potatoes, especially in northern and central regions, did make something of a difference in the nutritional regimen. Still, dietary surveys and travelers' reports indicate strong continuity in the consumption patterns of most Russians. Tastes in beverages underwent more significant change as tea and vodka became widely used at all levels of society.

Bread, generally the familiar dark rye loaf, remained the staff of life. Wheat bread became a little more common, especially in the Black Earth areas of the Ukraine and in the Volga provinces, but most wheat was produced for export. A working man commonly ate 3 to 5 pounds of bread daily. Kasha was also a frequent dish. On feast days, and sometimes more often in prosperous households, dough was used to make *pirogi* filled with meat, cottage cheese, cabbage, or berries; or *blini,* thin yeast-leavened pancakes rolled up and filled with sweets or smothered in butter and sour cream; or *knyshi,* pastry puffs filled with cream.

Cabbage and cucumbers were the most important vegetables, but serf and free-peasant gardens generated a variety of produce. Onions and garlic continued to be popular seasonings, and peas, melons, berries, turnips, and other garden produce were appreciated during the summer. Oils from hemp, flax, and sunflower seeds (another American introduction) were used in cooking. Mushrooms, nuts, and berries were collected in the forest and could be salted or dried for the winter. Apiaries, providing honey, were common, and many peasants kept pigs, sheep, and/or poultry. The diet was monotonous and often lacked protein, especially for the poor. A rural doctor in the 1860s blamed the bad health of peasants in Pskov Province largely on their diet, which was mostly rye bread and cabbage. However, a study of villages in Tambov Province suggested that serfs in the early nineteenth century had better diets than contemporary French or Belgian peasants. In particular, these rural Russians enjoyed more meat.

The most important addition to the diets of most nineteenth-century Russians was the potato. Except in the Baltic and Polish provinces, potato cultivation was negligible until the 1830s. The peasants saw no need for them, especially since land and labor would have to be diverted from rye, and some even opposed potatoes on religious grounds. But government interest in and encouragement of potato cultivation grew after famines in the 1830s to the extent that heavy-handed official pressure produced several potato riots. By 1843, however, a German traveler, Baron von Haxthausen, noted that potatoes were being introduced into parts of Yaroslavl Province. Some peasants were interested in the tubers, others were coerced into planting them, and potato cultivation spread slowly. Nobles sometimes used them to feed livestock. In general, the potato spread into Belorussia and the northwestern provinces during the 1840s and 1850s, and thence into most of northern and central Russia and the Ukraine. By 1900 it had become a staple in most areas, often eaten in soup.

Meat and dairy products remained too expensive for most peasants, but the growing towns provided a market for cattle and milk. Milk and butter were most extensively consumed in the Baltics and in the north; peasants in the south and in the Ukraine generally had more meat. Even in areas of the south and southeast with large cattle herds, few peasants ate beef. Cattle were destined for urban markets. Peasants were more likely to eat pork, mutton, or poultry, the frequency of such meals being directly correlated with household wealth. Fish remained an important food during the numerous fasts, especially for those living near rivers and lakes or wealthy enough to purchase dried or salted fish.

Diets of the gentry were obviously richer and more diversified than those of the peasantry, but they varied greatly according to wealth and individual preference. City dwellers, including the merchant and artisan groups, had access to more imported foods and items from distant parts of the empire than all but the most opulent country residents. Many nobles spent the summers on their estates, where fresh foods were readily available, and wintered in the city. Even the petty rural landowner tended to take afternoon tea with pastries, biscuits, cheeses, caviar, jellies, jams, and other snacks, and have a heavy evening meal.

Hospitality was generous on country estates, and guests could expect to be well fed. Picnics were popular on pleasant days. In the evening, diners enjoyed *zakuski,* followed by a soup course with *pirogi,* a fish or poultry course often served cold, and a meat course with potatoes and vegetables. Salads remained unusual. Beef was especially popular with those who could afford it. Appropriate wines and champagnes might be served with each course. A meal would be capped by sweets and cognac or a dessert wine. Wealthy nobles sometimes maintained fishponds and built hothouses to provide fruits and vegetables off-season and icehouses to preserve them. Rich and even middle-class Russians employed skilled cooks, sometimes specially trained serfs, in their kitchens. A French- or Paris-trained chef was a mark of distinction. Conspicuous food consumption, the use of luxury foods and beverages from abroad, and elaborate meals for guests were marks of high status and gentility.

Servants in great houses ate less grandly, though they did have access to leftovers and could sometimes appropriate items meant for the master's table. Still, if the recommendations of the leading nineteenth-century cookbook are any indication, household servants ate better than the peasants. For breakfast they might have had potatoes with fried eggs or porridge; dinner menus included *shchi* with buckwheat kasha, or *borshch* with dumplings, or barley soup and roast beef with mashed potatoes, or vegetable soup with a meat and barley kasha. On feast days servants were to have meat or poultry and assorted *pirogi.*

Alcoholic Beverages

Patterns of beverage consumption showed some dramatic changes in the nineteenth century. *Kvas,* a barely alcoholic product of bread or grain fermentation over a few days, was the basic daily drink and an important part of the diet. It was widely made and consumed in the home and dispensed by peddlers in towns and markets. *Kvas* could be produced from barley, oats, rye, and wheat, or, in the Ukraine, from beets, and was sometimes flavored with berries or fruit. It was most popular in central Russia and Siberia. There were numerous regional varieties.

Light beer *(braga)* and beer were popular, especially in the Baltics, Belorussia, and the Ukraine, but were less widely consumed in Russia and Siberia. Much was home-brewed, but taverns selling commercial beers appeared in the villages and towns. The state levied heavy taxes on commercial beer. Mead continued to decline and became a rarity by midcentury. Tea drinking, accompanied by sugar, spread slowly but became widespread in the villages by the 1880s.

The drink that became most popular, most destructive, most controversial, and most profitable for the government was vodka. According to legend, Vladimir of Kiev, the ruler who chose Orthodox Christianity as the new religion in 988, rejected Islam because strong drink was "the joy of the Rus." Small-scale distilleries began operating in the late sixteenth century in the Baltic region and along the trade routes between Moscow and the White Sea port of Archangelsk, but vodka, "little water," did not begin to make inroads in the general population until the second half of the eighteenth century.

Distillation of grain was a monopoly of the state and privileged nobles and was heavily taxed. As early as the 1720s, liquor taxes made up 11 percent of government revenues; the percentage had almost doubled by midcentury. In 1767 liquor monopolies in central Russia were sold to contractors and, except for a brief period of state monopoly in the 1820s, liquor farmers controlled the trade in central Russia until 1863. The farmers operated small drinking places scattered in the villages and towns. Their profits, although extensive, were reduced by the sums they paid the government for their local monopolies and by bribes paid to officials of all ranks.

From 1863 until the 1890s the state again assumed a monopoly to raise additional revenues, after which free trade and an excise tax system were introduced. During the period from 1805 to 1913, receipts from alcohol sales, primarily vodka, averaged 31.4 percent of all state revenues. Free trade prevailed in the western provinces, keeping prices lower and, thus, consumption higher. In the early twentieth century, state production of a uniform product at relatively low cost also encouraged greater consumption.

Social commentators, doctors, church leaders, and sometimes even government officials displayed growing concern over alcoholism during the nineteenth and early twentieth centuries. Vodka was the problem, not *kvas* or beer. Russians consumed 40 times more alcohol in the form of spirits than as beer or ale. Indeed, per capita beer consumption in the 1850s was less than 2 liters a year, far below the roughly 20 liters in the Polish provinces or 50 liters in Britain. Yet per capita vodka consumption was no higher than the use of distilled spirits in other European countries. As in early-nineteenth-century America, the problem was binge drinking; drinking simply to get drunk.

Drinking remained, as in previous centuries, partially linked to social and religious rituals and to mutual-aid activities like barn raisings or group harvest efforts. Cultural restraints on alcohol consumption, however, tended to weaken in the countryside and were especially weak in the cities. Contemporary observers decried the impact of the taverns on family and economic life and on the health of heavy drinkers. Reform efforts were hampered by the crucial role that vodka played in state finance. But concern was clearly rising, and in 1914 Russia embarked on a widely ignored experiment in prohibition.

The Soviet Period

The revolutions of 1917 inaugurated several years of severe food shortages. The new Bolshevik regime inherited food production and distribution difficulties as well as the alcohol problem from its Tsarist predecessor. These were compounded by World War I, the bloody Civil War, and the flounderings of the new regime. Despite many drastic policy changes, Russian patterns of eating and drinking showed substantial continuity with the past.

The industrial north continued to be a grain-deficit region with cities and rural dwellers that had to be supplied from the south and, increasingly, from Kazakhstan and Siberia. Improvements in internal transportation facilitated grain flows and allowed fruits and vegetables to reach European Russia from the Transcaucasian and central Asian republics. Much of central Asia, especially Uzbekistan, became a food deficit area with an economy based on cotton monoculture. Collectivization of agriculture, conducted during the 1930s at great human cost, did not solve the grain production problem, nor did the plowing of "virgin lands" or massive attempts to grow maize during the post-Stalin period.

Grain imports from the West have been necessary almost annually since the 1960s. Livestock production and meat consumption increased but continued to lag far behind Western norms, although in the years after World War II, efficient Russian fishing fleets roamed distant seas, providing more fish for Soviet consumption. Government policies kept food prices artificially low, with rationing and inflation masked by periodic shortages and long lines in shops.

Collective farmers were allowed to work small plots for their own profit. These intensively worked gardens produced a large proportion of the meat, eggs, milk, and fresh fruits and vegetables that appeared in urban markets. Armenian, Georgian, and central Asian entrepreneurs even found it profitable to bring melons and other produce from their sunny climes to the cold cities of northern Russia.

Rural diets did not begin to show major changes until after 1953, and even by 1960 there was remarkable continuity with prerevolutionary times. Table V.C.7.1, calculated from data presented by Basile Kerblay, demonstrates that (except for legumes, which are not shown), rural consumption levels in 1940 were still a little below averages prevailing at the end of the Tzarist rule. Cereals, potatoes, vegetable oils, sugar, meat, and fish were consumed in lower quantities in 1940 than before the revolution; people ate only marginally more vegetables, dairy products, and eggs.

In 1913, vegetable foods provided 84.2 percent of calories consumed by peasants, and 62.8 percent of the total came from cereals (Table V.C.7.2). In 1960 the comparable figures were 80 percent from plant sources, with 56 percent from grains. The most important change from 1940 to 1960 was the greater share of calories provided by vegetable oils and sugar. Consumption of foods of animal origin, especially fish and eggs, had increased significantly in the postwar years.

Official consumption data averaged for the entire population of the Soviet Union are shown for 1913, 1965, 1970, and 1976 in Table V.C.7.2. Quantities of meat, eggs, fish, dairy products, vegetables, fruits and berries, and sugar rose dramatically, with major gains in eggs and dairy products in the decade after 1965. Grains contributed less, with most of the decline coming before 1965. Government data paint a picture very much like those of Kerblay.

Table V.C.7.1. *Indexes of food consumption by collective farmworkers (1896–1915 = 100)*

	1940	1960
Cereals	63–71	58–66
Potatoes	85–91	104–12
Vegetables and fruit	96–114	132–58
Vegetable oils	76	214
Sugar	69	510
Meat, fat, and poultry	75–84	139–56
Fish	47–57	148–82
Milk and dairy products	110	149
Eggs	108	310

Source: Data from Kerblay (1962), p. 894.

Table V.C.7.2. *Consumption of major foods, 1913–1976 (kg/person/yr; except eggs)*

	1913	1965	1970	1976
Meat and meat products	29	41	48	55
Milk and dairy products	154	251	307	315
Eggs (units)	48	124	159	206
Fish and fish products	6.7	12.6	15.4	18.5
Sugar	8.1	34.2	38.8	40.4
Vegetable oils	–	7.1	6.8	7.7
Potatoes	114	142	130	119
Vegetables and melons	40	72	82	85
Fruits and berries	11	28	35	37
Bread and pasta	200	156	149	142

As in Tsarist Russia, members of the elite in the Soviet Union enjoyed a far greater variety and higher quality of foods and beverages than the bulk of the population. Ranking party officials and favored athletes, dancers, scientists, musicians, and other prominent persons had access to the finest domestic and foreign goods in special stores that were off-limits to workers and peasants. Such privileges marked a new elite and gave them excellent reasons to conform to the system.

Although food prices were heavily subsidized for most of the Soviet period, Russians continued to devote a substantial, though declining percentage of their incomes to food. Data for urban workers and employees of collective farms, presented for the period from 1940 to 1990 in Table V.C.7.3, show steady declines for both groups. It is interesting to note that the poorly paid farmers had to spend a higher proportion of their incomes for food than did urban contemporaries. Many toiled on farms that specialized in grain or cotton production, but even those who raised crops for themselves on private plots still had to buy much of their food.

Urbanization has been a major theme in the twentieth-century history of Russia, and urban diets have undergone somewhat more change than those of rural areas. Most of the improvements have come since the late 1940s, following the horrors of collectivization, forced industrialization, and World War II. City dwellers do consume a wider variety of foodstuffs than in the past, and the amount of foods of animal origin has increased significantly. Indeed, greater livestock production became a major goal with Stalin's successors. Still, travelers and medical observers continue to describe a diet heavy in starches and low in fresh vegetables and fruits. Throughout the post-1945 period, production problems and a primitive distribution system have meant periodic shortages and long lines in shops. Meat and poultry remain expensive and of low quality. Sausage is a major component of meat consumption. Fat intake has risen and is, along with alcohol, implicated in rising rates of cardiovascular morbidity and mortality.

The Soviet regime never solved the alcohol problem it inherited from Tsarist times. Prohibition collapsed during the war, and with the establishment of stability in the early 1920s, old drinking habits reappeared. During the 1920s and 1930s there were intensive efforts to reduce drinking both in cities and in the countryside, but these had little impact. Officials decried the adverse effects of excess drinking on production and health, but the state continued to reap huge revenues from liquor sales. For example, during the 1960s and 1970s, taxes on alcohol produced about 10 percent of the state's income. Home distillation began in earnest during the Soviet period, as people coped with high prices and poor-quality state production and evaded periodic temperance campaigns by making *samogon.* Normal vodka had an average alcohol content of 40 percent; the alcohol content in *samogon* ranged from 25 to 75 percent. In the late 1950s and early 1960s, however, ethanol shortages led many to consume stolen wood alcohol, with sometimes fatal results. Cheap sugar, available from Cuba from the early 1960s, was a boon to *samogon* producers.

Table V.C.7.3. *Food as a percentage of family expenditure, 1940–90*

	1940	1965	1970	1975	1980	1985	1990
Industrial workers and employees	53.8	37.9	35.7	32.9	35.9	33.7	29.9
Collective farmworkers	67.3	45.2	40.4	37.1	39.6	36.3	32.4

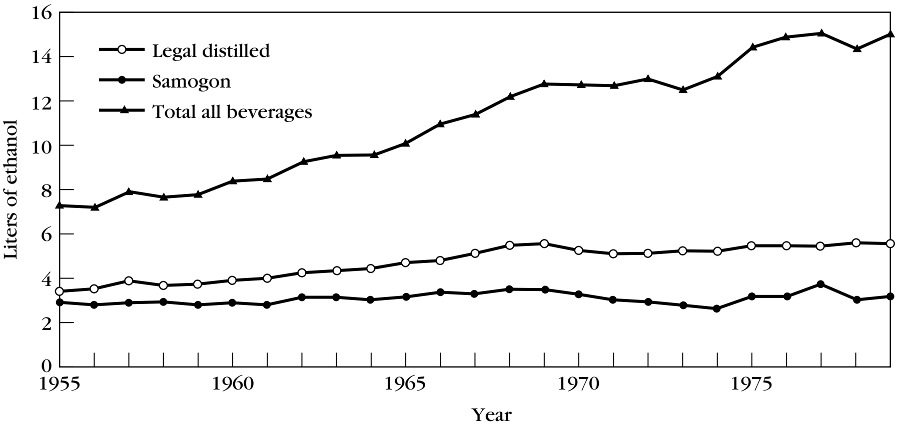

Figure V.C.7.1.1. Pure alcohol consumption per person over 15 years old, 1955–79. Total includes *samogon*, state-produced "strong" drinks, and state-produced wines and beers. Totals do not include home-brewed beer, *braga*, or wine, estimated by Treml as the equivalent of at least one additional liter of pure alcohol per person over 15 per year. Also excluded is consumption of stolen industrial alcohol. (Data from Treml, 1982, p. 68.)

Fig V : C : 7 : 1

Officials continued to decry the costs of alcohol abuse, and in the 1980s both Yuri Andropov and Mikhail Gorbachev attempted to control sales and enforce moderation in drinking habits, but their campaigns had little success. Indeed, as Figure V.C.7.1 shows, per capita alcohol consumption rose steadily and alarmingly in the years from 1955 to 1979, and it has remained high since then. Beer, *braga,* and wine consumption were clearly eclipsed by "strong" distilled beverages, although use of the former also rose. The heaviest drinkers were males in the Baltic and Slavic republics, especially Russia, Estonia, and Latvia. Per capita consumption was less in the traditional Islamic regions and in the wine-producing republics of Armenia and Georgia.

In 1970 it was estimated that Soviet citizens over the age of 15 spent an average of 13 percent of their incomes on state-produced alcoholic beverages. For Russia, the figure was 15.8 percent. These estimates do not include *samogon* or home-produced beer or wine. It is not surprising that health officials have placed much of the blame for high death rates among middle-aged and elderly Slavic males on alcohol abuse. Acute alcohol poisoning killed almost 40,000 people in 1976, a rate almost 90 times that of the United States. The impact of alcoholism on diseases of the liver and the cardiovascular system was also much greater than in the United States.

Famines

A final aspect of food history in Russia must be mentioned: famine. In Russia, as in most other preindustrial societies, bad weather and war often resulted in serious food shortages, sometimes over large regions. In contrast to the Western experience, however, famines continued to ravage Russia until the mid-twentieth century. Major famines have been recorded from the tenth century until 1946–7; even in the nineteenth century there were famines or serious, widespread food shortages in roughly one year out of five. Bad weather, primarily cold in the north and drought in the south and in the Volga provinces, triggered many famines, but war and government policies frequently compounded or, sometimes, even created them.

Other factors made Russia particularly vulnerable to dearths. The deep poverty of most Russians meant that personal food reserves were usually inadequate to carry families over bad years. Many of the central provinces suffered serious rural overpopulation by the nineteenth century; seasonal labor migration to cities or richer agricultural areas and permanent migration to the Volga region and Siberia were inadequate safety valves. The Tsarist government made some efforts to monitor agricultural conditions and store grain for emergencies, yet lack of revenue and bureaucratic ineptitude hampered relief efforts. The government was usually too weak to control hoarding and speculation, even when it tried. But fortunately Russia was so large that the whole country could not be affected by the same adverse weather conditions or, usually, the same war or disorders, so there were always food surplus regions that could supply suffering provinces.

Large-scale movement of foodstuffs was, however, hindered by huge distances and a backward transportation system. Even the development of a national rail network in the late nineteenth century, although certainly helpful, was inadequate to meet needs. When frosts came too early or too late, or when the rains failed, peasants tightened their belts. They adulterated bread with a variety of wild plants and weeds, collected what they could from woods and fields as famine foods, and slaughtered their animals. Frequent dearths and the vagaries of the annual dietary cycle gave the peasants ample opportunity to learn to cope with food shortages.

Despite folk wisdom, peasant toughness, and relief efforts, the death tolls from famine were sometimes enormous. The 1891–2 famine killed roughly 400,000 people, despite government relief measures that were far more successful than critics of the regime would admit. Millions perished in 1921–2 when famine, caused by drought, the devastation of the Civil War, and ideologically driven state policies, swept the Volga provinces and part of the Ukraine. Only massive aid from the United States and Europe prevented a much greater catastrophe. The horrible famine of 1933–4, which ravaged most of the Ukraine and parts of the Volga basin and the northern Caucasus, was the direct result of Joseph Stalin's drive to collectivize agriculture and destroy the more prosperous stratum of the peasantry. Death tolls are currently being debated, but it is clear that several million perished. Similarly, the postwar famine of 1946–7, which killed at least several hundred thousand people, owed more to recollectivization of zones liberated from the Germans and government reconstruction priorities than to dry weather.

Conclusion

It would be wrong to conclude this survey on such a bleak note, especially as the Russian, Belarussian, and Ukrainian peoples are attempting to create new economic and political orders. Privatization of agriculture and free retail trade should bring better quality and more variety to grocery shelves. Russia is once again open to new dietary influences, ranging from McDonald's, Pepsi, and pizza to haute cuisine from France. By the same token, Russian foods, from caviar and beef Stroganoff to pirogi and borshch, have enriched the cuisines of many countries as Russian, Ukrainian, and Jewish migrants have brought them to Europe and North America.

The History and Culture of Food and Drink in the Americas

V.D.1 ⁂ Mexico and Highland Central America

The diversity of the natural environment in Mexico and highland Central America has influenced the development of food and dietary patterns. From the aridity of the great Sonoran Desert in the north, through the temperate basins of the Valley of Anahuac, to the tropical forests of the south, different climates and soils have conditioned what and how people ate. Within the larger regions, hundreds of microregions have had their own environmental and dietary characteristics, and for millennia cultures have modified these environments to suit their food needs. Three especially profound events that have influenced environment and diet are the emergence of agriculture, the arrival of Europeans (1519), and the technological and organizational changes of the twentieth century.

Early Diet

Before the advent of agriculture, hunting, fishing, and gathering provided the nutrients for Mexican diets. Most large mammals had become extinct by about 7200 B.C., and four plants in particular – mesquite, nopal, maguey, and wild maize (teozinte) – increasingly complemented a diminishing amount of animal protein provided by fishing and hunting. Even after the rise of sedentary societies dependent on agriculture, food gathering continued to provide essential nutrients for most indigenous groups. Densely populated communities in the central highland valleys and seminomadic peoples in the arid north enriched their food supply by collecting larvae, insects, and grubs, in addition to small mammals and reptiles.

As food production became more abundant, the quantity of collected foods declined, and it was on the base of domesticated crops that Mexican civilization rested. Maize, squash, beans, tomatoes, chillies, amaranth, several cactus varieties, and many fruits (among them avocado and guava) constituted the diet of the vast majority of Mexicans.

Maize was the main food of the sedentary peoples of all of highland Middle America. In the highlands of Guatemala one Quiché Maya word for maize is *kana,* which means "our mother." Maize was so important to some cultures that without it there was a cultural sense of hunger, even if other foods were available (Herrera Tejada 1987: 230–3). Maize is a particularly fertile and nutritious plant, capable of providing abundant calories and nutrients. When it is eaten with beans, another staple of the highland diet, the lysine, isoleucine, and tryptophan deficiencies in maize are overcome, and provides a pattern of amino acids similar to that of animal protein. Moreover, the traditional preparation of maize, which involves soaking the kernels in a lime (CaO) solution, releases niacin for the consumer and provides significant amounts of calcium.

Maize's centrality to the diet can be seen in the diverse ways that it was prepared. First eaten raw for its juices or toasted over a fire, its preparation as a food gradually took many shapes and forms. When ground finely and added to liquid, it formed the gruel known variously as *atole, pozole,* or *pinole.* As a *masa,* or dough, it was a food for the most versatile of cooks. In addition to diverse tortillas (thin griddle cakes) and tamales (dumplings steamed in corn husks), maize was cooked in myriad other shapes with such names as *peneques, pellizcadas, sopes,* and tostadas. In addition, it could be popcorn, a preparation now well known the world over. Maize has served as a plate to support other foods (as in a taco), as the base for complicated dishes (for example, an enchilada), and as a napkin.

Another important food for the sedentary people of Mexico was squash, by which we mean a number of plants belonging to the genus *Cucurbita,* which includes pumpkins, squash, and zucchini, among others. All were fully employed as food sources. Their stems constituted an ingredient of a soup now called *sopa de guias;* the tasty yellow flowers have also long been a part of soups, stews, and quesadillas, and the fruit itself can be boiled. In recent times, brown sugar and cinnamon have been added to form a thick syrup that transforms the boiled fruit into *calabaza en tacha,* the classical dessert for the *Día de los Muertos.* Pumpkin seeds are usually left to dry in the sun and then are toasted and eaten with a dash of salt. By weight, they have a higher content of isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine than maize, beans, amaranth, and even egg whites. These seeds are also known as a medicine to get rid of tapeworms.

As already mentioned, many wild foods, some of them peculiar to Mexico's Central Valley region, were essential to the diet. *Tecuitlatl (Spirulina geitleri),* an algae collected from the surface of lakes in the valley, was particularly important as a source of protein, vitamins, and minerals. According to sixteenth-century reports, sufficient amounts of the algae were available to make it nutritionally significant.

Animal foods complemented the many plants that were the basis of the highland diet. Along with domesticated rabbits, dogs, and turkeys, the Aztecs enjoyed a variety of wild animals, birds, fish, reptiles, amphibians, and insects. Many of these food sources have remained parts of nutritional regimes into the twentieth century. Indeed, the turkey has subsequently gained greater importance in the cuisine. Despite the availability of wild fowl and then of domesticated ducks and chickens introduced by the Spaniards, the turkey survived as a culturally important food in Mexico. In contrast, Mexican hairless dogs *(xoloitzcuintli)* are no longer eaten.

The pre-Columbian diet of Middle America was also complex. The region dominated by the Maya had as much diversity as the central highlands. Along the coast and river estuaries, fish and shellfish provided essential nutrients. Cultivated maize was supplemented by plants such as *chaya (Cnidoscolus chayamansa)* and *ramón (Brosimum alicastrum). Ramón* may have been an especially significant foodstuff. Under cultivation, this tree produced large quantities of edible seeds that had a protein content between 11.4 and 13.4 percent, substantially higher than local grains (Puleston and Puleston 1979). Several root crops provided carbohydrates for the diet: *jícamas (Pachyrhizus erosus), camotes (Ipomoea batatas), yuca (Manihot esculenta),* and *malanga* (*Xanthosoma sp.*) (Vargas 1984: 278).

The quantity and quality of food in early diets remain open to interpretation. Anthropological evidence provides insights into specific sites during narrow time periods, but it does not help in the problem of generalizing for the region. One approach to the question of diet has been to analyze the carrying capacity of the land (population density versus potential food resources) on the eve of the arrival of Europeans. But even if it were possible to determine the precise carrying capacity of any region, it would not necessarily reveal how much people ate. Based on carrying capacity, estimates for the central region of Mexico range from 1,400 to 2,629 calories per person per day (Ortiz de Montellano 1990: 80).

One line of investigation that has revealed new insights into the quality of the diet has focused on Aztec cannibalism. The investigation took its modern form when Michael Harner published a widely cited article that emphasized protein deficiency as a reason for Aztec cannibalism (Harner 1977). According to his reasoning, the dense population of central Mexico, so dependent on a maize diet, lacked adequate numbers of domesticated animals, and hunting and gathering could not have supplied sufficient whole protein to compensate for its lack in the diet. Climatic uncertainties and recurring droughts in the late fifteenth century further contributed to deficiencies in the Aztec food supply.

Debate over such issues has led to different conclusions. One, which counters the protein-deficiency argument, stresses that the Aztec diet delivered plenty of good-quality protein. In addition, there is evidence showing that Aztecs suffered from gout, a condition associated with too much protein (Ortiz de Montellano 1990: 86, 121). Also useful in the debate is recognition of the success of Mesoamerican agricultural practices. Systems of terracing, irrigating, fertilizing, and the justly famous *chinampas* (artificial islands that could yield as many as four harvests a year), all combined to produce abundant quantities of food. Intercropping, or the growing of several crops together, was also beneficial. Intercropping was particularly useful when beans were planted with maize because the nitrogen-fixing beans helped increase maize yields (Ortiz de Montellano 1990: 94–7). In addition, the traditional *milpa* practice of planting squash and maize and letting edible wild herbs grow next to the latter served both to deter pests and to provide additional foods before the corn harvest, a time when there could have been scarcity.

Food preparation and consumption practices also contributed to good nutrition. As mentioned, maize, when prepared as a *masa* and eaten with beans and amaranth, delivers proteins comparable to those from animal sources. Other culinary staples added to the nutritional well-being of indigenous peoples as well. Chillies, full of vitamin C, were commonplace in the Aztec diet. So were tomatoes, as significant sources of minerals and vitamin C, and *quelites* (wild edible herbs), rich in vitamin A.

Far from being a monotonous and boring series of dishes, Mexican cuisine had great culinary variety, the result of an imaginative mixture of ingredients and methods of preparing them. Sauces or moles were common, and different combinations of chillies gave them different flavors. One such sauce is *pipián,* a thick mixture with a special texture made from ground squash seeds. A well-chosen combination of sauces could add different flavors to vegetables and meats while also providing more protein.

Mesoamericans also knew how to ferment several vegetable products, the best known of which is the sap of maguey *(agave),* used to produce the mildly alcoholic beverage *pulque.* They also fermented several maize products. *Pozol* was and is a popular preparation made with a combination of several varieties of corn, whereby the *masa* is made into small balls, which are covered with leaves and left to ferment. The balls are then dissolved in water to make the *pozol.* Mexican biologists and chemists (Cañas et al. 1993) have found that this kind of fermentation enhances the amount of protein the drink contains because of the growth of microorganisms.

Contact and Dietary Change

The arrival of the Spaniards in Middle America initiated dietary and cultural changes that have continued until today. The precise extent and pace of such changes remain subjects for research and interpretation, but the broad outlines of the process can be addressed.

Although the Spaniards expected to replicate their traditional food patterns in the New World, the extent to which they fulfilled this expectation depended on local geographic and cultural forces and on policies of trade and commerce. In the Caribbean, climate and culture hindered the establishment of Spanish alimentary regimes. There, Spanish culture survived through adaptation to local conditions and through an elaborate system of trade that supplied the islands. Wheat, the staple of the Spanish diet, was central to the trade.

In Mexico and the highlands of Central America, soil and climatic conditions encouraged the establishment of wheat production. The quantity and flavor of wheat grown in the valleys of the central highlands and in the broad plain of the *Bajío* became renowned throughout Middle America. Production of wheat often exceeded demand, and in the eighteenth century wheat exports fed soldiers and sailors garrisoned in Havana. As wars increased in frequency, the demand for wheat grew, and Mexico lost the Caribbean market to the United States, not because of insufficient grain for export but because of the higher cost of transporting Mexican grain.

Wheat was always a political issue in Mexico following the Conquest. In the late 1520s in Mexico City, legislation mentioned the importance of a supply of "white, clean, well-cooked and seasoned bread, free of barley and sand" (*Actas del Cabildo* 1889–1916, 1: 146–7). By the eighteenth century, when the capital city may have been consuming over 40 million pounds of bread a year, the problem of sufficient wheat bread had become considerably more complex. The quantity and quality of bread available was the result of the interaction among *hacendados* (wheat farmers), *molineros* (millers), *panaderos* (bakers), *pulperos* (small shopkeepers), and harried public officials who tried to regulate prices and quality (Super 1982; García Acosta 1989).

Other grains, barley and rye in particular, were introduced to Mexico but assumed only regional importance. After wheat, rice probably had the most success of any of the imported grains among all ethnic and social groups in Middle America. By the middle of the seventeenth century, Panama was already producing enough of a surplus to support a small export trade to Peru (Castillero-Calvo 1987: 428). In Mexico, Indians came to depend on rice as a complement to or substitute for maize. External influences on the preparation of rice continued into the twentieth century. *Morisqueta,* rice prepared by a technique supposedly introduced by the Japanese, became common in the rural Mexican diet in the 1940s, and rice achieved even more fame as the basis for a drink known as *horchata,* prepared with rice flour, sugar, cinnamon, and ice (Horcasitas 1951: 162–3).

Even before they planted these grains, Spaniards introduced new sources of animal protein to Middle America. Pigs in particular were the animals of conquest – they were mobile, adaptable, and efficient producers of fat and protein. Their rapid proliferation presaged a century in which animal foods were more abundant than ever before or since. Sheep multiplied almost as rapidly. By the end of the sixteenth century, the Tlaxcala-Puebla region counted 418,000 head of sheep; Zimatlán-Jilotepec 360,000; and the Mixteca Alta 238,000 (Dusenberry 1948; Miranda 1958; Matesanz 1965).

Cattle followed pigs and sheep, transforming dietary patterns wherever they went. Enormous herds dominated the central and north-central regions of Mexico, where the landed estate system began to take shape in the late sixteenth century. Cattle were valuable for their hides; meat was of secondary importance, as reflected by the very low price of beef.

Meat-based diets were widespread throughout Mexico and Middle America, extending south to Panama. Indeed, meat may have been more abundant in the Panamanian diet than in that of the Mexican (Castillero-Calvo 1987: 432–4; Super 1988: 28–32). The period of abundant meat in the central areas, however, came to an end as the great herds exhausted the grasslands. But the period itself left a dietary legacy that continued through succeeding centuries. Fat from cattle had become the substitute for the European's olive oil and butter. Ignaz Pfefferkorn, a Jesuit very concerned with his stomach, summarized the situation in the eighteenth century: "The art of buttermaking is as unfamiliar in Sonora as it is in all of America" (Pfefferkorn 1949).

Wheat and meat were the staples of the diet, providing the energy necessary for the establishment of Spanish society in Mexico. Along with the staples came scores of other foods, most of them basic to the Spanish diet at home. Among the vegetables common in the sixteenth century were onions, garlic, carrots, turnips, eggplants, and lentils; common fruits included peaches, melons, figs, cherries, oranges, lemons, limes, and grapefruit. Most of these foods had become regular items in the diet by the end of the sixteenth century and remain so today.

Olives and grapes did not follow this pattern. Both were essential to the Spanish diet, but neither had lasting success in Mexico. After an auspicious start, the cultivation of both was deliberately limited to ensure that southern Spain had a captive export market. Much olive oil and wine was still being imported at the end of the eighteenth century, but their dietary importance had declined because of Spanish mercantilist regulation and changing food preferences.

Sugar has a special place among the foods that came to the New World. In Mexico, Hernando Cortés was the first landholder to devote large areas to the cultivation of sugarcane. Production soon increased and sugar was exported; at the same time it became widely appreciated by the Mexican people. Its availability and price made it a good substitute for the relatively more expensive honey and the syrup fabricated by boiling the sap of the maguey plant. With a cheap and readily available sweetener, Mexicans were soon experts in preparing a wide variety of desserts and sweets that became characteristics of the cuisine (Zolla 1988).

Formation of the Creole Diet

The blending of indigenous and European foods and food techniques began immediately after the Conquest. The result was the emergence of a *comida novohispana,* which in turn became the basis of Mexican regional cuisines. Some elaborate dishes are elegant testimony to the fusion of the two food traditions. *Mole poblano* is one of the most highly regarded, with its chocolate base seasoned with different types of chillies and nuts. To this dish Europeans contributed foods and spices that they brought with them from the Old World: onions, garlic, cloves, cinnamon, and nutmeg. The fowl in the dish, almost secondary to its flavor, was either turkey (native to Mexico) or chicken (introduced into Mexico after the Conquest). Although dishes such as mole and *chiles en nogada* (chillies stuffed with minced meat and fruits, covered with a thick nut sauce) rightly deserve notice, an even more basic fusion was taking place. As mentioned, European livestock began providing the fat that native cuisine lacked, and fat from pigs, and then from cattle, was quickly absorbed into the Indian diet. Even dishes that might have seemed to be pure reflections of pre-Hispanic dietary regimes came quickly to depend for flavor on fat from Old World animals. *Frijoles refritos, gorditas,* quesadillas, and other traditional Mexican dishes were not prepared before the Conquest. The technique of frying itself was introduced only in the sixteenth century. Indeed, most of the dishes so closely associated with Mexican cuisine – *carnitas, tortas,* tacos, and *tamales* – are prepared with animal fats, cheeses, onions, garlic, and bread, all of which were introduced by Europeans.

The diffusion of these foods among different indigenous groups has been a matter of some discussion. Chickens, pigs, and goats quickly became familiar parts of Indian economic activity and regular items in the diet. When prices were low enough, meat from cattle and bread from wheat were also eaten. But there are questions of how rapidly and to what extent beef and wheat were integrated into the diet of indigenous groups. A traditional interpretation is that there was little fusion of the different food traditions and that the "Indians continued their almost exclusively vegetarian diet: corn in liquid and solid form, beans, vegetables and chile; for bread, meat, and other foods were far too expensive for them" (Gamio 1926: 116). Recent research on the colonial period, however, suggests that fusion was much more extensive and that Native American diets did include wheat and meat, foods traditionally associated with a European diet (Castillero-Calvo 1987; Super 1988).

The development of a new diet did not necessarily require the addition of new foods. For example, *pulque,* already mentioned as the fermented juice of the maguey plant, emerged as the most widely consumed beverage of the central highlands because traditions that had limited its intake before the Conquest weakened in the sixteenth century. The resulting widespread consumption continued into the twentieth century. Although *pulque* provided needed carbohydrates, minerals, and vitamins to the diet, it also contributed to the image of widespread alcohol abuse among Indians and mestizos in Mexico.

Commercial production of this beverage spread with Spanish society and the emergence of the hacienda. The technology of *pulque* production remained essentially the same as before the Conquest, but new storage vessels of leather and wood made it possible to produce larger amounts of *pulque* more easily. Drinks from sugarcane (many different types of *aguardiente* were popular by the eighteenth century) were also accepted by indigenous cultures but did not replace *pulque* as a daily beverage. Of all the foods and beverages of indigenous cultures in Mexico, *pulque* remained the most politicized, sparking medical, moral, and economic controversy into the twentieth century (Calderón Narváez 1968; Leal, Rountee, and Martini 1978; Corcuera de Mancera 1990).

It is impossible to reduce the complex changes that took place in the diet during the colonial period to a series of statistics measuring calories and other nutrients. Nevertheless, the weight of the evidence suggests that the collision of cultures in the sixteenth century resulted in an initial improvement in nutrition among the poorer classes. The gains made were difficult to sustain as the colonial period drew to a close, and by the end of the eighteenth century the nutritional status of the individual was probably lower than it had been two centuries earlier (Borah 1979–89; Castillero-Calvo 1987; Super 1988). It is also important to note that until the late nineteenth century, Mexican regionalism was very pronounced, which encouraged the continued independent evolution of local cuisines.

The Nineteenth Century

Patterns of food production and distribution were disrupted by the struggle for independence and subsequent economic dislocations. But independence did not lead to the development of new alimentary regimes. Despite new influences affecting food preparation techniques for the wealthy (French food fashions, for example), most Mexicans continued to rely on diets that had changed very little from the colonial period.

The emergence of new agricultural and land-tenure patterns in the second half of the century may have reduced dietary quantity, but it is difficult to generalize for the entire region. Some of the prices for basic foods – maize, beans, rice, and chillies – did increase sharply, especially during the final years of the nineteenth century and the first few years of the twentieth. But such prices usually reflected trends in central Mexico that were not representative of the country as a whole. During the nineteenth century, regional variation continued to characterize food availability, prices, and consumption in rural Mexico.

As during earlier periods, the complex labor relationships of the haciendas influenced the availability of food. These in turn had regional variations. For example, in the Puebla-Tlaxcala region of central Mexico, although the *peones alquilados* (daily, weekly, or seasonal laborers) might have had high wages, they seldom received food rations. In contrast, the *peones acasillados* who lived on the haciendas often received fixed amounts of food and had the right to work a small amount of land, called a *pegujal,* for their own benefit. An interesting dimension of rural labor arrangements was the obligation of the *servicio de tezquiz,* whereby daughters and wives of rural workers prepared *atole* and tortillas for hacienda personnel. This, as with fieldwork, was paid for both in specie and in kind. In the latter case, the women received up to one *almud* (4.625 liters) of maize for performing this service (Coatsworth 1976; Cross 1978; Borah 1979–89; Nickel 1982: 125–48).

The traditional view is that a marked decline in nutrition occurred in the late nineteenth century. There is, however, some evidence to counter this view, which is based on wage and price data that can be misleading when local labor relationships are not understood. In many areas of rural Mexico, peasants continued to hold on to their land, producing for subsistence and then for the market. Workers who were entirely dependent on their employers often had access to rations that provided for their own – and their families' – basic caloric needs. Salaries, although low, were sufficient to buy some meat and nonessential foods. This is not to suggest that diets were good, or perhaps even adequate. But they were, it seems, not as bad as traditionally described.

The Twentieth Century

Like the struggle for independence that began the nineteenth century, the Mexican Revolution (1910–17) created disruptions in the production and distribution of food. As severe as these were in some areas, they were essentially transitory and had little lasting impact on food and diet.

More important were two gradual processes that would shape the history of food in the twentieth century. First was the continuing commercialization of food production, a process with origins in the advent of sixteenth-century European agricultural practices. It gained momentum during the colonial period and then surged under the rule of Porfirio Díaz (1876–1911) in the late nineteenth century as more and more land was devoted to agricultural products for an export market, particularly cattle, sugar, coffee, and two nonfood crops – cotton and henequen.

The latest step in this process has been the increase in the production of fruits, vegetables, and meats for the U.S. market, beginning in the 1960s. Related to this was the leap in the production of sorghum (used for cattle feed), which has become a leading crop in Mexico (Barkin 1987: 281). Similar to soya in Brazil, sorghum emerged to satisfy the demands of the export market rather than internal needs. One consequence has been increasing pressure on resources traditionally used to produce foods for local consumption.

The second process has been the industrialization of food production and distribution. The *molino de nixtamal,* a mill for maize flour, has had particularly far-reaching impact. Making tortillas by hand is a time-consuming process, once performed daily by homemakers, but with the introduction of the *molinos* in the early years of the twentieth century, and then of new methods of packaging and distributing tortillas, the traditional social roles of women changed. Freed from a daily four to six hours of labor with tortillas, women have had to adjust to new social and economic relationships. Cultural attitudes toward maize, still a sacred food among some highland Guatemala peoples, also changed as maize production was subjected to mechanization (Keremitis 1983; Herrera Tejada 1987; Vargas 1987).

The establishment of the *molino de nixtamal* is only one example of the growing consolidation of the processing and distribution of food. As in other societies experiencing rapid urbanization and industrialization, Mexico has seen its food systems undergo a profound alteration. National and transnational corporations influence everything about food from price to fashion, with the result that traditional foods and methods of preparation are giving way to national and global food processing and distribution systems. Such changes have also accentuated the loss of Mexican self-sufficiency in food production (Barkin 1987; Vargas 1987).

All of these changes have meant a new era in the history of Middle American food habits. Unfortunately, the new era has not yet shown the capacity to eliminate the nutritional problems that still plague many people, especially the poor in rural areas. Although malnutrition seldom reaches the level of starvation, high rates of infant mortality, low birth weights, and chronic illness and development problems afflict the poor. Average caloric intakes, some 2,600 per person per day in Mexico in the 1970s, obscure the regional inequalities in diet. People in rural zones of the south might consume less than 2,000 calories – an intake comparable to the poor of India, Kenya, or Vietnam (Pineda Gómez 1982: 104–7).

The Mexican government has created several programs to counter problems of malnutrition and the negative effects of the globalization of food production and distribution. It first directed its efforts toward the creation of a national marketing system, the *Compañía de Subsistencias Populares* (CONASUPO), whose mission has been to regulate the price and availability of food by intervening in national and international markets. A much heralded governmental effort was the *Sistema Alimentario Mexicano* (SAM), a program launched in 1980. SAM aimed to improve national nutritional well-being by focusing resources on the increased production and distribution of domestic foods. This was accomplished by providing technology, credit, and price supports to small producers, thereby encouraging them to contribute more effectively to satisfying national nutritional needs. On the heels of SAM came the *Programa Nacional de Alimentación* (PRONAL), an even more comprehensive effort that focused on creating an integrated national food system. New governmental policies that have favored free enterprise and international commerce have hindered public programs intended to increase food availability to the poor.

One solution to the problem of malnutrition is a reliance on the natural diversity and traditional foods of a region. The significance of traditional foods, such as *quelites* (cultivated and wild herbs), for example, has been increasingly recognized as a result of a classic 1946 study of the very poor Otomi Indians of the Mezquital valley. Despite the almost total absence of foods common to middle-class urban diets, especially meat, wheat bread, dairy products, and processed foods, the Otomi, who consumed *quelites,* showed few signs of malnutrition (Anderson et al. 1946).

Conclusion

Mexico's food system has suffered a long and complicated evolution. Elements of the past combine every day with those of the present on Mexican tables. Old Mesoamerican foods such as chillies, squash, beans, avocados, and all kinds of maize derivatives are considered necessary in a meal. These are enriched with foods from the Old World such as pork, beef, lettuce, rice, oranges, and coffee. Some of the old foods still have a special place in social gatherings. For instance, a traditional wedding deserves a *mole de guajolote* just as the typical breakfast on the day of a child's first communion is unthinkable without hot chocolate and *tamales.* Families going out at night patronize restaurants specializing in *pozole,* a stew with grains of corn, meat, and old and new spices. New foods appear continually: Coca-Cola is already a staple; hamburgers and hot dogs are everywhere; new Chinese restaurants and pizza parlors open every day. It is interesting to note that many of these foods become "Mexicanized." For example, the large hamburger restaurants offer chillies and Mexican sauces, and one can order a *pizza poblana* with long strands of green chilli and mole on it.

The increased modernization and internationalization of Mexican food and cuisine is clearly not without negative consequences. The variety of foods that characterized nutritional regimes in the past is declining; vast areas of land that once carried edible wild plants and animals have been cleared for agriculture, cattle raising, and expanding towns and cities. Packaged and processed foods, often less nutritious than their natural counterparts, are becoming more widespread, and there is still acute and chronic malnutrition in several parts of Mexico, even as obesity is a growing problem in affluent sectors of cities. Despite these problems, Mexico has a wide range of natural and cultural resources that may be called upon to help ensure a future where good diets are available to all.

V.D.2 ~ South America

The continent of South America has been a place of origin of many important food plants. Moreover, plant and animal introductions to the Americas made both before and after Columbus have provided an extraordinary diversity of food sources. Culinary traditions based on diverse foodstuffs show the imprint of indigenous, European, and African cultures. This is because food production and consumption in these lands stem from an environmental duality of both temperate and tropical possibilities. Moreover, throughout the twentieth century in South America, the binary distinction between food produced for commercial purposes and for subsistence needs has continued in a way that is unknown in North America. Contrasting nutritional standards and perturbations in supply add to the complexity of the total food situation in South America.

Domesticated Food Sources

The pre-Columbian peoples of South America domesticated more than 50 edible plants, several of which were such efficient sources of food that they subsequently have served as nutritional anchors for much of the rest of the world. The potato, manioc, and sweet potato, each belonging to different plant families, are among the top 10 food sources in the world today. The potato (*Solanum tuberosum* and related species) clearly originated in South America, where prior to European contact it was cultivated in the Andes through a range of 50 degrees of latitude. Archaeological remains of these tubers are scanty, but there is little doubt that Andean peoples have been eating potatoes for at least 5,000 years. The center of greatest morphological and genetic variability of potatoes is in southern Peru and northern Bolivia where they fall into five chromosome (ploidy) levels. That the potato is an efficient source of carbohydrates is well known, but it also provides not insignificant amounts of protein (in some varieties more than 5 percent), vitamins, and minerals. In the Andes, the tuber is traditionally boiled, but now it is also fried. *Chuño,* a dehydrated form of the fresh tuber, may have been the world's first freeze-dried food. Working at high elevation, Indians still go through the laborious process of exposing fresh potatoes to both above- and below-freezing temperatures before stepping on them with bare feet in order to make this easily stored form of food.

Manioc *(Manihot esculenta)* is another root crop from South America; it is grown and eaten in one form or another as far south as Corrientes Province, Argentina, and in the Andean valleys as high as about 2,000 meters above sea level. It is the top-ranking staple in the Amazon Basin where more uses and forms of processing are known than elsewhere. Its ability to grow in infertile soils, resistance to insect pests, and high caloric yield make it an attractive crop. The low protein (average of 2.5 percent) and the high levels of toxicity in certain varieties that force elaborate processing are its major disadvantages as human food.

The sweet potato *(Ipomoea batatas)* was known among early farming people of South America as far back as 4,000 years ago, but its origin is less understood than that of the potato because of the lack of plausible wild ancestors. The enlarged roots contain 25 to 28 percent carbohydrates, as well as about 5 percent sugar. In South America it is normally less of a staple than one might expect. Eaten usually in boiled form, it is also baked.

The rich array of South American root crops includes many scarcely known outside the continent. Probably domesticated before the potato in the Andes were *ullucu (Ullucus tuberosus), oca (Oxalis tuberosa),* and *añu (Tropaeolum tuberosum),* all three starchy additions to the stew pot. *Arracacha (Arracacia esculenta)* grows at lower elevations, primarily in Andean valleys from Venezuela to Bolivia. Its taste is reminiscent of parsnips. The tubers of jícama *(Pachyrhizus tuberosus)* and *ajipa (Pachyrhizus ahipa)* are typically eaten raw for their sweet flesh with a crunchy texture. *Achira (Canna edulis)* is a very starchy addition to the diet of some people in the Andean valleys. There are also several other tubers with very local distributions that are relics of a prior time and can be expected to become extinct.

Several "pseudo-cereals" survive as crops in the Andes, the most important being quinoa *(Chenopodium quinoa),* which is planted from Colombia to Chile and Argentina. Its average protein content of 13 percent is higher than that of wheat, and its high concentration of essential amino acids, especially lysine, has helped make it a staple for Andean people for at least two millennia.

The hardiest chenopod crop is *cañihua (Chenopodium pallidicaule),* now localized on the Altiplano of southern Peru and Bolivia. The tiny seeds are toasted or cooked in porridge, and the protein content is at least as high as that of quinoa. Growing in warm and dry valleys of the Andes as a relict crop is *kiwicha (Amaranthus caudatus).* Its nutritious seeds, sometimes popped, are usually eaten as a gruel.

Two leguminous seed plants are also among South America's contributions to the world's food inventory. The peanut *(Arachis hypogaea),* a major crop in Asia and Africa today, was probably domesticated in the zone circumscribed by Paraguay and southern Brazil. At least this is the region where the world's center of peanut diversity is found. This crop has both large amounts (25 to 35 percent) of protein and a high fat content (43 to 54 percent). The seeds have been eaten raw, boiled, and toasted, but the major use of the peanut today is for its oil. The other leguminous seed plant is the kidney bean *(Phaseolus vulgaris),* which may be of South American origin, although a wild relative is found as far north as Mexico. There is considerable diversity in the size, shape, and color of the kidney beans in South America, which are basic sources of vegetable protein for millions of people in South America and elsewhere in the world.

Several kinds of domesticated cucurbits are South American in origin. Crookneck squash *(Cucurbita moschata),* winter squash or *zapallo (Cucurbita maxima),* and *achokcha (Cyclanthera pedata)* are used in soups and stews.

Valuable fruit-bearing plants were domesticated in South America and in some cases have spread elsewhere in the tropics. The pineapple *(Ananas comosus)* had spread throughout the New World tropics by the time Columbus arrived, but it is certainly of South American origin. However, which one of the numerous wild-growing species of *Ananas* is the direct ancestor of this noble fruit has not yet been resolved. The fruit of this perennial, herbaceous plant is highly regarded around the world for the distinctive flavor of its sweet flesh and juice.

Papaya *(Carica papaya)* yields a more fragile fruit with a soft, sweet pulp around an inner mass of small round seeds. Its place of origin appears to be in warm eastern Andean valleys, but its earliest recorded use was in Central America.

Three South American members of the Solanaceae yield an edible fruit. One of these is the *pepino dulce* or melon pear *(Solanum muricatum),* with a sweet and juicy yellowish flesh reminiscent of cantaloupe. A second fruit in this family is the tree tomato *(Cyphomandra betacea),* yielding a red fruit the size and shape of an egg that tastes like an acid tomato. The third member is *naranjilla* or *lulo (Solanum quitoensis);* it comes from a bushy herb with seedy fruits that are the size of a small orange. Its vitamin-rich juice is greatly appreciated in Ecuador. Although no mention of this fruit appears in the historical record before the seventeenth century, much about it suggests that it was domesticated earlier.

Passiflora is a genus of edible fruits that grows on climbing herbaceous vines. The two major species, *Passiflora edulis (granadilla)* and *Passiflora quadrangularis (maracuja),* are grown for their sweet-tart juice containing 8 to 10 percent sugar. Cold fruit drinks and an ice cream flavor are made with the juice.

Colonial Transfer: Wheat and Olive Oil

The pre-Columbian inventory of crops and animals sustained the people who consumed it just as well as the late medieval food sources provided for Europeans. Nevertheless, when the potential of Spanish agriculture was added to the indigenous inventory, the nutritional possibilities were enhanced. Some of the European plants and animals fit into one or another ecological niche better than the native domesticates and gradually became indispensable.

Among Europeans in South America, the most desired of Old World foods was wheat. In addition to its flavor and texture, wheat bread had a strong symbolic identification with Spanish culture, whereas maize, after reaching Iberia, had a much lower standing as a food suitable to and for the Spanish palate. But within South America, wheat could not be successfully grown in warm, wet zones, thus eliminating the Amazon Basin, the Llanos, most of the Brazilian Planalto, the Guianas coast, and most other coastal plains in the tropical parts of the continent.

Hardtack *(bizcocho),* the earliest wheat food in South America, was imported from Spain. Wheat production was important in the Andes from Venezuela to Bolivia, and by the 1550s and 1560s, fresh bread was widely available. The grain was ground on gristmills turned by a horizontal waterwheel. In fact, wheat production, once important in the region, could become important again if imports were cut off. In the early 1980s, for example, Brazil imported almost as much wheat as it produced. But in 1988, this country achieved self-sufficiency in wheat, the result of paying Brazilian farmers three times the world price.

Another basic staple among the Iberians was olive oil, which was shipped to South America for more than a century in the early colonial period. Although other vegetable oils could readily substitute for olive oil, the latter had a particular flavor that Spaniards much appreciated. Starting an olive grove in the New World required patience; the trees did not begin to bear fruit profitably for 30 years, and they could only be grown in certain places. Olive trees require a climatic regime of winter rains and summer drought, and they tolerate no (or only very light) frost. These conditions could be found only in central Chile, although on the desert coast of Peru and in rain-shy western Argentina, olive trees would grow and yield fruit under irrigation. Elsewhere, olive growing was out of the question.

Common Prepared Foods

All of South America except Patagonia has granted to maize a place in the diet. In Colombia and Venezuela, corn is commonly ground into meal or flour to make an *arepa,* a bland undercooked ball of grilled corn dough. Wrapped in banana leaves and steamed, maize dough is made into tamales called *hallacas* in Colombia and Venezuela, and *humintas* in Ecuador, Peru, Bolivia, and Argentina. As in North America, boiled green corn on the cob is also eaten, especially in the Andean countries.

Wheat in the form of bread has continued to be much favored throughout South America, even in places where the grain cannot be successfully grown and supplies must be imported. Other ways of using it are in turnovers; filled with meat or cheese, they are much loved especially in Chile, Argentina, Bolivia, and Uruguay. Another wheat product, pasta, is now an important food in South America, and every country has semolina factories set up by Italian immigrants.

Unlike in Africa or Asia, no cultural barriers in South America have inhibited the consumption of meat, except that of the horse and the donkey. Beef, pork, and chicken are most widely consumed, though production of the latter has been industrialized only in this century. As in North America, the flesh of cattle is the preferred meat, with the difference being that South Americans willingly consume a wider range of the edible parts of the animal. The kidney, brain, and tripe that are processed into pet food in the United States are considered delicacies by many South Americans. Peruvians have such a special affinity for cubed, marinated, and skewered beef hearts *(anticuchos)* that they import substantial quantities of this organ from Argentina. Meat in South American butcher shops is sold mostly in slabs or chunks, not the particular cuts familiar to North American or European cooks. The four native domesticates – llama, alpaca, guinea pig, and Muscovy duck – are not major food sources. Wild game and land turtles, sold in markets, are still a source of meat in the Amazon Basin, although river fish supply most of the animal protein in this region. Saltwater fish form a basic element of diet in coastal towns and cities around the continent, somewhat more so on the Pacific side than on the Atlantic. Unlike in Europe, inland locales depend little on fish in the diet, a legacy in part of the poor transportation that has hindered its shipment.

Introduced fruit-bearing plants add to the wide range of produce that overflows markets from Bucaramanga to Brasília. But they have not necessarily turned adults into high per capita fruit eaters. Not infrequently, fruit production exceeds consumption, and much is left to rot. Bananas, including plantains, are nutritionally the most important fruit, and especially in tropical lowland locales, various kinds of bananas and plantains are a staple carbohydrate. Citrus is abundant in all countries, primarily as fresh fruit; a daily dose of orange juice is not yet part of Latin American custom. Mangoes are especially plentiful in hot, tropical areas with a pronounced wet and dry season. Avocados, native to Central America, are not as popular as one might expect, given a fat content (up to 30 percent) that is quite extraordinary for a fruit. The southern cone countries grow high-quality pome fruits; apples and pears from the Argentine valley of Rio Negro have long been exported to the tropical countries to the north.

Condiment use cannot be easily generalized. Most South Americans do not follow the Mexican pattern of the lavish use of chilli peppers. Yet, some local cuisines in western South America, for example those of Arequipa, Peru, make abundant use of capsicum, and are quite different from, say, the bland food that characterizes Florianopólis, Brazil, or Mendoza, Argentina. Generally, the more one goes into a diet focused on meat, the lower the seasoning profile. Heavy doses of onions and garlic often flavor food, and a good squirt from a lemon or lime cuts the grease in fried meats. Fresh coriander is a favorite cooking herb used in the Andean countries.

After the sixteenth-century introduction of sugarcane, honey was pushed into the background as a sweetener. Sweet desserts and liquids were one of the dietary outcomes of expansive sugar production and consumption. Brazilians prefer a sugary paste of guava or quince or a coconut-based sweet. In Hispanic countries, caramelized milk custard (flan) is the customary way to end a meal, clearly a transfer from Spain. Most people eat no cakes or pastries. As in Iberia, confections made with eggs, nuts, and sugar have been a specialty of convents. The nuns sell them to the public at designated times of the year. Beginning in this century, commercially manufactured candies featuring chocolate have satisfied the urban craving for sweets.

Forms of Preparation

Except for fruit, little food is eaten raw in South America. Salads of uncooked greens were rarely eaten before the twentieth century and still are not common in most diets. In Brazil, Japanese immigrants were the first people to commercialize salad vegetables seriously. Especially in São Paulo, Japanese-Brazilians grow and market fresh produce, an outgrowth of what was initially a desire to satisfy their own ethnic preferences.

Cooking methods vary regionally to some extent. Boiling is the traditional method of preparing many foods, and pre-Columbian peoples used ceramic pots for cooking. The Spaniards and Portuguese also had this tradition. Hearty soups and stews that combine meat, fat, and vegetables are found in different countries under local names – *puchero* in Argentina, *cazuela* in Chile, *chupe* in Peru, and *ajiaco* in Colombia. Their warmth is especially welcome in the high-altitude chill or during the winter months in the south. Stew was first on the list of dishes in nineteenth-century Lima, Peru. Common ingredients marked a European tradition: beef, mutton, salt pork, sausage, pig's feet, cabbage, banana, rice, and peas; the native contribution was sweet potato, manioc, annatto and chilli pepper (Squier 1877). Because no major source of cooking oil existed in the pre-Columbian period, frying was introduced to South America by Europeans. Both frying and boiling are fuel-efficient ways to cook in fuel-deficient areas. Zones of high meat consumption feature roasting and barbecue.

Regional Dietary Traditions

Each national society and some areas within countries have their own dietary peculiarities. Brazil is especially characterized by the widespread acceptance of manioc, even among people of European origin. Wheat flour was often not available, and this alternative carbohydrate was close at hand and cheap. Brazilians consume much manioc in the form of a toasted flour *(farinha).* Rice is another basic carbohydrate in Brazil because it grows well in tropical environments; when it is combined with black beans, whole protein is added to the diet. Thin slabs of meat, typically barbecued, form an element of the Brazilian diet, except among the very poor. *Feijoada,* a grand totemic dish of peasant origin, cuts across socioeconomic and ethnic boundaries. Although not recorded before the nineteenth century, *feijoada* has now come to symbolize Brazilian identity. This hearty concoction consists of rice, black beans, dried meats, sausage, and toasted manioc flour, and is garnished with kale and orange slices. Within Brazil, the northeast has the most original cookery. *Vatapá,* a famous dish of Bahia, combines shrimp and peanuts served with highly spiced coconut milk and palm oil. *Cuscuz paulista,* derived from the couscous of North Africa, uses cornmeal, not seminola, as the principal farinaceous ingredient.

The diets of the peoples of highland South America from Andean Venezuela through Bolivia are heavy in carbohydrates. The potato is a major element of the diet; maize is another staple food in this region. Meat is eaten much less in the highlands than in other parts of South America.

Carnivory has given the two Rio de la Plata countries a special nutritional cachet. With a developing-world income profile, Argentina and Uruguay have nevertheless a per capita meat consumption of more than 100 kilograms (kg) per year. Internal beef consumption has been so high at times that foreign demand has not always been adequately supplied. Fish resources are curiously underutilized. White bread is a staple food for this zone, the prime wheat-growing area of all of Latin America. The Mediterranean origin of the great majority of Argentines and Uruguayans partly explains the high-per capita wine consumption.

Chilean diets depend on seafood to a far greater extent than do diets elsewhere in Latin America. Markets are full of swordfish, oysters, mussels, shrimp, scallops, abalone *(locas),* and sea urchins. Fishing is rewarding in Chile's productive cold waters and is reinforced by the country's maritime orientation and limited extent of good livestock pasture. Within South America, the artichoke is a common vegetable only in Chile. Chileans are avid bread eaters and also have developed creative ways to use fruit.

The Guianas have non-Iberian food traditions. The complex ethnic patterns there range from African, East Indian, Amerindian, Javanese, Dutch, and British to French, making it difficult to generalize about cuisine in this zone of northern South America. The one dietary constant among most people in this region is an emphasis on rice.

Food specializations also give rise to a critical attitude and an inclination to make quality judgments. Argentines are cognoscenti in such questions as what quality of beef constitutes prime sirloin. Coastal-dwelling Chileans know the precise balance of ingredients that makes the most savory *chupe de mariscos.* Peruvians of all classes are knowledgeable about the culinary virtues of different varieties of potatoes. Paraguayans pass easy judgment on the right texture for *chipá,* a baked product made with manioc flour.

Nutritional Standards

Caloric intake within South America varies widely from more than 3,000 calories per day in Argentina to between 2,000 and 2,200 calories per day in Bolivia, Peru, and Ecuador. Throughout the 1980s, Argentina's animal protein consumption was more than three times that of Bolivia and Peru. Even in Venezuela, where per capita income is somewhat higher than in Argentina, the people enjoy less than half the protein intake. In spite of the country's developing-world economy, Argentina's has been one of the best-fed populations in the world. However, Argentina's cornucopian reputation has suffered as economic stagnation and hyperinflation have sharply reduced the purchasing power of the majority. In 1989, supermarkets in Rosario and elsewhere were mobbed by people who could not pay the inflated prices for staple items.

In analyzing South America as a whole in the late twentieth century, one must conclude that, despite the richness of the region's dietary patterns, many poor people have diets that can only be termed bad. Infants and children of poor families get insufficient protein for proper development. Milk consumption is low in South America, a result of various factors: nonavailability in remote areas, the high cost of canned milk, and/or lack of education about its nutritional importance. Lactose intolerance, especially among people of native and African origin, is also probably a very important factor in explaining low levels of milk intake.

Protein deficiencies seem especially incongruous in countries that have fishing industries. After World War II, for example, Peru exported fish meal to Europe largely as chicken feed. It was only with the revolutionary military regime of Juan Velasco, who came to power in 1969, that there was a serious attempt to get fish beyond the coastal ports to the highlands. By 1973, refrigerated fish depots began operating in several highland towns. Yet a decade later, these government-managed marketing channels were gone and fish consumption correspondingly dropped there. Peasants do not always eat the protein they produce themselves. Eggs and poultry in the Andes are often sold on the market rather than consumed at home, in part perhaps a legacy of the Spanish colonial period when eggs and live hens were a tribute item to government officials and payment in kind *(camarico)* to the local priest.

Food-Related Customs

South Americans have given special importance to the family-centered midday meal, a custom transferred from Mediterranean civilization. But in recent decades, the North American pattern of a quick, light lunch has made inroads in large South American cities where some business people have adopted a hectic "time is money" attitude. Evening meals in urban settings are typically late, especially in places where a collation is taken in the late afternoon. Snacking is common, fostered by food vending in public places. In most South American towns and cities, many poor people eke out a precarious living by preparing and selling foods on the street. Some rural folk in the Andean highlands follow a two-meal pattern that permits uninterrupted agricultural labor throughout the day. Among people with little formal education, food is often categorized as being either "hot" or "cold," referring not to its actual temperature but other, often ineffable, qualities. The result is a complicated etiquette determining which foods or drinks should accompany or follow others.

The eclecticism of food intake that characterizes present-day North America is less elaborated in South America where, because of a lack of many wide choices, monotony of diet is scarcely an issue. Only large cities offer exposure to foreign cuisines; moreover, many people are cautious about experimenting with new foods or food formats. The tradition of having domestic help and daily marketing reduces demand for canned and frozen foods in the diets of many people who could afford to buy them. The middle-class practice of hiring cooks of peasant origin reinforces culinary conservatism within families.

No national cuisine in Latin America completely exploits the subtleties of flavor offered by its nutriments. Emile Daireaux, a Frenchman who traveled in Argentina in the 1880s, noted the splendid array of inexpensive food available, but the absence of epicurean discrimination. His explanation evoked the lack of a refined culinary tradition in southern Spain whence early Argentine settlers came (Daireaux 1888). Much more so than in Europe, large food portions became a measure of proper hospitality. Among the Latin American underprivileged, overweight has been a sign of well-being. Ideas about the links between diet and health are less developed than in the Puritan colossus to the north where cholesterol counting and vitamin content preoccupy consumers. Nonetheless, food movements such as vegetarianism and a preference for organic foods do exist in South America among small circles of urban people open to foreign influence.

Beverages and Drinks

Although coffee was hardly known in Latin America before the nineteenth century, it has subsequently become the outstanding hot beverage of the continent. Its preparation in the various countries meets very different standards (high in Brazil, low in Peru, for example). Many people in Uruguay, Paraguay, Argentina, and southern Brazil still prefer yerba maté, which in the late colonial period was also consumed in Bolivia and Peru.

Bottled beer, produced in commercial breweries started mostly by Germans, has become the preferred alcoholic beverage in South America. In hot climates such as Brazil, cold beer is especially popular, but even in the gelid Andes, bottled beer, imbibed at room temperature, is now the preferred vehicle for sociability. Partly due to intense propaganda *(beber cerveza es beber salud)* in this region, bottled beer has made deep inroads even in zones of traditional *chicha* consumption. The latter is a local fermented corn beverage of the Andes, often made under unsanitary conditions. Its popularity has waned in much the same way as has *pulque* in Mexico. Wine competes seriously with beer only in Argentina and Chile, doubtlessly because these countries both have major viticultural production. Carbonated, sweetened, and flavored soft drinks are wildly popular in South America and serve as a double foil for water loss in hot climates and impure water supplies. Much is bottled under license from multinational firms, such as Coca-Cola. In Brazil, native fruit flavors, such as the highly popular guaraná, expand the range of soft drinks.

Distilled beverages, led by rum, have been an important social lubricant among Latin Americans since the nineteenth century. A colonial reserve toward the popular consumption of these spirits broke down after independence was achieved in most countries. Much sugarcane is grown for rum; in some countries its only competitor is grape brandy, called *pisco* in Peru and Chile, *singani* in Bolivia, and *aguardiente* in Argentina. Unlike the high value placed on sobriety in Mediterranean Europe, inebriation is a regular and rather shameless outcome of social drinking in South America.

Food Exports and Imports

Food sent to international markets has been a critical source of foreign exchange in South America, but it is no longer as central a trade item as it once was. In Venezuela, food exports are insignificant compared to the income generated by petroleum products. In Colombia, coffee is important, but less so than cocaine, which does not enter into trade statistics. Ecuador is still a leading banana exporter, but petroleum has relieved that country's dependency on that one fruit. Sugar production has greatly declined in Peru since the government turned the big estates into cooperatives. Bolivia cultivates less than one percent of its territory and exports hardly any foodstuffs.

Chile, on the other hand, has found an export niche in fresh fruit: Table grapes, peaches, nectarines, pears, plums, and kiwifruit now fill American supermarket produce displays from December to May at a time when domestic sources of these items are not normally available. By the late 1980s, the Chilean fruit industry employed some 250,000 people, earning 12 percent of the country's export income. Chile is also the world's leading exporter of fish meal and has enjoyed a large growth in fish farming in the south. Brazil exports soybeans, coffee, and sugar in large quantities and a number of specialty items, such as hearts of palm. Of all the South American nations, Argentina and Uruguay have depended most heavily on food export. Meat and wheat from these two countries helped to feed Europe during much of the twentieth century. Throughout the 1980s, food comprised more than half of all Argentine exports, far more in percentage terms than that of any other country of the continent. Nevertheless, in Argentina only 11 percent of the population was engaged in agriculture in 1987, compared to 43 percent in Bolivia and 38 percent in Peru.

Several South Americans countries have imported staples to cover food deficits. In Venezuela, processed foods, especially from the United States, dominated the middle- and upper-class market basket until the 1960s. But then Venezuela increasingly restricted these imports, favoring the Venezuelan subsidiaries of the North American–based firms (Wright 1985). Poor countries have been recipients of food aid, also largely from the United States. Under U.S. Public Law 480 ("Food for Peace"), passed in 1954, large quantities of wheat, powdered milk, and cheese were subsequently distributed, some sold for local currency ("Title 1") and some donated ("Title 2"). Brazil and Colombia formerly received this kind of food aid; Peru and Bolivia still do.

In 1990 the United States provided $85 million in food aid to Peru, which reached 13 percent of the population. But serious structural problems arise when city dwellers are able to buy imported food that is often sold cheaper than local farmers can produce it. Agriculture is undermined, exacerbating dependency on foreign food and intensifying the pattern of rural-to-urban migration. Regional self-sufficiency correspondingly declines. In the Peruvian and Bolivian Andes, the rice, sugar, wheat flour, noodles, and cooking oil brought from the coast or abroad have partially replaced the traditional staples, which used to be acquired by barter among peoples in different environmental zones.

Food Supply Problems

In most South American countries, food production has not kept pace with the growth of population. The slow rise or even decline in per capita agricultural output on the continent has several causes. Misuse of land resources is one such cause; many areas are seriously eroded, and this is reflected in declining yields. Ill-conceived agrarian reform programs have reduced the ability of countries to feed themselves. The breakup of large estates in Bolivia in the 1950s, Chile in the 1960s, and Peru in the 1970s each had this effect. At the same time, state and private investment in rural development has been sparse compared with investments that go to urban areas. The number of food producers in South America falls every year, a phenomenon that, however, is not matched by increases in productive efficiency. The meager return for unremitting hard work has accelerated rural-to-urban migration.

Natural hazards have periodically caused food shortages in South America. Droughts at distressingly frequent intervals in northeastern Brazil have shriveled standing crops, killed livestock, and brought mass starvation. During the "grande sêca" of 1877–9 in Ceará, between 200,000 and 500,000 people died, and most survivors were forced to migrate out of the region. The long history of famine in the Brazilian northeast prompted Josue de Castro to aim a Marxist critique at the problem in his book translated into several languages, including English as *The Geography of Hunger.* In 1955–6, a famine brought on by drought scourged the highlands of southern Peru. Food relief was not well timed or organized, with the result that some peasants starved, others were dispossessed, and some resorted to selling their children. The ability of modern South American governments to bring food relief to needy people has generally improved throughout the decades. But parts of the continent are still vulnerable to starvation if crops fail. In some ways, food production and distribution in South America reached its acme during the Inca Empire (A.D. 1200 to 1531). Surpluses of grains and chuño, moved by llama trains to specially constructed storehouses, were redistributed when regional or local food shortages occurred.

As one of the offshoots of Western civilization, South America shares some food characteristics and customs with Europe and North America. But tropical conditions, a strong indigenous presence, and weakly developed economies have greatly influenced the content of its food inventory, traditions, and nutritional profiles.

V.D.3 The Caribbean, Including Northern South America and Lowland Central America: Early History

In writing the history of culinary practices, there is a tendency to emphasize the ethnic character of diets (González 1988). Yet nowhere are historical entanglements more apparent than in the international character of modern cuisine, even if explicit ethnic territories are strongly defended. Foods are often defined with apparent regard to national origin: Indian corn, Irish potatoes, Italian tomatoes, Dutch chocolate, and Hawaiian pineapple, to name but a few. However, the plants that form the basis of many European cuisines in fact originated in the Americas (Keegan 1992), and American diets were transformed in what Alfred Crosby (1986) has described as the creation of the neo-Europes.

"You call it corn, we call it maize." Contrary to the American television commercial in which a very Navaho-looking women makes that statement, the word is actually of Taino origin. Peter Martyr was among the first Europeans to describe this plant that the native West Indians called *maíz (Zea mays)* (Sauer 1966: 55). Other Taino words for plants and animals have also entered the English lexicon, including *cazabi* and *yuca* (*Manihot esculenta* Crantz), *guayaba* (*Psidium guajava* L.), *bixa* (*Bixa orellana* L.), *iguana,* and *manati* (*Trichechus manatus*) (Oviedo [1526] 1959: 13–16; Taylor 1977: 20–1).

Cultigens from the circum-Caribbean lowlands have also been of significant effect (Keegan et al. 1992). Tomatoes (*Lycopersicon esculentum* Mill.) were first encountered in coastal Mexico, where the Spanish were also treated to a drink called *chocolatl,* a blend of cacao (*Theobroma cacao* L.), peppers (*Capsicum* spp.), and other spices (including *Bixa orellana* L.). Cacao won immediate acceptance; together, it and vanilla (*Vanilla* spp.), a semidomesticated lowland orchid, have become the most important flavorings in the world. In contrast, the *tomatl* (tomato) languished under the specter of its membership in the "deadly" nightshade family of plants. First grown as an ornamental, and only much later as food, the tomato eventually reshaped Italian cuisine.

American foods have been reinterpreted in ever-changing dietary contexts since their "discovery" by Europeans. Maize, in particular, has been manipulated for use as a building material, lubricant, automobile fuel, and universal hardening additive. The objective of this review is to introduce a well-structured methodology for examining past diets, while at the same time providing comprehensive empirical coverage of the regions first reached by the Spaniards after 1492.

We begin with the native Tainos who occupied the Greater Antilles and Bahama Islands at the time of European contact (see Figure V.D.3.1). Their culinary practices are traced through the Saladoid expansion to their mainland South American origins. The earlier "preagricultural" Caribbean peoples, called Archaic in the regional parlance (Rouse 1986, 1992), are then briefly considered. Although little is known of Archaic diets, it has been suggested that the Tainos developed from the synergy of Archaic and Saladoid cultures (Chanlatte Baik and Narganes Storde 1990). The scope is then expanded to include pre-Columbian plant migrations into the circum-Caribbean.

Taino Diet and Nutrition

The study of prehistoric diet and nutrition in the Caribbean is a relatively recent phenomenon. Moreover, the investigators who have concerned themselves with these issues have approached the subject in a variety of ways. The earliest efforts involved the enumeration of plants and animals described in the contact-period chronicles (Fewkes 1907; Rouse 1948; Sturtevant 1961, 1969; Sauer 1966). More recently,

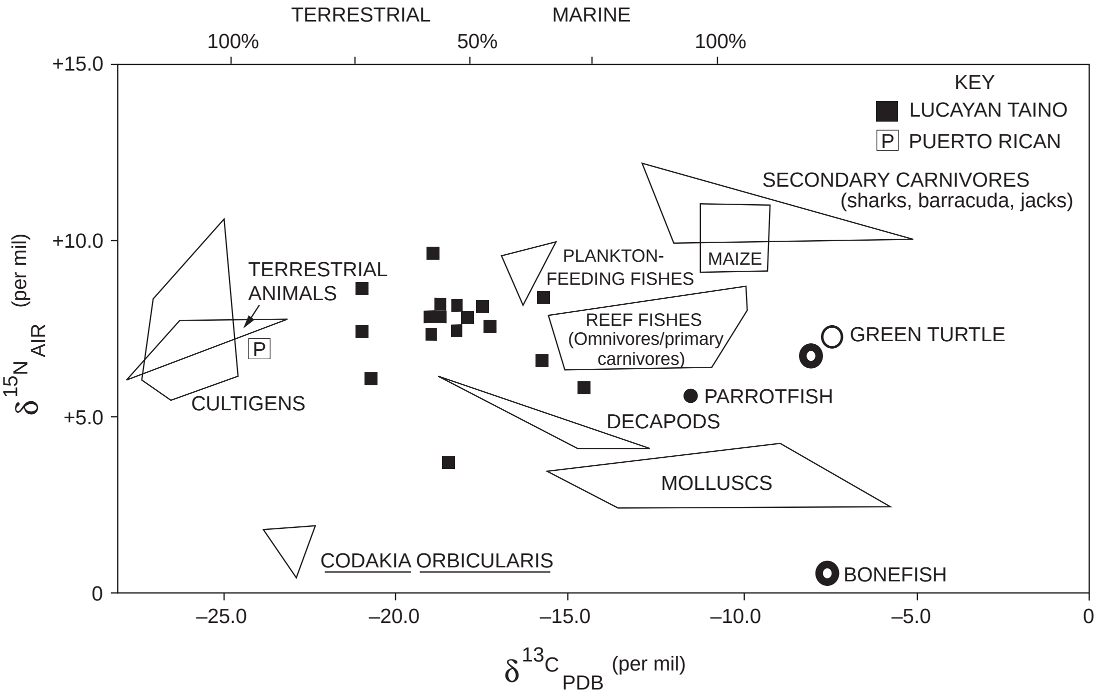

Figure V.D.3.1. Isotopic reconstruction of Lucayan consumption. (After Keegan and DeNiro 1988: Figure 2.)

attention has been drawn to the importance of diet and nutrition (Wing and Brown 1979). The analysis of animal remains in archaeological sites has been underway for some time (Wing and Reitz 1982; Wing and Scudder 1983). The investigation of archaeological plant remains has also been initiated. Although most of these studies are not yet published, they are investigating pollen, phytoliths, wood charcoal, and carbonized structures for the purposes of identifying cultigens, firewood, and modifications of the landscape (for example, Fortuna 1978; Pearsall 1985; Piperno, Bush, and Colinvaux 1990; Newsom 1993). Stable-isotope analysis has been used to investigate prehistoric diets (Keegan and DeNiro 1988; Klinken 1991), and studies of human skeletal remains have uncovered evidence of diet-related pathologies (Budinoff 1987).

Because different investigators approach questions of diet and nutrition from different perspectives, there has been a problem with the integration of their results. The author of this chapter has argued that diverse empirical studies need to be integrated in a well-structured research methodology (Keegan 1987; Keegan and DeNiro 1988). Such a methodology must include explanations for why people ate what they did, must predict what people should have eaten, and must incorporate techniques for determining the variety of foods people consumed.

The study of West Indian diets described here uses models developed in evolutionary biology under the title "Optimal Foraging Theory" (Winterhalder and Smith 1981; Smith 1983; Keegan 1986a; Smith and Winterhalder 1992). It was hypothesized that Caribbean diets would reflect the efficient capture of the aggregate nutritional currencies – calories and protein. The theory was examined with data derived from ethnological, ethnohistorical, zooarchaeological, paleobotanical, and other techniques, which specified what foods were eaten and the relative costs of obtaining these foods (Keegan 1985). Finally, osteochemical techniques were used to evaluate what food items were consumed from the record they left in the human skeleton (Keegan and DeNiro 1988). This three-tier approach provides a robust solution to questions of prehistoric diet and nutrition (see Bell 1992).

West Indian Food Items

The first task in reconstructing prehistoric diets involves compiling a list of the plants and animals that were consumed. Ethno-historic reports described the Taino in the Greater Antilles as practicing a mixed economy of root-crop horticulture and hunting-fishing-collecting (Fewkes 1907; Rouse 1948; Sauer 1966; Wing 1969; Wing and Reitz 1982).

The Spanish chroniclers reported that the Tainos cultivated manioc (*Manihot esculenta* Crantz),[1] sweet potatoes (*Ipomoea batatas* [L.] Lam.), yautía or cocoyam (*Xanthosoma sagittifolium* Schott), llerén (*Calathea allouia* [Aubl.] Lindl.), peanuts (*Arachis hypogaea* L.), maize (*Zea mays* L.), beans (*Phaseolus* spp.), cucurbits (*Cucurbita* spp.), chilli peppers (*Capsicum frutescens* L. or *Capsicum annuum* L.), and fruit trees, including mamey (*Mammea americana* L.), jagua or genipop (*Genipa americana* L.), hicaco or cocoplum (*Chrysobalanus icaco* L.), guanábana or soursop (*Annona muricata* L.), bixa or annatto (*Bixa orellana* L.), guava (*Psidium guajava* L.), and cupey (*Clusea rosea*) (Fewkes 1907; Rouse 1948; Sturtevant 1961, 1969; Sauer 1966; Guarch 1974; Nadal 1981). Most of these cultigens were carried into the Antilles by the Island Arawak (see Ford 1984; Schultes 1984). A variety of wild or quasi-domesticated plants were also in use, including the stems of the cycad *Zamia,* primrose (*Oenothera* sp.), purslane (*Portulaca* sp.), mastic-bully (*Mastichodendron foetidissimum*), sapodilla (*Manilkara* sp.), cockspur (*Celtis iguanaea*), palm fruits, sea grapes (*Coccoloba uvifera*), pigeon plum (*Coccoloba diversifolia*), and panicoid grasses (*Setaria* spp.) (Sturtevant 1969; Fortuna 1978; Newsom 1993). The carbonized remains of maize, chilli peppers, palm fruits, and at least two unidentified tubers (probably manioc and sweet potato) are among the plant remains identified in West Indian sites (Newsom 1993).

As is the case with modern tropical horticulturalists, life revolved around garden cycles (Malinowski 1978; Johnson 1983). Garden plots (called *conucos* by the Tainos) of about one to two hectares per household were cleared at regular, possibly annual, intervals. Clearing involved the use of stone axes or shell tools to slash brush, fell trees, and girdle large trees so that they would drop their leaves. After clearing, the brush was left to dry and was then burned, releasing the nutrients stored in the vegetation.

Planting came next and was done with a sharpened digging stick. Manioc was planted in small mounds of loose earth, called *montones.* After planting, the gardens were weeded and the mature crops harvested; replantings were made on a continuous basis until the garden was abandoned. (Unlike temperate gardens that die in the winter, tropical gardens can be maintained for years.) After a few years, garden production was reduced to certain tree crops, and new gardens had to be prepared. The old garden was then left fallow until covered by at least secondary forest growth, at which time it might again have been cleared. The importance of the agricultural cycle is reflected in stone alignments, which were used to chart the summer solstice and the rising and setting of stars that were important in Native American agricultural calendars. The most notable examples are site MC-6 on Middle Caicos in the Turks and Caicos Islands and La Plaza de Chacuey in the Dominican Republic (Castellanos 1981; Aveni and Urton 1982; Alegría 1983).

Taino cultigens grew and matured at different rates. Consequently, the diet of the inhabitants changed continuously with the seasons. Nonbitter maniocs and other root crops would have been available throughout the year. Boiling was the usual method of cooking. Bitter maniocs, so-called because they contain toxic levels of cyanogenic glucosides, must be grated and squeezed before consumption (Roosevelt 1980: 129). The juice releases its toxins when exposed to air or cooked; the boiled juice, called *cassirepe,* is a base for pepper pots and manioc beer. The pulp is dried for use as starch (flour); it is also toasted to make farina or for use as an ingredient in tapioca. The reward for so much additional processing effort is indefinite storability (Roosevelt 1980: 129). Water is added to the starch to make pancake-like cassava bread that is baked on large, round, pottery griddles called *burénes.*

Manioc was the staple crop intensively cultivated on mounds at the time of European contact (Sturtevant 1969). Maize is reported to have been grown for roasting ears and, to some extent, for bread grain, but it was not a major foodstuff (Sturtevant 1961; Sauer 1966). Maize was apparently a late introduction and may have been the focus of agricultural intensification in the Greater Antilles at the time of Spanish contact (Keegan 1987; compare Lathrap 1987).

In addition to "outfield" garden plots, there were house gardens closer to and around the dwellings. House gardens contained new varieties of cultigens, herbs and spices, medicinal and narcotic plants, vegetable dyes, fruit trees, and other cultigens that required special attention or were needed frequently in small quantities (Lathrap 1977, 1987). A list of possible house-garden plants is given in Table V.D.3.1.

A meal without meat would not have been considered complete. As is typical of most islands, the West Indies have a depauperate terrestrial fauna (Keegan and Diamond 1987). Indigenous land mammals are limited to bats, rodents of the tribe Oryzomyini, spiny rat (Echimyidae), and small rodents (*Geocapromys* sp., *Isolobodon portoricensis, Plagiodontia* sp.). Opossum (*Didelphis virginiana*), agouti (*Dasyprocta aguti* L.), and armadillo (*Dasypus novemcinctus*) were introduced from the South American mainland (Eisenberg 1989). In addition, a type of small deer called brocket (*Mazama americana*) was known in Trinidad, which was connected to the mainland until the end of the Pleistocene (Wing and Reitz 1982). Other land animals include iguanas (*Iguana* sp., *Cyclura* spp.), crocodiles (*Crocodylus* sp.), a variety of small reptiles (e.g., *Anolis* sp.), land crabs (*Cardisoma guanhumi, Gecarchinus* sp.), numerous birds, and a land snail (*Caracolus* sp.) (Wing 1969; Wing and Reitz 1982; Wing and Scudder 1983; Steadman et al. 1984; Watters et al. 1984; Morgan and Woods 1986; deFrance 1988, 1989; Fandrich 1990). The Tainos kept domesticated Muscovy ducks *(Cairina moschata)* and dogs *(Canis familiaris)* (Sauer 1966; Wing and Scudder 1983). It is also likely that a variety of grubs and insects were consumed (see Johnson and Baksh 1987).

A number of these animals, such as *Isolobodon* (Reitz 1986), crocodile (McKinnen 1804; deFrance 1991), and iguana (Iverson 1979), suffered local extinctions after the arrival of Europeans (Olsen 1982; Morgan and Woods 1986).

The main component of prehistoric Antillean vertebrate faunal assemblages is marine fishes (Wing and Reitz 1982). In the Bahamas, marine fishes account for more than 80 percent of the estimated maximum vertebrate biomass in the sites with analyzed assemblages (Wing 1969; Wing and Scudder 1983; Keegan 1986b; deFrance 1991). A representative list of fish species identified in Lucayan sites is presented in Table V.D.3.2.

In addition to fishes, several large aquatic animals have also been identified in Antillean sites. These include marine turtles (mostly Chelonidae), porpoises (Delphinidae), West Indian monk seals *(Monachus tropicalis),* and manatees *(Trichechus manatus)* (Wing and Reitz 1982; Watters et al. 1984). These large reptiles and mammals have been emphasized in the subsistence activities of peoples throughout the circum-Caribbean (Nietschmann 1973; Davidson 1974; Campbell 1978; Wing and Reitz 1982; McKillop 1985).

The final category of subsistence remains is marine mollusks. Molluscan shell is the most abundant type of refuse in prehistoric sites in terms of both volume and mass. Despite this abundance, molluscan shell represents relatively small edible packages. The most important mollusks were queen conch *(Strombus gigas),* West Indian top shell *(Cittarium pica),* tiger lucine clams *(Codakia orbicularis),* chitons (*Chiton* spp.), and nerites (Keegan 1985; deFrance 1988).

Meats were roasted over a fire or barbecued ("barbecue" is derived from a Taino word). It has been suggested that the Lucayans may have used another traditional form of tropical-forest cooking called the "pepper pot." Pepper pots are stews, kept simmering over a low fire, to which meats and vegetables are added to replenish the pot. The large, thick clay pots made in the Bahamas and in the Lesser Antilles were well suited to this type of food preparation (Allaire 1984).

When viewed with regard to the number of different ways in which individuals could satisfy their hunger, the West Indies are noteworthy for the surfeit of options. It is difficult to imagine that anyone ever went hungry. Yet the fact that these people were selective in their food choices provides an important challenge. It is not sufficient simply to list the items that were, or may have been, eaten; rather, the criteria upon which dietary selections were based must be identified.

Because there is too much local variability to treat all West Indian diets as equivalent (deFrance 1988), the following study focuses on the subsistence decisions of the Lucayans. The Lucayans are of Taino ancestry. They occupied the Bahama archipelago between A.D. 600 and 1500 (Keegan 1992). Lucayan diet breadth is evaluated by comparison with an economic model of the diet that would result from the cost-efficient capture of nutritional currencies.

Table V.D.3.1. *Comparison of house-garden cultigens in native Amazonian and prehistoric West Indian gardens*

	Native Amazonian house gardens		
House garden plants	General	Machiguenga	Prehistoric Antilles
Agave sp. (sisal fiber)	–	–	St
Anacardium occidentale (cashew bush)	X	–	–
Anadenanthera peregrina (leguminous tree)	X	–	–
Ananas sp. (pineapple)	X	X	–
Annona sp. (soursop fruit)	–	X	St
Arachis hypogaea (peanut)	–	X	S, St
Bixa orellana (red dye)	X	X	S
Bocconia sp. (plume poppy)	–	–	F
Bromelia sp.	–	X	F
Bursera simaruba (gum elemi)	–	–	F
Capsicum sp. (pepper)	X	X	S, St
Carica papaya (papaya fruit)	X	X	F
Cassia sp.	–	–	X F
Cecropia peltata (mulberry)	–	–	F
Chenopodium ambrosoides (lamb's-quarters)	–	–	F
Chrysobalanus icaco (cocoplum fruit)	–	–	St
Chtysophyllum caimito (caimito fruit)	X	–	F
Crescentia cujete (calabash tree)	X	X	F, S
Cucurbita sp. (squash)	–	X	St
Cyperus sp. (sedge)	–	X	F
Datura sp. (moonflower, fish poison)	–	X	–
Digetaria sp. (grass)	–	–	F
Genipa americana (genipe, black dye)	X	–	S
Gossypium sp. (cotton)	X	X	S
Guazuma ulmifolia (chocolate)	–	–	F
Guilielma gasipaës (peach palm)	X	–	–
Helecho sp. (tree fern, fire box)	–	–	F
Inga sp. (guaba fruit)	X	X	F
Jacquemontia petantha (chainnindo)	–	–	F
Jatropha cura (psychic nut)	–	–	St
Lagenaria sp. (bottle gourd)	X	X	St
Mammea americana (fruit tree)	–	–	S
Nicotiana sp. (tobacco)	X	X	F, S
Peperonia sp.	–	–	F
Piptadenia peregrina (cahoba, narcotic)	–	–	S
Psydium guajava (guava fruit)	X	X	F
Puosopis juliglora	–	–	F
Ricinus comunis (castor bean)	–	–	F
Roystonea hispaniolana (palm)	–	–	F
Sapindus saponatia (soapberry)	–	–	F
Solanum sp.	X	X	F
Spondias mombin (cashew bush)	–	–	F
Syzysium jambas (jambolan plum)	–	–	F
Theobroma sp. (cacao)	X	X	–
Thrychilia hirta	–	–	F
Vetiveria alliacea	–	–	F
Wallenia sp.	–	–	F
Zamia debilis (cycad, starchy bread root)	–	–	F

Note: Native Amazonian lists are based on Lathrap's (1977) general list (column 1), and Johnson's (1983) list of minor cultigens in Machiguenga gardens (column 2). Prehistoric Antillean cultigens (column 3) are identifed in ethnohistoric reports (*S* = Sauer 1966; *St* = Sturtevant 1961) and in Fortuna's (1978) analysis (denoted by *F*) of pollen samples from Sanate Abajo, Dominican Republic (A.D. 1020). Many of these "cultigens" are actually managed, tended, and transplanted non- or quasi-domesticated species. (Johnson's [1983] longer list of 80 cultigens was shortened by deleting major cultigens [manioc, maize, beans], historic introductions [sugarcane], and plants that were not identified by their taxonomic name.)

Table V.D.3.2. *Fishes identified in Lucayan sites*

Fish genera (most common = >90% of genera)
Haemulon (grunt)
Sparisoma (parrot fish)
Lutjanus (snapper)
Acanthurus (surgeonfish)
Scarus (parrot fish)
Epinephelus (grouper)
Mulloidichthys (goatfish)
Pomocanthus (angelfish)
Calamus (porgy)
Albula vulpes (bonefish)
Other fish genera (<10% of genera)
Inshore-estuarine habitat
Lactophrys (trunkfish)
Gerreidae (mojarro)
Eucinostomus (mojarro)
Diodon (porcupinefish)
Sphoeroides (puffer)
Lachnolaimus (hogfish)
Stronbylura (needlefish)
Belonidae (needlefishes)
Centropomus (snook)
Sciaenidae (drums)
Selene (lookdown)
Banks and reef habitats
Halichoeres (wrasse)
Elegatis (wrasse)
Holocentrus (squirrelfish)
Holocanthus (angelfish)
Flammeo (squirrelfish)
Chaetodon (butterfly fish)
Serranidae (groupers)
Ocyurus (yellowtail snapper)
Gymnothorax (moray eel)
Two or more habitats
Scorpaena (scorpion fish)
Balistidae (triggerfish)
Carangidae (jacks)
Sphyraena (barracuda)
Sharks and rays

Lucayan Diet Breadth

Lucayan diet can be described as consisting of inputs from five general sources: cultivated roots and tubers, maize, terrestrial animals, marine fishes, and marine mollusks (Sears and Sullivan 1978; Keegan 1992). These foods were obtained from the forest, the coastal strip, and the sea. To evaluate the Lucayan's behavior as cost-efficient foragers, the capture of foods in the three habitats is reviewed first. After identifying the foods and their associated costs, their return rates are compared by using a model derived from Optimal Foraging Theory. Finally, the diets predicted with the model are compared to the isotopic signatures in the bones of 17 individuals. The isotopic signatures reflect the foods that these individuals consumed.

Lucayan Food Procurement

The main component of the forest habitat was gardens. These were probably prepared in coastal accumulations of humic enriched sandy soil and would have followed the pattern of other tropical gardens (Ruddle 1974; Johnson 1983). Gardens were stable patches where output could be modified in response to changing needs. Root-crop horticulture provides high total and marginal rates of return. Average yields of manioc in Brazil are reported as 14.2 million calories per hectare (Roosevelt 1980: Table V.D.3.1). Using a generous estimate of human caloric needs (2,700 calories per day), 14 adults could have been supported on one hectare of land for an entire year. The availability of calories in other foods, which have higher net return rates, would have precluded the need for complete reliance on manioc production.

Because manioc does not require fertile soils for efficient tuber production, a single plot can be cultivated for many years. Long-term land use is not practiced in the tropical forest today because total human protein requirements also are met through garden production. The characteristics of maize make long-term, cost-efficient production on a single plot of land impossible (Keegan 1986a). Furthermore, yields from long-term manioc gardens can be increased by intercropping other cultigens (for example, sweet potatoes, cocoyams, fruit trees). These crops do not interfere with the growth of the manioc plants; rather, they increase yields per hectare for the additional investment of planting and harvesting, they aid in preventing weed growth, and they fill areas that would otherwise go unused (Ruddle 1974; Brierley 1985; Keegan 1986a). It is likely that the initial colonists planted small gardens with a diversity of crops, with garden size set by the caloric returns from manioc in relation to the caloric needs of the group. As population increased, garden size would have increased and other cultigens would have been added to the gardens.

The principal shortcoming of manioc is its low protein content (Roosevelt 1980). Since human nutritional requirements cannot be satisfied with manioc alone, other sources of protein had to be sought. In addition to animal protein sources, such cultigens as maize, beans, or ground nuts could have been added to the garden as protein supplements. These cultigens are more expensive in terms of harvesting and processing, contribute to a more rapid exhaustion of garden soils, and are available only during specific seasons.

Maize is the most cost-efficient of the high-protein cultigens. From Allen Johnson's (1983) studies it was estimated that maize has a marginal return rate of 20 grams of protein per hour of labor (Keegan 1986a). This return rate is higher than that for many other Lucayan foods. This would have promoted its acceptance when it became available after about A.D. 1100 (Keegan 1987). The disadvantages of maize production are the plant's need for fertile soils, its availability during only one season of the year, and the high cost of storing and processing maize when it is grown for use throughout the year. Thus, maize constituted only a partial solution to the problem of protein production.

Marginal return rates for animal species that inhabit the forest favor their use over horticulture. These animals (that is, hutia, iguana, and land crabs) could not, however, satisfy total needs. Their combined densities are equivalent to 1,861,950 calories per hectare, which could support only two individuals for a year if every animal was captured. But (in economic terms) intensive use would have rapidly reduced the frequency of encounters (that is, animals would not be seen very often), with the result a decline in the average return rate to a level below the marginal rate for other food sources (including horticulture). When this decline reached that level, those other foods would be added to the diet (Winterhalder and Smith 1981; Smith 1983). For the Lucayans, this other source of protein was the sea.

The inference from the economic model is that terrestrial animals were pursued whenever they were encountered. It is probable that game was taken in or near gardens (Linares 1976) and during visits to the coast. The forest is a difficult patch to traverse, and hunting trips in the forest were probably infrequent, especially after the decline of initially high prey densities. Since all of these small game were regular visitors to the coastal strip, the most efficient strategy would be to forage in this area. Travel along the coast is also less difficult, and other food sources would doubtless have been encountered (for example, wild plants, littoral mollusks).

The one exception to the forest-hunting proscription is land crabs, which congregate in the low areas that provide for moist burrows. These locations could be identified, and hunting could be accomplished with guaranteed results. But even land crabs can be taken on the coastal strip, especially when they congregate for mating (Gifford 1962; deFrance 1988).

The coastal strip is comprised of the beach patch and the rocky intertidal patch, and it provides access to marine habitats. The beach patch was the site of seasonal monk seal aggregations, turtle nesting grounds, and the accidental beaching of whales. In addition, terrestrial animals frequent this patch. Because settlements were located on the coast, the Lucayans were in a position to monitor activities on the beach.

The highest average return rate was available in the beach patch, although the highest return species were not available in all locations at all times (for instance, green turtles, monk seals, and whales). Turtles would have been available from April to July, and monk seals for about six weeks centered on December. Both would have been the focus of procurement efforts during their seasonal abundances.

The rocky intertidal patch supports dense aggregations of West Indian top shells, nerites, and chitons. Top shells have a relatively high net return rate, and of the three they are the only ones used today with any frequency. However, the use of top shells is limited by two factors. Rocky intertidal zones are small, averaging less than three meters wide, and they are irregularly distributed. These snails also are easily exploited and would have rapidly disappeared following the start of human predation. The other common littoral mollusks have lower return rates. These low values suggest that they were exploited during periods of food shortage. In any case, chitons and nerites should have been among the last items added to the diet.

The marine environment is comprised of a tidal-flat patch and a reef patch. The tidal-flat patch can be further divided by procurement strategies into infaunal mollusk collecting (that is, in the mud–sand substrate), epifaunal mollusk collecting (that is, on the substrate), and fishing. These strategies are discussed in turn.

The tiger lucine clam, *Codakia orbicularis,* is the most commonly used infaunal mollusk species. They occur at high densities beneath shallow grass flats and would have provided a stable resource supply (Jackson 1972, 1973). In terms of weight, tiger lucine clams provided a more significant source of food than intertidal mollusks (Rose 1982). Yet, tiger lucine has low net return rates of both calories and protein. It is, however, possible that these rates have been underestimated in the present study. A study of pelecypod collecting in Australia indicated a caloric return rate that is twice that estimated for *Codakia orbicularis* (Meehan 1977). Historical evidence suggests that even if the return rates were underestimated, the ranking relative to other food items is accurate. Tiger lucine clams should therefore have also been one of the last items added to the diet.

The epifaunal gastropod *Strombus gigas* is the highest ranked marine resource. It is available at high densities on shallow grass flats (Doran 1958; Hesse and Hesse 1977) and was a significant component of the diet. The high return rates place *Strombus gigas* in the initial optimal diet. Foraging trips over the shallow grass flats would also have led to encounters with marine fishes, such as bonefish *(Albula vulpes).*

The net return rate for fishes has been calculated as an average for all fishing strategies. Higher returns could have been obtained by pursuing particular strategies, such as the capture of fishes encountered during *Strombus gigas* collecting trips, but present evidence is not sufficient to discriminate the return rates for alternative strategies (Johannes 1981; Kirch 1982; Keegan 1986a). The average values for all fishing strategies places fishing just below rock iguana in the ranking of protein returns.

Optimal Horticulturalists

Having discussed the major habitats and their patches, attention is next focused on the food quest. In which patch should food be sought first? How much time should be devoted to the food quest in each patch? When should new foods be added to the diet? More complete information on time allocation and predation rates are needed before a quantitative solution for patch selection decisions can be calculated.

A qualitative solution can be proposed in the Lucayan case because the net return rates for the second through eighth ranked resources are sufficiently similar to analyze dietary change in a diet-breadth framework (Table V.D.3.3). This approach is based on the identification of horticultural production as part of the original subsistence endowment, and by the distribution of higher ranked resources in forest, coastal, and marine patches. Furthermore, the location of permanent settlements on the coast would eliminate significant differences in the time invested in traveling between patches.

The logic behind the use of the diet-breadth model, rather than the patch-selection model, is as follows. Although the patch-selection model compares average returns from different patches (including transportation time), while the diet-breadth model compares marginal returns to the overall foraging efficiency, the marginal return rates calculated for Lucayan food sources include some time investments that are better considered as search time. (Search time is a component of average return calculations.) This conflation of average and marginal returns results from the character of the information available to calculate those rates.

A second factor is that foraging from a central place should require similar investments in the time required to travel between patches. The high-ranked items in the Lucayan diet all have population densities that would have been rapidly depleted after the start of human predation. This reduction of animal densities would produce a reduction in the average return rates. Since the marginal rates for high-ranked items are similar, as is the time invested in traveling between patches, the marginal return rates should approximate the long-term decision-making problem. In other words, foraging decisions can be modeled as reflecting habitat selection based solely on short-term differences in resource distributions in each of the patches. This type of patch selection is so "fine-grained" (homogeneous) that it closely resembles and even operates like the diet-breadth model.

The diet-breadth model predicts that diet breadth will be expanded (in other words, items will be added to the diet) when the marginal return rate for a resource is equal to the average return rate for all higher-ranked resources. Because manioc cultivation was practiced when the Bahama archipelago was colonized, the higher-ranked resources would also have been in the original optimal set. These high-ranked resources are hutia, land crabs, queen conch, and rock iguana. This analysis suggests that despite their current absence in archaeological samples, green turtles and monk seals would have been captured during their seasonal availabilities. The food items mentioned

Table V.D.3.3. *Return rates and resource rankings of Lucayan foods*

Food Sources	Average weight/ individual (kg)	Kcal/ kg	Grams protein (kg)	Handling time (hr/kg)	Pop. density (kg/ha)	E/h	gP/h	Rank E/h	Rank gP/h
Green turtles (*Chelonia mydas*)	19.0	1300	2.2	0.026	2609	50,000	84	1	1
Hutia (*Geocapromys* sp.)	1.4	1500	1.5	0.12	21	12,500	13	2	5
Land crab (*Cardisoma* sp.)	0.2	900	1.7	0.10	2000	9,000	17	3	3
Queen conch (*Strombus gigas*)	0.17	800	1.3	0.09	850	8,889	14	4	4
Rock iguana (*Cyclura carinata*)	0.7	2000	2.4	0.24	15	8,333	10	5	6
Horticulture									
root crops	–	–	–	–	–	5,000	–	6	–
maize	–	–	–	–	–	–	20	–	2
All fishes	0.25	1000	1.9	0.22	–	4,545	9	7	7
West Indian top shell (*Cittarium pica*)	0.035	800	1.3	0.25	1750	3,200	5	8	8
Chiton sp.	0.005	800	1.3	0.5	500	1,600	3	9	9
Codakia orbicularis	0.01	800	1.3	1.39	4000	576	1	10	10
Nerites (*Nerita* sp.)	0.002	800	1.3	1.4	400	471	<1	11	11

Note: E/h is calories per handling hour; gP/h is grams of protein per handling hour.

should have provided a diet sufficient to preclude the need to eat any other foods. One qualification to this is that high-ranked fishes, such as bonefish, were probably pursued when encountered during foraging on the tidal flats.

Terrestrial animals in the Bahamas are susceptible to overexploitation. Their availability would have rapidly declined after a short period of intense predation and as human population growth increased the demand for these foods (Iverson 1979; Jordan 1989). In addition, land clearance and other changes to the landscape would effect the survival of other species (Olsen 1982). The first response to a decline in high-ranked resources would be to migrate to previously unexploited habitats. Thus, the rapid decline in high-ranked terrestrial animals would have encouraged the rapid migration of people to unoccupied islands. When new areas were no longer available, then the intensification of foraging in the marine habitat should have occurred.

The redistribution of the human population was no longer a cost-efficient option when the presence of other settlements prevented people from moving into pristine areas. When such social circumscription occurred, the currency demands had to be satisfied in the vicinity of the village over a longer period of time. In response to the combined effects of increased demand due to population growth and declining returns due to long-term exploitation, the intensification of production could only focus on two options. These options were increased use of marine habitats and changes in garden breadth. The total contribution of land animals would have continued to decline as human population numbers increased. In marine habitats, sea turtles, *Strombus gigas,* and certain species of fish would have been the initial focus, with other fishes added to the diet as other fishing techniques were introduced, and ending with the highest-ranked littoral mollusk, *Cittarium pica,* the West Indian top shells. But this species would also have been rapidly exhausted in areas of human settlement.

During the final phase, the lowest-ranked foods (that is, nerites, chitons, and tiger lucine) would have been added in turn. *Strombus gigas* would have been sought at more distant locations, and a variety of more intensive fishing strategies would have been introduced. It is likely that fish traps were introduced early in this phase as the availability of such visible diurnal species as bonefish declined and as fishes had to be sought at more distant locations, such as along the barrier coral reef. Horticultural production would have been intensified with the addition of beans, groundnuts, and maize, all of which are high carbohydrate- and protein-producing cultigens. Fields might have been fallowed for shorter lengths of time, although the sandy soils may have supported production for longer periods than was possible on other tropical soils (as in the Yucatan Peninsula, Mexico; Roosevelt 1980). Nitrogen-fixing legumes could have helped to maintain soil fertility. In the final phase, agriculture was intensified by the terracing of hillsides, the irrigating of fields, and the building of raised and drained fields (Zucchi and Denevan 1979).

The preceding discussion has served to identify three discrete diets. An initial diet was composed of root crops, land animals, and a few high-ranked marine species. This was followed by a second diet that included the consumption of more marine foods, a continuing contribution from root crops, and a precipitous decline in the contribution from land animals. In the third diet, land animals were reduced to a very minor level of use, marine production was further intensified, and horticulture was expanded to include higher-cost cultigens, such as maize and beans, which increased total protein and carbohydrate returns from the garden. It is this final pattern that is evident in the Lucayan faunal samples that have been analyzed to date (Wing and Reitz 1982; Wing and Scudder 1983; deFrance 1991).

Stable Isotope Analysis

The three diets just described were proposed on the basis of data gathered from ethnographic analogy, ethnohistoric reports, ethnobiological analyses, and formal economic models. To determine how well these diets reflect the actual subsistence practices of the Lucayans, a different analytical technique must be used to avoid circular reasoning. Stable-isotope analysis provides such a technique (Schoeninger and DeNiro 1984; Sealey 1986; Ambrose 1987, 1993; Keegan 1989c; Schoeninger et al. 1989; Sillen et al. 1989; see Stokes 1995 and de France et al. 1996 for new perspectives on this question.)

The Lucayan diet was evaluated by first measuring or estimating the carbon- and nitrogen-isotope compositions of food items and then measuring these in bone collagen extracted from 17 Lucayan skeletons. The results were then compared in order to determine the most likely components of the Lucayan diet.

An immediate division into marine and terrestrial food groups was observed in the carbon-isotope ratios. The marine group has an average delta^{13}C of –11 per mil, whereas the terrestrial group has an average delta^{13}C value of –25 per mil. Using these averages, the diet delta^{13}C values calculated for the Lucayan individuals can be interpreted. For instance, a diet delta^{13}C value of –11 per mil would suggest complete reliance on marine foods, a diet delta^{13}C of –25 per mil would suggest complete reliance on terrestrial foods, and a diet delta^{13}C value of –18 per mil would suggest equal contributions from both. Based on an estimated ±1 per mil uncertainty in the fractionation factor between diet and bone collagen, the diets of Lucayan individuals range from an estimated 71 ± 7 percent reliance on terrestrial foods (–21 per mil) to an estimated maximum of 74 ± 7 percent reliance on marine foods (–14.6 per mil).

If this interpretation is correct, the range in delta^{13}C values estimated for the diets of Lucayan individuals can be interpreted as reflecting a shift in consumption practices through time. The three most negative delta^{13}C values (all around –20 per mil) match the first of the proposed diets in which land animals were abundant and only the highest-ranked marine organisms were consumed. The second dietary pattern would account for the majority of Lucayan individuals (n = 11), whose diet delta^{13}C values of –18 ± 1 per mil reflects almost equal contributions from marine and terrestrial sources. The remaining three individuals exhibit ideal consumption patterns in the 66 to 74 ± 7 percent marine range (diet delta^{13}C values of –15.2 ± .6 per mil). Such a strong reliance on marine foods is unlikely due to the relatively higher costs of marine fishing and collecting in relation to horticulture. An alternative interpretation is that the higher delta^{13}C values indicate that maize was being consumed in substantial quantities during at least part of the year.

The carbon isotopes confirm the presence of three distinct diets. One explanation for these differences is that they represent changes in diet breadth through time. Unfortunately, the skeletons came from burials in caves and were not associated with materials that could be used to date them (Keegan 1982; Keegan and DeNiro 1988). Other explanations, such as the influence of more localized factors, must be entertained. Further investigations are needed to relate the isotopic study to expectations based on empirical studies and theoretical projections.

A second part of the isotopic study examined nitrogen-isotope distributions. Nitrogen-isotope values for marine and terrestrial food sources overlap, and so they cannot be used to distinguish among the contributions of land animals, cultivated roots and tubers, maize, and reef fishes in the Lucayan diet (Keegan and DeNiro 1988). When the isotopic signatures of Lucayan individuals are compared to this average, 76 percent of the individuals (n = 13) fall within ±1 per mil of this range.

Deviations from that average diet can be explained with reference to the lower values of mollusks and the higher values of pelagic fishes and marine mammals relative to other dietary components. One individual from Crooked Island had a higher dietary value, which suggests that pelagic fishes and/or marine mammals comprised a larger component of his diet and that mollusks made a relatively minor contribution. The location of this burial in an area where the barrier coral reef approaches the shore and the reef flat has a restricted range places this individual in the vicinity of marine habitats that are the most likely sources of such a dietary combination (Keegan 1982, 1986b).

The three individuals' diet values that are lower than the average probably reflect a stronger reliance on mollusks and perhaps a corresponding reduction in the consumption of higher-order carnivorous fishes. All three of these individuals are from islands with extensive *Thalassia* seagrass meadows (Grand Bahama Island and Great Abaco on the Little Bahama Bank, and Providenciales on the Caicos Bank). These shallow banks provide access to extensive mollusk populations while restricting access to reef-associated fishes (Wing and Reitz 1982; Wing and Scudder 1983; Keegan 1986b). Two of the individuals are less than 0.6 per mil below the average range, which reflects an increase in mollusk consumption to a level of less than 10 percent of total consumption. The other is 2.4 per mil below the average range, which suggests a reliance on mollusks and possibly other marine invertebrates approaching 40 percent of the diet.

The carbon- and nitrogen-isotope ratios are significant in their unequivocal rejection of commonsense interpretations of archaeological deposits. These deposits are largely composed of marine mollusk shells, the size and durability of which have led some investigators to propose that mollusks comprised as much as 95 percent of the meat protein in Lucayan diets. It is clear in the isotopic signatures of the 17 Lucayans that mollusks played a much more modest role in the diet. The same is true for the slave populations that followed them (Armstrong 1983).

The physical examination of the skeletons from the Bahamas indicates that the Lucayans enjoyed good health and nutrition (Keegan 1982). They certainly did not suffer from the nutritional and diet-related disorders of other prehistoric horticulturalists (Cohen and Armelagos 1984). They also lack the dental pathologies observed in Saladoid and Ostionoid burials at the Maisabel site, Puerto Rico. Linda Budinoff (1987), who analyzed the Maisabel skeletons, concluded that sand adhering to foods, exoskeleton and shell adhering to invertebrates, and a high percentage of carbohydrates in the diet conspired to destroy the teeth. One result was that middle-aged people had mouths more typical of old people.

In sum, the preceding examination of Lucayan diet has drawn together evidence from a variety of sources. On a general level, the empirical findings are consistent with the expectations derived from the formal model. There is every reason to believe that the Lucayans, and by extension other Tainos, were efficient, even optimal, horticulturalists.

Culinary Origins of the Tainos

The origins of the Tainos are conveniently traced to the banks of the Orinoco River in Venezuela (Rouse 1989a). As early as 2100 B.C., villages of horticulturalists who used pottery vessels to cook their food had been established along the Middle Orinoco. During the ensuing two millennia, their population increased in numbers, and they expanded downriver and outward along the Orinoco's tributaries (Lathrap 1977, 1987; Roosevelt 1980; Sanoja Obediente and Vargas 1983). One path of expansion led these people to the coast of the Guianas (Rouse 1992). From the Guianas, the opening of the West Indies awaited only the discovery of Grenada, which is separated from Trinidad by the widest gap in the chain of islands leading to Puerto Rico.

The movement of these people down the Orinoco River and through the Lesser Antilles to Puerto Rico is well documented (Roosevelt 1980; Sanoja Obediente and Vargas 1983; Zucchi, Tarble, and Vaz 1984; Rouse 1986). It is easily traced because these people manufactured a characteristic type of pottery known as Saladoid after the archaeological site of Saladero, Venezuela, at which it was first described (Rouse and Allaire 1978). In particular, the use of white-on-red painted decorations has facilitated the identification of the path along which this population expanded. Another indicator of migration is the presence of certain animals in the island archaeological remains.

The Saladoid expansion into the Antilles occurred at a rapid pace. The earliest Ceramic-Age settlements in the West Indies date to about 400 B.C. (Rouse 1989b; Haviser 1991; Siegel 1991). Saladoid settlements appear simultaneously on Puerto Rico and the islands of the Lesser Antilles (Rouse 1992). Given what is known of human reproductive potentials and the time that elapsed between departure from the mainland and colonization of Puerto Rico, the inescapable conclusion is that only the very best locations on a few of the Lesser Antilles were settled at this time. The most likely scenario is that most islands were settled temporarily and were then abandoned in favor of more abundant food resources on other islands. Only those few locations with superior resource concentrations were settled for a period that could be considered permanent (Watters 1982; Keegan and Diamond 1987; Haviser 1991). This practice of establishing temporary settlements that were moved in response to resource availability is typical of extensive horticulturalists, which the Saladoid peoples are believed to have been (Conklin 1968; Ruddle 1974; Johnson 1983).

Since paleobotanical studies have only recently been attempted, the composition of the Saladoids peoples' gardens has been hypothesized from ethnohistoric and ethnological descriptions of cultivations (Sturtevant 1961; Roosevelt 1980), and from the presence of certain food-processing artifacts. It has been proposed that manioc was the staple, but that a variety of other cultigens were also grown. The hypothesized importance of root crops is consistent with the results obtained from stable isotope analysis.

The earliest known villages in the Lesser Antilles follow the riverine settlement pattern of the mainland. On Grenada, Antigua, St. Martin, Vieques, St. Croix, and St. Kitts, the villages were located inland on river terraces, which provided access to the best setting for gardens (Haviser 1991; compare Siegel 1991). The shifting, extensive character of gardening practices is evident from the absence of deeply stratified sites and from settlement patterns in which different components are arranged in horizontal and sometimes overlapping relationships (Watters 1982).

Shortly after the initial colonization of the Antilles, there was a rapid and almost complete shift from inland to coastal settlement locations. Although horticulture continued as the primary source of foodstuffs, the change in settlement patterns was accompanied by a shift in midden deposits from terrestrial to marine animal remains. At the earliest sites, the remains of land crabs predominate in archaeological deposits. However, following the shift to coastal villages, the shells of marine mollusks and bones of marine fishes are the main components of archaeological deposits (Carbone 1980a; Goodwin 1980; Jones 1985; deFrance 1988, 1989; Keegan 1989b; Fandrich 1990). Stable isotope analysis has confirmed this strong initial reliance on terrestrial foods. One individual from the Hacienda Grande site (Rouse and Alegría 1990), an initial-period Saladoid settlement on Puerto Rico (around A.D. 100), has been analyzed. This individual exhibits a 93 ± 7 percent reliance on terrestrial foods (Keegan and DeNiro 1988).

Two explanations have been suggested to account for this shift from an emphasis on land resources to one on marine resources. The first proposed that a growing human population soon depleted the availability of terrestrial resources, which resulted in the shift to marine resources (Goodwin 1979). The second explanation proposed that changes in climate resulted in drier conditions, which acted to reduce population densities of the humidity-sensitive land crabs (Carbone 1980a, 1980b). Both are possible, but the first seems to have had the larger effect.

The examination of subsistence change on the mainland is instructive. In her study of Saladoid peoples on the Orinoco River of Venezuela, Anna Roosevelt (1980: 230–3) projected a population growth rate in Parmana that is exactly the same as the rate estimated for St. Kitts (Goodwin 1979). This coincidence suggested the question: As a shift in protein sources occurred when the population density doubled from about 1.5 to 3.0 persons per square kilometer in Parmana, did anything similar happen on St. Kitts? In Parmana, there was a shift in protein sources to an emphasis on maize in the diet (Roosevelt 1980; Merwe, Roosevelt and Vogel 1981); on St. Kitts, it has been estimated that the shift from land crabs to marine mollusks occurred at an equivalent population doubling point (Keegan 1989b).

In sum, Saladoid peoples expanded from northeastern Venezuela and the coast of the Guianas through the Lesser Antilles and Puerto Rico to establish a frontier in eastern Hispaniola. The initial migration through the Lesser Antilles to Puerto Rico took place in less than one century (Keegan 1995), a period that was insufficient for the establishment of permanent communities on every island in the Lesser Antilles. One stimulus to this rapid expansion was the small size of these islands and their limited terrestrial resource bases (Harris 1965). These constraints are apparent in the rapid and almost complete shift from terrestrial to marine sources of animal protein at the same time that the shift to coastal settlement locations provided ready access to the marine environment. The completion of this transformation of a riverine people to an island people was the economic foundation on which Taino societies developed.

Archaic West Indians

Archaeological investigations have documented the presence of human groups in the Greater Antilles by 4000 B.C. (Rouse and Allaire 1978; Veloz Maggiolo 1971–72). By most accounts, these groups were aceramic, preagricultural hunter-fisher-gatherers whose lifeways emphasized the gathering of wild plants and the exploitation of marine resources (Rouse 1948; Veloz Maggiolo and Vega 1982; Sanoja Obediente and Vargas 1983; Keegan 1994). G. J. van Klinken's (1991) stable-isotope study of 24 individuals from Aruba, Bonaire, and Curaçao, in the Netherlands Antilles, indicated a diet of C_4 grasses and marine animals from seagrass and coral-reef habitats. Dave Davis (1988: 181) has pointed out that the assumed lack of cultigens is based on the weakest of evidence. Lee Ann Newsom's (1993) study of plant remains from archaeological sites has led her to propose that "preagricultural" West Indians (Archaic peoples) were managing, and possibly cultivating, a suite of indigenous seed-bearing plants. Such incipient cultivation is now well documented among foragers (Ford 1985; Vaquer et al. 1986).

In reconstructing Archaic subsistence, it is usually assumed that a population of hunter-gatherers called Guanahatabey (or erroneously, Ciboney) survived in western Cuba until European contact (Rouse 1948). The author of this chapter has recently shown that there is not sufficient evidence to support that belief (Keegan 1989a; compare Rouse 1992). Therefore, ethnohistoric reports of Guanahatabey subsistence cannot be used to illuminate Archaic diets.

Paleobotanical evidence for the Archaic is limited. Only the starchy stem of the wild cycad *Zamia* and a fruit known as cupey *(Clusea rosea)* have been recovered in excavations (Nadal 1981; Veloz Maggiolo and Vega 1982). Both of these plants were cultivated by the Tainos, and it is possible that other Taino cultigens (for example, soursop, sweetsop, hogplum, guava, pineapple) were also eaten (Davis 1988: 181). The most common fauna in Archaic sites are mollusks and reef fishes from shallow offshore habitats.

Marcio Veloz Maggiolo and Bernardo Vega (1982) propose an initial "adaptation" model of archaic subsistence in the Caribbean commencing around 9000 B.C. on the western coast of the United States and extending through Panama around to Trinidad. Trinidad was connected to the mainland until about 6000 B.C., with the Banwari-type occupation dating between 5500 to 3500 B.C. The diet was based on gathered plants and mollusks, with an emphasis on mangrove swamps, along with the hunting of small-to-middle-size game. Archaeological sites in the Dominican Republic date from between 2000 and 1500 B.C. *Zamia* and *cupey* were already present by this time, and land snails (*Polydontes* sp., *Caracolus* sp.), oyster (*Crassostrea rizhoporae*), intertidal gastropods (*Cittarium pica*), land crabs (*Geocarcinus lateralis*), marine cockroach (*Acanthopleura* sp.), parrot fishes (Scaridae), iguana (*Cyclura* sp.), and medium-size rodents (*Heteropsomys* sp., *Isolobodon* sp., and *Nesophontes* sp.) were also eaten.

The second adaptation, called Barrera-Mordan, dates to around 3000 B.C. in Cuba, Puerto Rico, and the Dominican Republic, and shows affinities with sites in the Colombian lowlands and Venezuela. This occupation was characterized by a more specialized emphasis on mollusks from sandy beaches (for instance, *Arca* spp., *Codakia orbicularis*), and the disappearance of mortars and pestles, suggesting a decline in the use of seeds, roots, and berries.

The third adaptation was based on fishing and mollusk gathering from beaches and mangrove swamps. It is distinguished by the high frequency of shell tools and occurs in Sambaqui-type shell mounds in northern Venezuela, including the offshore islands of Cubagua and Manicuare, Trinidad, Cuba, and the Dominican Republic (Sanoja Obediente and Vargas 1983). These sites date to around 4000 B.C. in Venezuela and 2000 to 1200 B.C. in Cuba and the Dominican Republic.

These relationships among the peoples whose material remains have been used to characterize these adaptations await further specification. It is interesting to note that in contrast to the horticultural Saladoid peoples, whose earliest adaptation seems to have emphasized terrestrial resources, the Archaic peoples had a more pronounced emphasis on the marine environment. Davis (1988) has commented on the absence of land crabs in Archaic sites, given the importance of land crabs in early Saladoid sites. It is likely that the availability of an efficient calorie producer (manioc) allowed the early Saladoids to pursue the higher-ranked but less abundant animals of the interior, whereas the Archaic peoples had to emphasize calorie capture in coastal habitats. The shift to marine resources by Saladoid peoples shows a convergence in diet with regard to protein capture that would reflect the decline in terrestrial animals.

When Old Met New

The arrival of the Spanish brought dramatic changes to the circum-Caribbean (Keegan 1996). The most notable change was the rapid decline in the native population due to warfare, disease, and abuse. Prior to their demise, the native peoples were the major suppliers of food for the European colonists. By 1497 the five major *cacicazgos* (regions ruled by a paramount *cacique* or chief) were providing tribute in the form of food and labor, a practice that mirrored tribute made to Taino caciques (Moscoso 1986). Manuel García-Arevalo (1990: 272) has noted that "dietary patterns and foodways were among the most important of the Taino contributions to be integrated into colonial culture" and that "cassava bread came to be known as the 'bread of the conquest.'"

The Spanish also introduced a variety of animals into these depauperate islands. Cattle *(Bos taurus)*, which were brought from the Canary Islands multiplied in unprecedented fashion on Hispaniola (Reitz 1986: 319, 1988), where cattle ranching became a significant occupation (Ewen 1990). In addition, pigs *(Sus scrofa),* goats and sheep, horses (*Equus* sp.), chickens *(Gallus gallus),* and rats and mice *(Rattus norvegicus, R. rattus, Mus musculus)* were introduced, the latter as unintended stowaways (Crosby 1972, 1986; Reitz 1986). It is interesting to note that the Spanish presence in early contact-period sites is more often identified by the occurrence of pig and rat bones than by European objects (Deagan 1988). Cattle, pigs, goats, and chickens adjusted to the climate. Pigs were so well adjusted that they were released on islands to form feral herds that could be hunted when needed. As Charles Ewen (1991: 108–9) expressed it, "[T]he diet of the colonists [showed] a mixture of the Iberian barnyard complex of peninsular Spain and the mixed hunting-fishing strategies of the indigenous peoples."

In colonizing the circum-Caribbean, the initial Spanish objective was to recreate their Iberian homeland (Crosby 1972, 1986). The colonists who founded St. Augustine in Florida brought seed stock for planting wheat and other cereals, cuttings for vineyards, and animals for breeding stock. They soon learned that the climate and soils were unsuited to this economy. Cereals withered on the stock, olives and grapes failed to grow, and their preferred meat source, sheep, did not thrive (Scarry and Reitz 1990: 344). In addition to raising cattle, the Spaniards introduced sugarcane as a cash crop. By 1545, there were 29 sugar mills belonging to prominent people on Hispaniola (García-Arevalo 1990: 275). Sugar was the magnet for the next invasion (Mintz 1985).

Subsistence practices in the sixteenth-century Spanish colonies mirrored those of the native economies that preceded them. The major change was the use of domesticated animals as a meat source, comprising from 20 to 50 percent of the vertebrate taxa (Reitz 1986: 319). In addition, peaches, melons, and watermelons produced well (Scarry and Reitz 1990: 350). Lastly, the Spanish continued to import Old World foodstuffs that would not grow in the colonies, including wheat, olives, and wine, but these supplies were rare and unreliable (Sauer 1966). According to Margaret Scarry and Elizabeth Reitz (1990: 344–5): "One soldier testified [in 1573] that rations were often short and that 'when there was nothing they ate herbs, fish and other scum and vermin.'"

British and African Arrivals

The British colonies pursued two very different types of plantation economies. In Jamaica and the Lesser Antilles, sugarcane was grown by slave labor for export, whereas in the Bahamas, cotton, utilizing far fewer slaves, was the main commodity (Craton 1978; Riley 1983; Saunders 1985; Craton and Saunders 1992). In both areas the vegetable portion of the meal was grown largely on provision grounds, although wheat flour and locally unavailable foodstuffs were imported. Indian corn (*Zea mays*) was the staple. In addition, true yams (*Dioscorea* sp.), sweet potatoes, eddoes (*Colocasia* sp.), okras (*Hibiscus esculentus*), pigeon peas (*Cajanus cajan*), red peas or cowpeas, black-eyed peas, snap beans, cabbage, pumpkins, castor oil, and Guinea corn (sorghum) were also grown (Farquharson 1831–2; Handler and Lange 1978). The new additions to this list were imported from Africa and Asia in the course of the slave trade. Kimber (1988) provides a remarkable discussion of plant introductions and use on the island of Martinique.

Some livestock and fowl were raised on the plantations, but most of the meats that were consumed were imported. Imports included salt beef and salt pork. It is ironic that salt fish, imported from North America, was a staple. In the study of faunal remains at Drax Hall, Jamaica, Douglas Armstrong (1983) detected little in the way of fresh fish, mollusks, or other sorts of wild game. However, following emancipation, there was a strong reliance on rocky intertidal mollusks.

Although foodstuffs were usually distributed to slaves for cooking, a main meal was sometimes served from a central kitchen on Barbadian plantations in the nineteenth century (Handler and Lange 1978). Slaves prepared their meals on an open fire by roasting or boiling. Jerome Handler and F. W. Lange suggest that meals were nutritious and monotonous, and that food allowances were often of insufficient quantity. As a result, the theft of food was common, and it was not considered wrong to steal from the master.

Slaves were also given allowances of rum, one effect of which was a condition called "dry bellyache." Handler and colleagues (1986) have shown that dry bellyache was caused by lead poisoning. Lead was the "demon" in rum; it was used in the equipment in which rum was distilled.

D. Gail Saunders (1985: 166) and others have noted that African foods such as accara, foo-foo, agedi, and my-my are remembered and still cooked in the Bahamas today. She describes accara as being a patty made with black-eyed peas, okras, onion, red peppers, flour, thyme leaves, tomato, and salt. With emancipation, what was remembered of African foodways was mapped onto the local environment.

Garifuna Diet

All of the preceding examples find their ultimate expression in the Garifuna. The Garifuna, often referred to as Black Caribs, presently occupy the coast of Central America from Belize to Nicaragua. They developed from intermixture of the Island Caribs and Africans in a social environment that was manipulated by white Europeans. By 1700, a new society that was racially and culturally distinct from the Island Caribs had developed on St. Vincent (Kirby and Martin 1972). What is striking about the Garifuna is that their diet reflects "the various exotic cultural influences experienced over the past 400 years" (González 1988: 98).

The best-known item in the Island Carib diet is human flesh. It was in reference to the Island Caribs that the term "cannibal" originated. More recently, investigators have questioned whether the Island Caribs did, in fact, consume human flesh or whether this practice was ascribed to them in order to permit their capture as slaves under Spanish law (Myers 1984; Davis and Goodwin 1990; Wilson 1990). The present consensus is that anthropophagy was practiced in ritual settings, perhaps even as a display of fierceness, but that it never served as a source of dietary protein as has been suggested for the Aztecs (Harner 1977; compare Garn 1979).

It is likely that many of the cultigens attributed to the Tainos were also cultivated by the Island Caribs. The staples of their diet were cassava bread made from bitter manioc, and fish. They also cultivated sweet potatoes, chilli peppers, peanuts, beans, guava, soursop, and mamey. Pineapple (*Ananas comosus* [L.] Merr.) is described as having been fermented into wine (Rouse 1948; Sturtevant 1969), an activity still practiced by the Garifuna.

Oranges, citrons, grapefruits, figs, rice, bananas, and plantains were introduced from the Mediterranean by the Spanish (González 1988: 101). Cacao was introduced from the mainland because of its importance as a European trade item, an importance it maintains today. The introduction of coconut, the most important source of oil for the Caribs, is not recorded. The Spanish also introduced fowl and pigs. Feral pig herds achieved substantial numbers following their release. Okra, akee (*Blighia sapida* Konig), pigeon peas, marijuana, senna (*Cassia italica*), yams (*Dioscorea* sp.), sorghum, and plantains accompanied slaves from Africa (Sturtevant 1961; Grimé 1979; González 1988: 101). Finally, mangoes, sugarcane, coffee, and arrowroot (*Maranta arundinacea*) were introduced at an early date, the latter by the Tainos (Sturtevant 1969; Handler 1971; González 1988: 101; Newsom 1993). Nancie González's (1988: Table 5.1) summary of modern ceremonial foods by probable date of introduction neatly summarizes the successive waves of culinary influence (Table V.D.3.4).

Table V.D.3.4. *Garifuna ceremonial foods and the probable time of their introduction*

	Prehistoric	Sixteenth century	Nineteenth century	Twentieth century
Uwi	Fish Iguana Crab Fish roe	Chicken Eggs Pork	Lobster White cheese	Bologna
Breadkind	*Areba* Malanga Cassava gruel Sweet potato pudding Sweet manioc	–	Plantains Tamales Green bananas Rice and beans Banana fritters Tomato slices Rice gruel	Spaghetti White bread Cabbage
Sweets	–	Mangoes Watermelon	Coconut candy Cashew fruit	Cookies Hard candy
Beverages	*Hui*	–	Rum Coconut water	Kool-Aid Coca-Cola Orange pop Beer

Source: After González (1988), Table 5.1.

Through the eyes of the Garifuna, Nancie González (1988) describes the progressive homogenization of tropical diets among peoples of African ancestry. The pepper pot of the Island Caribs has today been replaced by *falmou,* a concoction of fish, tubers, and coconut milk. Both *Capsicum* (chilli peppers) and *cassirepe* (boiled juice of bitter manioc) have fallen out of favor. Fish stews similar to *falmou* are also popular with the Miskitos and other Belizean creoles (Nietschmann 1973: 37). Bitter manioc continues as an important source of food, and it joins maize, rice, and wheat as ubiquitous starches, along with mango, papaya, and watermelon as ubiquitous fruits on both sides of the Atlantic (González 1988: 105-6). Yet despite this convergence in food items, the menus maintain their separate ethnic dimensions.

Summary

Caribbean diets were strongly influenced by the diffusion of domesticated plants and animals. The initial conditions were established more than 10,000 years ago as biogeographic processes shaped the indigenous vegetation and fauna (Watts 1987). With the arrival of humans, this landscape was irrevocably modified to serve human needs. It is possible that the earliest immigrants did not bring new plants or animals with them, and that their procurement strategies had little impact on the islands. They were, however, followed by extensive horticulturalists who slashed and burned the forests and introduced a suite of new plants. Every wave of immigrants brought new cultigens and new ways to process or prepare those that were already present. In the end, the more than 40 different cultigens have been mentioned in this review.

Animals were also introduced. The earliest introduction was the dog, and others, such as hutia, agouti, and guinea pig, had their insular distributions enlarged. The Spanish made the biggest impact, bringing cattle, chickens, goats, rats, sheep, horses, and donkeys. These animals helped transform luxuriant tropical vegetation into scrub forage. As some animals were introduced, others became extinct (Olsen 1982; Morgan and Woods 1986). Manatee, monk seal, and sea turtles are either extinct or nearly so, and even the ubiquitous queen conch is now in short supply (Hesse and Hesse 1977).

Today, most West Indians have forsaken agriculture and instead rely on imported foods. For instance, Ifill noted in his study of Grenada that "in 1974 the estimated daily calorie intake per capita was 1,958.4 of which 1,535.9 [was imported]. . . . With respect to protein per capita, daily intake was 46.03g, of which imported food supplied 31.72g" (quoted in Brierley 1985: 52). Despite this national reliance on imported foods, rural peoples remain dependent on local production on both provision grounds and kitchen gardens.

This infield (kitchen garden)-outfield (provision grounds) division finds its recent origins in the slave plantation economy, but it mirrors practices that can be traced to South America and Africa. Present-day kitchen gardens reflect both continuity with and a synthesis of the past. For example, J. S. Brierley's (1985: Table 2) list of 20 common plants in Grenadian kitchen gardens includes crops from South America, Africa, Asia, Europe, and Oceania, as well as the Caribbean (1985: Table 5). As Brierley (1985: 55) points out, these are not simply a random selection of available cultigens; rather, the "nutritional balance of [the] crops must be attributed . . . to traditional knowledge and a process of selection governed by the dietary needs and ecological potential of the region."

Despite repeated waves of new peoples and new dietary items, the climate and ecology have shaped culinary practices. Until the very recent reliance on a cash economy, diets have been shaped by the low-cost caloric productivity of root crops (manioc, sweet potato, yams, dasheen), the paucity or expense of terrestrial animals (hutias, iguanas, cattle, sheep, and goats), and abundant but labor-intensive marine organisms (fishes, turtles, queen conch). In some ways, the more things changed, the more they remained the same. One result is a convergence of diets throughout the tropics as cultigens and animals are shared around the world.

William F. Keegan

Notes

1. Manioc occurs in both bitter and nonbitter ("sweet") varieties, although these varieties are members of the same species.

V.D.4 The Caribbean from 1492 to the Present

Following 1492, the Caribbean basin became a cultural meeting ground that remains unsurpassed for the variety of influences: European, Asian, African, and American. At times, the clash of cultures led to tragedy, such as the destruction of pre-Columbian Indians by European diseases or the centuries of African enslavement on sugar plantations. But the Caribbean people have also produced cultural triumphs, not the least of which are the tropical dishes of island cooking.

Cuisine can provide important insights into the process of cultural change. Each new group of immigrants to the Caribbean, from Taino "natives" (originally from South America) to Spanish conquistadors and from African slaves to Asian laborers, brought with them their knowledge of foods and how to prepare them. Island cuisine drew together maize and manioc from America, domesticated pigs and cattle from Europe, garden plants, such as okra and akee, from Africa, and citrus fruits and rice from Asia. Unfortunately, notwithstanding this rich variety of foods, poverty has made malnutrition a recurring problem in the region. Slaves (and many whites) suffered from a frightful variety of nutrition-related diseases, many of which have returned to haunt the impoverished masses of the twentieth century. Modernization has, meanwhile, threatened to replace traditional dishes with a processed and packaged uniformity of industrial foods. But island cooks have adapted to pressures, both economic and ecological, to create a genuinely global cuisine with a uniquely local taste.

The Columbian Exchange

The arrival of Europeans transformed the ecology of the Caribbean basin, but it did so in an uneven manner. Sixteenth-century Spaniards concentrated their colonizing efforts on the Greater Antilles, comprising Cuba, Hispaniola, Jamaica, and Puerto Rico. The newcomers brought with them the staples of Mediterranean life, including plants, animals, and diseases (the latter having a disastrous impact on the native population), but they made little effort to consolidate their hold over the region. The Lesser Antilles, stretching from the Virgin Islands just east of Puerto Rico to the Venezuelan coast, did not attract European attention until the seventeenth century, when British, French, Dutch, and Danish colonists began challenging the Iberian New World monopoly. These new settlers, although left with only smaller islands unsettled by the Spanish, soon built wealthy plantations based on sugar harvested by African slaves. By the eighteenth century, the sugar economy had spread to encompass virtually the entire Caribbean.

Culinary Encounters

Spanish settlers, having exhausted the Caribbean's scant gold deposits within a few decades, recognized that a different approach was necessary in order to make their fortunes in the New World. For a model, they looked to the Canary Islands, off the coast of Africa, which had fallen to Spaniards in the last two decades of the fifteenth century. The natives there had quickly disappeared, either through death from European diseases or through intermarriage with European settlers, and the conquerors had reshaped the islands' ecology by introducing Mediterranean plants and animals. Spanish settlers hoped to create still more of these island replicas of Europe in the Caribbean (Crosby 1986: 80-100).

The Taino inhabitants of the Caribbean consumed foods that were quite different from those of Europe.

Their staple crops were not grains but rather roots, such as manioc *(Manihot esculenta),* sweet potato *(Ipomoea batatas),* and tania (*Xanmthosoma* spp.). Maize *(Zea mays)* was also cultivated although it did not add significantly to the native diet. Islanders prepared cassava "bread" from the poisonous manioc by grating the root, squeezing out its toxic juice, pressing the meat into a flat bread, and baking it on a griddle. Native fruits and vegetables included pineapple *(Ananas comosus),* guava *(Psidium guajava),* mamey *(Mammea americana),* pawpaw *(Carica papaya),* cashews *(Anacardium occidentale),* common beans *(Phaseolus vulgaris),* and lima beans *(Phaseolus lunatis*). These plants occasioned different reactions from the Europeans, who ate some eagerly and fed others to pigs. The conquistadors marveled at the game eaten by the Indians – "all sorts of wild and poisonous beasts" – including dogs, snakes, rodents, raccoons, armadillos, lizards, tapirs, opossums, and spiders. Seafood was more to the Spaniards' taste, with such items as bagre (a catfish of Caribbean and South American waters), mullet, herring, mackerel, tunny, shark, rayfish, dogfish, crayfish, shrimp, mussels, clams, oysters, crab, conches, and turtles (Morison 1963: 216–19; Sauer 1966: 53–9; Newson 1976: 41–57).

Notwithstanding the bountiful native foods, European settlers yearned for more familiar fare. Their habitual Mediterranean cuisine consisted of three staple items: wheat bread, olive oil, and vinifera wine. Spaniards considered wheat *(Triticum aestivum)* essential for both body and soul. According to an eleventh-century papal edict, it was the only grain that could serve as the Holy Eucharist (Ross 1977: 61–9). Wine from grapes *(Vitis vinifera)* fulfilled an equally important role in the Catholic Mass as the blood of Christ. And although priests could proceed in their work without olives *(Oleo europea),* Spanish cooks certainly could not. Christopher Columbus brought wheat seeds on his second voyage in 1493, but the grain refused to grow in the tropical climate, and transplanted vine cuttings and olive seedlings fared no better. Even imported Communion wafers "did bend like to wet paper, by reason of the extreme humidity and heat" (Crosby 1972: 65; Newson 1976: 84–6).

European livestock, by contrast, multiplied rapidly in the islands. In 1493 Columbus introduced horses, cattle, pigs, goats, and sheep to the New World. The goats and sheep proved ill adapted to the humid Caribbean air, but the other animals prospered. Diego Velázquez claimed that by 1514, the pig population of Cuba had increased to 30,000. Puerto Rico became an important center of cattle raising and exported large quantities of jerked beef and prepared hides during the seventeenth century. Spanish sailors purposely turned breeding stock loose on islands so that future visitors would have access to pork and beef. Unfortunately, rats and other vermin, inadvertently carried by the Europeans, likewise became firmly established on the islands (Crosby 1972: 75–9; Newson 1976: 88–90; Dietz 1986: 8).

Caribbean gardens and orchards became much more diverse as a result of the Columbian exchange. Colonists planted cabbages (*Brassica* sp.), onions *(Allium cepa),* carrots *(Daucus carota),* lettuce *(Lactuca sativa),* radishes *(Raphanus sativus),* garlic *(Allium sativum),* and chickpeas *(Cicer arietinum).* Large numbers of Asian plants arrived in the New World during the sixteenth century. In some cases, they had previously been introduced to Spain by the Muslims; in other instances, they reached the Caribbean via the slave trade. Citrus fruits included lemons *(Citrus limon),* limes *(C. aurantifolia),* and sour oranges *(C. aurantium),* as well as the European sweet orange *(C. sinensis).* Other Asian plants that thrived in the Caribbean were muskmelons *(Cucumis melo),* pomegranates *(Punica granatum),* plantains and bananas *(Musa paradisiaca sapientium),* eggplants *(Solanum melongena),* ginger *(Zingiber officinale),* cinnamon *(Cinnamomum zeylanicum),* and rice *(Oryza sativa).* Coconuts *(Cocos nucifera),* of undetermined origin, were present on the Pacific Coast in pre-Columbian times, but Spaniards probably introduced them to the Caribbean. The most significant of the new arrivals, however, was sugarcane *(Saccharum officinarum),* which ultimately dictated the social structure of most of the region (Watson 1974: 8–35; Newson 1976: 46, 84–7).

These new crops gave little compensation to the natives for the destruction caused by European diseases and labor drafts. Conquistadors received grants of Tainos entrusted to their care *(encomienda),* ostensibly for conversion to Christianity, but certainly as a source of labor as well. Moreover, the Spanish crown condoned outright slavery in the case of Carib tribes because of their "warlike nature" and supposed cannibalistic practices. The harsh working conditions for both Tainos and Caribs alike would have precipitated high death and low birth rates. But epidemics, such as that of smallpox, which began in 1518, also joined in the slaughter because the Indians had little resistance to European diseases. Indeed, it was with only small exaggeration that Bartolomé de las Casas claimed in 1542 that the Caribbean natives had virtually disappeared. By 1570, Indians in the Spanish Antilles numbered 22,000, a fourth of the entire population of those islands. And having resisted enslavement for centuries, a handful of Caribs survive to the present on Dominica (Sauer 1966: 203–5; Newson 1976: 149, 170; Knight 1990: 41–3; Hulme and Whitehead 1992: 345).

Following the conquests of Mexico in 1521 and Peru in 1532, the majority of colonists proceeded to the mainland, hoping to make their fortunes from Indian labor and silver mines, and the Greater Antilles were left with only a few small settlements of people who subsisted on corn and cassava. Havana became the leading port because of its strategic location on the route of silver fleets returning to Spain. For the next two and a half centuries, Spain's Caribbean colonies served mainly as defensive outposts, guarding against incursions by rival European powers.

The Tyranny of Sugar

Spaniards established sugar mills on Hispaniola as early as 1515 and operated a thriving business in the mid-1500s, but by the end of the century production had stagnated. Portuguese plantations in Brazil then dominated New World sugar production until 1630, when the Dutch West India Company invaded the South American colony. After the Dutch were finally driven out, they carried the Brazilian techniques to French and English planters in their newly founded colonies in the Lesser Antilles.

Sugar monoculture first took root in Barbados and then spread to other British and (later) French islands. The initial settlers of Barbados had made a meager living growing low-quality tobacco and cotton on small estates. But the introduction of sugar by Dutch merchants, beginning in the 1630s, transformed the island. Thanks to Europe's developing sweet tooth, the new industry proved enormously profitable, causing land values to rise astronomically. Smallholders sold out to an emerging planter elite, who, in their hunger for land, cleared much of the remaining forests until most of the island's acreage was planted in cane or food crops to feed whites and their slaves. But Europeans on the islands soon became a minority as tens of thousands of African slaves were imported to work the plantations. By 1680, sugar estates had gained similar domination over the rest of the British Antilles. The French were slower to make the transition from small farms, where they grew tobacco and cotton, to large plantations devoted to sugarcane grown by slaves. Nevertheless, by the mid-eighteenth century, Saint-Domingue, Guadaloupe, and Martinique had become major centers of sugar production, and by the latter part of the century, Caribbean sugar production amounted to nearly a quarter of a million tons (Dunn 1972: 46–62; Mintz 1985: 32–5; Watts 1987: 296–300; Tomich 1990: 15).

Sugar exports from the Spanish Antilles did not revive until the mid-eighteenth century. Royal trade regulations prevented colonial producers from selling sugar to northern European markets and limited the supplies of African slaves. Tax reforms undertaken in the 1740s reversed this situation, and exports to Spain increased massively. This trend accelerated in 1762 after British forces had captured Havana and imported thousands of additional slaves. When the Spanish regained control of the island the following year, they allowed Britain to continue trading with the port, and delighted by the additional tax revenues, officials encouraged cane production on Puerto Rico and Hispaniola as well. By the mid-nineteenth century, following the revolution on Saint-Domingue, Cuba had become one of the most profitable colonies in the world (Hall 1971: 98–100; McNeill 1985: 162–70; Dietz 1986: 19–20; Watts 1987: 301–4).

One final element of the Columbian exchange that resulted directly from the labor demands of sugar plantations was the transportation to the New World of huge numbers of African slaves. Philip Curtin (1969: 265–9; 1976: 595–605) estimated that Caribbean planters imported almost 5 million slaves, fully half the total brought to the Americas. And with them came African foods. Plants introduced to the Americas via the slave trade included watermelons *(Colocynthis citrullus),* okra *(Hibiscus esculentus),* taro *(Colocasia esculenta* – called eddo in the West Indies), oil palms *(Elaeis guineensis),* pigeon peas *(Cajanus cajan),* and yams (*Dioscorea* spp.) (Harris 1965: 92–3, 115; Newson 1976: 161). But familiar foods notwithstanding, the journey to America made significant changes in the diets of enslaved Africans.

Plantation Nutrition

The food aboard slave ships provided an ominous portent of life in the New World. The standard fare consisted of a dreary soup of rice, yams, horsebeans, palm oil, and red peppers. Illness followed the slaves throughout the voyage, from the initial shock of seasickness to lingering bouts of dysentery and, finally, the bleeding gums of scurvy (Kiple 1984: 57–64). A slave who survived the trip could expect little improvement on the plantation because, as J. Harry Bennett (1958: 37) explained, "he ate from his master's purse, and every mouthful was measured in cash." Virtually every nutritional deficiency disease was experienced by slaves somewhere in the West Indies. But although the African population ate poorly, Europeans spared no expense on their own, often imported foods.

Slave Subsistence

Sidney Mintz (1985: 55–61) has demonstrated that Caribbean sugar plantations, although worked by slave labor, were managed as capitalist enterprises. Planters faced enormous risks in the fluctuating world sugar market and sought to minimize their operating expenses whenever possible. Although buying slaves represented a substantial fixed investment, feeding them offered endless opportunities for cost cutting. Thus, in the early years when sugar prices were high, many estate managers planted every available acre in cane and fed their slaves with imported grain and dried meat. But as competition drove prices down, planters economized by reducing rations and allowing slaves to cultivate subsistence crops, especially on mountain slopes unfit for sugar cultivation. But despite marginal lands and limited free time, slaves with their own fields consumed a better diet than those who worked exclusively in the cane fields.

In practice, plantation diets fell between the two extremes of entirely ration-fed slaves and those who had to be self-sufficient. But even on the most heavily planted sugar islands, such as Barbados, Antigua, and St. Kitts, slaves kept small kitchen gardens with herbs, squash, peppers, and okra, and certain fields called "Negro fields" or "Negro ground" were set aside for slave use. Conversely, on islands with large areas of mountainous terrain, such as Jamaica and Martinique, plantation managers often bought staples, including corn, rice, manioc, yams, plantains, and bananas, rather than allocating provision grounds and free time to the slaves. Moreover, slaves on virtually all of the islands depended for animal protein on imports of dried meat and salted fish (Kiple 1984: 67; Morrissey 1989: 51–7;Tomich 1990: 271).

Mercantile policies dictated that provisions for the Caribbean sugar islands come from within each empire.Thus, British merchants supplied their plantations with salt cod and corn from New England, jerked beef from Ireland, herring from the North Sea, and rice from South Carolina. Many smaller Jamaican estates with less-favorable lands also produced staple crops for sale to the sugar plantations (Milling 1951: 82; Dunn 1972: 210, 276; Kiple 1984: 69).The French settlements of Guadeloupe, Martinique, and Saint-Domingue, meanwhile, imported a significant portion of the codfish harvested off Newfoundland (McNeill 1985: 112).And as Spanish sugar production expanded in the nineteenth century, planters on Cuba and, to a lesser extent, Puerto Rico began importing large quantities of rice and jerked beef (Humboldt 1969: 305; Dietz 1986: 19–20).Yet despite the intentions of colonial officials, smugglers cut across imperial lines on a regular basis (Liss 1983: 77; Pérotin-Dumon 1991: 65).

Imperial regulations also attempted to assure that slaves received adequate rations.The French *Code Noir,* promulgated in 1685 by Finance Minister Jean-Baptiste Colbert, required masters to issue each adult slave two pounds of salted beef or three pounds of fish and six pounds of cassava bread or the equivalent of manioc flour. British slave codes were more concerned with preserving order than protecting slaves, and it was not until the late eighteenth and early nineteenth centuries that a standard ration of about three pounds of meat or fish per week began to be prescribed. Eighteenth-century Spanish authorities, likewise, made belated calls for a weekly meat ration of three pounds. But once again, plantation reality differed sharply from imperial regulations, and many managers admitted feeding their slaves half of the required amounts, and they were often in such a rancid state that most of the nutrients were gone. Although slaves responded by stealing food whenever possible, this expedient was no substitute for adequate rations (Dunn 1972: 239; Friedman 1982: 507; Kiple 1984: 68, 77; Dirks 1987: 61–7, 100; Stein 1988: 52).

Slaves prepared their rations using simple cooking techniques taken from their African homelands or borrowed from native Indians. Cassava bread was made by means of pre-Columbian procedures for removing the toxic juice and then baking the grated flesh into a flat bread. Slaves who grew their own maize on provision grounds preferred to roast whole ears and eat them on the cob. But as a ration, they typically received corn in the form of meal, which was made into a thin gruel called "loblolly" or "coo-coo." Other foodstuffs, including salted meat or fish, yams, plantains, and vegetables, were boiled together in an iron pot.The ingredients of these stews varied among the islands according to availability. For example, slaves on Antigua reportedly ate a breakfast of eddo (taro), okra, yams, and other vegetables. On Jamaica, the pepper pot contained greens, such as callaloo, starch from yams or plantains, red pepper, and bits of fish (Harris 1965: 115; Dunn 1972: 278–9; Kiple and Kiple 1980: 202; Dirks 1987: 53–4).

Even this simple fare was threatened in the late eighteenth century, however, when imperial warfare and natural disaster led to a major subsistence crisis. Trouble began in 1774 when the American Continental Congress resolved to stop exporting goods to British dominions, including the West Indies. By 1776, the revolutionaries succeeded in rendering the British sugar industry unprofitable, and famine appeared on Barbados, Antigua, and St. Kitts. At first, Jamaican slaves fared better because of the availability of provision grounds. But beginning in 1780, the islands were struck by a series of hurricanes that killed thousands and destroyed provisions. Even after the final storms of 1786, thousands more died from malnutrition, dysentery, and other epidemic diseases. The British government compounded the disaster by refusing to allow a resumption of trade with the newly independent United States (Sheridan 1976: 615–41; Dirks 1987: 80).

The decade-long crisis demonstrated the need to make the islands more self-sufficient. One response of the British government was to import new food crops to the islands. In 1778, slave ships brought the akee fruit *(Blighia sapida)* to Jamaica from West Africa. An Asian domesticate, the mango *(Mangifera indica),* arrived a few years later, and both fruits became important for slave subsistence. In 1787, the Royal Navy dispatched HMS *Bounty* under William Bligh to bring the breadfruit *(Artocarpus incisa)* from Tahiti. Thwarted at first by a notorious mutiny, in 1793 Bligh succeeded in his mission with the HMS *Providence,* earning a handsome reward from the Jamaican assembly. Unfortunately, the Jamaican slaves refused to eat the unfamiliar fruit, and for the next fifty years it was fed to pigs (Parry 1955: 1–20).

A more important change came from the expansion of slave provision grounds and slave markets. Slaves in Jamaica and Saint-Domingue had long produced staple crops on their provision grounds, and they even dominated the island markets. Amelioration laws, issued in the British Antilles late in the eighteenth century, encouraged more slaves on other islands to grow their own provisions. French officials on Martinique likewise allowed provision grounds and free time to grow substitutes for the rations handed out by masters (Mintz 1974: 180–213; Kiple

1984: 67–71; Tomich 1990: 262–5). And slaves who produced their own foods ate substantially better diets. According to Barry Higman (1979: 373–86), better nutrition was the reason that American-born slaves grew taller in the Bahamas than on islands where sugar was the primary crop. But despite attempts at amelioration, slave diets contained grave deficiencies.

Diet and Disease

One of the most notable aspects of the West Indian sugar industry was the failure to develop a self-sustaining slave population. Caribbean planters, unlike their North American counterparts, had to import tens of thousands of workers each year to replace those who had died. This policy may have developed in the seventeenth century from the cold calculation that it was more expensive to maintain slaves in good health than to work them to death and import replacements. But planters did not see their work force reproduce even after the abolition of the slave trade in the nineteenth century. One of the primary reasons for the slaves' failure to reproduce was the inadequate levels of nutrition. Diet-related diseases ran the gamut from protein and vitamin deficiencies to hypertension and lead poisoning.

Kenneth Kiple (1984: 77–81) has shown that slave diets were nutritionally deficient even if slaves actually received the provisions specified by legal requirements. For example, prescribed rations of dried beef and fish would appear to have exceeded the modern recommended dietary allowance of protein, but in fact, the slaves received these foods in a less-than-ideal state. One observer described the fish as "little better than a mass of foetid matter, containing as little nutrition as the brine in which they lie" (Kiple 1984: 80). Beef likewise lost much of its protein from the curing process. Protein deficiency weakened the slaves' immune systems and led in turn to widespread outbreaks of tuberculosis, dysentery, and other infectious diseases. Poor sanitary conditions unquestionably contributed to these epidemics, but slaves could have resisted many of these diseases with adequate supplies of protein (Kiple 1984: 142–3; Dirks 1987: 85).

Kiple has also documented shortages of most important vitamins, as well as calcium and iron. The most serious problems resulted from deficiencies of vitamin B_1 (thiamine) and B_3 (niacin). Slaves subsisting on white rice were at risk of developing beriberi, a thiamine-deficiency disease that takes two distinct forms. Both wet beriberi, with symptoms including swelling of the limbs and cardiac failure, and dry beriberi, characterized by muscular deterioration and paraplegia, were common to the Caribbean under the names "dropsy" and *mal d'estomach.* Corn rations, meanwhile, led to pellagra, a niacin-deficiency disease that caused dermatitis, dysentery, dementia, and death. Requirements for other vitamins, such as A and C, might have been satisfied by tropical fruits and chilli peppers. Unfortunately, low quantities of dietary fat prevented full utilization of vitamin A, and as a result, night blindness often reached epidemic proportions. The incidence of scurvy symptoms, including bleeding gums, festering wounds, and frequent bruises, implies a similar deterioration of vitamin C, probably due to excessive cooking. Deficiencies of A and C also slowed the absorption of calcium and iron, leading in turn to rheumatism, periodontal disease, dental caries, and anemia, although iron cooking pots would have helped offset the latter problem (Kiple 1984: 76–103).

Nutritional diseases took their worst toll among young children. Malnourished mothers often gave birth prematurely, and even full-term infants were often significantly underweight. The mother's poor health continued to have an adverse effect on her children throughout nursing. Neonatal tetany, caused by calcium shortages in the mother's milk, killed large numbers of infants in the first few weeks of life. Thiamine deficiencies were also passed on to children in the form of infantile beriberi because slave mothers, who did not themselves display symptoms of beriberi, were often unable to provide sufficient quantities of thiamine to their children. Youngsters, even after surviving the critical first year, still faced great risk at the time of weaning. The gruel given to replace a mother's milk contained little protein, and physicians frequently reported the swollen bellies symptomatic of kwashiorkor. Infant mortality rates on Caribbean plantations were higher even than among slaves in the United States, which helps explain the much greater number of Africans imported to the islands (Kiple 1984: 113–34; Dirks 1987: 85).

With the numerous deficiencies in the slave diet, it is ironic that one potentially serious health problem may have resulted from excessive consumption of sodium. West Africa was a particularly salt-poor region, and the inhabitants apparently adapted to this shortage by naturally retaining sodium. Experiments, for example, have shown that the perspiration of Africans contains much less sodium than that of whites. But once in the Caribbean, African slaves frequently found themselves confronted with sodium in the form of salted beef and fish, and especially with a substantial ration of salt itself. Thomas Wilson (1987: 257–68) has estimated that slaves may have received 20 times the modern recommended amount of salt. The resulting hypertension, although difficult to diagnose without a blood pressure cuff, probably contributed to the incidence of death by "dropsy." To relieve this chemical imbalance along with other nutritional deficiencies, many slaves engaged in "dirt-eating" (pica). Planters often believed this practice to be a method of committing suicide, and they muzzled slaves suspected of it (Kiple 1984: 46; Dirks 1987: 86–7).

Some Caribbean slaves also suffered from acute lead poisoning from a wide variety of sources. Water channeled by lead gutters, and foods exposed to the lead glaze of earthenware pottery, were potential sources of lead, as were lead-lined boilers and gutters used in sugar refining. Worst of all, slaves who drank cheap rum could have taken in large amounts of lead in alcohol, which was distilled in equipment with lead pipes and fittings. The body retains this excess lead in soft tissue, such as the brain, producing disastrous effects, including headaches, paralysis, coma, and death. One prominent symptom of lead poisoning was the "dry bellyache" – extremely painful intestinal cramps accompanied by severe constipation – which a contemporary described as an "excruciating torture of the bowels" (Handler et al. 1987: 140–66). Sailors, soldiers, and other poor whites also experienced this malady.

Malnourished slaves seldom challenged the society that held them in bondage; what planters feared most was the sudden burst of energy that came with the harvest around Christmas. Robert Dirks (1987: 167–84) has described the effects of relief-induced agonism, a condition of extremely aggressive behavior exhibited by people allowed to eat plentifully after a long period of semistarvation. Slaves in the British West Indies consumed little during the fall months as both sugarcane and provision crops matured. In December, when the end of the hurricane season brought merchant ships and planters handed out special bonuses of sugar, rum, and fish, the slaves suddenly had an overabundance of food. They responded by indulging in orgiastic revels of drinking, dancing, and occasional rebellion. This "Black Saturnalia" provided a temporary reversal of roles in which planters cringed as slaves approached, but after a few days of release, the slaves' world returned to its grim normality.

Dining in the Great House

Some plantation owners, while limiting slave rations to save a few pennies, often spent outlandish sums to maintain their own extravagant lifestyles. For example, the governor of Barbados celebrated a 1688 holiday by setting a 250-foot table for the island's leading citizens and opening wine casks in the streets for less distinguished souls. Richard Dunn (1972: 263–4, 280) has speculated that this penchant for conspicuous consumption derived from the hierarchical significance attached to food and clothing in early modern Europe. Each social class had a distinctive style of diet and dress, and nouveaux riches planters adhered to these standards, regardless of the discomforts involved in eating heavy roasts on a humid afternoon or wearing woolen coats and trousers under the tropical sun. But notwithstanding the determination of sweaty, constipated settlers, the islands demanded some adaptation or creolization of European cuisine.

The essentials of proper British dining comprised beef, bread, and beer, but reproducing this diet proved difficult in the tropics. Fresh meat spoiled virtually overnight, and so planters had to rely on salted beef, pork, and fish, although the fish was mackerel and salmon rather than the cheap cod fed to slaves. Wheat, likewise, tended to go bad on the long voyages from Bristol and Philadelphia; thus, planters consumed hard biscuits rather than the soft bread favored in England. Finally, beer proved highly perishable in the tropical climate, and so settlers slaked their thirst with rum, punch, fruit juices, and imported wines and brandy. But what the meals lacked in quality was made up for in quantity; dinner parties with heavily piled tables constituted the sine qua non of planter affluence. A guest at one such party was so impressed by a table with massive piles of meats, fruits, and cakes that she "kept her feet out from under the table for fear it would collapse" (Dunn 1972: 272–81; quotation from Dirks 1987: 45).

The Creole inhabitants of Cuba and Puerto Rico similarly sought to recreate traditional Spanish life in the tropics. Havana cooks used olive oil and garlic with a Mediterranean generosity that overwhelmed Fanny Calderón de la Barca (1966: 28), the Scottish wife of a Spanish minister, on her visit to the island in 1839. She did, however, take great pleasure from the custards, ices, meringues, and other Spanish sweets available on the island. Berta Cabanillas de Rodríguez (1973: 336) likewise emphasized the Spanish character of recipes in the anonymous 1849 volume *El Cocinero Puertorriqueño.* To satisfy the demand for Iberian foods, the islands imported large amounts of Mexican wheat flour and Spanish wines and liquors (Humboldt 1969: 300; Lipsett-Rivera 1990: 463).

Frenchmen living on Guadeloupe, Martinique, and Saint-Domingue were no less eager to enjoy the foods of their homeland. Dominican priest and bon vivant Père Jean-Baptiste Labat imported French wine to the Caribbean as early as 1693 and insisted on drinking a glass with dinner, even after he had been captured by the Spanish. A nineteenth-century visitor observed that French cooking in the Antilles was done in the style of Provence rather than Paris, with olive oil instead of cream, perhaps as a concession to the environment. But French bread remained an invariable staple, and bakeries on Martinique employed women to carry fresh loaves to country estates on a daily basis so that planters did not have to forgo this national treasure (Hearn 1970: 112, 350; Labat 1970: 57, 186).

Despite these links with metropolitan capitals, Europeans never escaped their dependence on African slaves. On the islands of Jamaica and Saint-Domingue, slaves dominated local markets with produce from their provision grounds. They reportedly drove very hard bargains, and even merchants complained that they could not afford fresh eggs, poultry, and produce. If having to buy groceries from slaves caused consternation among whites, the fear that the food might be poisoned provoked genuine terror. Mass hysteria swept Saint-Domingue in the 1780s, and a number of slaves suspected of using poison were put to death. A fear of the slaves was not unfounded, as demonstrated by a slave rebellion in the 1790s that destroyed the colony's sugar economy and threatened the entire Caribbean plantation society (Hall 1971: 68–72; Geggus 1991: 100).

Modern Diet and Nutrition

In 1789 the French declared liberty to be one of the "rights of man," and a short time later the slaves of Saint-Domingue launched their own revolution to attain this goal. After more than a decade of fighting, in 1804 Haiti finally gained independence; to preserve it, the former slaves systematically destroyed the island's sugar economy. Terrified of the Haitian revolution, Caribbean planters fought hard to prevent its spread. Emancipation came slowly to the region. It began in the British colonies in 1834 (followed by a so-called apprentice period) and culminated in Cuba in 1886. However, as emancipation proceeded, planters replaced the slaves with indentured servants from the Far East. Independence, likewise, remained elusive. As European empires retreated, the United States came to dominate the region. Cuban and Puerto Rican sugar plantations passed into the hands of companies like the American Sugar Refining Company, while the cane workers remained destitute. So, although the citizens of the islands long ago escaped slavery, they have subsequently gained only limited control over their destinies.

Asian Transplants

Even as European legislators debated slave emancipation in the early 1800s, Caribbean planters began searching for an alternate source of labor. Imperial expansion into the Far East offered the prospect of endless supplies of indentured Asians to replace the liberated African slaves. In 1838, the year in which slavery ended in the British Antilles, the first boatload of indentured servants arrived from India. Cuba, likewise feeling the pinch of British abolitionism because of the Royal Navy's war on the slave trade, began to encourage Chinese migration from ports opened after the first Opium War (1839–42). Indentured Asians suffered working conditions little better than those of African slaves, but fortunately, the period of servitude ended much more quickly. By 1920, when the last indenture contract was canceled, Asians had made a significant impact on Caribbean culture and cuisine.

The number of Asian workers who migrated to the West Indies, although fluctuating with the sugar market, totaled more than 500,000 by the end of the nineteenth century. The typical contract specified five- to seven-year terms of indenture and offered minuscule wages, but agents stationed in the ports of Calcutta and Madras had no trouble attracting workers from the impoverished Indian countryside. British Guiana and Trinidad received the majority of the Indian migrants, about 380,000 in all, while some 45,000 went to Jamaica and other British islands. In 1860 the British government allowed French agents to recruit 6,000 Indians annually to work in the West Indies, and a decade later the Dutch received a similar concession. Only about 18,000 Chinese migrants went to the British Antilles. Cuba was their preferred destination, and between 1847 and 1874, nearly 125,000 Chinese came to work on Spanish sugar plantations (Tinker 1974: 52–4, 99, 112; Look Lai 1993: 292).

Indenture contracts usually required workers to return to their homeland at the end of the term, but Asians nevertheless established permanent communities on a number of islands. East Indians in Trinidad took advantage of slumps in the sugar market to entrench themselves in the local economy by growing rice. Chinese immigrants, meanwhile, sought to establish a niche in the Caribbean grocery trade. Competition from these newcomers was often resented, and Chinese people living in Jamaica sometimes became the targets of racial violence. Another barrier to the formation of Asian communities in the Caribbean was the shortage of women. Planters contracted far greater numbers of East Indian men than women; nevertheless, by the end of World War I, additional migration had evened out the sex ratio among East Indians in Trinidad and Martinique. Chinese men faced an even greater imbalance, for Cuba accepted only 62 Chinese women in the nineteenth century. As a result, men tended to marry Creoles and became assimilated more thoroughly than did the East Indians (Tinker 1974: 34, 364, 372; Johnson 1987: 82–95; Look Lai 1993: 188–216).

Asians made significant contributions to the cuisine of the islands. Rice had already been established by Spaniards and Africans centuries before the first Asians arrived. But East Indians carried *massala,* the unique spice combinations that form the basis for curry. They also introduced ghee, the clarified butter essential for traditional Hindu cooking, and roti, a form of flat wheat bread often served with curry. Foods have fulfilled an important role as part of the Hindu *yagna* celebrations that propagate religious and ethnic values in Trinidad. Chinese immigrants were more generally assimilated along with their foods, such as steamed fish and stir-fried vegetables, which became an important part of Cuban cuisine (Lambert Ortiz 1986: 7, 352; Vertovec 1990: 89–111; Mackie 1991: 144).

New Peasants, Old Problems

Caribbean slaves, once freed from the plantations, proceeded to form what Mintz (1974: 132) has called a "reconstituted" peasantry. Across the Caribbean, tens of thousands of freedmen and their families abandoned the lowland estates to build new villages in the highlands where sugarcane did not grow. The new yeoman farmers enlarged their provision grounds and expanded the production of export crops, such as allspice *(Pimenta officinalis),* coffee *(Coffea arabica),* bananas, cotton, ginger, and arrowroot, which had been grown for the first time during the later slave period. Improved nutrition led to a dramatic fall in the infant mortality rate, and African-Americans in the Caribbean finally began to reproduce their numbers naturally. The population of Jamaica, for example, nearly doubled in the half century after emancipation.

And despite political turmoil, Haiti likewise recorded demographic growth in the nineteenth century, a clear indication that the revolution improved conditions for the island's black majority (Kiple 1984: 118; Watts 1987: 456-64, 507-15).

In the twentieth century, population growth accelerated to dangerous levels, however, as a result of government programs to control disease and improve nutrition. Mosquito eradication campaigns finally began to bring yellow fever and malaria under control around the turn of the century. Authorities acted more slowly to alleviate the problems of malnutrition; nevertheless, by the 1970s, most of the islands had begun educational campaigns aimed at promoting adequate childhood nutrition. After 1959, Fidel Castro brought Cuba to the forefront of the movement to improve the health of rural children. Unfortunately, these reforms stimulated Caribbean population growth at rates in excess of 3 percent annually from 1950 to 1970 – some of the highest rates in the world. And ever-increasing populations have placed enormous pressure on island ecology. For example, Haitian peasants now cultivate subsistence crops on mountain slopes so steep that they need ropes to support themselves. The resulting erosion makes it even more difficult to sustain agriculture on the island (May and McLellan 1973: 145, 174, 220; Kiple 1984: 175-87; Watts 1987: 518).

Dietary deficiency diseases continue to afflict children throughout the Caribbean. Statistics from the United Nations Food and Agriculture Organization (FAO) reveal that the inhabitants of several islands, particularly Hispaniola, consume significantly below the recommended dietary allowances of vitamins and minerals. And because these figures represent nationwide averages, the poorest segments of Caribbean society suffer serious malnutrition. In the 1970s, the FAO estimated that protein-calorie deficiency strikes 30,000 to 50,000 Jamaican children, with the most serious cases exhibiting symptoms of kwashiorkor and marasmus. Moreover, studies of childhood deaths on the island indicate that a majority are nutrition related, and fully a third may have resulted directly from malnutrition. A survey of children in the Dominican Republic found only 25 percent with adequate nutrition levels, and of those admitted to hospitals, 39 percent suffered from kwashiorkor and 90 percent from anemia. Haiti recorded one of the highest infant mortality rates in the world, with 146.5 deaths per 1,000 live births in the 1970s. And village surveys found Haitian children to be as seriously malnourished as those of the neighboring Dominican Republic (May and McLellan 1973: 125, 177, 225; Kiple 1984: 184-6).

The problems of food shortages have been exacerbated by government attempts to implement crash industrialization programs and reliance on imported food. Such a lack of self-sufficiency was not unusual; as early as the 1880s, the small island of St. Pierre had become so dependent on canned foods from the United States that an American steamer was called a "food ship." Nevertheless, industrialization programs further reduced the region's capacity to support itself, as Puerto Rico's "Operation Bootstrap" demonstrated, beginning in 1949. Although aggregate incomes rose dramatically, the problem of unemployment remained, and in 1974 the United States government was forced to extend the food stamp program to the island. This, in turn, distorted the local economy, creating black markets in goods and labor and ruining the island's small farmers. It meant not only that people bought rice from California instead of the countryside but also that they discarded traditional dishes in favor of sugar-laden processed foods. Elsewhere in the region, the urban poor could not afford expensive imports, leading to widespread malnutrition and, at times, political unrest, such as the 1984 food riots in the Dominican Republic (Hearn 1970: 294; Weisskoff 1985: 60-4; Dietz 1986: 27, 63, 122; Knight 1990: 323).

Socialist Cuba attempted to balance modernization with equality, but despite some initial success, by the 1990s hunger had become widespread. Prior to Castro's revolution, malnutrition had been a serious problem in the Cuban countryside, with the daily diet deficient by 1,000 calories. Although Castro created a successful rural health-care system, initial mistakes in agricultural development led to a reliance on subsidies from the Soviet Union. By the mid-1980s imports had fallen from one-third of total food consumption to below 20 percent, at the same time that per capita intake of calories and proteins increased. But just a few years later, the collapse of communism in Eastern Europe closed markets for Cuban sugar and ended the subsidized petroleum supplies. While ration cards had long been a fact of life, in the early 1990s hunger, again, became a serious problem (Zimbalist and Brundenius 1989: 103-9; Miller 1992: 130-3).

The failure of Caribbean industrialization has driven millions to flee the region in search of a better life. Puerto Ricans, taking advantage of their United States citizenship, have flooded into New York, particularly the South Bronx. New York has also become home to large numbers of Jamaicans, Haitians, and Dominicans, while Cuban refugees have turned Miami into the second largest Cuban city. Shortly before Dutch Guiana became the independent state of Suriname in 1975, nearly 40 percent of the population had migrated to the Netherlands. The human tragedy of such an exodus from the Caribbean is best illustrated by the boatloads of Haitians braving the sea to escape the successive dictatorships and intense poverty of their homeland (Richardson 1989: 203-28).

Transnational Cuisine

The Caribbean people have been relatively slow to adopt the concept of nationalism, either within individual island states or as a pan-Caribbean phenomenon. This has resulted, in part, from the lingering colonial presence of the United States and European powers. Most of the British Antilles did not gain their independence until the 1970s, and foreign rule persisted until recently in the Netherlands Antilles. The Virgin Islands and Puerto Rico are part of the United States, just as Guiana, Guadeloupe, and Martinique are French departments. None of these has achieved the status of an independent nation. The diversity of ethnic origins has likewise impeded the formation of Caribbean nationalism, as even basic definitions of "race" within the region defy easy explanation (Mintz 1974: 315–24). Finally, massive migration, both from the islands to former colonial capitals and among different islands, has diffused the pressure for unifying nationalist ideologies. Yet, for all the regional and ethnic diversity, it is nevertheless possible, as Mintz (1974) has shown, to identify a uniquely Caribbean culture and cuisine.

Of course, the Caribbean traveler could find many different styles of cooking, perhaps the least representative being that served in tourist hotels. A typical menu might include fresh grilled fish, garnished with tropical fruits and washed down with a rum cocktail. But for the majority of the people in the Greater Antilles, seafood has meant salt cod rather than fresh fish. Moreover, hotel restaurants import the majority of their foods; even the tropical fruits often come from Florida. And those "authentic" island recipes, generally, have little real connection with the foods of the common people. Bonham Richardson (1992: 109) noted that visitors "find the mock authenticity of tourist-oriented dinner menus appealing, but they probably would not tolerate the fare consumed by Caribbean working classes."

While tourists seek sanitized versions of local cuisine, the natives have turned in ever-greater numbers to processed foods from the United States and Europe. Each new import, from spaghetti and canned soups to Nescafé and Johnny Walker, gains gourmet status because of its high cost, and poor islanders suffer acute embarrassment if they cannot offer guests a can of Spam (Wilson 1973: 22, 107). The adoption of Western consumption patterns led one Bahamian housewife to declare that she had given up preparing meals because her family "snacks outside continuously" (May and McLellan 1973: 13). Big Macs and Kentucky Fried Chicken have become common on the islands, and even socialist Cuba has succumbed to the lure of pizza parlors. The 1989 opening of the first McDonald's in Barbados saw serious traffic jams as cars lined up to enter the drive-through lane (Kurlansky 1992: 98).

Despite the encroachment of processed foods, however, it is still possible to recognize a peasant-based, pan-Caribbean cuisine. The simultaneous diversity and continuity of this food can be seen in the ubiquitous meal of rice and beans. This combination appears in Spanish-speaking islands as *moros y cristianos* (Moors and Christians), among French dominions as *pois et riz* (beans and rice), and in Jamaica as rice and peas (although it is generally made with dried red beans instead of fresh pigeon peas). Regional variations exist, even within the larger islands. In Cuba, for example, the residents of Havana eat the small black beans of neighboring Yucatán, whereas people in Oriente Province prefer the red beans common to Jamaica and Puerto Rico. Many other methods exist for preparing the staple, rice, among the most extravagant of which are the Haitian favorite *riz au djon-djon* (rice with black mushrooms) and Venezuela's rich, caramel *arroz con coco* (rice with coconut milk). Nevertheless, rice with beans remains the basis of regional cooking (Lambert Ortiz 1986: 258–82; Mintz 1974: 227; Sokolov 1991: 64).

Although relatively expensive compared to such root crops as cassava and yams, beans and rice provide a source of protein that is much cheaper than that from animal products. Neither beans nor rice alone yields a high-quality protein because the former lacks the essential amino acids methionine and cystine, while the latter is deficient in lysine. But together, each offsets the deficiency in the other, creating a complete amino acid chain that allows the body to build tissue efficiently. This nutritional synergism seems all the more fortuitous given that the American bean did not encounter Asian rice until after 1492 (Sanjur 1970: 26).

Similar eclectic combinations abound throughout the Caribbean. Codfish and akee, the national dish of Jamaica, originated with slaves who mixed the salt fish rations provided by planters with the akee fruit, an African domesticate that did not arrive in the island until 1778. Another common dish dating back to the period of slavery is callaloo soup, which takes its name from the leaves of the taro, and also includes okra and salt pork. Tamales, corn confections originally from Mexico, are widely prepared in Cuba, Martinique, and Venezuela. The dish most commonly associated with the French islands of Martinique and Guadeloupe is, ironically, a curry, *le colombo.* Elizabeth Lambert Ortiz (1986: 2) has observed that the identification of a food with a particular island has little to do with the dish's origins because of the wide travels of gifted cooks. It is this constant migration of diverse peoples that has defined the culture and cuisine of the Caribbean.

V.D.5 ~ Temperate and Arctic North America to 1492

In writing about the history of food and drink in pre-Columbian North America, one is reminded that for the temperate part of the continent, we are describing cultures primarily known only through archaeological and archival research. Very few native populations survived the events of the past five centuries, and those that did endured considerable cultural modifications. Nonetheless, many of the foods and drinks they used became important legacies to the new North American and global foodways that emerged after 1492, and certainly such foods were critical to the survival of the first European colonists who established permanent communities there.

Perhaps the most important of these were pumpkins, squash, beans, and maize (corn), and although few of these crops were originally domesticated in temperate North America, today they, as well as indigenous cultivation and preparation techniques, continue to be valued.

The practice of mixing maize, beans, and squash in gardens was developed by Native Americans, who also contributed many maize dishes, including hominy, grits and other gruels, breads made with corn flour, corn on the cob, and succotash (Hudson 1976: 498–9). Early North Americans gave sunflowers to the world's economy and contributed to the development of modern strawberry, blackberry, raspberry, blueberry, cranberry, hickory, and pecan varieties (Trager 1970: 278–80; Hedrick 1972). Finally, such preservation techniques as drying fruits or vegetables and curing meat by smoking over hickory coals have Native American antecedents (Hudson 1976: 499).

Native North American cuisine is important to scholars for its contribution to knowledge about adaptations to tropical, temperate, and arctic environments. In the sixteenth century, the continent was not occupied by a single people making use of a limited suite of plants and animals. Instead, many different peoples wove the resources of their regions into complex and specialized strategies that were finely adapted to local environmental features.

Subsistence patterns in the northern portion of the continent may be broadly generalized into subarctic and arctic hunting traditions and temperate seed-gathering traditions (Spencer and Jennings 1965: 2). The latter were widespread, forming the basis for farming lifestyles that developed in many areas. A farming tradition was being widely practiced in the temperate eastern sector of the continent and in the Southwest when the first European explorers arrived. The farming traditions of the temperate Eastern Woodlands had a profound impact on the earliest European colonists; indeed, those who survived did so only because they adapted to North American conditions, melding their own foodways with native North American dietary traditions (Reitz and Scarry 1985). In the sixteenth century, the "transplanted Spaniard" either adapted, left the colony, or died.

Because of the importance of Eastern Woodlands farming traditions to sixteenth-century European colonization, this chapter focuses on that region and, for historical depth, traces Mississippian dietary practices from their antecedents in the nonhorticultural Paleo-Indian and Archaic cultures into the horticultural traditions of the Late Archaic and Woodland periods (Table V.D.5.1). It concludes with an examination of the impact of native foodways on sixteenth-century Spanish colonies. Common names are used throughout the text; however, scientific names of plants and animals frequently found in Eastern Woodlands sites are provided in Tables V.D.5.2 and V.D.5.3.

Table V.D.5.1. *General chronological sequence*

Period	Age
Contact	A.D. 1520–1700
Mississippian	A.D. 1000–1520
Late Woodland	A.D. 600–A.D. 1000
Middle Woodland	A.D. 1–A.D. 600
Early Woodland	700 B.C.–A.D. 1
Late Archaic	4000–700 B.C.
Early and Middle Archaic	8000 B.C.–4000 B.C.
Paleo-Indian	?–8000 B.C.

Source: Modified from Steponaitis (1986).

Table V.D.5.2. *List of scientific and common names for plants*

Scientific name	Common name
Wild fruits and berries	
Amelanchier spp.	Serviceberry
Asimina triloba	Papaw
Celtis occidentalis	Hackberry
Crataegus spp.	Hawthorn
Diospyros virginiana	Persimmon
Fragaria virginiana	Wild strawberry
Gaylussacia spp.	Huckleberry
Gleditsia aquatica	Honey locust
Ilex verticilliata	Winterberry
Malus coronaria	Crabapple
Morus rubra	Red mulberry
Nyssa spp.	Black gum
Opuntia spp.	Prickly pear
Passiflora incarnata	Maypop
Physalis spp.	Groundcherry
Prunus americana	Plum
Prunus serotina	Wild black cherry
Rhus spp.	Sumac
Ribes spp.	Gooseberry
Rubus spp.	Blackberry–raspberry
Sambucus spp.	Elderberry
Solanum americanum	Black nightshade
Vaccinium spp.	Blueberry
Viburnum spp.	Blackhaw
Vitis spp.	Wild grape
Yucca spp.	Common yucca
Nuts	
Carya glabra	Pignut hickory
Carya illinoensis	Pecan
Carya laciniosa	Shellbark hickory
Carya ovata	Shagbark hickory
Carya tomentosa	Mockernut hickory
Castanea dentata	American chestnut
Castanea pumila	Chinquapin
Corylus spp.	Hazelnut
Fagus spp.	Beechnut
Juglans cinerea	Butternut
Juglans nigra	Black walnut
Quercus alba	White oak
Quercus coccinea	Scarlet oak
Quercus macrocarpa	Burr oak
Quercus prinus	Chestnut oak
Quercus rubra	Red oak
Quercus velutina	Black oak
Edible seeds and greens	
Amaranthus spp.	Pigweed
Ambrosia trifida	Giant ragweed
Ambrosia cf. *artemisiifolia*	Common ragweed
Arundinaria gigantea	Large cane
Arundinaria tecta	Small cane
Chenopodium album	Lamb's quarter
Chenopodium berlandieri	Goosefoot
Echinochloa spp.	Cockspurgrass
Euphorbia maculata	Spruge
Impatiens spp.	Jewelweed
Iva ciliata	Marshelder
Leersia oryzoides	Rice cutgrass
Lepidium virginicum	Peppergrass
Phaseolus polystachios	Wild bean
Phytolacca americana	Pokeweed
Plantago rugelii	Plantain
Portulaca oleracea	Purslane
Rumex spp.	Dock
Sabal palmetto	Cabbage palm
Serenoa repens	Saw palmetto
Strophostyles helvola	Wild bean
Vicia spp.	Vetch
Roots and tubers	
Acorus calamus	Sweet flag
Allium cernuum	Wild onion
Allium canadense	Wild garlic
Amphicarpa bracteata	Hog peanut
Apios americana	Groundnut
Camassia esculenta	Wild hyacinth
Dentaria spp.	Toothwort
Helianthus tuberosus	Jerusalem artichoke
Ipomoea pandurata	Wild sweet potato
Medeola virginiana	Indian cucumber
Nelumbo lutea	American lotus
Orontium aquaticum	Golden club
Peltandra virginica	Arrow arum
Sagittaria spp.	Arrowhead
Scirpus validus	Bulrush
Smilax spp.	Greenbrier
Typha spp.	Cattail
Zamia spp.	Coontie
Beverages and condiments	
Acer spp.	Maple
Ilex vomitoria	Yaupon, black drink
Ilex cassine	Dahoon holly
Lindera spp.	Spicebush
Liquidamber styraciflua	Sweet gum
Persea borbonia	Sweet bay
Sassafras albidum	Sassafras
Eastern Woodland cultivated or domesticated plants	
Chenopodium berlandieri ssp. *jonesianum*	Domestic chenopod
Cucurbita pepo ssp. *ovifera* v. *ovifera*	Gourd–squash
Helianthus annuus v. *macrocarpus*	Domestic sunflower
Hordeum pusillum	Little barley
Iva annua v. *macrocarpa*	Domestic sumpweed
Lagenaria siceraria	Bottle gourd
Phalaris caroliniana	Maygrass
Polygonum erectum	Erect knotweed
Introduced tropical domesticated plants	
Amaranthus hypochondriacus	Pale-seeded amaranth
Capsicum sp.	Chilli pepper
Cucurbita argyrosperma (formerly *C. mixta*)	Cushaw squash
Cucurbita pepo ssp. *pepo*	Pumpkin–marrows
Cucurbita moschata	Moschata squash
Phaseolus lunatus	Lima bean
Phaseolus vulgaris	Common bean
Zea mays	Maize
Introduced Old World cultigens	
Citrullus vulgaris	Watermelon
Corylus avellana	Domestic hazelnut
Cucumis melo	Melon
Ficus carica	Fig
Pisum sativum	Common pea
Prunus persica	Peach
Triticum spp.	Wheat
Vigna unguiculata	Cowpea
Vitis vinifera	Wine grape
Wild progenitors	
Cucurbita pepo ssp. *ovifera* v. *texana*	Texas wild gourd
Chenopodium berlandieri	Wild goosefoot
Iva annua v. *annua*	Wild sumpweed
Fish poisons	
Aesculus spp.	Buckeye
Tephrosia virginiana	Devil's shoestring

Table V.D.5.3. *List of scientific and common names for animals*

Scientific name	Common name
Crustacea	
Penaeus spp.	Shrimp
Callinectes sapidus	Blue crab
Menippe mercenaria	Stone crab
Freshwater bivalves	
Actinonaias spp.	Mucket
Amblema spp.	Threeridge
Anodonta spp.	Floater
Cyclonaias tuberculata	Purple wartyback
Elliptio spp.	Spike
Fusconaia spp.	Pigtoe
Lampsilis spp.	Mucket
Lasmigona spp.	Heelsplitter
Obovaria spp.	Hickorynut
Pleurobmea spp.	Pigtoe
Quadrula spp.	Pimpleback
Tritogonia verrucosa	Pistolgrip
Uniomerus tetralasmus	Pondhorn
Marine bivalves	
Brachidontes spp.	Mussel
Geukensia demissa	Ribbed mussel
Anadara spp.	Ark
Glycymeris spp.	Bittersweet
Agropecten spp.	Scallop
Crassostrea virginica	Oyster
Mactra fragilis	Eastern mactra
Donax spp.	Coquina
Tagelus spp.	Tagelus
Polymesoda carolinana	Marsh clam
Chione spp.	Venus shell
Mercenaria spp.	Hard clam
Protothaca spp.	Venus
Freshwater gastropods	
Campeloma spp.	Campeloma
Pomacea spp.	Applesnail
Marine gastropods	
Littorina irrorata	Periwinkle
Strombus spp.	Queen conch
Crepidula spp.	Slipper-shell
Polinices duplicatus	Shark eye
Busycon spp.	Whelk
Melongena spp.	Crown conch
Ilynassa obsoleta	Mud nassa
Nassarius spp.	Nassa
Fasciolaria spp.	Tulip shell
Pleuroploca spp.	Horse conch
Sharks and rays	
Ginglymostoma cirratum	Nurse shark
Odontaspis taurus	Sand tiger shark
Carcharhinus leucas	Bull shark
Carcharhinus plumbeus	Sandbar shark
Galeocerdo cuvier	Tiger shark
Rhizoprionodon terraenovae	Sharpnose shark
Sphyrna mokorran	Great hammerhead shark
Sphyrna tiburo	Bonnethead shark
Sphyrna zygaena	Smooth hammerhead
Pristis pectinata	Smalltooth sawfish
Dasyatis spp.	Stingray
Aetobatis narinari	Spotted eagle ray
Myliobatis spp.	Eagle ray
Rhinoptera bonasus	Cownose ray
Freshwater fishes	
Acipenser spp.	Sturgeon
Lepisosteus spp.	Gar
Amia calva	Bowfin
Notemigonus crysoleucas	Golden shiner
Carpiodes cyprinus	Quillback
Catostomus spp.	Sucker
Ictiobus spp.	Buffalo
Hypentelium spp.	Hog sucker
Minytrema melanops	Spotted sucker
Moxostoma spp.	Redhorse
Ameiurus spp.	Bullhead catfish
Ictalurus spp.	Freshwater catfish
Noturus spp.	Madtom
Pylodictis olivaris	Flathead catfish
Esox spp.	Pike
Exox masquinongy	Muskellunge
Lepomis spp.	Sunfish
Micropterus spp.	Bass
Pomoxis spp.	Crappie
Perca flavescens	Yellow perch
Aplodinotus grunniens	Freshwater drum
Marine fishes	
Acipenser spp.	Sturgeon
Albula vulpes	Bonefish
Clupeidae	Herring
Arius felis	Hardhead catfish
Bagre marinus	Gafftopsail
Opsanus tau	Oyster toadfish
Centropomus spp.	Snook
Morone spp.	Temperate bass
Centropristis spp.	Sea bass
Pomatomus saltatrix	Bluefish
Caranx spp.	Jack
Chloroscombrus chrysurus	Atlantic bumper
Archosargus probatocephalus	Sheepshead
Bairdiella chrysoura	Silver perch
Cynoscion spp.	Sea trout
Leiostomus xanthurus	Spot
Menticirrhus spp.	Kingfish
Micropogonias undulatus	Atlantic croaker
Pogonias cromis	Black drum
Sciaenops ocellatus	Red drum
Mugil spp.	Mullet
Paralichthys spp.	Flounder
Chilomycterus	Burrfish
Diodon histrix	Porcupine fish
Amphibians	
Siren lacertina	Greater siren
Amphiuma means	Two-toed amphiuma
Rana catesbeiana	Frog
Reptiles	
Alligator mississippiensis	Alligator
Chelydra serpentina	Snapping turtle
Macroclemys temmincki	Alligator snapping turtle
Kinosternon spp.	Mud turtle
Sternotherus spp.	Musk turtle
Chrysemys picta	Painted turtle
Deirochelys reticularia	Chicken turtle
Graptemys spp.	Map turtle
Pseudemys spp.	Cooter
Malaclemys terrapin	Diamondback terrapin
Terrapene carolina	Box turtle

Table V.D.5.3. *(continued)*

Scientific name	Common name
Trachemys spp.	Slider
Gopherus polyphemus	Gopher tortoise
Apalone spp.	Softshell turtle
Chelonidae	Sea turtle
Colubridae	Nonpoisonous snake
Viperidae	Poisonous snake
Birds	
Gavia immer	Common loon
Podilymbus podiceps	Pied-billed grebe
Phalacrocorax auritus	Cormorant
Ardea herodias	Great blue heron
Botaurus lentiginosus	American bittern
Casmerodius albus	Great egret
Egretta tricolor	Tricolored heron
Aix sponsa	Wood duck
Anas spp.	Dabbling duck
Aythya spp.	Diving duck
Branta canadensis	Canada goose
Chen caerulescens	Snow goose
Cygnus spp.	Swan
Lophodytes cucullatus	Hooded merganser
Oxyura jamaicensis	Ruddy duck
Mergus spp.	Merganser
Spatula clypeata	Shoveler
Coragyps atratus	Black vulture
Buteo platypterus	Broad-winged hawk
Colinus virginianus	Quail
Meleagris gallopavo	Wild turkey
Rallus elegans	King rail
Porzana carolina	Sora
Fulica americana	Coot
Grus canadensis	Sandhill crane
Charadrius vociferus	Killdeer
Catoptrophorus semipalmatus	Willet
Galinago gallinago	Common snipe
Laridae	Gull
Ectopistes migratorius	Passenger pigeon
Zenaida macroura	Mourning dove
Strix varia	Barred owl
Picidae	Woodpecker
Corvidae	Crow
Muscicapidae	Thrush
Mimidae	Thrasher
Mammals	
Didelphis virginiana	Opossum
Sylvilagus spp.	Rabbit
Sciurus spp.	Squirrel
Tamias striatus	Chipmunk
Marmota monax	Woodchuck (groundhog)
Geomys spp.	Pocket gopher
Spermophilus spp.	Ground squirrel
Ondatra zibethicus	Muskrat
Castor canadensis	Beaver
Erethizon dorsatum	Porcupine
Tursiops truncatus	Bottle-nosed dolphin
Canis familiaris	Dog
Canis latrens	Coyote
Canis lupus	Gray wolf
Urocyon cineroargenteus	Gray fox
Ursus americanus	Black bear
Ursus arctos	Brown bear
Procyon lotor	Raccoon
Lontra canadensis	Otter
Mephitis mephitis	Striped skunk
Mustela frenata	Long-tailed weasel
Mustela vision	Mink
Spilogale putorius	Spotted skunk
Taxidea taxus	Badger
Felis rufus	Bobcat
Felis concolor	Cougar
Alces alces	Moose
Cervus elaphus	Elk or wapiti
Odocoileus virginianus	White-tailed deer
Rangifer tarandus	Caribou
Bison bison	Bison or buffalo

Cultivation, Domestication, and Horticulture

Evidence of horticulture is lacking for some areas of the Eastern Woodlands, which may signify either that horticulture was not practiced everywhere or that plant use in some locations is still poorly studied. Likewise, evidence of a domesticated plant variety in one area does not mean that this variety was grown throughout the region at the same time or that it was grown universally at any time.

As Richard Ford (1985a) has observed, the paths from wild to domesticated plants and from foraging to farming were not direct. A continuum exists between the wild and domesticated states, and doubtless plants passed through stages when they were intentionally tended, tilled, transplanted, or sown, but were not fully domesticated (Ford 1985a). Domestication is difficult to demonstrate with archaeological materials unless a phenotypic change can be spied that corresponds with genetic changes reflecting human intervention. Changes in color, for example, are often associated with domestication in both plants and animals, but are not normally found in the archaeological record. "Cultivated" plants are found in the archaeological record – often in large numbers in some deposits – indicating that they were probably intentionally propagated. But morphological changes providing evidence of the domesticated state are not observed (Ford 1985a; Fritz 1990). Plants are considered "domesticated" when archaeological remains reveal those signs of phenotypic alteration that indicate that domestication did take place. A domesticated plant would not normally be found unassociated with humans and, in fact, they often cannot survive without human intervention.

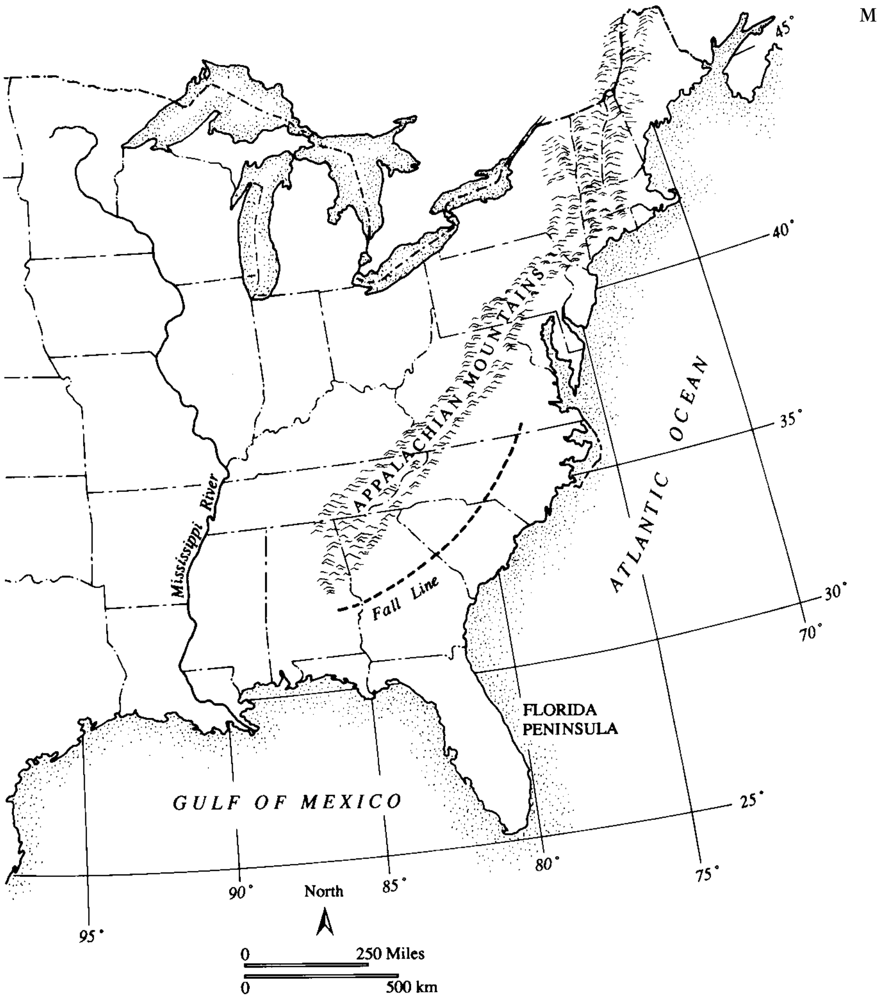
In North America, both cultivated and domesticated plants were grown under horticultural rather than agricultural conditions. Entirely different energy inputs are required by these systems because agriculture involves domestic animals and horticulture does not (Kottak 1987: 269–71). Agricultural techniques must produce adequate calories not only for humans but also for a complex of domestic animals, whereas horticultural production only meets human nutritional needs.

Although domestic crops in the Eastern Woodlands were grown under horticultural conditions, this does not mean that farming was limited to temporary fields or small garden plots. Rather, plants were grown in many large fields (Riley 1987; Woods 1987) that were permanently maintained with digging sticks and hoes, classic horticultural implements, and not with the agricultural plow.

Because cultivation and domestication of plants is achieved gradually, it is unlikely that North American farmers completely abandoned the use of wild foods. Certainly this would have been the case in the Eastern Woodlands, where those proteins, fats, vitamins, and minerals derived from animals could only be obtained through foraging, trapping, hunting, and fishing.

The Eastern Woodlands

Most of temperate North America from the Gulf of Mexico and Atlantic seaboards westward beyond the Great Lakes region is characterized by extensive, mixed-deciduous forests (Map V.D.5.1). The northern boundary of the Eastern Woodlands is defined by a mean annual January temperature of –10° C and the western boundary by a line marking rainfall equal to 80 percent evaporation (Shelford 1974: 17). It is the southern half of the Eastern Woodlands that is most closely associated with the Mississippian tradition of the sixteenth century (Smith 1986). The northern border of the Southeastern Woodlands is around 38° north latitude, roughly corresponding with the farthest glacial advance, which occurred around 16,000 B.C.



Map V.D.5.1. The Eastern Woodlands.

(Shelford 1974: 19; Delcourt and Delcourt 1981). Winters are relatively short and the growing season long. Annual rainfall varies from 100 to 150 centimeters (cm) and is greatest in the spring and summer, especially along the coasts and in the mountains (Shelford 1974: 56). The Southeastern Woodlands are well watered, with numerous rivers, floodplains, marshes, swamps, and lakes. Systems, such as that associated with the Mississippi River, drain vast portions of the continent. There are many smaller drainage systems throughout the region, particularly along the Atlantic and Gulf coasts.

Climate and vegetation in the Southeast were dynamic in the late Pleistocene and early Holocene (King and Lindsay 1976; Wright 1976; Delcourt and Delcourt 1981, 1983). During the late Pleistocene, the northern portion of the continent was covered by glaciers. At the peak of continental glaciation, about 16,000 B.C., boreal forests of spruce, jack pine, fir, and some deciduous trees covered much of the unglaciated interior plateau, whereas deciduous oaks and hickories mixed with southern pines were found on the coastal plain (Delcourt and Delcourt 1981, 1983; Smith 1986). At the same time, Gulf and Atlantic sea levels were 60 to 130 meters lower than today, and so the coastal plain was considerably broader (Blackwelder, Pilkey, and Howard 1979).

Temperate conditions began to replace boreal ones about 12,000 B.C., and by roughly 8000 B.C., temperate deciduous vegetation dominated most of the region between 34° and 43° north latitude (Delcourt and Delcourt 1981, 1983). South of this area there had generally been little change in vegetation since about 18,000 B.C. About 7000 B.C. the postglacial trend of rising temperatures culminated in a warm, dry period known as the Hypsithermal Interval (Deevey and Flint 1957; Wright 1976). Temperatures began to cool again after about 5000 B.C., and by 3000 B.C., an essentially modern climate prevailed, with forests achieving distributions similar to those of the sixteenth century (Wright 1976; Delcourt and Delcourt 1981). Important additional events at this time were a rise in sea level (with modern sea levels reached about 3000 B.C.) and changes in regional hydrology (Wright 1976: 586; Delcourt et al. 1980; Brooks and Sassaman 1990).

Origins of Mississippian Foodways

Humans probably came to the Eastern Woodlands sometime between 40,000 and 15,000 years ago, first crossing from Asia to North America while the floor of the Bering Strait was exposed by low Pleistocene sea levels (Dincauze 1985; Steponaitis 1986). Prey species important to humans, such as brown bear, moose, elk, white-tailed deer, and bison, had made a similar crossing somewhat earlier (Kurtén and Anderson 1980: 410, 416–17). Caribou probably originated on Beringia itself (Kurtén and Anderson 1980: 315).

Late Pleistocene conditions are associated with what is known in human terms as the Paleo-Indian period (Table V.D.5.1; Smith 1986; Steponaitis 1986). Information about subsistence in the Eastern Woodlands during this time is limited. Most people probably lived in small hunting and gathering bands using an impermanent residential pattern to take advantage of seasonal fluctuations in resources. From the limited evidence available, the foods commonly consumed by Paleo-Indians appear to have included hackberry, blackberry–raspberry, blueberry, hickory, walnut, goosefoot, bivalves, gastropods, fish, turtle, wild turkey, rabbit, squirrel, elk, and white-tailed deer (Adovasio et al. 1978). Although a number of now-extinct Pleistocene animals, such as giant land tortoise, ground sloth, mastodon, mammoth, horse, and tapir, lived in the Eastern Woodlands at this time, few remains have been found in contexts that conclusively prove that extinct animals were hunted by Paleo-Indians (Bullen, Webb, and Waller 1970; Wood and McMillan 1976; Clausen et al. 1979; Graham et al. 1981; Dincauze 1985; Grayson 1991).

Modern geological, climatic, and biological conditions are associated with the Archaic period, which began about 8000 B.C. (Table V.D.5.1). The Early and Middle Archaic periods were characterized by the use of modern animal species by peoples who employed a combination of gathering, hunting, and fishing techniques (Neusius 1986). The *atlatl,* or spear thrower, was used in hunting, whereas netsinkers and fishhooks indicate that fishing was part of the subsistence strategy. Nets could also have been used to capture reptiles, birds, and mammals. Grinding stones suggest that some foods were ground or pulverized.

Evidence for plant use in the Early and Middle Archaic is limited (Byrd and Neuman 1978; Yarnell and Black 1985; Neusius 1986). Seeds of fleshy fruits, such as papaw, hackberry, persimmon, plum, wild black cherry, elderberry, and wild grape, are abundant relative to other seeds throughout the Archaic period. Although walnut and acorn were commonly used in the Archaic, hickory is the most abundant nut found in archaeological deposits (Yarnell and Black 1985). However, Richard Yarnell and Jean Black (1985: 97) argue that in terms of nut food consumed, acorns were the most important plant food in the Southeast until the Mississippian period, at which time they were replaced by maize. Their estimates of dietary contribution suggest that acorns contributed 75 percent of the nut food consumed, whereas hickory nut comprised 20 percent (Yarnell and Black 1985). American chestnut, hazelnut, and beechnut were used in small amounts. Seeds of plants used for greens, such as pokeweed and purslane, are relatively abundant in some Early and Middle Archaic deposits (Yarnell and Black 1985). Some of the starchy-seed plants that later became important as cultivated and domesticated plants, such as goosefoot, may have been used for their leaves rather than for seeds during much of the Archaic period. This would account for their low numbers in Early and Middle Archaic deposits (Bye 1981; Yarnell and Black 1985).

The Late Archaic period is characterized by signs of demographic growth and sedentism in many parts of the Southeast (Steponaitis 1986). Large Late Archaic shell middens are characteristically found along streams and estuaries. There is evidence that residences in some aquatic and estuarine settings may have been multiseasonal, if not year-round (Reitz 1988). Elsewhere, dense midden deposits suggest increased and/or long-term use of specific locations. Large middens, as well as storage pits, indicate a higher degree of sedentism than earlier, although it has been suggested that subterranean storage facilities may indicate concealment of storable foods during periods when villages were abandoned (DeBoer 1988).

Cooking techniques such as stone boiling in baskets and stone bowls had probably been utilized throughout the Archaic period, but clay vessels reflect widespread adoption of food-preparation methods requiring containers that could be placed directly in or over fires and left to simmer unattended for long periods of time. Late Archaic fiber-tempered ceramics from the southeastern Atlantic coast are among the earliest known in the hemisphere (Smith 1986; Steponaitis 1986).

The Late Archaic is marked by changes in the use of plant resources. Nuts continued to be relied upon extensively, but starchy and oily seed use increased (Yarnell and Black 1985; Fritz 1990). Seeds found in large numbers in Late Archaic deposits include ragweed, goosefoot, wild beans, hog peanut, maygrass, and erect knotweed. The relative abundance of seeds from plants used for greens but not for seeds, such as pokeweed and purslane, declined from earlier Archaic levels and remained low until the Mississippian period (Yarnell and Black 1985). Yarnell and Black interpret this as evidence that starchy seeds contributing both greens and seeds, such as goosefoot, may have replaced plants that provided only greens, such as pokeweed and purslane (Yarnell and Black 1985). Seeds from such fruits as hackberry, persimmon, plum, blackberry–raspberry, elderberry, blackhaw, and wild grape are commonly identified in Late Archaic deposits, although the degree to which specific fruits and berries were used varied regionally (Kay, King, and Robinson 1980; Johannessen 1984; Watson 1985). Remains of American lotus at some sites indicate use of aquatic plants.

The Late Archaic is characterized by evidence for plant cultivation and domestication in some midlatitude, interior locations (Asch and Asch 1985; Cowan 1985; King 1985; Watson 1985, 1989; Smith 1989; Fritz 1990). Maygrass was probably a cultivated plant by 2000 B.C. (Cowan 1978; Yarnell and Black 1985). Domestication is first clearly demonstrated for the Eastern Woodlands with the identification of domestic chenopod, sunflower, and sumpweed at some Late Archaic sites (Yarnell 1969, 1972, 1978; Marquardt 1974; Asch and Asch 1978; Conard et al. 1984; Heiser 1985; Smith 1985b, 1989; Yarnell and Black 1985; Fritz 1990). Important indigenous cultivated and domesticated plants suggest that the development of horticultural traditions in the Eastern Woodlands was not dependent upon introductions from tropical America (Yarnell and Black 1985). The increase in cultivated and domesticated plants is associated with an increase in pollen of species commonly found in disturbed habitats, such as garden plots (Delcourt 1987).

Occasional identifications of gourd–squash indicate the presence of this plant after 5000 B.C. at a few eastern locations, although its status is currently being debated (Ford 1981; Conard et al. 1984; Asch and Asch 1985; King 1985; Decker 1988; Decker and Newsom 1988; Watson 1989; Fritz 1990; Decker-Walters 1993). There is, however, growing evidence for domestication of some varieties of gourd–squash in the Late Archaic Eastern Woodlands (Kay et al. 1980; Ford 1981; Conard et al. 1984; King 1985; Yarnell and Black 1985; Smith 1987b, 1989; Decker 1988; Fritz 1990). Recent work suggests that a native wild plant closely related to the gourd–squash, the Texas wild gourd, was present in North America and might have been the source of domestic gourd–squash found in the Eastern Woodlands (Decker 1988; Smith 1989; Fritz 1990; Decker-Walters 1993). Gourd–squash includes acorn squash, scallop squash, fordhook, crookneck, and most of the ornamental gourds (King 1985), although the gourd–squash found in deposits about 2000 B.C. were probably woody varieties used for containers and oily seeds, rather than the fleshy vegetable found in the sixteenth century (Yarnell and Black 1985; King 1985).

The origin of bottle gourd is also in doubt (Heiser 1989; Smith 1989; Fritz 1990). Very small seeds and thin-walled fragments of bottle gourds found at two Eastern Woodlands deposits, dated between 5350 and 2300 B.C., suggest that they may have been used very early. Remains of bottle gourds that were clearly domesticated are found in contexts that date from around 1300 B.C. or a little before (Smith 1985b; Yarnell and Black 1985; Fritz 1990; Yarnell 1993). It is probable that the recovery of bottle gourd remains from contexts with early dates indicates that this plant reached the Eastern Woodlands serendipitously (Heiser 1989; Fritz 1990), perhaps by floating to the eastern seaboard from tropical America or Africa (Smith 1985b, 1989; Yarnell and Black 1985; Heiser 1989; Fritz 1990). It seems likely that bottle gourds were valued as containers, rather than as food (King 1985).

Although plant use was highly dynamic at the end of the Archaic period, use of animal resources seems to have remained stable at those few locations for which stratigraphic sequences are available. Archaic peoples consumed a broad range of animals, which suggests subsistence strategies making use of the most efficient resources available in a particular setting. In general, animal remains indicate strategies that combined white-tailed deer and a wide range of other species. Other taxa included bivalves and gastropods, gar, bowfin, sucker, catfish, sunfish, freshwater drum, snapping turtle, mud-musk turtle, box turtle, pond turtle, softshell turtle, snakes, opossum, rabbit, squirrel, woodchuck, pocket gopher, muskrat, beaver, black bear, raccoon, badger, and elk (Curren 1974; Stoltman 1974; Parmalee, McMillan, and King 1976; Neusius 1986). In some areas, migratory waterfowl were taken in season, but usually birds other than quail, wild turkey, and passenger pigeon were not a major part of Archaic diets. In coastal settings, this list becomes even more complex, with estuarine mollusks and fishes dominating the diet, whereas mammals, including white-tailed deer, were rarely consumed (Reitz 1988).

The Archaic is followed by the Woodland period, which began about 700 B.C. (Table V.D.5.1). In the Eastern Woodlands, extensive earthworks were constructed during this period; some of these assumed large geometric patterns, although many were conical earthen burial mounds. There were numerous villages of various sizes, of which some were occupied throughout the year. Villages were particularly common at coastal and aquatic settings, from which a complex of wetland, aquatic, and estuarine resources were used. Evidence for regional variation in diets is much stronger for the Woodland period than for the Archaic period, perhaps because more data are available.

During the Woodland period, there was an increase in the cultivation of starchy and oily seed crops and a corresponding decrease in reliance on nuts, although hickory and acorn continued to be important resources (Yarnell and Black 1985). Pawpaw, persimmon, wild strawberry, honey locust, maypop, plum, sumac, blueberry, wild grape, wild beans, and American lotus were also used (Watson 1969: 53; Munson, Parmalee, and Yarnell 1971; Byrd and Neuman 1978; Johannessen 1984; Yarnell and Black 1985; Gardner 1987). Seeds from greens are recovered from archaeological sites in low numbers, and remains of starchy seeds are notably more abundant in Woodland deposits than in Archaic ones (Yarnell and Black 1985).

The energy base for increased sedentism and mound construction in the interior upland areas of the Eastern Woodlands probably came from cultivated and domesticated plants (Yarnell and Black 1985; Fritz 1993). Little barley, maygrass, and erect knotweed were probably cultivated at this time, joining chenopod, sunflower, and sumpweed that had been domesticated in the Late Archaic (Ford 1981; Smith 1985b; Yarnell and Black 1985; Steponaitis 1986). This group of indigenous cultivated and domesticated grains comprises what is known as a starchy seed complex. Little barley and maygrass were summer-maturing starchy seeds, whereas erect knotweed and chenopod were fall-maturing seeds (Smith 1985a), as were the oily seeds of sunflower and sumpweed. Yarnell (1993) estimates that at one site, starchy and oily seeds contributed as much as 76 percent of the plant foods in the diet, and starchy seeds may comprise as much as 90 percent of the seeds recovered from a Middle Woodland deposit (Yarnell and Black 1985). Domestic gourd-squash and bottle gourd were grown along with food crops in small gardens (Smith 1985b; Yarnell and Black 1985).

Maize is the only domesticated food plant of clearly tropical origin found in Middle Woodland deposits (Fritz 1990). It was introduced to the Eastern Woodlands from Mesoamerica sometime around A.D. 200 (Conard et al. 1984; Chapman and Crites 1987), although isotopic and other studies of human skeletal systems do not show that it was more than a minor component in the diet until many centuries later (Merwe and Vogel 1978; Bender, Baerreis, and Steventon 1981; Boutton et al. 1984; Ambrose 1987). A domesticated tropical pumpkin-marrow variety was introduced from Mesoamerica at the very end of the Woodland period, probably about A.D. 1000 (Smith 1989).

The increase in horticultural activities during the Woodland period is reflected in wood-charcoal and pollen studies in several locations. Late Archaic wood-charcoal assemblages at several sites are dominated by plants associated with floodplains, but in Middle Woodland samples, floodplain species drop to 10 percent of the wood spectrum (Johannessen 1984; Fritz 1990). Trees associated with disturbed habitats, such as pine, red cedar, tulip tree, and giant cane, increase during this same period (Fritz 1993). This evidence indicates that stream-terrace vegetation was cleared for planting (Chapman et al. 1982; Delcourt 1987; Smith 1987a; Fritz 1990). Many of the plant species used in the Eastern Woodlands also thrive in open or disturbed habitats, demonstrating this preference by living as commensal plants around human habitations (Yarnell 1982; Gremillion 1989).

Not all of these plants were grown throughout the Eastern Woodlands, although there is evidence for a Late Archaic-Woodland tradition that featured small starchy seeds in some portions of the region (Smith 1985a; Fritz 1993). One of the intriguing problems is that the starchy seed complex appears to have been of minor importance on the coastal plain. This may be because appropriate recovery techniques have not been used at archaeological sites below the fall line, or it might indicate that an entirely different complex of resources supported communities on the coastal plain and in the lower Mississippi River valley.

Evidence for Woodland animal use is much more abundant than for the Archaic period. It suggests, however, continuity rather than discontinuity in the animals harvested (Munson et al. 1971; Parmalee, Paloumpis, and Wilson 1972; Byrd and Neuman 1978; Springer 1980; Styles 1981; Kelly and Cross 1984;

Reitz, Marrinan, and Scott 1987; Reitz 1988; Reitz and Quitmyer 1988; Styles and Purdue 1991). This is surprising for two reasons. Sometime in the Woodland period, bows and arrows began to be used to hunt animals, augmenting the earlier spears. Additionally, the increased use of cultivated and domesticated plants might have called for an alteration of the strategies used to capture animals due to schedule conflicts or different opportunities to capture garden-raiding species. With more data we may find that subtle, site-specific changes did occur, but at present it would appear that there were no dramatic changes. All of the animals listed in Table V.D.5.3 have been found in most Woodland samples. The Archaic tradition of combining white-tailed deer with many other species continued into the Woodland period. Often those other species were aquatic or estuarine animals, which sometimes were used more frequently than land mammals, including white-tailed deer (Styles 1981; Reitz 1988; Reitz and Quitmyer 1988).

Mississippian Cuisine

Mississippian societies were among the most complex north of Mexico (Table V.D.5.1). The area associated with the Mississippian tradition includes most, although not all, of the Southeastern Woodlands (Smith 1986). It was densely populated in the sixteenth century by farmers who lived in villages organized into complex, hierarchical chiefdoms. The chief was a governing figure who inherited the role (Steponaitis 1986; Welch 1991). Many Mississippian communities had at least one flat-topped pyramidal earthen mound, and some of the larger towns had smaller subsidiary villages affiliated with them.

Chiefs who commanded large numbers of warriors collected tribute from vassal communities. This often took the form of goods, such as ceramic or copper objects, but it included maize, shell beads, bear canines, and deer hides as well (Welch 1991). Mississippian societies were not found universally throughout the Eastern Woodlands, but they had become widespread in the region after A.D. 1000, and in the sixteenth century, it was this lifestyle that was most frequently encountered by European explorers of the Southeast.

Mississippian cuisine included three types of resources: wild plants, wild animals, and cultivated and/or domesticated crops. A representative but incomplete list of some food resources and their scientific names is presented in Tables V.D.5.2 and V.D.5.3.

Wild Plants

Wild fruits, berries, and nuts were widely used in the Southeast (Medsger 1976; Byrd and Neuman 1978; Yarnell and Black 1985). Perhaps the most widely used fruit was persimmon, but many fruits and berries were included in Mississippian diets. In the sixteenth century, Old World watermelons, figs, and peaches were added to the list. These fruits achieved such rapid acceptance by Native Americans that they preceded European explorers, who often thought them to be indigenous (Hudson 1976: 295). Such nuts as hickory, pecan, black walnut, and a wide variety of acorns were also frequent components of Mississippian meals.

Wild plants added a variety of greens, roots, tubers, and grains to the Mississippian diet. Large cane, wild beans, and vetch were often eaten by Mississippian peoples, depending on availability. Unfortunately, archaeological evidence for greens is limited unless seeds accompanied the leaves to be eaten, as in the case of ragweed. In addition, jewelweed, peppergrass, pokeweed, and purslane provided greens. Many of these plants are now considered weeds and are often found around human habitations, whereas others are abundant in low-lying damp locations, such as river valleys (Medsger 1976). Fungi may have been consumed, but little archaeological evidence survives for their use (Swanton 1946: 244).

Roots and tubers were an important wild resource for Mississippian peoples, although archaeological evidence is extremely rare due to preservation biases. From ethnographic evidence we know that sweet flag, wild onion, wild garlic, hog peanut, groundnut, wild hyacinth, toothwort, Jerusalem artichoke, wild sweet potato, Indian cucumber, greenbrier, and coontie were all used. Many of these plants are found in swamps, on marshy ground, and along lakes and streams (Medsger 1976). Some of the tubers and roots used are actually found in water, including American lotus, golden club, arrow arum, arrowhead, bulrush, and cattail.

Some plants provided condiments, beverages, and oil. Honey locust, maypop, sumac, maple, spicebush, sweet gum, and sweet bay were made into sweeteners and beverages (Hudson 1976: 309; Medsger 1976). Sassafras was used not only as a drink but also to thicken soups (Hudson 1976: 309). One of the most remarked upon drinks was cassina, made from yaupon holly. Yaupon could be made into a simple caffeinated beverage or into "black drink." Black drink had an emetic effect and was important in rituals on the coastal plain (Medsger 1976: 215–16; Hudson 1979; Welch 1991: 113–14). Plants, particularly the nuts, provided oil. Salt was obtained from salt licks as well as through trade with coastal peoples (Swanton 1946: 242, 268, 300–4; Hudson 1976: 316; Muller 1984), and some plants offered salt substitutes (Swanton 1946: 270, 303).

Wild Animals

Although many nutrients associated with plants could be obtained from either wild or cultivated–domesticated plants, sources of meat and animal-derived proteins, fats, minerals, and vitamins were almost entirely wild, with the possible exception of the dog, which may have been consumed in some locations (Hudson

1976: 289–90). Animals may be roughly divided into forest and aquatic–estuarine categories. In some respects this division is an artificial one because many animals that do not actually live in water are found in close proximity to it.

A wide range of forest animals were consumed by Mississippian peoples (Reitz 1982; Kelly and Cross 1984; Reitz et al. 1987; Carder 1989). Land resources often overlooked in discussions of Mississippian diets include box turtle, gopher tortoise, and snake. Quail, wild turkey, passenger pigeon, mourning dove, and a variety of small song birds were also sometimes included in Mississippian diets. Likewise, such mammals as opossum, rabbit, squirrel, woodchuck, black bear, raccoon, elk, and white-tailed deer were widely consumed.

Many Mississippian sites are found on river floodplains and bottomlands, and so it is not surprising that numerous aquatic animals were used by Mississippian peoples (Springer 1980; Hale 1984; Carder 1989). Where freshwater bivalves and gastropods were eaten, they accumulated into very large middens. However, the nutritional contribution of mollusks is uncertain (Parmalee and Klippel 1974).

Remains of fish are abundant in many deposits. In freshwater settings, fish may include gar, bowfin, sucker, catfish, pike, sunfish, and drum. Amphibians are not frequently found in Mississippian deposits, but sirens, amphiuma, and frogs were clearly eaten in some communities. A wide range of reptiles, including alligator, snapping turtle, mud turtle, musk turtle, map turtle, cooter, slider, softshell turtle, and snakes, were used. Wetland birds were used in large numbers only at sites located along important migration routes. At such sites heron, duck, and geese were consumed. In addition to these resources, such aquatic mammals as muskrat, beaver, and otter were eaten.

Coastal sites with access to estuarine settings form a special case. Archaeological evidence for use of a wide range of animal resources is abundant. This array includes crustacea, bivalves, gastropods, sharks, rays, and bony fish. Turtles were commonly consumed, particularly those found only in estuarine settings, such as diamondback terrapin. Evidence for use of sea turtle meat or eggs is very limited, as is evidence for widespread use of birds and land mammals. Remains of white-tailed deer, for example, are often nonexistent at coastal Mississippian sites (Reitz 1985, 1988; Reitz and Quitmyer 1988). Mammals restricted to marine settings, such as dolphins and manatees, were occasionally eaten, but at most villages they were probably not commonly used.

Cultivated and Domesticated Crops

Farming was a key Mississippian subsistence activity. Cultivated crops included little barley, maygrass, and erect knotweed, whereas domesticated ones included chenopod, gourd–squash, sunflower, sumpweed, and bottle gourd (Yarnell and Black 1985; Steponaitis 1986; Fritz 1990). All were indigenous to the Eastern Woodlands, and in some communities starchy seeds contributed an average of 78 percent of the total identifiable seeds (Johannessen 1984). Although none of these plants individually constituted a complete protein source, their nutritional value was quite high and, when combined with other plants, would have provided a complete protein (Asch and Asch 1978; Cowan 1978; Crites and Terry 1984; King 1985). Maygrass is higher in protein than the other starchy seeds and is similar in protein density to fish (Crites and Terry 1984), although like all plants, it is inadequate in at least one essential amino acid (Asch and Asch 1978; Crites and Terry 1984). Sumpweed and sunflower seeds have a high oil content, with sunflower seeds yielding 20 percent oil (Medsger 1976). Chenopod, little barley, maygrass, and erect knotweed are high in carbohydrates (Crites and Terry 1984).

The domestic plants considered most characteristic of Mississippian diets, however, were introduced from tropical America. These included pale-seeded amaranth, pumpkin–marrow, the common bean, and maize (Fritz 1984; Yarnell and Black 1985). Tropical plants were introduced to the Eastern Woodlands just prior to or during the Early Mississippian period, but as already mentioned, maize was a minor crop throughout the Southeast for several centuries and only became important in most areas sometime between A.D. 800 and 1100 (Fritz 1990). At some sixteenth-century Mississippian sites, maize was clearly the most significant domesticated plant and had already become far more important than indigenous cultivated or domesticated plants. But at other sites, starchy seeds continued to be more abundant than maize (Scarry 1993a). The tropical common bean may have been added to the Mississippian diet as late as the 1400s (Fritz 1990).

Very little is known about either wild or domestic plant use by Mississippian peoples living in coastal settings. Although there have been lengthy discussions about the role of maize in coastal Mississippian economies, there has been little archaeological evidence of its importance (Yarnell and Black 1985; Reitz 1988, 1990).

Food Procurement Technology

The combination of wild fruits, nuts, tubers, seeds, and animals with maize and other crops provided a solid subsistence base characteristic of the Mississippian period. Such a base could have been exploited in a number of different ways to produce a surplus for storage and exchange. Many cultivated and domesticated crops were grown together in large, permanent fields, as well as in smaller gardens on river terraces (Swanton 1946: 304–10; Hudson 1976: 290–1; Smith 1985b; Riley 1987; Woods 1987).

Mississippian peoples living near large population centers appear not to have engaged in slash-and-burn or swidden cultivation, although people living in smaller communities may have done so. In some places, raised fields were constructed to improve drainage (Riley 1987; Woods 1987). The primary horticultural implements used were stone and bone hoes, stone axes, and digging sticks. Horticultural activities were largely the domain of women, although men participated in the initial clearing of the fields (Hudson 1976: 295).

Numerous techniques were used to acquire wild resources (Swanton 1946: 265–304, 310–44; Hudson 1976: 272–88), with many of these so sufficiently generalized that they could be applied to the acquisition of more than one resource. Wild berries, nuts, seeds, and tubers were gathered with the aid of beaters, skin bags, baskets, and digging sticks. Similar techniques and tools could have been used to collect most of the mollusks. Fish may have been captured using trotlines, gorges, spears, nets, weirs, and traps, and there is some evidence for the use of fish poisons (Swanton 1946: 246–7, 332–44; Rostlund 1952: 127–33). The latter are most effective in quiet waters, and many of the fish found in Mississippian sites are common in calm aquatic locations.

Fish were also caught with handlines or speared (Rostlund 1952: 113–26), and trotlines and traps would have been ideal for capturing aquatic turtles and mammals. Sirens, frogs, and snakes might also have been caught with such devices, and traps of various kinds, decoys, and snares would also have been useful for capturing most land animals (Swanton 1946: 328–32). Indeed, although larger animals, such as elk and white-tailed deer, could be hunted using spears, clubs, blowguns, and bows and arrows, traps and snares would have been considerably more efficient.

A particularly useful hunting strategy would have involved the careful visiting of gardens and fields each morning and evening in order to surprise garden-raiding animals (Linares 1976). Many of the birds and mammals commonly consumed by Mississippian peoples are attracted to crops, so that traps set in or near fields should have been productive. Hunting at night with torches would also have been effective, and communal surround drives were employed in some areas in the Southeast (Swanton 1946: 313; Hudson 1976: 275–6). Mississippian peoples may have burned forest underbrush in order to improve the growth of vegetation preferred by white-tailed deer. At the same time, this would have made more abundant the nuts and other plants that prefer open habitat (Yarnell 1982).

Foods were prepared in a number of ways (Swanton 1946: 351–72; Hudson 1976: 300). In addition to being consumed fresh, fruits, nuts, seeds, greens, roots, tubers, and meats were preserved by drying either through simple exposure to sun and air or by smoking. Mortar and pestle were employed to pulverize or grind foods to ready them for preservation, as well as for immediate consumption (Hudson 1976: 301, 307).

Maize was consumed in many forms. In addition to use as a vegetable (such as roasted "corn-on-the-cob"), it was treated with wood-ash lye and made into hominy. The lye treatment increases the amounts of the amino acid lysine and of the vitamin niacin available from maize (Katz, Hediger, and Valleroy 1974). From hominy, a number of maize dishes were made (Hudson 1976: 305). Hominy might be eaten whole or ground into flour for breads that were fried, boiled, or baked. In addition, maize was often combined with other foods, such as nuts and beans. Combinations of beans and maize were particularly common and are nutritionally interesting because each plant complements the limiting amino acids in the other, so that together they provide a complete protein source (Katz, Hediger, and Valleroy 1974).

Elsewhere in North America

Not all of the peoples living in North America in the sixteenth century were farmers. Two of the most distinct examples of nonhorticultural foodways were to be found on the Northwest Coast and in the Arctic. Although both of these areas had early contact with Europeans, it is probably significant that this contact was largely intermittent and did not lead to permanent sixteenth-century European settlements, such as those that developed on the Atlantic coast.

The Northwest Coast is a long, narrow area stretching along the Pacific coast of North America from, roughly, 60° to 42° north latitude. It has a relatively mild climate but a rugged topography and a temperate rain forest that is broken at frequent intervals by streams used by anadromous fish, especially members of the salmon family. The area is well known for its large sedentary villages, elaborate woodworking skills, and complex social organization supported without horticultural input (Stewart 1977; Isaac 1988; Suttles 1990b).

In large part, the reason for the lack of horticulture was a well-developed marine fishery, especially one associated with the vast, but highly seasonal, salmon runs into coastal rivers. Salmon, surf perch, rockfish, greenling, lingcod, sculpin, red Irish lord, and many other fish were the source of most of the meat in the diet (Mitchell 1988; Wessen 1988; Wigen and Stucki 1988; Suttles 1990b). But whales, porpoises, harbor and fur seals, sea lions, and sea otters were also consumed. Many of these mammals were high in fat, and a smelt, known as eulachon, provided an edible oil. Mussels and clams were taken from the marine environment, as was a wide range of ducks and other birds.

Freshwater fish and mammals, such as beaver and otter, were frequently eaten, although gastropods and bivalves were apparently seldom used in most areas. Land mammals, such as bear, raccoon, elk, deer, and caribou, were consumed, but not as commonly as marine resources. Inasmuch as many of these animals were only abundant seasonally, preservation techniques, including drying and smoking and the liberal use of oil as a preservative, were well developed.

Such an elaborate marine fishery has often obscured the fact that plants gathered but not cultivated played an important role in the diet (Spencer and Jennings 1965; Suttles 1990a). Many species of fruits and berries were consumed, including salmonberry, gooseberry, currant, red elderberry, huckleberry, salal, and cranberry (Suttles 1990a). These were dried and combined with oil and fish to form pemmican. Rhizomes, such as bracken, sword fern, lady fern, spiny wood fern, male fern, and licorice fern, were consumed, and rice-root lily, chocolate lily, camas, tiger lily, wild onion, fawn lily, wild hyacinth, and a tuber known as wapato were also eaten. Several marine algae were part of the diet, as was the edible cambium of spruce, pine, hemlock, alder, and cottonwood bark; tree lichen; and, in some locations, mushrooms (Suttles 1990a). Nuts were also consumed, but seeds were not widely used (Suttles 1990a).

In sharp contrast to the foodways of the Northwest Coast and the Eastern Woodlands were the Arctic hunting traditions developed in the far north of the continent by Eskimos, or Inuits (Damas 1984b). The southern boundary of the Arctic roughly corresponds with the tree line, where the boreal forest ends and the northern treeless region, or tundra, begins. This also marks the distribution of prey species significant in the hunting strategies practiced in the Arctic region (Damas 1984a: 1).

Both plant and animal resources have been limited in the Arctic, and prior to the sixteenth century, most peoples there specialized in a maritime strategy that focused on whales, walrus, and seals. But many also hunted hares, ground squirrels, and especially caribou, along with the flesh and the eggs of ducks, geese, sea birds, and ptarmigans. Fishing and mollusk gathering were also important activities. Since many of these resources were highly mobile, as well as markedly seasonal, Arctic peoples adapted their settlement patterns to correspond with the seasonal cycle of animals important to their diets. This unique inventory of animals was hunted with a highly complex technology (Balikci 1984).

Until recently, the Arctic diet was distinctive for its low content of plant resources, which meant little in the way of carbohydrates. In the absence of plant carbohydrates, humans can utilize protein only in the presence of fat; and an important characteristic of many of the animals consumed in the Arctic region was their high fat content (Freeman 1984: 45). Nonetheless, several plant foods were consumed in season. These included salmonberry, cranberry, crowberry, blueberry, cow parsnip, a lily bulb, licorice root, willow leaves, sourdock, cowslip, anemone greens, parsnip, and kelp and other algae (Lantis 1984: 176; Ray 1984: 289).

Native Foodways and European Colonies

The first Europeans to maintain a permanent presence in temperate North America were the Spaniards. The Spanish colony of La Florida, which encompassed a portion of the Atlantic coastal plain and the Florida peninsula, was established in 1565 and lasted for 200 years. Unfortunately, very little archival evidence is available for Spanish diets in the Southeast during the sixteenth century. We do know that supply lines to La Florida were unsatisfactory and subject to interruptions. Natural disasters and attacks by a variety of human foes contributed to the unreliability of imported staples, munitions, and other supplies. Disease and other natural disasters further hampered efforts to develop the colony. In the records that are available, Spanish governors complained bitterly of starvation and of eating unwholesome foods. If we are to believe the official correspondence, sixteenth-century St. Augustinians, at the least, had very little to eat, and sometimes subsisted on extremely unpalatable foods, or even nonfoods.

Data on plant and animal use recovered from archaeological sites in Florida indicate, however, that complaints of food shortages in the colony were probably exaggerated (Reitz and Scarry 1985). This is not to deny that food might have been scarce occasionally. But there is nothing in the archaeological record to suggest that starvation of the sort reported by some Spanish governors was a common phenomenon or that inedible, nonnutritious resources were consumed often enough to become noteworthy.

Rather, what we have is evidence that the colonists adapted to North American conditions and blended their own foodways with native North American dietary traditions (Reitz and Scarry 1985). During the first few years of colonization, the plant and animal foods consumed by Spaniards and Native Americans were very similar (Reitz 1985; Scarry and Reitz 1990).

Domesticated and wild plants employed by indigenous Native Americans dominated the list of plants consumed by Spaniards in the sixteenth century (Reitz and Scarry 1985; Scarry and Reitz 1990). Squash, sunflower, beans, and maize comprised about half of the vegetable part of the diet, with nuts and wild fruits making up an additional third. The primary Old World domesticated crops in the diet were watermelon, melon, and peach (Reitz and Scarry 1985: 56). Efforts to grow wheat were generally unsuccessful. It is interesting to note that indigenous New World domesticated crops, such as chilli peppers, moschata squash, and lima beans, previously unknown in La Florida, were apparently imported from Mesoamerica by the Spaniards.

Sea and land animals used by Spaniards in the sixteenth century were mostly wild (Reitz and Scarry

1985; Scarry and Reitz 1990). Over a third of their meat came from sharks, rays, and bony fishes, with the most common the hardhead and gafftopsail catfish, sheepshead, Atlantic croaker, black drum, red drum, and mullet. A wide range of reptiles, including sea turtles, entered the diet, but predominating were the estuarine diamondback terrapin and freshwater turtles, such as the cooter and slider. Ducks, Canada geese, and turkeys were the most important of the wild birds that were harvested. Although opossum, rabbit, squirrel, and raccoon found their way to Spanish tables, deer and gopher tortoise were generally the most prevalent wild land animals. Domestic animals contributed less than half of the meat consumed by Spaniards: Beef was probably more common in the diet than either pork or chicken (the only domesticated bird); sheep and goats were very rare.

Archaeological data indicate that the Spaniards combined Eurasian and American foods into a locally viable cuisine, but like the Native Americans, Spaniards were heavily dependent upon indigenous crops and wild animals. To this complex of local resources they brought some Eurasian plants and animals that could do well on the coastal plain. In terms of animal resources, this strategy continued with little modification until the end of Spanish governance in the eighteenth century (Reitz and Cumbaa 1983).

Conclusion

A study of native North American subsistence strategies is important for the contribution it can make to our knowledge of foodways in temperate environments and for an understanding of the importance that such strategies had for European colonists. A survey of food and drink in North America shows that Native Americans employed the resources available to them in complex and specialized ways. The foodways of the Eastern Woodlands combined a wide range of wild, cultivated, and domesticated plants and many different wild animals into a mixed subsistence strategy. The resources used were primarily low-cost, calorically productive ones acquired from nearby fields, forests, and waterways. The archaeological record of the Eastern Woodlands suggests that patterns established in the Archaic continued with subtle modifications into the Mississippian period and even into the early years of European expansion. Over time, however, subsistence strategies came to include an increasingly diverse complex of crops and wild resources. The most significant changes that took place in foodways in the Eastern Woodlands were the development of indigenous cultivated and domesticated crops and the eventual addition of tropical cultigens to local farming traditions. These changes resulted in a cuisine that supported large numbers of people with complex political and economic systems.

The native foodways of the Eastern Woodlands had a profound impact on sixteenth-century Spanish colonists, who benefited from the well-established mixed economy practiced in the region. They altered indigenous practices primarily through the introduction of domestic animals and by adding a few of their plants to augment a diet based on American crops. Not only did this interchange enable European colonial efforts to succeed but it also ensured that many of the foods and drinks used by native North Americans would survive to be included in North American and global foodways in the twentieth century.

Elizabeth J. Reitz

I am grateful to Gayle J. Fritz, David R. Huelsbeck, and C. Margaret Scarry for their assistance in the preparation of this chapter. I am particularly pleased that Dr. Scarry was willing to share with me the text of the book she was editing while it was still in manuscript form. Errors in interpretation, however, are my own.

V.D.6 North America from 1492 to the Present

The food history of Native Americans before the time of Columbus involved ways of life ranging from big-game hunting to (in many cases) sophisticated agriculture. The history of foodways in North America since Columbus has been the story of five centuries of introduced foodstuffs, preparation methods, and equipment that accompanied peoples from Europe, Asia, and Africa, with the food culture of North America having been enriched by each addition.

The Sixteenth Century

Most narrative histories of North America give little attention to the sixteenth century, even though two earthshaking events took place during this time that were to alter the continent's history fundamentally. One was the demographic collapse of the native populations in the face of Eurasian diseases, such as smallpox. This made possible the second, which was the establishment of European settlements along the eastern seaboard without substantial native resistance.

The Native Americans

The peoples of North America, who numbered perhaps 20 million in 1492, dwelled in societies of many different types, with their cultures shaped by their foodways. Thus, those who depended on hunting and gathering usually lived in roaming bands, whereas maize agriculture normally implied settled life in villages or towns. In the north and west of the continent, the hunter-gatherer lifestyle still predominated in 1492. Game varied from bison on the Great Plains to rats in the deserts of the Southwest. Men hunted and women gathered in these usually nomadic, band-level societies. Some bands, like the Mi'kmaq of Nova Scotia, grew one crop, such as tobacco, and hunted and gathered the remainder of their food supply (Prins 1996). It is important to note that the European picture of Indians as primitives did not allow for such sophistication. The Mi'kmaq knew perfectly well what agriculture was but chose to obtain their food from the wild and to plant only tobacco, which the wild could not provide. Where a staple food could be collected easily, such as in parts of California (where acorns were the daily fare) or in northern Minnesota (where wild rice was the staple), the natives frequently formed settlements (Linsenmeyer 1976).

An agricultural complex had been developing for centuries in eastern North America when Ponce de León stepped ashore in 1513. Older staples, such as Jerusalem artichoke and sumpweed, had given way to Mexican maize, beans, and squash. Varieties of maize adapted to extreme conditions permitted horticulture to flourish as far north as the Dakotas.

In the Southeast and the Mississippi Valley, the area of the Mississippian culture, intensive agriculture supported cities resembling those of Mexico and Peru, with thousands of inhabitants, elaborate social systems, and multiple castes (Duncan 1995). Maize, beans, and squash, along with fish and game, fed the masses. A ceremonial beverage made from yaupon holly, called "black drink," was a caffeine-containing stimulant similar to tea or coffee (Hudson 1979). (It is strange that alcohol was almost unknown among North American natives, although some made a sort of ale from maize or maple sap; after European contact, however, alcoholism would become a serious problem for them.) The "Gentleman of Elvas," chronicler of Hernando De Soto's expedition (1539–42), described one Mississippian city – near the future site of Augusta, Georgia – that was ruled by a queen he called the "Lady of Cofachiqui" from a pyramidal mound topped by her large wooden house (Duncan 1995). Fields of maize stretched as far as the horizon. The surplus from the fields went into granaries to feed people in need – a mark of true civil society (Crosby 1986). Clearly, these people and others, like those who built the mounds at Cahokia in Illinois (Middle Mississippian ancestors of the Siouan-speaking Indians), had sophisticated state-level societies with governmental systems, long-distance trade, and complex religions.

Cofachiqui also had four huge barns wherein the dead from a smallpox epidemic were mummified, and by 1650, her elaborate society had vanished, likely because of further outbreaks of disease (Duncan 1995). Perhaps 90 percent of North America's native population died in a series of "virgin-soil" epidemics, and much knowledge of foodstuffs and other cultural traditions was lost forever in this immense demographic disaster (Crosby 1986).

In addition to their deadliness, the epidemics were demoralizing, as traditional religious and medical practices proved useless. Some Native Americans believed that the end of the world had come, and needless to say, diseases precipitated a great deal of migration: Tribes moved to escape the pathogens, to flee from enemies that they were too weak to resist, or to invade the territory of decimated foes. The map of aboriginal America was altered beyond the scholar's power to reconstruct. The Mississippian peoples vanished, and tribes having no knowledge of the origin of the great mounds took their places.

The Spanish Borderland Settlements

During the sixteenth century, Spanish priests and soldiers established several missions in the Southeast. St. Augustine was the most important, but others came into being along the coasts of Georgia, Carolina, and (briefly) Virginia. Both literary and archaeological evidence indicate that the Spanish imported a large amount of food, including wine and wheat flour (Milanich 1995). But more important for day-to-day survival were native foodstuffs, such as maize, yaupon, and wild game, provided by Indians living at the missions.

Spanish explorers also distributed wheat flour to native rulers and passed out European seeds as gifts to natives, with translated instructions for growing them; the peach orchards of the Mississippi Natchez stand as testimony to how far these plants spread (Farb 1968; Milanich 1995). In the warm climate, mission gardens yielded favorites brought from Europe, such as melons, figs, hazelnuts, oranges, chickpeas, greens, herbs, peas, garlic, barley, pomegranates, cucumbers, wine grapes, cabbage, lettuce, and even sugarcane. In addition, the Spanish carried the sweet potato of the Caribbean to Florida, where it was previously unknown (Milanich 1995).

Such plant transfers – not only from the Old World to the New but also from one area of the New World to another – resulted in confused, albeit enriched, foodways. Moreover, as Alfred Crosby (1986) has pointed out, Old World species exhibited an ability to edge out their New World counterparts, with "ecological imperialism" the result. Large numbers of wild horses, cattle, and hogs multiplied in an environment free of accustomed predators, and even the honeybee (native to Eurasia) thrived, while the pollen it spread about fertilized imported European plants that depended upon it. The result was an abundance of food in virtually all the neo-European societies of the New World – a situation that has continued to the present (Crosby 1986).

The Seventeenth Century

The Chesapeake Region

The seventeenth century saw the planting of permanent English colonies in North America, including the beginning of European settlement of the Chesapeake. Colonists usually brought provisions reflecting the diet of contemporary Britain, which was based on grains, meat, and milk products. Bread, the daily staple, ranged from the mixed-grain bread of the poor to the "white" bread of the wealthy. Luxurious meals for the upper classes included elaborate spicing, many pastries, and complex cooking methods reminiscent of those of the Near East, with copious use of rose water, almonds, and currants (Hess 1992). *Martha Washington's Booke of Cookery* (Hess 1981), a seventeenth-century manuscript recipe book (although some recipes in it are a good deal older) passed down in the Custis family of Virginia, provides a glimpse of this cuisine, with its profusion of custard curd dishes, rose water, garlic (later to be virtually forbidden), almond-scented meats, and practical hints on preserving foodstuffs (cherries, peas, turnips, and even oysters pickled in barrels) and distilling homemade medicines. Among other recipes is one for apple pie, foreshadowing its status as an American icon; oat "greats" (groats), soon to be replaced by American "grits" of corn (maize), are mentioned as well.

In the mid-1580s, English settlers landed on Roanoke Island in present-day North Carolina, but the first permanent British colony was Jamestown, Virginia, established in 1607 by 105 Englishmen, among whom there was but a single farmer. In an ensuing period of starvation, poisonous "Jimson" weeds, oysters, maize (stolen from the local Powhatan Indians), and even, apparently, human flesh kept the colonists from dying out completely (Smallzreid 1956). Thereafter, much more attention was paid to crops. British wheat did poorly in the climate of the Chesapeake, and the settlers came to depend on cornbread, grits, and pork. Their hogs ate maize, along with acorns and peanuts. "Ashcake" and "hoecake," baked in ashes on the blade of a hoe, were the staples of poor whites and, later, of black slaves, some of whom had known maize in Africa because of the slave traders, who imported the plant to feed slaves awaiting transport to the Americas. Bread was baked on coals or fried in pork fat, and meat was roasted, fried, or boiled (Fischer 1989). Cornbread was the food of the poor because of the ease with which maize could be grown, but the wealthy enjoyed its taste as well (Horry 1984). However, an overreliance on maize was to lead to malnutrition and vitamin deficiencies in the South, with poor health a consequence (Kiple and King 1981).

It is worth noting that some food historians attribute numerous American dishes, ranging from strawberry shortcake to Brunswick stew, and their means of preparation to the native peoples (Root and de Rochemont 1976). However, although the native origin of such foodstuffs as maize and venison is obvious, a survey of the foodways of the Powhatans of Virginia reveals that they contributed little that was exotic to the English settlers. For example, a feast prepared in 1607 at Arrohateck, Virginia, included mulberries and strawberries boiled with beans, cornbread, "meale," and a "land turtle" – hardly sophisticated fare (Rountree 1989). The truth of the matter was that the Indians of the Eastern Woodlands lacked salt and spices (even the hot peppers of Mexico and Peru), as well as frying pans and other iron utensils, ovens, wheat, sugar, dairy products, and all domestic animals save the dog. Thus, to assert that strawberry shortcake derives from an Indian dish that was nothing more than berries and maize or beans boiled together is, perhaps, something of an exaggeration. It is important not to confuse the Indians of North America with those of Central or South America: Although many have written that the native peoples of North America had, for example, the potato and the chilli pepper, as did, respectively, the Inca and the Aztecs, this was simply not the case.

New England

The Massachusetts area received its first white settlers with the *Mayflower* in late 1620. Following a harsh winter during which many of them died, the colonists learned from the Native American Wampanoags how to hunt and fish in the new land and how to plant crops. The following November established a landmark in American culinary history: the first "thanksgiving dinner," prepared by the Pilgrims and their Wampanoag hosts. In truth, the modern Thanksgiving holiday dates back only to Civil War times, and as for the Pilgrims' thanksgiving, there is no mention of the famous turkey.

In 1630, 1,000 colonists arrived on the 17 ships of the Winthrop fleet to found the Massachusetts Bay colony. Their provisions included cheese, salt fish, pork and beef, oatmeal, hard biscuit, bread and butter, peas, onions, raisins, prunes, and dates, with cider, beer, water, sweet wine, and small amounts of brandy, called "aqua vitae" (Smallzreid 1956). Because a virgin-soil epidemic had reportedly annihilated the local Indians in 1617, the landing of the settlers went unchallenged, and they proceeded to found a colony of self-sufficient farmers. They ate well, if somewhat monotonously; an average of 3,200 to 5,000 calories a day was the norm in New England (Derven 1984). As did their neighbors to the south, these settlers also consumed maize meal, both as porridge and as bread or "johnnycake," but the diet did not focus on "hog and hominy," as it did in Virginia.

The use of land for small farms meant that both rich people and poor were rare in New England (Lockridge 1985). The cold climate enabled rye to grow successfully, resulting in "rye'n'injun" ("rye and Indian," a bread baked with rye and maize meal) and "Boston brown bread," made from rye, wheat, and maize that was steamed over a kettle of beans cooking with pork and molasses. (The careful cook allowed the residual heat of the oven to keep beans warm for Sundays, when – for religious reasons – no cooking or other work was permitted.) Although yeast will not act well on any grain but wheat, the rye and maize breads of colonial America could be raised with "pearl ash" (potassium bicarbonate, made from wood ashes) or with beaten eggs (Hess 1992). The most ubiquitous dishes were pies, baked (like bread and beans) in wood-fired brick ovens modeled after those used in England. Indeed, a "Yankee" was to be defined as someone who ate pie for breakfast. The types of pies reflected the seasonal availability of fruits; and because the pie makers made use of first one fruit and then another throughout the year, there was a virtual calendar of pies (Fischer 1989).

Molasses was the usual sweetener (white sugar was expensive), and it was also employed in making rum. Drinking in New England centered on alcoholic beverages, with hard cider and some beer competing with rum. Although wine grapes would not grow, bees thrived, and a few settlers managed to make honey mead, which they had known in England (Wolcott 1971). Bread, cookies, and even beer could be made from pumpkins, which were a staple for New Englanders. In fact, the ease of growing pumpkins meant that "old Pompion was a saint," and "pumpkin sause [pumpkin stewed with butter, spices, and vinegar] and pumpkin bread" were on every table (Crawford 1914: 382; Wolcott 1971).

The Middle Region: Pennsylvania and New York

The New Amsterdam colony, which became New York, and the Quaker settlement in Pennsylvania were two other sites of seventeenth-century colonization, both settled by peoples whose foodways reflected diverse origins. In New Amsterdam, the Dutch relished heavy meals of meat and bread, washed down with tea (a Dutch favorite before it became popular in England) and followed by large amounts of rich pastry. Perhaps one-fourth of the houses in New Amsterdam sold beer, tobacco, or spirits (Booth 1971).

In seventeenth-century Pennsylvania, the colonists were a mixture of Quakers, other English settlers, and some Swedes (Nash 1968). David Hackett Fischer (1989) has claimed that the northern British origin of the Quakers encouraged a distinctive pattern of foodways, of which the consumption of apple butter and dried beef was typical. By contrast, Karen Hess (1992), who has examined the Penn family cookbook and other early American sources, found nothing unique about Quaker cookery, and it has also been pointed out that the distinctive cuisine of the north of England (including Yorkshire), based on grain porridge, oatcake, and ale, did not resemble Pennsylvania cooking (Brears 1987). Thus, there is little consensus about the cuisine of the Pennsylvania Quakers (Lea 1982), although perhaps its distinctiveness could be argued because of what was *not* consumed. The Quakers' wish to isolate themselves from the sinful world led to abstinence from many foodstuffs. Some, for example, refused to use sugar because it was made by slaves. Others rejected spices, saying that they altered the taste of food (Fischer 1989).

The Spanish Borderlands

By the 1600s, the Spanish settlements along the Carolina and Virginia coasts had been abandoned, although St. Augustine in Florida continued as home to a small Spanish colony that imported much of its food. Aside from game, the local foodstuffs consumed were maize and yaupon holly, from which was made the Indians' "black drink," containing caffeine. A priest explained that yaupon was drunk "every day in the morning and evening" and that "any day that a Spaniard does not drink it, he feels that he is going to die" (Sturtevant 1979: 150)

In the Southwest, which had been settled from Mexico during the sixteenth century, the traditional cookery of Native Americans came to include Spanish imports, such as domesticated food animals, sugar, tea, and coffee. As the hunter–gatherer Navaho and many other tribes became pastoralists, they adopted a diet of mutton, bread, and coffee (Driver 1961). Perhaps ironically, many Indian groups in the Southwest learned maize agriculture from the Spaniards, and beef and maize became the staples for many in this ranching land. Food was plentiful, if judged by a book on early California cooking that lists five daily meals. For dinner, a well-off family in Spanish California might have a selection of foods that mixed Iberian fruit preserves and wine, a salad of local pigweed, Mexican tortillas, beans, and succotash, and such European-influenced dishes as fried rice and coffee (Smallzreid 1956).

The Eighteenth Century

In America, the eighteenth century brought a "golden age" for the planters of the Chesapeake region. Cultural amalgamation among the several colonies meant the end of religious uniqueness for the New England Puritans and Pennsylvania Quakers. The Indians were forced beyond the Appalachian Mountains, and the colonies' political consolidation that began with the Albany Plan of Union ended with American independence and the Constitution of the United States. This political union meant that, in the long run, neither the Native Americans nor the Spaniards would retain their lands. The field of cookery also became "independent," as English cookbooks were succeeded by the first American cookbooks.

In all American societies, food availability depended on the seasons. Autumn saw an abundance, but late winter and early spring meant the "six weeks' want" (Farrington 1976). It was a time when greens and roots were used to relieve the monotony of stale meal and beans before the first garden vegetables came in. The southern colonies had longer growing seasons and thus less of an annual time of "want." However their warmer climate encouraged a hostile disease environment, with the result that New England families were larger and life spans longer (Fischer 1989).

It has been claimed that, in general, early Americans disliked, or at least seldom consumed, vegetables, and it was certainly the case that – in an age without refrigeration – green vegetables kept poorly. Moreover, without a marketing and transportation system, availability was limited; once the season for a particular food had passed, there would be no more of it until the following year. Perhaps most importantly, modern varieties of vegetables did not exist: There was no tomato designed to ripen slowly off the vine, nor a maize cultivar that stayed sweet. To obtain and cook vegetables required a certain tenacity, and in an age ignorant of vitamins and fiber, some people simply did not bother with them.

In spite of these factors, however, many Americans seem to have enjoyed vegetables and fruits. Amelia Simmons, in compiling her 1796 cookbook, evidently assumed that any good meal included vegetables (Simmons 1965). Vegetables were cooked for longer periods than they are today (in order to ensure their safety and edibility by those with few or no teeth) but were not necessarily boiled into mush, as is sometimes asserted. The eighteenth-century South Carolina housewife Sarah Rutledge, for example, boiled her cauliflower for only 15 minutes (Rutledge 1979).

Many people raised fruits and vegetables in abundance. An example comes from an 1806 gardening calendar kept by a Charleston lady who grew fruit trees, strawberries, gooseberries, currants, raspberries, thyme, savory, hyssop, peas, beans, cabbage, lettuce, endive, potatoes, artichokes, and Jerusalem artichokes (Tucker 1993). Thomas Jefferson and his Paris-trained slave-chef James Hemings kept a huge garden of peas, cauliflower, cabbage, lettuce, parsley, kale, tarragon, broccoli, spinach, "corn salad," endive, savory, turnips, carrots, beets, salsify, parsnips, radishes, onions, eggplant, melons, and beans (Tucker 1993). They even sprouted endive in the cellar to provide salads in wintertime.

New England

In the eighteenth century, the people of Massachusetts were suppliers of rum for slavers and ships for whaling and fishing. The colony was a hub of trade: Spices and foodstuffs from all corners of the globe passed through New England markets. However, its own cooking centered mostly, as before, on bread, beans, fish, and salt meat. The British habits of overcooking meat and greens persisted, as did such customs as brewing special beers for special occasions (Crawford 1914). Quilting bees ended with tea served in the English style, featuring sweets, "sage cheese" (flavored with that herb), and pastries (Crawford 1914). A favorite meal was the "boiled dinner" comprised of boiled meats and vegetables and, perhaps, boiled "bag pudding" for dessert (Farrington 1976).

Substantial meals were the rule, and pie for breakfast meant plenty of calories to start the day. A visitor to Boston in 1740 remarked on the abundance of poultry, fish, venison, and butcher's meat available. The ordination of a minister called for a celebratory meal of turkeys, pumpkins, cakes, and rum. Harvard students, however, ate meager meals of cold bread and hot chocolate (Crawford 1914). There was little opposition to alcohol consumption in early America, and pastor and congregation alike drank it before Sunday church services, as well as at every meal (Rorabaugh 1979). In addition to huge amounts of bread, porridge, and cheese, the average New Englander annually consumed some 32 gallons of hard cider, 15 pounds of butter, 40 gallons of milk, between 2 and 3 pounds of tea, more than 150 pounds of meat, 10 pounds of sugar, and 1 gallon of molasses (Derven 1984).

Trade made the merchant class wealthy in what had once been an egalitarian colony, and the menus of the wealthy could be elaborate. John Adams, certainly well-to-do, served a dinner of Indian pudding with molasses and butter, veal, bacon, neck of mutton (a dish also featured in Martha Washington's cookbook), and vegetables (Fritz, 1969). A Quaker friend outdid Adams with "ducks, hams, chickens, beef, pig, tarts, creams, custards, jellies, fowls, trifles, floating islands [a custard dish], beer, porter, punch, and wine" (Smallzreid 1956: 61). Nonetheless, despite such heavy eating habits, the old Puritan ideals died hard: Jokes had it that a New England family made the same roast gander serve as a main course for seven days in a row (Crawford 1914)!

The Middle Region

In the eighteenth century, Pennsylvania became home for large numbers of German settlers (later known as the "Pennsylvania Dutch"). Deemed not assimilable by many, they colonized the back country and prospered. Many joined the great migration southward along the Appalachian Mountains and ended up in Virginia and the Carolinas. Along with the iron cookstove, these Germans contributed waffles, "shoofly pie," scrapple, new kinds of sausage, vinegar, and more pastries – including doughnuts (Farrington 1976).

Technological innovations spread from the middle colonies. By 1750, a cast-iron pot – with a rim on the lid to hold coals – was in common use. Called a "Dutch oven," it was used to bake bread, roast meats, and make stews and other dishes; in modified form, it has remained in use to this day (Ragsdale 1991). The famous stove of inventor and ambassador Benjamin Franklin improved on German models. Franklin was perhaps the most famous vegetarian of his time, having been inspired by English vegetarian and pacifist Thomas Tryon (Spencer 1995). Franklin eschewed meat and beer in order to improve his health and drew up lists of vegetarian dishes for his landlady to prepare. Toward the end of his life, however, he returned to eating some meat.

As the century came to a close, the cosmopolitan city of Philadelphia had 248 taverns and 203 boardinghouses (Pillsbury 1990). Its diverse population of English, Germans, Swedes, and Africans contributed to a varied cuisine, including the famous "Philadelphia pepper pot," which, although attributed to George Washington's cook, is similar to a Caribbean dish of the same name.

Like Pennsylvania, New York contained a mixture of cultures. Foods in this port city included so much fish and fowl that servants (who apparently wanted more meat) complained if salmon was served more than once a week or heath hen (a bird now extinct) more than three times (Farrington 1976). Such an abundance of animal food on the table was unlike Old World cuisines, which relied on porridge, bread, and potatoes. Each year, two crops of peas and one of buckwheat came from the rich soil, which also produced rye, barley, maize, potatoes, and turnips (Tucker 1993). Food for the city of New York also arrived from the "garden colony" of New Jersey (Farrington 1976) and from what is now upstate New York, where Dutch and German settlers had introduced new kinds of plows and wagons to make their farms more productive. The "Dutch plow" or "Rotherham plow" (in fact, it originally derived from China) had a share and moldboard cast in one continuous piece (Temple 1986), and its advanced design greatly eased the task of plowing. The crops on Dutch farms were diverse, with those farms reflecting the intensive use of space typical of the Netherlands.

European fruits did well; farmers planted great orchards of apples to make cider, a favorite alcoholic beverage, which was often distilled into "Jersey lightning" by means of freezing it until a core of alcohol remained within the ice. But apples were also used in numerous other ways. For example, apple pie and milk were the nightly fare for "Hector St. John" (Michel G. J. de Crèvecoeur, author of *Letters from an American Farmer*) in the late eighteenth century (Sokoloff 1991). Long before the American Revolution, eating shops and taverns provided places to dine out in New York (Pillsbury 1990). One of these was the Queen's Head (soon known as Fraunces Tavern), which opened in 1770 and was still in business over a century later (Root and de Rochemont 1976). By the end of the eighteenth century, New York had 121 taverns and 42 boardinghouses that served food and drink (Pillsbury 1990).

The Chesapeake Region and the South

As mentioned, the eighteenth century was a "golden age" for some in the Virginia tidewater. The period saw a shift from tobacco monoculture to the mixed growing of tobacco and grain, although the former continued to dominate the region. Plantations worked by African slaves yielded an abundance of maize and other foodstuffs, and maize remained the staple for the slaves, as well as for poor whites. For others, there was either bread (made from dough that rose by the addition of beaten egg) or "beaten biscuit" (made with wheat flour) that was laid on a stump and struck repeatedly with an ax handle until it began to rise (Farrington 1976).

The predominance of maize in baking meant much cornbread, almost always eaten hot; when cornmeal was fried, the result was "hushpuppies." Maize was also fed to hogs, the principal source of meat in the South until the twentieth century. In addition, the mash made from maize was distilled into corn whiskey, which was popular even before the Revolution. Later, with rum from the British West Indies more difficult to obtain, corn whiskey became the liquid staple of what has been termed the "alcoholic republic" (Rorabaugh 1979). Rum or whiskey was mixed with water and sugar to become toddy; with fruit and sugar, it was punch (Farrington 1976). Some beer was drunk, including "Roger's best Virginia ale," brewed in Williamsburg (Hume 1970). But English beer yeasts spoiled in the American summer heat, and winter killed them, making beer brewing a difficult proposition (Rorabaugh 1979). Although Virginians also made cider and some wines in the colonial period, distilled spirits kept the best (Hume 1970).

Some of the gentry were voracious consumers of alcohol. When the governor of Virginia, Lord Norborne Berkeley Botetourt, died in 1770, he left behind more than 2,000 bottles of wine, brandy, and ale and many kegs of spirits (Hume 1970). Three years later, his successor, Lord John Murray Dunmore, ordered 15 dozen bottles of both ale and strong beer from England, as well as wine glasses, cloves, and 20 dozen packs of cards (Smallzreid 1956).

Wine, tea, coffee, and the spicy dishes of the early modern period figured prominently as the kitchens of the planters began to turn out the first high cuisine in British America (Fischer 1989). Much of this has been attributed to African cooks, who knew how to use flavorings and spices. Most plantations maintained kitchens in buildings separated from the main house (because of a fear of fire), as well as icehouses (where winter ice was stored in layers of straw), barns for grain and animals, springhouses (for storage of dairy products in cold water), and smokehouses (for preserving meat, such as the famous Virginia hams, by smoking).

Plantation dinners could be elaborate, multicourse affairs with abundant meats, hot breads, seasonal vegetables and fruits, and large amounts of alcohol. At Westover Plantation on the James River, blue-winged teal (duck), venison, asparagus, and garden peas were common on William Byrd's table (Fischer 1989). Other favorite dishes were "spoonbread" (a maize casserole), ham cooked in any of a dozen ways, oysters ("cooked any way"), fried chicken, fricassee of chicken, lamb, game, pies filled with meat or fowl, and the region's own peanut soup and peanut pie.

Foods in the South were preserved by drying, salting, and smoking, and although English cookbooks had long advised preserving fruits in brandy, this was a costly treat, available only for the rich. In general, for most in colonial Virginia, winter meant monotonous meals of cornbread, beans, and ham; variety in off-season meals had to await canning, which came with the Industrial Revolution.

English colonization spread farther south in the late seventeenth and early eighteenth centuries. In 1670, settlers and slaves from the crowded sugar island of Barbados had landed on the coast named "Carolana" for Charles I, with its capital city of Charleston, named for Charles II. By the early eighteenth century, Carolina was thriving, its semitropical economy based on the growing of indigo, hemp, sugar, and rice. The whites of Charleston drank beer and whiskey, both made from maize, and ate cornbread, but they also became – in that time, at least – the only society of English-speaking people to eat rice as a dietary staple (Rutledge 1979). They retained wheat for bread making, but meals were centered on rice, which even today is more prominent on Charleston tables than on many others in America.

Slaves, some of whom had known rice in Africa, provided much of the knowledge for planting, harvesting, and cooking it, although some innovations, such as the use of tidal flows to drive water into the rice paddies, were conceived by the whites (Dethloff 1988). Rice was generally prepared in the "Indian" or "African" manner, in which boiling was followed by steaming. Among the favorite rice dishes were "pilau," made with pork, "hoppin' John," made with black-eyed peas and ham hocks, and breads made with rice and wheat flour (Hess 1992). This rice-eating plantation society spread to coastal Georgia, and in both colonies, the isolation of African slaves on rice-growing sea islands led to the distinctive culture, language, and cookery of the African-American "Gullahs." Abundant seafood, rice, maize meal, and hot peppers were combined in such Gullah dishes as "down'ya stew" and shrimp-and-grits (Junior League of Charleston 1950).

Harriott Pinckney Horry, daughter of a prominent South Carolina Huguenot family, left a recipe book written at the end of the eighteenth century that provides some insight into the local cuisine. Her "journey cake" was made from either rice or maize; she also cooked with tomatoes, fresh ginger, and chilli peppers (Horry 1984). Clearly, her kitchen was the scene of good, and sometimes spicy, cooking.

Canada and American Independence

To the north, there was another society as different from Massachusetts as Massachusetts was from Virginia. In Quebec and Acadia, settlers from Normandy brought with them ways of cooking and bread making that persisted into the twentieth century. The center of their diets was the *pain de campagne,* or "bread of the countryside," made from a mixture of grains and baked in a wood-fired oven of clay or brick (Nightingale 1971). This bread – made in large loaves, four pounds being usual – was also the common bread of France during this period (so-called French bread was not made until the nineteenth century) (Boily-Blanchette 1979). Such dishes as meat pie (spiced with cinnamon or cloves) and yellow pea soup still survive in Quebec and Acadia (Gotlieb 1972).

Local ingredients modified the French-derived cookery of Quebec. Maple syrup found its way into everything from meat glazes to dessert pies, sometimes with disconcerting results, and hams were boiled in maple sap at sugar-making time (Benoäit 1970; Gotlieb 1972). The famous Oka cheese (similar to cheddar) also originated in this era (Gotlieb 1972), and American chillies were used to season pickled onions (Benoäit 1970).

British Canada's cooking was English in derivation, and plain dishes, such as boiled mutton and calf's head, as well as sweet custards, were common (Nightingale 1971). As in Massachusetts, entire meals were boiled in one iron pot; bacon, cod, and eggs, cooked together with potatoes and turnips, was one such sturdy meal (Nightingale 1971). Boiled "bag puddings," made with flour, eggs, and fruit, were often served for dessert (Benoäit 1970). As with other European colonies in North America, there was an abundance of foods. Oats grew well in Canada and went into oatmeal and bread; there were even "pilafs" made from oat groats instead of rice. "Grits" (Martha Washington's "greats") meant oat groats instead of corn, although "corn cake" did grace some Canadian tables (Benoäit 1970).

On the coast, oysters were a poor man's dish, and lobsters were so common as to be practically valueless, making people ashamed to eat them (Gotlieb 1972). Clams and cod went into pies, which in Canada were as popular as in New (and old) England (Benoäit 1970). Salt pork was so universal that it was even used in sweet cakes (Nightingale 1971). To accompany these dishes, Canadians made a variety of "wines" from all sorts of foodstuffs. Their "port wine," for example, was a concoction of whole wheat, currants, raisins, and potatoes that contained no grape juice. "Parsnip wine" and "beet wine" were other drinkables (Nightingale 1971). These country wines, like rum, owed their fermentation to sugar that Maritime settlers obtained from the sugar islands. Rum is still a preferred beverage in New Brunswick, where a "black rum" unknown in the United States is a favorite (Personal communication from Charles Morrisey 1996).

Canada and the colonies to the south were to be separated politically as well as in culinary matters. The American Revolution led to significant changes both on and off the table. American corn whiskey became more popular than rum, and it has been claimed that many drank coffee instead of tea as a show of loyalty to the new republic. But although tea was no longer available through British channels (as it had been before the Revolution), American traders began to obtain it directly from China. The switch from tea to coffee began in the early nineteenth century as Brazil began shipping more coffee to North America. This dramatically reduced prices and thus encouraged more widespread use of the beverage (Cummings 1940).

The Revolution affected the cooking of Canada, as thousands of loyalists fled the thirteen colonies to settle there. Some refugees from Virginia baked cornbread on the hearth or in a skillet (Nightingale 1971), although their "johnnycake" became decidedly Canadian with the addition of maple syrup. Fried chicken and "spoonbread," suggestive of a southern influence, were also enjoyed in Canada, and the chicken curry that came north was, as in South Carolina, called "country captain" and attributed to sea trade with India (to conform to local tastes, the Nova Scotian version of the dish called for only a single teaspoon of curry powder for a four-pound chicken) (Nightingale 1971). Yankee influence, in the form of Boston baked beans, was apparent in Nova Scotia as well (Benoäit 1970). Tea remained the preferred hot beverage, and teahouses were opened there as well as in other regions of Canada.

A Canadian cookbook of this period dealt apologetically with chilli peppers because they were a part of recipes from "Old Country people" and "Western dishes" for "a man's world" (Benoäit 1970: 86, 175, 182). On the other hand, "green tomato chow," a version of "chowchow" (a relish common in the American South), contained red peppers, and its apples and cucumbers link it, like chowchow, with the mixed fruit-and-vegetable pickles of medieval

England (Benoäit 1970). Perhaps Canada's most eccentric contribution to American cooking resulted from the resettlement of the Acadians, or Cajuns, in Louisiana. These exiled French-Canadians adopted the hot spices, rice, and seafoods of their new home and created a cuisine unlike any other (Root and de Rochemont 1976).

Cookbooks and Cooking

The first cookbook published in America was E. Smith's *The Compleat Housewife,* a 1742 reprint of a 1727 British volume (Smallzreid 1956). Other English cookbooks, such as Hannah Glasse's *The Art of Cookery,* were also printed in America but reached few readers in a land where many were illiterate and any kind of book ownership was rare. In 1796, Amelia Simmons, styling herself "an American orphan," published *American Cookery* in Hartford, Connecticut (1965). It was the first cookbook to include recipes employing such American staples as maize and pumpkins. For "johnnycake" or "hoecake" (the first recipe for cornbread in English), she instructed the reader to "scald 1 pint of milk and put to 3 pints of indian meal, and half pint of flour – bake before the fire" (Simmons 1965: 57). The author also included numerous recipes for vegetables and mentioned five kinds of cabbage and nine different beans. Kitchen gardens were apparently common in her world, as she supplied information on how to plant and harvest.

Simmons's book indicates how tastes had changed in Anglo-America since colonial times (for one thing, spicy dishes were no longer in favor) and also reveals several continuing trends in the food history of North America. First, there was still the immense abundance of food available that has already been noted. Second, cookery retained its English character, with minimal seasoning and meat as the center of the meal. Third, the authorities on cookery were not (as, for example, in France) a restaurant-trained elite but rather housewives and home cooks. Although Simmons herself was careful about cooking, the attention to quality of ingredients and cooking methods that later distinguished the *grande cuisine* of France were, on the whole, lacking in American cooking. It was apparent that, in cooking, America had inherited both the good and the bad from England.

The Nineteenth Century

During the nineteenth century, Native American populations continued to decline as European, African, and some Asian peoples filled the North American continent. Wild game, although still common, had been hunted to the point that several species, such as the passenger pigeon, beame as extinct as some of the Indian peoples who had once preyed on them (Root and de Rochemont 1976).

Three nineteenth-century trends combined to revolutionize the American diet. One was immigration, involving a mass of Europeans, as well as the arrival of the first Chinese immigrants in the west of the continent. The second (which created the first) was the Industrial Revolution. The third (made both possible and necessary by the first two) was the use of industrial technology to provide the growing population of European-Americans with a quantity and variety of foods undreamed of in previous ages. The quality of that food, however, was – and remains – questionable.

Regional Foodways of America

The North and urban squalor. Urban workers seldom enjoyed well-balanced meals. Americans who had migrated from rural regions crowded together with immigrants in the "slum" areas of northern cities, where fresh foods were largely unavailable, and hunting, fishing, and gardening were difficult, if not impossible. Consequently, as a rule, the diet of urban workers was inadequate in all but calories; fresh vegetables and fruit were almost absent from their tables, save for a few weeks in the summer and fall. Throughout the United States, the favorite vegetables were potatoes and cabbage, and the favorite fruit remained apples in their hundreds of local varieties (Levenstein 1988).

Southern and African-American foodways. The nineteenth century's antebellum epoch brought with it increasing polarization between North and South. As the nation lurched toward the Civil War, northern religious reformers and abolitionists attacked the institution of slavery, while southerners from the Chesapeake region, the "Rice Coast," the back country, and the western states of the newer South defended it. These disparate regions of the South became united, first by the slaveholding ideology, and then by the Confederate "Cause."

Southern cooking at this time was still marked by a preponderance of locally produced staples, such as maize, salt pork, and garden greens. Beef was little known and fresh milk almost nonexistent (Hilliard 1988). Whether or not the diet of black slaves was adequate has long been debated, but one conclusion is that although adequate in calories, it lacked sufficient protein and vitamins. Protein-calorie malnutrition and vitamin deficiencies are attested to by contemporary evidence (Kiple and King 1981). Some slaves kept garden plots or animals – a source of economic independence – but although a few could hunt or fish, most relied almost solely on rations. These provided a relatively monotonous diet of salt pork, maize meal, and, sometimes, molasses or sweet potatoes, although most slaves were given vegetables in season (Hilliard 1988). The use of fatty rather than lean pork for slaves was justified by the conviction that fat provided the energy needed for hard labor. The slaves' diet was the basis for modern "soul food."

For the planter class, excess was frequently the rule. One of the most astounding of many extravagant dishes was the "Carolina wedding cake" made in 1850, which called for, among other things, 20 pounds each of butter, sugar, flour, and raisins, as well as 20 nutmegs and 20 glasses of brandy (Junior League of Charleston 1950). One author has estimated that it would have required 1,500 eggs and weighed a total of 900 pounds (Smallzreid 1956). Similar excesses were evident among cooks who deep-fried entire turkeys and garnished tables with great bowls of turtle steaks, merely to whet appetites (Hilliard 1988). One dinner on record featured ham, turkey, chicken, duck, corned beef, fish, sweet potatoes, "Irish" potatoes, cabbage, rice, beets, 8 pies, syllabub, jelly, "floating islands," and preserves (Rutledge 1979). Peach brandy and corn whiskey washed all of this down.

Virginians were as proud as South Carolinians of their reputation for gracious living. Tomatoes figured prominently in Mary Randolph's *The Virginia House-Wife,* originally published in 1828 but actually based on plantation cookery from the colonial era. Randolph, a relative of Thomas Jefferson, presented such recipes as hot-pepper vinegar, buttered okra, and stewed tomatoes, along with plenty of others for pork dishes and cornbread. Other writers, such as Letitia Burwell (1895), reveled in the colonial and antebellum past with exuberant nostalgia. Among her memories was afternoon tea with Robert E. Lee, who displayed the Custis silver of Mount Vernon at his table amid a truly English array of cakes and pastries. But such fondly recalled luxuries were not typical of Southern living, with its sharp polarization of the culture by class and race, at the table as well as in church and home.

Emancipation from slavery brought no freedom from a restricted diet, and after the Civil War, the poor – both black and white – lived on a regimen of cornbread, beans, grits, biscuits, and salt pork. Cornbread predominated over wheat bread even among those who could afford the latter: Southerners had come to prefer its distinctive taste (Hilliard 1988). The poorest chewed dirt, apparently to relieve the symptoms of hookworms, and frequently suffered from pellagra. This nutritional deficiency disease was the result of a diet lacking in niacin (one of the B vitamins) and progressed from diarrhea and dermatitis to dementia and death. Ingestion of any niacin source, such as fresh meat, was the cure (Cummings 1940). Poverty shaped the diet of the South in other ways. The poor used sorghum syrup to sweeten their coffee, pastries, and cornbread (because store-bought sugar was too expensive), and sorghum, an African plant, is still grown in the South to provide a flavorful sweetener (Cummings 1940). Similarly, the southern poor used cayenne *(Capsicum annuum),* which could be homegrown, instead of store-bought black pepper (Hess 1992).

The West and Hispanic foods. The foods of the Southwest added still another culinary experience for the American palate. During the second quarter of the nineteenth century, the United States expanded, by conquest and by land purchase, into this large area with its predominantly Hispanic population. The region's culinary heritage was rooted in part in the chilli-laced tamales and tortillas of the Aztecs and their predecessors and in part in the culture of Iberia. Shipments of olive oil, hams, wine, and even saffron arrived regularly from Spain (Linsenmeyer 1976). The last Spanish governor of California was inaugurated in 1816 with a gala affair featuring poultry, game birds, cordials, wine, fresh fruit, breads, and cakes (Linsenmeyer 1976). Salmon, crab, and pork were cheap in this new land, and the vines left by the Spanish friars formed part of the foundation for today's California wine industry (Lichine et al. 1982).

Cultures and foodways blended as time passed. A Texas landowner took stock of his garden in 1839. The fruits alone comprised peach, fig, raspberry, quince, plum, "sour orange," melon, pomegranate, and strawberry; in addition, there were 13 herbs and 22 kinds of vegetables (Tucker 1993). That he grew such Spanish favorites as quince and chilli peppers is worth noting, and clearly a blending of cultures took place at his table. By contrast, the early Anglo settlers of Arizona stuck to such familiar favorites as roast beef, sourdough bread, and rhubarb pie (DeWitt and Gerlach 1990).

Also in the nineteenth century, a spicy stew of meat, beans, and chillies received its name, *chile con carne.* In 1828, a writer mentioned it as the staple of the poor, and although no recipe was given, it is clear that the dish was prepared with ingredients similar to those that go into it today. Linked to cowboys (for whom beef and beans were staples), to Mexico (where similar dishes had been served for some time), and to the "chili queens" who served it from market stalls, *chile* soon became a regional favorite (DeWitt and Gerlach 1990). By 1896, an Army cookbook included "Spanish" recipes that were actually Mexican, such as tamales, tortillas, *chiles rellenos,* and refried beans with cheese (Levenstein 1988).

Before the Civil War, white settlers had moved into Oregon and Washington, where they found a potential culinary paradise. The Indians of the area had scorned agriculture because game and fish were so abundant. The salmon, abalone, and wild berries of the Northwest were supplemented by the white settlers with grain, meat animals, and fruit trees, all of which prospered in that climate (Root and de Rochemont 1976).

The Plains. The slaughter of the American bison (and of the Indians who depended on them) opened the Great Plains to white settlement. The artifact that increased the area's attractiveness was the steel plow, which enabled farmers to turn the tough sod of the plains and, thus, to grow wheat, with the result that wheat bread became available throughout the entire country (Root and de Rochemont 1976). A staple of these plains pioneers and others was sourdough bread, leavened by a yeast starter that was kept active by periodic feedings of water and flour. Known from California to the Canadian wilderness, it formed the basis of loaves of bread, pancakes, and even sweet desserts, and "sourdough" became the nickname of inhabitants of Alaska (Gotlieb 1972).

Pioneers also ate all kinds of game. Imaginative cooks made such dishes as stuffed moose heart and smoked gopher; others improvised French-style soups with fish from Canadian lakes (Gotlieb 1972). German and Czech pioneers brought one-pot casseroles to the region. A favorite on the trail was dried-apple pie: A cook rolled the crust out on the wagon seat, reconstituted the dried fruit by soaking, and had a pie ready to bake in the Dutch oven at day's end (Tannahill 1988).

No such treats characterized the foodways of the rapidly disappearing Indian population. Equipped with guns and horses, the Plains tribes had hunted the buffalo, using every part of it for food, implements, and shelter. But the wars against the whites ended with the natives confined on reservations and dependent for food on government handouts. Ruth Little Bear of the Blackfoot tribe recalled her grandmother's tales of food in a previous time, when buffalo tripe was stuffed with tenderloin, and neither spices nor utensils were used. She also provided recipes for fried bread, yeasted bread, and "bannock," the Scottish name for pan-baked bread, a staple among Indians subsisting on government-issued salt pork, flour, and rice (Hungry Wolf 1982). Other Indian dishes, dating from a time before the reservations, included a soup made from berries, "prairie turnip" (a wild root gathered by the tribes), and many kinds of smoked and boiled meat (Laubin and Laubin 1957).

Immigration

With the advent of steamships, the second half of the nineteenth century became a period when, for the first time, large numbers of non-English-speaking peoples poured into the United States to challenge the cultural dominance of the Anglo-Saxon "Old Americans." Of these, perhaps the most prominent in bringing new tastes were the Italians and the Chinese. Although immigrants from other areas also contributed ethnic dishes to the American repertoire, the Italians and Chinese founded the first "ethnic restaurants" and brought in new foods that Americans accepted, albeit after some initial misgivings.

European immigration. Irish settlers, fleeing the potato famine of the late 1840s, comprised the first wave of nineteenth-century immigrants. Like the English, the Irish had little tradition of refined cuisine, and those who were immigrants to hardscrabble Newfoundland continued to make such peasant dishes as "colcannon," a mixture of mashed potatoes, kale, and butter (Gotlieb 1972). In New York, Irish immigrants relied on bread, fried meats, pastries, and tea (Shapiro 1986). The Irish also brought Catholicism, with its insistence on Lenten fasts and meatless Fridays. However, despite their centuries-long experience in brewing and distilling, the Irish had little influence on American alcoholic beverages. American beer takes after German beer, and American whiskey was a unique maize product unknown in the British Isles until relatively recently.

Italians arrived toward the end of the century. Their traditions of cuisine, which stretch far back into history, were sophisticated, shaped in part by the variety of foods in sunny Italy and in part by the chronic scarcity in that country of fuel for fires, meaning that quickly cooked foods were cheaper to prepare. Their many contributions to American cuisine include pasta, olive oil, the versatile tomato, and wine. It is the case that as early as the time of Jefferson, some Americans were growing tomatoes and cooking pasta; indeed, Jefferson bought a pasta-making machine in Italy. But it was in the late nineteenth century that Italian immigrants inundated the Northeast, bringing with them a desire for fresh vegetables (especially tomatoes) and other staples of their Mediterranean homeland. During the depression of the early 1890s, the city of Detroit offered gardeners the use of vacant lots, and by 1896, this practice had spread to some 20 other cities, including New York. Reporters remarked on the lavish plots of tomatoes, peppers, and eggplant grown by Italians (Tucker 1993).

Immigration from Eastern Europe brought large numbers of Poles and Jews to America. Their culinary contributions included the dark rye breads of their homelands and the complex kosher dishes that were the stock-in-trade of the original Jewish delicatessens. Highly seasoned cold meats made the prohibition of cooking on the Sabbath more tolerable, and still do, although today such delicatessens, which are everywhere, are frequented by Jews and Gentiles alike.

The Jewish dietary laws that were cherished in the Old World, however, were frequently disregarded in the New. Jewish writers, such as Harry Golden (1958), have commented wryly that Chinese dishes, which nearly always included pork, were simply too much of a temptation for Jewish people. In fact, the Reform denomination of Jews set aside kosher dietary laws.

Other Eastern Europeans also came to America, in many cases settling in ethnic enclaves within large cities. Food festivals and church events helped to preserve the customs and dishes of such lands as Serbia, Lithuania, and Slovakia.

Chinese immigration. Far more exotic to Americans than the Eastern Europeans were the Chinese immigrants. The first Chinese came to America around 1820, and significant numbers followed during the California gold rush. Mostly Cantonese, they grew Asian vegetables in their garden plots and introduced stir-frying, the use of new seasonings, and above all, the Chinese restaurant (Linsenmeyer 1976; Tucker

1993). Preserved ginger, Chinese oranges, dried seafoods, and bean curd were imported, and each immigrant was allowed to carry in two jars of ginger for personal use (Linsenmeyer 1976). Shipping records show imports of foodstuffs as mundane as rice and as exotic as sharks' fins (Linsenmeyer 1976). Because of the southern Chinese origin of these immigrants, however, they did not bring with them the potted dishes and wheat breads of northern China, which remained unknown in America for another century and a half (Tropp 1982).

Restaurants

In the early decades of the nineteenth century, virtually no restaurants existed outside of the eastern cities with their grand hotels, although, of course, inns and taverns offered food (Root and de Rochemont 1976). But soon the excellent fare and low prices of Chinese restaurants made them a success despite an American apprehensiveness born of rumors that accused the Chinese of eating cats and dogs. Such "Chinese" dishes as "chop suey" and "chow mein" were actually invented in America and became American favorites; chop suey even made its way along with the Canadian Pacific railroad into the depths of that northern land (Smallzreid 1956; Benoäit 1970).

The most famous restaurant in the Northeast was Delmonico's in New York; first opened in 1825, it offered a menu and cooking style that were largely French, with some American concessions, such as "hamburger steak" (Pillsbury 1990). Eleven restaurants and three generations later, Prohibition caused the last Delmonico's to close in 1923 (Root and de Rochemont 1976), having served every president of the United States from 1825 to 1900; other clientele had ranged from Mark Twain to the Prince of Wales.

Toward the end of the century, Italians had also begun opening restaurants, and these joined other restaurants and saloons as welcome additions to the urban landscape of industrial America. In addition, industry and capitalism brought forth the first national chain restaurant, the Harvey House, founded in 1876 (Pillsbury 1990), which served standardized fare in locations along railway lines.

Food and Technology in the Nineteenth Century

The Industrial Revolution, which introduced mechanical power to produce consumer goods in quantity, brought widespread dietary changes, not least among them the advent of processed foods. By 1876, America was exporting yearly to Britain a million pounds of margarine, or "butterine," made from waste animal fat (Tannahill 1988). "Crisco," a mixture of fats, became a popular product that freed the housewife from having to render or strain hot grease, and powdered gelatin eliminated the labor of boiling calves' feet (Nightingale 1971). Roller mills manufactured white flour, which – despite its cheapness – kept longer, made loaves that rose higher, and was easier to digest than brown flour (Tannahill 1988). In addition, it made much better sauces and pastries.

The Industrial Revolution also ushered new technology into the kitchen. The cast-iron stove meant that women no longer needed open fires for cooking, and the age-old risk of serious burns or even death for women who cooked at open hearths began to disappear (Smallzreid 1956). Refrigerated railcars and ships made fresh foods available far from their points of origin, and canning enabled the storage of large amounts of these and other foods for consumption out of season.

Fruits and vegetables had been preserved since Roman times by pickling or cooking with honey. With the 1809 development in France of "bottled" foods, and the later invention of the screw-top Mason and Ball jars in 1858, home "canning" became reliable and safe, and factory canning a multimillion-dollar industry (Root and de Rochemont 1976). The first tin cans were handmade, but the invention in 1849 of a machine that could produce them meant substantially lower prices for the food that they contained. The invention came just in time for the California gold rush, and by 1850 the miners were already eating large amounts of canned fish, shellfish, tomatoes, and peas (Root and de Rochemont 1976). The most significant food to be canned was milk, a process pioneered by Gail Borden and patented in 1856. His firm supplied large amounts of sugared, canned milk and juice to the Union army during the Civil War (Cummings 1940) and was still in business, although struggling, at the end of the twentieth century.

Recipe books provided instructions on canning for American housewives, who might each put up hundreds of jars of preserves each year, in addition to numerous crocks of pickles, relishes, "piccalilli," homemade catsup, and sauerkraut (Smallzreid 1956). Vegetables from the home garden and fruit from nearby orchards and farmers' markets were combined with spices in family recipes, and women often worked together to can as much as possible while a fruit or vegetable was in season.

Another method of keeping food was the icebox whose invention seems to have taken place in Maryland at the beginning of the nineteenth century – the broiling summers there doubtless the "mother" of this invention. But the ice had to be changed frequently, which would ultimately be remedied by home refrigeration. The discovery of the vapor-refrigeration principle and the invention of various compression machines were initial steps in this direction, and by the end of the Civil War, ice-making machines existed. By 1880 some 3,000 patents had addressed the topic of refrigeration – and some of these in turn led to a revolution in the meat industry.

The dominance of pork began to wane – even in the South – as southwestern cattle drives and the Chicago stockyards made available an enormous amount of beef (Levenstein 1993). Industrial workers' families, who had eaten only small amounts of fresh meat in the 1830s, consumed two pounds daily in 1851, and fresh meat was much more nutritious than the salted and preserved meats of colonial days. Milk consumption doubled, and the use of vegetables increased greatly (Cummings 1940).

Chicago's stockyards were modernized in the 1860s, and by 1875, manufacturers such as Swift and Armour, boasting of the cleanliness of their production facilities, had established their brands as leaders in the meat-packing industry, positions they still hold. In the 1870s and 1880s, railcars and ships, now equipped with refrigerators, carried meat to all parts of America (Root and de Rochemont 1976), and as Kathleen Ann Smallzreid (1956: 103) has noted, "refrigeration probably did more to change the flavor of the American meal than any other invention, and in doing so brought health as well as enjoyment to the table."

The newly mechanized stockyards used all parts of the animals they processed, including bone for china and glycerin for explosives (Smallzreid 1956). Unfortunately, federal inspection was negligible in the era of "robber barons"; sanitation was nonexistent, and by the turn of the century, conditions in Chicago meatpacking plants were horrific. When, in 1906, socialist writer Upton Sinclair published his eyewitness account of this situation, entitled *The Jungle,* the public was outraged. Meat sales dropped by half as people read of diseased animals, dirt, and excrement – as well as human body parts severed in accidents – being canned and sold along with the meat (Sinclair 1984). In reaction, President Theodore Roosevelt urged passage of the country's first Pure Food and Drug Law, mandating (among other things) inspection of meats sold in interstate commerce (Root and de Rochemont 1976). Despite this action, however, even as late as the 1970s, such foods as chicken pie were still being made under conditions considerably less than sanitary.

In addition to meat, trains carried fresh vegetables and fruits. Navel oranges from Bahia, Brazil, were planted in Florida in 1870 and in California in 1873. In 1887, California shipped 2,212 railcar loads of citrus fruit, mostly navel oranges. Five years later, that number had swollen to 5,871 carloads of oranges and 65 of lemons (Smallzreid 1956). Grapefruits were popular as well; in 1889, Florida shipped 400 tons of them. Bananas from Costa Rica were already arriving in quantity when in 1899 the United Fruit Company was founded. Thus began a monopoly of banana production in Central America and the Caribbean as well as a monopoly of distribution in the United States that would last throughout most of the twentieth century (Smallzreid 1956).

Sales of sugar doubled between 1880 and 1915 (Cummings 1940), and new sweets began to appear. Chocolate, once known to the Aztecs as a bitter spice and to the Spaniards as a beverage, was first made into candy in the second quarter of the nineteenth century. In 1876, "milk chocolate" was invented (Root and de Rochemont 1976). Cake making became easier – a result of improved baking powder – and ice cream, a rare treat before the invention of refrigeration, became available to all (Cummings 1940; Smallzreid 1956). In Canada, however, many rural areas saw almost no store-bought candy; even in the 1870s, candy was still made at home from maple syrup (Nightingale 1971).

The purchase of staples at stores was more typical as the century passed. The "New Woman" of the late nineteenth century was ready to give thought and action to such problems as women's rights, suffrage, and education because many household tasks had been eliminated. (It has recently been argued that mechanization increased housewives' workloads, but anyone who has cleaned clothes using lye soap and a boiler, or cooked a four-course meal over an open hearth, may appreciate why so many felt the immense appeal of the new technology.) As a rule, women no longer made soap, pickles, cheese, and cloth; nor grew vegetables, fruits, and medicinal herbs; nor butchered nor made beer at home (Smallzreid 1956).

Until the 1890s, the main meal ("dinner") was still eaten at noon, as it continued to be in much of rural America well into the twentieth century (Plante 1995). Typical meals in the late nineteenth-century Northeast might include a breakfast of corn muffins, fried potatoes, and fish, and a dinner might begin with macaroni soup and move on to duck salmi, baked potatoes, oyster salad, canned peas, and celery sauce, finishing with pumpkin pie. Supper, much lighter, could be muffins, dried beef, tea rusks, and baked apples (Smallzreid 1956).

Drinking in the Nineteenth Century

Drinking also changed drastically in the nineteenth century. The massive consumption of hard liquor in the early years peaked around 1840 at perhaps five gallons of alcohol annually per adult (Rorabaugh 1979). It subsequently declined for two reasons. The first was the rise of the American beer industry. German immigrants brought with them the knowledge of brewing lager, a much lighter beer than had previously been available to Americans, and the end result was the German-American beer of the twentieth century. The second reason had to do with the temperance movement. Its advocates railed against "Demon Rum" and urged its replacement by tea, coffee, or pure water (available for the first time in American cities).

Until the last decades of the century, coffee was usually made in the old way, by roasting beans over a fire or on the stove and grinding them at home; eggs and salt were used to get the coffee to settle (Smallzreid 1956). Inventors, however, had turned their attention to the improvement of coffee processing, and, in 1880, Joel Cheek of the Atlantic and Pacific Tea

Company developed a coffee roaster that allowed less flavor to escape during the roasting process. He marketed the coffee produced by this new method through his company's stores, naming the brand after the Maxwell House hotel in Nashville, where it was first served (Smallzreid 1956).

Ladies still met in the afternoon for tea, but this practice had nowhere near the popularity that it possessed in Canada and Australia, which had retained ties of tea and government with Great Britain. As late as 1834 in New York, tea (and coffee) was served in bowls as well as in cups, and into the twentieth century, some tea and coffee drinkers kept to the Chinese practice of pouring their drink from the cup into the saucer, from which they could sip it as it cooled (Pillsbury 1990).

Health, Nutrition, and Food Fads

The increase in the consumption of fruits and vegetables as well as meat and dairy products meant significant changes in the health of Americans. By the 1860s, life expectancy had lengthened, and Union soldiers during the Civil War (1861 to 1865) were, on the average, a half inch taller than soldiers had been in the period from 1839 to 1855 (Cummings 1940). Some researchers have claimed that average American stature subsequently decreased with the immigration of shorter peoples from southern and eastern Europe. In the 1880s, however, clothiers had to work from a scale of sizes larger than that previously in use, and a modern *corsetière* lamented that patterns from the nineteenth century were useless in the twentieth, indicating further increases in height and changes in body shape.

That nutritional improvements were taking place in America is borne out by the fact that health and stature did continue to increase as the turn of the twentieth century approached and passed. Harvard undergraduates in 1926, for example, were an inch taller than their fathers had been; the women of Vassar and Mount Holyoke were more than an inch taller than their mothers, and the width of their hips had decreased. In the same year, Boston schoolboys were three inches taller than boys of 1876 (Cummings 1940). Increasingly larger sizes of clothing at the end of the twentieth century suggested that, for better or for worse, Americans are continuing to get larger.

To return to the trend of the nineteenth century, however, it would seem that the presumed deleterious effects of using canned food, white flour, and too much sugar were more than offset by the abundance of fresh foods that Americans ate (Cummings 1940). Moreover, nutritional health was improving not only in spite of the increase in industrial food processing but also in the face of a number of faddish nutritional theories that, despite their shortcomings, enjoyed wide popularity.

The nineteenth century saw some strange food practices, with "Grahamism" perhaps the best-known example. Sylvester Graham combined a romantic admiration for "nature" with a fear of processed foods – especially roller-milled, white, bread flour – and preached that poor health could be remedied by regular bathing, drinking water instead of alcoholic beverages, exercise, vegetarianism, and avoidance of sexual activity.

Indeed, Graham took vegetarianism to a new extreme by rejecting sugar, mustard, catsup, pepper, and white bread, as well as meat (Root and de Rochemont 1976), and along with others of his ilk, he imagined that the classical Greeks and Romans had also been vegetarian, or at least partly so (Green 1986). "Grahamists" ate whole-wheat bread, dairy products, fruits, vegetables, and "Graham crackers," made with whole-wheat flour and molasses and invented by Graham, who claimed that such a diet would prevent illness and insanity and lessen sexual desire. Graham made many converts – despite hostility from butchers and bakers – and special boardinghouses opened to provide the food he recommended. Called "the prophet of brown bread and pumpkins," he counted among his disciples Sojourner Truth, Horace Greeley, and the entire sect of Shakers, who were vegetarians for about 10 years (Green 1986), although their rules later permitted some meat consumption.

Other nutritional theorists also linked religion, sex, and food. Mrs. Horace Mann, author in 1861 of a stern work on food and righteousness entitled *Christianity in the Kitchen,* argued that rich concoctions, such as wedding cake, suet-laced plum pudding, and thick turtle soup, were masses of indigestible material, which should never find their way to any Christian table, and that "there is no more common cause of bad morals than abuses of diet" (Shapiro 1986: 130; Tannahill 1988).

Another reformer, the Reverend Henry Ward Beecher (brother of Catherine Beecher and Harriet Beecher Stowe), feared processed flour as much as Graham did. Beecher argued that "the staff of life . . . has become a weak crutch," and his daughters held that store-bought white bread was "so much cotton-wool" (Root and de Rochemont 1976: 22).

New "health foods" were another legacy of Grahamism, with cold breakfast cereal the most prominent. The Seventh Day Adventists, members of a church founded in 1863, held that meat, spices, tea, coffee, tobacco, and alcohol were both unhealthy and immoral and that "foods of vegetable origin" paved the way to salvation and to "God-given health and happiness" (Smallzreid 1956: 150; Root and de Rochemont 1976). They therefore began to manufacture healthy and "moral" foods in Battle Creek, Michigan, where, in 1876, Dr. John H. Kellogg invented breakfast flakes made from wheat. C. W. Post, a client, joined the quest for "moral" foods. He began to sell "Postum" (a coffee substitute) in 1895 and "Grape Nuts" cereal in 1898 (Smallzreid 1956). "Shredded Wheat," another health-food favorite, was invented in 1891 by Henry Perkey, a non-Adventist entrepreneur (Smallzreid 1956). In all cases, commercial versions of these products, which incorporated a great deal of sugar, bore little resemblance to the ascetic foods envisioned by their inventors.

An even stranger fad than Grahamism was "mastication," the brainchild of Horace Fletcher. Fletcher believed that a "filtering organ" in the back of the mouth performed most digestion and that an inordinate amount of chewing was necessary to stimulate it. Chewing each bite of food 32 times was recommended, and college students were recruited to practice it. But because excessive chewing interfered with the pleasure of eating, the mastication theory was soon abandoned (Levenstein 1988).

A more important influence on American foodways in the late nineteenth and early twentieth centuries was that of "domestic science." Beginning in the last quarter of the nineteenth century, increasing numbers of women learned about cooking through classes centered on the application of science to the kitchen. Such women as Catherine Beecher, author of a book on "frugal housewifery," urged women to take control of the household economy in order to save money on food and other expenses (Shapiro 1986). But although the ideas that they learned (such as balancing protein and carbohydrates so as to provide nutritious and inexpensive meals) were good ones, the results of their application were not necessarily so. Breakfasts of fruit, stewed corn, baked potatoes, and hot water won approval, whereas hot bread and griddlecakes were abhorred (Shapiro 1986). "Manly" meals of beans, potatoes, and beef alternated with "ladies' luncheons" of salads, marshmallows stuffed with raisins, and "Dainty Desserts for Dainty People," which allegedly appealed to "delicate" feminine tastes (Shapiro 1986: 99).

Another product of the period's obsession with "science" was the work of Fannie Farmer. A teacher at the Boston Cooking School, she originated the concept of "level measurement," which was probably the first challenge in all of history to the slapdash practice of using a pinch of this and a smidgen of that. Farmer's 1896 *Boston Cooking-School Cook Book* incorporated cooking-school methods and level measures in the belief that anyone who read it could learn to cook. Every cookbook that gives exact measurements is a tribute to the tremendous impact of this woman (Farmer 1896). The use of cookbooks and level measurements and the influence of cooking schools and nutritional theories would come to predominate in American kitchens of the twentieth century.

The Twentieth Century

The twentieth century saw far-reaching changes in the foodways of America. The development of hybrid maize and other crops, the application of high technology to food processing and cooking, and the growth of such commercial interests as fast-food restaurant chains and supermarkets all contributed to these changes.

Although most Americans entered the century with their near-Puritanical distaste for "fancy cooking" well intact, this attitude coexisted alongside the allure of the exotic. "Theme restaurants," looking like Arabian tents or Southern mansions, arose to serve the same steak and lobster as more mundane establishments. The most popular place for lunch in the early twentieth century – as before – was the saloon, with its free food for customers who purchased alcoholic beverages.

The early part of the twentieth century saw a continuation of the gorging of the previous century. In 1913, a New York dinner hosted by Frank Woolworth (founder of the "five-and-ten" store chain) featured caviar, oysters, turtle soup, pompano with potatoes, guinea hen, terrapin, punch, squab, grapefruit-walnut salad, ice cream, cake, coffee, and wine (Levenstein 1988). But change was in the air, occasioned by an ever-growing interest in home economics and nutrition and an awareness of the lighter meals served in other parts of the world.

The diets of ordinary people were improved, as more and more could afford to take advantage of new technologies, such as refrigeration and canning. Certainly there was a greater abundance of vegetables consumed, as farmers' markets made them readily available during the season; preservation and storage for consumption later in the year had also become easier. Thus, in the early part of the century, steelworkers in Pennsylvania, for example, ate typical American suppers of meat, beans, potatoes, fruit, beets, and pickles. Other meals served by their wives included spinach, tomatoes, and eggplant (Levenstein 1988). Towns famous for particular fruits or vegetables began to hold festivals to celebrate their abundance of such crops as artichokes, or apples, or pumpkins, or pecans, or garlic (Levenstein 1993).

Like their eastern counterparts, midwestern farm families ate much meat, milk, vegetables, and fresh fruit in the early twentieth century (Cummings 1940). However, this was not true for many in the South. Kentuckians in 1919 and 1920 were relying on pork and maize meal augmented with white flour, and many in the Blue Ridge mountains had similarly restricted diets, with coffee and flour the only store-bought foods (Cummings 1940). When federal relief came to the South during the Great Depression, such foods as whole-wheat flour and grapefruit juice were as alien as coconuts to those in rural areas, who often ignored these introduced foods because they were unfamiliar (Cummings 1940).

The nutritionists of the early twentieth century failed on several counts. One problem was their belief that "mixed foods" were hard to digest. Thus, immigrants were pressured to give up nourishing ethnic dishes, such as Hungarian goulash, for pork chops and applesauce. Another problem was the contemporary enthusiasm for canned foods, even in preference to local, fresh ones, which meant that vitamins and minerals were often inadequate. A third problem was the continued hostility of the nutritionists toward spices and flavorings as well as "fancy cooking" (Shapiro 1986; Levenstein 1988). This often resulted in bland and insipid dishes that made it difficult to interest anyone in this "new nutrition." Even fresh, hot bread was frowned upon as indigestible by the experts, who advised immigrant families to buy their breakfast bread and pastries during the evening before they were to be eaten so as not to endanger their family's health (Shapiro 1986).

These same experts told black migrants from the South to abandon "corn pone" and pork in favor of codfish balls and Boston brown bread, although few of them actually did so (Shapiro 1986). Some immigrants also resisted the pressure to conform, most notably the Italians (Shapiro 1986), although the restaurants they established served Italians and others with Americanized versions of spaghetti, garlic bread, and more (Levenstein 1993).

A final problem with the new nutrition was the inconvenience of lengthy food preparation, such as the making of stews, which the nutritionists favored. But greater changes in working-class foodways were afoot. The same era that saw the failed efforts of the nutritionists also witnessed the birth of an American tradition when, in 1916, the nineteenth century's "hamburger steak" was made into a sandwich by the founders of the White Castle restaurant chain, Billy Ingram and Walter Anderson (Pillsbury 1990).

The Era of Prohibition

In 1919, the United States adopted Prohibition. The Volstead Act – a constitutional amendment outlawing the commercial manufacture and sale of alcoholic beverages – had its roots in the temperance movement that had arisen in reaction to the endemic drunkenness of the late eighteenth and early nineteenth centuries. Long unsuccessful at the national level, the movement had gained momentum during World War I, and suddenly the saloons and free lunches were no more. Prohibition also encouraged the conversion of bars to sandwich counters and hamburger "joints," while chains of "family restaurants," such as White Tower, its rival White Castle, and Howard Johnson's, spread across the nation (Pillsbury 1990).

Once Prohibition laws were in place, organized criminal syndicates and smugglers began providing illegal liquor and beer to those thirsty Americans who were not already making their own. But concern over the rise of crime and violence associated with Prohibition, as well as the onset of the Great Depression, ultimately combined to ensure the repeal of the Volstead Act.

The Great Depression and World War II

The crash of the stock market in late 1929 signaled the start of a decade of severe economic difficulties for the United States, as well as for the rest of the world's developed nations. Oral history and folklore recount stories of "making do," and the outright hunger and dietary changes brought about by the depression are reflected in national statistics of the time. Meat consumption dropped from an average of 130 pounds per person per year to 110 pounds. Americans ate an average of just under 10 pounds of dried beans to fill up; the average in 1920 had been just under 6 pounds (Brewster and Jacobson 1978).

The Great Depression was followed by World War II, which shaped the course of world history for the next 50 years. Both world wars had stimulated vigorous drives to persuade the public to eat perishables so that such staples as wheat and beef could be sent overseas to the troops. However, this was not necessarily a hardship. "Meatless days," the aim of a program established to restrict meat consumption, were bearable when Americans could eat salmon, lobster, or tuna instead (Levenstein 1988). Likewise, because candy companies received large rations of sugar, candy consumption went from 13 pounds per person in the 1930s to 21 pounds in 1944 (Brewster and Jacobson 1978). "Victory gardens" helped to ease the shortage of rationed foods, although, in terms of rationing, Americans were scarcely as deprived as their European counterparts (Tucker 1993). Campaigns prompted people to can foods, and pressure cookers were made available (often on loan from the government), with the average family putting up 165 jars of canned goods annually (Levenstein 1993). In 1941, wartime nutritionists drew up the first table of recommended dietary allowances (RDAs) for the chief nutrients. Flour and milk were quickly "fortified" with them (Levenstein 1993), with the augmentation viewed as an inexpensive way to attract consumers (Brewster and Jacobson 1978).

Changes in agricultural technology also began to affect the American diet. In the 1940s, the use of hybrid strains of maize had increased the U.S. maize yield from 30 bushels per acre to 40; by 1980, yields of 100 bushels per acre were the norm. Because hybrid seeds were produced by crossing parent strains, however, farmers who wanted the greater yields that hybrids made possible had to buy seed each year, instead of saving it, as had been the case in the past. Immense profits followed for seed companies as hybrid tomatoes, cotton, and other crops were developed (Kloppenburg 1988). One result has been that older, open-pollinated strains of maize and vegetables have been neglected and, in some cases, pushed to extinction. Another result, in the eyes of critics, is that because much of the increased maize yield has served as animal fodder and only reaches consumers secondhand in the meat they purchase, much energy and land is devoted to (and pollutants created by) what might be seen by some as waste on a massive scale.

"Convenience" Foods and the Homogenization of Tastes

With the 1950s, the new "consumer society" began to demand convenience in food preparation and consumption. Sales of fresh fruit dropped from 140 pounds per person in the 1940s to 90 pounds in the 1960s, whereas those of preserved fruit – loaded with sugar – increased (Brewster and Jacobson 1978). Intensive marketing of soft drinks (the amount consumed went from 90 servings per person per year in 1939 to 500 in 1969) led to a drop in coffee drinking, although the consumption of tea (mostly iced tea) increased very slightly (Brewster and Jacobson 1978). With the promise of more leisure time for cooks and their families, the proliferation of packaged foods put on the table such dishes as a so-called Welsh rarebit, made easier to prepare with Kraft's "Cheese Whiz" – a processed, foamy "cheese" product sprayed from an aerosol can – introduced in 1953 (Levenstein 1993). Another new food for many 1950s Americans was pizza, made by Italians in local restaurants, and a treat for Mom on her "night off" (Levenstein 1993). Pizza, as is true of many other Americanized foods, soon bore little resemblance to that made in the nation associated with it.

Local menus became more homogeneous in the twentieth century as canned and frozen foods, along with air-shipped fresh foods, increasingly meant that the same foods were available everywhere. As a result, it was (and is) easier for Virginians to buy kiwifruit (imported from New Zealand) than papaws (grown in their own state). Another consequence of the mass movement of staples was the establishment of fast-food restaurant chains. These differed from the chain restaurants of the nineteenth and earlier twentieth centuries in that the standardization of food preparation produced procedures that could be performed by low-paid, unskilled workers. McDonald's, perhaps the best known of the fast-food chains, began its rise in 1954, when Ray Kroc bought the McDonald brothers' restaurant and began to expand its hamburger business (Kroc 1977). By 1990, McDonald's had 8,000 outlets in the United States alone. Each served standardized foods, such as french fries made from Russet Burbank potatoes of uniform size, which were aged for a predetermined period to ensure that uniformity. The mid–1950s also saw the beginnings of Kentucky Fried Chicken, Burger King, Lums, and a number of other chains that soon followed (Pillsbury 1990).

These restaurants owed their success to several factors. First, identical portions of food could be refrigerated or frozen and shipped to any restaurant in the chain, ensuring that food that tasted the same could always be found under a familiar sign. Second, fried chicken and grilled hamburgers could easily be turned out in assembly-line style, with prices so low that local restaurants had great difficulty in competing. Third, diners generally served and cleaned up after themselves.

Fast food is almost always high in sugar and fat, and the nature of the business, until recently, made fresh fruit and vegetables unlikely offerings. However, in view of the health and environmental concerns of the 1990s, some chains have made salads and pasta available and have added lowfat products.

Revolutions in Food Technology and Distribution

Over the course of the twentieth century, American grocery shopping increasingly centered on large chain stores, which offered a vast variety of foods, ranging from fresh meats and fish to canned and baked goods to an ever-increasing array of frozen foods. Credit for the latter belongs to Clarence Birdseye, originator in the late 1920s of the brand of frozen foods that bears his name. He developed the "quick-frozen" method, along with cardboard packages that allowed food to freeze and thaw while maintaining an attractive appearance (Levenstein 1993). General Foods purchased his company and prospered, as many American households – even during the depression years – acquired refrigerators with freezing compartments. Others prospered as well; as early as 1941, there were already some 250 firms marketing frozen foods. Refrigerators in the home brought about a reduction in the consumption of canned condensed milk and a concomitant increase in the use of fresh milk (Brewster and Jacobson 1978).

The use of twentieth-century high technology in mass-production food processing was matched by technological advances in the kitchen at home. In general, however, the latter was more an adaptation of traditional cooking strategies to new technologies than the development of a truly new style of cooking. Thus, although the wood-fired ovens of the early nineteenth century were replaced by gas and electric ovens, the cook still put food inside and shut the door to bake, roast, or warm it. Pots were placed on gas or electric burners, just as they had been on wood stoves. Even "new" cooking methods that came into widespread use, such as stir-frying, were rooted in much older cooking techniques (Tropp 1982), while boiling, broiling, frying, and other methods of great antiquity continued to be basic.

Technology, however, has resulted in better and more convenient stoves, cooking "islands" in the kitchen, and a whole array of food processors, choppers, blenders, and toasters. One product of recent technology is the microwave oven, which was common by the 1980s despite widespread misconceptions that it emitted dangerous radiation and made food radioactive. The main advantage of the microwave oven is that it can heat food faster and with less energy than a conventional stove.

Advances in food technology and distribution, however, have not resolved the problems faced by those of low socioeconomic status. Since World War II, government food programs have aimed at not only promoting good nutrition but providing it. Food stamps feed a large number of needy Americans, and the Women, Infants, and Children Program (WIC) distributes nutritious foodstuffs to pregnant and nursing mothers and to children under age 5. This effort has resulted in measurably higher birth weights and a lower percentage of birth defects (Levenstein 1993). There is opposition to these and other aid programs, but they do provide even the poorest Americans with access to supermarket foodstuffs.

Health Concerns

The large amounts of meat in the American diet has increasingly become a matter of concern in a country whose people consume one-third of all the meat available in the world (Root and de Rochemont 1976). The same is true of sugar. In the 1970s, American sugar consumption reached 99 pounds per person per year, or more than 4 ounces per day (Root and de Rochemont 1976; Mintz 1985), while the consumption of carbonated beverages totaled 107 billion bottles per year. The American "sweet tooth" doubtless has much to do with such health problems as weight gain, rotten teeth, indigestion, and heart and pancreatic troubles, including hypoglycemia and diabetes. It is also arguable that the replacement of more nourishing vegetable foods by sugar is a cause of iron and calcium deficiency (Root and de Rochemont 1976). The fact that Americans in 1976 took in 125 percent of the fat, yet only 75 percent of the carbohydrates, that had been consumed in 1910 has also become a cause for worry, as heart disease, cancer, and hypertension are all believed to be linked to a fatty diet (Brewster and Jacobson 1978; Robertson, Flinders, and Godfrey 1976).

The nutritionists of the 1970s began to shift the emphasis to holistic health and lifestyle, as it seemed clear that cancer and heart disease involved factors other than diet, such as smoking, lack of exercise, and stress. Cholesterol, a fatty substance that accumulates in arteries, began to receive blame for heart attacks with the meat and milk consumption of the previous century viewed as the reason for high cholesterol levels (Levenstein 1993), and in 1977, alarmed by this news, many Americans started to alter their eating habits by consuming more chicken, fish, and vegetables and less red meat and butter (Levenstein 1993). In something of a contradiction, however, overall beef consumption actually increased, largely because of an increasing reliance on fast foods. Food companies have responded to health concerns by marketing lowfat dishes in frozen and fresh forms (Levenstein 1993), but, of course, lowfat and diet foods often contain a plethora of chemical additives (Belasco 1989).

Alcohol is often seen as posing another health problem. Drinking has had an uncertain status in America since the repeal of Prohibition, and liquor, in particular, has come under attack for its empty calories. On the other hand, since the advantages of moderate wine consumption in the prevention of heart disease were discovered in studies of the "Mediterranean diet," it has become clear that moderate consumption of any alcohol can be preventive.

Alcoholic beverages from America's past have been resurrected. The hard cider enjoyed by colonists returned in the 1990s, and two brands share popularity with a variety of "microbrewed" beers (some of which are reminiscent of the beers of yesteryear that were brewed in taverns and private houses) and their mass-produced competitors. Even colonial pumpkin beer has returned. In addition, regional wineries as far north as British Columbia have begun to flourish, using hybrid grape strains capable of producing wine of varying quality. It is unfortunate that many of these, and other, alcoholic beverages often depend for their flavor and consistent quality on chemical additives.

Suspicion has been focused on additives since the late 1950s, when scientists found that the hormones used to fatten chicken and cattle were carcinogenic. Such concerns have resulted in tougher labeling laws and in the banning of dangerous chemicals, such as DDT (Levenstein 1993). Because such bans are generally based on studies involving rats and mice, there are also jokes about how everything gives cancer to mice. Less humorous, however, is the possibility of risks they pose for humans, who consume unknown (but apparently considerable) amounts of additives and chemicals every year. In the eyes of some, food companies argued for years to their discredit that all their ingredients were "natural" before they bowed to consumer pressure for change (Belasco 1989).

Recent Developments in Foodways

The "counterculture" movement of the 1960s brought about an idealistic renewal of interest in vegetarian diets, gardening, and subsistence agriculture. In addition, rural, agricultural communes were formed to pursue "alternative" or "spiritual" ways of life, although most of them were not vegetarian, and many raised animals for consumption. Commune recipes collected in 1970 and 1971 exhibited a heavy use of soybeans and whole grains (Horton 1972).

Food cooperatives, begun in the 1960s, provided members with access to unusual, foreign, and organic foods in exchange for labor. The most famous of these, Berkeley's "Food Conspiracy," gave rise to others. A 1990s form of collective food buying was community-supported agriculture (CSA). Thirty or more members belonged to a collective and paid large annual fees (perhaps as much as $1,000) to support a family farm, the produce from which was then divided among its supporters (Iggers 1996). Another new and different way of acquiring food has involved delivery companies that send shipments of meat and other foods (usually frozen) to fill members' home freezers. Such a service could save substantial amounts of money for members who buy in bulk, as well as ensuring that, as a rule, the meat they consume is of better quality than that offered to the general public.

The emphasis on healthy eating begun in the 1960s continues, as do attempts at self-sufficiency. In the 1990s, about 29 million Americans kept gardens, 26 million fished, and 14 million hunted game (Tucker 1993). Surveys in 1994 and 1997 indicated that at least 2 million Americans were vegetarians; many more, perhaps 10 million, avoided red meat. An estimated 500,000 of these went beyond vegetarianism to become "vegans," those who eat no foods of animal origin, such as milk, eggs, or honey (Personal communication from the Vegetarian Resource Group 1997). Inspired by "reverence for life" and "animal rights" ideals, vegans hope to create a lifestyle devoid of cruelty to animals. There is a large and growing body of information and misinformation available for vegetarians. The most famous vegetarian cookbook, *Laurel's Kitchen,* a volume replete with nutritional information, vegetarian and vegan recipes, and moral exhortations, was compiled by members of a vegetarian collective in Berkeley, California (Robertson, Flinders, and Godfrey 1976). Like Sylvester Graham before them, the authors of *Laurel's Kitchen* abhor spices, white flour, and meat.

Laurel Robertson and her colleagues drew heavily on the influential work of Adelle Davis and Frances Moore Lappé. Davis was a key figure in Rodale Press's network of organic gardening cooks and writers. Accused in the late 1950s and early 1960s of providing readers with potentially harmful information on vitamins and minerals, as well as disquieting cooking and eating practices, she was labeled "potentially dangerous" long before her death from cancer – a disease that she believed her pattern of mineral and vitamin consumption would prevent. She also thought that it would prevent heart disease, yet her editor, J. I. Rodale, died of a heart attack (Levenstein 1993).

Lappé, author of *Diet for a Small Planet,* advocated replacing meat protein with "complementary" proteins found in grains and beans in order to lessen the stress placed on the world's environment by the feeding of grain to meat animals. Lappé's inspiration had been another fad diet, "macrobiotics," invented by George Ohsawa in Paris and allegedly based on Zen monastic cooking from Japan. This regime consisted of a series of diets, each more restrictive than the last. At first, converts partook of fish, noodles, clam sauce, and vegetables, according to the season (round food was eaten in winter, for example). But at the most restrictive level of macrobiotics, no food was permitted save brown rice and 8 ounces of liquid per day. The American Medical Association condemned macrobiotics, but this has only made it more attractive to "cranks" and conspiracy-minded "brown-ricers" (Levenstein 1993).

Then there have been fads, normally involving relatively small numbers of people, concerning cooking utensils. An example was the German *Römertopf* ("pot of the Romans"), an unglazed clay vessel used to bake meat and vegetables without the use of oil. Although capable of producing interesting results, the pot was difficult to use with many traditional recipes and proved to be a commercial failure in the United States (Tropp 1982). Another fad, backyard grilling, represents a considerable expansion of men's role in home cooking, which early in the twentieth century was limited to carving the meat (Levenstein 1993).

In a wider and somewhat contrasting development, the increase in career options for women has brought about a partial eclipse of regional and ethnic cooking traditions, as fewer families cook traditional meals "from scratch" at home. Although such meals were never fads, the often laborious preparation of such ethnic foods as tamales or raviolis is now generally confined to holidays.At the turn of the 1990s, only about 15 percent of American households regularly cooked and ate three meals a day at home (Belasco 1989).

Nonetheless, the appeal of the exotic is stronger than ever, with fads for ethnic cuisine coming and going much like technological fads such as home bread- and pasta-making machines. One important result has been to make exotic ingredients increasingly more available. Native American foods, such as Jerusalem artichokes and wild mushrooms, can be found in giant chain stores side by side with Thai lemongrass, fresh habanero peppers, Italian mushrooms, and sun-dried tomatoes. Honey mead, nowadays little known in the Western world, can generally be found in Ethiopian restaurants; "chicken Kiev" and fried rice, once rare treats, are now available in grocery stores in both frozen and unfrozen forms (Levenstein 1993).

Another exotic influence has to do with the latest influx of Spanish-speaking peoples to the United States during the latter half of the twentieth century, along with an increase in the number of Americans who speak Spanish. This trend has led to a nationwide acceptance of "Mexican" or "Tex-Mex" (meaning a combination of Texan and Mexican) foods. Chi-Chi's, Taco Bell, and other restaurant chains serve various versions of "Tex-Mex" cuisine to millions of customers, and burritos, tacos, and salsa are available in restaurants and supermarkets everywhere. Indeed, sales of salsa surpassed those of catsup in the 1990s.

The chilli pepper became a trend in itself in the 1990s. Catalogs listed hundreds of varieties of hot sauce, and representations of peppers decorated everything from china to underwear (DeWitt and Gerlach 1990). Monthly magazines and Internet Web sites listed enormous numbers of hot and hotter dishes; some incorporated explosive amounts of capsaicin (the chemical that produces the chilli's characteristic burning sensation), which is derived from specially bred varieties of peppers. Just one Red Savina, the hottest chilli pepper marketed in 1996, was alleged to be capable of producing spicy "heat" in 200 pounds of sauce!

Chilli peppers also figure prominently in the new cooking of Asian-Americans. The presence of Chinese people in California since the days of the gold rush has introduced the sophisticated culture and cookery of China to consumers. Changes in immigration laws in 1965 permitted a new wave of Asian immigrants, many of them Chinese, who found a tradition of Chinese-American cooking already in place. The 1980s fad for stir-frying induced supermarkets to carry Oriental vegetables, bean sprouts, soy sauce, and other Chinese sauces. Woks and Chinese steamers appeared in gourmet food stores, and earlier Cantonese restaurants were joined by Sichuan, Hunan, and "Peking"-style eateries. Ordinary Americans discussed and ate "pot-stickers" and other dim sum (a series of small portions of a variety of foods), and the availability of Asian foods – including Korean, Vietnamese, and Thai, among others – continues to grow.

Food writers and chefs, such as Julia Child, Craig Claiborne, James Beard, and Martin Yan also helped to introduce exotic cooking techniques and ingredients in their television programs and cookbooks. Child was perhaps the most influential in a drive to bring French cuisine to the American table; Yan's "Yan Can Cook" combined Chinese-American food with comedy and culture; and Beard's cookbooks are valuable resources for anyone studying gourmet cooking. The popularity of such books and programs has encouraged in Americans both a receptiveness to new ingredients and a demand for produce, meats, and seasonings that are absolutely fresh.

The Future

It is not easy to predict the future of foodways in America. Such major trends as preservation by freezing, dehydration, irradiation, and the use of additives will doubtless continue. The near future may bring "tissue culture," a technology that can produce coffee, spices, and drugs without growing entire plants (Kloppenburg 1988). The accelerating demand for speed and convenience in the 1990s that resulted in so many new time-saving products will probably also stay with us. Examples of really "fast" foods are packaged salads, sold with dressing so that the consumer simply opens the package and eats; microwave brownies, "baked" in a microwave oven; caramel topping that requires only pouring onto baked apples; "no-bake" cheesecake in machine-made pie crusts; and even ready-made omelettes that can be microwaved.

It seems clear that more and more processed foods of every kind, including those altered by biotechnology, will confront the consumers of the future. Probably we will also continue to witness the phenomenon of one ethnic food fad succeeding another, this accompanied by the marketing of ethnic foodstuffs in "Americanized" forms to satisfy desires for foods that are exotic but nevertheless familiar. Health and environmental concerns will doubtless lead to an increasing consumer insistence on accurate labeling and honest marketing procedures. As the planet becomes increasingly crowded in the twenty-first century, more efficient strategies will be required to feed growing numbers of people. America's vast bounty will likely be called upon, and it is to be hoped that the response will be both thoughtful and caring.

V.D.7 The Arctic and Subarctic Regions

Traditional foodways have played an intrinsic part in the daily lives of the Native American peoples in the Arctic and Subarctic. Unlike other Americans, whose visits to their local grocery stores for food are seldom memorable, the people of Minto could look at a piece of dried fish and remember where they caught it, the activity on the river, and congratulations received from family members. The point is that food is more intimate for those who catch, grow, or gather it than for those who simply drop it into a shopping cart. The procurement, processing, preparation, and serving of food unites such people with their history, their future, and each other. The use of local resources serves as a direct emotional and spiritual link to the environment on which they depend.

This chapter explores the prehistoric, historic, and current dietary patterns of Native Americans in Alaska, Canada, and Greenland. Because of the wide variety of cultures in the Subarctic and Arctic, this is necessarily a general discussion.

The People

The Native American groups of the Arctic and Subarctic consist of two major genetic and linguistic populations – the Northern Athapaskan Indians and the Eskimo. In Alaska and Canada, the Eskimo are generally coastal people who are believed to have entered North America some 9,000 years ago. The older denizens are the Northern Athapaskans, located for the most part in the interior of Alaska and Canada, who are thought to have crossed the Bering Strait about 15,000 years ago.

Environment

Subarctic

The Tanana people are Athapaskans who reside in the area of Minto Flats on the Alaska Plateau, which is dissected by the Yukon, Tanana, and Kuskokwim rivers. The landscape includes mountain ranges of 3,000 to 4,000 feet, rivers, streams, marshes, grassy fields, and islands.

There are four seasons in this Subarctic region. The winter – long, dark, windy, and very cold – is a time when minimal light and extreme cold limit travel. Spring is associated with the thawing of the rivers and boat travel, but frequent stops to warm up with tea and snacks are necessary to combat the cold. Spring weather is variable from day to day, with warm days and cold nights. Summer is short, warm, and without darkness, with rainy days often bringing concern about flooding rivers. These are the months that are associated with travel on the rivers and roads and, of course, with fishing and gathering. Autumn is marked by the gradual darkening of the night and colder days. By late autumn, the leaves have changed color or fallen, the snow has returned, and the focus is on moose and duck hunting.

A wide variety of flora are present in the Subarctic. Tree types include aspen, white spruce, birch, poplar, and willow. The spruce, birch, and willow are used for medicine, building materials, and fuel. Edible plants include wild rhubarb, Indian potato, wild onion, lowbush cranberry, highbush cranberry, blueberry, wild rose, and raspberry.

Animal populations that are hunted and trapped are mountain sheep, moose, bear, muskrat, rabbit, beaver, porcupine, and duck. A variety of fish are available, including salmon, burbot, grayling, whitefish, pike, and sucker.

All Northern Athapaskan populations practice a subsistence strategy of hunting, gathering, and fishing, which varies with location. It is a seminomadic subsistence strategy which, for some, involves moving from their villages to winter, summer, fall, and spring camps in order to take advantage of the local resources of each, although many now reside permanently in the winter camp.

There are, of course, regional variations. For example, the Tanaina, who reside in a lush coastal and riverine environment around the Cook Inlet in southern Alaska, have access to a wide variety of marine and inland resources. They are primarily hunters and fishers who procure mussels, crabs, seals, beluga, moose, caribou, and groundhogs. But their diet also incorporates a wide variety of plant resources during the spring, summer, and fall.

By contrast, more northerly populations, such as the Koyukon, live in a riverine environment considerably more mountainous. Like the Tanaina, these people also depend on hunting and fishing but rely more heavily on the latter throughout the year because of their access to the Yukon River. Salmon (chinook, chum, coho, and sockeye) has long been a primary resource for the Koyukon.

Arctic

The Arctic is designated as a high-altitude region, usually lying above the tree line. It includes a broad expanse of land stretching from western Alaska through Canada as well as Greenland. The ground is frozen year-round (permafrost), and minimal precipitation occurs.

The diversity of food sources in the Arctic is low compared to the Subarctic region. Eskimo populations throughout the Arctic depend mostly on marine species, including seals, whales, walrus, and fish (Freeman 1984). But inland fish are also procured, including char, trout, pike, grayling, and salmon (Freeman 1984). The most important land mammals that provide food are the caribou, arctic hare, and musk ox.

Precontact Subsistence

The majority of precontact Northern Athapaskan groups were interior populations of hunters, fishers, and gatherers, whose seasonal rounds were similar to the pattern seen today.

In winter – a time of minimal subsistence activity – large groups congregated at winter camps, where local resources were processed for food and clothing, and some celebrations were held. When the weather improved, from spring through fall, the larger groups divided into individual family groups that traveled to smaller camps, permitting greater access to food resources. Each family group tended to visit the same camp sites – loosely considered the group's own "territory" – every year. Some, such as the Upper Tanana people, were more dependent on large game, but they nonetheless fished the inland lakes and tributaries and the Tanana River. Spears, bows and arrows, fish traps, gill nets, dip nets, lures, and hooks were all employed in this seasonal harvest of protein, the storage of which was, obviously, important for the coming winter months (Sullivan 1942; VanStone 1974).

Throughout the spring, summer, and fall, the Northern Athapaskans dried, froze, and stored food in birchbark baskets above and below ground. The caches aboveground were small boxlike shelters on stilts with cutout openings or doors. Belowground the caches were dug into the permafrost and covered with wood to seal in the cold air and to protect against animals.

The mobility of the Northern Athapaskans allowed consistent access to food sources, yet their small groups were able to avoid depletion of such sources in any one subsistence area by having a variety of sites. The Tanana Valley people, for example, still continue to use a number of different sites during the year, moving from one to another by birchbark canoe or by snowshoe (Sullivan 1942; VanStone 1974).

In the spring and summer, the major foods obtained included whitefish, salmon, duck, and birds' eggs. Gathered products, such as blueberries and cranberries, were also stored during the late summer and fall months. The important foods during autumn were moose, caribou, duck, grouse, and rabbits. In the winter, stored foods were supplemented by trapping small game and by ice fishing.

Throughout the year, families spent considerable time exploiting other resources as well. Ducks were hunted in the spring as soon as the weather warmed and people could safely travel by boat. In the summer, berries and small animals were sought, in addition to fish, whereas larger mammals were hunted or trapped mostly during the fall. Such a pattern of seasonal subsistence was common for Indian populations, such as the Kutchin, Koyukon, Ingalik, Kolchan, Tanaina, and Ahtna (Clark 1981; De Laguna and McClellan 1981; Hosley 1981a; Slobodin 1981; Snow 1981; Townsend 1981).

In addition, some populations, such as the Ahtna and the Tanaina, who resided close to mountainous regions, could hunt Dall sheep (De Laguna and McClellan 1981; Townsend 1981). The Koyukon, who are northwest of the Tanana, actively traded with the Eskimo, which increased their subsistence region (Slobodin 1981), and some populations in the Subarctic, such as the Tanaina, hunted sea mammals along the coast of southern and western Alaska (Townsend 1981).

Almost all native Alaskan populations continued their seminomadic lifestyle until the turn of the twentieth century, when increased mining and fur-trading activities eventually brought about the development of permanent villages. But even today there are still many hunting and gathering populations that carry on in a traditional manner (Hosley 1981a; Berger 1985). Older members pass on subsistence knowledge to the rest of the population, which links the generations together (Berger 1985).

Contact and Chance in Subsistence and Diet

Prolonged contact with Western culture brought a dependence on trade goods, such as guns, iron chisels, knives, and axes and gradually led to the development of sedentary camps around the trading posts, which disrupted traditional subsistence activities (VanStone 1974; Martin 1978; McClellan 1981; Frank 1983; Newman 1985, 1987; Yerbury 1986).

In Canada, reliance on trade goods brought an increasing interdependence between Indians and trading-post inhabitants, as many of the former entered into economic relationships with traders. They hunted and fished for them, receiving trade items, such as guns, for their efforts.

One need only consider the disruption brought about when the Canadian Iroquois began, in the mid-seventeenth century, to hunt for furs instead of food. After depleting their own traditional hunting grounds of both food and fur-bearing animals, they began to encroach on the territories of neighboring groups. And as food resources continued to decline, they became increasingly more dependent on the trading posts. By the early 1800s, the moose and caribou had been overhunted and a dietary change had taken place, forcing the Indians to rely on hares, fish, and purchased food (Martin 1978). Yet even as food resources declined, sedentary life fostered Iroquois population growth, which considerably enhanced the risk of severe food shortages (Ray 1974).

To obtain goods to trade for food, many Alaskan natives turned to trapping in the late 1800s (McClellan 1981; Schneider 1986). The steel trap gained importance around 1900 and accelerated the pace of trapping animals for economic rather than subsistence reasons. Cash and trade relationships with the Alaska Commercial Company and the Western Fur and Trading Company, in particular, enabled Alaskan natives to purchase Western foods and products from trading posts and from Europeans moving through the region.

Animal populations declined as trapping increased and native human populations became more sedentary. Native trappers traveled ever farther away from these settlements in search of quality pelts, and it became necessary to leave family members behind, often for days. Moreover, as native populations continued to nucleate into fewer, and larger, settlements on the main rivers, the decrease in nomadic patterns led to a summer–winter dualism. By the middle to late 1930s, many families had established a pattern of occupying fishing camps during the summer and trapping and hunting from more permanent villages in the winter (Hosley 1981a). Finally, and obviously, an exchange of the traditional subsistence lifestyle for a kind of Western economic mode of living meant that increased sedentism also disrupted traditional dietary patterns.

Trade goods offered unique tastes in compact forms that were intriguing to the native populations. Foods high in carbohydrates, such as the white potato or crackers, infrequently found in the traditional diet, seemed attractive because they added variety. Other items, such as coffee, tea, flour, and sugar, quickly became staples to be purchased in bulk, and they are still bought in large quantities today. Coffee and tea quickly replaced the beverages decocted from local plants because they were easier to acquire than the traditional items.

The seductive appeal of trade goods reached out even as far as to the Greenland Eskimo (Freuchen 1935). Their participation in European whaling activities was rewarded with a variety of Western foods, such as tea, coffee, crackers, oatmeal, and chocolate (Freuchen 1935). The growing dependence on such foods was well documented by Peter Freuchen: "[T]he coffee beans they purchase raw and roast them to a crisp. To make them go a long way, the Eskimos mix the beans with rice or barley. . . . This form of coffee turns them into near-addicts. When they are without coffee, they say they feel worse than when they are starving" (1935: 109).

Disruption of traditional life by the fur trade was further exacerbated by the gold rush (1884 to 1920). Alaskan natives who had become dependent on Western products now encountered much difficulty in obtaining them. Competition for scarce food resources pushed the price of Western foods beyond their purchasing ability, and as a consequence, natives took jobs for wages in mining towns and on riverboats to increase their purchasing power. The trend toward sedentism that had begun with the fur trade accelerated, with some people abandoning all of their traditional subsistence activities as a result of the high wages to be obtained in the towns and on the rivers. And, as highways and roads were built in Alaska, the natives sought jobs associated with their construction.

Although such activity was generally destructive of old ways, such goods as firearms and dogsleds did help some people to adhere to traditional subsistence activities and diets. Certainly the rhythm of subsistence hunting was altered dramatically with the introduction of firearms, as hunting changed from a communal to an individual activity. It was the use of the rifle that ensured that moose and caribou would continue to be overhunted. Indeed, the caribou were ultimately decimated because they traveled in large herds, and with decreasing caribou, native populations focused their hunting strategies on the moose. Along with the greater access to food resources permitted by the rifle, hunters also increased their harvest of fur-bearing animals.

The adoption of sleds pulled by dogs was yet another factor that affected Indian lifestyle. Dogsleds permitted travel in the winter months, which extended the trapping season. In addition, as Robert A. McKennan (1981) points out, the introduction of the dog team increased both the need and the market for dried fish, an easily transportable dog food.

With an increased demand for fish, the Lower Tanana Indians adopted the use of the fishwheel, which meant larger quantities of fish for both human and animal populations. But because the fishwheel required deep and fast-moving water in order to be functional, Indian populations began moving away from the smaller rivers to the larger Tanana River.

Other dramatic changes came with the introduction of transportation based on fossil fuels (Cohen 1974), such as gasoline-powered boats, snowmobiles, and automobiles. Boats greatly increased access to local resources, especially during the fowl- and moose-hunting seasons. Water travel thus became more efficient, and winter and summer villages were able to be more widely separated (Hosley 1981a: 551).

Other gasoline-powered vehicles also allowed native people to move within their subsistence area faster and more frequently. In the 1960s, the Canadian Netsilik used snowmobiles to chase caribou. Unfortunately, it was this combined use of gasoline-powered vehicles and firearms that brought about the near total destruction of caribou in Canada (Neatby 1984). Another technological factor that encouraged this sort of overhunting was the home freezer, which led to the taking of more game and fish than could be immediately used.

Current Dietary Patterns

The Mix of Western and Traditional Foods

Current diets in the Subarctic and Arctic contain a mixture of traditional and Western foods. Many native populations eat such a combination because they are unable to obtain adequate foodstuffs by reliance on either traditional subsistence activities or Western resources alone. Traditional activities are frequently limited by participation in wage labor, yet many people are unable to afford the cost of Western foods on a daily basis.

This reliance on both subsistence foods and trade goods is aptly described by Kristin Borre (1991: 49) for an Inuit population of North Baffin Island, Canada. In this Arctic region, traditional hunting activities are of great importance, with children ages 7 to 15 contributing 40 percent, men 37 percent, and women 23 percent of the effort to capture most of the protein consumed. But despite a high level of traditional subsistence pursuits, the Inuit are also incorporating Western foods, purchased for immediate consumption, into their diet. Among other things, Western foods are increasingly attractive to younger members of the community.

A similar pattern can be observed among the Inupiat of Alaska's North Slope. Although many of the adult men work as wage laborers in the oil development at Prudhoe Bay, the Inupiat still need to rely on traditional food hunting and gathering for about 45 percent of foods consumed. Their increased income has resulted in the consumption of junk foods, especially soda pop and candy by the children (Kruse, Kleinfeld, and Travis 1982).

The uneasy juxtaposition of Western foods and traditional foods in the diet is evident in Richard K. Nelson's description of Athapaskan Alaskan life: "Sitting down for an evening meal, members of an Athapaskan family might find moose meat, bear grease, and wild berries on the table along with store-bought soup, bread and butter, and canned fruit. Before eating, someone may give a Christian blessing; and then a young daughter might be told not to eat a certain food because it is tabooed for a woman her age" (1986: 214).

Ceremonial Diet

Ceremonial food use, which also features a variety of traditional and Western foods, deserves consideration in any discussion of food and drink among current Subarctic and Arctic populations. Thus, the ensuing discussion highlights Alaskan Athapaskan potlatches observed by this author in 1987 and 1989, which illustrate the incorporation of both, along with comparative examples drawn from both Canada and Greenland.

Potlatches serve the important purpose of marking an event taking place or a stage of life. Such events include death, the memory of a person (and perhaps the making of a memorial song), a birthday, the first salmon catch of the season, a moose killed, a marriage, and important meetings. The largest potlatches are the funeral and memorial ceremonies. Family members give a memorial potlatch some one to five years after an individual's death. Memorial song potlatches are organizational ceremonies to create a song about the life of the person who died. Important meeting potlatches usually occur when a weighty decision has to be made concerning the village. The occasion may specifically involve an individual, or a family, but the holding of a potlatch often radiates out gradually to include the entire village, as well as other villages, due to the interrelationships existing within the population. The extensive quantity of food available during potlatches means that the Northern Athapaskan people understand them to be feasts as well.

Knowledge of an impending major potlatch, such as a birthday or a memorial, spreads quickly through villages in interior Alaska – especially the ones in proximity to Minto by river travel or to Fairbanks by air. People in different villages have developed close ties at potlatches, events that encourage them to reevaluate long-held traditions, relationships with friends, and village ties.

At another level, the potlatch is an occasion for distributing goods (Langdon and Worl 1981). During any type of potlatch, people who attend receive both food and gifts. The latter are given in respect and gratitude by the people hosting the potlatch. At a funeral potlatch, for example, some of the possessions of the deceased are given as presents, which makes them emotionally significant for the recipients.

Extensive quantities of food are common in ceremonies in the Subarctic and Arctic. One example is the Northern Alaskan Coast Eskimo Messenger Feast, which is a matter of competition among villages, with the village giving the feast attempting to "overwhelm a guest with food" (Spencer 1984).

A wide range of traditional foods, featuring both animal and plant items, is served at potlatches. Important animal dishes are moose, duck, salmon, beaver, and whitefish. Plant foods include a variety of berries, such as blueberries and highbush and lowbush cranberries, all boiled with water, flour, and sugar.

At a major potlatch, such as a funeral, the chiefs and other men receive the most highly desired portions of food, such as the large bones with moose meat still attached and the heads of salmon. Fish heads, considered a high-status food, are also served to the elder women.

Although moose meat is an important traditional food served at every potlatch, it obviously is of greatest importance at a first moose potlatch. After a family obtains its first moose of the season, its members hold a potlatch during which moose may be the only traditional food served.

The use of a traditional food as the primary dish also occurs at a first salmon potlatch, which is held in the village after someone catches the first salmon in the spring. Following the first catch, every effort is made to procure enough salmon for everyone. At the potlatch, the salmon is cooked in a variety of ways – boiled, in soup, and its eggs are also served.

Other protein foods, such as beluga, are important ceremonial foods for the MacKenzie Delta Eskimo. Marine animals are also used by the Iglulki to supplement "feasts of boiled meat . . . to which the whole camp was invited" (Mary-Rousseliere 1984: 440).

Western foods too are consumed at the potlatches, although these products are generally considered supplemental to traditional foods. Of all the village potlatches, the birthday ceremony contains the greatest variety of Western products, such as barbecued chicken, hot dogs, carrots, celery, green salad, fruit salad, white cake with frosting, deviled eggs, cauliflower, margarine, jam, and sweet soft drinks.

By contrast, at funeral potlatches mostly traditional foods are employed. Funeral potlatches have been a tradition of the Minto people for a long time, which explains the greater use of traditional foods, whereas birthday potlatches are relatively new (elders have indicated that they never used to celebrate the event). Thus, the presence of more Western foods corresponds with the newness of the birthday potlatch.

Current Dietary Patterns and Health

Traditional diets in both the Subarctic and Arctic provided much protein with a good ratio of unsaturated to saturated fats, and they were low in sugar and carbohydrates. But current Western foods incorporated into the diet do just the opposite in that they deliver high levels of saturated fats, sugar, and carbohydrates.

H. H. Draper (1977) discusses the contrasting health effects of traditional and Western foods in the diet of the Arctic Inuit. The traditional diet yielded much protein, and the consumption of the stomach contents of caribou, along with seasonal plant harvests, contributed important vitamins and minerals to the regimen. But the addition of dairy products, sugar, and carbohydrate-laden foods to the diet has created serious health problems. In the case of dairy products, Native American populations lack the ability to absorb lactose, and lactose malabsorption can produce cramping and diarrhea (Harrison 1975). There are other health difficulties that arise from the sugar and carbohydrates in the Western diet, ranging from tooth decay and obesity to diabetes and heart disease. In short, a departure from traditional diets to which they were well adapted has created a frequently life-threatening crisis of health for native peoples of the Subarctic and Arctic regions of the Americas. Alleviation of that crisis must begin with this realization.

V.E

The History and Culture of Food and Drink in Sub-Saharan Africa and Oceania

V.E.1 Africa South from the Sahara

Describing the principal sources of food for the inhabitants of Africa south from the Sahara is a relatively easy task. Most diets are dominated by products made from a single staple crop, and there are not all that many of them. Maize, sorghums, pearl or bulrush millet, and rice are the prominent grains, and cassava, yams, and bananas or plantains account for most of the vegetatively propagated varieties. Furthermore, their general geographies can be explained, for the most part, by annual totals and seasonality of rainfall. For example, near the dry margins of cropping, pearl millet makes its greatest dietary contribution, whereas the equatorial zone is where bananas and plantains come to the fore. Even adding in the role played by livestock, one that varies from insignificant to crucial, does not overly complicate the picture. Among farmers, fowl are fairly ubiquitous, while sheep, goats, and cattle are kept wherever diseases, especially sleeping sickness, do not prohibit them. When aridity intervenes to make crop cultivation too hazardous to rely upon, the herding of camels or cattle becomes the primary subsistence activity.

The problems come when attempting to go much beyond this level of generality. There is a plethora of other foods that are important to diets, including those from wild sources, and matters get even more difficult to sort out when issues of history, culture, and nutritional adequacy must be addressed. The region's human diversity is enormous, and most food systems display a complex interweaving of influences, ranging from the distant past to the present. Unfortunately, trying to understand what has happened through time is hindered by a dearth of information. The written record is sparse before the twentieth century, and archaeology, so far, has produced very few dates. As a result, temporal insights often must rely on somewhat less precise sources of information, such as paleobotany, historic and comparative linguistics, and cultural anthropology.

Our understanding of current diets and their adequacy is only slightly better informed. During recent decades, Africa south from the Sahara has replaced China and India as the "land of famine." Actual famine, however, has visited only restricted areas, such as portions of the Sahel, Somalia, and Mozambique. Elsewhere, people have not been starving, although only a few elites enjoy the luxuries of Western-like food abundance. Serious nutrition-related health problems clearly exist, especially among young children and reproductive-age women, and the food production data do point to an ever more precarious supply situation throughout much of the region. But surveys that allow for comparing diets and nutritional well-being are woefully inadequate.

As a result, the following presentation is offered in the spirit of being one best estimate. It begins with an overview of African "agricultural origins and dispersals," to borrow a title from Carl Sauer (1969), which, contrary to many earlier interpretations, were not all by-products of Egyptian influences. Other Africans engaged in their own domesticating processes, leading to the crops that provided the basic raw materials for the transition to food-producing ways of life. The most significant imports, the subjects of the next section, entered already existing agricultural systems. A brief discussion of food preparations and eating habits follows, and the final section is devoted to an assessment of what appear to be the most widespread diet-related disorders, excepting famine.

African Agricultural Origins

We can begin some 9,000 years ago when all Africans southward from the Sahara still gathered, hunted, and fished for their foods, with the particular dietary mix governed by what the local environment could provide. For example, on the vast savanna-covered plateaus, the abundance of game animals allowed meat to be eaten regularly, along with a variety of nuts, berries, roots, and tubers. Meat was harder to come by in more densely forested habitats, but freshwater fish were widely available as complements to vegetable foods, whereas along some coastal sections, extensive middens testify to the dietary importance of shellfish. Virtually all of the area appears to have been occupied, at least on a seasonal basis; exceptions were the higher elevations, the heart of the Sahara Desert (much less extensive then than now), the narrow strip of the Namib Desert, and the deeper recesses of the equatorial rain forest. For the most part, people lived in small, mobile bands exploiting territories that necessitated the use of tens of square kilometers to supply the subsistence needs of one adult.

By way of contrast, certain riparian habitats north and east of the equatorial rain forest supported higher population densities and more sedentary occupancy. They did so because of Late Stone Age technological advances that allowed people to use a diverse array of plants, including wild grass seeds, for foodstuffs, as well as to engage in an intensified exploitation of fish and waterfowl (Sutton 1977). The evidence to date points to such locales as these as having been at the forefront of domestication activities in Africa south from the Sahara, thus lending support to the agricultural origins models developed by D. Rindos (1984) and R. S. MacNeish (1992). Shortly thereafter, other movements in the direction of agriculture took place along the rain forest–savanna ecotone of western and central Africa and within what is now Ethiopia.

Whether there were broad zones or precise centers of domestication activity at the outset cannot be determined, but no matter which situation prevailed, the diffusion pattern evolved into one of multiple frontiers carrying a variety of crops and animals. And the pace of change varied considerably. In some instances, Stone Age economies seem to have given way quickly, but the norm was for agriculture to gain ascendancy over gathering, hunting, and fishing only very gradually.

Crops

The earliest signs of possible domestication come from two sites within the Sahara. One is at Nabta Playa in western Egypt, where a number of sorghum-type seeds have been found in deposits dated 8,100 years ago (Wasylikowa et al. 1993). Whether they were cultivated or gathered, however, cannot be determined. The other is in the Ahaggar and contains a seed, two pollen grains, and grain impressions, dated between 6,850 and 5,350 years ago, of what could be pearl millet *(Pennisetum glaucum)* (Muzzolini 1993). This is not much to go on, but the Ahaggar does fall within the biogeographical range of related wild varieties, while the timing corresponds to a moist episode that would have supported millet cultivation at favorable Saharan locales, such as in the highlands and along the shores of then fairly numerous lakes and rivers (Harlan 1989). Also dated to approximately the same time as the Nabta Playa and Ahaggar finds are Neolithic sites that have yielded pottery, grindstones, and rubbers. Their presence by no means guarantees cultivation, but the large numbers of artifacts add extra fuel to the speculation that something of significance was indeed taking place (Camps 1982).

Farther south, events moved more slowly, although both botanical and linguistic research indicates that domestication processes were trending in the direction of agriculture within several different zones during the period from 5,000 to 4,000 years ago. One zone followed the Sahel–savanna country stretching from the upper Niger River valley, through the Lake Chad basin, to Dar Fur. Overall, the western half appears to have been more active, accounting for African rice *(Oryza glaberrima),* fonio *(Digitaria exilis),* guinea millet *(Brachiaria deflexa),* watermelon *(Colocynthis citrullus),* and Bambara groundnuts *(Voandzeia subterranea).* The area east of Lake Chad was where the first sorghums *(Sorghum bicolor)* seem to have been cultivated. Later activities produced a variety of specialized sorghum races that would serve as the principle food source for peoples inhabiting the semiarid and subhumid regions of not only Africa but also India (Harlan 1989 and 1992).

So far, this vast zone to the south of the desert has yielded only two archaeological sites with substantiated evidence about the course of early crop cultivation. The oldest is Dhar Tichitt located in what is now south-central Mauritania, where P. J. Munson (1976) has documented a progression from an earlier riparian-type economy to a village-based one growing pearl millet by 3,100 years ago. No in-migration is indicated, thus pointing to diffusion from the Sahara as the likely source for the millet. The other site is Daima on the western side of Lake Chad. Here, excavations of earthen mounds have revealed the presence of a mixed economy involving fishing, hunting, gathering, herding, and crop cultivation centered on sorghums dating back to 2,500 years ago (Connah 1981). The agriculture practiced at Daima was advanced enough to support villages of more than 100 inhabitants and, therefore, must have been preceded by earlier developments that have not yet been unearthed.

Ever since the days of N. I. Vavilov (1926), the area within and around the Ethiopian highlands has been identified as a likely source of indigenous crop domestication. Now well established as coming from the cooler, seasonally rainy uplands of the center and east are teff *(Eragrostis tef),* noog *(Guizotia abyssinica),* and finger millet *(Eleusine coracana),* whereas ensete *(Musa ensete)* and coffee *(Coffea arabica)* are ascribed to the warmer, wetter southwestern forests. Dates are unconfirmed, but opinion based on linguistic analyses favors something on the order of 5,000 years ago for the upland crops (Ehret 1979; Phillipson 1993). This date may be fairly accurate because when wheat and barley arrived from south Arabian sources, about 3,000 years ago, they seem to have been incorporated into already well established agricultural systems.

Finally, various African communities appear to have been experimenting with yam cultivation (primarily *Dioscorea rotundata* and *Dioscorea bulbifera*) along a wide front following the savanna–rain forest ecotone in western Africa (Alexander and Coursey 1969). How far back in time this goes cannot be determined, but it must have been by at least 5,000 years ago because of the association of yams with several major population migrations dated to around this time (Ehret 1982). Because of the workings of humid climates and acidic soils on a plant that is inherently perishable to begin with, archaeology is unlikely ever to shed much light on the origins of yam cultivation, and, thus, further insights will have to continue to be based primarily on advances in botanical and linguistic research.

Kersting's groundnuts *(Kerstingiella geocarpa),* cowpeas *(Vigna unguiculata),* and the oil palm *(Elaeis guineensis)* are other crops thought to derive from the same general ecotone environment (Harlan 1992), but so far only cowpeas have been archaeologically confirmed. These come from the several Kintampo sites focused on central Ghana, and are dated to around 3,800 years ago (Flight 1976). The inhabitants of Kintampo also made considerable use of oil palm kernels, but these probably came from the harvesting of stands of protected wild trees.

Livestock

Unlike its crops, Africa south from the Sahara has depended upon external sources for its most important livestock. No possible ancestors for sheep or goats existed on the continent. Instead they arrived in several waves, from southwestern and central Asian sources, and quickly became integral parts of agricultural systems developed in Egypt and the Maghreb. The first cattle also seem to have entered from the east, although it is possible that indigenous varieties of *Bos primigenius* were domesticated within the Sahara (Smith 1992). These were all humpless types from which the fully domesticated *Bos taurus* arose. Later, but at least by 2,500 years ago, came humped *Bos indicus* types that probably entered Africa both via Egypt and from seaborne contacts with India along the east coast. Eventually, *B. taurus* and *B. indicus* crosses produced several distinctive African breeds, such as the Fulani, Sanga, and Afrikander (Blench 1993; Clutton-Brock 1993).

One initial route of livestock diffusion went upstream along the Nile, as is evidenced at the archaeological sites of Kadero and Esh Shaheinab near the junction of the White and Blue Niles. Wheat and barley may have been grown here as well, but it was sheep, goats, and cattle that constituted the main additions to a preexisting riverine-based Stone Age economy by 7,000 years ago (MacNeish 1992). From here, livestock continued to spread inland, reaching the region of Ethiopia between 5,000 and 6,000 years ago (Ehret 1979).

Roughly contemporaneous with Kadero and Esh Shaheinab are signs of other emergent livestock-based economies within and around the Saharan highlands of Dar Fur, Tibesti, Air, and Ahaggar. The evidence includes animal skeletons, material cultural remains, and, most convincingly, rock art at the remarkable site of Tassili-n-Ajer (Lhote 1959). Preserved there since approximately 7,000 years ago are scenes of what clearly are domesticated, humpless, long-horn cattle, along with their herders (Camps 1982).

When camels first made their way to Africa remains unclear. The dromedary had been domesticated in the Arabian peninsula by at least 3,800 years ago, but it does not seem to have become important in Egypt and the Sahara until much later, perhaps not until Roman times. Rather than entering with caravans crossing via the Sinai, as most experts have tended to think, camels may have first reached Africa by being transported across the Red Sea, a route which would help to explain their seemingly greater antiquity among desert-dwelling nomads in this corner of the continent (Zeuner 1963).

Even more mystery surrounds the entry of the common fowl *(Gallus gallus)* into Africa. We know that they were present in Egypt over 3,000 years ago, but that is about all (Simoons 1961). The usual assumption is that they probably spread from here up the Nile Valley corridor, and it is possible that chickens could have been carried across the Sahara once they had reached the Maghreb. A still later introduction (about A.D. 500) may have been with Malayo-Polynesian voyagers, who touched at points along the Indian Ocean coast on their way to Madagascar. Today, chickens are kept by farmers virtually everywhere, although much of their popularity seems to be quite recent.

Africa can claim two animal domesticates, neither of which, however, became important sources of food. One is the ass *(Equus asinus),* for which the Nubian wild race seems to have provided most of the genetic material (Zeuner 1963). It was in use as a beast of burden in Egypt, and presumably in Nubia, by 5,000 years ago, and from there spread to Ethiopia, the Horn, and the Sahel/Sudanic zone of western Africa at uncertain dates. The other is the guinea fowl, derived largely from *Numidia meleagris galeata,* which appears to have been first raised in the savannas of western Africa. Appreciated more for its aesthetic qualities than anything else, it often cannot be easily differentiated from the wild varieties that are still found widely outside the rain forest zones (Donkin 1991).

These are the essential domesticates that supported the rise of food-producing economies in Africa south from the Sahara. Over a span of 4,000 to 5,000 years, they have been carried across the subcontinent's diverse environments by a complex mix of population migrations and technological diffusions.

Many of these, however, can only be speculated about.

Regional Agricultural Dispersals

Western Africa

The pace of agricultural development in the Sahelian and Sudanic zones of western Africa seems to have intensified under competition and population pressure from southward-drifting livestock herders seeking respite from the ever-worsening aridity that had set in by 4,000 years ago. The evidence points to their having been members of a rapidly diverging Nilosaharan language group, other members of which were also the likely first cultivators of pearl millet (Ehret 1993). The most attractive destinations would have been the water and grazing resources along the upper Niger River valley and its tributaries, the Senegal River valley, and Lake Chad, then much larger than it is now. The Lake Chad area seems to have been occupied by yet other Nilosaharans, in all probability growing sorghums. In the other two areas, however, the herders would have encountered members of the Mande and Atlantic branches of the Niger-Congo language group. It was among them that agricultural systems of production were developing around African rice, fonio, and guinea millet. From all appearances, the Nilosaharans were absorbed, but they did leave livestock as one of their legacies.

Eventually, pearl millet and sorghums spread throughout the Sahelian and Sudanic zones, cultivated either in the flood plain style known as *crue* and *decrue* or else on the interfluves as parts of land-extensive systems of shifting cultivation (Harris 1976). Cattle, sheep, and goats also spread throughout the region, although often herded by specialists, most notably the Fulbe or Fulani. Their origins are traceable to the Senegal River valley, where they may have arisen out of a synthesis of Nilosaharan herders and resident Atlantic-speaking cultivators (Smith 1992).

The Kintampo sites demonstrate that agriculture was on the fringes of the tropical forest zone of western Africa more than 3,000 years ago. Crops were probably still less important than gathered plant foods, but there is strong evidence that goats and sheep had achieved considerable economic importance (Stahl 1993). How long it took from the time of Kintampo for agriculture to reach into the forest itself cannot be determined, although it is unlikely that much of a move was made prior to 2,000 years ago. Then it arrived from two directions. In the west it accompanied the migrations of Atlantic- and Mande-speaking peoples who brought their African rice with them. Farther east, yams accompanied the expansion of other Niger-Congo speakers, this time affiliated with the Kwa and Ijoid families. Eventually, a line that still holds today at approximately the Bandama River in the Ivory Coast came to separate distinctive rice- and yam-eating zones.

A few domesticates from the tropical forest were added to the crop inventory as supplements to the staples. Those in most widespread use include okra *(Hibiscus esculentus),* kola *(Cola sps.),* akee *(Blighia sapida),* and the melegueta pepper *(Aframomum melegueta).* Also associated with the forest are dwarf varieties of humpless short-horn cattle that are somewhat tolerant of virtually ubiquitous sleeping sickness but yield very little milk. Most likely, they are adaptations of the types represented at Tassili (Blench 1993).

Ethiopia and the Horn

In general, the Ethiopian food crop domesticates remained rather narrowly confined to their original environments. The major exception is finger millet, which spread along with the migrations of Southern Cushites that began around 4,000 years ago. A branch of the Cushitic division of the Afroasiatic group that originated in Ethiopia, these people left their highland home for present-day Kenya and Tanzania (Ehret 1979). Taking with them livestock as well, the Southern Cushites were entering virgin agricultural country, but in such few numbers that most of it remained the province of hunter-gatherers until the arrival of later agriculturists.

Some other Cushites had become livestock specialists and claimed the semidesert and desert lands surrounding the Ethiopian highlands. The most ancient are the Beja (the Blemmeys of the Egyptians), who took possession of the lands astride the Red Sea coast. When their migrations first began is unclear, but they probably date to between 4,000 and 3,000 years ago. Camels were crucial to their advance through the desert, and if the time estimates are correct, they would have been Africa's original camel herders and the likely source for the animal's introduction into Egypt. Later, camels fueled the expansions of the Afar and Somali, who occupied the arid lands stretching from Djibouti to the Tana River in Kenya.

Equatorial Africa

The first agriculturists to approach the equatorial rain forest were proto–Central Sudanic (Nilosaharan group) speakers. They did not, however, enter the forest, remaining instead in the savanna and woodland country to the north, where they could cultivate sorghums and tend herds of cattle, sheep, and goats. Getting closer were Ubangian communities whose settlements reached the northern fringes of the forest (David 1982). Early yam–oil palm cultivators located in the Cameroon highlands, they had begun an expansion around 5,000 years ago that took them eastward through the lands straddling the watershed of the Nile and Congo rivers.

It was left to yet another group of yam-cultivating Niger-Congo speakers, the Bantu, to take food-producing economies into the rain forest proper. Originating in the vicinity of the Cross River valley of present-day Nigeria, they had entered the equatorial forest by

4,000 years ago (Ehret 1982). Avid fisher folk as well as farmers, the pioneers followed the Atlantic coast and river valleys west of the immense swamp along the lower reaches of the Ubangi River before it joins the Congo. Subsistence needs kept the frontier moving until advance communities eventually reached the forest's southern end. Some people then headed east and followed northward-flowing rivers back into the forest, completing a cycle by 2,000 years ago that created a linearlike pattern of Bantu-speaking fishing–farming villages surrounded by bands of pygmoid gatherer-hunters in the deeper forest recesses (Vansina 1990).

Eastern Africa

The transition of eastern Africa from a region of gatherer-hunters to agriculturists was linked to a complex interweaving of population migrations that spanned some 3,500 or more years. As noted, peoples of Southern Cushitic linguistic background introduced finger millet–based agriculture into parts of eastern Africa. Their migrations seem to have centered on better-watered upland areas, such as the slopes of mounts Kenya and Kilimanjaro (Nurse 1982).

At about the same time, or only slightly later, Central Sudanic agriculturists with sorghum and livestock entered the interlacustrine region of present-day Uganda, and may have eventually reached as far south as the Zambezi River valley. As with the Southern Cushites, their numbers were few, and they gave way between 3,000 and 2,000 years ago to Bantu migrants who had tracked through the equatorial forest following easterly rather than southerly routes. Adding Central Sudanic grain-farming and livestock-rearing technologies to their yam-based agriculture, the Bantu were set to claim most of eastern Africa's cultivable lands as their own (Ehret 1982). By 500 years ago, they had created a wide variety of agricultural systems, ranging from intensively irrigated ones to those using land-extensive methods of shifting cultivation.

The noncultivable lands of eastern Africa, ranging from semiarid to desert, fell to various herding peoples. The north of what is now Kenya was claimed by Cushitic-speaking Somali and Oromo, who (because of the aridity) emphasized camels, while cattle-oriented Nilotes (Nilosaharan group) took possession of the richer grassland and savanna habitats of the interior plateaus.

Southern Africa

As in equatorial and eastern Africa, food-producing economies reached the southern portions of the continent in the company of migrants. Some of them were Khoe-speakers, now called Khoikhoi (formerly Hottentot). They acquired (probably from Bantu sources) sheep and maybe goats, but not crops, somewhere in the vicinity of the middle portions of the Zambezi River valley about 2,000 years ago. From here they spread southward into the semiarid range lands bordering the Kalahari, and thence into the summer rainfall country from the Orange River valley to the Cape of Good Hope, either displacing or intermingling with bands of San (formerly Bushman)-speaking hunter-gatherers (Elphick 1977).

Following the Khoikhoi, but entering different environmental zones, were various communities of Bantu. Some were related to those who had moved through the equatorial rain forest. Continuing on a southward course, they entered the vast expanses of drought-prone and soil-poor brachystegia or miombo woodlands that stretch beyond the Zambezi River. Poorly suited to yam cultivation, at the outset the migrants were forced to rely on gathering, hunting, and fishing for subsistence. But then, sometime just prior to 1,500 years ago, sorghums and millets were acquired from yet other Bantu groups that had begun moving south from eastern Africa. With these crops, much of the area could support at least land-extensive forms of shifting cultivation. Although livestock also were introduced, their roles were restricted by the widespread prevalence of sleeping sickness.

Much better habitats were encountered by the eastern stream of Bantu. One favored route led around lakes Tanganyika and Nyasa and onto the Zimbabwe plateau, and thence to the high veld of South Africa. By A.D. 500, these areas, free from sleeping sickness and comparatively well watered, had been reached by advance communities with grain-growing and livestock-herding economies, although cattle do not seem to have been important until the advent of the New Iron Age after A.D. 1,000. Yet another route followed by Bantu agriculturalists went along the coast through Mozambique and into Natal, which also seems to have been reached by around 1,500 years ago (Hall 1990).

It thus took about 6,000 years from the signs of its first appearance for agriculture to make its way to the extreme southern end of the continent. To an almost exclusive degree, the crops involved were of African origin. However, some of the more important later developments were hinged to imports, and it is to these that the discussion now turns.

Later Imports

Plantains and Bananas

The first of the later imports to have widespread agricultural repercussions in Africa south from the Sahara were plantains and bananas *(Musa sp.)*. Two routes of entry from their southeast Asian source of origin seem possible. The first could have brought them to Egypt over 2,000 years ago via trade with India; from Egypt they spread along the Nile to its headwaters in the Great Lakes region of eastern Africa. The second possibility involves Malayo-Polynesian voyages to the east coast on the way to settling Madagascar. Cuttings could have survived the long sea voyages, and therefore joined other crops, such as cocoyam *(Colocasia antiquorum)* and sugarcane *(Saccharum offici-*

narum), sometime during the second half of the first millennium A.D.

By whatever route, the adoption of bananas and plantains became crucial to the spread of agriculture through the lowland equatorial rain forest. People now had a high-yielding crop that allowed for relatively permanent villages to be established away from the river valleys and deeper into the forest proper. Bananas and plantains also played an important role in augmenting agricultural productivity throughout the moister zones of the Great Lakes region and in the uplands of eastern Africa, such as around the lower slopes of mounts Kenya and Kilimanjaro, thus helping to create some of Africa's most densely settled areas outside Egypt.

Asiatic Yams

It is possible that Asiatic yams (principally *D. alata* and *D. esculenta*) also reached Africa with the Malayo-Polynesian voyages. Their rise to prominence, however, seems mainly to have followed their importation by the Portuguese during the sixteenth century. Because of higher yields, they have largely replaced the indigenously developed varieties throughout the yam belt of western Africa and elsewhere, to the point where the latter serve more for ritual than staple-food purposes (Coursey 1976; Harris 1976).

Maize

Reports continue to circulate about the cultivation of maize having been widespread prior to the Columbian voyages, but it was only after the introduction of American varieties *(Zea maize)* that the crop became an important component of many African food systems. Although the evidence is far from definitive, it does point to the Portuguese as, once again, the carriers, and if this is true, then maize probably had many points of entry along the Atlantic and Indian Ocean coasts. Indeed, there is really no other way to explain its seemingly sudden appearance by the seventeenth century in places as far apart as the Senegal River valley, the Congo basin, the Natal coast of South Africa, and Zanzibar (Miracle 1966).

The frontiers of maize have been moving ever since, to the point where today its now numerous varieties have become the predominant staple for many people in Africa south from the Sahara. Areas where it is particularly important include the highlands of Kenya, Rwanda and Burundi, Malawi, the coastal savanna gap from eastern Ghana to Benin, the Bie Plateau of Angola, and the well-watered areas from Zambia to South Africa. The attractions of maize have been its high yields and invulnerability to bird attacks in comparison with millets and sorghums. About the only places where it does not show up among the list of important crops are in the lowland equatorial zone, the Sahel, and highland Ethiopia, and among rice growers in western Africa. Maize is Africa's most researched food crop, and the development of varieties that are more drought resistant and that will grow in cooler highland climatic conditions has added to its attractions.

Cassava

There is little doubt about cassava *(Manihot utilissima* or *M. esculenta)* having been brought to Africa by the Portuguese. They found it growing in Brazil and, as with maize, seem to have taken it with them to many of their African landfalls. Initially, the most important of these was the Kongo Kingdom, located south from the Congo River below Malebo Pool. Cassava gained favor here early in the sixteenth century and rather quickly spread both north and south around the equatorial rain forest, apparently being welcomed as a high-yielding alternative to yams and sorghums (Jones 1959). As the slave trade intensified across this region, cassava became even more important. Harvesting could await the disappearance of the turbulence brought by slavers, and cassava flour could be made into cakes for storage and long-distance travel. As the demand grew, some peoples responded by forming their own slave-run plantations to grow cassava. Ironically, its appearance in central Africa probably kept populations growing sufficiently so that the slave trade and slavery could continue (Miller 1989).

A link to slavery may also partially explain cassava's importance in and around the Niger delta, although much of its spread there, and elsewhere in coastal West Africa, seems to have occurred after 1800 (Jones 1959). Commercial agriculture had begun to expand across the region from Ghana to Nigeria, and cassava's adoption may have been a response to a decline in other food crops as more land was given over to cacao *(Theobroma cacao),* another import from the Americas, and oil palm cultivation.

Cassava's tolerance to a wide range of soil types and moisture conditions, along with the ability to remain unharvested after ripening, made it a favorite of many colonial agricultural officials. They viewed cassava as an ideal famine-prevention food, and thus encouraged plantings in such areas as the upper Guinea Coast and interior eastern Africa where it had not found an earlier enthusiastic reception. Today cassava is tropical Africa's most widely planted crop, and the region has become the world's leading producer.

Two other American crop introductions need to mentioned. One is the groundnut *(Arachis hypogaea).* Groundnuts serve both as a food and cash crop for many Africans in the subhumid and semiarid parts of the continent, with the rural economies of Senegal and northern Nigeria particularly dependent on them. The second crop introduced from the Americas is the sweet potato *(Ipomoea batatas).* Although not really a staple anywhere in Africa, it is nevertheless an important secondary food source virtually everywhere it can be grown.

Food Preparation and Eating Habits

In Africa a staple food crop is just that – the principal item in the diet, eaten most days if not virtually every day. If a grain is used, most often it will be pounded into a flour, whereas root crops frequently are grated before being boiled. In either case, the end product is a stiff porridgelike substance that is normally formed into bite-size balls. These are then eaten with a variety of stews and soups. Greens of one kind or another will almost always be one of their ingredients, and onions are increasingly common. Otherwise, the additives will depend on local availability and preferences. Meat is always desired but is infrequent. Along coasts and rivers, small amounts of fish are commonly put into stews and soups, and oils, mostly from palms and groundnuts, are in regular use. Salt is a necessity, but the use of other spices varies considerably. In general, tastes tend to be on the bland side throughout most of eastern, central, and southern Africa, while in parts of western Africa and Ethiopia, the stews are often fired with chilli peppers.

Other kinds of preparations include roasting maize ears and steaming sliced cassava, plantains, and sweet potatoes in leaf wrappers. Rice is prepared in the usual boiled manner, and to an ever-increasing extent, imported varieties are preferred because of their higher quality. Such preferences are especially true of urban dwellers, who have created a demand for imported wheat flours to make leavened breads as well. Cassava flour is also used for bread, and in Ethiopia a flat bread made from teff or wheat is the staple source of carbohydrates for people living in the highlands.

All kinds of other foods, especially gathered ones, find their ways into African diets. By far the most common are greens of one kind or another; mushrooms are also widely eaten. Termites are popular, as are various caterpillars and mollusks. These days, game meats are increasingly uncommon, and the vast majority of people will never have occasion to eat them. In fact, game meats have fallen out of favor, even when made available as a part of government game-cropping schemes. Far preferred, if affordable, are beef, mutton, and goat. Vegetarianism by choice is not part of any African cultural tradition.

Contrary to what might be expected, pastoralists, such as the Fulbe and Maasai, also eat very little meat. They rely on fresh and soured milk, along with butter, as their staples, and slaughter animals only for special ceremonial occasions or when these become old and feeble. Milk products are uncommon for most other Africans, as is indicated by the high rates of lactose intolerance that exist, especially in western and equatorial Africa (Kretchmer 1977).

The normal pattern is for one large meal to be served each day. Both morning and evening meals tend to be more like snacks and often involve leftovers. Almost everywhere, men eat separately from women and young children and are served first. Individual plates are not used; rather, each person takes from common bowls and pots.

Meals are seldom accompanied by beverages, except if these are part of feasts. The drinking of alcoholic beverages, however, is virtually ubiquitous, except among Muslims. Traditional products are all basically variations of two themes. The most widespread is the fermentation of one of the crops into something beerlike. Finger millet is the grain generally employed by many eastern and central Africans, whereas maize is popular in South Africa. Also widely used are sorghums and bananas, with the higher sugars from the latter yielding greater alcohol content. A favored practice is to add honey to the fermentation to push the alcohol level even higher. The second theme is found mainly within the equatorial zone and along the coast. Here palm trees are topped to produce a sap that is turned into palm wine, which achieves greater strength than the beers.

In recent decades, commercially distilled spirits and brewed beers have become the alcoholic drinks of choice for many people. As a consequence, alcoholism is now a serious social and health problem, especially in Africa's rapidly growing cities.

Many food avoidances exist, the most widespread of which is attached to eggs. Some peoples, particularly in Kenya, eschew eggs altogether, equating them with excrement, but more often the restriction falls on girls and reproductive-age women. Reasons stated vary from eggs causing sterility or excessive sexuality to adversely affecting fetal development (Simoons 1961). Less widespread, but of considerable cultural and historical interest, is the avoidance of fish by peoples from Ethiopia southward through Kenya to Tanzania. They are all of Cushitic linguistic affiliation or others who have been heavily influenced by them (Murdock 1959). The reasons are lost in antiquity, but may relate to the low-caste status of fisher folk in the development of Cushitic society, one in which the vast majority of people are either farmers or herders.

Diet-Related Disorders

As a whole, Africa south from the Sahara has become characterized by a worsening food-supply crisis. This is illustrated by the sequence of famines, beginning with the Sahel and Ethiopia in the early 1970s and continuing to Somalia and Mozambique at the outset of the 1990s, and by a regionwide decline in per capita food production over roughly the same period of time. Only by the importation of more and more staple foodstuffs have famines and near famines been averted elsewhere.

Both because of their episodic nature and the coverage they have received, Africa's famines are not discussed here beyond a note of the complexity of their causes. Although natural events, particularly droughts, have often been involved, these have largely been triggers setting off deeper economic and political charges that initiate the famines. Attention is focused here, however, on more chronic diet-related disorders. These include the various syndromes of protein–energy malnutrition (PEM), vitamin A deficiency, anemias, and goiter.

Protein–Energy Malnutrition

There is very little doubt that, taken together, the syndromes of protein–energy malnutrition constitute the most widespread and serious diet-related disorders in Africa south from the Sahara. From the sketchy evidence available, it does seem that pure cases of kwashiorkor are rather rare today. Apparently, all of the earlier research on it has paid off, particularly with regard to recognizing kwashiorkor in its early stages and alerting parents to take children with symptoms to clinics and hospitals (Newman 1995). The current status of the other two clinical syndromes of marasmus and marasmic kwashiorkor is less certain. Early weaning onto inadequate breastmilk substitutes and exposure to bacterial contamination are still widespread, and in fact, the kinds of poverty, especially in urban areas, that favor this combination of health threats have been growing rather than declining. Unfortunately, the available medical and survey data are inadequate to the task of making any kind of reasonable statements about comparative frequencies.

Somewhat more can be said about the several growth measurements that are used to identify mild-to-moderate forms of PEM. Stunting, for example, is widespread, with rates for children under 5 years of age running from a low 16.6 percent in the Ivory Coast, to 47.8 percent in Burundi, to 53.7 percent in Malawi (Carlson and Wardlaw 1990). One can argue about the standards used for such determinations, but what we know from other sources about food availability in such places as Burundi and Malawi would confirm that many young children are suffering from chronic malnutrition that quickly can go from mild-to-moderate to clinical when infections strike.

Vitamin A Deficiency

Vitamin A deficiencies that lead to vision impairment are far more localized than PEM. They are almost completely absent from humid tropical regions, where sources of preformed vitamin A and beta-carotene are abundant. In contrast, these can be in short supply (especially seasonally) in drier environments, and this is where the problems are concentrated. Some fairly good studies of different time periods have come from Nigeria, and they document a north-to-south incidence gradient (Nicol 1949; Oke 1972). Similarly, the dry Luapula Valley is Zambia's trouble spot, with a recent study having recorded a deficiency rate of 75 percent among preschool children (Lubinga 1989).

The symptoms of severe vitamin A deficiency run a gamut from Bitot's spots, through night blindness, to keratomalacia. When the latter stage is reached, death usually follows within a short time because of the problems of caring for the blind in physically hazardous environments. Treatment of vitamin A deficiency is inexpensive and can easily prevent the occurrence of impaired vision, but sadly, access to treatment is still wanting in poorer, more remote areas (Sommer 1982).

Anemias

Two kinds of diet-related anemias seem to afflict many African women and are especially health threatening during their reproductive years. One is the megaloblastic variety, which develops from a severe deficiency of folic acid. The primary source for folic acid is green leafy vegetables, and most women do, in fact, ingest adequate quantities of these. However, seasonal shortages can occur, especially in more arid habitats, and during times of drought, greens may be almost totally unavailable.

A more widespread anemia stems from iron deficiency, although seldom is the cause dietary. Sometimes it results from metabolic malfunctioning that inhibits iron absorption, but much more common are cases associated with parasitic infestations, notably malaria, hookworm, and roundworm (Latham 1965).

Goiter

Goiters, resulting from a dietary deficiency of iodine, can be encountered in many parts of the continent where the ancient basement geological complex predominates as the bedrock. Because it lacks iodine, so, too, do the soils and, therefore, the plants. The center of endemicity seems to be Zaire, where incidences of up to 100 percent have been recorded within some communities (DeVisscher et al. 1961). Also possibly contributing to the high rates are goitrogenous agents in widely eaten cassava and cabbage. The majority of goiters occur to young women because of the thyroid stresses resulting from menstruation, pregnancy, and lactation. Most are temporary, having little or no health impact, although several studies have found a connection between community incidences of endemic goiter and cretinism (Bastinie et al. 1962; Delange and Ermans 1971).

V.E.2 Australia and New Zealand

Australia and New Zealand are Pacific Rim countries situated on the southwestern edge of that vast ocean. But although Australia has been peopled for at least 50,000 years (some now say 70,000), and New Zealand for just over 1,000, the dominant foodways of both have been shaped over just the last 200 years – since the beginning of British settlement in Australia in 1788. The indigenous people, the Aborigine in Australia and the Maori in New Zealand, are now minorities in their own lands (Aborigines comprise less than 2 percent of Australia's population and Maori about 15 percent of New Zealand's), and the foods and beverages they consume have been markedly influenced by food and drink of British origin. Indeed, from a contemporary perspective, food and drink in Australia and New Zealand – the lands "down under" – predominantly derive from the strong British heritage.

In this chapter, the environments of Australia and New Zealand are briefly described, not only because they are notably unique but also because they were so amenable to "ecological imperialism" (Crosby 1978). The food systems of the indigenous peoples, although now vastly altered, are also outlined, but the bulk of the chapter is devoted to the processes that produced contemporary patterns of food and drink consumption among both the immigrants and the indigenous peoples.

Natural Environments

Australia

Because of its transitional position between the low and middle latitudes, about 40 percent of Australia is located within the tropics. However, the southwestern and southeastern littoral zones lie within the midlatitudes and have temperature and rainfall regimes somewhat similar to those of western and Mediterranean Europe and, consequently, have proven conducive to the naturalization of European flora and fauna. The continent is an ancient and stable one. Large parts of it have an aspect of sameness, with almost monotonous expanses of flat land and sweeping vistas (McKnight 1995), and only in the Eastern Highlands is there great topographical variety.

Climatically, two features stand out: aridity and tropicality. Central and western Australia are arid, and well over half of the continent receives less than 15 inches of rainfall a year. By contrast, northern Australia (away from the east coast) has a monsoonlike climate, which brings abundant moisture between November and March, followed by a seven- or eight-month dry season. The northeastern coast is humid and hot, but the southeast has true midlatitude conditions with adequate precipitation, although the summers are hotter than in comparable latitudes in the Northern Hemisphere. The southwest enjoys a subtropical dry-summer/wet-winter situation – a "Mediterranean-type" climate.

The flora and fauna that developed in Australia and provided the subsistence for its indigenous people are unique, primarily because of nearly 100 million years of isolation, during which the present biota evolved and diversified without interference from immigrant species. About 80 percent of Australia's 25,000 species of plants are endemic, with two genera, the eucalypts or "gums" (*Eucalypt* spp.) and the acacias or "wattles" (*Acacia* spp.) overwhelmingly dominant. Furthermore, much Australian flora exhibits pronounced xerophytic (drought-resistant) characteristics. Only over the last few million years has there been a limited exchange of biota between Australia and (the biotically rich) Southeast Asia. In the past 200 years, the introduction of new species, mostly of European origin, has dramatically impacted the landscapes, especially of temperate Australia.

Australia's assemblage of terrestrial animal life is also unique. The more familiar placental animal groups are absent, their place being taken by marsupials, the majority of which are herbivores, including the macropods (kangaroos and wallabies, rat kangaroos, wombats, phalangers, "possums," and koala). There are also a number of carnivorous marsupials ("mice," "moles," "cats," and "devils") and a group of numbats (anteaters), as well as omnivorous marsupials called bandicoots. Additionally, Australia has two monotremes (egg-laying mammals), the duck-billed platypus *(Ornithorhynchus anatinus)* and the spiny anteater *(Tachyglossus aculeatus).* Placental mammals are recent arrivals, which until the introduction of European species after 1788 were mostly rats, mice, and bats from Southeast Asia. Australia also has a wide variety of reptilian fauna, an exceedingly varied and singular avifauna, and abundant insects and arthropods but limited amphibian and freshwater fish life.

New Zealand

In contrast to Australia, New Zealand is characterized by sloping land, true midlatitude climates, and dense vegetation. It is located along the "Pacific Rim of Fire," and vulcanism is evident in the North Island; alpine mountains dominate parts of the South Island. Everywhere else, hill country and small valley plains dominate, except in the eastern part of the South Island where the Canterbury Plain, New Zealand's largest lowland, is located.

Overall, the climate can be characterized as "marine west coast," dominated by air from the oceans, especially from the west. Some parts of the east (leeward) side of major mountains are relatively dry, but in most of the country, the precipitation averages between 30 and 60 inches annually, with mountain regions receiving more. Temperatures are moderate (50° F to 80° F in summer and 30° F to 70° F in winter), again except for the mountains.

Prior to human occupation, the islands were heavily forested, with more than 75 percent of the total area covered with what the early British settlers called "bush." Much of this was actually a sort of temperate rain forest, which had evolved in relative isolation under unstable (volcanic and glacial) environmental conditions. The fauna inhabiting this environment was conspicuous by the lack of land mammals (other than a species of bat) and was dominated by bird life, a distinctive feature of which was the relatively high degree of flightlessness. The kiwi, New Zealand's national emblem, shares this characteristic, along with a variety of rails, woodhens, and other species.

The most notable nonflying birds were the two dozen species of moa – ostrichlike birds, now extinct, some of which were very large. Various types of waterfowl, parrots, and innumerable "bush birds," large and small, were also present in abundance, along with some species of lizards, but there were no amphibians save for a few species of frogs. A rich marine-mammal population included fur seals, sea lions, leopard seals, elephant seals, dolphins, and many species of whales, as well as an abundance of fish and mollusks.

Indigenous Food Systems

Australia

The unique and remote Australian environment provided a home for the Australian Aborigines, who comprised a distinctive society of hunters, gatherers, and fishers. Arriving from what is now Southeast Asia possibly as many as 70,000 years ago, over the subsequent millennia they spread across and occupied all parts of the continent at varying densities, depending on local environmental conditions. Mostly they led a seminomadic existence, but their movements were not helter-skelter (Davis and Prescott 1992). It is thought that there may have been from 500 to 600 tribes or tribelets, with each recognizing the territoriality of others.

Within each tribe there were usually several clans of a few dozen people each. Although there is no evidence of formal agriculture, the gathering and distribution of seed, the management of natural vegetation by fire, and the rudimentary cultivation of yams (*Dioscorea* spp.) in certain areas indicate some degree of plant husbandry. There were no domesticated animals except the dog. The total population of Aborigines at the time of European contact is not known. The most widely accepted estimate is about 300,000, although some authorities place the number as high as 1.5 million (McKnight 1995). Geographic distribution, density, and mobility were closely related to the availability of food, water, and other resources (Berndt and Berndt 1988).

Most Aboriginal languages had special terms for vegetable foods, as distinct from terms for the flesh of animals, birds, reptiles, fish, mollusks, and insects. Generally, foods from vegetable sources fell into three main categories: roots and tubers, fruits, and seeds (although some plants produced more than one type of food item, and, in a few instances, it was the pith of the plant that was consumed). There were considerable differences in the importance of various types of plant foods between ecological zones. In the vast desert and semiarid areas, Aborigines utilized between 60 and 100 edible species of plants (Latz and Griffin 1978; Peterson 1978). However, this extensive list could be reduced to about a dozen staples. (A staple is a plant species that singly or in combination with another accounts for at least 50 percent of the diet during the period it is consumed.)

Principal staples were the roots of various species of *Ipomoea* (convolvulus), *Vigna lancelota,* and *Portulaca oleracea* ("pigweed"); the fruits of *Solanum* (for example, the "bush tomato"), *Ficus,* and *Santalum* (the "quandong") species; and *Leichardtia australis* (the "bush banana"). Other principal staples were the seeds of various *Acacia* species ("wattles"); grasses, such as those of the genus *Panicum;* and herbs, such as *Rhyncharrhena linearis* (the "bush bean") (Peterson 1978; Palmer and Brady 1991). It is estimated that plants provided some 70 to 80 percent of the diet (in terms of bulk) consumed by desert Aborigines (Gould 1969).

In the more humid southeast, about 140 species of plants were eaten (Flood 1980). These included the roots and tubers of various lilies (such as *Aguillaria minus,* the "vanilla lily"); at least 20 species of terrestrial orchids (for example, *Gastrodia sesamoides,* the "potato orchid"); bulrushes *(Typha orientalis* and *Typha domingensis);* and the bracken fern *(Pteridium esculentum).* Also consumed were the roots and tubers of various dandelionlike plants, including the "yam daisy" *(Micoseris scapigera),* the "native carrot" *(Geranium solanderi),* and the "Australian carrot" *(Daucus glochidiatus).* Seasonal fruits, such as the "native cherry" *(Exocarpus cuppressiformis),* "native raspberries" *(Rubus triphyllus),* currants *(Coprosma quadrifida),* and the "kangaroo apple" *(Solanum* *linearifolium),* entered the diet. The pith of tree ferns (*Dicksonia antarctica* and *Cyathea* spp.) was also consumed. More plant foods were eaten in the coastal regions of the southeast than in the highlands, but on the plains of the eastern interior, grass seed, especially the native millet *(Panicum decompositum),* was the staple plant food.

In the tropical north, there were also a large number of plant foods. One study has identified 47 species of root crops and 49 of fruit or seed used by Aborigines (Crawford 1982), although the staples varied between coastal regions and river valleys and the interior (Turner 1974; Levitt 1981). Among the roots and tubers eaten, various yam species (for example, *Dioscorea transversa,* the "long yam," and *Dioscorea bulbifera,* the "round yam") were the most important, but the tubers of various convolvulus species (*Ipomoea* spp.), lilies (for example, the "blue water lily," *Nymphaea gigantica*), the "swamp fern" *(Blechnum indicum),* and the "wild kapok" *(Cochlospermum gregorii)* were also consumed.

Seeds from numerous trees, including various *Acacia* species (Levitt 1981), as well as seeds from some species of *Sorghum* were consumed in the north, along with a large number of nuts – from the Zamia palm *(Cycas angulata),* the Pandanus *(Pandanus spiralis),* and the "nut tree" *(Terminalia grandiflora).* Fruits included several species of *Ficus,* the "jungle plum" *(Buchaninia arborescens),* the "native gooseberry" *(Physalis minima),* the "big green plum" *(Planchonella pohlmaniana),* the red "wild apple" *(Syzygium suborbiculare),* and the "wild prune" *(Pouteria sericea)* (Davis and Prescott 1992).

Considerable variation also existed in the types of flesh eaten. Snakes and lizards, especially two species of "monitor" lizard or goanna *(Varunus varius* and *Varunus giganteus),* were commonly consumed, as were a number of small marsupials and rodents (Peterson 1978; Flood 1980). In wetter areas, "possums" (phalangers) were frequently a part of the diet (either the "brushtail possum," *Trichosurus vulpecula,* or the "mountain possum," *Trichosurus canicus*), along with various gliders (for example, the "squirrel glider," *Petaurus norfolcensis,* and the "greater glider," *Schoinobates volans*), the koala *(Phascolarctos cinereus),* and various types of "flying foxes" (*Pteropus* spp.).

Bandicoots (*Perameles* spp.) and other marsupial "rats" and "mice" (for example, *Antechinus* spp. and *Sminthopsis* spp.) served as food, as did rodents of various types (for example, the "broad-toothed rat," *Mastocomys fuscus,* and the "bush rat," *Rattus fuscipes*). In addition, larger marsupials contributed to the human diet, although in arid and semiarid areas they were relatively limited, and even in wetter areas were problematic to hunt, requiring cooperative ventures that involved considerable numbers of hunters. The latter generally used fire (Peterson 1978), but in the New England tablelands, large permanent nets were employed (Flood 1980). The red kangaroo *(Macropus rufus),* the "Euro" *(Macropus robustus),* and the gray kangaroo *(Macropus fuliginosus),* as well as numerous wallaby species (for example, the "red-necked wallaby," *Macropus rufogriseus*) were all hunted. In the wetter areas, wombats *(Vombatus ursinus)* became important dietary items.

It has been estimated that in coastal and riverine regions, fish, shellfish, and crustaceans made up perhaps as much as 40 percent of the diet (Flood 1980). In the southeast, fish – caught by line, net, trap, or spear – included mullet (mainly *Mugil cephalus*), snapper *(Chrysophrys auratus* and *Trachichthodes affinus),* and various types of wrasses (for example, parrot fish and red cod, *Pseudolabrus* spp.). Such shellfish as the pipi *(Paphies australis),* cockles *(Chione stutchburyi),* mussels *(Perna canaliculus* and *Mytilus edulis),* the catseye *(Lunella smaragda),* and the mudsnail *(Amphibda crenata)* were very important food items, as were crayfish (*Jassus* spp.), gathered along rocky shorelines.

In the coastal areas of the tropical north, a diversity of marine resources was enjoyed. Green sea turtles *(Chelonia mydas)* were hunted and their eggs gathered. The dugong *(Dugong dugon),* a herbivorous marine mammal, was another valuable source of animal protein, especially in the Torres Strait region and off the coasts of Arnhem Land (Turner 1974). There is no question, however, that in the coastal regions of the north, where they were obtainable throughout the year, fish were the staple food.

Other marine resources that made important contributions to the diet in some areas included freshwater fish, shellfish, and crustaceans. In the watershed of the Murray-Murrumbidgee system (Flood 1980), the Murray cod *(Maccullochella macquariensis),* the "trout cod" *(Maccullochella mitchelli),* the silver perch *(Bidyanus bidyanus),* crayfish, mussels, and the platypus *(Ornithorhynchus anatinus)* were captured and consumed. In the far north during the monsoon, the barramundi *(Lates calcarifer),* a large, tasty fish, was hunted with spears across the inundated floodplains (Davis and Prescott 1992). Rivers flowing to the Tasman Sea throughout the southeast of the continent contained eels (*Anguilla* spp.).

Birds constituted an important source of food, although in very dry areas they were probably only substantial food items following the infrequent heavy rains (Frith 1978). On the more humid plains of the north, east, and southwest, emu *(Dromiceius novaehollandie)* were plentiful and available throughout the year, but they were difficult to catch (Flood 1980). Ducks, such as the "mountain duck" – *Tadorna tadornoides* – of the southeast, were abundant in swamps and lagoons and along the rivers, as were black swans *(Cygnis atratus)* and a variety of other waterfowl. Wild turkeys (the Australian bustard, *Eupodotis australis*) were another excellent source of food on the open plains, and smaller birds were probably an important source of protein because they could be hit with stones relatively easily (Flood 1980). Eggs also provided food and, in some places, were seasonally very important. For example, in the Daly River country, just south of Darwin, the goose-egg season could be counted on for an abundant harvest (Berndt and Berndt 1988).

Valuable contributions to the diet were made by various types of insects, with perhaps the most widely utilized the larvae of various moths, collectively called "witchetty grubs" (Peterson 1978). Among these, probably the most important were the larvae of the Cossidae family, especially *Xyleutes lencomochla,* which feed on the roots of certain acacias. In the southeast, especially in the granite peaks of the highlands, another moth, the bogong *(Agrotis infusa),* was important. During the spring and early summer, these moths migrated to the mountains, where they occupied fissures, clefts, and caves in summit rocks and could be collected and eaten in vast numbers (Flood 1980).

The primary beverage of the Aborigines appears to have been water. It does not seem that there were any intoxicating beverages, although in some areas, plants (for example, wild honeysuckle and pandanus fruit), honey, and such insects as crushed green ants were mixed with water (Massola 1971). In the more tropical parts of the continent, the Aborigines chewed the leaves of three plants *(Nicotiana gossei, Nicotiana excelsior,* and *Duboisia hopwoodi)* (Berndt and Berndt 1988), and on the north coast, tobacco was introduced by Makassan traders sometime after the sixteenth century (Berndt and Berndt 1988).

The seasonal distribution of edible plants and the movements of fish and animals imposed seasonal patterns of diet, as well as patterns of movement over territories (Crawford 1982). Any single Aborigine territory encompassed a variety of ecological systems and, thus, was capable of producing a variety of food supplies throughout the year.

In general, during the dry season (the winter in the north and the summer in the southwest), the Aborigines lived in the river valleys, and those in the Kimberleys, for example, started exploiting the first of the roots reaching maturity when the rains ceased around April or May (Crawford 1982). By June and July, they were digging up root plants in the alluvium along the banks of creeks and rivers, and at this time, they began burning spinifex and cane-grass to stimulate the regrowth that attracted kangaroos. Water lily tubers were harvested in August and September when water levels were low, and as the weather became hotter, ephemeral pools were poisoned for fish.

When the rains came in December, the camps were moved onto higher ground, although fruits and seeds were still gathered in the valleys. In the rich coastal areas of the southeast, seasonal movement was less than that elsewhere, but it did involve getting food from the bush during the winter and from the rivers and coasts during the summer (McBryde 1974). People in the highlands and tablelands had a more nomadic existence, moving away from the higher land in the winter. Tribal territories were generally much smaller in the humid areas than in semiarid and desert areas.

Apart from knowing the right season, the right times for certain foods, and the right places to find them, obtaining them involved the use of implements and tools (Berndt and Berndt 1988). For plant foods, gathered almost exclusively by women, the most important tool was the digging stick. Men knew how to interpret the spoors of various creatures and to decoy animals and birds, and they had to be adept at spear throwing. Fire was commonly used in both hunting and food gathering (Latz and Griffin 1978). People were conscious of the abundance of food plants after burning but attributed this phenomenon to associated ceremonies performed to increase rain and food. The effect of frequent burning was to produce a series of small patches – at different stages of recovery from fire – that sustained different plant and animal communities.

Culinary practices were fairly rudimentary. Some fruits and tubers required no preparation and were usually eaten when and where they were found. Most roots, however, were cooked for some minutes in hot ashes or sand. The more fibrous roots were pulverized, and bitter or poisonous tubers were sliced, soaked, and baked, often several times (Crawford 1982). Grass seed was crushed in a stone mortar and mixed with water, with the resultant "dough" baked in hot ashes (Massola 1971). Small animals were cooked in hot ashes, and larger ones in earth ovens. Sometimes foods were mixed to improve their flavors and to make them more palatable; additives included gums from acacia trees, water sweetened with honey, and crushed green ants (Crawford 1982).

New Zealand

The first humans to settle in New Zealand (who came to be called Maori in the early nineteenth century) were Polynesians who arrived between 1,000 and 2,000 years ago (Davidson 1984). The precise dates are unknown, but there is no hard evidence of settlement before A.D. 800, and recently, dates of A.D. 1000 to 1200 have been suggested (Anderson 1989). Like the eastern Polynesian societies from whence they came, Maori obtained their food by gardening, raising domestic animals, hunting (particularly fowling), fishing and shellfish gathering, and gathering uncultivated and semicultivated plants (see Nancy Davis Lewis, chapter V.E.3.). However, in this temperate, midlatitude land, gardening (as practiced elsewhere in Polynesia) was at best marginal and at worst impossible. Indeed, there is now considerable evidence to suggest that even in regions most amenable to horticulture, gardens may have contributed only about 50 percent of the means of subsistence (Jones 1995).

Thus, the food quest in some communities can truly be described as "hunting-and-gathering."

Two aspects of Maori foraging and farming have dominated discussions of prehistoric subsistence (Davidson 1984). Hunting for *moa* has captured both popular and scientific interest for more than a century. But more recently, scholars have been equally impressed by the Maori achievement of adapting the sweet potato or kumara *(Ipomoea batatas)* to an annual cycle in a temperate climate. Moreover, it has been recognized that Maori moa hunting was merely one aspect of more general hunting activities, and that the use of other plants, particularly the bracken-fern root, or *aruhe,* also constituted very important adaptations in some areas (Young 1992).

Of the range of tropical crops that the Polynesian settlers must have tried to introduce, only six species survived until early European times: the sweet potato, taro *(Colocasia esculenta),* yam or *uhi (Dioscorea alata* and *Dioscorea esculenta),* the "bottle gourd" or *hue (Lagenaria siceraria),* the "paper mulberry" or *aute (Broussonetia papyrifera),* and a species of "cabbage tree" or *ti (Cordyline terminalis).* In 1769, Captain James Cook and his companions identified all six, but soon thereafter the yam and the paper mulberry seem to have died out (Davidson 1984).

The three main cultivated food plants were sweet potatoes, taro, and the bottle gourd, of which sweet potatoes were by far the most important. Indeed, the whole question of the introduction of horticulture in New Zealand has been bedeviled by controversy, which has centered on the sweet potato, because to grow it in New Zealand required both its adaptation to new climatic conditions and the protection of the plant and its fruits from extremes of temperature and heavy winter rains. The Maori developed an array of pits in which to store tubers – a departure from methods used elsewhere in Polynesia, where the plants grew perennially and were planted from shoots, and the tubers remained in the ground until required. Exactly how the sweet potato – an American plant – reached New Zealand (and the rest of Oceania, for that matter), let alone how its cultivation and storage came to be, remains a subject of speculation. We do know that by the twelfth century, sweet potato cultivation seems to have expanded from the northern part of the North Island into the southern part and, soon thereafter, into the northern South Island.

The species of cabbage tree, *Cordyline terminalis,* was brought to New Zealand from the tropics, but other cabbage trees *(Cordyline pumilio, Cordyline australis,* and *Cordyline indivisa)* are natives and were also exploited for food. The white inner trunk of young trees and the fleshy taproot were both used. Roots, often a meter in length, were split in two and cooked in an earth oven, and the trunks were prepared in the same manner (Young 1992).

Like cabbage trees, the *karaka (Corynocarpus laevigatus)* was also "semicultivated," yielding bountiful crops of plum-size, oval berries that turned orange when ripe. The outer flesh of this fruit is tasty, but the bulk of the food value is in the kernel, which is highly poisonous if eaten raw. Ripe berries were gathered from the ground and trod upon with bare feet to work off the outer flesh (Burton 1982). Next, the kernels were steamed in an earth oven for 24 hours, steeped in running water for a lengthy period to extract the bitter alkaloid poison, then preserved by drying in the sun; subsequently, they were stored in baskets.

Between the gardens and the bush lay areas where the bracken fern *(Pteridium aquilinum* var. *esculentum)* grew. The tips of the new fronds can be eaten raw or boiled, but the roots (*aruhe* in Maori) were the major parts of the plant that were consumed. This fern was usually dug up in the spring, at a time when the roots are about an inch thick and break crisply to reveal a white interior with a few black fibers. They were dried on shaded platforms by the wind, then roasted, scraped, the inner flesh pounded, and baked into small loaves.

Truly "wild" foods were secured from the forest. There are at least 190 edible native plants found in New Zealand (Crowe 1997), and Maori used most of them. A variety of roots were utilized, including those from two species of bindweed (*Calystegia* spp.); terrestrial orchid tubers (examples include those of the "potato orchid," *Gastrodia cunninghamii,* the "onion orchid," *Microtes unifolia,* and the "sun orchid," *Thelymitra longifolia);* the roots of the bulrush or *raupo (Typha orientalis);* and the rock lily *(Arthropodium cirratum).*

Shoots and leaves from a wide range of other species were used as greens. Important among these were the young fronds of a number of ferns, such as the curling buds of the hen-and-chicken fern, *Asplenium bulbiferum* (which taste like asparagus) and especially the "sow thistle" or *puha (Sonchus asper).* An introduced species, *Sonchus oleraceus,* is still eaten today. Like the pith of the cabbage tree, that of the black tree fern of the forest *(Cyathea medullus)* was baked for several hours on hot embers, then peeled and eaten, or, alternately, steamed in an earth oven, sliced, and dried on sticks.

The berries of numerous trees were consumed, but those of the *hinau (Elaeocarpus denatus),* the *tawa (Beilschmiedia tawa),* and the *tutu* (*Coriaria* spp.) underwent elaborate processing. *Hinau* berries, for example, were pounded and sifted to remove the hard kernels, and the meal was then kneaded into a paste and formed into dark brown, oily cakes that were cooked and could be stored. A somewhat simpler procedure subjected the kernels of *tawa* berries to roasting in hot ashes or steaming in an earth oven. Perhaps *tutu* berries underwent the most complex processing. The only part of these that was not deadly poisonous was the purple juice of the sepals enclosing the fruits. That juice was first sieved, with any vestiges of seeds, stalks, or leaves discarded, after which it was permitted to set until it became a relish, or it was boiled with the pith of tree fern or with pieces of bull kelp *(Durvillea antarctica)* to form jellies.

A large number of other trees supplied insignificant amounts of small berries, but these were not staple foods. They were often called "children's food," although many were regarded as delicacies. Sweeteners also were obtained from the bush, mainly from the nectar of flowers and from certain vines, such as the *rata (Metrosideros fulgens).* A very important food item in some areas was the pollen of the *raupo (Typha orientalis),* which was dried, stripped from the stems, sifted, mixed with water, then made into loaves and steamed.

Of the Polynesian domestic animals (the pig, *Sus scrofa,* the chicken, *Gallus gallus,* and the dog, *Canis canis*) described by Nancy David Lewis (chapter V.E.3.), only the dog seems to have survived the journey to New Zealand. Dogs were kept as food animals as well as for hunting birds, and their dietary importance varied from place to place. They were probably seldom a major source of protein but always a steady and reliable one (Davidson 1984). In addition, the small Polynesian rat *(Rattus exulans)* accompanied humans to New Zealand, and although it can hardly be viewed as a domesticated animal, it was a scavenger around settlements and a fruit-eating forest dweller that was esteemed as a delicacy. "Rat runs," where snares were laid, were so valuable that they were virtually "owned" by families, or by individuals.

There were also numerous hunted animals, particularly the fur seal *(Arctocephalus forsteri),* and a wide variety of birds to capture, including the large flightless moa, already mentioned. The importance of the fur seal in the pre-European diet has only recently been appreciated. When Polynesians first arrived, the fur seals bred prodigiously, and as one seal represents an enormous amount of meat, they were probably as important in the diet as moa. They were gradually reduced in number and driven from their northern breeding grounds before the arrival of the Europeans, but they remained important in the south. Other marine mammals, such as sea lions, leopard and elephant seals, dolphins, and whales, were eaten when they were occasionally captured or, in the case of whales, washed up on beaches.

Although moa may not have dominated the early human diet in New Zealand as once thought, they were an important food item everywhere. While the dates of the final disappearance of moa from different parts of the country are not established, the birds seem to have survived in some localities until about the fifteenth century. Apart from moa, the most important birds eaten were shags, penguins (especially the Little Blue), ducks (particularly the Grey, *Anas gibberifrons,* and the Paradise, *Tadorna variegata*), the sooty shearwater (the "mutton bird" of later times), and various rails.

A variety of "bush" birds were eaten as well. These included the *kaka (Nestor meridonalis),* the pigeon *(Hemiphaga novaeseelandiae),* the *tui (Prosthermadera novaeseelandiae),* the *kiwi* (*Apteryx* spp.), the *kakapo (Strigops habroptilus),* parakeets (*Cyanoramphus* spp.), wattled birds, albatrosses, mollyhawks, and various gulls.

Birds were captured or killed with nets, spears, and snares, and by hand collection of the young. Bush birds were most commonly snared and speared in the autumn and early winter when berries were ripe or when nectar was in the flowers early in the summer. Bird carcasses were preserved in fat in airtight containers made from either gourds or bull kelp (Belich 1996).

Shellfish formed a very important item of Maori diet, especially by the eighteenth century and in the northern part of the country, where the most productive shellfish beds were located (Davidson 1984). Shellfish gathering was largely women's work, as was the gathering of crabs, sea urchins, and *kina.* In contrast, the catching of fin fish was largely done by men (Young 1992). Hook-and-line fishing, as well as various types of nets and traps, were used to catch snapper, red cod, barracouta, trevally, yellow-eyed mullet, and various wrasses. Many other fish were also caught and consumed, but there was considerable regional variation in the most important species. In the north, snapper dominated, but in the south it was barracouta and red cod. A considerable quantity of the fish caught was baked and hung from poles and racks to dry for future use. Seaweed, especially a type called *karenga (Porphyra columbina),* was also consumed, as was bull kelp (*Durvillaea antarctica,* which served additionally to make storage containers for other foods) and sea lettuce *(Ulva lactuca).*

Inland dwellers utilized small freshwater fish, such as the *kokopu* (a native trout), grayling, postlarval young trout returning upstream (known as *inanga* or whitebait), and a species of lamprey. Freshwater crayfish and mussels were consumed, but the most important freshwater creatures were eels, taken in basketwork traps. In some locations, elaborate weirs were constructed to channel eels during their migrations.

Although methods of preserving and preparing food have been mentioned, the latter deserve further comment. The earth oven (a circular hole in the ground about 2 feet in diameter and about 1 foot deep), called either a *hangi* or an *umu,* was the principal method of cooking (Crowe 1997). A fire was made in the hole, and a layer of stones laid upon it; these, when heated, were removed, and the embers cleaned out. The heated stones were returned to the hole, covered with green leaves, and sprinkled with water; then more leaves were added, and food baskets or leaf-wrapped food placed on this layer. The food was covered with still more leaves, wet flax mats, old baskets, and the like, and the whole sprinkled liberally with water and covered with earth so that the steam could not escape. A family's food would normally cook in an hour or less, although larger amounts took longer. In addition, some food was doubtless roasted in hot ashes. Another technique, stone boiling, was also in common usage. Water and food were placed in a wooden trough, and red-hot stones added to bring the water to a boil.

Finally, a comment upon cannibalism is necessary. Human flesh did constitute part of the diet (at least of eighteenth-century males) (Davidson 1984), but the practice seems to have been a form of revenge *(utu),* desecrating the victims beyond the grave by turning them into cooked food (Belich 1996). Although it fascinated and revolted early European observers, the preponderant evidence indicates that those cannibalized were enemies captured or killed in war, and cannibalism was primarily an ultimate way of subjugating adversaries (Hanson and Hanson 1983).

By way of summary then, broadly speaking, New Zealand in the eighteenth century was divided into three areas in terms of the mix of foods consumed (Cumberland 1949; Lewthwaite 1949). In the northern area, horticulture was most successful, and the many harbors and estuaries contained rich fish and shellfish resources. Along the coasts of the southern North Island and northern South Island, and in the interior of the North Island, horticulture was more marginal, and hunting and gathering much more significant. Apart from the northern fringe, people in the South Island depended on hunting, fishing, and the gathering of wild plants.

The period between A.D. 1350 and 1600 was one of transition. The early settlers had exploited the premium game animals, such as moa and seals, to the point of exhaustion, and this led people to move into areas suitable for gardening, particularly in the north; it also resulted in an increased reliance on fishing and gathering throughout the islands. Large-scale marine fishing seems to have increased in importance after 1600, but the hunting of smaller birds and the trapping of eels were also significant. Gardening certainly dominated in the north, but elsewhere the "semicultivated" plants also grew in importance in the diet.

After European contact, the Maori were quick to adopt a variety of European plants, in part to vary the diet in those areas where traditional horticulture had been practiced, and in part to create a new dimension in economics where traditional horticulture had been impossible. More vigorous varieties of sweet potatoes and taro were introduced, as was the white potato *(Solanum),* which probably dates from the early 1770s. Because it was easier to grow than the sweet potato and provided a higher yield, it rapidly gained popularity everywhere (Burton 1982; Belich 1996). Less popular European vegetables introduced in the eighteenth century were carrots, pumpkins, cabbages, turnips, and parsnips (Burton 1982) – although fruit trees, especially peaches, were welcomed. Maize was the first cereal to gain acceptance; wheat was adopted only during the 1840s and 1850s.

Of the European animals, the pig – well established and running wild by the early nineteenth century – was the earliest and most successful introduction. No other animal in New Zealand yielded such a large quantity of meat, and pork became an important source of protein. In fact, pork and white potatoes joined native *puha* (sow thistle) and sweet potatoes, foods from the sea, and birds from the forest as the Maori diet in the early decades of the nineteenth century. At first, all of these new introductions may have contributed to an improvement in nutrition, but once Maori began selling land and losing access to the resources of the bush and water, the quality of the diet diminished (Pool 1991).

From Colonies to Nations

The British Heritage

Although numerous Dutch, Portuguese, French, Spanish, and British explorers had touched the shores of Australia and New Zealand from the late sixteenth century onward, it was only in the late eighteenth century that European colonization of these lands commenced. The 1769 voyage of Captain Cook initiated this process, and the establishment by the British of a penal colony at Botany Bay in 1788 (soon moved to Sydney Harbour) marked the beginning of their (since then) permanent – and largely unchallenged – presence in these southern lands.

Several other penal colonies and one free-settler colony (South Australia) were established by 1840, but in the early years it was Sydney that dominated British affairs in the South Pacific. Among other things, Sydney was the base from which New Zealand's resources – enumerated as flax, timber, whales, seals, sex, and souls by James Belich (1996) – were exploited, and it was not until after 1840 that the direct settlement of New Zealand proceeded. Even then, Australian influences remained strong, especially with regard to food and beverage habits.

The free settlers (both working- and middle-to-upper class) who went to Australia and New Zealand after 1840 were from very similar socioeconomic backgrounds, and not surprisingly, the economies of the two countries developed in very similar ways. Australia was a little more Irish (and Catholic) than New Zealand because in Australia's formative years, more than one-third of the settlers (both convicts and assisted migrants) were from Ireland. In New Zealand, by contrast, approximately one-quarter of the settlers were Scots, and only 19 percent were Irish. Nonetheless, according to Michael Symons (1982), the Irish influence on antipodean food included a strong preference for potatoes, the method of cooking them (boiling in a cauldron), and a liking for strong drink consumed away from home at pubs.

English settlers comprised barely a half of those arriving in the colonies, and the overall mixed British – in contrast to purely English – character of the population also had considerable influence on eating and drinking in the region. Indeed, the food and beverage habits carried to Australia, and later to New Zealand, were basically those of Britain's burgeoning urban underclass: potatoes, bread, and tea, with a little sugar, milk, and occasionally bacon (see Colin Spencer, chapter V.C.4.).

On the other hand, some of the assisted migrants, from the working and lower-to-middle classes, were from rural backgrounds and accustomed to a bit more diversity in their diets (potatoes, bread, cheese, butter, bacon, milk, tea, sugar, peas, turnips, and a little meat). Moreover, the officers and officials of the Australian penal colonies and, later, the wealthier settlers in both Australia and New Zealand brought with them the food habits of a middle class, sometimes with upper-class aspirations. Colin Spencer (chapter V.C.4.) describes a late-eighteenth-century middle-class meal in England as consisting of three boiled chickens, a haunch of venison, a ham, flour-and-suet pudding, and beans, followed by gooseberries and apricots. As a rule, large amounts of meat were consumed by those who could afford it, and such vegetables as cabbages, carrots, spinach, Brussels sprouts, and turnips were common. Beer and ale were the most popular drinks until distilled spirits, such as gin and crude rums, took over during the eighteenth century.

Pastoral Economies

In both Australia and New Zealand, the early years of settlement were characterized by a failure to establish successful farms and achieve self-reliance in food production. The area around Sydney was poor farming country, and in the early nineteenth century, sheep farming for wool production became the lifeblood of Australia. Sheep reached New Zealand a bit later (1833), pastoralism expanded in the 1840s, and by the late 1850s, wool was also central to the New Zealand economy.

In Australia, a lasting dependence upon imported foodstuffs developed. New Zealand also depended on imports, but in addition, such settlements as Auckland, Wellington, New Plymouth, and Nelson came to rely on a flourishing Maori agriculture for their supplies of potatoes, maize, onions, cabbages, peaches, sweet potatoes, pumpkins, grapes, melons, apples, and quinces, as well as flour (milled in Maori mills), fish, chickens, geese, turkeys, and goats (Belich 1996). It was only in the late 1850s that settlers began to produce much of their own food and the role of the Maori as food providers began to decline.

The last half of the nineteenth century brought stunning transformations to Australia and New Zealand. The gold rushes that began in both countries during the 1850s precipitated rapid social and economic changes, including the growth of urban areas, so that by 1900, these areas encompassed about 50 percent of the population (Symons 1982). In addition, railway networks opened up areas for the production of food of all types, not only for local consumption but also for export. After the 1870s, and especially after the inauguration of refrigerated shipping in 1882, both Australia and New Zealand became producers of meat (mutton, lamb, and beef), dairy products, and later fruit, for the British market. By the late nineteenth century, livestock ranching and the growing of both temperate and tropical cereals, fruits, and vegetables were all well established in areas suited to them, and in Australia, irrigated farming was developing along the Murray-Murrumbidgee river system. In well-watered, temperate New Zealand, the native vegetation was largely replaced by exotic pasture grasses to feed the introduced animals (Crosby 1978), and in southeastern Australia and along the northeastern coast (where the growing of sugar and tropical fruits came to dominate), the landscapes were transformed as well.

One outcome of the success of pastoralism was that Australia and New Zealand became nations of meat eaters. Up through the 1870s, there was no overseas market for meat, which, as a consequence, was inexpensive relative to people's incomes (Burton 1982). Meat in large amounts was eaten at every meal: beefsteaks or mutton chops at breakfast, cold beef at luncheon, and roast or boiled beef or mutton at dinner (Symons 1982; Walker and Roberts 1988).

"Rations" and "Crew Culture"

Convicts (under sentence of "transportation" to Australia) along with their guards, working-class settlers bound for New Zealand, and assisted migrants to both countries (not to mention the crews of the ships carrying them all) were all provided with "rations." The voyage from the British Isles was a long one, with three to six months the norm (the "First Fleet" to Australia in 1787 and 1788 took eight-and-a-half months), and although officers and cabin passengers enjoyed a satisfactory diet, the rations for the rest – which were not satisfactory – remained remarkably the same for more than 70 years.

By way of illustration, the weekly rations for each of the Royal Marines aboard during the First Fleet's voyage to Botany Bay were 7 pounds of bread, 2 pounds of salt pork, 4 pounds of salt beef, 2 pounds of peas, 3 pounds of oatmeal, 6 ounces of butter, three-quarters of a pound of cheese, and a half-pint of vinegar, along with 3 quarts of water a day (Symons 1982); the convicts' rations were two-thirds those of the marines. More than a half-century later, during the 1840s, New Zealand Company settlers were provided with 3.5 pounds of salt meat and 5.25 pounds of biscuit weekly, supplemented with rice, flour, oatmeal, dried peas, dried potatoes, raisins, butter, sugar, coffee, and tea.

Nor did the issuance of rations necessarily end when one stepped ashore. In Australia, the convicts and guards from the First Fleet had to subsist on rations for nearly three years, because agriculture had not yet developed (Walker and Roberts 1988). In the early settlements in New Zealand, ordinary migrants lived on New Zealand Company rations so long as the Company's money lasted (Belich 1996). But it was sheep farming that firmly entrenched the "ration mentality" in Australian and New Zealand food culture.

Sheep grazing required complements of shepherds as well as gangs to shear the sheep, usually made up of itinerant males, who were the founders of many working-class traditions in both countries. Shepherds were partially paid in rations; handed out on Saturday nights and supplemented with spirits and a paycheck, this food eventually earned the name "Ten, Ten, Two, and a Quarter" because it usually included 10 pounds of flour, 10 pounds of meat, 2 pounds of sugar, a quarter-pound of tea, and salt (Symons 1982).

"Ten, Ten, Two, and a Quarter" was the monotonous diet of the rural workforce until well into the twentieth century, and it was very characteristic of the diet of "crews" of coastal seamen, soldiers, sawyers, millworkers, construction workers, road and railway builders, miners, gum diggers, and farmhands. The "crew culture" was a factor in quite a few industries, and despite the many different kinds of work, involved a number of common characteristics: The work was dangerous; the crews lived in rough conditions; they used similar slang; most members were single; most spent their money on binges; and most ate a ration-style diet.

Basically, then, for the first half century, the majority of Australians were reared on what might be called prison rations – a practice that was transferred to New Zealand. In both countries, crew culture was reinforced by the dominant means of cooking: an open fire, whether at a campsite or in a hut or cottage. With the necessary implements – hatchet, knife, quart-pot (the "billy can"), and frying pan – the standard rations made a "damper," a fry of meats, and pots of tea. The "damper" was flour and water, cooked in the ashes of the fire; the meat was salt pork, corned beef, or freshly slaughtered mutton; the tea, although taken with plenty of sugar, usually lacked milk. Its abundance meant that meat was consumed at every meal.

More Genteel Food Habits

In contrast to the diets of the lower classes, the foodways carried to these new lands by the more genteel folk reflected the social differences of the Great Britain they had just left. Cabin passengers breakfasted on rolls, toast, cold meat, and hot chops. At luncheon, the fare was ham, tongue, beef, pickles, bread, and cheese, and in the evening they dined on preserved salmon, soup, goose, saddle of mutton, fowls, curry, ham, plum puddings, apple tarts, fruit, and nuts, all of this washed down with stout, champagne, sherry, and port (Belich 1996).

Once ashore, these elite few endeavored to maintain their notions of genteel dietary regimes. Thus, as early as 1789, it is recorded that the governor of New South Wales, the senior officers of the regiment guarding the convicts, and the senior officials of the civil administration sat down to several courses of fish, meat, and game (Clements 1986). Or again, in New Zealand of the 1850s, the meal served at an elegant dinner party might have included local fish, beef, sweet potatoes, Irish pork, Lancashire ham, and Cheshire cheese (Burton 1982). Indeed, just a few years later, an upper-class "colonial banquet" in Australia consisted of asparagus, turtle soup, trumpeter (a local fish) with butter sauce, lamb *à la poulette,* roast kangaroo, Australian blue cheese, wines, and liqueurs with coffee (Symons 1982). Later in the century, a suggested menu for a dinner party included oysters, turtle soup, baked barramundi, "beef olives" and chicken cream, roast fillet of beef, roast turkey and bread sauce, asparagus on toast, "angel food" cake, cherries in jelly, fruit, olives, and deviled almonds (Symons 1982).

Generally speaking, middle-class meals were enormous. Breakfast consisted of porridge, bacon and eggs or lamb cutlets, and perhaps curry or fish (Burton 1982). Luncheon might feature soup, a roast joint, vegetables, and cooked pudding or fruit. Four- or five-course family dinners were not uncommon, beginning with an "appetizer" of soup or fish, continuing with a roast, vegetables, and a pudding, and topped off with fruit and cheese.

Diet and Modernization

Food habits were considerably influenced by late-nineteenth-century technological developments, such as urbanization, railroads that rapidly transported products, and breakthroughs in food processing and preservation (including refrigeration). Australia and New Zealand were becoming modern, mass-consumption societies.

Giant roller mills producing refined white flour began to appear in the 1860s, and from this time on, workers, like their counterparts in Britain, began to enjoy a cornucopia of biscuits, macaroni, jams, confectionery, cordials, pickles, condiments, and snacks. These products, with their brand names, were advertised extensively and commonly sold in the emerging grocery shops. Also in the 1860s, beer (now "bottom fermented" and thus capable of longer-term storage and long-distance transportation) was brewed, and by 1900, today's major brewery corporations were already in existence.

Cooking technology also changed. At the beginning of the nineteenth century, cooking was mostly done over an open fire, where meats were roasted and stewpots suspended. One refinement at this time was the "Dutch oven" or "camp oven," a round pot with legs and a handle so that it could either stand or hang. By the middle of the nineteenth century, the "Colonial oven," a simple cast-iron box with a door in front that sat in the fireplace, had come into widespread use. Cast-iron ranges were imported beginning in the 1850s, and by the 1870s, locally manufactured stoves had entered the market (Burton 1982). This was at about the same time that the first gas stoves were introduced, permitting better control of the cooking process.

By the early twentieth century, a new array of processed and packaged foods – that supplemented the basic bread, mutton, beef, pork, milk, eggs, fruit, vegetables, and tea – were in common use. As Symons (1982) has noted, tea was the national beverage, and alcohol was not usually drunk with meals (other than by the upper classes), but rather was imbibed separately in hotel bars (Wood 1988). By the time of World War I, both Australia and New Zealand had seen the development of strong temperance movements, which proved powerful enough to persuade governments to hold referendums on the outright prohibition of alcoholic beverages, and some of the voting was very close. During the war, hotel bar hours were curtailed (Symons 1982), with closing time usually at 6:00 P.M., leading to the infamous "six o'clock swill."

During the 1920s, numerous developments further standardized eating habits. Fresh fruits and nuts were heavily promoted, as were pasteurized milk and ice cream (Symons 1982). Bread – a staple in urban areas since the time of early settlement – was baked mostly in mechanized bakeries, and to see it wrapped for sale in grocery stores was becoming common in Australia. Iceboxes were now widespread, and by the 1920s, wealthier housewives were looking forward to owning their own refrigerators.

The 1920s also saw an increased American influence on food, as sundae shops and soda fountains arrived and such big American food companies as Heinz, Kellogg, and Kraft moved in. These, along with such others as Nestlé (Switzerland) and Cadbury (England), came to dominate Australian and New Zealand eating and drinking habits. They pushed early "convenience" foods, defined as those that needed no cooking outside of the factory, which simplified breakfast and provided after-school and bedtime snacks. One product epitomizes this era. "Vegemite," made from brewery waste (spent yeast), became a runaway success after its alleged health attributes were extensively advertised during the 1930s and 1940s (Symons 1982). The post–World War II baby boom created a huge new market for "Vegemite, the family health food."

At this time, too, food companies and women's magazines promoted a more dainty cuisine aimed at the afternoon tea market: "Lamingtons" (chocolate-and-coconut-coated cubes of cake), "Anzac biscuits" (made of coconut, rolled oats, and golden syrup), and especially the "Pavlova" (made of whipped egg whites, corn flour, vinegar, sugar, a few drops of vanilla essence, and a pinch of cream of tartar, baked and topped with whipped cream and fruit – especially passionfruit and, today, kiwifruit). Pavlova, named after the famous ballerina ("It is as light as Pavlova"), is alternatively said to have originated in both Australia and New Zealand (Symons 1982).

World War II had much influence upon food and beverage habits. Rationing was introduced, which curtailed the use of sugar, tea, flour, and meat. However, the demand for more fruit and vegetables created by the presence of U.S. military forces in Australia and New Zealand brought about an increase in the acreage planted with both. Vegetables were also increasingly canned and, later, dehydrated to provide the military with preserved food. The meat-processing industry was compelled to upgrade its standards and put out new canned meats, such as *chile con carne,* luncheon meats, "Spam," and Vienna sausage (Symons 1982). Coca-Cola came with the American troops and stayed after they left.

Until the 1960s in both Australia and New Zealand, bread, milk, vegetables, groceries, and meat were all delivered. But with the advent of relatively inexpensive automobiles (first in Australia and quite a bit later in New Zealand) and universal ownership of refrigerators, supermarkets began to control food sales, all of which had the effect of furthering the trend toward nationally standardized and distributed food. Supermarket giants came to dominate food marketing with "prepackaging," bright labels, and an emphasis on low prices rather than on quality. These chain-store companies did not like dealing with small producers and growers. Because they preferred products with long shelf life, they tended to offer canned, dried, and frozen rather than fresh foods, processed by industrial-size producers who could guarantee regular supply, consistent quality, and steady prices.

By identifying gaps on the supermarket shelves, such producers brought forth a new array of foodstuffs, many of a "convenience" nature, such as "Muesli," reconstituted orange juice, teabags, pizza, frozen fruits and vegetables, and the like. Foods of this sort were marketed as "labor-saving," were usually aimed at target groups after extensive market research, and were given scientific credence through the endorsement of "home economists" and "nutrition experts" (Symons 1982). This was especially characteristic of the frozen-food industry, which included such internationally known brand names as Birdseye (owned by Unilever in Australia and New Zealand), as well as local processors (for example, Watties in New Zealand) that began freezing peas, corn, berry fruits, Brussels sprouts, beans, and asparagus during the 1950s and later expanded into fish products, "TV dinners," frozen chips, cakes, poultry, and meats.

As has been the case in developed countries elsewhere, recent decades have also witnessed the sacrifice of family farms to agribusiness, monoculture, the intensive use of fertilizers and pesticides, and the arrival of scientifically "engineered" fruits and vegetables, made possible by agricultural research and funded by both governments and private corporations (Symons 1982). Recently, however, new "alternative" farming ventures have also arisen that produce organic fruit and vegetables and market them directly to consumers through resurrected city markets. At the same time, the "back to the earth" movement has supplemented the limited information prevailing in industrial societies concerning the imitation of developing-world cuisine (Symons 1982). In Australia, the food items of the original inhabitants have begun to be noticed again, but as yet in New Zealand, there has not been the same level of interest in "Maori" food other than breads, seafoods *(kai moana),* and foods cooked in the traditional earth oven (Osborne 1989; Paul 1996).

Eating Out

Eating establishments have existed since the beginnings of settlement in Australia, and in fact, in 1800 the Freemason's Arms in Sydney served excellent French-style food. More commonly, early eating houses and taverns dished out boiled mutton and broths, but both the Australian and New Zealand colonies had numerous eating houses with reputations for excellent "British cookery" (Symons 1982). The belle epoque for fine restaurants was between 1890 and World War I, when in all of the major cities, gourmet restaurants served a wide range of continental cuisines. Following the war, however, gourmets could lament that the two countries had only one diet: steaks, chops, beef, mutton, potatoes, and gravy, with suet pudding and slabs of cheese (Symons 1982).

For the less wealthy, "fourpenny" and "sixpenny" restaurants, serving basic meats and vegetables, had come into being at about the middle of the nineteenth century (Symons 1982). The fish-and-chip shop, a feature of Australian and New Zealand life that has remained, albeit modified, to the present day, arrived somewhat later. Another such feature is the ubiquitous meat pie brought by the British, which evolved over a long period to become the standardized dish common since the 1920s (Symons 1982). Men commonly ate meat pies at sporting events and as a counter lunch item in hotel bars. By World War II, the meat pie had become a "national dish" in both countries. The New Zealand Food and Drug Regulations of 1973 state that meat pies shall be encased in a pastry shell and contain not less than 25 percent cooked or manufactured meat (Burton 1982).

Until recently, "going out to dinner" for many Australians and New Zealanders meant the fish-and-chip shop or the "pie cart," a mobile, trailerlike café parked at a convenient location, which served meat pies with various accompaniments (for example, mashed potatoes and peas, known all together as "pea, pie, and pud"), as well as various other types of portable food to its customers (Burton 1982). Even as late as the 1960s, the only alternatives to the fish shop and the pie cart were the dining rooms of hotels and exclusive private clubs, both of which served a very standard antipodean cuisine: steak and chips, roast meats and vegetables, bread and butter, tea, and ice cream with passion fruit (Symons 1982).

By the late 1960s, however, the pie carts and the fish-and-chip shops began receiving stiff competition from American-style fast-food outlets. Kentucky Fried Chicken was the first, in 1968, and McDonald's and Pizza Hut were not far behind. A decade later, such fast-food franchises were everywhere, although their products did not completely replace fish-and-chips and meat pies, and many of the traditional fish-and-chip shops have recently expanded their "takeaway" (carry-out) menus to include Chinese food as well as a variety of European fast foods, such as gyros and kebabs. Fast-food outlets of this type, often operated by recent immigrants, have contributed significantly to the diversification of foodways in Australia and New Zealand.

Of even more importance, however, has been the recent explosive growth of all types of restaurants. Some of this growth can be attributed to the influence of immigrants from Europe soon after World War II and, more recently, from Asia and the Pacific region. But as affluence grew in both Australia and New Zealand, more people began to visit Europe and other places around the world, and as they did so, they discovered that there was more to the "good life" than steak-and-eggs and chips.

Contemporary Food and Beverage Ways

Migrants, overseas travel, the window to the world opened by television, affluence, and the continuing globalization of food have all contributed to the diversification of Australian and New Zealand diets. Another significant change has been in drinking habits. An accompaniment to the growth of diversified, quality eating places has been the proliferation of locally produced wines, some of fine quality, some not. Although Australians and New Zealanders were and are beer drinkers, they have also historically drunk sweet wines, characteristically "screw-topped Riesling" (Symons 1982).

Grapes have long been grown, since 1791 in Australia and 1819 in New Zealand (de Blij 1985). Wine making developed early in Australia: By the 1820s, it was successful around Sydney and had expanded to the Hunter Valley. In the 1830s and 1840s, viticulture and wine making began in Victoria and South Australia, and a solid market for sweet and fortified wines developed. During the 1960s and the years that followed, the industry was transformed, with new, high-quality cultivars planted; technological and wine-making improvements led to a vastly expanded and diversified array of wines to meet developing consumer tastes.

Large-scale wine making is much more recent in New Zealand, which had only 200 acres planted with wine grapes in 1945. But the industry expanded enormously after 1960, with white varietals initially dominating. Today, red varietals have also come into their own, and there are more than 140 vineyards marketing wine in New Zealand. Some are owned by large corporations; yet there are also many small producers making excellent wines.

"One Continuous Picnic"?

Symons (1982) has characterized eating and drinking in Australia since 1788 as "one continuous picnic," and the contention here is that the same has been true in New Zealand. Both peoples were dispatched to the antipodes with packed provisions – "rations" – of salt pork and ship's biscuits. Pastoralists were paid in rations of flour (for damper), "billy tea," and slabs of meat, and the indigenous peoples learned their new foodways from the "crews" who were transforming their lands. The railways sent Australians and New Zealanders jaunting off with a litter of tins and bottles. More recently, semitrailer trucks have brought in Coca-Cola, frozen puff pastry, and "Big Macs." The concept of a picnic highlights the most essential character of Australian and New Zealand food right from the beginning: portability. Even the penchant for outdoor barbecuing (the "put-another-shrimp-on-the-barbie" syndrome) can be interpreted in this light. Broiling meat and seafood over hot coals harks back – nostalgically? – to an earlier age, when men (and women, when they were present) cooked their rations over open fires with a minimum of equipment.

V.E.3 ~ The Pacific Islands

In the Pacific Islands (or Oceania) great distances, distinct island environments, and successive waves of peoples reaching island shores have all shaped foodways, including gathering, hunting, and fishing, agricultural practices and animal husbandry, and modern food distribution systems.

The peoples of Oceania (which was subdivided by Eurocentric cartographers into Melanesia, Polynesia, and Micronesia) arrived at their island homes over a span of many thousands of years. The various islands have substantial differences in natural resources, and the inhabitants have had different experiences with explorers, colonizers, and missionaries. But since the 1960s, many of the peoples and lands of Oceania have had in common their own decolonization and integration into the global economy. What follows is a description of the history and culture of food and nutrition in the Pacific Islands that recognizes diversity yet also attempts to leave the reader with an impression of the whole.

The Pacific Region

In the vastness of the Pacific Ocean are some of the world's smallest nations and territories. Politically there are 22 states, excluding both Hawaii and New Zealand. The region's giant is Papua New Guinea. With a total land area of 462,000 square kilometers, it is over five times larger than all the other Pacific states combined. This nation, inhabited for many thousands of years longer than the rest of the region, is also home to over 60 percent of the region's population of 6 million individuals, whose diversity is illustrated by the more than 800 languages spoken in Papua New Guinea alone. Fiji is the only other Oceanic territory with a population of more than 500,000. By contrast, Tokelau, a territory of New Zealand, is made up of three coral atolls with a combined land area of 10 square kilometers and a population of 1,600. Cultural definitions of the region, however, incorporate New Zealand as well as Hawaii. New Zealand is treated elsewhere in this work, but for comparative purposes, this chapter includes several references to its original inhabitants, the Maori.

The Environment

The island types of Oceania range from the large, mountainous eastern half of the island of New Guinea, which the nation of Papua New Guinea shares with Indonesian Irian Jaya, to tiny coral atolls dispersed across the central and eastern Pacific. The dominant tectonic feature of the region is the Pacific Plate, which is moving slowly to the northwest and underthrusting the Asian land mass. Its western boundary forms the Pacific "Rim of Fire," characterized by volcanism and earthquake activity. In broad outline, the region presents a continuum of environments, from larger continental islands, extensions of the Asian land mass, and andesitic volcanoes in the western Pacific to basaltic volcanic islands and coral atolls in the north and east.

There are three major island types: continental, volcanic, and coral atolls. The islands in the west, many of which are continental islands, tend to be larger and geologically complex. Typically they include intrusions of andesitic volcanic rock and are surrounded by fringing and barrier reefs. These islands have a varied topography, contain metal-bearing ores, and can develop diverse soil types, rendering large areas suitable for agricultural development. The volcanic islands, produced by andesitic, explosive volcanoes west of the Andesite line and basaltic shield volcanoes in the Pacific Basin, are much more homogeneous. Weathering produces islands with steep, rugged interiors. Fertile soils may develop on weathered slopes and in the rich alluvial deposits on valley floors.

Coral islands are the third major island type in the region. Some cultures of the Pacific are found exclusively on these resource-limited islands. Most islands in the tropical Pacific are surrounded by barrier or fringing reefs. As the final stage in the evolution of these islands, only the coral remnants remain, leaving either an atoll, a ring of coralline islets surrounding a central lagoon, or a raised coral reef. Several variations of these two main types exist. Coral islands have a more limited agricultural potential, although the upraised limestone islands may develop fertile soils under some conditions. Water is often a limiting factor because of a lack of orographic precipitation and limited storage capacity.

The Climate

Whereas almost all the islands fall within the tropics and have high year-round temperatures, these conditions are moderated by oceanic location and offshore winds. In the eastern Pacific, north of the equator, the dominant trade winds are from the northeast; south of the equator, they are from the southeast. But in the western Pacific, seasonal monsoons influence weather patterns. The northwest monsoon reaches as far east as Papua New Guinea, the Solomons, and the Carolines, bringing storms and rain in the winter. During the rest of year, the dry southwest monsoon often brings drought. Trobriand islanders refer to this as the *molu,* or hunger season.

Between the two trade-wind belts are the doldrum areas, the largest of which extends as far west as the Solomons. The doldrums are characterized by low wind velocities, high humidity, cloudiness, and high temperatures. There, atolls with no orographic precipitation, especially those close to the equator, such as the Northern Line Islands in the eastern Pacific, can be subject to extreme drought. On high islands in the trade-wind belts there is significant dissymmetry between wet windward and dry lee shores. Typhoons (hurricanes) are also a threat throughout the region.

In addition to influencing climate, the ocean currents of the Pacific have played a major role in determining flora and fauna of Oceania. Those currents, along with prevailing wind patterns, also set the parameters for long-distance sea voyaging. Oceanic peoples with sophisticated navigational techniques and maritime skills reached these remote islands in the Pacific to complete humankind's occupation of the globe about a thousand years ago.

Flora and Fauna

The flora and fauna of the island Pacific are products of their distance from Asia and, to a lesser degree, from Australia. They are also products of the great distance between islands in the eastern Pacific and North and South America. Other variables include rainfall, altitude, soil, soil salinity, groundwater, insolation, and human activity (Oliver 1989). Terrestrial plants had to have reproductive parts capable of being carried by wind or birds or humans, or of surviving immersion in salt water. Generic diversity drops significantly as one moves from west to east. As the water gaps become larger, this tendency is increased, producing a significantly more depauperate flora and fauna in the eastern Pacific.

D. Oliver (1989) has listed the natural vegetation complexes encountered in the region. Seacoast or strand vegetation, confined to narrow coastal areas, is found on most islands. Additional lowland vegetation types include mangrove forest, swamp, and rain forest found on both continental and volcanic mountainous islands. Lowland rain forest, the most widespread vegetation type in the Pacific, provides important resources for food, medicines, fiber, and building materials. But population pressure and the search for exploitable resources such as lumber have led to encroachment and environmental degradation.

Other vegetation types are more restricted in their distribution. With increasing altitude or distance from the equator, for example, at 3,000 feet in equatorial Papua New Guinea and at 900 feet in Fiji, high montane cloud forests are found. Alpine vegetation is encountered only on the highest islands – extensively only on Papua New Guinea and Hawaii and in patches on the Solomons. Finally, grasslands and savanna woodlands, resulting from either insufficient rain or anthropomorphic processes such as burning, occur on New Guinea and lee areas on some of the other islands of Melanesia (including Viti Levu), on Hawaii, and on Easter Island in Polynesia.

The fauna is equally depauperate. West to east, there is a severe attenuation of terrestrial vertebrate genera. When the Polynesians first reached Hawaii's shores, the only mammals they found were the hoary bat *(Lasiurus)* and the Hawaiian monk seal *(Monaachus)*. A similar attenuation can be seen with land birds. There are 869 species in Papua New Guinea and only 17 in Tahiti. This pattern is also evident in freshwater fauna. Marine species are more widely distributed; however, the marine biota is also less diverse in the eastern Pacific than in the west. For example, there are 60 species of cowries in the Marianas Islands in western Micronesia and only 35 in Hawaii.

Peoples of the Pacific

The complex history of the Oceanic peoples is less well understood than the region's natural environment, and it is a history that is continually being revised as archaeologists, linguists, ethnobotanists, and geneticists uncover new evidence.

In discussing the interplay of productive practices and social systems, the geographer B. Currey (1980) borrowed from earlier ethnographic depictions to characterize the Melanesians as gardeners, some of whom developed complex systems (revolving around the raising of pigs) in which status was more individually than communally derived, and leaders were seen as "Big Men." Polynesians were depicted as gardeners and fishermen, with societies built on group solidarity and relatively equal access to food (although some highly stratified societies developed, especially in Tahiti and Hawaii). The Micronesians were described as traders who developed interisland trading networks and various forms of class stratification. Although this is a gross generalization, for our purposes it is a useful one. But where did these people come from?

It is now evident that Pacific Island peoples, and most of their domesticated plants and animals, originated in Southeast Asia. Between 60,000 and 8,000 years ago, two distinct "races" of modern-type humans inhabited the islands to the west of New Guinea: Mongoloids in the north and west and Sundanoids (also known as Australoids or old Melanesians) in the south and east (Oliver 1989). By 40,000 years ago, during periods of lowered sea level, Sundanoids moved into New Guinea and the Sahul shelf of Australia (Bellwood 1979). The earliest occupation of New Guinea, however, was probably even earlier, although permanent sites were not established in the highlands until 25,000 years ago (Gorecki 1986).

Oliver (1989) has suggested that between 10,000 and 5,000 years ago, four important introductions reached the Pacific Islands: (1) genes carrying Mongoloid traits, (2) languages of the Austronesian family, (3) objects relating to animal domestication and plant cultivation, and (4) knowledge to improve seagoing craft and boat handling. The latter began an era in which the far reaches of the Pacific were discovered and inhabited.

By 5,000 years ago, most of the Sundanoid peoples of Southeast Asia had been replaced or absorbed by others with different traits, such as lighter skin, straighter hair, rounder crania, and flatter brow ridges. These pioneers began to move into the Pacific Islands, possibly from the region bordering the Celebes Sea. They reached western Micronesia (Palau and the Marianas Islands) about 3,600 years ago, having crossed open ocean distances of some 500 miles. At about the same time, another group that was more or less Mongoloid moved along the north coast of New Guinea to the Solomons, Vanuatu, and Fiji.

These eastward-moving peoples were farmers and fishermen, who kept dogs and pigs, developed sophisticated fishing techniques, and also hunted. Their cultivated crops included taro, yams, bananas, sugarcane, breadfruit, coconut, the aroids *(Cyrtosperma* and *Alocasia),* sago, and, probably, rice, although at the time of European contact rice was found only in the Marianas.

The absence of rice in most of the Pacific Islands is one of prehistory's most tantalizing questions. Works by Peter Bellwood (1979) and J. Clark and K. Kelly (1993) suggest that rice was somehow lost from the horticultural complex and that sagos and taros replaced it in swampy areas, whereas yams and tree crops were grown in dry fields and swamp-garden margins. But in another interpretation, M. Spriggs (1982), who posited a Southeast Asian origin for Pacific agriculture, has argued that the techniques used for irrigated taro reached the Pacific before rice was established as a staple in Southeast Asia.

Some 3,500 to 3,300 years ago, a wave of Mongoloid-featured, Austronesian-speaking migrants moved southeast across the Pacific and rapidly established settlements in Fiji, and then in Tonga and Samoa. Those who arrived in Samoa and Tonga were the ancestors of present-day Polynesians. They brought with them Lapita ware – a type of stamped and incised pottery that probably originated in the Admiralty Islands and the Bismarck archipelago. They had a well-developed maritime technology, were expert fishermen, and also were horticulturalists who raised pigs and chickens. They developed sophisticated exchange networks, transporting goods across long distances. Some 600 years later, another migratory group from the west, with different traits, reached Fiji to mix with the islanders and become ancestors of the Fijians (Oliver 1989).

From Tonga and Samoa, the rest of Polynesia was settled over time with differentiation in language and other aspects of culture. Spriggs and A. Anderson (1993) have argued for settlement dates of A.D. 300 to 600 for the Marquesas, sometime after A.D. 750 for the Society Islands, and A.D. 600 or later for Hawaii. Anderson (1991) has suggested dates of A.D. 1000 to 1200 for New Zealand and the end of the first millennium for Easter Island.

There has been less research for Micronesia, in part because it presents a more difficult environment for archaeological investigation. As mentioned previously, the Marianas were settled by Austronesian-speaking Mongoloids at least 3,600 years ago. Recent evidence suggests that descendants of the first inhabitants of Palau and the Marianas moved east into the Caroline Islands before Oceanic-speaking peoples migrated to Micronesia via the Solomons, Gilberts, and Marshalls (Oliver 1989). Migrants had reached the southern Gilberts by 3,500 to 3,000 years ago.

Plant Foods of the Pacific

Because they share a tropical and subtropical climate, as well as a flora and fauna with common origins, it should be no surprise that there are many similarities in the history and culture of food and nutrition among the peoples of the Pacific. Some plants have been identified as specifically Pacific cultivars, notably the fruited pandanus, sugarcane, and the *Australimusa* banana. The coconut may have had multiple domestication sites (Sauer 1971). The major staple root crops, yams *(Dioscorea)* and taros *(Colocasia esculenta, Cyrtosperma chamissonis,* and *Alocasia macrorrhiza),* are from Southeast Asia, as is the *Areca catechu* palm (Lebot, Merlin, and Lindstrom 1992). Bellwood (1979) has discussed evidence of gardening and pig raising in the central highlands of New Guinea from 5,500 to 6,000, and possibly as many as 9,000, years ago. More recent evidence suggests that agricultural techniques appeared independently in Papua New Guinea 9,000 years ago, possibly predating their development in neighboring Southeast Asia. There is evidence of 9,000-year-old domestication and cultivation from the Kuk Swamp in Upper Wangi, New Guinea (Gorecki 1986), but it seems likely that intensive and continuing horticulture was not established in highland Papua New Guinea until about 4,000 years ago.

D. Yen (1991), the preeminent Pacific ethnobotanist, has recently proposed a model that attempts to explain the diffusion of agricultural crops across the Pacific: Agriculture began with the independent early domestication of endemic species in the New Guinea region about 10,000 years ago. It was accelerated by the introduction of species from Southeast Asia (about 6,000 years ago), and again by the advent of crop plants from the Americas, most notably the sweet potato. These arrived in Polynesia in prehistoric times but were not introduced into western Melanesia, including Papua New Guinea, until Western contact.

The timing of the introduction of the sweet potato and its role in the development of highland New Guinea's complex agricultural systems, which supported very large populations, has been the subject of considerable academic speculation. A parallel controversy surrounds the timing of the precontact introduction of the sweet potato into eastern Polynesia (see the discussion under "Root Crops").

Root Crops

Taro. Taro refers to four members of the Araceae family, *Alocasia macrorrhiza* (giant taro), *Cyrtosperma chamissonis* (giant taro or swamp taro, grown largely on atolls), *Xanthosoma* sp., (kong kong taro or American taro, a post-Columbian introduction from South

America), and *Colocasia esculenta* (true taro). The last is the most widely distributed, and in many places in Oceania, it was the favored staple. Ancient Hawaiians, perhaps Oceania's most sophisticated agriculturalists, recognized between 150 and 175 distinguishable varieties of taro (Murai, Pen, and Miller 1958). Taro was the main staple of Hawaiians and Samoans.

Colocasia taro is believed to have been among the first root crops to be domesticated (Pollock 1992). Traditionally, it was found from South Asia through Indonesia to the Pacific. Recent evidence suggests widely distributed multiple sites for the domestication of taro, with one of those sites being highland Papua New Guinea (Yen 1993). Polynesian taro, however, could be derived from a narrower genetic base that had its origins in Indonesia, although New Guinea may have been the immediate area of domestication (Yen 1991). Archaeologist Spriggs (1982), relying in part on similarities in the irrigation technologies of New Guinea and island Southeast Asia, argued that taro originated in Southeast Asia and diffused from there into the Pacific.

Recent evidence suggests human use of *Colocasia* 28,000 years ago in Kilu Cave, a Pleistocene site in the Solomon Islands. This discovery supports the hypothesis that the natural distribution area of *Colocasia,* and perhaps other aroids, included Australia, New Guinea, and the northern Solomons (Loy, Spriggs, and Wickler 1992). *Colocasia* (true taro), whose corm and leaves are both eaten, grows best in shady, well-watered settings, such as lowland and montane rain forests to about 7,000 feet (Oliver 1989). As was the case in Indonesia and Melanesia, *Colocasia* was also produced in sophisticated valley terrace systems in the Cook Islands, in eastern Polynesia, and with a system of aqueducts in Hawaii.

Cyrtosperma taro grows in coastal freshwater marshes. It is a much larger tuber that remains edible in the ground for several years and was an important crop in Micronesia because of its tolerance of stagnant, brackish water. Shoots of the rootstock are also planted, with compost and soil, in pits dug into coral to reach the freshwater lens. *Cyrtosperma* is labor-intensive, and some island peoples have surrounded its production with much secrecy while growing huge specimens for ceremonial exchange. *Alocasia* taro requires the least moisture and is the hardiest, but the edible starchy stem contains oxylate crystals and must therefore be processed prior to consumption. Usually a subsidiary food, it is highly valued in Samoa and Tonga.

Yams. Dioscorea are grown throughout the tropical world, and the relationship of those in the Pacific to those in Africa, tropical America, and Asia has not been fully established. *Dioscorea alata* and *Dioscorea esculenta,* the most common Pacific species, may well have been domesticated in Southeast Asia. In order to produce a large tuber, *D. alata* needs a prolonged dry season and, thus, in the Pacific tends to be an upland rather than a lowland crop. Yams also need deep planting in light, well-drained soil; where good drainage is wanting, the technique of mounding is employed, with the vines trained to climb poles or trees.

The tubers, which can reach 9 feet in length and more than 100 pounds in weight, are often prized for size rather than food value, as the flesh of such large specimens is too coarse to eat. Their production, like that of *Cyrtosperma* taro, is often surrounded with much ritual and secrecy. Farmers gain prestige for their skill as gardeners, and yam production is at the center of a number of Melanesian societies. In Fiji, where yams were the focus of the diet, the calendar revolved around their growing season. The tubers can be left in the ground or stored for months. Traditional yam storage houses are sometimes very elaborate, as those in the Trobriand Islands.

Sweet potato. As already noted, the presence of the sweet potato *(Ipomoea batatas),* like the absence of rice, has been the subject of much speculation by those concerned with the history of Oceania. This is because at the time of European contact, the sweet potato (an American plant) was found in almost every high-island archipelago, and those who suggest a New World origin for Pacific human populations have made the plant a part of their argument.

Yen (1974), citing botanical and linguistic evidence, has suggested that the sweet potato reached the Pacific from South America in three separate introductions, all via human agency, because the sweet potato does not propagate after lengthy immersion in seawater. According to this hypothesis, the plant was first introduced into the Marquesas, in the eastern Pacific, between A.D. 400 and 800. This took place after the first settlement of the Marquesas and before the subsequent settlement of Hawaii and Easter Island. From there the sweet potato was carried to other parts of Polynesia and eastern Melanesia. What this implies for proponents of eastward or westward voyaging is one of the intriguing dilemmas of Oceanic prehistory. Another hypothesis posits a second post-Columbian Portuguese introduction, in which the sweet potato supposedly traveled (via Africa and India) through Indonesia to New Guinea and New Britain during the sixteenth century. Finally, it is believed that in the seventeenth century, still another introduction took place in the Manila Galleons from Mexico to the Philippines; after that, sweet potatoes were carried to the Marianas and East Asia.

Sweet potatoes grow in a wide range of conditions and can be cultivated at high elevations. They are fairly tolerant of dry, sandy soils and typically are grown in mounds. Sweet potatoes were part of the highly complex agricultural systems that evolved in Papua New Guinea and were also important in Hawaii and Easter Island. Because of the difficulty of production in cooler climates, they became a valued luxury in temperate New Zealand.

Tree Crops

A large array of fruit and nut crops are found in Melanesia, but they become fewer in the more restricted environments that occur as one moves to the east. Only the main food tree crops – coconut, sago, breadfruit, pandanus, and banana – are discussed here; *Areca catechu* (betel nut) is treated along with kava and toddy in a later section.

Coconut. Perhaps the Pacific region is associated more with the coconut palm, found along the littoral of most tropical islands, than with any other plant. *Cocos nucifera* is widespread, but because of temperature requirements, it is not found in New Zealand above about 1,000 feet, and it has been extinct on Easter Island for over 600 years. Although considerable debate has surrounded the role of humans in the distribution of the coconut palm, and although the plant can propagate itself, most stands have been planted by humans (Oliver 1989). It is a very important supplement to starchy staples throughout the region.

As a result of centuries of selection and propagation, Pacific Islanders recognize many horticultural varieties of the coconut. The immature nut is filled with liquid, which, over time, turns into a layer of hard, white meat. The meat is often eaten as a snack, and it is also scraped and pressed to produce coconut "cream," an important component of Pacific dishes. At full development, the center of the nut contains a spongy, jellylike mass of embryo known as "spoon meat," which is sometimes fed to infants or to those who are ill. The "milk" of immature nuts ("drinking nuts") is an important source of liquid when water is in short supply. Coconut oil can be extracted after grating the meat and exposing it to the sun for several days.

The production of copra (dried coconut meat) for export has been a mainstay of Pacific economies since the 1860s, as it can be stored on and transported from the most remote of island locations. Copra, however, is an intermediate commodity; the ultimate product is coconut oil for food and industrial purposes. Unfortunately, global economic changes, transportation costs, the increasing use of substitute oils, and alleged health risks associated with consuming coconut oil have rendered copra an increasingly marginal export commodity.

Sago. Metroxylon sp. is a pinnate-leafed palm that reaches 30 to 50 feet tall and grows in swampy areas as far east as Samoa and the Caroline Islands. The trunk is filled with a starch that the plant employs to nourish its inflorescence; thus, the tree is commonly harvested just before flowering (at about 8 to 15 years of age). Sago palms are high-yielding, producing about 300 pounds of starch per tree. The tree is felled, split, and the pulp pulverized. The starch is then washed out of the fiber and allowed to dry, producing sago "flour," which keeps for months. The flour is made into pancakes, cooked as a porridge, and can also be used as a thickener for other dishes. Sago has been a staple for many groups in Papua New Guinea and a dietary supplement for others there and in the Solomons and Vanuatu, although it is not now as widely exploited as it once was (Connell and Hamnett 1987). It was rarely used in Polynesia or Micronesia.

Breadfruit. Artocarpus sp., with origins in the Malay archipelago, is a handsome tree growing to 60 feet in height, with large, shiny, lobed leaves. It does especially well in the Marquesas Islands, where it provides the staple food. William Dampier, who found breadfruit on Guam in 1686, may have given it its English name (Murai et al. 1958). One hundred years later, Captain William Bligh's fateful voyage of the *Bounty* began as an effort to carry breadfruit from Tahiti to the West Indies. The plant was successfully transported there in 1792 but did not become a food for slaves as was originally intended. They refused to eat it.

Artocarpus altilis and *Artocarpus incisus* are both seedless, whereas *Artocarpus mariannensis,* the variety found in Papua New Guinea, contains seeds. The fruit, cultivated primarily in Micronesia and Polynesia, is round or elliptical and reaches up to 10 inches in diameter. Breadfruit tolerates less salt than both coconut and pandanus and, hence, is more restricted in its coastal distribution. It is also drought-intolerant. The fruit is eaten cooked, but the seeds may be consumed raw. Where it is an important staple, the fruit is traditionally preserved for months or years at a time in a covered pit, in which it ferments, producing a distinctive and, to Pacific Islanders, delicious flavor. Production is seasonal, with a large summer harvest and a smaller winter one.

Pandanus. Pandanus sp. (also called the "screwpine") is an Indo-Pacific genus with several species. It has long, narrow, prickly leaves and aerial roots. Both edible and inedible varieties grow in the Pacific region. In some parts, cultivated and semicultivated plants are a primary food source, most notably among some groups in Papua New Guinea and on the coral islands of Micronesia and Polynesia. In the latter areas, a number of parts of *Pandanus tectoris* are eaten: the "heart" or terminal bud of the branch, young leaves, the tips of aerial roots, and the seeds and fleshy portion of the fruit (Oliver 1989). In cultivated varieties, the fruits can weigh as much as 30 pounds, with 50 or more phalanges or keys with seeds at the end.

Pandanus is high in sugar, carbohydrates, and vitamin A. It can be eaten raw, but it is also cooked and made into a flour or a paste, both of which can last for months. In some parts of the Pacific, the paste is wrapped in plaited pandanus leaves and tied with coconut cord. In former times, these bundles could reach up to 6 feet in length and 1 foot in diameter (Murai et al. 1958). Pandanus is a major staple on coral atolls and once provided an important food source for long-distance voyaging.

Banana. Before European contact, the bananas of Oceania were either "cooking bananas" or plantains, and not the sweet ones eaten raw, although *Musa paradisiaca* (sweet bananas) and *Musa troglodytarum* (cooking bananas) are both of Southeast Asian origin and have a number of cultivars. In most cases, bananas were a supplement to the diet rather than a staple. Today, some of the varieties introduced by Europeans are preferred in the green stage for cooking, as in Samoa. In Polynesia, bananas were grown both as part of shifting cultivation and as perennial herbs in gardens and around settlements. Western perceptions to the contrary, the traditional diets of Pacific Islanders were not complemented by an abundance of fresh fruits. Citrus fruits and pineapple were introduced to Oceania by Westerners. Pacific fruits like the papaya were typically given away or, in modern times, sold. Both papayas and mangoes are fed to pigs.

Other Crops

Sugarcane. Saccharum officinarum, which when chewed satisfies both hunger and thirst, and *ti (Cordyline fruticosa, Cordyline terminalis),* with a root very high in sugar, were among the plants that Polynesians carried with them on their voyages, and both became widely established species. The former is best known in Oceania as a plantation crop on Hawaii and Fiji.

Manioc (cassava). Manihot esculenta or *Manihot utilissima,* an American plant, was introduced early into the Pacific by the Spaniards, but it did not become widespread as a food until the middle of the twentieth century. Since then, it has become an important staple in the Pacific, as elsewhere in the developing world. In Fiji, manioc superseded taro decades ago in total area under cultivation (Thaman 1990). Sometimes perceived as a lazy man's crop because of its ease of cultivation, it has been planted in areas where cash crops have captured the most productive land. With long, thin, tuberous, edible roots, most varieties contain toxic hydrocyanic acid and must be processed before consumption. Manioc grows best in wet climates, but it can survive dry periods. Usually baked or boiled, it can be processed and stored like flour. It is high in starch but low in vitamins and minerals, and, hence, its widespread displacement of traditional staples is decried by some nutritionists.

Food Production Systems

Oliver (1989) has noted that a major generalization which could be made about food production in Oceania is that individual plants have been planted and tended there, in contrast to the sowing of large quantities of seed. Fire, adzes, and axes were used to clear the land, and digging sticks were employed for planting. Weeds and pigs were common problems, and islanders appealed to the supernatural for protection against crop pests and diseases. During recent research in Fiji, an Indian farmer suggested to me that it was still much better to pray than spray.

Agriculture

Agricultural production systems are closely tied to land tenure, which in most Pacific societies was, and to a large degree remains, communal. Land itself has a deep spiritual meaning in Pacific societies (Bonnemaison 1984). P. Cox and S. Banack (1991) have noted that in much of Polynesia, land and most equipment was the common property of descent groups and was allocated at the lowest unit of the group. This practice was modified in the most highly stratified societies, as in Hawaii, where at the time of Western contact, chiefs directly controlled the land. Many groups in Oceania had access to several microenvironments, such as strand and swamp. Typically, in Polynesia, the units of land tenure were pie-shaped wedges, from mountaintop to outer reef, that spanned four or five ecological zones. These lands were used both for production and for hunting and gathering (Oliver 1989).

Writing of Polynesia, P. Kirch (1991) has argued that the range of production systems reflected an adaptation not only to the wide range of environments that the islanders encountered but also to demographic and sociopolitical circumstances such as expansion and intensification. The agronomic complex of any location was also influenced by other factors. Not all food plants and animals made or survived voyages to new islands, and the voyagers themselves may not have been vested with all the agronomic lore of their home islands.

As already mentioned, there is a west-to-east decline in numbers of cultivated and husbanded species of plants and animals that mirrors, to a degree, the decline of indigenous flora and fauna but may also reflect the attrition wrought by long voyages. Moreover, as islanders moved from high to low islands, there were many adaptations in food production that reached their extreme in temperate New Zealand, where most tropical crops did not thrive. Taro could be grown in the north, but not very successfully, and other important crops, such as coconut, breadfruit, and banana, did not become established. The edible fern, *Pteridium esculentum,* became an important staple, and New Zealand Maori were highly dependent on both the rich avifauna and marine species.

In general, according to Oliver (1989), extended kin groups (those who slept together and ate together) constituted food-producing units, except in societies where gender segregation dictated eating and sleeping patterns. In Melanesia, males were primarily responsible for site preparation, climbing high trees, and felling sago palms. Females were usually, although not universally, responsible for weeding, planting, and harvesting. Kirch (1991) wrote that in

Polynesia most agricultural labor was done by males, with assistance from women in weeding, mulching, harvesting, and carrying crops. But in other societies, especially where dry-field cultivation was the norm (as on the islands of Hawaii and Maui), more female labor may have been required. Even in the 1990s, the role of women's labor in agricultural production was underestimated. Women's roles in gardening and pig rearing in Melanesian societies also had implications for women's roles in political and ritual life in these societies (Manderson 1986).

Types of production systems. Kirch (1991) described five types of agricultural systems in Polynesia, and these can be modified for Oceania as a whole. The initial phase in most high-island locations was shifting cultivation with aroids and yams. It was often succeeded by arboriculture and field rotation.

The second, dry-field cultivation, developed out of the intensification of shifting cultivation. Both shifting cultivation and dry-field cultivation are practiced today.

Water control, a third system, included inundated fields created by terracing, drained garden systems in swampy areas, and pit cultivation. The most highly developed forms include the miles of intricate drainage systems for sweet potato gardens on the marshy valley floors in highland New Guinea and the sophisticated taro drainage and irrigation systems found in New Caledonia, Fiji, Hawaii, and elsewhere in Polynesia. Yen (1991) has noted that irrigation has been the most commonly used method of raising *Colocasia* taro. Growing taro under irrigation is highly productive, resulting in considerable surplus, and Kirch (1984) has argued that such surpluses were important to the rise of Polynesian chiefdoms in late precontact Hawaii.

Arboriculture, the fourth system, was typical of lowland Melanesia with a mix of fruit- and nut-bearing species. Although arboriculture declines to the east, monocropping of breadfruit (*Artocarpus* sp.) did develop in Polynesia, especially in the Marquesas. Other important tree crops include the almost ubiquitous coconut, *Spondias dulcis -vi* or Kafika apple, and *Inocarpus fagifer,* the Tahitian chestnut.

Kirch identified animal husbandry as a fifth system in his classification and noted that pigs, dogs, and chickens (the Southeast Asian triad) were the three species raised in Polynesia, although one or more may have been absent in marginal eastern Polynesia and on some atolls. Most were found on Pacific islands at the time of Western contact, although chickens were absent in much if not most of Melanesia. In some New Guinea societies, wild cassowaries were captured and raised for food (Oliver 1989). Dogs were more marginal than pigs in most Pacific societies and usually survived by scavenging, except in Hawaii, where they were tended and fed. The chicken *(Gallus gallus)* was also a scavenger, although it was carefully husbanded on Easter Island (where the dog and the pig were absent), and there it served some of the ceremonial purposes that pigs did on other islands. Dogs were used in hunting where there were sufficient ground animals, as in Melanesia and New Zealand, but also served as food themselves in Hawaii and the Society Islands (Oliver 1989).

Pigs played a central role in many of the cultures of Oceania, especially in Melanesia. They were probably introduced to New Guinea from Indonesia as early as 5,000 years ago, but their range did not extend to Micronesia or, as noted, Easter Island, and they were not found in New Caledonia or New Zealand at the time of Western contact (Oliver 1989).

These pigs *(Sus scrofa)* were thin, long-legged "razorbacks," unlike today's much larger and fatter domestic pigs. Different husbandry strategies for pigs evolved, such as letting them forage exclusively, or feeding them occasionally, or constraining and feeding them all the time. In parts of Melanesia, much attention was lavished on pigs; their births were surrounded with ceremony, and they were suckled (as were dogs in some places), bathed, and fed premasticated food. They were a very important symbol of wealth and central to ritual, social relationships, and political power. In highland New Guinea, sweet potato gardens supported the production of large numbers of pigs, typically for ceremonial exchange (Megitt 1974), although many pigs were also slaughtered for ceremonial purposes (Oliver 1989) and consumed by kin and other social groups.

Hunting and Gathering

Hunting, gathering, and fishing in coastal and riverine locations were the only food-producing activities of humans in Oceania for the first 20 or so millennia (Oliver 1989). In most traditional societies (exceptions were a few in Papua New Guinea), hunting, although an important source of protein, did not provide the bulk of calories, which came from wild plants, grubs, insects, and, especially, marine foods.

Because of the paucity of mammals on the islands to the east, the hunting of avifauna, for both food and feathers, was well developed. In New Zealand, the arrival of the earliest inhabitants rapidly led to the extinction of 11 species of *moa* – giant flightless birds – and other species as well. In many parts of Oceania, the gathering of seabird and turtle eggs supplemented the diet, and fruit bats were hunted as far east as Samoa and Tonga.

It bears repeating, however, that the major constraint on hunting and gathering in the islands of the eastern Pacific was the severe attenuation of indigenous species of both plants and animals. E. S. C. Handy and E. G. Handy (1972) listed the wild species used in Hawaii as six species of ferns, six of roots or tubers, eight of nuts and berries, two of tree fruits, four of leaves, numerous species of seaweed, and many species of birds, but only one insect, the grasshopper.

Fishing

There is also an attenuation of both freshwater and marine fish species from west to east. Marine foods were a key to the peopling of the Pacific, and fishing was and remains a very important food-securing activity in the region, especially on the high islands and atolls of the central and eastern Pacific. Traditional fishing methods were many and varied. Relatively sessile marine creatures, such as mollusks and sea urchins and other slow-moving animals, were caught by hand in the inshore waters. Harvesting sea turtles was also common in many locations. On the reef and in the lagoon, stupefacients were used, as well as mesh nets, draft nets, spears, nooses (for eels and, in Hawaii, sharks), traps and snares, and lines for angling (Oliver 1989). The fishhooks of Oceania reveal a fascinating array of special-purpose applications.

The collection of *limu* (seaweed) has been particularly important in Polynesia, as was documented in the extensive work of I. Abbott (1991). There are 63 Hawaiian names for edible marine and freshwater plants, representing about 30 separate species. Hawaiians considered *limu* and *poi* a particularly satisfying dish. Elsewhere in Polynesia, *limu* was typically consumed with coconut cream or grated coconut, and the fact that *limu* was not eaten with coconut in Hawaii has been used to argue for a relatively late arrival of the coconut there (Handy and Handy 1972).

Culinary Practices

Beginning with the early explorers, discussions of the meaning of food and of meals in Oceania have been confused by Western preconceptions. For example, Nancy Pollock (1986, 1992), using evidence from Fiji, Hawaii, Tahiti, and elsewhere, has noted that the concept of a "meal" is less important than it is in Western societies (although the meaning of meals may be changing with the fast-food culture in the West). Typically, meals, as defined by Westerners, were consumed once or twice a day and consisted of a starch and an accompaniment, with perhaps a condiment, such as salt, mashed shellfish in brine, crushed insects, or seaweed.

Oliver (1989) has described the main meal, usually freshly cooked, as generally eaten in the late afternoon after the day's work was over. The first meal of the day might have been a light one consisting of leftovers from the previous day, and lunch was often foodstuffs collected and cooked during work, such as breadfruit roasted over an open fire. Oliver (1989) has also made some interesting generalizations about the various food habits of the region, which, although diverse, share many similarities. The peoples of Polynesia and Micronesia have tended to have more food recipes, even though they had fewer nonmarine food resources, than those of Melanesia, and oven baking has been more common in Polynesia and Micronesia. Polynesians and Micronesians also had more food-preparation instruments – pounders, graters, spitters, and fire tongs. The implements used in eating included breadfruit or *ti*-leaf "plates," sharpened sticks, and sometimes wooden bowls, baskets, and seashells. Fingers also served as eating implements.

Food Preparation

Some Oceanic foods were eaten raw – small fish, marine invertebrates, pandanus "keys," coconut, and some fruits – although, as already noted, the adult diet typically did not include much fruit (Oliver 1989).

Cooking methods included broiling over fire or on hot ashes or stones, with the food either uncovered or leaf-wrapped, and sometimes hot stones were put in the body cavity of an animal. Where clay pots were part of the material culture, foods were sometimes boiled. In the early 1800s, whalers and missionaries introduced boiling pots and frying techniques.

The most distinctive cooking style, and one that is indigenous to Oceania, involves the use of the earth oven or *umu*. There are both household and communal ovens (Pollock 1992), with the latter a significantly larger version of the former. There were variations in the oven preparation, but generally a pit was dug and lined with stones upon which a fire was lit. Following this, the heated ash was brushed aside, some of the stones removed, and the remaining stones covered with green leaves. The foods to be cooked were placed on the stones, then covered with hot rocks and ash, leaves, fronds, perhaps earth, and, today, a burlap sack. Although such a slow-cooking technique is laborious, it persists in the region, particularly for feasts and Sunday meals.

No regionwide survey of cooking responsibilities has been carried out, but examples from 21 societies in Oceania revealed situations where women did all the cooking, others where women did the daily cooking and men cooked for feasts (which may be the most common), still others where both men and women cooked daily and for feasts, and the example of Truk, where men did most of the cooking on a daily basis as well as for festive occasions. In at least one society (Yap) each gender regularly cooked for itself, and in Tahiti there was some prohibition against women eating foods cooked by men (Oliver 1989).

Preservation

The storage of food, especially for times of natural disaster or human conflict, was well developed in parts of Oceania, perhaps especially so in the more environmentally sensitive areas. Pollock (1992) has argued that this practice developed not only for times of shortage but also because of a preference for the added taste of fermentation, as in *poi*, the taro dish of Hawaii, or in fermented breadfruit. In the famine-prone Marquesas, breadfruit was traditionally prepared by young men (it was believed that it would store longer if the men were virgins), fermented, and placed in *ti*-lined wooden vessels, and the *ma* was stored in underground pits for months or years. Similarly, taro and breadfruit paste were left to ferment and, sometimes, stored for 10 years or more.

Polynesian arrowroot and, more recently, manioc were preserved as flour. Sago starch was dried, fish were dried and/or salted, and bananas could also be dried or stored in tightly wrapped packets. Well-aired storage houses were used for yams, and food was also preserved by not harvesting it. As already noted, *Cyrtosperma* taro grown in pits can survive in swampy areas for a number of years, and both *Dioscorea* yams and manioc can be left in the ground.

Feasting and Ceremonies

Because they figure so predominantly in Pacific life, feasts have received a great deal of ethnographic attention. They were often dictated by political motives and defined by structured social relationships and religious considerations. They were also important mechanisms for exchange and had considerable economic significance.

Feasts, surrounded with rules and rituals, usually involved large numbers of individuals and a great amount and variety of food. In some societies, all food was prepared and eaten at the location where the feast took place; in others, cooked or uncooked food was given to guests for later consumption (Oliver 1989).

In Melanesia, feast preparations might have included the slaughter of hundreds of pigs. As mentioned previously, there and elsewhere, as in Pohnpei in Micronesia, gardeners would jealously and often secretly raise huge yams. No longer edible, these tubers nonetheless displayed the agriculturalist's prowess and earned credit in ceremonial exchange. Often an enormous amount of food was prepared – much more than could be consumed – and this also carried ceremonial and sociopolitical significance.

Food Taboos

Throughout Oceania, eating was governed by taboos based variously on age, sex, marital status, pregnancy, social grouping and rank, illness, and bereavement. According to Oliver (1989), the most widespread prohibitions were those based on totemism whereby groups would not eat food items (including many wild species) with which they were perceived to have a spiritual relationship. Food taboos for women in Oceania were common, and in ancient Tahiti, women were generally prevented from eating pig, dog, turtle, albacore, shark, dolphin, whale, and porpoise – all foods highly valued or in short supply (Manderson 1986).

Jocelyn Linnekin's book *Sacred Queens and Women of Consequence* (1990) has described a situation in Hawaii in which the dichotomies between chief and commoner or male and female defined social reality. Women were prohibited from eating with men, and cooking was men's work. The choicest foods were offered to chiefs and sacrificed to the gods. Such foods were prohibited to women, although female chiefs were exempt from punishment (which could be death) for infractions.

Further light is shed on food taboos for women in Polynesia by Pollock (1992), who cited J. Williams's (1838) comments about the Cook Islands:

> Females at Rarotonga were treated as inferiors. They were neither allowed to eat certain kinds of food which were reserved for the men and the gods, nor to dwell under the same roof with their tyrannical masters, but were compelled to take their scanty meal of inferior provisions at a distance while the "lords of creation" feasted upon the "fat of the land" and the "abundance of the sea." (Williams 1838: 180)

Women typically had even more restricted food choices during pregnancy, as the maternal diet and development of the fetus were directly associated (Manderson 1986). A woman might, for example, have avoided eating a fish with a displeasing appearance for fear that her child might resemble the fish. Taboos were not, however, exclusive to women. Pork, a highly valued food, was prohibited to women in a number of Pacific societies, but in a few others, for example among the Etoro of New Guinea, the situation was reversed. For men, pork consumption was believed to deplete strength (Rappaport 1968). In the stratified societies of Polynesia, chiefs also imposed prohibitions on certain foods (e.g., pork, specific fishes, or food crops) for sociopolitical reasons, to assure the supply or protect the resource. Feasts might accompany the lifting of such prohibitions.

Eating and Body Size

In most of the societies of Polynesia, and especially among the nobility, large stature and obesity were highly regarded in both men and women. Large size was associated with status and hospitality; thus, a fat chief signified a wealthy society. Moreover, in some societies, such as that of Tahiti, obesity meant increased sexual attractiveness (Oliver 1989). There are numerous accounts of individuals of chiefly rank consuming seemingly impossible quantities of food and achieving a size that rendered them largely immobile. But even ordinary individuals took great pleasure in gorging on huge quantities of food, especially in Polynesia. One explanation for this practice is that it was a response to the seasonal availability of food. Pollock (1992) has noted that if taro was plentiful, it was not unusual for an adult to eat 5 to 10 pounds of it at a sitting.

Oliver (1989), though, referring to the work of M. Young (1971), pointed out a contrasting example, the Kalauna people of Goodenough Island in southeastern New Guinea, whose goal was "full gardens and small bellies." The latter was associated with physical beauty and was attained by hunger-suppressing magic and willpower.

Cannibalism

The role that cannibalism played in the Pacific has probably been exaggerated, and in fact there is evidence to suggest that in some instances, tales of cannibalism were fabricated by islanders to shock naive Europeans. Labeling enemies as cannibals was probably also a popular strategy. There are, however, credible reports of the practice of cannibalism in New Guinea, the Bismarcks, the Solomons, the New Hebrides, New Caledonia, Fiji, New Zealand, the Marquesas, the Gambiers, and Easter Island (Oliver 1989).

The practice was most prevalent in Melanesia (although not all Melanesians were cannibals), to which the appellation "Cannibal Isles" was applied. Oliver (1989), with some reservations about attributing motive, distinguished three categories of cannibalism. In the first, the purpose was to obtain meat (or, specifically, human meat); the second involved punishment, usually of a foreigner or, less commonly, of a local offender, and the practice also was used as a gesture of extreme contempt toward the victim. The third category invoked the realm of magic: In this case, the eating of an enemy, friend, or relative was done to absorb one or more of his or her important attributes. In this latter case, only specific parts of the body, such as the brain, the eye, the heart, the liver, or the genitals, were consumed.

Cannibalism for the purpose of punishment seems to have been the most widely practiced form, and cannibalism for magic ends was more common in Polynesia than Melanesia. In Micronesia, the only evidence we have of cannibalism has been the consumption of token parts of deceased relatives in Truk. A similar practice in highland New Guinea, where parts of the brain were consumed, especially by women and children, led to the transmission of the slow viral disease *kuru.* Cannibalism in the region probably reached its height in Fiji and the western Solomons after firearms were introduced. In the Solomons, firearms rendered raiding and head-hunting more efficient, and in eastern Viti, Levu chiefs imposed a levy of human bodies for consumption. The material culture of Fiji included special wooden cannibal forks, which today are reproduced for sale as tourist "art."

To Drink and Chew

Kava

With a few localized exceptions in the western Pacific, Oceania has had only two traditional drug plants, kava and betel, but only kava, a narcotic infusion of the pulverized root of *Piper methysticum,* is indigenous to the region. V. Lebot, M. Merlin, and L. Lindstrom (1992) have argued that kava was domesticated in the northern islands of Vanuatu about 3,000 years ago. Although kava is not technically classified as a drug because it does not promote addiction or dependence, its active ingredients, kavalactones, have mild narcotic, soporific, and diuretic properties. It is also a muscle relaxant.

The origin of kava is a prominent theme in Oceanic mythology (Lebot et al. 1992). Uprooted after several years of growth, the roots are dried or, less frequently, prepared green. The preparation of kava is often surrounded by highly ritualized ceremonies, and it is an integral part of religious and social life, especially in Tonga, Fiji, Pohnpei, and Samoa.

Two traditional patterns of kava use can be distinguished. In Samoa, Tonga, Fiji, Rotuma, Futuna, Uvea, and Vanikoro, the primary use has been ceremonial and the effects mild. The dry roots are prepared with a substantial quantity of water. But in Hawaii, eastern Polynesia, Vanuatu, Choiseul, and parts of New Guinea, where drinking has tended to be a more individual activity, green roots were often employed with less water added. This mixture was more potent and often resulted in sleep and paresis of the lower limbs.

Whereas kava consumption has generally been and remains a male activity, some age and gender restrictions have been relaxed, and practices are not uniform throughout Oceania. In Fiji, it is believed that drinking moderate amounts of kava when pregnant is good for the fetus and that it will ease childbirth. The drinking of kava during breast feeding is thought to favor the production of milk. In other Pacific societies, infertility has been attributed to kava, and it was also used as an abortifacient. In addition to its ceremonial role, kava has a more general place in Pacific societies. Laborers in rural areas share kava after a hard day's work, and in the towns, others gather at bars for the same purpose (Lebot et al. 1992).

In recent years, kava has become a cash crop in several Pacific countries, and it is now exported from Vanuatu, Tonga, and Fiji to other island countries and nations with Pacific Island populations. There is also an increasing market to meet the demands of the European pharmaceutical industry.

Betel

Betel is the other traditional Pacific drug, although betel chewing is more restricted than the consumption of kava and is found primarily in parts of Melanesia and western Micronesia, notably Palau, the Marianas, and Yap. Betel is employed in exchange and has some ceremonial significance, but its use is not nearly as ritualized as that of kava. It is not usually prohibited to women, although it is more commonly chewed among men.

The shorthand term "betel" refers to a combination of the hot and acrid nut of the *Areca catechu* palm, the bean or stem of the *Piper betel* vine (of the same family as kava), and slaked lime (from either seashells, coral, or mountain lime). There are various methods of using betel, but typically the ingredients are made into a wad, chewed in the mouth, and pressed against the cheek, irritating the mucous membrane and producing a localized sensation. The red fibers and juices are expectorated. The alkaloid arecoline is a stimulant with nicotine-like properties, and betel chewers believe it increases work capacity. As a rule, users of betel have darkened teeth and red stains around the mouth.

Toddy

Another drug used in some Pacific societies, most notably in Micronesia, is palm wine or "toddy," made from the sap of the coconut palm. The practice of collecting the sap from incisions made in the bound spathe of the palm's inflorescence probably originated in the Philippines. The sweet, milky-white sap is high in vitamin B and is consumed fresh. It is considered an ideal food for infants, the sick, and the elderly; it is also used as a flavoring agent in cooking and is boiled as a confection. Processed, it was sometimes stored as a famine food, but left to ferment for several days, it becomes an alcoholic drink.

Alcohol

Alcohol use has become common in the Pacific, although patterns of consumption vary throughout the region. In places where ceremonial kava drinking was traditional, the use of alcohol (usually beer) tends to be a social rather than a solitary activity, and drinks are consumed quickly – an entire bottle of beer in one draft, akin to drinking the entire bowl of kava.

By contrast, in his studies in Papua New Guinea, M. Marshall (1982) found that beer drinking tended to be patterned more on the Australian "mateship" and egalitarian model. Although per capita consumption of alcohol is less than it is in developed nations, high levels of individual intake are common, with drunkenness the major goal, especially among young men.

The Contemporary Pacific

Dietary Colonialism?

In most Pacific Island societies, explorers, whalers, and ships' crews stopping for provisions provided the earliest contact with the West. Later, the economic history of the Pacific came to be dominated to varying degrees by colonization, missionary influences, land alienation, and the production of primary products for export. At first it was the production of copra that altered patterns of daily life and land use in much of the region. Following this it was sugar, bananas, cacao, coffee, oil palm, pineapple, and other tropical export crops.

In Fiji and Hawaii in particular, such activities also altered the ethnic composition of the population, which has influenced the cuisines that we find in those places today. For example, beginning in the 1880s, East Indians were brought to Fiji as indentured laborers for the sugar plantations, and today approximately half the population is East Indian. No wonder that curries are common there.

At the northeastern anchor of the Polynesian triangle, in Waikiki, one can, if so inclined, order rice and Portuguese sausage at McDonald's. This offering, however, is but a pale example of the diversity of cuisines available on almost any business street in Honolulu, largely a legacy of the successive waves of immigrants – Chinese, Japanese, Portuguese, and Filipino – who began arriving in the 1850s to labor on the sugar and pineapple plantations of Hawaii. Later immigrants, the largest numbers from Korea and Southeast Asia, have added to the rich tapestry of ethnic cuisines. In the 1990s, chefs of Hawaii blended the culinary techniques and flavors inherited from the Pacific, Asia, California, and Europe to create their own versions of the new regional cuisines (Henderson 1994).

The Political and Economic Context

Although the Pacific's most international cuisines are found in Hawaii, some foods and foodstuffs from distant places have long been available to those in the urban and port areas throughout Oceania. The salt beef, weevil-laden flour, stale cabin biscuits, and moldy apples that were the fare of the earliest missionaries have been supplanted by tinned fish, frozen meats (including lamb flaps and turkey tails – leftovers from the livestock and poultry industries of Australia and New Zealand), rice, soft drinks, and "cheese twists." In addition to Western food staples, elements of a simplified Chinese-style cuisine, such as dried fish imported from Asia, rice, and condiments, are found in the many parts of the Pacific with Chinese immigrants, and one can find "take-aways" selling "chop suey" in Apia, Western Samoa, whereas "chicken longrice" (rice noodles) and *lomi lomi* salmon (an adaptation from the salt salmon of sailing ships) have become part of the typical "traditional" Hawaiian luau.

Nonetheless, although by the 1990s the island states of the Pacific were, to a greater or lesser degree, integrated into the global economy, in many ways they continue to occupy its fringes, or, as a prominent geographer has suggested, "the Earth's Empty Quarter" (Ward 1989). Although the majority are politically independent or self-governing, true economic independence eludes most, and this marginal role in the global economy can (with remoteness and a continued dependence on agricultural exports) influence contemporary diets in complex ways. The agricultural mosaic that one finds in the Pacific has been strongly influenced by the colonial experience, when economic activities focused on the production and export of primary crops produced on plantations, either through myriad cooperative schemes or as cash crops. But despite the beginning of decolonization in the early 1960s, this pattern has continued, with development officials and international aid agencies strongly urging the production of export crops, hailing such activity as the "road to development."

Consequently, prime garden lands were often converted to the production of cash crops, and subsistence plots were moved to more distant and more marginal land. Especially in Melanesia (Hau'ofa and Ward 1980), where women are the primary subsistence gardeners, such events increased the workload of women, demanding more of their time and energy, which may in turn have had a negative nutritional impact on the entire family, or at least on the young children.

By the early 1980s, as the nutritional and economic fallacy of cash-crop dependence became increasingly apparent, a more balanced approach, stressing food self-sufficiency and the production of indigenous crops, was adopted. This new approach reflected general changes in development thinking, but it was also the result of the efforts of academics, nutritionists, and others (Parkinson 1982) who advocated changes in government policy. The shift took place at a time when Pacific nations began to gain their political independence, and advocating food self-sufficiency became an important symbolic component of the process.

The production of food and other agricultural products remains the dominant economic activity for most of the population of Oceania. Yen wrote in 1980 that a mix of subsistence production and cash-cropping was the most common form of agriculture in Oceania, and this was probably still true in the 1990s. Pollock (1992), using data from 1980 to 1985, noted that foodstuffs constituted approximately 25 percent of total imports by value, but thought that this proportion was beginning to drop, perhaps because of efforts at food self-sufficiency. Data from eight of the countries in the region in the mid-1970s indicated that from 15 to 26 percent of total import dollars was spent on food, with the average somewhat under 20 percent (Lewis 1981). More recent data have suggested rates closer to 15 percent, especially for the more populous countries like Papua New Guinea, Fiji, and the Solomon Islands. But there are exceptions such as American Samoa, whose people spend 62 percent of total import dollars on food (South Pacific Economic and Social Database 1993) and a few islands where virtually all food is imported.

Urban and Rural Diets

Approximately 30 percent of the population in the Pacific can be classified as "urban," although this is a relative concept in the region. Many families produce some garden crops in periurban and urban areas, and many also receive produce through members of their extended families who reside in rural areas. It is no surprise that there tends to be a continuum from traditional to Western (or modern) diet as one moves from rural to urban areas and, for that matter, from the less "developed" parts of the region, like highland Papua New Guinea, to the more developed, as for example, Guam.

Families in rural areas are more dependent on locally produced foodstuffs, both because less imported food is available and because they have less money with which to purchase it. But it would be a mistake to assume that today's rural diets are the same as precontact diets (Pollock 1992). Rural producers in periurban areas may also have diets dominated by imported staples. Employing a household strategy designed to meet an increasing need for cash, rural producers may sell a truckload of taro and other produce and then, at considerably lower cost, purchase enough rice and flour to feed their families. The diet may be less expensive and less nutritious, but cash will be available for other needs.

Moreover, although the situation is beginning to change, in part as a response to government policy and incentives, it is not uncommon, depending on the season in urban markets, to find traditional staples, such as yams, taro, or sweet potatoes, and fish priced beyond what many urban consumers can afford (except, perhaps, for special occasions).

What People Eat

Since their earliest encounters with the West, Pacific peoples have been introduced to new foods, and these have become part of both the regular diet and, in some cases, the status food employed for ceremonial exchange. It is thought that the first canned product encountered by the Samoans was canned pea soup *(pisupo)* – a term used today for another imported and highly valued product, corned beef. Not only is *pisupo* common fare in Samoa, but kegs of beef in brine and case upon case of canned fish make up part of the exchange that accompanies ceremonial occasions.

As already noted, a rough continuum with respect to diet exists in the region, although only rural peoples in Melanesia and, perhaps to a lesser degree, remote parts of Fiji, Polynesia, and Micronesia have diets similar to those eaten by their forebears. In urban areas, people eat a mélange of traditional and Western foods on a daily basis and also patronize "take-aways" and fast-food establishments. At one time, the McDonald's in Guam was the largest in the world, and although it has lost this distinction, there are now three McDonald's franchises on that island. But for ceremonial occasions, and perhaps on Sundays (particularly in Polynesia), urban dwellers, like their rural counterparts, prepare a traditional meal and share it with the extended family.

Although one might decry the dietary change, the reasons for it are not difficult to understand. Foremost among them are the cost, degree of availability, and preparation time required for many traditional foodstuffs, as well as the influences of advertising and changing tastes. Certainly the highly refined imports of flour and rice, sugar, soft drinks, frozen meats, and high-fat corned beef make up a large part of the urban diet. Probably the most likely to be malnourished are the poor, often recent migrants to the towns, who have the least access to garden produce and the least cash to buy nutritionally sound foodstuffs. They may also be living in circumstances that do not facilitate food preparation.

Pacific Markets

Urban markets have existed, often in the same location, since colonial times, as products of the introduced cash economy. In one section there will be mounds of root and tree crops – yams, taro, sweet potatoes, cassava, coconuts, bananas, breadfruit, and other traditional foodstuffs. In another section, tables are piled with market garden produce and vegetables – greens, cabbages, squash, onions, and pumpkins. Fish and marine products are displayed in yet another section, whereas in still another, partly in response to increasing tourism, handicrafts may be found – woven pandanus and coconut-frond mats, baskets, hats, and fans, tapa, shells, shell and tortoiseshell jewelry, and wooden carvings of varying quality. In a central market there may be booths that sell a limited assortment of grains and canned or processed food. In Suva or Lautoka, Fiji, there are stalls selling *yaqona* (both kava root and the powdered form), and others with burlap bags overflowing with tumeric, chillies, and garam masala, the colorful Indian spices. In addition, prepared food and drink is often available.

Larger urban centers have supermarkets that sell fresh, frozen, and canned imported products and, sometimes, a limited selection of local ones. Some of these stores are modern versions of the old Burns Philp's or Morris Headstrom outlets of the colonial Pacific. But there are also smaller, less well-stocked groceries.

Rural stores tend to be small and often precarious business operations. In remote areas, tinned meats or fish, flour, rice, cabin biscuits, cooking oil, and tea may or may not be available. More prosperous operations may have a freezer with fish and meat, but the frozen food is often of questionable quality given the vagaries of electricity and appliance repair.

Health and Nutrition

A great deal has been written about diet, health, and nutrition in the Pacific, with much of the focus on the nutritional and health consequences that have resulted from incorporation into the global economy. This transition has been accompanied by an "epidemiological transition" (Omran 1971), in which dietary change and concomitant obesity have emerged as causal factors (Taylor, Lewis, and Levy 1989), and chronic and noncommunicable diseases have taken the lead as causes of death in the more modernized or "Westernized" parts of the Pacific.

Early studies of hypertension, such as that of more than 30 years ago by I. Prior and F. Davidson (1966), found that blood pressure did not increase with age in some traditional Pacific societies. But more recent studies show increases in blood pressure with modernization: Examples include elevated blood pressure (above 160/95) in 36 percent of males in Nauru and 34 percent of male Chamorros in Guam. Elevated blood pressure is also found in 7 percent of urban Fijians, as compared with 2 percent of rural Fijians (Coyne 1984). Hypertension is more common in the more developed Polynesian and Micronesian societies than those of less developed Melanesia. That lifestyle appears to play a significant role was made clear by P. Baker and J. Hanna (1981), who found blood pressures among the lowest in the world in a traditional Western Samoan village and among the highest in the world among Samoans in Hawaii.

Researchers have also found some of the world's highest rates of diabetes mellitus II (DM) in the Pacific. Prevalence rates in the region ranged from none in highland Papua New Guinea to 30.3 percent in adults in Nauru and were generally higher among females than males, as is typical elsewhere (Taylor and Bach 1987). The DM rates in Nauru rival those of the Pima Indians of the United States, previously thought to have the highest rates in the world. Other studies found elevated rates (over 12 percent) in both urban and rural Fijian Indians, Western Samoans in San Francisco, urban dwellers in Papua New Guinea, and Wallasians living in New Caledonia (Lewis 1988). Recent data for Hawaii give age-adjusted DM rates of 46.2/1,000 for Hawaiians and 22.5/1,000 for non-Hawaiians (State of Hawaii 1992). In the over-65 population, rates for Hawaiians are almost three times those of non-Hawaiians. A number of risk factors have been identified, including genetic predisposition, obesity, diet, levels of activity, and more subtle effects of modernization.

Baker (1984) has elaborated on the "thrifty gene hypothesis" proposed by J. Neel (1962) to suggest that long-distance voyaging and bouts of acute short-term starvation following natural disasters (trials endured by those who settled the remote Polynesian and Micronesian islands) produced genotypes suited to such conditions. With the adoption of modern lifestyles, however, these genotypes may be predisposed to elevated blood pressure, obesity, and diabetes mellitus.

The role of diet in shaping contemporary health patterns in Oceania is complex and much remains to be discovered. Pollock (1992) calls researchers to task for equating "traditional diets" with modern rural diets in urban–rural studies. There are also important biological differences between populations, and such studies have employed a Western biomedical framework of analysis that largely ignores the meaning of food in Pacific societies.

Unfortunately, undernutrition as well as overnutrition is a problem (and an increasing one) in the Pacific, particularly, but not exclusively, in urban areas. As elsewhere, it is the nutritionally vulnerable young children and, sometimes, the elderly who suffer the most severe consequences. Throughout the region, the high cost of imported goods, a lack of knowledge about healthful diets, and a lack of gardening land in urban areas have served to undermine nutrition. In the Solomon Islands, a national survey found malnutrition affects 22 percent of children aged 0 to 4. In the Marshall Islands, 11 percent of urban children are underweight, and one-third of all deaths are of children under age 5. At the other end of the nutritional spectrum, 30 percent of the urban population over age 15 have diabetes (Republic of the Marshall Islands 1990, cited in Bryant 1993).

Summary

We have only an incomplete understanding of the role of diet in health and disease in the Pacific region. We have a somewhat better, but still incomplete, picture of what people are eating. It is a mix of foods that tends to more closely mirror traditional diets in the less developed and more rural parts of the region, although these diets are certainly not unmodified. But in other parts of the Pacific, especially in urban areas, diets are made up of imported foods, often of poor nutritional quality. However, traditional meals and feasts are still important in the Pacific.

There are cultural as well as economic and nutritional reasons for reexamining traditional diets within a framework that is relevant for the populations involved. Food remains an important cultural symbol and can be an important component of cultural identity. The Waianae Diet Program, a community-based program developed in response to high rates of obesity and chronic disease among native Hawaiians, is founded on traditional diets and cultural values and includes group support and a weight-loss protocol that is not calorie-restricted. Short-term results indicate significant reductions in weight, blood pressure, serum lipids, and serum glucose (Shintani et al. 1994). Although long-term research is needed and the positive results for individuals may be difficult to maintain over time, this culturally sensitive program is an example of the efforts being made to reassess and encourage traditional Pacific diets.

Holo i'a ka papa, kau 'ia e ka manu. This Hawaiian proverb, literally translated, means: "When the shoals are full of fish, birds gather over them" – a familiar and welcome sight to island fishermen. Its proverbial meaning is that where there is food, people gather (Puki 1983). The sharing of food – for ceremonial or merely social purposes – remains a dominant thread in the complex, rich fabric of culture in the Pacific. The thread and fabric will continue to evolve and change as they have done over the course of history, as the islands and islanders, increasingly less isolated, nonetheless continue to reassert their Pacific identities in a rapidly changing modern world.

Culinary History

Since the 1970s, historical studies of food in particular cultures have emerged as a new field, "culinary history." Culinary history studies the origins and development of the foodstuffs, equipment, and techniques of cookery, the presentation and eating of meals, and the meanings of these activities to the societies that produce them. It looks at practices on both sides of the kitchen door, at the significance of the food to the cook and to those who consume it, and at how cooking is done and what the final product means. Consequently, culinary history is widely interdisciplinary. Studies make connections between the sciences – medical, biological, and social – and the humanities and draw heavily on anthropology, economics, psychology, folklore, literature, and the fine arts, as well as history. These multidisciplinary perspectives are integrated along geographic and temporal dimensions, and as a consequence, culinary history encompasses the whole process of procuring food from land or laboratory, moving it through processors and marketplaces, and finally placing it on the stove and onto the table. It emphasizes the role that food-related activities play in defining community, class, and social status – as epitomized in such fundamental human acts as the choice and consumption of one's daily bread.

Culinary history can also be defined by what it is not. It is not, for example, simply a narrative account of what was eaten by a particular people at a particular time. Nor is it a matter of rendering entertaining stories about food, or telling anecdotes of people cooking and eating, or surveying cookbooks. But it *is* informed analysis of how food expresses the character of a time, place, society, and culture. Put plainly, culinary history goes beyond anecdotal food folklore and descriptions of cuisine and cooking at a particular point in time to incorporate historical dimensions.

Times, Places, and Themes

Culinary history can (and should) be part of a number of avenues of investigation, such as social history, women's history, and anthropological analyses of food habits, systems, folklore, and material culture. There follows a brief examination of each of these.

Culinary History As Social History

In Europe, which has been the dominant geographic focus of culinary historians, there are basically three strands of investigation: First, there are the cuisines of the prosperous classes, including traditions of court and aristocracy; second, there is the food of middle and lower classes in urban settings; and third, there are the cuisines of rural societies of all classes. The presence or absence of haute (high) cuisine is itself a socially significant part of culinary history (Goody 1982).

Culinary history also plays an important role in regional and, later, national social histories, such as those of England, France, Spain, Germany, and Italy (Toussaint-Samat 1992; Brillat-Savarin 1995). French "*Annales* School" publications on food in social history (Braudel 1966), annual Oxford Food History Symposia, and historical analyses of European food folklorists are examples (Fenton 1986; Teuteberg 1993; Mennell 1996).

Thematic studies examine such topics as the historical significance of agricultural stresses in classical Greece (Garnsey 1990); the culinary impact of sugar and cooking ideas brought by North Africans to Spain and Italy (Peterson 1980); the insatiable demand for spices, which led Portuguese and Italian explorers – and, ultimately, Columbus – to search for new sources of supply (Laurioux 1985, 1989); the importance of the North Atlantic fisheries and their related salt fish industries; and the determinants and consequences of European demands for exotic food items, such as sugar, coffee, tea, and chocolate (Lippmann 1929; Mintz 1985; Coe and Coe 1996).

The impact of the "Columbian exchange" on both sides of the Atlantic has been told through the histories of food plants, their agricultural modes of production, and the techniques of food processing (Crosby 1972; Long 1996). The new foods and their impact on production, processing, and marketing – and on regional, national, and local cuisines – have been traced by European historians and food ethnologists, who follow evidence of introductions and diffusions through herbals, agricultural or botanical histories, food trade records, and other literary or documentary sources (Arnott 1976; Fenton and Owen 1981; Kaneva-Johnson 1995).

The diffusion and adoption of New World foods such as potatoes, maize, and chilli peppers – and the cultural, social, nutritional, and demographic changes occasioned by this – also created new food economies and cultures in Asia and Africa as these foods supplanted numerous older ones (Miracle 1966; Anderson 1988; Hess 1992). The shifts from traditional coarse grains (such as sorghums and millets) to maize in East Africa and from yams to cereal grains or cassava in Central and West Africa, as well as the commercialization of livestock, provide fine examples of the ways in which social history can be traced in terms of culinary history. Colonization and subsequent internationalization of food economies permanently affected gender and age relations in production, consumption, and cuisine.

Another significant watershed is the Industrial Revolution, which in Britain was driven in part by a widespread availability of sugar calories from the New World (consumed in relatively new beverages such as tea, coffee, and cacao) (Mintz 1985) and calories from the highly productive New World potato, which also fueled wars of nationalism in Germany (Salaman 1985). A history of caffeinated beverages from this period can tie together vastly changing food patterns all over the globe as well as economic issues of social history, like changing landholding and cropping patterns, slavery, and imperialism.

In the Western Hemisphere, European colonization resulted in the blending of foods of New and Old World origins. Later watersheds in the culinary history of the United States include the Civil War and its aftermath, with the growth of large industrial agribusinesses (Levenstein 1988); ethnic migrations from Europe in the nineteenth and twentieth centuries, and from Asia after the 1950s; and post–World War II migrations of African-Americans from the predominantly rural southern states to the urban northern states (Jerome 1980). The resulting cuisines have been analyzed in terms of "acculturation" or "changing food habits" of the ethnic populations (Mead 1964; National Research Council 1981) and in terms of their food components, formats, and cycles (see Goode 1989). In the case of Jewish-Americans, for example, their use of food is seen as a principal element in struggles either to maintain or reshape identities (Joselit, Kirshenblatt-Gimblett, and Howe 1990; Roden 1996).

All such phenomena, however, are presented within the larger context of a changing American culinary mosaic. Such national and regional analyses of culinary practices in relation to significant changes in the social order can also be found in the literature of the food habits of Europe (Fenton and Owen 1981; Rotenberg 1981), India (Katona-Apte 1976; Appadurai 1988), and China (Chang 1977; Anderson 1988; Simoons 1991). All interlink major temporal divides or points of transition with the construction of new cuisines.

Culinary History As Women's History

Culinary history, especially in the United States, has emerged, albeit slowly, out of women's history. In the past, feminist historians' analyses of women's domestic work (private sphere) – as contrasted with wage work (public sphere) – tended to focus more on child rearing and other household tasks (Strasser 1982; Cowan 1983). These scholars avoided looking at cooking, allegedly because the kitchen symbolized submission to the oppression of patriarchy, whereas their goal was to elucidate the historical sources and contexts of women's empowerment.

Important linkages of kitchen concerns to the public sphere, however, are found in Catharine Beecher's writings (and schools) of domestic science (Beecher 1869; Sklar 1973) and in the New England Kitchen, established by Ellen Richards and her Boston associates as a place where immigrants could learn to cook and enjoy Yankee cuisine as one dimension of their American assimilation (Levenstein 1988). In their eagerness to hasten the assimilation of immigrants, the New England Kitchen reformers overlooked the reluctance of groups to give up traditional foods in exchange for unfamiliar ones. As a result, this "noble experiment" was a failure.

Serious scholarly attention to domestic culinary arts has grown with the maturation and acceptance of women's history as an academic field and with the recognition that cookbooks, diary descriptions of food acquisition and eating events, and kitchen material culture are important dimensions of that history. Gender analysis, applied to the preparation and consumption of food, reveals cultural differences influencing what male and female cooks prepare, as well as changes over time and place. As a case in point, nineteenth- and twentieth-century cookbooks provide evidence that men and women were expected to eat differently. Such books make distinctions between "men's" (heavy meat dishes) and "women's" (lighter) foods. They also show that gender biases against domestic cooking by men have tended to lessen in later suburban contexts of backyard grilling. Moreover, connections made between meat and fat consumption and heart disease have significantly altered notions about the appropriateness of the "heavy" foods for males (Shapiro 1986).

Cookbooks published by women's voluntary associations often provide obvious links between women's history and culinary history. The tradition of these books began in the United States just after the Civil War, when women formed groups to aid veterans or their widows and orphans (e.g., Ladies Relief

Corps 1887). Since that time, thousands of such books have been published by groups of women all over the United States and sold to support churches, synagogues, schools, museums, and other community institutions, or to memorialize the favorite recipes of multigenerational families or groups of friends. In most cases, such books are the only records these groups left behind. They offer a unique resource for examining women's roles as community builders, especially where they contain chapters on the history of their communities, with particular attention given to the history and accomplishments of their own organizations (Brown and Brown 1961; Cook 1971; Wheaton 1984).

Culinary History As Nutritional Anthropology

Culinary history has also grown out of (but goes beyond) the study of cultural cuisines, defined as the culturally elaborated and transmitted body of food-related practices of any given culture. The latter includes descriptions of characteristic foods and their flavorings and textures, along with their symbolic combination in meals, menus, formats, and seasonal or lifetime cycles of ritual foods and eating (Rozin 1973; Messer 1984; Goode 1989). Nutritional anthropology, however, considers the distances and means by which food ingredients travel over time; the origins and diffusions of processing techniques; and the routes of commercial or customary distribution of foods from sites of production to final consumption destinations. The discipline adds to historical studies a biological dimension that probes the significant coevolution of cultural culinary components and cuisines and human populations. Evolutionary biocultural studies of the consumption of milk (McCracken 1971) and sugar (Messer 1986) are two examples of the types of anthropological studies of foodways that also fit the category of culinary history (Ritenbaugh 1978).

Biological anthropologists have tried to understand the evolution of favorable nutritional patterns – the mechanisms by which traditional peoples "unlock" potential nutritional values in their staple foods through cooking methods and dietary preferences. Studies have analyzed the significance of culinary techniques (such as the alkali processing of maize or the calcium/magnesium-salt processing of soy) in optimizing the nutritional quality of dietary food staples. Additionally, researchers have assessed the ways in which combinations of food components, such as maize with beans and squash seeds, or rice with soybeans, enhance nutritional values and have charted the distribution and diffusion of processing techniques, dietary combinations of foods, and dietary staple foods from their traditional areas to new locales (Katz 1987).

Moreover, anthropologists connect the history of diet with the history of disease. Their studies examine age- or gender-related dietary beliefs and practices, the impact of these practices on infant and child mortality (as well as pregnancy outcomes), and the circumstances under which such beliefs and practices change. Nutritional anthropological studies also analyze the so-called diseases of civilization (diabetes, coronary heart disease, hypertension, and various types of cancers) that seem to have accompanied dietary "Westernization" (including increased fat consumption) in most places where it has occurred (reviewed in Messer 1984).

Comparisons of recent with earlier ethnographic data on food systems and diets in Latin American, Asian, and African localities provide excellent opportunities for tracking changing relationships between food and the social order and elucidating the range of forces – from local to global – that influence such changes. One current of change has been proposed by cultural materialists, who view diet as shaped mainly (or exclusively) by ecological and political–economic ("material") conditions (Harris 1979).

Another current has been illuminated by symbolic or structural anthropologists, who emphasize how food and cooking express ideological–structural dimensions of social groups and their interrelationships. Notions of "purity and pollution" dominate Hindu rules, regulations, and rites surrounding all aspects of food, its preparation and serving, and social behavior (e.g., Khare 1976). M. Douglas discerned a structural logic of "pure" versus "anomalous" categories operating as the basis of food avoidances among the African Lele and then extended that principle to "The Abominations of Leviticus" (Douglas 1966). She moved on to decipher the social meanings of meals in European society (Douglas 1972) and food and the social order across cultures (Douglas 1984).

Claude Levi-Strauss's three-volume analysis of indigenous South American mythologies demonstrates how food and the "cooking" idiom are key to understanding social organization and cosmology (Levi-Strauss 1969, 1973, 1978). All of these analyses demonstrate that eating, cooking, and thinking are essentially philosophical operations, although most culinary studies tend to focus on sensory, technical, or instrumental dimensions of nutrition (Curtin and Heldke 1992).

In summary, anthropologists analyzing changes in foodways or food systems (culinary history) employ a combination of mental and material dimensions and approaches (Messer 1984, 1989). Anthropological approaches to understanding traditional cuisines and dietary change range from the social-structural, cognitive, and symbolic to the psychological, ecological, economic, and political, and to the relationships between nutrition and health. Studies go far back in time to elucidate culinary techniques beginning with elementary hunting, digging, processing, and use of fire (Gordon 1987; Stahl 1989) and extend forward through the present to the food of the future (Messer 1996b). Ethnographers, in the course of fieldwork, may increase their understanding by actively engaging in culinary activities of the past. Archaeologists, too, use experimental ("hands-on" or experiential) approaches, especially to increase their understanding of stone-tool manufacture, the use of such tools, and food-related artifacts in the archaeological record.

"Hands-on" Approaches to Culinary History

Culinary historians share some of the same pleasures and problems experienced by art historians and musicologists. Theory is an important dimension of such studies, but historical discussion must be tempered with a thorough understanding of the craft in order to interpret sources accurately. For culinary historians and the curators of living-history museums, this means researching and producing period meals that employ traditional techniques and authentic ingredients (within the limits of availability) (Noel Hume and Noel Hume 1978; Oliver 1995; Scully and Scully 1995; Dalby and Grainger 1996). Sometimes, substitutions must be made for ingredients no longer known or available, such as the replacement of silphium by celery seed in recipes for a Roman banquet (Arndt 1993). But the ingredients used must be appropriate to the period rather than to modern culinary conventions; for example, mushrooms or walnuts – not tomatoes – go into a catsup recipe from eighteenth-century North America. As with the written mode, such active culinary research compares food-related activities at different times and places using truly interdisciplinary frameworks and methods of analysis.

Museums have joined the enterprise with increasingly well-informed displays of their collections. Among these are reconstructions of cooking and dining venues such as the exhibitions of tables set in the modes of historical eras at the Historical Museum in Stockholm, the Alimentarium at Vevy in Switzerland, the Musée de l'homme in Paris, and the royal tables at Versailles (Musées Nationaux 1993), along with reenactments of cooking and dining, all of which illuminate the uses of culinary space and materials (see, for example, Deetz 1996).

Sources and Venues

Culinary historical scholarship draws on conventional documentary sources, such as diaries, letters, and travelogues, and also on less conventional sources, such as cookbooks and anthropological data.

Manuscript Sources

Diaries, account books, and letters are rich in data that can provide culinary understanding of peoples and periods. Samuel Pepys's diaries abound in accounts of meals. Lady Mary Wortley Montague took note of what she ate. The letters of Voltaire (François-Marie Arouet), too, show his tastes in food (and friends): Inviting a friend to dinner, he offered "a truffled turkey as tender as a squab and as fat as the bishop of Geneva." Felix Platter, a sixteenth-century Swiss medical student at Montpelier, described the pungent foods served him and how he, a Protestant, evaded the rigors of the Lenten fast by cooking eggs over a candle in his room (Wheaton 1983).

Diaries and letters can be accessed by first consulting annotated bibliographies, then turning to specific texts or collections of letters. Examples with numerous food references include *Jane Austen's Manuscript Letters in Facsimile* (Carbondale, Ill., 1990); *Boswell's Journal of a Tour to the Hebrides with Samuel Johnson, LL.D.* (New York, 1936); *Mary Chesnut's Civil War* (New Haven, Conn., 1981); and *The Diary of a Country Parson: The Reverend James Woodforde* (London, 1924–31).

In addition, unpublished correspondence and other personal papers of leading American culinary figures such as Julia Child, Irma Rombauer, and M. F. K. Fisher are available in the manuscript collections of the Schlesinger Library at Radcliffe College.

Printed Literature

Travel literature. Travelers often describe food acquisition, preservation, and preparation, as well as meals. Such descriptions, however, should be used cautiously, because national, religious, class, and personal prejudices all work against dispassionate reporting. Sentimentalism, naivete, and ignorance are additional problems, because travelers without linguistic competence must frequently depend on interpreters and native informants who, whether reliable or not, may not be completely understood. Moreover, travelers have been known to copy from one another's accounts and to exaggerate – if not lie about – what they have seen. To this we might add that the memories of travelers are not infallible, and they are sometimes very gullible. Marco Polo, for example, is credited with having introduced pasta into Italy because he speaks of eating noodles during his travels in China. However, vermicelli was being produced on a commercial scale in Sicily a full century before his birth (Perry 1981). Culinary legends, once started, are hard to eradicate.

The use of travelers' accounts and diaries as sources for culinary history is usually a two-stage process. Annotated bibliographies are useful for pointing to accounts that contain relevant material. For descriptions of Russia, for example, one might begin with H. W. Nerhood's *To Russia and Return: An Annotated Bibliography of Travelers' English-Language Accounts of Russia from the Ninth Century to the Present* (1968). This in turn can lead to individual accounts, such as *The Russian Journals of Martha and Catherine Wilmot* (not published until 1934) and *Russia . . . and the Interior of the Empire* by Johann G. Kohl (1842), which are replete with descriptions of Russia's nineteenth-century foods. Examples of such works for other locales are those by P. Gerbod (1991 edition) for eighteenth-century France; W. Mayer (1961 edition) for early European travel in Mexico;

A. Tinniswood (1989) and W. Matthews (1967) for England; L. Arksey, N. Pries, and M. Reed (1983–7) for the United States; and J. Robinson (1990) on the subject of women travelers. The periodical *La Vie Quotidienne* (published in Paris since the 1930s) draws on travel diaries kept in many times and places.

Science and medicine. Travel literature is also a useful entry point for exploring food and nutritional health beliefs and practices. From Herodotus and Pliny the Elder onward, classic travel or "natural history" accounts influenced medieval and later European "epitomizers" and "cosmographers," whose often fanciful anecdotes of food customs lived on in the herbals and materia medica of both the Renaissance and the early modern period. Herbals and bestiaries contain information about how different kinds of plants and animals were believed to affect the human mind and body; they were one of the principal venues through which the nutritional and medical theories of antiquity and of the Islamic world were conveyed to a larger audience (Arber 1953, 1990; Anderson 1977).

Medical histories and encyclopedias of materia medica trace the diffusion of humoral health and nutritional theory from the classical and Islamic worlds into Europe (Siraisi 1990). Excellent comprehensive histories of the technology of the Old World are the eight-volume *A History of Technology* (1954–8), by C. Singer and colleagues, and J. Needham's *Science and Civilization in China* (1954–88); both works include extensive information on agricultural sciences.

Agricultural and cooking technology. Farm books offer insights into household and commercial agriculture, food processing, and storage technologies and demonstrate how rural estates were managed (Serres 1804; Markham 1986). They provide one class of information on the larger topic of cooking technologies that controlled and varied the character of local cuisines over time (Toomre 1992). Cooking arrangements set limits on what could be cooked. Shifts from hearths to freestanding cookstoves and ovens, as well as changes in fuel types, provide historical indicators of social standing (Cowan 1983) and also show up as a nutritional constraint where the cost of fuel is a major cooking expense, as it continues to be in contemporary developing countries.

Cooks used the heat of both kitchen fires and the sun to dry fruits and vegetables for winter storage and, occasionally, to preserve fruit in sugar. The milder warmth of the kitchen dried herbs, and the steady temperature of the earth preserved foods where cellars provided the only refrigeration. Even in the nineteenth century, ice houses were a luxury for most people. The culinary history of developing countries includes efforts by food technologists to overcome constraints on the seasonal availability of vitamin- and mineral-rich fruits and to encourage more economical food purchases through improved storage and preservation methods (Riddervold and Ropeid 1988; see also occasional publications of the Program against Micronutrient Malnutrition, based in Atlanta, Georgia).

Watersheds in the history of technology, in addition to enclosed-firebox stoves and gas-powered stoves, include running water, electricity, refrigeration, home freezing, the food processor, and the microwave oven (Drummond and Wilbraham 1991). The works by Singer and colleagues (1954–8) and Needham (1954–88) offer a treasure trove for exploring culinary technology the world over (see also Forbes 1955–65 and the following citations). Changes in European cooking technologies can be gleaned through histories of domestic science instruction (McBride 1976; Davidson 1982; Attar 1987) and also through histories of the changing roles of domestic servants (Maza 1983; Fairchilds 1984).

Legal documents. Legal frameworks constitute another category of historical data revealing what were generally elite understandings of food qualities. From Roman times onward, governments usually attempted to supervise and control the quality and price of the principal staple – in the case of Europe, either flour or bread (McCance and Widdowson 1956; Kaplan 1976).

Governments also have regulated consumption of food and drink through control of the grain trade, sumptuary laws, and taxes on commodities such as salt, tea, and alcoholic beverages. Some regulations, such as the classical Athenian ban on speculation in grain, were intended to prevent hoarding of scarce food supplies. Others were meant to maintain class distinctions and to minimize trade deficits. Thus, in Renaissance Florence, wedding banquets of the bourgeois class were limited to three courses, and in eighteenth-century Sweden, coffee consumption was restricted to limit the importation of this expensive foreign product. Such efforts, however, were usually not very successful: The Florentine cooks invented delicacies that circumvented the course limit imposed, and the flavor of coffee became so desirable in Sweden that it was – and still is – used in making pot-roast gravy. In the 1560s, French sumptuary laws limiting the size of meals were simply ignored (Braudillart 1878–80).

Famine and food relief (or the history of hunger) is also a growing field of inquiry. The field includes global, regional, and period-specific studies (Newman 1990) that trace the ecological and political (trade and aid) causes of food shortages and analyze the motivations and relative effectiveness of emergency and other assistance. J. Drèze and A. Sen (1989) and R. Huss-Ashmore and S. Katz (1989, 1990) have produced analytical frameworks and case studies for the period during and following World War II. Although most emergency food aid is conceived to be humanitarian, M. Wallerstein (1980) has demonstrated how, during the Cold War, food aid was mostly political, intended to reward and to influence the behavior of friendly nations.

In developing countries, objectives of food aid have also included the development of tastes, and thereby markets, for the products of developed countries. This is a process connected to macroeconomic policies favoring the production of cash (export) over subsistence crops and the importation of cheap food (Lappe and Collins 1978). The recent history of food relief can be gleaned through the biannual *Hunger Report* of the Brown University World Hunger Program (Messer 1996b), the annual *Disasters Report* of the International Federation of Red Cross–Red Crescent Societies, and research publications of the Institute of Development Studies, Sussex (Maxwell and Buchanan-Smith 1994).

Dictionaries and encyclopedias. Dictionaries, lexica, and encyclopedias are rich sources for understanding food names, distributions, and associated lore. In both the New and Old Worlds, many contain entries on both individual ingredients and cuisines as a whole (see Brokgauz and Efron 1898; Rodinson 1949; Lewis, Pellat, and Schart 1965; Yule and Burnell 1968; *Kodansha Encyclopedia of Japan* 1983; Long 1996). New World "deadly nightshades" (tomato and potato) in Europe, for example, were labeled dangerous "apples" associated with lust, illness, or evil, which retarded their acceptance (Wheaton 1983). Word lists tend to highlight in special ways those foods that are most culturally important. For example, it was recorded – in sixteenth-century Spanish lists of words of the Aymara, a South American people – that the Aymara calculated time in terms of how long it took to boil a potato (Coe 1994).

Lexica also offer period-linked data on plant and animal food names, culturally recognized flavors and aromas, and other sensory or cultural qualities by which people in particular times and places ranked foods and food processing (see, e.g., Johns 1990). Word lists also document judgments of similarity and dimensions of difference between old and new foods; for example, New World "maize" was initially glossed "turkie wheat" (that is, foreign wheat) by the English *(Oxford English Dictionary).*

Folklore. Folklore, myth, and legend also tend to feature food and the quest for it (Darnton 1984). The European story of Hansel and Gretel, in which children deprived of food become prey to some wicked monster but then are able to overcome such evil by trickery or the help of some animal companion, has variants the world over. Children's literature instructs the young; cultural mythologies offer archetypes of how staple foods came to be and describe their cultural association with heroes or gods and their relationship with other cosmological elements, such as sun, wind, and rain.

Knowledge of fermentation and associated culinary techniques are also embedded in folklore. Indigenous Mexican folklore celebrates (and people imbibe) the effervescent products of fermented maguey in weddings and saints' rituals (see essays in Long 1996). In the Near East, wheat and barley – leavened into beer and bread – also leavened social life and carried their own mystique. The festival of the unleavened bread separated the new from the previous year's grain in ancient Middle Eastern cultures, a ritual later transmitted to modern times as the Jewish Passover. Unleavened bread (matzo) lately finds its greatest folkloric elaboration in factories in Brooklyn, New York (run by ultra-Orthodox Jewish sects), that squeeze operations for each cake of matzo into a magical 18 minutes to avoid any (unlucky and forbidden) fermentation (Jochnowitz 1996). Folklorists also record and analyze food ceremonies marking yearly and human life cycles and map distributions of food usages and terminologies (Hoefler 1908; Bächtold-Stäubli 1927–42; Gennep 1927; Wildhaber 1950).

Fiction, plays, and poetry. Since the time of Homer, descriptions of food have been used in literature to advance plot, characterize place or setting, and describe characters. Greek and Roman writings depict eating by both gods and humans and are mines of useful culinary information (Gowers 1993). Gastronomy appears as a major theme in Molière's comedy *Jean-Baptiste Poquelin* (Tobin 1990) and in *Dead Souls,* the work of Gogol. Careful descriptions of what people were eating are also part of the great literature of Charles Dickens and James Joyce (Armstrong 1992).

Visual Materials

Moving pictures. A modern media analogue to folklore, although more for entertainment than moral message, are films featuring food. Although many earlier films (such as *Gone with the Wind* and *Tom Jones*) featured blockbuster food-preparation and eating scenes, the 1980s and 1990s have witnessed an explosion of films principally devoted to the sensory and social dimensions of culinary arts. *Tampopo, Babette's Feast, Like Water for Chocolate,* and *Eat, Drink, Man, Woman* are four key examples. Even the violent satire *Pulp Fiction,* although principally a gangster story, interspersed some of its bloodier episodes with eating scenes that spoofed commercial food advertising and restaurant scenes from other films.

Food documentaries are the other major category of video that depict food culture. Special topics in the United States include the economic significance of restaurants and markets for immigrant groups (e.g., Cambodian-run donut shops) and documentaries about authentic preparation of ethnic foods (chicken soup, gefilte fish, Italian bread, Asian noodles). Food films increasingly are collected and shown at "ethnographic film" festivals, and food preparation is a growing theme for television. Public television stations around the country devote considerable airtime to cooking programs.

Still pictures. More conventionally, "still" pictures – drawings, paintings, photographs, and prints – provide period records, although, as with written sources, they must be used with care (Fare 1976; Henisch 1985; Bergstrom 1989). Sources include cookbooks and herbals, as well as more conventional art. Unfortunately, until the nineteenth century, most cookbooks did not include illustrations; exceptions are Bartolomeo de Scappi's *Cuoco Secrete di Papa Pio Quinto* (Cooking Secrets of Pope Pius V) (Venice, 1570), and Marx Rumpolt's *Ein Neu Kockbuch* (Frankfurt, 1581). From the seventeenth century, herbals offer increasingly naturalistic plant representations, and at all times there are eating scenes in ritual texts and paintings. Culinary historians who use works of art as source materials must be aware of the many conventions that dictate what is represented. For example, European still-life paintings focus in loving detail on foodstuffs both raw and prepared. Meats, fish, and the humbler vegetables appear in kitchen and market scenes. More luxurious vegetables, as well as fruit, confectionery, baked goods, and game, are shown in dining rooms and out-of-doors on terraces. Usually, readily recognizable foodstuffs are depicted, such as poultry roasting on a spit in eighteenth-century English genre scenes or pancakes being fried in the seventeenth-century Low Countries.

Some iconographical themes are especially good sources for pictures of food and food uses. Among Biblical topics, one finds everything from the miraculous fall of manna in the desert and the first Passover in the Old Testament to the wedding at Cana and the miraculous feeding of the five thousand in the New Testament. The "Seven Works of Mercy" (from Christ's Sermon on the Mount) include feeding the poor, caring for the sick, and giving drink to the thirsty. Secular subjects feature public rituals such as the Lord Mayor's banquet in London, coronation feasts, soup kitchens, and, by the nineteenth century, restaurants and genre paintings. Family portraits and conversation pieces often show gatherings around tables. Vincent Van Gogh's *Potato Eaters* (1885) is one of a number of household eating scenes by European oil painters that document the increasing significance of the humble tuber (Tilborgh 1993), and art criticism surrounding this and Jean-François Millet's earlier *Potato Planters* reveals much about the lingering snob appeal of bread versus potatoes in European diets and class structures (Murphy 1984).

Kitchen representations can be supplemented by works on architecture that offer ideas about how kitchens were laid out, as well as by examination of surviving cooking rooms, kitchens, and equipment (l'Orme 1567; Musée des Augustins 1992; Landesdenkmalamt Baden-Württemberg und der Stadt Zürich 1992). Archaeological and anthropological evidence also contributes useful findings that can amplify or modify evidence from visual and written sources.

Anthropological Evidence

Archaeological reports and dietary reconstructions detail histories and movements of food components and associated modes of preparation, storage, and distribution. Recent findings and analyses of the intestinal remains of well-preserved human "bog" specimens provide spectacular information about the diets and nutritional deficiencies of yesteryear. More routinely, skeletal and bone mineral analyses indicate seasonal or chronic malnutrition, particularly over periods of transition from foraging to farming (see essays in Harris and Hillman 1989). To determine culinary histories of particular sites and regions, archaeological reconstructions use the material remains of plants and animals, along with cooking and storage implements and architectural remains.

Ethnographic reports include descriptions of dietary life that become benchmarks for historical and cross-cultural comparison. Anthropological studies also draw on linguistic and literary sources, matching them to material remains and documentary evidence, which together allow the reconstruction of cuisines at particular points in and over time. Semiotic analyses of symbol, myth, and ritual, such as Levi-Strauss's *The Raw and the Cooked,* provide particularly rich metaphorical constructs for linking culinary practices to cultural transformations and patterns of migration, along with the ways in which the significance of particular food plants or animal species, or specific manners of preparation, are marked in myth and ritual and change over cultural time and space.

Ethnographic data also document changing food preferences and tastes and link them to major changes in food and political–economic systems and nutritional–health beliefs and practices. Anthropologists extend the dicta "tell me what you eat and I'll tell you who you are" (from the French) and "you are what you eat" (from the German) from the food itself to its preparation, distribution, and consumption, which are cultural and social markers as well. Recent studies explore how major transformations in agricultural technologies and available plant varieties, such as "Green Revolution" grains and the expansion of world agricultural trade and aid, can influence nutrition, health, and culture in developing areas. Among the results of such changes is increasing worldwide literacy and, consequently, the availability of written recipes from nonlocal sources (Appadurai 1988).

Cookbooks and Cooking Journals

Cookbooks provide specific information about ingredients, equipment, and techniques that cannot be found elsewhere. Some also contain information about daily life, gender roles, regional and economic differences in diet and literacy, and the development of a culinary language. They must, however, be seen in the context of the time and place in which they were produced and in the context of their relationship to other cookbooks (Toomre 1992). For example, most cookbooks published in the United States in the early twentieth century were addressed to women cooking at home, whereas most published in France before the middle of the nineteenth century were addressed to men cooking for patrons from among the wealthiest segments of society.

Bibliographies of cookery books from Europe and the United States include Theodor Drexel, *Katalog der Kochbücher-Sammlung* (Frankfurt-am-Main, 1885); Georges Vicaire, *Bibliographie Gastronomique* (Paris, 1890); Katherine Golden Bitting, *Gastronomic Bibliography* (San Francisco, 1939); Arnold W. Oxford, *English Cookery Books to the Year 1850* (London, 1913); Elizabeth Driver, *A Bibliography of Cookery Books Published in Britain, 1875–1914* (London, 1989); Virginia Maclean, *A Short-Title Catalogue of Household and Cookery Books Published in the English Tongue, 1701–1800* (London, 1981); Dena Attar, *A Bibliography of Household Books Published in Britain, 1800–1914* (London, 1987); Eleanor Lowenstein, *Bibliography of American Cookery Books, 1742–1860* (Worcester, Mass., 1972); Richard M. T. Westbury, *Handlist of Italian Cookery Books* (Florence, 1963); and Jacqueline Newman, *Chinese Cookbooks: An Annotated English-Language Compendium Bibliography* (New York, 1987).

Scholarly Societies and Symposia

Culinary history is being pursued on a worldwide basis in many different venues – in museums, libraries, and universities, and by scholars working outside of any formal academic institutional framework. *Petits Propos Culinaires* (essays and notes on food, cookery, and cookery books) and *Food and Foodways* are publications dedicated to culinary history, as was (to a lesser extent) the *Journal of Gastronomy,* which was published for several years by the American Institute of Wine and Food. In addition, the Foodways Section of the American Folklore Society, with partial support from the Michigan Traditional Arts Program, publishes the biannual journal *Digest: An Interdisciplinary Study of Food and Foodways.* Scholars of culinary history meet at conferences, the most long-standing of which is the biannual or triannual International Ethnological Food Research Congress.

Oxford Symposia on Food and Cookery have been published by Prospect Books (London), and the proceedings of one-day conferences held at the Brotherton Library in Leeds were published in six volumes of *Food and Society* by Edinburgh University Press. The Schlesinger Library of Radcliffe College and the Culinary Historians of Boston (CHB) cosponsored and published proceedings from a conference, *Current Research in Culinary History: Sources, Topics, and Methods* (Cambridge, Mass., 1985).

Madison, Wisconsin, was the site of the 1997 joint meeting of the Agriculture, Food, and Human Value Society (AFHVS) and the Association for the Study of Food and Society (ASFS) – the latter a 12-year-old international interdisciplinary organization dedicated to studying the complex relationship between food and society. The meeting attracted several hundred food scholars – organic farmers, sociologists, chefs, medical historians, anthropologists, and nutritionists. Occasional conferences on specialized food topics have multiplied in recent years. In 1982, the Dublin Seminar for New England Folklife chose "Foodways of the Northeast" as the topic of its annual conference and later published the papers as its *Annual Proceedings 1982.* The Russian Research Center at Harvard University sponsored a conference in 1993 entitled "Food in Russian History and Culture," the papers of which appeared in a book of the same name (Glants and Toomre 1997). The University of New Hampshire held an interdisciplinary conference on food and culture; Boston University sponsored its sequel in 1995.

Additional venues are "living-history" museums, pioneering examples of which are Skansen in Stockholm, Sweden, and the Netherlands Open-Air Museum in Arnhem. In the United States, Sturbridge Village, Plimoth Plantation, and Colonial Williamsburg regularly sponsor programs in culinary history that include both lectures and demonstrations of culinary implements and hearthstone cooking. In conjunction with the Quincentenary (1992), museums on both sides of the Atlantic sponsored exhibits and conferences on the "Columbian exchange," such as the Smithsonian Institution exhibit and conference "Seeds of Change" (Viola and Margolis 1991). In Texas, the George Ranch, outside of Houston, emphasizes the history of black cowboys and chuck-wagon cooking, whereas the Jordan-Bachmann farm in Austin focuses on nineteenth-century German influences in the area, including regional foodways.

Scholarly and professional societies publish various materials of interest. The London Classical Society hosted *Food in Antiquity: Studies in Ancient Society and Culture* (Wilkins, Harvey, and Dobson 1995). Food and nutrition panels are featured at the annual meetings of major academic professional societies such as the American Anthropological Association (Huss-Ashmore and Katz 1989, 1990; Sharman et al. 1991), the American Studies Association, and the American Sociological Association (Maurer and Sobal 1995; Whit 1995). Food history panels are also found at the Eighteenth Century Society, the French Language Association, the American Historical Association, the American Association for the Advancement of Slavic Studies, and the Society for French Historical Studies. The breadth of interest in the field is shown by the wide range of scholarly and trade journals that publish food articles emphasizing cultural, social, historical, or literary themes, with special issues devoted to food topics in history, art history, regional foodways, literature, or films.

Since 1980, Boston has become a center for the study of culinary history. The Schlesinger Library of Radcliffe College, which is devoted to women's history, houses a growing culinary collection of over 12,000 volumes on food and, since 1990, has hosted monthly meetings of the CHB and a professional chefs' forum. Other active groups of culinary historians in the United States are located in the cities of Ann Arbor, Michigan, New York, Houston, Texas, Honolulu, Hawaii, and Washington, D.C., as well as in various cities of California. Activities are also expanding in Mexico, where scholars from the fields of history, anthropology, and biology orchestrated a symposium marking 500 years of European–New World food encounters (Long 1996), and where ethnobiologists and food anthropologists sponsor lectures and publications predominantly on food history topics, including an "Antropologia y Alimentacion" section of *Antropologicas,* a periodical of the Instituto de Investigaciones Antropologicas of the National Autonomous University of Mexico (UNAM).

Conclusion

Culinary history is emerging as an academic specialty. Programs at Boston University's Metropolitan College, courses taught at the Radcliffe College Seminars, and courses within the New York University (NYU) Food Studies Program combine culinary history with cultural studies and, at NYU, nutrition. Apart from these more humanistic approaches, histories of crop plants, agricultural and food processing technologies, and food commerce offer a growing literature on food within the history and sociology of science and technology. Ingredients and technology play off each other to create change in cuisine. Illustrative are the modern varieties of grains and tubers that since the 1970s have been changing the basic foods people eat in developing countries. Another example is the new enzyme processing, which is leading to the replacement of cane sugar by corn syrup in processed foods and, consequently, is influencing sugar- and corn-based economies all over the world. Yet another example – about which much will be written in coming years – concerns the history of foods formulated and aggressively marketed by transnational corporations such as Coca Cola and McDonald's, along with the nutritional and cultural consequences for populations that consume these products rather than other foods. These are but three illustrations of the ever-expanding list of aspects of food and nutrition that culinary historical perspectives help elaborate.

In addition, we can expect growing interest in culinary history on at least four fronts. The first is a growing medical interest in the history of food, diet, and nutritional health, prompted by concern about the extent to which diets play an etiologic role in coronary heart disease, hypertension, cancers, and diabetes. This avenue of investigation seeks to understand the sources of dietary variation and the circumstances under which food habits have changed in the past. The second is a growing agricultural–biological interest in the diversity of food species (and varieties) and their histories. This interest forms part of a global effort to conserve biodiversity. The third is the growing interest in culinary arts in the humanities, both as a part of women's history and also as a special area of literature and the fine arts. Finally, many with political–economic and ethnic-studies perspectives within anthropology, political science, economics, sociology, and history are becoming increasingly interested in the history of food and cuisine for the ways these shape – and are shaped by – social forces. Culinary history will continue to have numerous disciplinary voices.

PART VI

History, Nutrition, and Health

Part VI takes up questions of food and nutrition that have historical as well as contemporary relevance. It begins with two chapters that continue a now decades-long debate over the extent to which improved nutrition may be responsible for reduced mortality within populations – a debate that has centered on, but certainly has not been limited to, the circumstances surrounding the population increases of the countries of Europe since the eighteenth century.

These are followed by a group of chapters that, although not specifically addressing matters of mortality decline, do help to illuminate some of its many aspects. An elaboration of the concept of synergy, for example, emphasizes the important role that pathogens (or their absence) play in the nutritional status of an individual, whereas the chapter on famine reveals the circumstances within which synergy does some of its deadliest work.

Stature, discussed next, is increasingly employed by historians as a proxy for nutritional status, and final adult height can frequently be a function of the nutrition of the mother before she gives birth and of the infant and child following that event – a subject treated in the following chapter. A chapter on adolescent nutrition and fertility, harking back to matters of population increase, is succeeded by another concerned with the linkage between the nutrition of a child and its mental development.

By way of a transition to a second group of chapters in Part VI focusing on culture and foods is a chapter on the biological and cultural aspects of human nutritional adaptation. This discussion is followed by chapters that scrutinize food choices, food fads, food prejudices and taboos, and social and cultural food uses. Probably since humans first set foot on earth, they have believed in the magical properties of some foods and the medicinal qualities of others; both of these aspects of eating are examined in chapters on foods as aphrodisiacs (and anaphrodisiacs) and as medicines.

Not necessarily unrelated is the subject of vegetarianism, both condemned and embraced as a way of life, not to mention as a dietary regimen. Because of the controversial nature of vegetarianism we have both pro and con chapters on the matter to close out Part VI.

VI.1 Nutrition and the Decline of Mortality

Together with economic growth and technological advances, improvements in health and longevity are the typical hallmarks of a population's transition to modern society. Among the earliest countries to undergo such experiences were England and France, where mortality rates began declining steadily during the eighteenth century. Elsewhere in western and northern Europe, health and longevity began to improve during the nineteenth century. In the twentieth century, this pattern has been replicated in developing countries throughout the world.

Understanding the causes that underlie this pattern of mortality decline is important not only as a matter of historical interest but also because of the practical implications for policies that aim to improve life in developing countries, and for forecasting changes in mortality in developed countries. Accordingly, there has been much interest in identifying the causes of patterns of mortality decline and measuring their impact. By the 1960s, a consensus had emerged that the factors underlying mortality trends could be delineated within four categories, as reported in a study by the United Nations (UN) (1953): (1) public-health reforms, (2) advances in medical knowledge, (3) improved personal hygiene, and (4) rising income and standards of living. A later UN study (1973) added as an additional category "natural causes," such as a decline in the virulence of pathogens.

McKeown's Nutrition Hypothesis

Against this consensus view, the British epidemiologist Thomas McKeown argued in a series of influential articles and books from 1955 to the mid-1980s that the contribution of medicine to the decline of mortality before the twentieth century had been relatively small. Rather, relying on a residual argument that rejected other factors as plausible explanations, he proposed that improvement in nutrition was the primary cause of the mortality decline.

McKeown's view was best set forth in his 1976 book, *The Modern Rise of Population.* In it, he argued that the modern growth of population was attributable to a decline of mortality rather than to changes in fertility, and he sought to identify what had brought about death-rate reductions since the eighteenth century. His investigation relied heavily – indeed, almost exclusively – on cause-of-death information, which had been nationally registered in England and Wales since 1837. McKeown himself was aware that his evidence was geographically limited and did not fully cover the time period during which mortality had declined. Nevertheless, he believed that his findings could be generalized to explain the modern mortality experience of other European countries.

McKeown's analysis of causes of death in England and Wales during the period from 1848–54 to 1971 led him to the conclusion that the reduction of the death rate was associated predominantly with infectious diseases. Of the decline in mortality during that period, 40 percent resulted from a reduction in airborne diseases, 21 percent from reduction in water- and foodborne diseases, and 13 percent from reduction in other types of infections. The remainder (26 percent) was attributable to a lesser incidence of noninfective conditions. Thus, McKeown found that three-quarters of the mortality decline since the mid-nineteenth century could be explained by the reduction in infectious diseases. He further reasoned that despite sketchy historical evidence from the period before the beginning of cause-of-death registration, this trend could be extrapolated backward to the start of the modern mortality decline around the beginning of the eighteenth century. By his reckoning, 86 percent of the reduction in death rates from then until 1971 had resulted from a decline in mortality from infectious diseases. For McKeown, then, this conclusion was the central feature of mortality decline and constituted evidence against which the merits of alternative explanations of mortality decline would be judged.

McKeown methodically classified possible reasons for the lesser incidence of mortality from infectious diseases into four categories: (1) changes in the character of the diseases themselves, (2) advances in medical treatment, or the prevention and treatment of diseases by immunization and therapy, (3) reduced general exposure to disease, and (4) increased general resistance to disease because of improved nutrition. Taking these categories one at a time, he systematically considered each of the major disease groups (airborne infections, water- and foodborne infections, and other infections) in turn, and concluded that the only category that satisfactorily explained the decline in mortality was increased disease resistance resulting from improved nutrition.

In examining changes in the character of diseases as a possible explanation of mortality decline, McKeown found little reason to believe that this had been responsible for a substantial reduction in deaths from infectious diseases. By changes in the character of diseases he meant changes in the interaction between the infectious microorganism and the human host and whether such changes meant a decline in the virulence of the pathogen or an increased resistance in the human host through natural selection.

Although he acknowledged that a change in the character of scarlet fever did result in a reduction of deaths from that disease in the latter half of the nineteenth century, McKeown thought it "frankly incredible" that the other major airborne diseases of the period, which included tuberculosis, influenza, and measles, had all undergone such fortuitous changes simultaneously. On the contrary, he pointed out that tuberculosis, for example, continues to have devastating effects on populations not previously exposed to it. Nor did he think it likely that natural selection could have increased people's resistance to such diseases, leading to a decline in mortality. For such genetic selection to have occurred, McKeown pointed out that certain deleterious effects of early industrialization and urbanization, such as crowding, should have produced high mortality in the eighteenth century. Through natural selection, that experience would have left a population with greater resistance to the airborne diseases, which would account for lower mortality rates later on. However, McKeown believed that death rates during the eighteenth century had simply been too low to support such a theory.

Water- and foodborne diseases warranted a similar conclusion. McKeown did not altogether rule out the possibility that changes in the character of those diseases could have played some role in the reduction of mortality associated with them. But he thought that improved hygiene, leading to reduced exposure, was a much more convincing explanation. As for vector-borne diseases, typhus was mentioned as one that might have been affected by a change in its character. However, the contribution of the decline of this disease to the fall of mortality over the past three centuries was small.

The next possible reason for a decline in mortality from infectious diseases that McKeown dealt with was medical advances, and it is here that his arguments impressively marshaled historical evidence. He built his case against a significant role for medical treatment by examining the temporal pattern of death rates of the most lethal diseases. He first took care to point up the distinction between the interests of the physician and those of the patient. Although since the eighteenth century many important advances have been made in medical knowledge and institutions, such advances were not always immediately effective against diseases; they often required considerable intervals before becoming of practical, demonstrable benefit to the patient. In making this distinction, McKeown contended that whether different preventive measures and treatments in history had been effective could not be judged reliably from contemporary assessments; instead, their efficacy would best be determined in light of critical present-day knowledge.

Tuberculosis, the largest single cause of death in the mid-nineteenth century and the decline of which was responsible for a fifth of the subsequent reduction in mortality, served as a case in point. The identification of the tubercle bacillus by Robert Koch in 1882 was an important event in the progress of medical knowledge, but its immediate contribution to reducing tuberculosis was minimal. In addition, of the numerous treatments that were tried in the nineteenth and early twentieth centuries, none could be judged by modern medical knowledge to have been effective against the disease. Rather, McKeown suggested that effective treatment actually began only with the introduction of streptomycin in 1947 and *bacille Calmette-Guérin* (BCG) vaccination on a large scale in England and Wales from 1954. By these dates, however, mortality from tuberculosis had already fallen substantially. Roughly 60 percent of the decline since 1848–54 had already taken place by the turn of the twentieth century, and this decline continued up to the introduction of effective chemotherapy around 1950. If the medical contribution was meaningful only after 1950, it was therefore impossible for medical advances against tuberculosis to have been a major factor in the mortality decline, most of which had taken place by then.

Similarly, when the temporal patterns of mortality decline from the other major airborne diseases of the nineteenth century were compared with the dates of introduction of effective treatment or immunization against them, McKeown found that most of the fall in the death rates they produced had also occurred before effective medical measures became available. An exception to this was smallpox, the decline of which since the mid-nineteenth century was thought to be the result of mass vaccination. But McKeown pointed out that the reduction in smallpox mortality was associated with only 1.6 percent of the reduction in the death rate from all causes. McKeown also doubted that the rapid decline of mortality from diseases spread by water and food since the late nineteenth century owed much to medical measures. He thought that, in many cases, immunization was relatively ineffective even at the time he wrote, and that therapy of some value was not employed until about 1950.

Finally, reduced exposure to infection was considered as a possible explanation of mortality decline. In the case of airborne diseases, McKeown once again found little reason to think that reduced exposure had been a major factor in their decline. Indeed, he thought that the fall in deaths from measles and scarlet fever owed very little to reduced exposure, and although he allowed that reduced exposure did play a role in the decline of other airborne diseases such as tuberculosis, whooping cough, diphtheria, and smallpox, he believed that this was only a secondary consequence of other influences that lowered the prevalence of disease in the community.

In the case of water- and foodborne diseases, McKeown conceded that reduced exposure had played a greater role in reducing mortality than it had with airborne diseases, especially during the second half of the nineteenth century. Purification of water, efficient disposal of sewage, provision of safe milk, and improved food hygiene all contributed to the decline of mortality. He also felt that personal hygiene, particularly regular bathing, may have encouraged the abatement of typhus in the eighteenth and nineteenth centuries.

In summary, McKeown dismissed the ability of both changes in the character of infectious diseases and advances in medical treatment to account for the modern mortality decline. He thought the contribution of sanitation and hygiene had been somewhat more significant but still of limited scope and primarily confined to the second half of the nineteenth century. Therefore, advances in general health based on improved nutrition constituted the only possibility left that could explain the mortality decline, and, in McKeown's view, it was also the most credible explanation.

In support of his circumstantial case for nutrition, which he had arrived at by a process of elimination, McKeown offered some pieces of positive evidence. First, he pointed out that the great expansion of the English and Welsh populations during the eighteenth and early nineteenth centuries had been accompanied by an important increase in domestic food production. However, as McKeown conceded, the central question for the nutritional argument was whether the amount of food per capita, rather than total food consumption, had increased during that period. He found that evidence to settle the matter directly was unavailable and chose instead to consider the relationship between malnutrition and infection. Thus, as the second piece of evidence in support of nutrition, he pointed to the situation in developing countries, where malnutrition contributes largely to the high level of infectious deaths. Malnourished populations are more susceptible to infections and suffer more seriously when they are infected. McKeown also emphasized the dynamic interaction that exists between nutrition and infection, frequently characterized as synergism. Since infections adversely affect nutritional status, a vicious cycle between disease and malnutrition often results – a cycle characteristic of poverty and underdevelopment.

Reaction to the McKeown Thesis

McKeown's thesis drew the attention of scholars from a wide spectrum of disciplines. As it provided a theoretical framework that wove together such themes as industrialization, urbanization, rising standards of living, changing health, and shifting demographic patterns, it could hardly have failed to attract the interest of social scientists, especially demographers and economic historians. A number of studies extended McKeown's argument to the history of mortality rates in the United States (Meeker 1972; Higgs 1973, 1979; McKinlay and McKinlay 1977). In all probability, the contemporary interest in McKeown's nutritional thesis was also in part a consequence of great public concern over the "population bomb" – the fear that the explosive worldwide population increase in the post–World War II period would eventually lead to catastrophic shortages of food and other natural resources. It is not difficult to understand that an audience constantly reminded, and so vividly, of the Malthusian link between food supply and population growth would have been receptive to McKeown's argument giving primacy to nutrition as the factor explaining the decline of mortality.

Reaction to the McKeown thesis, however, was by no means uniformly favorable. Although acknowledging that nutrition had played a role in mortality decline, many scholars nevertheless felt that McKeown had greatly overstated its importance. Of particular concern to critics of the nutrition hypothesis were the gaps in historical evidence. McKeown himself had freely conceded that the basic data were inadequate, but he had still believed that enough pieces existed to "cover the canvas" with a sketch or a comprehensive interpretation, the details of which could be filled in later as data and methodology improved. Not surprisingly, much of the research that countered his viewpoint addressed this evidential gap: Some offered differing interpretations of the sparse existing data, whereas others unearthed new evidence. Whatever the merits of McKeown's own arguments, there is no question that the debate he ignited over the role of nutrition in the modern decline of mortality was productive in that it defined the issues to be researched and spurred the search for new evidence.

Some critics were skeptical that an insufficient supply of food had been responsible for the high mortality rates in preindustrial societies. P. E. Razzell (1974), for example, questioned the food-supply hypothesis, citing the absence of a significant mortality differential between social classes. If nutrition was the critical factor, one would expect the aristocracy to enjoy lower mortality levels than the poor. Yet, in what came to be known as the "peerage paradox," he found that there was little difference in the mortality rates among the peerage and those of the laboring classes in England before 1725, and although presumably the poorer classes should have benefited more from any overall improvement in diet, the reduction in mortality after 1725 was greater among the aristocracy. Moreover, M. Livi-Bacci (1991) noted that in several other European countries as well, the aristocracy had not enjoyed any advantage in mortality over the lower classes. Furthermore, his examination of the European experience from the time of the Black Death to the era of industrialization led him to doubt whether nutritional improvement had shown any long-term interrelationship with mortality rates.

Other criticisms of the McKeown thesis were mainly directed against his underestimation of the role of public health. S. H. Preston and E. van de Walle (1978) concluded that, at least in France, water and sewage improvements had played a major role in urban mortality decline during the nineteenth century. Similarly, S. Szreter (1988) and A. Hardy (1993) argued that in England, preventive public-health initiatives had made significant contributions to the decline in prevalence and severity of a number of diseases, including smallpox, typhoid fever, typhus, and tuberculosis. In addition, purification of milk was thought specifically to have contributed to the fall in infant mortality (Beaver 1973).

McKeown's heavy reliance on English and Welsh data may also have caused him to overstate the case for nutrition. In an analysis of changes in mortality patterns among 165 populations, Preston (1976) pointed out that the English and Welsh experience was exceptional. Between 1851–60 and 1891–1900, decreased mortality from respiratory tuberculosis accounted for 44 percent of the drop in age- and sex-standardized death rates in England and Wales, whereas the normal reduction in other countries had been 11 to 12 percent. Similarly, a decrease in deaths from other infectious and parasitic diseases accounted for 48 percent of the mortality decline in England, compared to the standard 14 percent elsewhere. Preston (1976: 20) concluded that "the country with the most satisfactory early data appears to offer an atypical account of mortality decline, a record that may be largely responsible for prevailing representations of mortality reduction that stress the role of specific and readily identified infectious diseases of childhood and early adulthood."

During several decades of often heated debate over the nutrition hypothesis, virtually all aspects of McKeown's argument have been examined in great detail by critics and supporters alike. The points on which there is agreement after such prolonged and extensive investigation are certainly worth noting. That nutrition did play a role in the mortality decline is not disputed; the disagreement is over the magnitude of its contribution. Although McKeown was generally not receptive to criticisms of his thesis, in a later work (1988) he did acknowledge that the contribution of public-health measures had been greater than he had originally concluded. One important point of McKeown's that has survived intact is that specific therapeutic medical treatments had little impact on mortality reduction.

Generalizing the last point, some critics have commented that no single factor by itself – including nutrition – appears able to account for the mortality decline. Preston (1976) found that nutrition, as proxied by income levels, accounted for only about 20 percent of the fall in mortality between the 1930s and the 1960s. In fairness to McKeown, however, it should be noted that the period covered by Preston's study coincides with the era of antibiotics, whereas McKeown's arguments relied on the trends of mortality patterns before that time.

Diet versus Nutritional Status

In the debate over the role of nutrition in mortality decline, a great deal of confusion has been caused by differences in the ways the term "nutrition" has been understood and used by different investigators. Some have interpreted nutrition to mean food supply or diet, whereas others have followed epidemiologists or nutritionists by taking it to mean nutritional status, or net nutrition, which is the balance between the intake of nutrients and the claims against it. McKeown, the original proponent of the nutrition hypothesis used the term in both senses, although his writings indicate that he was aware of the difference between the two concepts. Lately, R. W. Fogel (1986, 1993, 1994) has suggested that when nutrition is mentioned in connection with food, the terms "diet" or "gross nutrition" be used. He advocated that the term "nutrition" itself be reserved for use in the sense of net nutrition – the balance of nutrients that becomes available for cellular growth – to avoid any further confusion.

There are clear advantages to adopting such a definition, not least of which is that it clarifies and suggests new avenues of research (as discussed shortly). However, as this new definition of nutrition is still not completely free of some pitfalls that could lead to further misunderstanding, it is worth considering in some detail what it actually means. That is, what are the determinants of nutritional intake, and what factors count as claims against that intake?

In a broad sense, nutritional intake may be taken to mean food supply, as has often been assumed in the debate over the historical role of nutrition. But complications exist even in the quantification of this relatively simple measure. Leaving aside the difficulty of obtaining reliable figures for gross food production in the past, one must also face the tricky issue of how to estimate the losses in nutrients that occur because of different, and often inefficient, food-storage, preparation, and preservation technologies.

These considerations, in turn, immediately suggest that quality, as well as quantity, is an important aspect of nutrition, a fact that may go far in explaining the peerage paradox. McKeown (1976) maintained that the peerage must have been eating unhealthy, or even infected, food, in which case the larger quantities they consumed could hardly be taken as grounds for expecting better health than that found among the lower classes. Fogel (1986) has also pointed out that toxic substances in the diet of the aristocrats, such as large quantities of salt and alcohol, would have had negative effects on their health and mortality. He has emphasized that the impact on the overall mortality rate of the peerage would have been especially large if it showed up mainly as high infant mortality, possibly because of adverse effects on the fetuses of mothers who apparently imbibed huge quantities of wine and ale on a daily basis. Moreover, Fogel has noted that the decline in infant and child mortality among the peerage after 1725 was paralleled by a gradual elimination of the toxic substances from the aristocratic diet between 1700 and 1900.

Another important way in which nutritional intake can be significantly influenced is through the presence of diseases that affect the body's ability to absorb nutrients. This ability can be measured as Atwater factors – food-specific rates at which the energy value of a person's food intake is transformed into metabolizable energy. Atwater factors are usually in the 90 to 95 percent range for healthy populations, but they can be as low as 80 percent among undernourished populations in which recurrent episodes of acute diarrhea may impair the absorption of nutrients (Molla et al. 1983).

Against the nutritional intake, all claims on nutrients must be deducted in order to arrive at the figure for nutritional status, or the balance that can be metabolized for cellular growth. The claims on nutrients can be broadly classified into three categories of energy expenditures: the energy required for basic maintenance of the body, the energy for occupational and discretionary activities, and the energy to fight infections. The first of these categories, basic maintenance, accounts for most of the body's energy usage and consists mainly of the Basal Metabolic Rate (BMR). BMR is the energy required to maintain body temperature and to sustain the normal functioning of organs, including heart and respiratory action. Roughly speaking, it is equivalent to the energy expended during rest or sleep and can be considered the default cost of survival in terms of energy.

Although there is some variation among individuals, BMR varies mainly by age, sex, and body weight. In particular, the association with body weight is strong enough that within any age/sex category, BMR can be predicted by a linear equation in body weight alone (WHO 1985). The BMR for an adult male, aged 20 to 39 and living in a moderate climate, ranges between 1,350 and 2,000 kilocalories (kcal) a day, which would amount to somewhere between 45 and 65 percent of his total daily energy intake. It should be noted that BMR does not allow for such basic survival activities as eating, digestion, and minimal personal hygiene.

Occupational and discretionary activities account for most, if not all, of the energy requirements beyond basic maintenance. Discretionary activities include walking, recreation, optional household tasks, and exercise. The pattern of energy expenditure among these categories will necessarily vary with individual activity patterns, which are influenced greatly by age, sex, occupation, culture, and technology. A World Health Organization (WHO) report (1985) estimated the energy requirements of a young male office clerk to be 1,310 kcal for basic maintenance (51 percent), 710 kcal for work (28 percent), and 560 kcal for discretionary activities (22 percent). The energy usage of a young subsistence farmer with a moderate work level in Papua New Guinea was given as 1,060 (40 percent), 1,230 (46 percent), and 390 (15 percent) kcal over the same expenditure categories. In yet another pattern of energy usage, a young housewife in an affluent society requires 1,400 (70 percent), 150 (8 percent), and 440 (22 percent) kcal, respectively.

The adverse effects of infections on nutrition go far beyond their impact on the body's ability to absorb nutrients. Fever directly increases metabolic demands, and the excess energy expenditure so induced by an infection therefore constitutes a separate, additional claim on nutrients. Other effects of infections that are similarly harmful include the loss of nutrients resulting from vomiting, diarrhea, reduced appetite, or restrictions on diet. For instance, R. Martorell and colleagues (1980) estimated that during an episode of diarrhea, the loss of total energy intake from reduced food intake alone can be as much as 40 percent. Malnutrition also has the effect of weakening the immune system and, thus, making the body more susceptible to infections, which can have further negative effects on nutrition in a deteriorating cycle.

The preceding discussion shows that nutritional balance is jointly determined by nutritional intake and various claims on that intake. Both intake and claims comprise a great range of factors, which appears to be broad enough to include almost every determinant of health and mortality. There is obviously a great difference between nutrition in the sense of diet and such a broadly inclusive concept as that of net nutrition. For some, it may seem natural to question whether the precision in the definition of nutritional status actually masks a vagueness in practical usability.

As a hypothetical example, suppose a new medical therapy is introduced that effectively cures a certain infectious disease, and that this therapy has the effect of substantially improving nutritional status by saving nutrients that would formerly have been lost to prolonged infection. If the overall result is a reduction in mortality, credit ought to go to the new medical treatment, but by definition, it can also be said that the lower death rate is the result of improved nutrition. Similarly, an effective public-health measure that lowers the prevalence of some infectious disease could still be considered a case in which improved nutrition leads to mortality decline.

Evidently the different causes of mortality decline can no longer be considered mutually exclusive when nutrition is defined as net nutrition, and it is no longer clear what to make of statements that compare the contribution of nutrition to that of medical treatment or public-health measures. This ambiguity is perhaps especially noticeable and problematic to those who continue to think about the role of nutrition in the context of the debate initiated by McKeown.

A related difficulty that follows from the new definition is that, even today, nutrition as a net balance is quite difficult to measure accurately. Estimating how nutritional status has changed throughout the past several centuries is even harder. In order to calculate claims against the intake of nutrients, the determinants of those claims – such as a population's body weight distribution (from which BMR is derived), its members' activity levels in work and leisure, and the prevalence, severity, and duration of infections suffered by them – all must be taken into account. Once again, the new definition does not appear to be very helpful for those interested in applying it directly to resolve issues raised by the nutrition hypothesis of mortality decline.

It should be noted, however, that ambiguity and difficulty of measurement are not problems newly introduced by the adoption of a definition of nutrition as net nutritional balance. Instead, the new definition serves to highlight the fact that the debate over the role of nutrition has lacked agreement on the exact meaning of nutrition. The view of nutrition as the balance between nutrient intake and energy expenditure also suggests that influences on health and longevity cannot be easily or even meaningfully sorted into discrete, measurable categories. Rather, health and mortality outcomes are now viewed as the joint result of several different processes that continually interact to determine health and aging.

In recent years, such a reassessment of the relationship between nutrition, health, and mortality has led some researchers, notably Fogel and his colleagues, to shift their focus away from the original debate over McKeown's nutrition hypothesis to other aspects of nutrition and mortality. The balance of this chapter briefly considers these new developments.

Anthropometric Measures

The difficulty of measuring or estimating nutritional status – especially with regard to the potential data deficiencies in historical research or in studies of developing countries – has prompted investigators to search for other measures that can be used as proxies for nutrition. Fortunately, there exists a class of measures that are comparatively easily observed (often even far back into the past) and are also known to be sensitive to variations in nutritional status. These are anthropometric measures, especially those of body height and body weight. Since weight is positively correlated to height, a measurement of weight-for-height is usually used, the most popular being the Body Mass Index (BMI), also known as the Quetelet index. It is derived as body weight in kilograms (kg) divided by the square of height in meters (m), or kg/m^2.

Height and BMI reflect different aspects of a person's nutritional experience. Adult height is an index that represents past cumulative net nutritional experience during growth. Studies in developing countries have shown that nutrition in early childhood, from birth to about age 5, is especially important in determining final adult height (Martorell 1985). Malnutrition among children of this age causes growth retardation, which is known as stunting. Although it is possible for some "catch-up" growth to occur later, this is unlikely to happen in an impoverished environment that was probably responsible for the malnourishment and stunting in the first place. BMI, in contrast, primarily reflects a person's current nutritional status. It varies directly with nutritional balance; a positive balance increases body mass, and a negative balance indicates that the body is drawing on its store of nutrients.

Interest in height and BMI as proxy measures for nutrition has, in the context of research on nutrition and mortality, naturally been directed to their association with morbidity and mortality. Although anthropometric measures had previously been used as predictors of the risks of morbidity and mortality for young children, H. Th. Waaler's (1984) large-scale study of Norwegian adults was among the first to show that height and weight could be used to predict morbidity and mortality risks for adults as well. When Waaler analyzed age- and sex-specific risks of dying by height classes among 1.8 million Norwegian adults between 1963 and 1979, he found that there was a stable relationship between adult height and mortality risk that could be characterized as a J-shaped curve. Within each age/sex group, mortality risk was highest among the shortest group of people and declined at a decreasing rate as height increased. This negative association between height and mortality risk has received much attention in historical research, which has sought to tie the increasing secular trends in the mean heights of different populations to parallel improving trends in their health and life expectancies (Fogel 1986; Floud, Wachter, and Gregory 1990; Komlos 1994; Steckel 1995).

Waaler also found a stable relationship between BMI and mortality risk, which can be characterized as a U-shaped curve. Risk is unresponsive to weight over a wide range, from about 20 to 28 BMI, but it increases sharply at either tail beyond that range. As historical data on weight distribution are harder to come by than data on height, little research making use of this risk–BMI relationship has yet been done. However, in an interesting development, some attempts have been made to use height and BMI simultaneously to predict mortality risk, rather than using each anthropometric measure separately (Fogel 1993, 1994; Kim 1996).

As height represents an individual's early nutrition and BMI his current nutritional status, the resulting height-weight-risk surface makes better use of all nutritional information than the height-risk or BMI-risk curves. Fogel (1994) used such a surface to suggest that the combined effect of increases in body height and weight among the French population can explain about 90 percent of the French mortality decline between 1785 and 1870, but only about 50 percent of the actual mortality decline since then. Another study, using a similar surface to track secular changes in height, weight, and the risks of old-age morbidity in the United States, also has found that factors other than height or BMI explain a larger share of elderly health improvement from 1982 to 1992 than during the period from 1910 to the early 1980s (Kim 1996).

In closing this chapter, it seems appropriate to devote a bit more attention to recent methodologies that may help to shed more light on the relationship between nutrition and mortality decline. For example, in addition to height and BMI, waist-to-hip ratio (WHR) is another anthropometric measure that has gained acceptance as a predictor of chronic diseases, especially for coronary heart disease and non-insulin-dependent diabetes mellitus (Bjorntorp 1992; Hodge and Zimmet 1994; Baumgartner, Heymsfield, and Roche 1995). Although BMI and WHR are generally correlated and are therefore both linked to the risk of chronic diseases associated with obesity, a weakness of BMI is that it does not indicate body composition such as lean body mass versus total body fat, nor is it indicative of the distribution of fat within the body.

By contrast, WHR, as a measure of central adiposity, has been found in a number of studies to have predictive power independent of BMI. J. M. Sosenko and colleagues (1993) have reported that WHR was significantly higher among diabetic women and also among men (although not as markedly as among women), whereas BMI failed to differentiate between diabetics and nondiabetics. Similarly, A. R. Folsom and colleagues (1994) examined Chinese men and women aged 28 to 69 from both urban and rural areas and found that abdominal adiposity – represented by an elevated WHR – was independently associated with cardiovascular risk factors. Although BMI was also associated in a similar direction with most of these risk factors, the mean level of BMI in this study was relatively low, ranging from 20.1 to 21.9 among 4 sex- and age-groups, confirming that WHR is useful as a predictor of cardiovascular disease even among a lean Asian population. S. P. Walker and colleagues (1996) found in a five-year follow-up study of 28,643 U.S. male health professionals that BMI was only weakly associated with stroke risk, but that WHR was a much better predictor even when BMI, height, and other potential risk factors were taken into account. Yet although these studies suggest that there is a strong case for using WHR in conjunction with or perhaps as a substitute for BMI, it should be remembered that data on BMI are often more easily obtained or reasonably estimated, making BMI useful as a predictor or proxy for health or nutritional status in studies involving historical populations or in other situations in which detailed anthropometric data are lacking.

The preceding discussion on the role of adult height as a predictor of morbidity and mortality in middle or old age, combined with the theory that nutrition during the very early stages of life is a major determinant of adult height, suggests the possibility that the roots of some later-in-life diseases can be found very early in life, and intriguing research carried out by D. J. P. Barker and others (Barker 1993, 1994) has made this possibility seem a probability. In focusing on events surrounding birth for explanations of diseases in later life, Barker and his colleagues located United Kingdom birth records from Hertfordshire, Sheffield, and Preston, all of which contained detailed information on the infants. The Hertfordshire records covered births between 1911 and 1930 and included birth weight, weight at 1 year of age, number of teeth, and other details. The records from Sheffield and Preston covered roughly the same period but were even more detailed, and their inclusion of length from crown to heel, head circumference, biparietal and other head diameters, placental weight, and (after 1922) chest and abdominal circumferences allowed the computation of various body proportions. Linking these birth records with those still surviving as adults and with the records of those who had since died made it possible to investigate any relationship between at-birth measurements and health events in later life.

This research, compactly summarized by Barker (1994), has uncovered numerous associations between various birth measurements and disease in later life, including hypertension, excessive levels of blood cholesterol, non-insulin-dependent diabetes, and death rates from cardiovascular disease. Among men, low birth weight and weight at 1 year of age were associated with premature death from cardiovascular disease. Females whose weight was low at birth but above average as adults also experienced increased death rates. Other measurements at birth that indicate slow fetal growth have also been found to predict higher death rates from cardiovascular disease. These include thinness (as measured by the ponderal index – birth weight/length^3), small head circumference, short length, low abdominal circumference relative to head size, and a high placental-weight-to-birth-weight ratio. As slow growth in utero is often followed by slow growth afterward, these findings suggest one pathway through which nutrition, adult height, and mortality in old age may be related (cf. Barker, Osmond, and Golding 1990).

From birth records linked to survivors rather than to death records, Barker and his colleagues were also able to analyze the connection between measurements at birth and chronic diseases or their risk factors among the survivors. Babies who were small for date or with a higher ratio of placental weight to birth weight, both of which indicate undernutrition in utero, were found to have higher systolic and diastolic blood pressure as children and as adults. These findings were independent of, or dominated, the effects of the later-life environment, including the current weight, alcohol consumption, and salt intake of the subjects. The blood pressure of the mother was also found to be a nonfactor. Reduced liver size, as measured by abdominal circumference, was associated with raised serum concentrations of total and LDL cholesterol levels in both men and women. Based on these findings, Barker has suggested that impaired liver growth in late gestation may permanently alter the body's LDL cholesterol metabolism, resulting in an increased risk of coronary heart disease later in life. In both men and women, low birth weight predicted higher rates of non-insulin-dependent diabetes and impaired glucose tolerance.

British birth records have also been useful in establishing a link between infectious disease in childhood and chronic disease in later life. A follow-up study of men from the Hertfordshire records, which recorded illnesses periodically throughout infancy and early childhood, showed that death rates from chronic bronchitis were higher among those who had low birth weights and low weights at 1 year of age (Barker et al. 1991). In addition, S. O. Shaheen and colleagues (1995) have reported that among survivors represented in the Hertfordshire and Derbyshire records, men who had suffered bronchitis or pneumonia in infancy had significantly impaired lung function as measured by mean FEV_1 (forced expiratory volume in one second). These findings support the hypothesis that lower-respiratory-tract infections in early childhood lead to chronic obstructive pulmonary disease in late adult life.

The relationship of maternal (and thus fetal) nutrition – and that of infants – with diseases of later life was one, of course, that McKeown did not examine. That such a relationship seems to exist is one more powerful example of the complex nature of nutrition on the one hand and mortality on the other.

VI.2 Nutrition and Mortality Decline: Another View

The importance of nutrition to the preservation of human health cannot be reasonably denied. However, the extent of its power may have been overstated in recent years. For millions of Americans, "natural foods and vitamins" are seen as almost magical preservers of health, beauty, and longevity. Indeed, claims for the healing properties of nutrients have become an integral part of the post–World War II "baby-boomer" generation's vision of the world. For many, "faith" in the power of proper nutrition is part of a secular religion that comes close to denying the inevitability of aging and death. Vitamin C is considered a panacea one day and beta-carotene the next, as are such foods as broccoli and garlic. With such a cornucopia of natural "medicines," who would ever think that the history of humankind would reveal so much disease and ill health?

Although such popular exaggerations of the benefits of various nutriments are easily dismissed by serious scholars, other more scholarly claims are not. One suggestion dealing with the historical importance of nutrition has received remarkably widespread support in academic circles and, among historians, has become the orthodox explanation for understanding a key aspect of the modern world: increased longevity.

The McKeown Thesis

The classic formulation of this explanation was provided by the medical historian Thomas McKeown (1976, 1979), who argued that the reasons for the decline of mortality in the Western world over the last three hundred years have been largely the result of rising living standards, especially increased and improved nutrition. Equally important, the decline was not the result, as so many had rather vaguely believed, of any purposeful medical or public-health interventions.

Such a theory, of course, was not long confined to historical debates because of its clear policy implications for the allocation of resources in the developing (and the developed) world today. If the historical decline of mortality in the West occurred independently of science and medicine, then the high death rates in the developing world could best be combated by vigorously pursuing higher living and nutritional standards. Not only was money expended on high-technology hospitals and doctors ill spent, but even funds for immunization campaigns were a waste of limited resources. As McKeown put it: "If a choice must be made, free school meals are more important for the health of poor children than immunization programmes, and both are more effective than hospital beds" (McKeown 1979).

This revolutionary theory has a number of emotional and intellectual attractions. First, it constitutes a devastating attack on the legitimacy and claims of societal "authority," represented in this case by the medical profession and, to a lesser extent, the public-health and scientific establishments. The "experts" who claim the right to guide and control society and its inhabitants, based upon their past accomplishments, are revealed as self-deluded, if not as outright frauds. Such a critical position resonates very well in an era characterized by relentless attacks on all types of authority and one in which the delegitimization of social institutions is a daily affair.

What radical social critic could have better put what many regard as an imperious medical profession in its place than McKeown, who wrote (in an attempt to dispel the "erroneous belief" that he was hostile to the medical profession): ". . . if medical intervention is often less effective than most people, including doctors, believe, there is also a need . . . for greater emphasis on personal care of the sick (the pastoral role of the doctor) . . ." (McKeown 1979: ix). (Later in the same work [p. 112], he stated that the key advance in personal medical interventions in the past was the control of cavities by the dental profession.)

Second, McKeown's view of the nature of health is also very congenial to the post–World War II generation's view of life, death, and aging: "Most diseases, including the common ones, are not inevitable. . . . [Modern medicine is based on a different idea.] It assumes we are ill and must be made well, whereas it is nearer to the truth to say that we are well and are made ill" (McKeown 1979: 117–18). In addition, his work has an appeal to earlier generations, especially his claim that persons in their 70s who lived a healthy life would be as vigorous and capable as they were in their 30s! What the thesis seems to promise is eternal youth, if not eternal life, completely under the control of the careful and concerned individual without the messy intervention of doctors and other self-proclaimed experts. Such a view, when coupled with impressive scholarship, is very persuasive by itself, and the fact that the medical profession had indeed severely exaggerated its performance historically has also made it easier for many to embrace the argument.

Third, the McKeown thesis can be and has been profitably used by people representing a wide variety of political and ideological positions. In the West, it can be aimed at established authority figures in attempts to delegitimize basic Western institutions. The supposed accomplishments of science, medicine, and the public-health service, which bolster the West's claims to superiority as a civilization, can be denied.

For leftists in the developing world, the McKeown thesis could free their countries from dependence on Western medical and scientific expertise and technology. Better a homegrown political upheaval with land redistribution than a measles shot or a CAT scan machine. Since good health is promised as a natural by-product of a rising standard of living and better nutrition, its eventuality depends on radical politics, not on "imperialistic" science or medicine (Muraskin 1995).

But the Right also has had reasons to be attracted to the McKeown thesis, which lends support to deemphasizing expensive medical care for the "masses," both at home and abroad. If medicine and technology are not the key to lower mortality, why waste money on them in a time of escalating, and certainly threatening, medical costs? If the poor are underserved by doctors, maybe they are better off than their richer neighbors who are plagued by ineffective medical personnel and their iatrogenic interventions.

Despite the appeal of the McKeown thesis to so many political sectors, there are a number of reasons for criticism, not the least among them that McKeown reached his conclusion about the importance of nutrition in the mortality decline through the process of elimination of possible alternatives. If all the other possibilities are false, then the last standing explanation is the correct one.

Almost all of those who have questioned McKeown's argument have been struck by this methodology. For such a procedure to be effective, it is mandatory that all possible alternatives be presented and adequately explored. But this is impossible because history, science, and medicine are full of unknowns. Thus, although such a procedure may be suggestive and help generate a useful hypothesis, strong direct evidence must be presented to make an adequate case.

McKeown postulated that there were only five possible reasons for the decline of mortality in the West:

1. Medical intervention (including immunizations).
2. Public-health measures (for example, better sanitation, water purification, and food hygiene).
3. Changes in the nature and virulence of microorganisms.
4. Reduced contact with microorganisms.
5. Increased and improved nutrition.

He then proceeded to argue that until recently, it was assumed that "medical" interventions were the primary cause of increased life expectancy. This term, however, tended to include both personal medical care and public-health policies – two types of activities that must be separated for purposes of analysis.

The main thrust of his argument was aimed at the claims of personal medical care. He demonstrated that the decline in mortality was well advanced long before medical science developed effective forms of disease therapy or prevention. His proofs were elaborate and rather convincing. Unquestionably, McKeown has clearly, and probably permanently, deflated the claim that personal medical care played a major role in increasing longevity in the West. But such a claim could exist only because of the ahistorical nature of most public discourse in the West.

If most laypeople and doctors felt that modern medicine had performed miracles, very few of them, if challenged, would have insisted that medicine's effectiveness went back much before the advent of antibiotics in the 1940s or sulphonamides in the 1930s. Although there were great scientific minds, like Robert Koch or Louis Pasteur, in the late nineteenth century, there was no adequate control over infectious diseases. For most, modern medicine was probably viewed as so miraculous specifically because the nineteenth century (and the first third of the twentieth century) was seen as so bleak and unhealthy. Thus, McKeown's debunking of a tendency to view earlier medicine with lenses of the present was, in fact, an easy victory.

His larger thesis, however, required similar attacks on other possible causes of mortality decline. He disposed of the importance of immunizations (which he grouped with personal medical care rather than public-health activities) by arguing, on the one hand, that they occurred significantly later than the decline in mortality for the various diseases they were created to treat[1] and, on the other hand, that vaccinations did little or no good in the absence of better nutrition.

He gave considerably more credit for the lowering of mortality to public-health measures, especially clean water and safe food, than he gave to personal medical care, but as with immunizations, he argued that these measures were put in place long after mortality had already significantly declined.

McKeown next considered the possibility that a decline in the natural virulence of microorganisms or a decrease in exposure of the general population to dangerous pathogens led to the decline of mortality in the West. His discussion of these possibilities, however, was far more cursory than his argument about the ineffectiveness of personal medical care. In short, his convincing argument against much of a role for clinical medicine in the improvement of life expectancy did not carry over into an analysis of the other possibilities he set forth. Thus, one could argue that McKeown presented a fascinating and stimulating hypothesis that somehow came to be understood as an established truth.

Attacks on the McKeown Thesis

One of the most interesting assaults on the credibility of the McKeown thesis originated with a Danish anthropologist, Dr. Peter Aaby. His extensive research on measles mortality in Guinea-Bissau, West Africa, provided a unique opportunity for such an attack because McKeown used the World Health Organization's (WHO) position on measles to support his argument for the importance of nutrition over immunization in the decline of mortality. McKeown (citing WHO) claimed that vaccination of an underfed child is not protective, whereas a well-nourished child does not need vaccination to survive the disease. In other words, another bowl of rice is preferable to a measles shot.

Aaby claimed to have shared such a view until his discoveries in Guinea-Bissau no longer supported it. He wrote that there are three general ways of looking at measles mortality:

1. Emphasizing "host factors" (malnutrition, age of infection, genetics).
2. Emphasizing "transmission factors" (greater exposure, more virulent strains, synergism between infections).
3. Emphasizing "treatment and medical care factors" (ineffective treatment or neglect of effective treatments). (Aaby 1992: 155–6)

Certainly, most of the emphasis has been on host factors. In the case of measles, which kills about one and half million children a year in the developing world, "[t]hose who die are seen as somehow weaker than other individuals," and "severe measles has been explained particularly with reference to [host factors such as] malnutrition, the age at infection, genetic susceptibility and underlying disease" (Aaby 1992: 156).

Such an interpretation, Aaby maintained, easily leads to the implication that severe measles is a disease of the weak who are on the road to death, if not from this disease then from another. The implication for policy is that little is accomplished by immunization because of the phenomenon of "replacement mortality." Thus, the solution to preventing death from measles is not to fight the disease but to fight general malnutrition. Clearly, this is a position strongly supportive of McKeown's own view.

Aaby, however, found that the situation in Guinea-Bissau was not so supportive. The children who died were not noticeably different in nutritional level from those who survived. Moreover, the general level of nutrition in the country was quite adequate – better, in fact, than in countries (such as Bangladesh) with much lower rates of mortality from measles. Instead of nutrition, according to Aaby, the factor differentiating those who died and those who did not was whether the child was an "index case" or a "secondary case" in a family.

Index cases (the first persons infected) were usually exposed outside the home. By contrast, secondary cases were usually the siblings of those index cases who had brought the infection into the home. The difference in mortality risk between the two groups was striking, with secondary cases much more likely to succumb to the illness. The apparent reason for the disparity was that the index cases had experienced much less exposure to the virus (contracted in social interactions outside the home) than the secondary cases – who were continuously exposed by actually living with an infected sibling. The key, according to Aaby, was not nutritional status in the face of measles, but rather the degree of exposure to the illness.

Aaby also compared rates of measles mortality between different countries. He found that Bangladesh had significantly lower rates than Guinea-Bissau despite poorer levels of nutrition. But in Guinea-Bissau, fully 61 percent of the children under 3 years old were secondary cases (with the case fatality rate [CFR] a horrifying 25 percent), whereas in Bangladesh, secondary cases were only 14 percent, and the CFR was 3 percent.

The reason proposed for the extreme variance was that "[l]arger families and a high incidence of polygamy mean[t] that children in West Africa h[ad] a much greater risk of becoming secondary cases . . ." because there were large numbers of young, susceptible siblings living at home (Aaby 1992: 160). This factor also seemed to account for the lower mortality rates Aaby found among East Africans when compared to West Africans – that is to say there were fewer wives and fewer children in East Africa.

In addition, Aaby observed that the severity or mildness of the disease in the index case correlated with the likelihood of mortality and secondary cases. In other words, the more severe the index case, the higher the rate of death in secondary cases; and the milder the index case, the lower the death rate of subsequent cases. There also seemed to be an "amplification phenomenon" in which severe cases brought into a household (or institution or military camp) created waves of infection, each more severe than the last.

The Guinea-Bissau research also uncovered other unexpected transmission factors that correlated with significantly higher levels of measles mortality. The most surprising finding was that infection by a member of the opposite sex produced a noticeably greater chance of death than infection by someone of the same gender. Studies in other developing countries have found a similar cross-gender transmission factor, and Aaby, doing historical research, discovered that such a situation existed in Copenhagen at the turn of the twentieth century (Aaby 1992: 162).

In addition, this concentration on transmission factors, rather than host factors, brought to light a "delayed impact," which constitutes a long-term measles effect. Most studies deal with acute measles death (that is to say within one month of the appearance of the rash). But in Guinea-Bissau, "children who had been exposed to measles at home during the first six months of their lives had a mortality [rate] between ages six months and five years which was three times higher than community controls (34 percent vs. 11 percent)" (Aaby 1992: 164).

When background factors were taken into account, "the mortality hazards ratio was 5.7 times higher . . . among the exposed children than the controls" (Aaby 1992: 164). The "delayed excess mortality" existed both among children who had measles and among those without clinical symptoms. In light of this finding, it seems possible that the total mortality from measles infection is far higher in the developing world than is assumed.

Aaby has speculated on the possible meanings of this delayed mortality. One is "some form of persistent infection and immuno-suppression" at work. In addition, community studies in Nigeria, Guinea-Bissau, Senegal, Zaire, Bangladesh, and Haiti have shown that children immunized against measles have experienced major drops in overall mortality in the years after vaccination:

> In all studies the reduction in mortality was greater than expected from the direct contribution of measles death to over all mortality. For example, in Bangladesh, the reduction in mortality between 10 and 60 months of age was 36% although measles accounted only for 4% of all deaths among the controls . . . Thus measles immunization seems to be highly effective in preventing both acute and delayed mortality from the disease. (Aaby 1992: 167)

Aaby believed that what he learned from Guinea-Bissau and other developing countries sheds light on the historical decline of mortality in the West. He suggested that transmission factors, rather than improved nutrition (or age of infection), can best account for the decline of measles mortality in the developed world. In summing up his detailed argument he wrote:

> It seems likely that the most important causes of measles mortality decline were social changes which diminished the risk of intensive exposure within the family. Chief among these were the fall in family size [that is to say fewer susceptible siblings at home to infect] and greater social contact among young children which increased the risk [and benefits] of infection outside the home. Furthermore, the continual reduction in the numbers of fatal cases has reduced the risk of transmission of measles in a severe form [and thus eliminated the amplification effect]. (Aaby 1992: 170–1)

This conceptualization of the decline of measles mortality in terms of transmission rather than nutrition, Aaby believed, provides a model that can be used for other diseases as well. For example, he maintained that McKeown severely underestimated the importance of smallpox vaccination to the decline of mortality in the West, and he suggested that smallpox (which struck the well nourished and malnourished alike) may have had the same kind of delayed mortality effect as measles. Thus, people weakened by smallpox may have been more vulnerable to tuberculosis (TB) or other diseases. He speculated that the decline of smallpox may have led the way to the decline of TB, and the latter, McKeown maintained, was the key to the decline of mortality in the developed world (Aaby 1992: 178).

The significance for us of Aaby's work is that transmission factors such as severity of exposure, size of family, cross-sex infection, and delayed mortality were not discussed and then successfully eliminated by McKeown's analysis. Thus, it would seem that whether Aaby is right or wrong about other diseases, or even about the decline of measles in the West, he has made the point that McKeown's nutrition thesis is vulnerable and, perhaps, has been embraced too readily.

A second attack was made by Simon Szreter, a specialist in British history, who challenged McKeown's work not simply on its relevance to other countries but even on its accuracy for Great Britain. He stated his thesis very succinctly:

> It will be urged that the public health movement working through local government, rather than nutritional improvements through rising living standards, should be seen as the true moving force behind the decline of mortality in [the late nineteenth century]. (Szreter 1988: 2)

Szreter pointed out that although McKeown explicitly recognized the positive role that hygiene improvements in public-health measures involving municipal sanitation played in saving lives, he nevertheless maintained that "their impact and effects were . . . very much of a secondary and merely reinforcing kind" (Szreter 1988: 3) compared to better nutrition. It is interesting to note that Szreter believed that the effect of McKeown's emphasis on nutrition and his "devastating case against the pretension of the 'technocratic' section of the post-war medical profession" has led to the belief that "organized human agency in general had remarkably little to do with the historical decline of mortality in Britain . . ."(Szreter 1988: 3).[2]

This belief, in turn, led Szreter to criticize McKeown for his failure to carefully assess "the *independent* role of those socio-political developments which were responsible for such hard-won improvements as those in working conditions, housing, education, and various health services" (Szreter 1988: 11). Moreover, given McKeown's emphasis on the role of food it might have been expected that he would look closely at the history of the fight against food adulteration, but he did not. Rather, McKeown treated political, social, and cultural changes that were also arguably important in the mortality decline as a simple "automatic corollary of changes in a country's per capita real income" (Szreter 1988: 11).

According to Szreter, though, in the last third of the nineteenth century, after the "heroic age" of public-health activism in Britain had ended without much success on the national level, countless underpaid and overworked officials fought bitterly but successfully for better sanitation and increased disease prevention at the local level. There was nothing automatic about either their struggles or their victories – though historians, said Szreter, have missed the importance of such activities by focusing on the apparent ineffectiveness of the *national* sanitation reform movement during the middle decades of the nineteenth century and the decline of that movement after 1871 (Szreter 1988: 21–5).

McKeown, however, contended that the key to the decline of mortality in Britain was the decline of TB, which is caused by an airborne pathogen that does not respond to public-health measures but does respond to improved nutrition, and that, in any event, the decline of the disease predated effective medical or public-health measures. In addition, he alleged that TB was in decline before most other major diseases. This chronology is important, because if TB declined after public-health interventions, or if other diseases declined first, then those previous events, rather than improved nutrition, might account for the fall in TB mortality.

McKeown claimed that TB declined in Britain from 1838 onward (that is to say quite early). However, Szreter contended that there was actually a fluctuation in TB mortality, which rose once more after 1850 and did not decline again until after 1866–7. Moreover, Szreter, like Aaby, pointed out that smallpox mortality had declined considerably earlier than TB; thus, even if tuberculosis had started to decline as early as 1838, McKeown would still have underestimated the possible effects of that prior decline on tuberculosis mortality (Szreter 1988: 15).

In addition, McKeown placed his emphasis on the decline in airborne diseases (as opposed to water- and foodborne diseases) because airborne diseases were not amenable to public-health interventions. Thus, their decline would seem to indicate an alternative source of amelioration. However, the airborne disease category that McKeown highlighted included not only TB, which did decline, but also a composite group – bronchitis, pneumonia, and influenza – that constituted the second most important cause of death in the mid-nineteenth century. That group of airborne diseases *increased* until after 1901, becoming the single most common cause of death and a greater killer than TB had been in 1850 (Szreter 1988: 13).

According to Szreter, one of the major effects of dividing the airborne diseases into two categories – TB and bronchitis/pneumonia/influenza – is that when the increased mortality of the latter group is set against the lower mortality of the former, it leaves the decline in food- and waterborne diseases as the most important reason for the decline of mortality, which does not support McKeown's argument. Yet Szreter pointed out that the almost complete elimination of smallpox, cholera, and typhoid during the late nineteenth century is proof of the effectiveness of public-health interventions, and that the rise of mortality for the bronchitis/pneumonia/influenza group "may well be evidence that in those areas . . . where preventive legislation and action was *not* forthcoming," problems occurred (Szreter 1988: 27). It is significant that clean air was an issue neglected by Victorian reformers, and the resulting urban smog probably goes far to help explain the high incidence of respiratory disease.

Szreter also indicated that infants did not benefit from the late-nineteenth-century decline of mortality in Britain; yet, after 1901, infant mortality fell rapidly. This reduction of infant mortality required the intervention of social services and the willingness of families to allow middle-class social workers to enter homes to instruct in hygienic food preparation (Szreter 1988: 28–31).

Thus, for Szreter, "[t]he invisible hand of rising living standards, conceived as an impersonal and ultimately inevitable by-product of general economic development, no longer takes the leading role as historical guarantor of the nation's mortality decline" (Szreter 1988: 34–5).

A third attack on the McKeown thesis comes from Leonard Wilson, an American historian. If Szreter argued that McKeown exaggerated the significance of the decline in TB mortality, Wilson directly challenged McKeown on the reason for TB's decline, which Wilson attributed not to improved nutrition but rather to segregation of those who had the disease.

In support of his position, Wilson highlighted a fact that exposes one of the more glaring weaknesses in McKeown's argument: Tuberculosis was widespread among persons of the upper classes, who were, of course, the most likely to be well nourished. McKeown, however, claimed that despite adequate nutrition, their defenses were overwhelmed by constant contact with the lower classes – among whom the bacteria was ubiquitous. Wilson pointed out that the problem with this line of reasoning is that it acknowledges that the key to infection for the upper classes was their degree of exposure, which is one of the possible alternatives to the theory of improving nutrition (Wilson 1990). Thus, at the very least, the McKeown thesis turns out to be a dual theory of the decline of TB: a nutrition theory for the poor and an exposure theory for the rich, which seems to render the nutrition thesis considerably less persuasive.

The thesis that Wilson advanced is that the decline of TB mortality was closely linked to the degree to which individuals with TB were segregated during the periods they were most infectious. He argued that in Great Britain the provision of poor relief in workhouses (rather than at home) and the establishment of sanatoria led to a decline in the TB death rate compared to other societies that allowed infectious individuals to live freely in the community in close contact with their families. He contended that McKeown underestimated the importance of these segregating institutions because most individuals spent only limited time in them, and they did not cure individuals with the disease. But Wilson suggested that some segregation, although less helpful than a lot of separation, was still better than none and was sufficient to account for the declining mortality rate. The failure to cure tubercular individuals, although a tragedy for them, was less important than preventing transmission to others.

To test this thesis, Wilson compared the experience of a number of countries and ethnic groups. He found, for example, that Ireland experienced both declining food prices and rising incomes in the years after 1870, but experienced no significant decline in TB mortality.

Yet during the same period, Ireland did enjoy a decline in the typhus death rate, which no one claims was nutritionally related. Typhus-infected individuals were segregated and the contagion was controlled. By contrast, tuberculosis victims, after being reduced to poverty, as were almost all TB victims, were given home relief, which allowed them to live surrounded by family members whom they continued to infect. But in England, in contrast to Ireland, relief was restricted to poor-law infirmaries and workhouses, which kept infectious individuals out of the community and away from their families during the period when they were most intensively infectious. Those segregating institutions also taught the infected how to dispose of their sputum and lower the danger of spreading the infection when they were again free to go home (Wilson 1990: 384).

According to Wilson, before the advent of antibiotics, the segregation of contagious individuals was a necessity if diseases like TB or typhus were to be controlled. He pointed out that leprosy also declined, in both England and continental Europe, with the isolation of lepers. An exception, however, was Norway, where lepers were not segregated, and there the disease not only failed to decline but actually increased during the nineteenth century (Wilson 1990: 384–5).

Wilson accused McKeown of dismissing the importance of the discoveries of Koch and others in the decline of tuberculosis mortality because no therapies came out of those scientific breakthroughs for generations. Such a view, he asserted, ignores the fact that many nations and municipalities instituted segregation and isolation procedures soon after the cause of TB was discovered. For example, in New York City after 1889, the Health Department emphasized the danger of contagion and pushed for sanitary disposal of sputum, disinfection of rooms, and the opening of special hospitals for TB patients. Vigorous policing helped maintain the long and steady decline of tuberculosis in the city from 1882 to 1918, at which point three large TB hospitals were built.

Thus, Wilson argued that the decline in tuberculosis was not the result of a rising standard of living but rather of reduced opportunities for patients to spread the infection, and he pointed out that the recognition of the importance of segregation came directly from Koch's discoveries (Wilson 1990: 381).

In another study by Wilson, this time of tuberculosis in Minnesota, he was able to look directly at the effect of standard of living on the decline of the disease and to test the relationship between nutrition (or at least standard of living) and TB in a kind of "natural laboratory" which existed in that state.

For many decades, Minnesota had the reputation of having a remarkably healthy climate – with a very low tuberculosis rate. This changed as European immigrants reached the state, many of them suffering from the disease. The Irish immigrants had the highest rate – in keeping with conditions in their native land, where home relief allowed ill individuals to remain with their families. In Minnesota, the Irish still continued to live at home if infected and, consequently, infected their relatives. Scandinavian immigrants also had high rates of tuberculosis, as did the countries from which they came. However, German immigrants had a low rate of TB, similar to conditions in their homeland.

These different groups settled in Minneapolis, where their social and economic conditions were remarkably uniform. There was no major difference in their standard of living, only in their TB rates, which reflected their countries of origin, not their current conditions. What ultimately brought those rates down for the Irish and Scandinavians was not better food and housing but the decision to build sanatoria and segregate infectious individuals (Wilson 1992).

Thus, Wilson argued, McKeown ignored the key role played by public-health measures in lowering the TB death rate by finding the source of infection and working to prevent its transmission. Going beyond Szreter, Wilson suggested that medical men, from Koch down to doctors in the sanatoria, were vital elements in this process.[3]

The scholarly articles of Wilson, Szreter, and Aaby go a long way toward a successful undermining of the claims that McKeown has made about the pivotal role of nutrition in the decline of mortality in the West. Their arguments have been significantly advanced by the publication of Anne Hardy's book, *The Epidemic Streets: Infectious Disease and the Rise of Preventive Medicine, 1856–1900* (1993), a detailed study of disease in London during the last half of the nineteenth century. Hardy looked intensively at the history of eight major infectious diseases of the period (whooping cough, measles, scarlet fever, diphtheria, smallpox, typhoid, typhus, and tuberculosis) but did not restrict herself to the relatively superficial level of citywide sources. She focused instead on the district level, and on many occasions provided elaborate quantitative analyses of disease incidence street by street in particularly unhealthy areas. What she illustrated is the incredible complexity of the disease situation that broad-based national and city sources obscure. Hardy skillfully integrated quantitative and qualitative materials, and by doing so, enabled the reader to appreciate the immense amount of ambiguity and confusion involved in questions of disease etiology.

Hardy's discussion required her to investigate the myriad social, cultural, economic, political, and biological factors that influenced the morbidity and mortality rate for each disease. For example, tuberculosis rates were determined by the nature and location of housing, the extent of overcrowding, culturally shaped fears of fresh air, medical and folk-nursing practices, occupational hazards, class-based food preferences, and the synergistic effects of simultaneous infections – to name just a few.

Hardy also discussed "high risk" occupations in which workers were exposed to filth and foul air in closed and unventilated rooms. These included not only tailors and furriers but also such well-paid (and well-fed) workers as printers and clerks. The growth, decline, and geographic concentration of different trades directly influenced the local TB rates. Popular fears of fresh air and night chills led to nursing practices that kept the sick in closed rooms where family members were exposed to concentrated doses of pathogens. Ethnic groups in London (Jewish, Irish, Italian) differed in their cleanliness and general hygienic practices, and in methods of child rearing; this differentially affected their disease rates – independent of their generally inadequate incomes.

Hardy made it quite clear that before investigators can generalize about infectious disease in broad fashion, they must have a firm knowledge of the complexities and subtleties of the ways in which people actually live. In her work, Hardy did what professional historians are best at doing: puncturing those grand theories that social scientists and historical amateurs sometimes produce.

Of course, the confusion and ambiguity of real history is less intellectually satisfying than sweeping theories of cause and effect. Hardy's detailed discussions often make the reader cry out for simplicity and certainty, but neither history nor Hardy is able to oblige. Nevertheless, Hardy was willing to present some broad conclusions from her study. In looking at the major infectious diseases that afflicted the people of London, she commented:

> The epidemiological record clearly suggests . . . that it was not better nutrition that broke the spiral of deaths from infectious disease after 1870, but intervention by the preventive authorities, together with natural modifications in disease virulence, which reduced exposure to several of the most deadly infections. . . . McKeown was a scientist speculating on historical phenomena, . . . and [he was] unfamiliar . . . with historical realities. (Hardy 1993: 292–3)

Like Szreter, Hardy found that the power of preventive medicine did not derive from national governmental policy but was rooted "in the persevering implementation of local measures based on local observation by a body of professional men whose sole responsibility was to their local community" (Hardy 1993: 292). As England's population was "above the critical threshold of under-nutrition below which resistance to infection is affected," it was consciously planned human intervention, not improved nutrition, that was the key to lower mortality rates (Hardy 1993: 292).

In summing up her survey of the eight major diseases she studied, Hardy pointed out the significant difference between those that affected children and those that affected adults. The latter were responsive to preventive actions, whereas the former were not. And it was among the adult diseases that the major drop in mortality in the late nineteenth century actually occurred:

> The impact of smallpox, typhoid and typhus, and (more arguably) of tuberculosis, was significantly reduced through the activities of the preventive administration . . . The reduction in deaths from both typhoid and typhus through diligent local activity and public-health education was a major achievement of the Victorian preventive administration. And for tuberculosis, similarly, general sanitary improvements, in the sense of slum-clearances, new housing, constant water supplies, and the growing emphasis on domestic cleanliness, were probably important.

> Environmental and occupational factors were clearly of considerable importance . . . and the Victorian evidence suggests that these were more potent . . . than . . . nutritionally satisfactory diet. (Hardy 1993: 290–1)

Hardy did not claim that her work ends the historical discussion of the role of nutrition in the decline of infectious disease in the West, but she has clearly moved the debate to a higher level by demonstrating, as did Szreter, that accurate knowledge of infectious disease requires intensive study of local materials.

Investigators of the modern developing world have also contributed to the search for explanations of mortality declines other than that of a rising standard of living and improved nutrition. John Caldwell, for example, has argued for the importance of "cultural, social and behavioral determinants of health" in the developing world (Caldwell 1993: 125). He reported on a major 1985 conference that looked closely at a group of health "success stories," in which poor countries achieved high life expectancy rates despite severely limited resources (for example, the Indian state of Kerala [66 years; per capita income $160–270], Sri Lanka [69 years; $320], Costa Rica [74 years; $1,430], China [67 years; $310]). The conference organizers concluded that "the exercise of 'political will'" by China, and of both "political and social will" by Kerala, Sri Lanka, and Costa Rica were keys to their success. They placed their "emphasis on comprehensive and accessible health programmes with community involvement and the importance of education, especially female schooling" (Caldwell 1993: 126).

Caldwell carried out additional analysis of the conference material, combined it with other data from high-achieving/low-income countries, and found that the strongest correlation with reduced mortality was the educational level of women of maternal age. He contended that the most efficacious of the noncommunist countries have benefited from a historical "demand for health services and education, especially the all-important schooling of girls, arising from the long-existing nature of the societies, particularly the independence of their women, [and] an egalitarian-radical-democratic tradition . . ." (Caldwell 1993: 126). These positive factors, however, although ultimately vital, could not bear fruit until modern health services became available: "When health services arrived here and elsewhere mortality fell steeply because of a symbiotic relationship between an educated independent population determined to use them and make them work, and readily available health services" (Caldwell 1993: 126).

Caldwell concluded from his research that mortality levels similar to those of industrial societies could be reached in the developing world within two decades if all children were educated through elementary school. Education and modern medicine interact as a potent combination. Thus, if Caldwell and his colleagues provided no direct evidence to undermine McKeown's claim that the standard of living and nutrition was the key to the decline of mortality in the West, they nevertheless undercut his argument for the relevance of such a notion for the developing world today.[4]

Clearly, Szreter, Caldwell, Wilson, and Aaby were not in agreement as to the reasons for either past or present declines in mortality. But they did agree on the conclusion that the importance of nutrition and rising standards of living has been substantially overstated. Each one of them provided a provocative and plausible alternative explanation that was either unknown to McKeown and his supporters or given insufficient attention. The work of these researchers and others (Christopher Murray and Lincoln Chen 1993) has kept alive the debate over the role of improving nutrition in the decline of mortality in the West.

William Muraskin

Notes

1. McKeown made a number of exceptions, such as smallpox, polio, and diphtheria antitoxin. However, he claimed that most of the decline in mortality resulted from lower rates of other diseases, especially tuberculosis, which did not have a vaccine or drug therapy until comparatively late.
2. Szreter said that the belief that the public-health movement in Britain had little effect on mortality is even accepted by British historians of public health. Interestingly enough, he believed that the McKeown thesis is clearly not relevant to other countries but only to Britain, and, thus, he does not discuss the "grander" McKeown thesis. He based his view on the work of Samuel H. Preston, whose work, dealing with countries other than Britain, he considered definitive (see, for example, Preston 1975). Szreter characterized Preston's position by saying that "it has been upward shifts in the level of medical technology and services available and the successful introduction of public health measures which has been markedly more significant than rising per capita incomes [i.e., general standard of living] . . . in accounting for their falling levels of mortality" (Szreter 1988: 4).
   Preston's views have not had as far-reaching an effect on the general view of the issue as Szreter believed. In fact, his key research was published in the 1970s, *before* the McKeown thesis became the established view. This is not to say that it is not useful for a critique of McKeown, but only that it has not been as successfully used for that purpose as Szreter believed.
3. Wilson's argument flies in the face of much of the new research on tuberculosis presented in such studies as Linda Bryder's *Below the Magic Mountain: A Social History of Tuberculosis in Twentieth-Century Britain* (1988) and Francis Smith's *The Retreat of Tuberculosis, 1850–1950* (1988). However, most of that work was written under the influence of the McKeown thesis and has a strong antimedicine and anti-public-health (at least insofar as it was represented by sanatoria) emphasis. Interestingly enough, however, Smith saw segregation of infectious individuals in English workhouses as important in the decline of tubercu-

losis – just as Wilson did. Nancy Tomes, in her excellent review of the new tuberculosis literature, commented on the tendency to ignore the importance of the new bacteriological research in creating the concept of disease communicability and preventability. It was, she said, also medical science that created the tuberculin test, a tool that made the tracking of TB possible, thus permitting contemporaries to discover the social and economic conditions that favored the spread of the disease (see Tomes 1989).

4. Whereas Caldwell suspected that maternal education would also explain the decline of mortality in the West during the early twentieth century, he accepted the work of Preston as proving that to be untrue. For Caldwell, the reason for the difference between the West and the developing world was that sufficient effective health knowledge and practical applications to counteract the effects of broad economic forces were simply not available to educated mothers. Fortunately, such knowledge was available for the developing world after World War II. Caldwell was especially impressed with the power of education to convince people that they can and should collaborate to reduce mortality. Such education is "essentially Western education, and it carries a powerful Western pro-science message" that overcomes many of the indigenous beliefs that prevent effective action by parents.

VI.3 ✣ Infection and Nutrition: Synergistic Interactions

The interactions of malnutrition and infection are synergistic, with each modifying the other in ways that cannot be predicted from studying just one condition or the other (Scrimshaw, Taylor, and Gordon 1968). The superimposed infection is more likely to be responsible for nutritional disease than a shortage of food alone. During recovery from infectious disease, however, the quantity and quality of food available is usually the limiting factor. Moreover, the frequency and severity of infections is increased for individuals whose nutritional status is poor. Although this increase depends in part on the social and environmental circumstances frequently associated with malnutrition, more important is the reduced resistance to infection directly associated with nutrient deficiency. This chapter examines the reasons why diseases are often more common and severe in the malnourished and discusses the metabolic and other functional consequences of infections.

Nutrition and Disease Morbidity and Mortality

The high frequency of diarrheal and respiratory diseases among young children in developing countries is both a major contributor to malnutrition and a consequence of lowered immunity in a poor sanitary environment combined with unsatisfactory personal hygiene (Mata 1978; Guerrant et al. 1983; Black, Brown, and Becker 1984). Furthermore, in both developing and industrialized countries, nosocomial infections (those originating in hospitals) are responsible for worsening the nutritional status of patients and thereby increasing overall morbidity and case fatality rates (Gorse, Messner, and Stephens 1989; Scrimshaw 1989).

In children whose nutritional status is poor, episodes of any of the common communicable diseases of childhood tend to be more severe and to have more secondary complications. In Guatemala, 50 percent of children with whooping cough require more than 12 weeks, and 25 percent more than 25 weeks, to recover the weight lost because of the disease (Mata 1978). In addition, there is recent evidence for a striking reduction of mortality after vitamin A supplementation was given to populations of underprivileged children in Indonesia (Sommer, Tarwotjo, Table V1.3.1. *108 Acute infections among 32 children ages 2 to 9 years observed in a "model" convalescent home in Guatemala City for 90 days*

Disease	Total no. of episodes
Infectious hepatitis	2
Measles	2
Bronchopneumonia	3
Bronchial asthma and asthmatic bronchitis	15
Gastroenteritis	5
Amebiasis	9
Parotitis	4
Chicken pox	3
Gonococcal vaginitis	11
Purulent otitis media	4
Acute tonsillitis	7
Upper respiratory infection	15
Fever of unknown origin	9
Urinary infection	1
Impetigo and cellulitis	13
Skin allergy	5

Source: Unpublished INCAP data.

Hussaini et al. 1983, Sommer, Tarwotjo, Djunaedi et al. 1986) and India (Rahmathullah et al. 1990) and, in general, to poorly nourished children who acquire measles (Barclay, Foster, and Sommer 1987; Hussey and Klein 1990; Coutsoudis et al. 1992).

Even under relatively favorable institutional conditions, morbidity rates for children or the elderly can be very high. Table VI.3.1 lists 108 infections over a 90-day period among 32 well-fed children 2 to 9 years old in late recovery from malnutrition in a model convalescent home in Guatemala City (unpublished data from the Institute of Nutrition of Central America and Panama [INCAP], Guatemala City, Guatemala). Similar reports have come from orphanages in other countries. Under the less favorable conditions of open pediatric wards in developing countries, cross-infections among children are increased by low resistance and add to the duration of morbidity and to mortality rates.

Malnutrition, Infection, and Growth

Many studies confirm a reciprocal relationship between morbidity from diarrhea and other infectious diseases and growth (e.g., in the Gambia, Rowland, Cole, and Whitehead 1977; in Uganda, Cole and Parkin 1977; in Mexico, Condon-Paloloni et al. 1977; in Bangladesh, Black et al. 1984; in Sudan, Zumrawi, Dimond, and Waterlow 1987). Significant negative correlation of young child growth with diarrheal and other infections is a constant finding (e.g., Kielman, Taylor, and Parker 1978; Lutter et al. 1989; Martorell, Rivera, and Lutter 1990). In children whose nutritional status is marginal, measles will strongly reduce growth in ensuing weeks (in India, Reddy et al. 1986; in Kenya, Duggan and Milner 1986; in Guatemala, Mata 1978). Even immunizations can affect the growth of poorly nourished children (Kielman et al. 1978). However, in the Guatemalan, Colombian, and Mexican studies, the negative effect of diarrhea on growth was prevented by a nutritious supplement. Thus, when the diet is adequate, the impact of acute infections on growth is usually transient (Lutter et al. 1989).

The Impact of Malnutrition on Resistance to Infection

It appears that every known nutrient deficiency can affect disease resistance if it is sufficiently severe, and this is also true for many nutrient excesses. A review of the logarithmic increase in research on nutrition and immunity clearly reveals that the same common mechanisms are affected by many different nutrients. The main mechanisms are still those identified in the 1968 World Health Organization (WHO) monograph, *Interaction of Nutrition and Infection* (Scrimshaw et al. 1968). These include physical barriers that depend on epithelial and other tissue integrity; phagocytosis; cell-mediated immunity; some forms of nonspecific resistance; and antibody formation. Recent advances in immunologic research and understanding have greatly enhanced knowledge of the mechanism of nutritional effects on both humoral and cell-mediated immunity.

One class of lymphocytes, the B cells, develop immunoglobulins or antibodies as integral proteins on their surface. The immunoglobulins are divided into five classes, A, D, E, G, and M, which vary in their susceptibility to nutritional deficiencies. Some lymphocytes function as memory cells for the production of large numbers of specific antibody-containing cells when the host is exposed to subsequent challenge or infection of the same kind. There is evidence that large numbers of these memory cells are attracted by the mammary gland when the mother develops an infection and contribute appropriate antibodies to breast milk (Hansen 1992).

Cell-mediated immunity offers a number of different stages in T-cell differentiation and function that can be affected by nutrient deficiencies. Both B cells and T cells recognize antigens and other mitogens, but the latter do not secrete antibodies. Some T cells have helper or suppressor cell functions through membrane surface receptors. Another subpopulation is that of the natural killer (NK) cells that function even before the other T cells respond and that can lyse particular cells without being previously sensitized. NK cells may be activated by interferon and influenced by eicosanoid-derived essential fatty acids (Byham 1991). The proliferation of both T and B cells in response to mitogens is impaired with various deficiencies that may include that of vitamin B_6 in the elderly (Meydani et al. 1990).

Humoral Immunity

Humoral immunity is lost in kwashiorkor (Olarte, Cravioto, and Campos 1956; Budiansky and da Silva 1957; Reddy and Srikantia 1964; Brown and Katz 1966), but once dietary treatment is initiated, antibody formation is restored (Pretorius and de Villiers 1962). M. G. Wohl, J. G. Reinhold, and S. B. Rose (1949) studied the antibody response to typhoid immunization in a Philadelphia hospital and found a markedly slower response in adult patients with albumin levels below 4.0 grams (g) per 100 milliliters (ml) and an improvement when those patients were given a protein supplement. R. E. Hodges and colleagues demonstrated conclusively that severe pantothenic acid and pyridoxine deficiency can interfere with antibody response to typhoid antigen, but it required a combination of deficient diets and metabolic antagonists to each of the vitamins (Hodges et al. 1962a, 1962b). Correcting the deficiencies returned the responses to normal. In experimental animals, it has been shown that sufficiently severe deficiencies of almost any essential nutrient can interfere with antibody formation (Scrimshaw et al. 1968). Although few of these experimental studies have public-health significance in human populations, they may be relevant to patients with metabolic and neoplastic disease and to some therapeutic regimens.

Phagocytosis

Phagocytic cells include both circulating leukocytes and the fixed macrophages in the reticuloendothelial system. A reduced phagocytic response with severe protein malnutrition was documented in the previously mentioned WHO monograph (Scrimshaw et al. 1968), but no other nutrients were mentioned in this regard. The phagocytic response in marasmus was reported to be normal, presumably because in marasmus (but not in kwashiorkor) amino acids are mobilized from skeletal muscle and are available for protein synthesis. Since 1968, much has been learned about nutritional interference with phagocyte function. Table VI.3.2 lists the antimicrobial systems that have been identified in the neutrophil (Stinnett 1983). Phagocytes contain a collection of neutral proteases and lysozyme, an enzyme that hydrolyzes bacterial walls, as well as lactoferrin. Most of these mechanisms for killing infectious agents have been found susceptible to deficiency of one or more specific nutrients.

Table VI.3.2. *Antimicrobial systems in the neutrophil*

Oxygen dependent	Oxygen independent
Myeloperoxidase dependent	Acid environment
MPO plus halide plus H_2O_2	Cationic proteins
Myeloperoxidase independent	Lactoferrin
Hydrogen peroxide (H_2O_2)	Lysosomal hydrolases
Hydroxyl radical (OH·)	Lysozyme proteases
Singlet oxygen ($^1O_2$)	Neutral proteases
Superoxide anoin (O_2·)	Sequestration of phagocytic vacuole

Source: Stinnet (1983).

Delayed Cutaneous Hypersensitivity

The delayed cutaneous hypersensitivity response is a sensitive indicator of poor nutritional status. It is based on a combination of sequential processes involving sensitization of T lymphocytes against a macrophage-processed antigen, the production of soluble mediators (lymphokines), and an inflammatory response when sensitized T cells recognize and interact with an intradermally injected antigen. Lymphokines released at the local site produce the dermal induration characteristic of the response.

Children with a subnormal rate of growth due to protein deficiency show an impaired delayed hypersensitivity response to tuberculin (Jayalakshmi and Gopalan 1958; Harland 1965; Chandra 1972, 1977; Neumann, Stiehm, and Swenseid 1977). This is illustrated in Figure VI.3.1, in which serum transferrin serves as an indicator of protein depletion (Chandra and Newberne

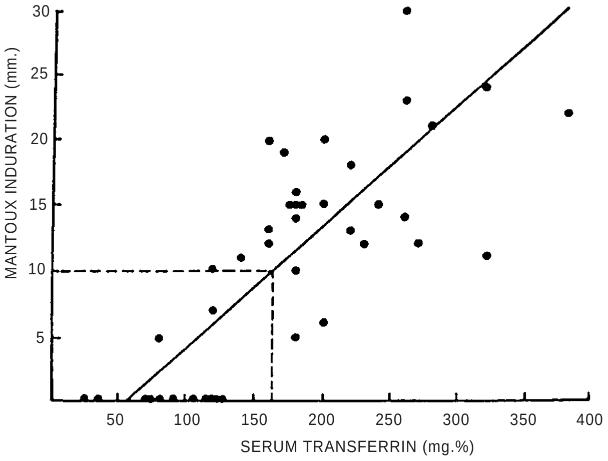

Figure VI.3.1. Cutaneous delayed hypersensitivity to 5 t.u. tuberculin related to serum transferrin concentration in patients with pulmonary tuberculosis. A positive Mantoux test, induration 10 mm, was generally observed in individuals with serum transferrin level of ≥ 162 mg. Patients studied through the courtesy of Dr. H. B. Dingley, Tuberculosis Hospital, New Delhi. (From Chandra and Newberne 1977.)

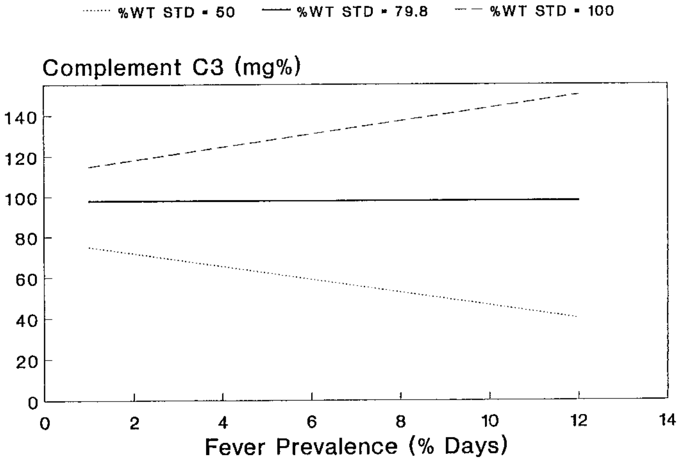

Figure VI.3.2. Serum C3 levels correlated with infection-morbidity indicated by the number of days of fever. Three weight categories in reference to the standard are shown. In well-nourished children, C3 concentration increases with infection. In the undernourished, C3 levels generally decrease. (From Kielman et al. 1976.)

1977). The failure to produce a response in malnourished children with the strong sensitizing agents 2,4-dinitrochlorobenzene and 2,4-dinitroflurobenzene has been reported by many authors (e.g., Smythe et al. 1971; Feldman and Gianantonio 1972; Chandra 1974; Schlesinger and Stekel 1974; Dutz et al. 1976; Smith et al. 1977). The case is similar with malnourished adults (Law, Dudrick, and Abdou 1973). Patients with iron-deficiency anemia also have a reduced delayed cutaneous hypersensitivity (Joynson et al. 1972).

Complement

Complement is a heat-labile opsonin in normal serum that can promote the lysis of other cells. It is a system of 17 protein compounds in two different pathways that sequentially activate specific proteases that deposit complement-3 on a particle to make it capable of being phagocytositized or lysed (Stinnett 1983). Complement-3 is susceptible to protein–energy deficiency (Sirisinha et al. 1973; Chandra 1975; Suskind et al. 1976; Neumann et al. 1977). Figure VI.3.2 presents data from India relating complement response to percentage of standard weight (Kielman et al. 1976).

Iron Withholding

Although, as indicated previously, iron deficiency is associated with increased morbidity and mortality from infections, it is a paradox that biological mechanisms for withholding iron from infectious agents appear to be an important means of inhibiting their replication. Both circulating transferrin and lactoferrin released by macrophages have an affinity for iron that is greater than that of bacterial sideophores. With infection, a rapid transfer of circulating iron to an intracellular compartment is mediated by the cytokine interleukin (Keusch 1990).

Other Mechanisms

Although included for completeness, nutritionally induced changes in tissue integrity are least important in explaining increased susceptibility to infection. Nevertheless, epithelial tissues and mucous membranes are barriers to the direct penetration of infectious agents. Examples are the dermatosis associated with kwashiorkor and pellagra, the spongy gums of scurvy, and the epithelial lesions of vitamin A deficiency. When the skin is affected, the epithelial layers of the respiratory and intestinal tracts are usually also affected. Wound healing, fibroblast response, and collagen formation are other processes affected.

The clearest evidence that intestinal flora play a role in resistance to some infections is the decrease of *Escherichia coli* infections among breast-fed infants (Ross and Dawes 1954; Gyllenberg et al. 1957; György, Dhanamitta, and Steers 1962). Endocrine changes, whether the result of nutritional or other causes, can also affect any of the aforementioned resistance mechanisms.

Antagonisms between Nutrient Deficiencies and Infections

The 1968 WHO monograph (Scrimshaw et al.) reported 40 studies in experimental animals in which diets that were severely deficient in one or more B vitamins inhibited infections, compared with 70 in which similar diets worsened them. In 14 studies examining low-protein diets, antagonism was observed and compared with 94 in which synergism was the outcome. The 3 studies that involved iron deficiency reported a synergism between iron deficiency and hookworm in rats, dogs, and cats. Because the degree of deficiency in human populations always seemed to be associated with synergism, these reports of antagonism between malnutrition and infection in some experimental studies were not deemed to be important to public health.

There have, however, been studies that reported giving large doses of iron to severely iron-deficient children with kwashiorkor (McFarlane et al. 1970; Murray et al. 1978b) and to severely anemic refugees in Somalia (Bullen 1976; Murray et al. 1978a), which resulted in overwhelming infections. Moreover, the principle of withholding an essential nutrient from an infectious agent or a tumor cell underlies modern antibiotic therapy and chemotherapy.

How Infections Worsen Nutritional Status

Anorexia

Even when efforts are made to maintain a constant food intake during illness, anorexia will generally lead to a consistent decrease in food consumption even with infections as mild as that produced by immunization against yellow fever (Gandra and Scrimshaw 1961). Anorexia reduces the intake not only of protein and calories but also of most other nutrients. This effect contributes to precipitating clinically evident deficiencies of any nutrients that are already limiting.

Cultural and Therapeutic Practices

When young children experience febrile infections and diarrhea there is a strong tendency of the caregiver to withdraw solid food. Commonly, a thin starchy or sugary gruel that is low in protein and energy density is substituted (Hoyle, Yunus, and Chen 1980; Khan and Ahmad 1986). In field studies it is not possible to separate the effects of anorexia from those of deliberate withdrawal of food for cultural reasons. R. Martorell and C. Yarborough (1983) described an average reduction of 19 percent in dietary energy intake with various infections in Guatemalan children. Intakes were consistently less in children with diarrhea than in those without at all periods from 15 to 60 weeks (Mata et al. 1977; Martorell, Yarborough, et al. 1980; Martorell, Rivera, et al. 1990). Energy intakes in children under 5 years of age in Bangladesh were more than 40 percent less during acute diarrhea than after recovery (Hoyle et al. 1980). In Peru they decreased from 10 to 86 percent among breast-fed children with diarrhea (Bentley et al. 1991).

Despite a decrease in both intake and absorption of nutrients due to anorexia accompanying an infection, these losses are very much less than when food is withheld (Chung 1948; Chung and Viscorova 1948). Although consumption of food is reduced by anorexia, purposeful withholding of food may have a much greater impact. The clinical and public-health lesson is that food should not be withdrawn during diarrheal and other infections.

Malabsorption

In addition to the decrease in food intake with diarrhea, protein absorption is commonly reduced by 10 to 30 percent and occasionally by as much as 40 percent. A. W. Chung and B. Viscorova (1948) reported that the absorption of nitrogen in four children with diarrhea varied from 40 to 74 percent, and absorption of fat varied from 39 to 67 percent. Data from the International Center for Diarrheal Disease Research, Bangladesh (ICDDRB), on patients with diarrhea due to rotavirus show average absorption rates of 43 percent for nitrogen, 42 percent for fat, 74 percent for carbohydrate, and 55 percent for total energy. Slightly higher averages are managed by patients with diarrhea due to enteropathogenic *E. coli* and *Shigella* (Molla et al. 1982). E. D. Moyer and M. C. Powanda (1983) have summarized additional literature indicating a range of malabsorption for subjects with diarrhea of about 40 percent for proteins, 23 to 50 percent for fats, and 73 to 77 percent for carbohydrates. The high incidence of diarrheal disease in young children makes this malabsorption especially important for them.

Bacterial, viral, and protozoan enteritides cause similar malabsorption, as do intestinal parasites such as hookworm, fish tapeworm, ascaris, and *Strongyloides,* and it is also observed in systemic disorders such as measles, tuberculosis, malaria, and streptococcal infections. The mechanisms of malabsorption with these infections include shortened intestinal transit time, physical blocking of mucosal surfaces, and mesenteric blood flow.

Some children with acute diarrheal disease of nonspecific origin develop a persistent carbohydrate intolerance and experience a much more severe and prolonged nutritional deficit (Rosenberg and Scrimshaw 1972). In addition, between 30 percent and 50 percent of individuals living in an unsanitary environment in warm climates develop tropical jejunitis with chronic changes in the intestinal epithelium that include flattening of the villi and loss of microvilli (Klipstein and Falaiye 1969; Keusch, Plaut, and Troncale 1970; Bayless, Swanson, and Wheby 1971; Lindenbaum, Harmon, and Gerson 1972). This phenomenon undoubtedly occurs in most developing countries, which include Haiti (Klipstein et al. 1968), India (Gorbach et al. 1970; Baker 1972), Thailand (Sprinz et al. 1962; Keusch 1972), Bangladesh (Lindenbaum, Gerson, and Kent 1971), Colombia (Ghitis, Tripathy, and Mayoral 1967; Mayoral et al. 1967), and Puerto Rico (Lugo-de-Rivera, Rodriguez, and Torres-Pinedo 1972). In addition, I. Rosenberg, N. W. Solomons, and R. E. Schneider showed in 1977 that most rural Guatemalans had reduced absorption of protein and carbohydrates.

Catabolic Losses

A catabolic response occurs with *all* infections, even when they are subclinical (Beisel 1972, 1975, 1977; Beisel and Wannemacher 1980; Keusch and Farthing 1986). This is true even for yellow fever immunizations (Gandra and Scrimshaw 1961) and asymptomatic Q-fever infections (Beisel 1977). Once an infection is established, the breakdown of skeletal muscle protein begins and alanine and glutamine are synthesized and transported to the liver, where they are used for gluconeogenesis. This process occurs whether or not the infection causes fever. Increased losses of vitamin A, B-vitamins, ascorbic acid, and iron are also observed.

The stimulus for these changes comes from the release of interleukin-1 when macrophages break down, and from the resulting endocrine changes (Wannemacher 1977). More than two-thirds of the negative nitrogen balance of a young man with tularemia was due to this metabolic response, and the remainder to a spontaneous decrease in food intake (Beisel et al. 1967). Even an individual with completely asymptomatic Q fever can have an increasingly negative cumulative nitrogen balance for as long as 21 days (Beisel 1977).

Anabolic Losses

There is a marked increase in nitrogen retention following chicken pox, despite only a modest decrease in retention during the period of the rash (Wilson, Bressani, and Scrimshaw 1961). During an infection, amino acids are diverted from normal pathways for the synthesis of immunoglobulins, lymphokines, C-reactive proteins, and a variety of other proteins, including key liver enzymes (Wannemacher 1977). This diversion accounts for the finding that the extra nitrogen retained during the recovery period in metabolic balance studies exceeds that accounted for by the magnitude of the negative balance measured during the acute phase of an infection.

Fever

Whatever its benefits in increasing resistance to infection-induced disease, fever has a metabolic cost. The regulation of normal body temperature within a narrow range is a complex phenomenon. It is modified by the endogenous pyrogenic activity of interleukin-1 released by mononuclear leukocytes in response to infection. The resulting fever increases the basal metabolic rate 13 percent for each rise in temperature of 1 degree Celsius (DuBois 1937). During a period of high fever, metabolism may increase by nearly one-third. There is a relationship between basal metabolic rate and temperature measured in various infections. The increase varies between 30 and 60 percent for a 3-degree rise.

Additional Intestinal Losses

Although difficult to measure separately from malabsorption, a significant contributor to malnutrition in some infections is the direct loss of nutrients into the gut. Protein-losing enteropathy has been described for measles (Axton 1975; Dosseter and Whittle 1975; Sarker et al. 1986), diarrhea (Waldman 1970; WHO 1980; Rahaman and Wahed 1983), and especially shigellosis (Rahaman, Alam, and Islam 1974). Alpha 1-antitrypsin is a simple and useful quantitative marker for estimating the loss of protein into the gut in diarrheal disease (Rahaman and Wahed 1983), and it should be used for this purpose in studying the effects of other kinds of infections.

In ICDDRB studies, nearly two-thirds of patients with enterotoxigenic *E. coli* (ETEC) and 40 percent of those with rotavirus diarrhea were also found to have an excessive loss of protein in the feces (Molla et al. 1983). Between 100 and 500 ml of serum was lost in the feces each day by shigellosis patients due to protein-losing enteropathy. Bleeding into the intestine from *Schistosoma mansoni* (hookworm) also represents a loss of energy, iron, and other nutrients.

Reduced Growth and Weight Loss

As described earlier, children subjected to frequent infections and borderline diets show reduced growth. The result is a decrease in nutrient requirements that is proportionately larger for protein than for dietary energy. This loss is because the requirement for average daily growth of a 2-year-old child is about 12 percent of the total protein requirement, only about 2 percent of total energy needs. The savings from growth impairment are generally not sufficient to avoid actual weight loss, an almost inevitable consequence of infection.

Infectious Diseases and Nutrient Requirements

Bacterial, Viral, and Protozoal Infections

As already emphasized, the metabolic consequences of systemic infections depend not on the specific causative organism but rather on a common sequence of metabolic events.

Parasitic Infections

As an acute febrile illness, malaria has the same consequences as other acute systemic infections (Barr and DuBois 1918; McGregor 1982; Tomkins et al. 1983). This is also true for febrile episodes associated with toxoplasmosis, onchocerciasis, leishmaniasis, and trypanosomiasis. However, there may be additional local effects from parasitic infections. Reduced intestinal absorption of nitrogen can occur in malaria as a consequence of reduced mesenteric blood flow (Migasena and Mae-Graith 1969). Anemia is a common sequel to *Plasmodium falciparum* infection and to a lesser extent in the other malaria types (McGregor et al. 1966), which is due in part to an increased iron loss because of hemolysis. Immunologic destruction of unparasitized erythrocytes may also occur (Zuckerman 1966).

Giardia lamblia has been well documented as a common cause of chronic malabsorption, including wasting, hypoalbuminemia, diarrhea, steatorrhea (Chauduri 1943; Amini 1963; Solomons 1982), and malabsorption of fats and carbohydrates (Veghelyi 1938; Palumbo, Scudmore, and Thompson 1962; Kluska 1972; Riis 1975; Khosla, Sharma, and Srivastava 1978). Poor absorption of vitamin A is seen in giardiasis (Chesney and McCoord 1934; Katsampes, McCowd, and Phillips 1944; Mahalanabis et al. 1979). Several investigators have reported evidence of ileal malabsorption of vitamin B_{12} as a result of this infection (Peterson 1957; Antia et al. 1966; Notis 1972). Low serum folate levels in patients with *Giardia* infections have also been described.

Intestinal helminths, such as ascaris (Venkatachalam and Patwardhan 1953; Tripathy et al. 1972; Gupta et al. 1977; Brown et al. 1980; Taren et al. 1987), hookworm (Layrisse et al. 1964), *Strongyloides* (Milner et al. 1965; O'Brien 1975; Carvalho Filho 1978), *Trichuris* (Jung and Beaver 1951; Layrisse et al. 1967), and heavy infections of *Trichocephalus,* may also reduce intestinal absorption of protein and other nutrients (Crompton 1986). Careful metabolic balance studies generally fail to detect a significant effect of mild to moderate worm burdens on intestinal absorption, although appetite may be reduced (Bray 1953; Kotcher et al. 1966; El-Mawla, Abdallah, and Galil 1966). Vitamin A malabsorption has been described with ascariasis (Sivakumar and Reddy 1972). *Ascaris* and *Chlonorichis* can also cause biliary and pancreatic obstruction (Rosenberg and Bowman 1982).

Of the hookworms, *Necator americanus* causes a loss of about 0.03 ml of blood per worm per day (Roche et al. 1957a, 1957b; Roche and Perez-Gimenez 1959), whereas *Ancylostoma duodenale* causes a 5 to 10 times greater blood loss per worm (Farid et al. 1965). Although approximately half of the iron is reabsorbed (Roche and Perez-Gimenez 1959; Giles, Watson Williams, and Ball 1964), the loss in heavily infected patients ranged from 14 to 45 ml of blood per day. Surprisingly, even with severe hookworm anemia, adequate dietary iron can fully compensate for these losses without removal of the worms. L. S. Stephenson, D. W. T. Crompton, M. C. Latham, and colleagues (1980) described growth impairment with *Ascaris* infection, and, later, Stephenson, Latham, K. M. Kurz, and colleagues (1989) showed that active antihelminth treatment improved the growth of Kenyan schoolchildren with combined hookworm, trichuris, and ascaris infection.

The massive bleeding from the intestinal tract, sometimes seen in *Schistosoma mansoni,* may require surgical intervention. This parasite can also obstruct lymphatic return and thereby interfere with fat absorption. Other reported nutritional consequences of heavy *S. mansoni* infections in human clinical studies include daily loss of albumin, zinc, and vitamin A; elevated fecal fat and glucose intolerance; and subnormal levels of serum carotene (Waslien, Farid, and Darby 1973). Most of the protein in the blood entering the gut due to intestinal bleeding in hookworm infection is reabsorbed, but in heavily infected patients, increased fecal protein loss may occur (Blackman et al. 1965). Individuals with *Schistosoma hematobium* lose blood in the urine and are also at increased risk of iron deficiency.

Because of their aggregate bulk, some parasites compete with the host for some of the nutrients essential to both. Where the Scandinavian custom of consuming marinated raw freshwater fish persists, massive infection of the fish tapeworm *Diphyllobothrium latum* is associated with megaloblastic anemia due to competition for vitamin B_{12} (Von Bonsdorff 1948, 1956, 1964). This effect (and that of *G. lamblia*) may also partially be caused by hypochlorhydria or achlorhydria in the stomach (Hoskins et al. 1967), which interferes with vitamin B_{12} absorption.

Effects of Infections on Specific Nutrients

Protein

All of the mechanisms for the impact of infection worsen protein status, and as a result, clinical protein deficiency is often precipitated in individuals whose nutritional status is borderline. Powanda (1977) has summarized data for a wide variety of acute infectious diseases in adults by adding the total nitrogen losses and dividing them by the number of days over which these losses occurred. For all infections, the average loss of 0.6 grams of protein per kilogram per day (g/kg/day) is equal to the mean estimated protein requirement for adults. Diseases associated with diarrhea or dysentery produced an average protein loss of 0.9 g/kg/day. Higher losses were observed with typhoid fever and other severe infections, reaching 1.2 g/kg/day.

Measurements of the catabolic response in infection using urinary 3-methylhistidine as a measure of muscle protein catabolism in the septic patient suggest an average additional protein loss in the urine during sepsis to be the equivalent to 1.14 g/kg/day (Long et al. 1977). None of these calculations include energy expended for the multiple anabolic responses or make allowances for dietary change or for nutrient malabsorption.

Both metabolic and field observations suggest that even with an optimum diet, it may take two to three times longer to replete than to deplete an individual. If the diet is not sufficient for a maximum rate of recovery, daily improvement is correspondingly reduced and the time required for complete recovery increased. The more severe and closely spaced the episodes of infection, the more likely that full recovery will not occur and that the adverse effects will become cumulative.

Infections are likely to precipitate clinical protein deficiency in children whose nutritional status is borderline. Diarrhea is reported from many countries to be the most common contributory cause of kwashiorkor (Scrimshaw et al. 1968). This is the case even when the episode is not necessarily severe, because it may be only the latest in a long series of diarrheal, respiratory, and other infections that are progressively depleting, when there is neither sufficient food nor time for complete recovery between episodes. Kwashiorkor has been reported to follow measles, chicken pox, German measles, whooping cough, and other common communicable diseases of childhood. Measles has a particularly strong impact on nutritional status, causing a sharp drop in serum albumin (Dosseter and Whittle 1975), lean body mass (unpublished data from Fernando Viteri, Institute of Nutrition of Central America and Panama [INCAP], Guatemala City, Guatemala), and growth rates (Mata 1978).

Table VI.3.3. *Intake of calories in acute state (A), and 2 weeks (R_1) and 8 weeks (R_2) after recovery (mean ± SD)*

Etiology	A	R_1	R_2
Cholera	74.9 ± 36.20	111.1 ± 35.4	109.59 ± 31.7
Rotavirus	68.5 ± 22.6	87.2 ± 26.2	115.0 ± 20.2
ETEC	70.7 ± 37.9	90.97 ± 28.4	114.9 ± 19.0
Shigella	70.0 ± 28.2	100.5 ± 27.8	109.3 ± 18.8

Source: Molla et al. (1983).

Energy

Obviously, the severity of an energy deficit is related to the duration and magnitude of malabsorption in each individual situation; rarely does such a condition pose a major threat to nutrition unless infection is chronic or recurrent. For most respiratory diseases the energy cost is minimal, but for diarrheal diseases and the common communicable diseases of childhood, it can add significantly to a chronic energy deficit. Food intake is observed to drop during acute infection and then to increase during recovery to above normal levels if the diet is sufficient. Table VI.3.3 shows the large increase in caloric intake during convalescence from diarrhea in Bangladesh when a good diet is available ad libitum (Molla et al. 1983).

Vitamin A

Vitamin A blood levels are appreciably reduced in pneumonia, rheumatoid arthritis, acute tonsillitis, and infectious hepatitis (May et al. 1940; Shank et al. 1944; Harris and Moore 1947; Jacobs et al. 1954). Vitamin A is not normally found in the urine but does appear there in at least some infectious diseases (Moore 1957; Goldsmith 1959). Lower serum carotene and vitamin A levels have been reported with hookworm disease (Rodgers, Dhir, and Hosain 1960).

The capacity of infections to precipitate xerophthalmia and keratomalacia in individuals already marginally deficient in vitamin A is well established (Oomen 1959; McLaren 1963; Sommer 1982; Sommer et al. 1983; Sommer, Katz, and Tarwotjo 1984; Stanton et al. 1986; Tielsch et al. 1986; De Sole, Belay, and Zegeye 1987). The effect is particularly severe with measles (Sommer et al. 1984). A significant drop in serum vitamin A levels has been observed in children with acute respiratory infection, gastroenteritis, and measles; levels return to normal after recovery (National Institute of Nutrition 1980).

The adverse effect of intestinal parasitic infections on vitamin A absorption has already been described. Enteric infections of bacterial and viral origin also have this effect (Nalin et al. 1980; West and Sommer 1985), as do systemic febrile illnesses (Heymann 1936; Shank et al. 1944; Lala and Reddy 1970; Sivakumar and Reddy 1975). B. Sivakumar and V. Reddy (1972) reported that only 30 to 70 percent of ingested vitamin A is absorbed by children with acute diarrhea and respiratory infections. Although infection clearly impairs both dietary carotene and vitamin A absorption (West, Howard, and Sommer 1989), sufficient amounts of supplementary vitamin A can still be absorbed orally for effective treatment of corneal xerophthalmia.

Ascorbic Acid

Ascorbic acid levels decrease in plasma and increase in the urine of infected individuals compared to noninfected persons living under comparable conditions. This is seen even with the common cold and with immunization against smallpox and measles (Scrimshaw et al. 1968; Hume and Weyers 1973). Historically, infections are associated with the onset of florid scurvy in individuals already on a borderline diet (Scrimshaw et al. 1968).

B-Vitamins

The classic nutritional diseases of beriberi and pellagra, caused respectively by deficiencies of thiamine and niacin, were known to be precipitated in vulnerable individuals by a variety of infections. This finding is of more than historical interest because alcoholics frequently consume diets low in B-vitamins, and infections increase the likelihood of clinically significant deficiencies of the B complex. Given the frequency with which infections occur in indigent alcoholics, physicians treating them should be aware of this connection. W. R. Beisel and colleagues (1972) have reported a marked increase in riboflavin excretion with infection.

Minerals

Iron. When anemia is present at the time of an infection (or even moderate iron deficiency without anemia) a number of normal resistance mechanisms are compromised. Impaired processes include phagocytic killing power; delayed cutaneous hypersensitivity, T-cell proliferation, and T-killer cell activity; and if the anemia is sufficiently severe, impaired antibody formation.

Yet when individuals compromised in this way are given parenteral iron or large doses of oral iron the result may be an overwhelming infection, as described for children with kwashiorkor (Baker et al. 1981; Lynch et al. 1984; Picciano, Weingartner, and Erdman 1984; Beard et al. 1988) and for severely malnourished adults (Murray et al. 1975, 1978a, 1978b; Barry and Reeve 1977; Bercroft, Dix, and Farmer 1977; Weinberg 1978, 1984). This occurs because the infective agent is supplied with iron before the host immune system has had time to recover. However, field studies have shown that iron fortification (supplementation of poorly nourished adults with up to 100 milligrams [mg] of iron daily, and proportionately less for children) always results in *decreased* morbidity from infectious disease (Scrimshaw 1990b).

Copper and zinc. Careful metabolic studies by C. Castillo-Duran, P. Vial, and R. Uauy (1988) have documented the impact of diarrhea on zinc and copper status. Metabolic balances of the minerals were strongly negative during the period of acute diarrhea, compared with strongly positive balances in the control subjects. During the recovery period, zinc balances became positive (405.3 ± 20.4 mg/kg/day), but copper balance remained negative, although less so (–21.5 ± 46.7 mg/kg/day).

The mechanism for the loss is wastage from the gastrointestinal tract through malabsorption and excessive endogenous losses. Since the normal state for the growing infant is net retention of these minerals, the true magnitude of such losses is somewhat greater. Clearly, the inevitable combination of reduced oral intake and increased fecal losses of minerals should be taken into account in the management of prolonged diarrhea. These losses cannot be predicted from serum levels because copper levels often increase during infections as a result of stimulation of the hepatic production of cerruloplasm (Kampschmidt et al. 1973).

It is noteworthy that in a study by R. F. Kampschmidt and colleagues (1973) serum copper levels were significantly lower in diarrhea cases than in control cases. Conversely, plasma zinc levels often decline during acute infections because of an internal redistribution of the metal to the liver. The reduced retention of zinc during diarrhea thus interacts with the redistributional influence of the infection. On the basis of this study, it is reasonable to suggest that treatment regimens for diarrhea should contain supplemental amounts of copper and zinc, but whether this addition would make a detectable difference in therapeutic results remains to be demonstrated.

Nutrient Allowances for Infectious Disease Morbidity

Although it is important to provide a nutritious diet and encourage adequate nutrient intakes during an acute infection, some decrease resulting from anorexia is almost inevitable, and it is generally useless to attempt to increase food intake *during* illness. For the multiple reasons discussed in this chapter, persons are normally depleted to a greater or lesser degree during an infection. However, during the *recovery* period, there is a metabolic window in which appetite is increased and the rate of retention, at least for protein, may be as much as nine times the average daily requirement.

A 1979 United Nations University report calculated that a malnourished 1-year-old child depleted by an infectious episode lasting 7 days would need approximately 136 kilocalories (kcals) (569 kilojoules [kjoules]) per kilogram per day, and 2.56 grams of protein per kilogram per day, for repletion in 30 days. It should be noted that the same weight deficit without infection would have required less than one-third the amount of protein per kilogram per day but approximately the same amount of energy. Despite clear evidence of the heavy burden of infection on the populations of developing countries, and the increased nutrient needs above normal requirement levels during convalescence from episodes of infectious disease, this issue is not dealt with quantitatively in national and international recommended nutrient allowances. The comment of a "Consultation on Energy and Protein Requirements" (FAO/WHO/UNU 1985) is illustrative of such vagueness: "[T]he increased requirement average of a population of school children would not be large." The report goes on to emphasize the need for preventing infections, rather than simply meeting increased requirements for recovery resulting from them. This emphasis is important but not helpful to the hundreds of thousands of children in developing countries whose diets are already deficient or borderline.

R. G. Whitehead (1977) recommended a 30 percent increase in energy and a 100 percent increase in protein to optimize nutritional repletion of young children depleted by infection. This recommendation is consistent with data summarized by Powanda (1977) and N. S. Scrimshaw (1977). Moyer and Powanda (1983) discuss the basis for significantly increased nutrient requirements during convalescence without arriving at quantitative recommendations. However, a task force report (Rhode et al. 1983) utilizing this and other information concluded that children should be offered 50 percent more than their usual diet for two to four times the duration of the illness *or* fed extra food daily until the weight prior to illness is regained or exceeded. Unfortunately, the diet of most infants and young children (and some adults) in developing countries is commonly too marginal to permit repletion before another episode of infection further depletes the individual.

The *energy* cost of depositing a gram of protein is estimated to be 24 kcal (100 kjoules), or about 6 kcal (25 kjoules) of total weight gain (United Nations University 1979). If this figure is applied to the observed protein losses previously summarized, average energy losses suggest a loss from this source alone of between 4 and 5 kcals (17 to 21 kjoules) per kilogram per day. This would correspond to 14, 22, and 29 kcal (59, 92, and 121 kjoules) per kilogram in children or adults. This loss appears to be minor, but it represents from 14 to 29 percent of the requirements of a 1-year-old child.

The energy cost of growth of children recovering from protein–energy malnutrition was found to be in the range of 4 to 5 kcal (17 to 21 kjoules) per gram of weight gain, with 40 percent of this amount considered to be fat tissue and 60 percent protein tissue (Jackson, Picou, and Reeds 1977). The energy cost of synthesizing a gram of lost protein is 7.5 kcal (31 kjoules) per gram and for replacing a gram of fat 11.6 kcal (49 kjoules). During the recovery period, this loss must be made up, together with deficits arising from malabsorption, infection-stimulated catabolism, and internal synthesis in reaction to infection. Such an increase in energy requirement during the convalescent period is difficult to quantify, however, because it is so variable.

Summary

The interactions of malnutrition and infection in human populations are almost always synergistic in the sense that each worsens the other. Deficiencies of protein, iron, and vitamin A are particularly likely to be responsible for an increase in morbidity and mortality from infectious diseases in underprivileged young children. In hospitalized patients, malnutrition often contributes to the severity of nosocomial infections. Mechanisms for increased susceptibility to infection with malnutrition include altered tissue integrity, impaired antibody formation, and many aspects of cell-mediated and nonspecific immunity. These include T-cell proliferation, killer T cells, helper T cells, complement C-3, phagocytic killing power, immunoglobulins G and E, delayed cutaneous hypersensitivity, and other parameters of cell-mediated immunity. Although iron deficiency interferes with several of these parameters of cell-mediated immunity, it can impair replication of some infectious agents. Severely iron-deficient individuals should receive supplementary iron to restore immunity, but never in high doses.

The mechanisms whereby systemic infections worsen nutritional status include anorexia, cultural withdrawal of solid food, increased metabolic losses, decreased intestinal absorption, and internal diversion of nutrients for immune proteins. The practical significance of these effects depends on the prior nutritional status of the individual, the diet during the infection, and the adequacy of the diet for prompt recovery. Intestinal parasitic infections, when sufficiently heavy, interfere with absorption of nutrients and have a variety of additional adverse effects that depend on their specific nature. Individuals who live in environments with frequent enteric infections develop chronic intestinal mucosal changes that impair nutrient absorption. Food intake should be maintained to the extent possible during an infection despite anorexia, and then increased during the convalescent period.

VI.4 Famine

Despite swelling populations around much of the globe, the enormous expansion of agricultural productivity, the rapid development of transport facilities, and the establishment of globally interlinked market networks have made it theoretically possible to provide adequate food for all. Yet famine and hunger still persist and, indeed, proliferate in some parts of the world. Their durable character represents a perplexing and wholly unnecessary tragedy (Drèze and Sen 1989; Watts and Bohle 1993b). Although the extent of hunger in the world will never be known with precision (Millman 1990), it has been estimated that in the early 1990s, more than 500 million adults and children experienced continuous hunger and even more people were deemed vulnerable to hunger, with over 1 billion facing nutritional deficiencies (WIHD 1992).

The community concerned with world hunger is far from unanimous in its understanding of the situation. S. Millman (1990) likens the situation to the parable of the elephant and the blind men, whereby hunger is perceived differently by those encountering different aspects of it. It is significant that these varying perceptions correspond to particular disciplinary or professional orientations, leading to different diagnoses of the nature of the problem and its underlying causes and implying distinct foci for policy interventions.

Problems of food supply, then, are among the most bewildering, diffuse, and frustrating of humankind's contemporary dilemmas. Within the lifetime of each of us, official views of the world food situation have oscillated from dire predictions of starving hordes to expectations of a nirvana of plentiful food, then back to impending doom. One expert states that famine is imminent, whereas another declares that our ability to adequately feed the world's people is finally within reach.

The term "famine" is one of the most powerful, pervasive, and (arguably) emotive words in our historical vocabulary. This in itself makes it all the more difficult to isolate its meaning and wider significance. But to this end, the ensuing chapter addresses the following topics: A brief review of famine in history; a definition of famine and its various dimensions; the identification and description of a range of cultural and social famine coping practices in traditional societies; an examination of the literature on the causes of famine, along with some of the recent attempts to model famine vulnerability and the famine process; and, finally, a focus on past and present attempts to develop famine policies.

Famine in History

Famines are woven into the fabric of history; indeed, as D. Arnold (1988) has pointed out, they are important historical markers, often used by chroniclers and historians in search of points in time when the normal rhythms of human life were interrupted, or when momentous developments appeared to have a discernible beginning or end. In singling out famines in this way, historians have done rather more than just seize upon convenient dates by which to slice up history into manageable portions. They have also followed the perceptions and traditions of the people themselves. In preliterate societies, particular famines, along with other collective catastrophes, served as a common means of recording and recovering the experience of the past.

We know that famines have led to untimely deaths for at least 6,000 years, which makes it necessary to simplify the enormously complex array of data and sources concerning them. W. A. Dando (1980) has identified a system of world famine regions for the period from 4000 B.C. to A.D. 1980. The first region, for the period from 4000 to 500 B.C., is Northeast Africa and West Asia, where the earliest authentic records of famine have been found, including several from the Nile Valley dated as early as 4247 B.C. The famine in Egypt of Joseph's day (1708 B.C.), recorded in the Old Testament, appears to have been part of a much more widespread scarcity throughout West Asia. Until 500 B.C., the literature of this area continued to be studded with accounts of famines.

In the thousand years after 500 B.C., the heaviest concentration of accounts mentioning famine are found in the region that became the Roman Empire. Imperial Rome may have brought order and organization to subjugated peoples, but Mediterranean Europe still experienced at least 25 major famines during this period. After A.D. 500, western Europe emerged as the region to which the extant accounts of famine most frequently refer. Up to A.D. 1500, the British Isles suffered from at least 95 famines, France suffered 75, and other famines or severe food shortages were recorded throughout these territories as well.

Indeed, famines are a much discussed part of the European experience until the nineteenth century. However, both the incidence and extent of major European famines seem to have begun to decline in the seventeenth and eighteenth centuries (Grigg 1985). Thus, the last major famine in England occurred in A.D. 1620, in Scotland in the 1690s, in Germany, Switzerland, and Scandinavia in 1732, and in France in 1795. During the nineteenth century, many parts of Europe were afflicted with harvest failure and high prices in 1816, and the 1840s were also a period of acute food shortage, including the "Great Famine" in Ireland (1846–51). But in general, even localized food crises diminished in Europe after the eighteenth century, and although until the mid-1800s most Europeans remained in a chronic state of undernourishment (Cipolla 1976), at least western Europe had shaken off the specter of famine.

The fourth famine region was eastern Europe, whose various sectors experienced more than 150 recorded famines between A.D. 1500 and 1700. Expanding the time frame a little, in Russia at least 100 hunger years and 121 famine years were recorded between A.D. 971 and 1974 (Dando 1980). Famine occurrence in imperial Russia reached its high point in the nineteenth century, but even after the revolution of 1917, the scourge of famine could not be eliminated. In 1921 and 1922, approximately 9 million people starved to death; in 1933 and 1934, the number was between 4 and 7 million, and in 1946 and 1947, it was nearly 2 million. The famines of 1921 and 1922 resulted from the breakdown of order associated with civil war, and those of the 1930s reflect Stalin's forced collectivization of agriculture. The famine of 1946–7 was also man-made. A decision to rigorously restore the provisions of the collective farm charter, which had been relaxed during World War II, coupled with a drought and the use of scarce grain in other segments of the world to promote communist goals, produced this famine (Dando 1980).

From A.D. 1700 to 1970, Asia emerged as the world's foremost famine area. In South Asia, legends and records document more than 90 major famines over the last 2,500 years, two-thirds of them after 1700, but most were localized (Kulkarni 1990), with only an occasional one (like the *Durga Devi* famine of the late fourteenth century in the Deccan) that covered a large area. Although all of India suffered to some extent in the early eighteenth century, without question the late eighteenth and nineteenth centuries were that country's time of famines. They devastated Bengal in 1770, the Ganges Valley, western India, the Deccan, and Madras in 1783, and almost all of the peninsula in 1790. In the first half of the nineteenth century, major famines took place from 1802 to 1804, in 1806 and 1807, in 1812, 1824, and 1825 and 1826, from 1832 to 1834, in 1837 and 1838, and in 1854. Most of these, however, were limited in their extent, although they did cause intense suffering and death regionally.

But the period between 1860 and 1880 in India was one in which five major famines and three local scarcities followed each other in rapid succession (Kulkarni 1990). The famines were widespread, but after 1880 there was a period when only local scarcities occurred and no famines. Then, in 1895, perhaps the most disastrous famine of the century began in the middle and upper Ganges Valley and spread, in 1896, to the whole South Asian region. This was followed by the famine of 1899 and 1900, which devastated a large area of the peninsula and the northwest as well.

There have also been a number of famines in the twentieth century in South Asia. In 1907 and 1908, one descended on the middle and upper Ganges Valley, but thereafter, although there were scarcities, no famine occurred until that of Bengal in 1943. Nor did scarcity and famine cease after India gained its independence in 1947. There was widespread scarcity (and probably starvation, despite denials of this by the

Indian central government and various state governments) in 1952 and 1953, and again between 1965 and 1967, 1970 and 1973, and in 1986 and 1987. In addition, Bangladesh was severely affected by famine in 1974.

Over the past 2,000 years, China has recorded perhaps as many as 90 famines per century. But, as in South Asia, the nineteenth century saw China's most devastating famines. Droughts, floods, locusts, hurricanes, and earthquakes were natural disasters that induced crop failures, but the breakdown of civil society and warfare also were important factors. Four of these famines alone (in 1810, 1811, 1846, and 1849) are reported to have claimed 45 million lives. Nine million died in the famine from 1875 to 1878 in northern China. Other severe famines were recorded in 1920 and 1929, and there was a particularly harsh one between 1958 and 1961, when it is estimated that between 14 and 26 million (and perhaps even as many as 40 million) people died (Kane 1988; Article Nineteen 1990).

Elsewhere in Asia there have been localized famines in many places over the past 200 years or so, and of late, areas such as Timor and Kampuchea have been afflicted. In the latter country, the decade of the 1970s was one of continuous food crisis, deepening into famine in 1975 and 1979; the latter has been described as the "most catastrophic famine in the history of the Khmer people" (Ea 1984).

Even North and South America, as well as the Pacific, have not escaped unscathed from famine. For example, in the middle of the fifteenth century, a four-year sequence of frosts and droughts produced a terrible famine in central Mexico (Townsend 1992), and famines, caused by a combination of drought and lack of political and economic cohesion, have been frequent in northeast Brazil (Cunniff 1996). Even in the lush, tropical Caribbean islands, famines were common during the seventeenth and eighteenth centuries, through a combination of physicoenvironmental, biological, and socioeconomic circumstances (Watts 1984). In the Pacific, small islands, vulnerable to environmental and societal perturbations, have always been susceptible to food shortages and famine (Currey 1980). Indeed, even in Hawaii, since European contact, famines have occurred on average every 21 years (Schmitt 1970).

Although famines have struck many parts of the world in the past two decades, sub-Saharan Africa has been especially hard hit and has afforded the contemporary world some extremely powerful and distressing visions of famine. However, famine in Africa is not a new phenomenon. Oral traditions from many areas mention numerous occurrences in precolonial times (Arnold 1988b), and colonial records document many more (Hill 1977; Watts 1983). Yet, as late twentieth-century events in Bosnia-Herzegovina reminded us, no place is free from famine, and one of its contemporary faces is worn by victims of war.

Nevertheless, although nearly 200 million people each year continue to be plagued by hunger, the trend in famines since the end of World War II has clearly been a downward one (Kates et al. 1988). This trend reflects both a lessening of famine generally and a major shift in incidence from populous Asia to less populous Africa. The Alan Shawn Feinstein World Hunger Program at Brown University, using data averaged for 7-year periods beginning in 1950, has found that the average number of people residing in countries in which *The New York Times* reported famine was 790 million annually from 1957 to 1963, but declined to an average of 265 million in the period from 1978 to 1984. Since that time, the average has dropped below 200 million.

Definitions and Dimensions of Famines

Millman (1990) has identified three hunger-related situations in the world today: food shortage, food poverty, and food deprivation. These situations are distinguished from one another primarily by the level of human organization (from an entire population to households to the individual) at which scarcity is manifested. "Food shortage" indicates a situation in which total food supplies within a bounded region are insufficient to meet the needs of its population. "Food poverty" refers to the situation in which a household cannot obtain enough food to meet the needs of all of its members. "Food deprivation" refers to insufficient food availability for an individual. At each level, the commonly used term "food security" can be taken to mean an ability to avoid the corresponding hunger situation. Food shortage is among the causes of food poverty, which in turn is among the causes of food deprivation. However, other factors may operate to cause food poverty when there is no food shortage, and food deprivation where there is no food poverty.

Thus, hunger is not a single, uniform experience. Its manifestations range from vulnerability resulting from dietary traditions that mesh imperfectly with variations in need over the life cycle, to household food insecurity rooted in poverty, to aggregate food-supply shortfalls, which, when they worsen, can become the massive hunger crises affecting large numbers within specified regions and generating substantial increases in mortality. The latter, in popular thinking, are called "famines." Certainly, the most poignant manifestations of hunger are famines, which we have become accustomed to thinking of as "disasters" of a particularly horrific kind, replete with human misery on a massive, almost unimaginable, scale.

Famine: A Subjective Window on Poverty and Hunger

One of the debates over famine that has emerged involves the question of whether it is a discrete event or merely the tip of an iceberg of underlying social, economic, and political processes (Currey 1992). Many writers (e.g., Mellor and Gavian 1987) have defined famine as a discrete event, separate from chronic hunger. Furthermore, the World Bank (1986) has separated transitory food insecurity from chronic food insecurity, and the World Food Programme has focused most of its attention on nutrition in times of disaster. B. Currey (1992), however, has questioned whether such crisis management is the most cost-effective means of reducing world hunger and has suggested that more efforts be directed toward building resilient agricultural systems and long-term monitoring of rural development.

Such differences in approach highlight one of the problems with famine, which, as a concept and as a historical phenomenon, presents us with a fundamental paradox: It is both event and structure (Arnold 1988). On one hand, it is clearly an "event." There may be widely different opinions as to exactly when a particular famine begins or ends, but there is common agreement that it occupies a finite span of historical time and human experience. Basically, famine signifies an exceptional (if periodically recurring) event – a collective catastrophe of such magnitude as to cause social and economic dislocation. It generally results in abnormal levels of destitution, hunger, and death. It can lead to the complete disintegration of customary patterns of work and subsistence and can greatly disrupt customary norms of social behavior, not to mention levels of mortality.

And yet, at the same time, famine cannot be meaningfully considered in isolation from the economic, social, and political structures of a specific society. Occasionally, we document a specific disaster, resulting in a famine, in a society that is otherwise relatively secure in its provisioning. More commonly, however, famine acts as a revealing commentary upon a society's deeper and more enduring difficulties. In other words, famine can be viewed as a subjective window on poverty and hunger. The proximate cause of a famine may lie in some apparently unpredictable "natural disaster," like a flood or drought, or in a human calamity like a civil war or invasion (Arnold 1988). But these are often no more than "triggering" events, intensifying or bringing to the fore a society's already extant vulnerability to food shortages and famine. Any historical understanding of famine must, therefore, be alert to its structural causes and to its social and cultural parameters, as well as to what happened during the crisis itself.

This approach to famine, as a meeting and intermingling of event and structure, partially derives from a perspective that sees history not as simply a narrative sequence of great events and personalities but as a search for underlying structures and recurrent patterns, famines among them (Arnold 1988). In a similar manner, it has been recognized among social scientists that individual action or agency is constrained by the relationship between agency and structure, and this dialectic takes place not only locally but on a world scale (Wisner 1993). Thus, although a famine can arise locally, the constraints on humans that create their vulnerability to it can originate in the influence of structures located on other continents.

Famines As History

Famines form an integral part of formal attempts to record and recall the past in many parts of the world. Among other things, they act as an aid to recall, as a reminder of their terrifying consequences, and, sometimes, as a key to their putative meanings. The practice of naming famines is one indication that in the popular memory at least, all famines were far from identical, whatever similarities they might bear for outside observers. For example, India's famines commonly bore the title of the Hindu calendar year in which they occurred. Others were named after vengeful deities or were seen as marking the onset of the *Kali Yuga,* the Hindu age of suffering, corruption, and human misery. In Africa, rural people have often named famines after what they exchanged or sold to get food, or after what people ate.

Such examples highlight the fact that famines are "hitching posts" of history (Shipton 1990) and the poles around which experiences and impressions are organized and collected. Thus, famine forms a link between the world of personal memory and the broader domain of collective consciousness, despite the fact that many academic historians have been skeptical about the authenticity of famine accounts found in folklore, oral history, and even chronicles.

In the past, as famines touched the lives of millions deeply and directly, they lived on in collective memory, and terror of their return kept them alive in that memory. We should remember that it has only been in the last century or so that people in Western societies have felt themselves immune to famine and discarded such cumulative folk experience as redundant. Perhaps it is this lack of fear of famine that most critically divides us from our own past and from the lives of a large part of the world's peoples today (Arnold 1988).

Famine As Demographic Crisis

One of the ways in which famines impress themselves upon collective memory and experience is through the colossal and devastating mortality involved. However, mortality statistics can give only a rough impression of a famine's magnitude, and it would be unrealistic to credit such data with any real precision. Until the last century or two, few governments kept reliable and detailed records of vital data. Historians who have attempted to reconstruct famine mortality in the remote past have tried to compensate for this deficiency by using parish records, tax returns, and similar sources. But these records seldom provide a dependable picture of mortality trends over a wider area, and even where there was some form of birth and death registration, famine mortality was often grossly underreported. Local officials themselves fell ill, died, or deserted their posts. The deaths of villagers who wandered off elsewhere in search of food passed unrecorded. Thus, it is not surprising that our understanding of the relationships between demographic processes and famine is extremely limited (Hugo 1984).

Indeed, although mortality is viewed as one of famine's major effects and is, in fact, an integral part of many of its definitions, there is surprisingly little data to precisely quantify the impact of famine on mortality rates, even in modern times; the famines of the 1970s and 1980s stand out as examples (Hugo 1984). Accounts of famines in preindustrial societies usually paint pictures of death on a massive scale. P. A. Sorokin (1942, 1975), one of the earliest writers to systematically summarize the demographic impacts of famine on mortality, has suggested that in affected areas, death rates sometimes reached 200, 500, or even 800 for every 1,000 people, as compared with normal rates of 10 to 30. He maintains that in the Soviet famine of 1921, for example, regional death rates reached 600 per 1,000.

The concept of "excess deaths" has been found to be useful in examining the impact of contemporary famines on mortality. "Excess deaths" refers to the "number of deaths over and above those that would have occurred if previous nutritional conditions had prevailed" (Bongaarts and Cain 1981). Very few studies have employed this concept. One of these, by A. K. Sen (1980), makes several reasonable corrections to the existing mortality data for the 1943 Bengal Famine and concludes that the total figure for excess mortality associated with that famine was 3 million. Another, by J. C. Caldwell (1975), estimates that the excess mortality for the entire Sahelian region during the famines of 1970 to 1974 was no more than 250,000, despite massive publicity that insisted that many more people were dying, and M. Alamgir (1980), in a third study, estimates the excess mortality for Bangladesh in 1974 and 1975 as 1,500,000.

Famines also seem to have distinct phases of mortality response (Ruzicka and Chowdhury 1978; Bongaarts and Cain 1981). There appears to be an initial phase during which mortality rates respond immediately to the food crisis. This is followed by a second phase that sees mortality rates at least twice as high as normal, and a third involving a gradual rate decline. Finally, there is a phase in which mortality rates are actually lower than "normal" because the most vulnerable groups in the population have already been severely pruned.

Demographers have also tended to neglect the differential mortality within subgroups in populations during famines. Best documented are excess death rates among infants and children. Illustrative is the Bangladesh Famine of 1974 and 1975, during which there was a 70 percent increase in the infant mortality rate in a sample of 228 villages containing 120,000 people, which meant 529 deaths per 1,000 live births (Ruzicka and Chowdhury 1978). A study of the 1980 famine in Daramoja, Uganda, measured an infant mortality rate of 607 per 1,000 live births.

The elderly also are especially vulnerable to excess mortality in times of famine (Chen and Chowdhury 1977), as are pregnant and lactating women (Bongaarts and Cain 1981). In addition, there is no doubt that famine mortality disproportionately affects poor and landless people. For example, in Bangladesh, the 1975 crude death rate among landless families was three times higher than among those with at least three acres of land (Chen and Chowdhury 1977). It also is clear that in the 1943 Bengal Famine, the most affected group in terms of excess mortality was that of agricultural laborers (Mukherji 1965).

Although discussion of the demographic impact of famine has concentrated on assessments of mortality, another important dimension is its impact on fertility (the demonstrated capacity of women for reproducing) and fecundity (a predisposition or latent capacity for reproducing). There is considerable evidence to suggest that fertility, as demonstrated by birth rates, follows a distinctive pattern during famines (Bongaarts and Cain 1981). Birth rates initially remain at prefamine levels, then rapidly decline, some nine months after the famine's onset, to rates only 30 to 75 percent of those that are normal (depending on the severity of the famine). The low point in birth rates usually occurs nine months after the end of the crisis. But following this point, the conception rate recovers quickly, and the famine-induced period of depressed fertility is followed by one in which the birth rate exceeds prefamine levels for up to three years. Reasons for this pattern are varied. Fecundity is decreased by minimal nutrition and psychological stress. Hunger also tends to diminish the frequency of intercourse, and spouses are often separated by temporary migration during famines. In addition, there is an increase in voluntary birth control, sexual abstinence, abortion, and, historically at least, infanticide (Sorokin 1942; Connell 1955; Ruzicka and Chowdhury 1978).

As yet, there is little information on socioeconomic differentiation in the pattern of fertility response to famine, but the scattered evidence suggests that it is the poor and landless who most reduce their rate of conception during such a crisis (Stein et al. 1975; Ruzicka and Chowdhury 1978).

A third important demographic feature of famine is migration, which in traditional societies has historically been one of the most important ways that people have coped with famine. Although migration should be studied in relationship to mortality and fertility, in this chapter it will be considered with other coping strategies.

Famine and Disease

Assessments of the demographic impact of famine are greatly complicated by the disease factor because, in most famines, mortality from epidemic disease has greatly exceeded that from actual starvation. For example, during the course of the Bengal Famine of 1943, starvation was identified as the cause of death in only about 5 percent of cases; cholera, malaria, and smallpox accounted for the great majority of the 3 million deaths. Moreover, in the 1940s, just as in the nineteenth century, the colonial administration in India was loath to acknowledge starvation as a cause of death. This situation has continued since 1947 because famine mortality in India has remained a political matter.

The reasons for the intertwining of epidemics and famine appear to be both physiological and social. Malnutrition can weaken the body's immune responses, creating a diminished resistance to infection and a reduced capacity to recover from it. Further, migration has the effect of spreading disease to areas not directly affected by hunger. During times of famine, personal hygiene also tends to be neglected. Debilitated people may fail to wash, and they may drink filthy or contaminated water. They may consume "famine foods" (unripe grain, grass, or roots) in an attempt to suppress hunger; this sometimes causes diarrhea and vomiting, which results in a further weakening of the body and a greater risk of spreading disease. The high level of famine mortality, in other words, is partially a consequence of the nature of the expedients people adopt to try to escape from hunger and partly one of the disruption created by famine in customary patterns of social behavior.

Famine Chronology

All famines have their own internal chronology. Because hunger seldom kills outright and immediately, the symptoms of growing hunger may not be apparent to outsiders until destitution and debilitation have already reached an advanced stage. Thus, the duration of famine can be reckoned according to a variety of different criteria, and definitions made by those actually subject to the famine may differ greatly from those made by officials. Those experiencing a famine might date its onset from the first warning signs of approaching calamity, such as the delayed arrival of the rains and the first withering of standing crops. Officials, by contrast, might see a famine as beginning only when food prices climb to abnormal heights or when the signs of distress among the starving poor are given governmental recognition. Equally, an official definition of famine might end with the closing of state-managed relief work, though this may occur well before survivors of the famine feel themselves free of its grip.

Traditional Cultural and Social Coping Practices

"Coping" is the manner in which people act, within the constraints of existing resources and the range of expectations of a situation, to achieve various ends (Blaikie et al. 1994). In general, such action involves no more than "managing resources," but more specifically, it usually means how this management is accomplished under unusual and adverse circumstances. Thus, coping can include defense mechanisms, active ways of solving problems, and methods for handling stress. Resources for coping with famine include labor power, land, tools, seed for crops, livestock, draft animals, cash, jewelry, other items of value that can be sold, and, of course, storable food stocks, as well as skills and specialized knowledge. In order for tangible resources to be mobilized, people must be entitled to command them, which may be achieved in many ways. Among them are using the market, exercising rights, calling upon obligations (of household members, kin, patrons, friends, and the general public, by appeals to moral duty as in alms and charitable giving), stealing, or even committing violence. In many cases, specialized knowledge is required with certain resources, for instance, in locating wild foods, determining the moisture capacity of certain soils, discovering water sources, or finding wage labor in distant cities or plantations.

Although the range of strategies to prevent or minimize the risk of famine is enormous, two generalizations can be made. First, the objective of many of these strategies is to secure necessities, such as access to a minimum level of food, shelter, and physical security, rather than to increase income. Second, maintaining command of these basic needs in a risky environment usually implies employing multiple, varied methods of access to resources. These include diversifying production strategies, setting up nonagricultural income sources, strengthening or multiplying social support networks, and developing a demographic strategy aimed at the creation, maintenance, and mobilization of human labor.

Diversification is one strategy, and the production of farming people is usually diversified, involving mixed cropping, intercropping, the cultivation of nonstaple crops, and the use of kitchen gardens. The result is often a "normal surplus" in good years because it is planned on the basis of meeting subsistence needs even in bad (but not the worst conceivable) years. Because planting a greater variety of crops provides the best chance of an optimum yield under all variations of weather, plant disease, and pest attack, it represents one of the most important precautionary strategies for coping with food shortages (Klee 1980; Wilken 1988).

Another important preventive/mitigating strategy involves the development of social support networks. These include a wide variety of rights and obligations among members of the same household (for example, wives and husbands, parents and children), within the extended family, and within other groups with a shared identity, such as clan, tribe, and caste. Parents may try to make strategic choices of marriage for children into comparatively wealthy families, which might increase their ability to call on resources in difficult times (Caldwell, Reddy, and Caldwell 1986). Within the household and family, successfully securing resources in potentially disastrous times depends upon the implicit bargaining strength of its members and on their "fallback" positions (Agarwal 1990) or "breakdown" positions, if cooperation in this bargaining position should fail (Sen 1988, 1990).

It has also been argued that in societies where people habitually live in the shadow of hunger, those people develop, or are the beneficiaries of, social and cultural practices that ensure that even the poorest will not starve to death. Such practices are based on ideas of "shared poverty" and "mutual assistance," which some writers term the "moral economy of the poor" (Scott 1976). Under circumstances of famine, those who have food share it with destitute kinsmen and needy neighbors. These noneconomic relations in times of hardship include those between patrons and clients and between rich and poor. They offer a minimum subsistence and a margin of security, and they constitute a "subsistence ethic" based on reciprocity. There are many examples of this type of relationship (see Bhatia 1963 on India and Scott 1976 on Southeast Asia).

Although most examples are drawn from the past, it would seem that this "moral economy" has not completely broken down in the contemporary world. For example, reports indicate that during the drought and period of extreme food shortage from 1980 to 1983 in southern India, the support system worked well, at least for the aged (Caldwell et al. 1986). Further, A. Gupta (1988) goes so far as to say that the continued existence of such support in present-day India is responsible for the retention of people in the countryside. In Nepal, it has been found that the wealthy are encouraged to avoid reducing daily wages for agricultural work in difficult times and to refrain from selling grain outside the village (Prindle 1979).

In general, it seems that when the outcome of a season is still uncertain, landlords and patrons make some provision for laborers and the poor. But once signs of a famine are evident, landowners respond by reducing their number of field hands. As the crisis deepens, workers in other sectors of an agrarian society, such as fishermen, artisans, and a range of rural dependents, become affected by the lack of patronage and support from the wealthy as well, a situation that has been documented in many parts of the world (Arnold 1988).

Rural households try to build up stores of food and salable assets. However, the first is difficult to achieve for people who are involved in a web of impoverishment and exploitation that is a normal and continuing part of life. In many parts of Africa, Asia, and Latin America (and in Europe in the past), even in "normal years," most households experience shortfalls in production for their own consumption. Furthermore, some staples, like potatoes (which simply cannot be kept for as long as a year – or until the next harvest), rot and become inedible. Hence the historical attractiveness of cereal crops, because they can be stored for long periods. However, most people do have a range of salable assets (e.g., furniture, cooking utensils, jewelry, farm implements, livestock, and land) that can be converted to food as necessary.

Another strategy to mitigate the potential impact of famine is that of having a large number of children, thus improving security by increasing possible future family income. This strategy is an important one in places like Bangladesh, where children are considered to be a less risky investment than land (Cain 1978).

Once famine has begun, precautionary mechanisms are put into practice. There are others, which cannot be developed in advance but which also come into play as the famine unfolds. When there is a potential food shortage and possible famine, the period during which stress develops can be long, allowing for a succession of strategies. A review of a number of major studies of coping mechanisms in the face of famine (Watts 1983b; Corbett 1988; Rahmoto 1988; Waal 1989; Agarwal 1990; Brown 1991; O'Brien and Gruenbaum 1991) clearly identifies a sequence of activities. These include religious rituals and ceremonies, identification of scapegoats, reduction of the amount of food consumed and a longer spacing out of meals, substitution of lower-quality and wild foods, and calling for resources from others (especially family and kin), along with generating household income by wage labor, petty commodity production, and the sale of easily disposable items (as long as such sales do not undermine future productive capacity). But as the food crisis deepens, loans from moneylenders and the sale of important items, such as draft animals, agricultural implements, and livestock, become common. Finally, if all preceding strategies have failed to maintain minimum food levels, migration often ensues. But let us now examine some of these coping mechanisms in more detail.

The cultural context of famine has everywhere been reflected in religion, and one of the first responses to famine in any society has likely been an intensification of ritual. Prayers offered up in churches, mosques, and temples are supplemented by special rituals and ceremonies in streets, fields, and public places. Deities, saints, even plants and animals, are invoked.

When rituals fail to bring relief, more divisive or desperate responses can follow. Sometimes, scapegoats are sought out. Other times, the physical and spiritual anguish brought on by famine and pestilence has bred religious fanaticism. In some instances, the persistence of famine has caused doubts about the gods of the established pantheon. For example, in the famines of the late 1870s in India and China, Western missionaries won converts by pointing to the apparent failure of local deities to protect worshipers from want. In some societies, however, the people place great faith in divine will and believe it blasphemous to question their gods' purposes and intentions.

As a famine marches remorselessly onward, societies respond more materially. For example, the planting of a crop might be delayed, crop varieties with shorter growing seasons or lower water requirements might be planted, parts of farms might be abandoned and effort focused on better locations, or seed grain might be consumed rather than sown. While this is happening, households might reduce the amount of food consumed at each meal and space meals out over longer and longer intervals (just as they do during the "hungry gap," a period of seasonal food shortage that is a part of normal life; during this time, people know that they will lose some weight and then recover) (see Garine 1991).

In order to eke out food supplies, adulteration of staples often occurs. As a crisis deepens further, wild, "famine" foods replace staples. Different items fall into this category in different parts of the world. In Niger, for example, the pith of palm trees and lily roots are used, and in nineteenth-century Ireland, it was nettles, berries, fungi, seaweed, frogs, and rats. In China, people have eaten grass, bark, and even earth to quell hunger. As "famine" foods were often found on communal lands, continuing access to such lands today can be especially significant in densely populated regions (Blaikie, Harriss, and Pain 1985; Agarwal 1990; Chambers, Saxena, and Shah 1990).

At this stage, people usually sell the few assets they have to buy food, especially once food resources available from family and kin have been exhausted, along with other sources of family income such as wage labor, petty commodity production, and artisanal work. Houses are stripped of their furniture, doors, and window frames. Women sell cooking utensils and jewelry, and finally, farm animals and implements are sold, thus jeopardizing prospects of agricultural recovery after the famine ends. People may try to borrow money, but often moneylenders and even banks are loath to give credit in years when there is no harvest to lay claim to. As a last resort, land might be sold, which (along with migration) is one of the unmistakable signs of acute and deepening crisis. In Bengal in 1943, for example, over 250,000 households sold all their land, and 600,000 more sold part of their holdings. Considering the importance of land, such sales are a sign of desperation. As in the past, losing land as a result of famine is still one way in which property holders sink into the residual class of landless laborers. The sale brings short-term relief from starvation but has the net effect of increasing vulnerability.

While all of this is happening, those in the worst-hit portion of the population frequently begin to contest their deprivation. Laborers and tenants petition landlords, patrons, and governments, demanding to be fed. In the past, and in some places today, a lack of response to such pleas for relief has led to the looting of grain stores, market stalls, warehouses, carts, trucks, and barges. It is at such moments of mounting tension, anger, and fear that the idea of the poor having a right to food is most forcefully evinced (Thompson 1971). But food riots in most places and times have not lasted indefinitely; rather, they died away once provision was made for the basic needs of the hungry or, more often, the situation deteriorated further until no food was to be had by any means.

One common alternative has been recourse to what officialdom and the propertied elites have seen as "crime"; like food riots and looting, this measure has been a characteristic and almost universal way of coping with famine. Famine crime has assumed many forms, ranging from an intensification of normal banditry, sheep stealing, and petty theft, to murder. Usually, as society fractures under famine's pressure, crimes against property and persons soar.

When all attempted strategies have failed to maintain minimum food levels, migration occurs. Although this can be considered a demographic response to famine, it is also an important coping strategy. Much famine migration has been short-term and over relatively short distances, and once conditions have improved, people return to their homes and farms. This was true in Europe in the past (Sorokin 1942), and it certainly has been the case in a variety of other places in the world. During the Indian famines of the nineteenth century, there were many such movements to unaffected areas, and to the cities, in search of relief. In Brazil, the northeast has witnessed temporary flights to the towns in 1878, in 1915, from 1930 to 1932, in 1942, and in 1958. The Sahelian crisis from 1970 to 1974 also produced large-scale population movement (Caldwell 1975), much of which focused on refugee camps. There was also much short-distance local migration, some of it to the cities.

But famine-induced migration also has a permanent dimension, which is one of the more enduring demographic consequences of famine. It can be documented from preindustrial Europe, where this type of "forced" migration resulted in the colonization of new agricultural areas. Perhaps the most spectacular famine-induced migration out of any area in Europe was associated with the Irish famine from 1846 to 1851, when about 1 million people migrated to the United States and England. Between 1852 and 1916, another nearly 5 million Irish left, three-quarters of them bound for the United States. During the Sahelian crisis, much of the famine-induced urbanization, especially of pastoralists, was permanent (Colvin 1981). The sequence of famines in the Brazilian northeast has produced a permanent migration of peasants to the tropical rain forests of Amazonia and to São Paulo and Rio de Janeiro. In the nineteenth century, famine was one of the impelling forces behind the Indian diaspora to Natal, Mauritius, Malaya, Fiji, Guyana, and nearby Sri Lanka (then Ceylon). The exodus from southern India to the tea and coffee plantations of Sri Lanka reached its peak during the 1870s, a time when a high level of labor demand was matched by famine in Madras.

Women and Famine

The burden of famine has fallen, and in many developing-world societies continues to fall, with exceptional severity on women. One reason for this is that, in many parts of the world, women traditionally either have been the main agricultural producers or have constituted a substantial part of the agrarian workforce. Colonial regimes often had no practical interest in developing opportunities for women. Education and new employment opportunities were directed toward men, who took up work in the mines, on the plantations, and in the cities, often far from their home villages, weakening their commitment to subsistence labor, which, more often than not, was left to the women. Thus, the onset of a famine hits women directly. Their food production dwindles, and when field laborers are dismissed or left without employment, they lose cash and in-kind income as well.

The burden of famine also has fallen heavily on women because of their customarily low status in patriarchal societies. In many societies there is a cultural expectation that women will sacrifice their food and, ultimately, their lives to enable their husbands and sons to survive. Women normally eat after the men, and when food is in short supply, female children tend to be neglected and resources concentrated on male children. There is a great deal of historical and contemporary evidence to show that part of the burden of hunger and suffering has been transferred to women through neglect, starvation, abandonment, and sale into prostitution. Women, in short, have been victimized in the interests of male survival.

Famines, therefore, impose enormous physical and emotional suffering upon women. Women have often killed their children; marital relationships can be strained to the point of divorce and abandonment; and hunger can drive women into prostitution and slavery. They have been sold by landowners, moneylenders, and other males with authority over them, for money and for food. Further, in many parts of the world, even today, one of the commonest responses to famine has been the sale of children, especially girls. Thus, the devaluing of life that occurs in a famine has often further favored male power and ascendancy.

Conflicting Ideas about Famine Causation

An enormous literature has grown up to explain why famines occur. Once, "acts of God" and "freaks of nature" were seen as self-sufficient explanations for why people hungered and died. Warfare, blockades, and deliberate hoarding of grain have also been commonly used to explain why famine happened. Today, writers on the causes of famine are more disposed to see these as only precipitating or contributory factors, and, increasingly, famine has come to be regarded as a complex phenomenon, more a symptom than a cause.

One of the main sources of confusion about the subject arises from the multiple causes of famines and their great variety in space and time. Some of the literature makes a distinction between "general and predetermining factors," or the time–geographic dimensions of famine (long-term, intermediate, and immediate), and the trigger mechanism of the actual famine (Currey 1979, 1980; Murton 1980). W. I. Torry (1986) uses similarly distinct "ultimate" and "proximate" causes of famine, and P. M. Blaikie and colleagues (1994) employ the terms "root causes" and "underlying pressures," which create "unsafe conditions." It is also important to acknowledge that if there are many combinations of factors and mechanisms that bring about famine, then each famine is unique. Indeed, the task of building theories of famines is particularly difficult because of the complexity of each specific case. Any theory will involve an understanding not only of the existing systems of production but also the distribution of food in terms of access to land and inputs, as well as the operation of the market, the determination of prices, and the behavior of traders in food staples (Canon 1991). Government policies with regard to food production and distribution (and famine relief) may also play a profound role. Then there is always a series of contextual events peculiar to each famine, a "sequence of events" (Alamgir 1981), or in Currey's (1984) parlance, a "concatenation."

Two main (and largely competing) types of famine explanation, based on differing sets of causal mechanisms, can be identified. Many commentators have assumed that a famine arises out of an actual shortfall in the means of subsistence, or as it is commonly labeled, a food availability decline (often abbreviated to FAD). Either some natural disaster occurs, causing a crop failure to reduce the aggregate amount of food available, or population in the long term outstrips the quantity of food available. The other mechanism involves the decline in some people's entitlements to food (abbreviated to food entitlement decline, or FED). According to this explanation, first articulated by Sen (1981), famine is a result of the ways in which access to food is reduced because of the operation of social and political processes that deny or lessen "entitlement" to food.

These processes may involve a deterioration in the ability of people to grow their own food or to buy it through various forms of exchange. To this context should be added the impact of various hazards that may not reduce the overall amount of food but instead affect the success of different groups of people in fulfilling their entitlements. This type of explanation focuses much more firmly on relations of power within a society that may account for the distribution of assets and income (unequal in "normal" times) that become a matter of life and death in times of famine. This model tends to reduce the causal importance of natural events, which although they may be limited to a decline in the aggregate supply of food (with the impact of drought, flood, or pest attack), are analyzed in the context of the political economy of root causes and predetermining factors. In other words, people are made vulnerable to the impact of a natural hazard by their place in the economic, political, and social processes that affect their exchange entitlements.

Food Availability Decline (FAD)

The school of thought that attributes famine to an aggregate decline in the supply of food is clearly linked to explanations of famine in terms of natural events. In particular, drought has been identified as a major immediate cause of crop failure and, therefore, of a decline in food supply. It is difficult to find pure supply-side explanations of famine in the recent literature, but between the decline in aggregate food supplies and its immediate causes (such as drought) on one side, and the detailed mechanisms that actually precipitate famines on the other, the emphasis is usually on the former (Blaikie et al. 1994).

In addition to analyses of recent famines, the historical literature contains considerable discussion of the long-term shifts of climate that have appeared to gradually undermine a society's apparently secure subsistence base. Generally, whereas most historians have been wary of embracing the type of "climatic determinism" posited by Ellsworth Huntington (1915, 1919) and have tended to see climatic variations as too short-term and peripheral to provoke major subsistence crises, others have acknowledged that a substantial number of historical famines in many parts of the world were preceded by partial or complete failure of the rains (Arnold 1988).

Unfortunately, much of the writing also tends to subtly argue that if famines could be attributed to natural causes, they could be explained in terms of exceptional events and not by continuing and normal social processes (Hewitt 1983b). K. Hewitt (1983a) even argues that a previous generation of academics and practitioners virtually ostracized those who sought explanations that went deeper than the impact of the natural hazard. Given the dominance of science and technology in the modern era, the publication of any analysis of causes that failed to suggest that hazards could be modified and responded to by technology resulted in the exile of its authors from the mainstream social explanation.

Another important element in the food availability decline approach has been the "overpopulation" thesis. Deeply rooted in Western thought, the thesis is most commonly identified with the writings of Thomas Malthus (Turner 1986), who believed that the food supply was relatively inelastic, increasing at best by arithmetical progression, whereas population rose in geometrical leaps and bounds. In periodically sweeping away the excess population, famines maintained a rough equilibrium between population and subsistence. However, this thesis was to prove untenable for Britain (and Europe generally), where a transformation of industry and commerce improved agricultural productivity and transportation and led to the increased importation of foodstuffs. Not only did rapid population growth fail to trigger famine, but standards of living rose. Increasing prosperity and material security, however, were also accompanied by a growing practice of birth control through various means.

Although Malthus's thesis seemed to square with nineteenth- and early-twentieth-century reality only in places like India and China, since the 1950s, famines and food crises in Africa and Asia have led to a strong revival of interest in his ideas. Population in the developing world has risen sharply, largely as the result of improved medical services and sanitation. Food production is frequently, but not altogether accurately, assumed to have not kept up, and with too little food to go around and too many mouths to feed, famine has been predicted on a global scale by numerous "prophets of doom," as for example, Paul Erlich (1968), and W. and P. Paddock (1967). But very often these dire predictions are based on simple measurements of global food supply stocks versus rising population rates, without taking into account high levels of wasteful food consumption in the West, the nature of foodstuffs produced, and the unequal nature of food distribution (between nations, and within states, classes, and even families).

Food Entitlement Decline (FED)

In *Poverty and Famines* (1981), the Indian economist Amartya Sen challenges the view that famines are caused by food availability decline. As already noted, he views famine as the result of the many and complex ways in which people's access to food is reduced because of the operation of social and political processes that deny or lessen their "entitlement" to food. Such an approach distinguishes between aggregate availability or supply of food and an individual access to, or ownership of, food. People obtain food through five different types of "entitlement relationships" in private-ownership market economies (Sen 1981; Drèze and Sen 1989, 1990): (1) There is production-based entitlement, which is the right to own food that one produces with one's own or hired resources; (2) there is trade-based entitlement, which describes the rights associated with ownership when they are transferred through commodity exchange; (3) there is own labor entitlement, which is the trade-based and production-based entitlement when one sells one's own labor power; (4) there is inheritance and transfer entitlement, which is the right to own what is given by others (gifts) and what is transferred by the state, such as pensions; (5) there are extended entitlements, which are entitlements that exist outside legal rights (for example, ownership) and are based on legitimacy and expectations of access to resources.

Such entitlements are not fixed and equal but vary according to an individual's position within a wider system of production, exchange, control, and distribution. Entitlements are either owned by a person or can be exchanged by that person for other commodities. People are vulnerable to starvation if their endowment does not contain adequate food or resources to produce food and their capacity to exchange labor or other goods and services cannot be translated into enough food. This situation can occur without a decline in aggregate food supply and without any disruption or malfunction of the market.

The food entitlements decline approach just discussed recognizes the relations of power within a society that may account for the distribution of assets and income and that become a matter of life and death in times of famine. It also acknowledges the importance of changes in purchasing power. Further, it disaggregates regional food production and availability and follows through how food is distributed to individuals (it permits analysis of intrahousehold food allocation and explains why the rich never die in famines and why some classes benefit from them). This approach involves the regional, national, and world economy in the analysis and draws attention to the possible prevention of famines by food imports.

There have, of course, been criticisms of the food entitlement decline approach. First, there is a scale and boundary problem: If the analysis is stretched to include a big enough area, there is always enough food to avert a famine. Second, some famines clearly have had their origins in food availability decline, and although it may be incorrect to identify this as an ultimate or even most important cause, it is inescapable that a fall in the amount of locally produced food (because of war, drought, or longer-term environmental decline) hinders the ability of people to find alternative sources of food. Third, initially, entitlements, as well as resources (endowments), were conceived of as static and given. But recent research (Watts 1991) has pointed out that they are fought over and constitute the terrain of struggle within societies in which group interests (defined by class, caste, gender, age, ethnicity) are in contradiction.

In conclusion, the entitlements approach to the analysis of famine has released famine study from theoretical constraints. However, this pursuit of a single theory of the mechanisms of famine has diverted attention from multiple causality and the possibility of famines at different times in the same place being caused by a mix of factors. This concern has led to the further development of the concept of famine vulnerability, to which the food entitlements decline approach alludes but fails to pursue in depth.

Famine Vulnerability Models

Two models have recently been proposed that attempt to take into account the multiplicity of factors that make people vulnerable to famine. The first, developed by M. Watts and H. G. Bohle (1993a, 1993b), argues that the locally and historically specific configuration of poverty and hunger defines what they call a "space of vulnerability." These researchers set out to provide a theoretical means by which this space can be "mapped" with respect to its social, political, economic, and structural–historical coordinates. They endeavor to radically extend the concept of entitlements, not simply in a social or class sense but in a political and structural sense, to take account of (1) the particular distribution of entitlements and how they are reproduced in specific circumstances; (2) the larger arena of rights in which entitlements are defined, fought over, contested, and won and lost (that is, empowerment or enfranchisement); and (3) the structural properties (what they call "crisis proneness") of the political economy that precipitate entitlement crises.

Watts and Bohle review the extensive literature relating to "entitlement and capability," "empowerment and enfranchisement," and "class and crisis." They emphasize that these processes can be grasped only relationally (as congeries of social relations), and they develop a tripartite structure that defines the space of vulnerability through the intersection of the three causal powers: command over food (entitlement); state–civil society relations seen in political and institutional terms (enfranchisement/empowerment); and the structural–historical form of class relations within a specific political economy (surplus appropriation/crisis proneness).

The intersection of these causal powers produces three parallel analytical concepts; economic capability, property relations, and class power. Economic capability emerges from particular configurations of entitlement and empowerment, property relations from the intersection of entitlement and political economy, and class power from specific forms of political economy and empowerment. The three causal powers or processes (entitlement, empowerment, political economy) are conceived of as accounting for mass poverty associated with specific long-term (structural) changes. Famine results from violent short-term changes in these same mechanisms.

The space of vulnerability also has an internal structure in which it is possible to locate vulnerable groups and regions. Because the concept of vulnerability is relational, the space and shape of vulnerability is given by its social relations. For example, if famine is described as a food entitlement problem, vulnerability is located in the realm of economic, and especially market, relations. If, conversely, famine resides in the powerlessness of individuals, classes, and groups to claim and enforce food entitlements, then vulnerability is determined by the power and institutional relations within civil society. Finally, if famine is driven by processes of exploitation and surplus appropriation, it accordingly occupies a location within the space of vulnerability that lies in the realm of class relations.

It is also possible to place both vulnerable groups (social) and vulnerable regions (spatial) within the space of vulnerability. In the former, vulnerable individuals, groups, and classes can be located according to the causal processes that present possibilities and constraints in the sphere of subsistence. Individuals and groups vulnerable to market perturbations and unable to cope with food entitlement decline because they are resource and/or asset poor, may be located in the "economic space" of vulnerability. If the likelihood of deprivation is rooted in politics that can be inscribed in gender (patriarchal politics), work (production politics), and the public sphere (state politics) – all of which may render individuals and groups powerless – their location in the "political space" of vulnerability is determined by power and institutional relations. Finally, if deprivation arises from processes of surplus extraction and appropriation, individuals and groups are located in the "structural-historical" space of vulnerability given by specific configurations of class relations. All these spaces obviously exist simultaneously. Determining the precise weighting becomes important in assessing the ways in which famine differs between Somalia, Kampuchea, or Bangladesh.

This social map of vulnerability has a geographic or spatial counterpart. Vulnerable regions can be located in relationship to the tripartite structure of causal processes. Economically marginal regions that regularly or sporadically experience fluctuation in productivity and prices are most liable to food entitlement crises (they occupy the "economic space" of vulnerability). Peripheral regions experience vulnerability through relations of dependency to a regional core that drains surpluses and resources away (they occupy the "political space" of vulnerability). Finally, regions shaped by endemic crises and conflicts (both economic and ecological) due to processes of commercialization, proletarianization, and marginalization are logically situated in the "structural-historical" space produced by class relations.

In summary, this modeling of the "spaces of vulnerability" integrates many of the factors identified by previous research on famine into a more logical and causal structure. It provides a way to integrate the intersections of structures, tendencies, and conjunctures as they impinge on the famine process. The specific content of the social space of vulnerability, the actual concatenation of events that might trigger famine, and the specific structural forces at work, although deriving from the abstract causal structure, will naturally be time- and place-specific.

Blaikie and colleagues (1994) also have produced a comprehensive dynamic framework, which they call an "access model." They focus on the way unsafe conditions arise in relation to the economic and political processes that allocate assets, income, and other resources in a society. Natural events are integrated into the model through a focus on how resources are allocated by social processes. "Access" involves the ability of an individual, family, group, class, or community to use resources that are directly required to secure a livelihood.

Access to those resources is always based on social and economic relations, usually including the social relations of production, gender, ethnicity, status, and age. Rights and obligations obviously are not equally distributed among all people, and it is argued that less access to resources leads to increased vulnerability. The model incorporates the notion of "trigger events": war, as in the case of Ethiopia (1984 and 1990), Angola, Chad, Sudan, and Mozambique (1984); or natural hazards, as in the case of the Sahel (1970–6), Sudan (1985), and Ethiopia (1973). The model analyzes the structures and processes of famine in relation to making a living in normal times. It is an iterative approach in which "external" shocks and triggers have their impact upon the structures and processes of political economy.

Famine Policy

Although an enormous literature has grown up to explain why famines occur and what to do about them, it is clear today that there is disjuncture between explanation and policy. Explanation is largely a product of the academic world. Policies for dealing with famine are a product of famine relief agencies, governmental advisers, and governments. The lack of affinity between the two types of literature is surprising. In an ideal world there should be a progressive and interacting relationship between theories of famine avoidance and relief and policy, but instead they are widely apart. The two sides are separated almost by a different language and are pervaded by different constraints and concerns.

Policy in the Past

Certainly, the fortunes of the state, whether in Europe, Africa, or Asia, have long been bound up with the containment or prevention of famine and, more generally, with provisioning the populace. Protecting its subjects from starvation and extreme want has for centuries been one of the primary functions of government and one of the principal expectations of the public. If we look for pre-twentieth-century evidence of the state as an agency of famine control and as a provider of famine relief, we can find it in places as far apart as China and Europe. In China, state paternalism, fostered by the ideology of the Confucian state, led to the protection of peasants from the worst effects of natural disasters, as well as measures for famine prevention and relief. But this system began to break down in the nineteenth century, and the situation remained chaotic until after 1949. Famine control was one of the first priorities of the new Communist state and, seemingly, one of its great successes, until the famine from 1958 to 1961 cruelly exposed the limitations of China's agrarian revolution.

In medieval times, European states did what little they could to avert the threat of famine. As Europe crossed the threshold from medieval to modern times, problems of provisioning (especially of the growing cities) increased, as did the problems of maintaining order in food-shortage situations. One response in England in the late sixteenth century was the issuing of orders, which became the bases for the English Poor Law, to counter the problem of vagrancy and destitution. In France, the provisioning of Paris received special attention from the government, and alarm over basic subsistence needs helped to make the revolution of 1789.

In Europe, however, as agriculture became more productive and increasingly market-oriented, governments sought to free themselves from the obligation to feed people and regulate markets. In France, attempts to make subsistence a matter of individual rather than state concern was short-lived, but in England, ideas of "free trade" gained increasing momentum in the late eighteenth century and the early years of the nineteenth. In 1814 and 1815 the Corn Laws, the last bastion of old protectionists and paternalists, were eroded, and in 1846, under Sir Robert Peel, they were finally swept away. By this time in Britain, policymakers were imbued with the belief that market forces should not be tampered with and that self-reliance must not be weakened or local effort superseded by the activities of the government. This commitment to laissez-faire, and the notion that the state should not intervene in famines, was immediately tested in Ireland, where initially the state's role was seen as being strictly confined to providing employment on public works. Only in 1847 was emergency relief belatedly instituted.

The Indian Famine Codes

In India, the East India Company administration also strongly supported the new orthodoxy. Even during the famines and shortages of the early nineteenth century, the presidency and provincial governments adhered firmly to the principles of noninterference in the operation of the market and trade. But it became evident, particularly during the heavy mortality of the 1860s and 1870s, that a policy of laissez-faire alone would not meet the extreme recurrent crises of famine. A number of reports demonstrated that the government had lost enormous amounts of revenue by not investing in irrigation, other preventive works, and railways to stimulate production and to move food to food-shortage areas. Although the general principle of nonintervention in the grain trade remained inviolate until World War II, by the late 1870s there were moves, however hesitant, toward greater state responsibility for the Indian economy and for the welfare of the Indian people.

This change in policy resulted in the first coherently written explanation of famine, linked to policy recommendation. From the 1860s extensive reports were written on famine, and in 1878 the First Famine Commission was appointed (Brennan 1984). Its reports of 1880 led to the drafting of the Famine Codes of the mid-1880s by each of the provinces of India. The reports also contained much speculation about the causes of famine. The reports are especially instructive on the relation between the theories of famine causation and policies of prevention, relief, and rehabilitation.

Reasonably effective policies were formulated from these efforts. The Famine Codes reveal a professed dislike of interference in the operation of the market through price controls, and contain the belief that free trade is the best guarantee of satisfying effective demand. There is also an aversion to charity and free handouts and a strong ethic of "self-help." Thus, the backbone of famine relief was massive public works generating guaranteed employment, plus free assistance for those unable to work. That the latter breached ideology was accepted as necessary to prevent people from dying. Tests were established to ensure that only the deserving received relief. There were detailed instructions in the Codes about early warning signs of impending famine; the duties of the police, medical officers, and other local officials; wages and rations; famine relief works; and many other practical instructions. The codes were used by the British until 1947. Their effectiveness is still the subject of heated debate, with an overstated radical and nationalist critique on one extreme and an imperialist apologist defense on the other, but since 1947, the Codes have continued to form the basis of famine prevention and relief. Thus, the Maharashtra drought of 1970 to 1973 was effectively prevented from triggering a famine by an employment guarantee scheme similar to that found in the earlier Codes.

Contemporary Policy Directions

Contemporary policymaking recognizes that for each link in any explanation of a famine there are a range of policy measures. A key issue that must be addressed is the relationship of policy action to the level of a problem where it can be effectively altered. Although an integrated explanation of famine may be intellectually fulfilling, a policy has to be located at a level at which it can make a significant impact: There must be a short-run effectiveness, as human lives often depend on it. However, often a focus on the short term can lead to a loss of any sense of the real causes of vulnerability. This is the contradiction that faces the makers of famine policy: They are restricted by temporal and spatial scales at which they must work and to which they must fit their policies.

Food Security

At the international and national level, achieving aggregate food security has been an important policy goal. In particular, national food self-reliance is frequently seen as a defense against famine. However, with global increases in flows of goods and information, localized and even national production failures have become increasingly remediable by imports of food, whether as trade or aid. At the global level, food supplies over the last couple of decades have been sufficient to provide an adequate (although near-vegetarian) diet to all, if distributed equitably. However, global food supplies are still not distributed according to need, and shortages at regional, national, and even subcontinental levels have continued.

During the 1980s and early 1990s, some shortages have been caused by the continuing difficulty that international humanitarian relief efforts have had in gaining access to affected populations caught up in civil wars. This has led to the discussion in a number of countries of when and how national sovereignty should yield to humanitarian care for people in disastrous situations. This problem is more than a relief policy issue, and it raises geopolitical and, above all, ethical concerns about the human right to food, shelter, and health care (Waal 1991).

The theoretical advances that Sen's entitlement theory has afforded have led to some reevaluation of the importance of food security at the national and international levels. The insights that form the theory also suggest that a disaggregated approach to food security is required, which has led to a growing policy concern for vulnerable groups at the local level and the promotion of the idea that entitlements should be strengthened. However, at the level of large regions and nations, concerns over food availability remain important, especially where agreements among countries to exchange grain are involved, as in the case of southern Africa.

Any discussion of food security must also consider the political and economic significance of food aid since World War II. The United States, as a major food surplus state, has used food aid as an important political tool. Food assistance has been withheld from Marxist-run governments but ensured to reliable and dependent allies. Yet, in addition to these political objectives, continuing food aid abroad has helped to save grain farmers from bankruptcy at home. Overseas aid has been vital to the U.S. economy as a safety valve for its domestic overproduction. In 1961 the Kennedy administration was faced with the greatest American food surplus in history, and it was this domestic situation, rather than humanitarian concern, that prompted massive grain shipments overseas in the following years, notably in 1966 when one-fifth of the entire U.S. wheat crop was sent to India to relieve the effects of famine in Bihar.

Food aid has accounted for 28 percent of U.S. overseas development assistance since 1946. The Agricultural Trade Development and Assistance Act of 1954 (Public Law 480) was debated and approved by Congress not for humanitarian reasons or for development ends, but in order to promote trade and dispose of existing surpluses. Food aid has served to open new markets for American farm products, especially in Africa and Asia, often to the detriment of local agriculture, and the threat of food withdrawal or denial has been used to put pressure on countries to accept other forms of American economic intervention and political control.

Relief and Development

The issue of food aid raises another very important question: Should famine prevention efforts be short-term, basically the giving of food relief, or long-term, and more of a developmental nature in scope? In many ways this is something of an academic question, because so long as there are food shortages and famines in the contemporary world and there are donors willing to provide food aid and cash, short-term relief assistance will continue to be important.

Today, in addition to relief provided by national governments in times of crisis, there are a number of United Nations agencies and numerous nongovernmental organizations involved in famine relief (see Busetto 1993; Cullinan 1993; Katona-Apte 1993; Longford 1993; Singer 1993). The earliest United Nations agency established to provide humanitarian relief was the United Nations International Children's Emergency Fund (UNICEF), set up in 1946 to help children in the aftermath of World War II. Various other agencies, such as the United Nations High Commission for Refugees, established in 1951, and the United Nations Relief and Works Agency, established in 1950, have been active in the provision of relief, but since 1963 the World Food Programme has been the primary international agency involved in food aid.

Over the past three decades, the World Food Programme has invested approximately $13 billion and has provided more than 40 million tons of food aid to combat world hunger and to promote economic and social development. Food aid has been used to assist more than 1,600 development projects and 1,200 emergency operations. Within the United Nations system, the World Food Programme is now the largest source of grant assistance to developing countries, the largest source of assistance for poor women, and the largest provider of grant assistance for environmental activities in developing countries. The agency is headquartered in Rome, and although it has employees in 85 countries, it spends less than 6 percent of its budget on administration.

From the outset, the agency aimed to serve as more than a mechanism for surplus disposal or a means of providing charity for the poor. Indeed, by the late 1980s, two-thirds of its resources were being spent on development activities. However, numerous emergencies since that time have channeled 60 percent of its current resources into relief operations, and in 1993, new development commitments received only $250 million, in contrast to $778 million in 1988. At present, the agency has at any one time about 5 million tons of food in transit on 50 chartered ships, but it is hoped that once present emergencies end it will again be able to emphasize development.

Throughout the world, there are also a very large number of nongovernmental organizations, such as Save the Children, Oxfam Lutheran World Federation, Red Cross, Africare, Food for the Hungry, and Catholic Relief, involved in relief activities. Although many have other objectives, because they operate at local levels they are well placed to provide famine relief, sometimes parallel to large-scale governmental and international aid and sometimes as a conduit for that aid. Many also endeavor to administer food relief in ways that strengthen local livelihoods in the long run. Basically, these groups are involved in both relief and development, as they realize that relief alone can create dependency. But the great number of such organizations can occasionally create the problem of "swamping" affected areas by official and nongovernmental organizations who frequently do not coordinate their activities and who often collectively provide excessive relief assistance but not enough help for long-term mitigation.

Longer-term mitigation involves less direct measures for preventing famine, and the most important policy requirement is the strengthening of rural livelihoods. Of course, these measures can have objectives other than famine prevention and have development goals that are justifiable as ends in themselves. For example, in India, the government has attempted land reform, improved agricultural production technology, encouraged better processing and storage, operated a fairly effective system of public distribution of food, and developed a well-tried decentralized emergency response mechanism. All of this means that a reasonably effective famine prevention strategy has emerged, although malnutrition is still widespread. Nevertheless, as we have seen, it is difficult anywhere to demonstrate the level of impact of general rural development policies in famine prevention because the causes of famine are conjunctional and always involve a complexity of factors.

Early Warning Systems

The Indian Famine Codes established the idea of warning indicators that could be used to predict the onset of famine. For long, they were the only "early warning system" in operation, but since the Sahelian famine of the early 1970s, a number of famine early warning systems have been established (Blaikie et al. 1994). There are many different approaches to such systems. Some involve the use of sophisticated technology, such as the Food and Agricultural Organization's Global Information and Early Warning System, developed in the 1970s, which predicts crop yields by establishing biomass from satellite imagery. Another comparable approach is the United States–funded Famine Early Warning System. Approaches like this are all based on the assumption that famines are primarily caused by natural events and that technological solutions will be important mitigating elements. However, other early warning systems are much less complex and involve the collection and collation of local-level information on food stocks, prices, and such things as the sale of household assets.

Summary and Conclusion

Although there is considerable uncertainty regarding the nature and extent of the world's food problems, hunger is a contemporary reality, even within rich countries. Everyone must eat, and because of this simplest of all imperatives, famine is a subject of urgent contemporary concern. It casts a harsh but clear light on the nature and problems of the societies it afflicts and the world in which it exists. However, "famine" is a rather imprecise term normally used to describe events associated with natural hazards such as drought, floods, and pest infestations, and with political events such as war, malicious or inappropriate state policies, and ethnic prejudice. Famine is often (though not always) preceded by prolonged malnutrition and hunger, and part of the difficulty in defining it arises from the need to make a distinction between "ordinary" hunger and the phenomenon of famine. The latter term is generally reserved for situations in which starvation affects large numbers of people in a distinct area, which has been influenced by a natural or political event, leading to a larger number of deaths from starvation and illness than would normally be expected. By contrast, ordinary hunger is conventionally explained as a result of the imperfections of economic systems. Clearly, then, famine remains in danger of being explained as something caused by an exceptional political or natural factor – one that is abnormal and outside the responsibility of the usual operation of economic and political systems.

Fortunately, of late it has been recognized that natural hazards or political events are no more than immediate "triggers" or proximate causes. The "ultimate causes" must be sought out and understood in the normal economic and political sphere. Basically, a proper understanding of famine and all its dimensions requires an approach that does not merely deal with shortages of food but focuses instead on the inability of people to consume enough food. Thus, instead of treating famine as a shortage of food, it is preferable to analyze the different ways in which people are prevented (by natural or human events) from getting enough to eat. Using this alternative approach, it can be asked why certain groups of people are predisposed to famine before the impact of any trigger event, natural or political. Such a predisposition has been termed vulnerability, and the ultimate causes of famine can then be analyzed as those that create the conditions in which certain trigger events lead to the collapse in people's ability to acquire adequate nutrition.

This issue is not merely theoretical because the policy implications of understanding famine as inadequate consumption rather than inadequate availability are likely to be very different. When famine occurs even though food is available, or when famine affects some groups but not others, then food aid may be irrelevant. This issue is now at the core of the interpretation of famine and associated policy directions. It is one not of food security but of entitlement security and its corollary, the reduction of vulnerability among those who are the most vulnerable.

VI.5 ~ Height and Nutrition

Scientists have long recognized that there is a close association between the height of a population and its nutritional status, and by the end of the nineteenth century governments were coming under increasing pressure to measure their citizens as a means of determining that status.[1] Many have done so in the twentieth century, as height and weight statistics have played an ever increasing role in health assessment programs (Tanner 1981). This chapter employs the data generated thus far to construct a general picture of changes in height and nutritional status in various countries during the course of the twentieth century.

The studies on which this chapter is based have taken a variety of forms. Most of the information about changes in average heights has been derived from school surveys, but a great deal of data on adult heights is also available. Many of these data have been derived from military recruiting records and are primarily concerned with the heights of adult men (Floud, Wachter, and Gregory 1990).

In addition, a number of investigations have focused on changes in the timing of growth spurts and in overall rates of growth. These investigations have tended to focus on the age of peak-height-velocity (PHV) in both males and females and the onset of menarche in girls (e.g., Matsumoto et al. 1980; Matsumoto 1982; Danker-Hopfe 1986). Some observers have also examined changes in the relative dimensions of different parts of the body, such as leg length and sitting height (Himes 1979; Tanner et al. 1982).

The relationship between social and economic changes and changes in height is both simple and complex. On the one hand, there is a clear association between the average height of a population and its standard of living. This is reflected in the unprecedented improvements in average height that have occurred in many parts of the world during the past one hundred years, and in the differences that continue to exist between the average heights of people from different socioeconomic backgrounds (e.g., Rea 1971; Rona, Swan, and Altman 1978; Jones, Nesheim, and Habicht 1985).

On the other hand, it is much more difficult to define the precise significance of different components of the "standard of living." Most observers, for example, would agree that the two most important environmental determinants of height are diet and disease, but it has proven extremely difficult to establish their relative importance (Roche 1979). Some have suggested that "health care may be more important than nutrition in the first year of life" and that "nutrition may be more important than health care" after the first year, but the evidence on which these suggestions are based is far from conclusive (Floud et al. 1990: 249).

Another area of difficulty concerns the relationship between environmental and genetic influences. There are evident differences among the heights and rates of growth of different ethnic groups, but the extent to which these differences are genetic or environmental in origin is not clear (Eveleth 1979: 388; Eveleth and Tanner 1991). However, it is reasonable to argue that changes in the average height of members of the same ethnic group over time reflect environmental and nutritional changes rather than changes in genetic potential (Floud et al. 1990). We can also seek to isolate the genetic determinants of growth by comparing the heights and weights of members of the same ethnic group in different circumstances and in different parts of the world (e.g., Moore 1970; Greulich 1976; Bindon and Zansky 1986).

It is important to remember that changes in social and economic conditions can affect heights and rates of growth in a number of different ways. In general, undernourished children who are subjected to repeated bouts of infection grow more slowly than children who are well nourished and live in a largely disease-free environment. Undernourished children experience the adolescent growth spurt at a later age, and although they continue to grow for a longer period, their final height is shorter. These differences mean that the gap between the heights of the two populations is at its greatest when the more favored children reach adolescence. The increase in the average value of children's heights has, therefore, been considerably greater than the increase in the average heights of adults (Floud et al. 1990; Eveleth and Tanner 1991).

The structure of this chapter follows that laid down in P. Eveleth and James Tanner's invaluable surveys of *Worldwide Variation in Human Growth* (1976, 1991). The first two parts examine the main trends in the average height of Europeans in Europe and the heights of Europeans outside Europe. This is followed by sections on the heights of Africans in Africa and the Americas; the heights of Asiatics in Asia and the Americas; the heights of Indo-Mediterraneans in the Near East; the heights of peoples in North Africa and India; and finally the heights of Australian Aborigines and Pacific Island peoples. The last section summarizes the evidence and considers some of the implications of that evidence for future health policy.

Europeans in Europe

Europeans living in Europe have been the subject of a particularly large number of anthropometric surveys. Many of the earlier investigations were concerned with the heights of adult male army recruits, but the present century has seen a growing concentration on the heights of schoolchildren. We also possess a considerable amount of data on the age at which European girls reach menarche, and there is some information about changes in European birth weights. The long history of anthropometric monitoring in Europe, combined with the availability of large amounts of data, has encouraged a number of investigators to use the heights of Europeans as "standards" against which to assess the growth of other population groups (e.g., Eveleth and Tanner 1976, 1991).

Studies of European heights provide some of the clearest evidence of the increase in average height that has occurred in most parts of the world during the course of the twentieth century. In 1991, for example, Eveleth and Tanner reported evidence of a secular trend toward increased adult height in

Table VI.5.1. *Changes in the heights of European army recruits circa 1900–1975*

Country	Period	Change in height (cm)
Belgium	1902/4–69	8.1
Denmark	1904/5–66/75	8.4
France	1900–60	7.5
Germany (Bavaria)	1900–58	4.2
Italy	1900–52	3.6
Netherlands	1907–75	11.1
Norway	1900-60	6.7
Spain	1903/6–55	3.1
Sweden	1900–74	8.1
Switzerland	1908/10–57	6.2

Source: Floud (1984).

Sweden, Finland, Norway, France, the United Kingdom, Italy, Germany, Czechoslovakia, Poland, Hungary, the Soviet Union, the Netherlands, Belgium, Switzerland, and Austria (Eveleth and Tanner 1991).[2] Similarly, in 1984 Roderick Floud showed that the average height of army recruits in 10 European countries increased by between 3.1 and 11.1 centimeters (cm) during the years 1900 and 1975 (Table VI.5.1).

Some investigators have attempted to infer changes in average height by comparing the average height of men and women of different ages at the same point in time. Thus in 1971 Erik Bjelke demonstrated that Norwegians who were born between 1920 and 1929 were between 1.7 and 1.8 centimeters taller than Norwegians who had been born a decade earlier (Bjelke 1971). In 1988, Mary Walker, A. Shaper, and G. Wannamethee compared the heights of 7,735 British men who were born between 1919 and 1939 and concluded that the average heights of successive birth cohorts had risen by approximately 1.3 centimeters per decade (Walker, Shaper, and Wannamethee 1988).

There have also been a large number of investigations into the heights of children. The average height of 5-year-old boys in London increased by 7.4 cm between 1905–12 and 1966, whereas the average height of 5-year-old girls increased by 7.5 cm (Cameron 1979). Even more dramatic was the average height increase of 12-year-olds in Oslo, which was 12 cm for boys and 12.5 cm for girls between 1920 and 1975 (Brundtland, Liestøl, and Walløe 1980). In Sweden, the average height of 12-year-old children increased by a similar amount between 1883 and 1965–71 (Ljung, Bergsten-Brucefors, and Lindgren 1974), and the average height of 13- to 14-year-old children in Holland increased by more than 20 cm between the mid-nineteenth century and 1965 (van Wieringen 1979).

In addition, there have been striking changes in the heights of children in central and eastern Europe. For example, the average height of Czechoslovakian 12-year-olds increased by between 12.8 and 15.5 cm between 1895 and 1968–70 (Suchy 1972), whereas the average height of 14- to 18-year-olds in Moscow increased by between 3.6 and 5.7 cm between 1925 and 1965 (Vlastovsky 1966). Moreover, the average heights of 12-year-old girls and 14- to 15-year-old boys in Zagreb increased by 10 cm and 13 cm, respectively, between 1951 and 1982 (Prebeg 1984).

Secular changes in birth weights and rates of physical maturation have also been examined by a number of authors. Of the two, the history of birth weights has received rather less attention, but new data are slowly becoming available (e.g., Ward 1988, 1990). In 1966, V. Vlastovsky demonstrated that the average length of newborn boys in Kursk City rose between 1930 and 1939 and rose again after the end of the Second World War. However, babies born in 1959 were only 0.1 cm longer than boys born 20 years earlier. The average weight of newborn boys increased from 3.43 kilograms (kg) in 1930 to 3.49 kg at the end of the 1950s. In 1988 Margit Rosenberg revealed that the average birth weight of children in Oslo, Bergen, and Trondheim increased by approximately 0.2 kg between 1860 and 1980. However, these increases are much smaller than the increases in the heights (and weights) of older children and adults (Malina 1979a). In 1981 Tanner estimated that the average birth weight of full-term males born at the end of the nineteenth century was only 0.1 kg less than that of European children today.[3]

By contrast, changes in the rate of maturation and in age of menarche have been much more dramatic. In 1962 Tanner suggested that mean menarcheal age had declined by 4 years in Norway between 1840 and 1950; by 1.7 years in Sweden between 1890 and 1950; by 2.3 years in Finland between 1860 and 1940; and by 3.0 years in Germany over the same period (Tanner 1962, 1966; Steendijk 1966).[4] There is also evidence after the Second World War of a continuation in this secular trend in Austria, Belgium, Bulgaria, Denmark, Finland, France, Germany, Greece, Hungary, Italy, the Netherlands, Poland, Romania, Spain, Sweden, the United Kingdom, Yugoslavia, and the former Soviet Union (Danker-Hopfe 1986; see also Venrooij-Ijsselmuiden, Smeets, and van der Werff Ten Bosch 1976; Laska-Mierzejewska, Milicer, and Piachaczek 1982; Helm and Helm 1984, 1987).

Some writers have suggested that the trend toward earlier maturation may be slowing down and that in some areas it may have ceased or even been reversed (Eveleth and Tanner 1976, 1991; Vercauteren and Susanne 1985). However, in 1986 Heidi Danker-Hopfe compared the median menarcheal ages of girls in eight countries in the 1950s and 1960s with the median menarcheal ages of girls in the same areas in the 1970s and 1980s and found an average decline in menarcheal age of approximately three and a half months (Table VI.5.2).

Table VI.5.2. *Median menarcheal age of girls in various European countries, 1950s-60s and 1970s-80s*

Country	Period	Change in median age at menarche (yrs)
Belgium	1965-80/1	-0.10
Croatia (Zagreb)	1964-82	-0.45
France (Paris)	1965/6-74	-0.22
Hungary (Szeged)	1958/9-81/2	-0.43
Italy (Florence)	1955/7-77	-0.58
Netherlands	1965-80	-0.15
Poland (Warsaw)	1965-76	-0.28
United Kingdom (N.E. England and Newcastle-on-Tyne)	1967-71/9	-0.06

Europeans Outside Europe

Despite a wealth of information about the heights of Europeans in Europe, we know much less about the secular trend in the heights of European descendants in other parts of the world. The one obvious exception to this rule is the history of changes in the heights of European descendants in the United States. But there is also some information about long-term trends in the heights of European descendants in Australia, the Caribbean, and parts of South America. There have, however, been very few studies of the heights of European descendants in southern Africa.

The main trends in the heights of white Americans in the United States have been summarized on many occasions, including the work of Thomas Cone (1961), Howard Meredith (1963, 1976), Robert Fogel (1986), and Richard Steckel (1989, 1992). In 1986, Fogel revealed that the average heights of native-born white Americans rose steadily from the beginning of the eighteenth century up until the middle of the nineteenth century. This was, however, followed by a sharp decline in the heights of those born during the second half of the nineteenth century, although there was a resumption of the general upward trend in the first third of the twentieth century. Some writers have suggested that the secular trend ceased after World War II, but this suggestion was subsequently contradicted (Bakwin and McLaughlin 1964; Damon 1968). In 1989 R. Bock and R. Sykes demonstrated that the heights of people attending the Fels Institute in Ohio continued to increase after 1945, and T. Greiner and C. Gordon (1992) claimed that the average height of successive birth cohorts of white Americans increased by 0.7 cm per decade between 1910-14 and 1970-4 (Bock and Sykes 1989; Greiner and Gordon 1992).

In addition to studying the heights of adult Americans, a number of authors have also attempted to examine the heights of children. Cone, for example, showed that the average height of Boston children increased by between 3 and 7 centimeters between 1877 and 1930-56, and Harry Bakwin suggested that this trend continued into the early 1960s (Cone 1961; Bakwin 1964). The most comprehensive survey of heights in the United States was carried out by Meredith in 1963, who found that there had been very little change in either the length or weight of newborn infants since the end of the nineteenth century, but that there had been substantial increases in the heights of children from the age of 1 onward.

It is unclear whether these increases have continued toward the present. Eveleth and Tanner found no evidence of any increase in the heights of children in the United States between 1963-70 and 1976-80, but D. Jones, M. Neshiem, and J.-P. Habicht claimed that there was an increase in the heights of poor children over the same period (Jones et al. 1985; Eveleth and Tanner 1991).

There have also been a number of investigations into changes in the age of menarche among U.S. girls. In 1962 Tanner suggested that the mean age of menarche in the United States fell from 14.2 to 13.0 years between 1900 and 1950. These results have been confirmed by Grace Wyshak and Madeline Goodman. In 1983 Wyshak demonstrated that the mean menarcheal age among women born before 1920 was 0.86 years greater than the mean menarcheal age of women born after 1940 (Wyshak 1983). Goodman studied the mean age of menarche of 3,205 Caucasian, Japanese, and Chinese women in Hawaii who had been born between 1900 and 1940. The menarcheal age of the Caucasian women declined by 2.28 months per decade, whereas that of the Japanese and Chinese women declined by 6.36 months and 5.24 months, respectively (Goodman 1983).[5]

In view of the available data, it is probably inevitable that the anthropometric history of European descendants outside Europe should tend to concentrate on the history of those in the United States. There is, however, some evidence of secular changes in the heights of European descendants in Australia, Cuba, Argentina, and Venezuela. In 1983, for example, Antonio Gordon found that the average height of Cuban men had increased by between 5 and 6 cm since the start of the century, although he denied that the nutritional condition of the Cuban population had improved during the course of this period.

In Argentina, H. Lejarraga and colleagues (1989) showed that the average height of 15-year-old children in Buenos Aires had increased by between 6.5 and 8.2 cm during the interval between 1938 and 1981, and that the average height of 15-year-olds in Entre Rios had increased by between 4.5 and 6 cm between 1950 and 1981. In 1981 N. Farid-Coupal, M. Contreas, and H. Castellano discovered that the mean menarcheal age of girls in the Carabobo district of Venezuela fell by 1.7 years between 1937 and 1969. Moreover, the average height of children in Carabobo increased by 1.6 cm between 1978 and 1987 (Blanco, Landaeta-Jiménez, and Castellano 1989).

We also possess a limited amount of information about the heights of European descendants in Australia and Mozambique. The average height of children in western Australia increased by between 2 and 6 cm between 1940 and 1971, and that of children in Sydney increased by between 2 and 4 cm between 1937 and 1965 (Blanksby et al. 1974). These increases are somewhat greater than those recorded among white children in Mozambique. The average height of 7-year-old children in Lourenço Marques increased by only 0.5 cm (boys) and 1.5 cm (girls) between 1930 and 1965 (Martins 1971).

Africans at Home and Abroad

There have been a number of investigations into the heights of African populations in recent years, but very few of these provide any clear opportunity for chronological comparison. The main source of information about secular trends in the heights of Africans and people of African ancestry has been the United States. The lack of information about secular changes in the heights of Africans in Africa, combined with the poor social and economic circumstances of most of the continent's countries, has made it difficult to construct normal standards for assessing the growth of African children. However, studies of well-off Africans and black populations in the United States have shown that black children grow more quickly than white children between the ages of circa 8 and 14 years and experience puberty at an earlier age. These studies also suggest that Africans and African-Americans are more long-limbed than Europeans and white Americans, but that there is little difference in their final heights (Eveleth and Tanner 1991).

In view of the long history of anthropometric measuring in the United States, it is not surprising that we should possess quite a lot of information about the heights of black Americans. In 1963 Meredith suggested that the average height of 1-year-old boys rose by 5.7 cm between 1918–19 and 1944–56, and that the average height of 6-year-old boys rose by 6.3 cm between 1896–8 and 1957–8. In a separate study, William Moore discovered that the average height of 12-year-old boys increased by 17.41 cm between 1890 and 1968, whereas that of 12-year-old girls increased by 19.57 cm over the same period (Moore 1970). It is not clear whether the heights of black Americans continued to increase after this date. In 1979 Eveleth, E. Bowers, and J. Schall claimed that the average height of black adolescents in Philadelphia had increased by approximately 3.3 cm between 1956–65 and 1977, but the most recent national survey suggests that there was no increase in the heights of black children between 1963–70 and 1976–80 (Eveleth and Tanner 1976, 1991; Jones et al. 1985).

The availability of separate information about the heights of blacks and whites in the United States provides a valuable opportunity to study the secular trend in the heights of different population groups in the same national environment, but it must be admitted that the overall results are somewhat unclear. In his 1963 paper, Meredith argued that black males experienced greater increases in average height between the ages of 0 and 3, whereas white children experienced greater rates of increase between the ages of 6 and 17 (Meredith 1963). Yet Meredith also argued that black men experienced a greater increase in average height during early adulthood, and Moore has claimed that the average height of 14-year-old black boys increased by 2.88 cm per decade between 1890 and 1968. Previous estimates, however, had placed the rate of increase among black and white boys at 1.95 cm and 1.92 cm, respectively (Moore 1970). By contrast, Greiner and Gordon's study of the heights of successive birth cohorts of U.S. army recruits contradicted both studies. They argued that the average height of black Americans born between 1910–14 and 1970–4 increased at less than half the rate achieved by white Americans during the same period (Greiner and Gordon 1992).

Despite such an abundance of information about the heights of African-Americans, we know rather less about secular changes in the heights of Africans in other parts of the world – including Africa itself. The most detailed information comes from southern Africa, where there have been a number of studies of the heights of South African blacks and Kalahari Bushmen. P. Tobias (1962, 1974) found that the average height of adult Bushmen (San) had increased by approximately 3.5 cm since the start of the century, and in 1985 A. Hausman and E. Wilmsen revealed that the heights of San children continued to increase between 1967–8 and 1979–80 (Tobias 1962, 1974; Hausman and Wilmsen 1985).

The situation regarding black populations in other parts of southern Africa is more unclear. Tobias (1975) has argued that most southern African populations "show either the absence of the secular trend . . . or a frankly reversed secular trend" (145), but A. Walker and B. Walker have claimed that the average heights of black children in South Africa rose by up to 6.9 cm between 1938 and 1976 (Tobias 1975; Tobias and Netscher 1976; Walker and Walker 1977).[6]

A number of other studies have focused on the secular trend in the heights of Africans and people of African ancestry in Gambia, Mali, Nigeria, and the Caribbean island of Aruba. In 1981 Elisabeth van Wering demonstrated that the average height of children aged 5 to 14 on Aruba had increased by between 0.7 and 5.8 cm between 1954 and 1974. In a 1979 study suggesting improving nutrition in Nigeria, G. Ucho and A. Okorafor found that the mean menarcheal age of girls had fallen by approximately four months per decade since the early 1960s. However, no evidence of a secular trend toward greater height has been found in either Mali or Gambia. In Mali, the average height of adult men increased by only 0.2 cm between 1902 and 1985 (Prazuck et al. 1988). A longitudinal study of the heights of adult men and women in Gambia between 1951 and 1975 indicated that there was a slight tendency for height to decrease with age, but this was attributed to improvements in measuring techniques rather than to any real improvement in the heights of later-born subjects (Billewicz and Macgregor 1982).

Asiatics in Asia and the Americas

The term "Asiatic" describes a wide range of peoples who are believed to have originated in what is now known as the "Far East." Thus present-day Asiatic populations include Mongols, Arctic Eskimos, American Indians, and Indonesian-Malays. The latter group alone includes the indigenous populations of Japan, China, Thailand, and the Philippines (Eveleth and Tanner 1976, 1991). So far as the secular trend in height is concerned, we have much information about the heights of Japanese people in Japan and the United States and about Chinese people in China and Hong Kong. There is a smaller amount of information about the heights of other Asiatic populations in the United States, South America, and Indonesia.

The Japanese are arguably the most-measured population group in the world. This is largely because Japanese authorities instituted a national program of anthropometric monitoring at the start of the twentieth century and have continued to publish the results ever since (Tanner 1986). In 1966 Eiji Takahashi showed that the average height of Japanese adolescents increased slowly but steadily between 1900 and 1937. Then there was a sharp fall in average heights during World War II, followed by an even sharper increase between 1945 and 1960. The average heights of Japanese adolescents continued to increase after 1960, and in 1982 Tanner and his colleagues found that the average heights of 12-year-old girls and 13-year-old boys had increased by 7.9 cm and 9.7 cm, respectively, between 1957 and 1977. The average height of Japanese adults increased by 4.3 cm (men) and 2.7 cm (women) over the same period (Takahashi 1966; Tanner et al. 1982; see also Meredith 1976).

Students of the growth of Japanese children have also examined changes in the rates of their ages of peak-height-velocity. In 1982 Kenji Matsumoto demonstrated that the age at which Japanese children achieved their peak-height-velocity had fallen steadily over the course of the twentieth century (Matsumoto 1982; see also Nagai et al. 1980). Matsumoto also noted that the age at which girls achieved their peak-height-velocity had fallen particularly rapidly since the end of World War II, and he attributed this change to the dramatic improvement in the nutritional status of Japanese women during that period (Matsumoto et al. 1980). These conclusions correspond closely to those reached by students of the age of menarche. The mean menarcheal age of Japanese girls fell from 15.0 years for those born between 1896 and 1900 to 12.5 years for those born between 1966 and 1970 (Hoshi and Kouchi 1981; Nakamura et al. 1986).

In addition to the Japanese data, there is also a growing body of information about the height of Chinese people in both China and Hong Kong. In 1984 Alan Piazza found that the average height of Chinese boys remained roughly constant between 1915–25 and 1951–8, but rose very sharply between 1951–8 and 1979. He was unable to locate representative data for Chinese girls in the earlier period, but he was able to show that their heights rose equally sharply from 1951 onward.[7] There have also been significant changes in the heights of Chinese children in Hong Kong. J. Ling and N. King found that the average heights of 12-year-old boys increased by 6.7 cm and those of 12-year-old girls increased by 4.2 cm between 1961–3 and 1982–4 (Ling and King 1987: 187; see also Leung et al. 1987). The mean menarcheal age of South Chinese children in Hong Kong fell from 12.85 years in 1961–3 to 12.59 years 16 years later (Low, Kung, and Leong 1982).

We also have some information about the heights of Asiatic peoples in the southern United States, South America, and Indonesia. Pierre van der Eng has argued that the average heights of Indonesian and Indo-European children probably increased between 1911 and the late 1930s, but he was unable to find evidence of any further change between the late 1930s and 1973 (Eng 1995). Robert Malina and A. Zavaleta (1980) have indicated that the average heights of Mexican-American children aged 6 to 8 in the southern United States remained unchanged between 1929–31 and 1968–72, but small increases were recorded in the heights of those aged 8 to 15. The average height of Mexican-American children increased at all ages and at a greater rate between 1968–72 and 1982, but the overall rate of increase still lagged behind that of other U.S. groups. Malina, R. Martorell, and F. Mendoza (1986) concluded that the low rate of secular increase among Mexican-Americans reflected their failure to benefit from social and economic improvements, but their data may have been distorted by the inclusion of an influx of new migrants from Mexico and other South American countries.[8]

It is interesting to compare the heights of Mexican-Americans in the United States with those of Asiatic peoples in South America. In 1974, Eveleth, F. Salzano, and P. de Lima studied the heights of 363 Xingo Indians in Brazil between the ages of 20 and 50 and found no evidence of any increase in the average height of successive birth cohorts (Eveleth, Salzano, and de Lima 1974). In 1982 G. Gonzales, I. Crespo-Retes, and R. Guerra-Garcia claimed that the average height of Puno Indians between the ages of 7 and 20 had increased substantially between 1945 and 1980, but they could find no evidence of any increase in adult heights (Gonzales, Crespo-Retes, and Guerra-Garcia 1982). The findings for adults, but not for children, were echoed by John McCullough in his study of the heights of Yucatec Maya between 1895 and 1968. McCullough concluded that the majority of Mesoamerican populations had failed to experience the secular increase in height that had been observed in most parts of the world since the beginning of the twentieth century (McCullough 1982).

Indo-Mediterraneans of the Near East, North Africa, and India

The term "Indo-Mediterraneans" is used to describe the indigenous populations of the "Near East," North Africa, and India. It includes a wide range of diverse groups, including Hamites, Indo-Dravidians, Egyptians, Kuwaitis, and Libyans, but we know comparatively little about the secular trend in their growth or development. The majority of the relevant published studies concentrate on the populations of different parts of India, but it is possible to supplement these with some observations about possible trends in the heights of people in Ethiopia, Egypt, and Turkey.

Although there have been a number of studies focusing on different aspects of growth and stature in various parts of India, no consistent picture has emerged. It would appear that the pattern of change has varied considerably both between periods and between regions. In 1976 P. Ganguly examined secular changes in the height of 60 population groups and concluded that the dominant trend was toward a diminution of height rather than an increase (Ganguly 1977). This conclusion was reinforced by a study carried out in Hyderabad in 1977, but other investigations contradict it (Shatrugna and Rao 1987). In 1982 L. Sidhu, L. Bhatraga, and A. Dubey argued that the average height of well-off boys attending the Yadvindera Public School in Patiala increased by 7.5 cm between 1948–52 and 1973–7, and S. Singh and P. Malhotra contended that the mean menarcheal age of girls in Patiala fell by 0.65 years between 1974 and 1986 (Sidhu, Bhatraga, and Dubey 1982; Singh and Malhotra 1988). In 1981 D. P. Kaur and R. Singh compared the heights of Gujarati parents with those of their adult offspring and found that the children's heights exceeded their parents' by an average of 2.2 cm (Kaur and Singh 1981).

In view of the uncertainty surrounding the secular trend in the heights of Indians, it is interesting to compare the results of a number of different surveys carried out at different points in time between 1938 and 1982–3. In 1938 A. Chatterjee examined the average heights of more than 33,000 Bengali schoolboys, and the results were republished by W. M. Krogman in *Growth of Man* in 1941. These figures can be compared with the heights of the Indian boys whose measurements were reproduced in Eveleth and Tanner's two volumes in 1976 and 1991. The results suggest that the average height of Indian boys may have declined between 1938 and 1956–65 and then increased sharply between 1956–65 and 1982–3 (Table VI.5.3). However, it is important to note that these surveys were carried out in different (although partly overlapping) areas and that they may have included different social groups.

One should also be mindful of such caveats when examining the secular trend in the height of other Indo-European populations. In the case of Egypt, information is available about the heights of 10- to 12-year-old boys in the whole of Egypt from 1956 to 1965 and about 10- to 12-year-old boys in East Cairo in circa 1981. The data show that the second group of children were between 3 and 4 cm taller than the first group, but this does not necessarily mean that the East Cairo children were taller than children from the same area or social background in the earlier study.

There is a similar problem with the data for Ethiopia, which show that "Ethiopian and Eritrean" children were between 5.2 and 6.7 cm shorter in 1958 than children in Addis Ababa and other urban areas 7 years later. In the case of Turkey, we can see that 13-year-old girls and 15-year-old boys in Ankara in 1950 were between 3.4 and 14.3 cm shorter than "poor" and "well-off" children in Istanbul in 1970. The figures suggest that average heights may have increased over time, but the difference between Ankara children in 1950 and poor children in Istanbul in 1970 is much less than the difference between the poor children and their well-off contemporaries.

Australian Aborigines and Pacific Island Peoples

This section reviews the available evidence regarding secular changes in the heights of the indigenous inhabitants of Australia, New Zealand, and the Pacific Islands. There have been a number of such studies of Aboriginal children, and in addition, a comparative study has been conducted of the heights of different groups of Samoan children. Insights can also be gained into the pattern of secular change by comparing the results of various surveys of the heights of people in Papua New Guinea.

The most detailed published effort examining Australian Aborigines in order to investigate the extent and nature of secular changes was that carried out by M. Barrett and T. Brown in 1961–9. They found that the adult heights of Aborigines in the central-western part of the Northern Territory were about 5.5 cm greater than the heights of comparable groups of Aborigines 30 years earlier (Barrett and Brown 1971). It is not clear, however, whether the experience of this group was typical of that of other Aborigines or whether the trend toward increased height has continued up to the present day.

In 1991 Eveleth and Tanner compared the heights of children in Barrett and Brown's survey with those of Aboriginal children in western Australia in 1983, and they found that the heights were almost identical. But, as they themselves pointed out, it was impossible to say whether this meant that the secular trend had been halted or merely obscured by cross-sectional

Table VI.5.3. *Average heights of selected groups of Indo-Mediterranean children at different periods*

Country	People or place	Period of study	Source	Height at age 13 (cm)
1. Males				
India	Bengal	<1938	Krogman 1941	147.9
India	India	1956–65	Eveleth & Tanner 1976	141.5
India	Calcutta	1982–3	Eveleth & Tanner 1991	151.5
Egypt	Egypt	1962–3	Eveleth & Tanner 1976	146.3
Egypt	East Cairo	<1981	Eveleth & Tanner 1991	149.0
2. Females				
Ethiopia	Ethiopia & Eritrea	1958	Meredith 1969	142.8
Ethiopia	Urban	1965	Eveleth & Tanner 1976	148.0
Ethiopia	Addis-Ababa	1965	Eveleth & Tanner 1976	147.1
Turkey	Ankara (urban)	1950	Meredith 1969	144.5
Turkey	Istanbul (well-off)	<1973	Eveleth & Tanner 1976	155.6
Turkey	Istanbul (poor)	<1973	Eveleth & Tanner 1976	147.9

Country	People or place	Period of study	Source	Height at age 15 (cm)
1. Males				
India	Bengal	<1938	Krogman 1941	161.3
India	India	1956–65	Eveleth & Tanner 1976	153.0
India	Calcutta	1982–3	Eveleth & Tanner 1991	162.4
Egypt	Egypt	1962–3	Eveleth & Tanner 1976	159.7
Egypt	East Cairo	<1981	Eveleth & Tanner 1991	167.5
Ethiopia	Ethiopia & Eritrea	1958	Meredith 1969	152.2
Ethiopia	Urban	1965	Eveleth & Tanner 1976	158.5
Turkey	Ankara (urban)	1950	Meredith 1969	152.7
Turkey	Istanbul	<1973	Eveleth & Tanner 1976	167.0
Turkey	Istanbul (poor)	<1973	Eveleth & Tanner 1976	159.9

regional variations (Eveleth and Tanner 1976, 1991; see also Abbie 1967, 1968).[9]

In addition to these investigations, we can also examine a more recent inquiry into the heights of three different groups of Samoans. In 1975–7 J. Bindon and S. Zansky compared the heights of children in a "traditional" community of Western Samoa with those of children in two more "modern" communities in American Samoa and Hawaii. They found that there was little difference between the American Samoan children and the Samoan children on Hawaii, but both were consistently taller than the "traditional" children in Western Samoa (Bindon and Zansky 1986). The heights of the Hawaiian Samoans were also considerably greater than those of native Hawaiian children who were measured almost half a century earlier. The average height of native Hawaiian children who were measured before 1930 was approximately 7 cm less than that of Hawaiian Samoan children in the mid-1970s (Krogman 1941).

Insights into the pattern of secular change among Pacific Island peoples can also be gained by comparing the results of a number of recent surveys of the heights of the Bundi and Manus peoples of Papua New Guinea. The Bundi, for example, were among the smallest people in the world when they were first measured by L. A. Malcolm in 1958–60, but their heights had increased considerably by the time a second survey was carried out in 1983–4 (Malcolm 1970; Zemel and Jenkins 1989).

There is also some evidence of an increase in the heights of Manus girls between 1966–8 and 1982, although the heights of Manus boys remained virtually unchanged (Heath and Carter 1971; Schall 1989). In view of the discrepancy between the data for boys and girls and the small number of children involved, it would probably be unwise to reach any firm conclusions about trends in the height of this population at the present time (Eveleth and Tanner 1976, 1991).

Conclusions

This chapter has shown that the average height of people in most parts of the world has increased since the beginning of the twentieth century and that most population groups are probably taller now than at any time in the recent past (Kates and Millman 1990). However, the secular trend toward greater height has been neither universal nor rectilinear (Roche 1979). The average height of populations has increased much more rapidly in Europe and the United States than in many parts of Africa, Asia, and South America, and even those countries that have registered the greatest increases in height have also experienced periods in which the secular trend has either been arrested or reversed (Takahashi 1966; van Wieringen

1979). Moreover, the distribution of heights in virtually all parts of the world continues to be marked by social and economic inequalities (Eveleth and Tanner 1991). This finding suggests that even within the "developed" world large numbers of children do not experience the nutritional and environmental conditions necessary for the achievement of their full height potential (Jones et al. 1985; Whincup, Cook, and Shaper 1988).

A number of writers have attempted to account for the secular trend and for the variations within it. Malina (1979b) attributed the trend to improvements in nutrition and sanitation, urbanization, industrialization, reduced family size, genetic selection, and heterosis. Eveleth and Tanner (1991) have credited improvements in nutrition, the control of infectious diseases, reduced family size, better health care, and population mobility. Other scholars who have examined the consequences of the secular trend have associated it with the reduction of mortality, the lengthening of the female reproductive span, changes in the relationship between children and adults, and increases in physical performance and efficiency (Himes 1979; Malina 1979a, 1979b; Waaler 1984; Eveleth and Tanner 1991).

Several writers have examined the relationship between changes in height (and other anthropometric indicators) and economic growth. In 1984 Floud concluded that variations in Gross Domestic Product (GDP) per head and in infant mortality rates explained "about 96 per cent of the observed variation in heights between and within western European populations since 1880," and that "an increase of one U.S. dollar (at constant 1970 prices) in GDP per capita has been accompanied by an increase in the average height of the population of 0.003 centimeters" (Floud 1984: 18). In 1988 H. Brinkmann, J. Drukker, and B. Slot argued that there was a close association between changes in GDP and the height of Army conscripts in Holland, and K. Liestøl found evidence of a similar relationship between changes of GDP and mean age of menarche in Norway (Liestøl 1982; Brinkmann, Drukker, and Slot 1988; but see also Mandemakers and van Zanden 1993). In 1988 L. A. Schmitt and G. A. Harrison concluded that "affluence" was the most important single cause of the differences that they observed in the average heights of 58 populations whose heights had been recorded in *Human Biology* and *Annals of Human Biology* over the previous 20 years (Schmitt and Harrison 1988).

Although economic growth is probably a necessary precondition for the long-term improvement of health and nutrition, it is not the only factor that has influenced trends in average height over the past 200 years. Both John Komlos and Floud have demonstrated that it is possible for the average height of a population to decline even when its GDP is increasing. In 1989 Komlos showed that soldiers who grew up in the economically more developed regions of the Hapsburg Empire during the second half of the eighteenth century were shorter than soldiers who grew up in the less developed regions, and Floud revealed that the average height of successive birth cohorts of British soldiers declined during the middle years of the nineteenth century (Komlos 1989; Floud et al. 1990). In 1983 Steckel concluded that differences between the average heights of 22 contemporary populations were attributable to variations in national income, income inequality, and welfare provision (Steckel 1983). These findings are reinforced by the dramatic increases in average height in China and those that have been achieved in some parts of India and Sri Lanka since the end of World War II (Drèze and Sen 1989; Kates and Millman 1990).

Bernard Harris

Notes

1. For example, in 1904 the British Interdepartmental Committee on Physical Deterioration urged the government to institute a national program of anthropometric monitoring as a means of providing accurate information about the health and physique of the British population (see Harris 1989).
2. There is also evidence of a secular trend toward greater adult height among the Skolt Lapps of northern Finland (see Lewin, Jürgens, and Louekari 1970).
3. Bakwin (1964) has demonstrated that the weight of Scottish newborns increased by several hundred grams in the 85-year period between 1850–60 and 1935–45. But this appears to be the exception rather than the rule so far as European studies are concerned.
4. It is likely that Tanner overestimated the decline in mean menarcheal age in Norway. More recent estimates suggest that the actual age of menarche in 1840 was between 15.6 and 16.0 years. This would mean that the decline in mean menarcheal age between 1840 and 1950 was between 2.4 and 2.8 years (see Bruntland and Walløe 1976; Brudevoll, Liestøl, and Walløe 1979, 1980).
5. Goodman interviewed 1,291 Caucasian women, 1,519 Japanese women, and 395 Chinese women. Results were based on personal recall (Goodman 1983).
6. It is important to note that the average height of black South Africans remained well below that of more affluent black populations elsewhere in the world, as well as that of white children in the same country (Walker and Walker 1977).
7. The average height of Chinese children between the ages of 7 and 14 increased by approximately 8.04 cm between 1951–8 and 1979. The rate of increase was greater than that of any European population and roughly equal to that of Japanese children in this period (Piazza 1984).
8. These findings contrast with those of Greiner and Gordon (1992), who claim that the increase in the average height of successive birth cohorts of Hispanic-Americans was greater than that of any other ethnic group. However, they also claim that the overall rate of increase for Hispanic-Americans, for a range of 22 bodily dimensions, was generally below that of the white population.
9. W. J. Fysh and colleagues (1977) compared the birth weights of infants at Cherborg and Palm Island Aboriginal settlements in 1953, 1963, and 1972. There was a small increase in the birth weights of male infants at Cherborg set-

tlement between 1953 and 1963 but a sharp decline between 1963 and 1972. By contrast, the birth weights of male infants at Palm Island settlement increased between 1963 and 1972. The birth weights of female infants remained unchanged in both settlements.

VI.6 ~ The Nutrition of Women in the Developing World

There are at least two reasons why the nutritional status of women should be distinguished from that of men. The first is that a woman's nutritional status has a direct impact on her children. Better-nourished mothers lead to better-nourished infants by virtue of prepregnancy nutritional status, weight gain during pregnancy, and diet during lactation. This approach to women's nutritional status encapsulates the traditional "breeder and feeder" view.

The second reason is that women exhibit certain nurturing and allocative behaviors, reflecting societal roles, that enhance the food and nutrition security of the entire household and of children in particular. This behavior is most commonly demonstrated in the way women allocate their time and their own income and is particularly visible in certain types of female-headed households. Through both the direct and indirect links, women are the "gatekeepers" of the food and nutritional status of their household's members.

The objective of this chapter is to summarize the literature underlying such links between gender and nutrition within a conceptual framework. Eight main links are identified and discussed in turn, although it should be recognized that this organization is merely a convenient representation of the issues, and that there is considerable overlap across links.

Link 1. Mother's Nutritional Status, Infant and Child Health, and Supplementary Feeding

Birth weight is the single most important determinant of neonatal and infant mortality and of child growth to the age of 7. A number of maternal factors have been shown to be significant determinants of birth weight; most important is the mother's progravid weight and weight gain during pregnancy. Women entering pregnancy with a low preconception weight are several times more likely to produce a low-birth-weight baby (one less than 2,500 grams). Mean birth weight increases, and the incidence of low birth weight decreases, as the preconception weight of the mother increases (Lechtig et al. 1975).

Birth weight and maternal weight gain during pregnancy are also highly correlated, in part, because prenatal weight gain is associated with a decrease in the incidence of prematurity (gestational age less than 37 weeks). If nutritional status before pregnancy, as judged by low progravid weight, is less than adequate, weight gain during pregnancy becomes even more important in influencing neonatal outcomes.

Unfortunately, data indicate that weight gain during pregnancy in developing countries is typically suboptimal. In developed countries the average weight gain during pregnancy is 10 to 12 kilograms, but in developing countries it is 2 to 7 kilograms (Ghassemi 1990). Moreover, for many women in developing countries, negative weight gains are common during pregnancy. Part of the reason for this is a tendency to either not increase food intake or, in some cases, to decrease the amount of food consumed – a phenomenon labeled "eating down" during pregnancy (Brems and Berg 1988).

Although limiting calorie consumption during pregnancy is practiced by some women, in many areas a high level of physical activity, uncompensated by additional calories, is the more common reason for low weight gain during pregnancy. For example, a study in Gambia showed that birth weights were decreased only after the peak period of agricultural labor; during nonpeak seasons, birth weights were close to international norms (Lawrence and Whitehead 1988). Such data indicate that when agricultural labor demands are high, women are unable to cope with pregnancy solely by increasing caloric consumption.

Certain types of illness patterns during pregnancy can also have an adverse effect on the development of the fetus and the neonate. The incidence of low birth weight is known to increase following rubella, and the early onset of labor is common for women with hepatitis and measles. Some maternal infections can cause intrauterine growth retardation, and these infections are more common where poor hygiene is prevalent, as is the case in many low-income areas of developing countries. Thus, a study in four villages in Guatemala indicated high rates of maternal infections during pregnancy and consequently intrauterine exposure of the fetus to infectious agents (Lechtig et al. 1974).

In more general terms, the morbidity of mothers also correlates with a higher incidence of low birth weight. Classification of women in the four Guatemalan villages into high or low morbidity groups found that 33 percent of infants born to those in the high morbidity group were low birth weight compared to 10.5 percent of infants from women of low morbidity (Lechtig et al. 1974). The authors also found that those in the high morbidity group tended to come from homes with low calorie availability; they interpreted this to mean that morbidity during pregnancy is likely to be associated with a low energy consumption.

These maternal characteristics often occur in combination with each other. In other words, women who begin pregnancy with a low progravid weight often gain inadequate weight and have a high incidence of infection during pregnancy.

Dietary supplementation schemes targeted to high-risk women have been one type of intervention aimed at reducing adverse outcomes of pregnancy. A number of investigations in developing countries have indicated that calorie supplementation during pregnancy results in improved birth weight, decreases rates of prematurity, increases weight gain of the mother, and decreases incidence of anemia and toxemia in program participants (Iyenger 1967; Lechtig et al. 1975; Kielmann, Taylor, and Parker 1978). However, not all programs have been successful, and some researchers have criticized supplementation schemes as being too expensive for the benefits produced (Beaton and Ghassemi 1982). Those deemed successful have certain characteristics in common; typically a large ration is targeted to nutritionally vulnerable women, usually in combination with prenatal health services (Kennedy and Knudsen 1985).

Now, however, maternal dietary supplementation schemes are a less popular type of nutrition intervention. Irregular participation because of little time for such an activity was a major factor limiting effectiveness. A more promising approach to improving women's nutritional status, including that of pregnant women, is to decrease their physical activity – particularly during the last trimester of pregnancy. This approach appears more culturally acceptable than promoting maternal weight gain in many developing countries.

Link 2: Women's Nutritional Status, Time Allocation, and Energy Expenditure: Output Effects

The general assumption is that better-nourished individuals will be more productive. However, the empirical literature that deals with the effects of improved nutritional status on physical and cognitive productivity in developing countries is relatively thin. The evidence is strongest for men, because male labor force data are most readily available. An example of the short-term impact of calorie intake on productivity and capacity may be found in E. Kennedy's 1989 study of women in the south Nyanza district of rural Kenya. There, increases in household income (in both female- and male-headed households), due to agricultural commercialization, raised female calorie intake but did not improve female nutritional status (according to anthropometric measures) or health status. Female body mass index actually declined during a time of rising calorie intake, suggesting that the energy intensity of female activities was increasing disproportionately.

Short-run income-enhancing attempts to alleviate the time constraint of women may not succeed, even if a woman is prepared to place her nutritional needs above those of her family. A 1988 study by S. Kumar and D. Hotchkiss of Nepalese hill districts found that because of low agricultural productivity, new land needed to be cleared to maintain household basic needs. However, the subsequent deforestation increased the time allocated by women to collect fuel. This meant less time for female agricultural labor input, which led to fewer calories from this income source, which, in turn, increased the need for deforestation, and so on, in a downward spiral.

Link 3: Women's Share of Household Income and Household Food Security: Roles, Preferences, and Constraints

Household food security has been defined as the access of all people at all times to sufficient food for an active and healthy life (World Bank 1986). Two of the biggest determinants of household food consumption are income and prices. Rising income and falling food prices increase a household's ability to obtain an adequate diet. However, an accumulating body of evidence now suggests that it is not simply the *level* of household income but *who earns* that income that is important in improving a household's food intake.

Income controlled by women, particularly in Africa, is more likely to be spent on food than is male-controlled income (Braun and Kennedy 1994). At similar levels of income, households with more women-controlled income are more likely to be food secure. Evidence for the positive influence of female control of income on household food expenditure (Haddad and Hoddinott 1991), calorie intake (Garcia 1991), and anthropometric indicators (Thomas 1990) is increasing in both Africa and Asia.

This influence may be explained by a number of factors: (1) societal gender roles that cast women in the role of "gatekeepers"; (2) different preferences (women may prefer to spend more on children's food because they spend more time with them); (3) different constraints (women may spend more on food when more income is earned because of a need to purchase more expensive calories that take less time to prepare); or (4) different transaction costs (women earn money in flows that are more easily spent on food). Whatever the reason, getting income into the hands of women seems to be one way of enhancing the household's food security.

Link 4: Women's Time Allocation, Energy Expenditure, and Household Food Security: The Value of Women's Time

During times of economic hardship, women tend to act as "shock absorbers" for the welfare of the household, reflecting the undervalued nature of their time. There is a certain invisibility to the economic contribution of women outside the home as measured by censuses and International Labor Organization (ILO) statistics. R. B. Dixon (1982) documented this invisibility for a number of countries by comparing data from ILO, the Food and Agricultural Organization of the United Nations (FAO), and national agricultural census estimates of the percentage of the agricultural labor force that is female. For many North African and South Asian states, these three sets of statistics are widely divergent, and the formal censuses tend to cloak secondary and tertiary female economic activities.

An example of this shock-absorber behavior has been characterized in Latin America as the "feminization" of poverty (Buvinic 1990). During economic crises that result in less male employment, women enter the labor force to bolster household income and food security. But because women are less well educated, they tend to accept jobs that men would not and are paid very low wages for those jobs because the supply of female labor outweighs the demand for it.

Link 5: Household Food Security and Preschooler Food Security: Intrahousehold Allocation of Food

The identification of pockets of malnutrition and poverty within otherwise "better-off" households is one indication that household resources are not always allocated equitably or according to need. A survey of 45 developing countries found that in all but two of these girls die at a higher rate than boys between the ages of 1 and 4 (MacCormack 1988).

Part of this gender disparity in mortality is because of intrahousehold resource allocation. There are strong indications that female children are discriminated against in the allocation of food and other resources in South Asia (Carloni 1981; Chen, Huq, and d'Souza 1981; Harriss 1986). In sub-Saharan Africa, however, evidence for the maldistribution of food and other resources away from girls is not as clear. A recent review of nutrition studies in Africa by P. Svedberg (1990) did not find girls disfavored relative to boys in terms of anthropometric indicators. One interpretation of these findings is that the economic value of girls to households is more explicit and obvious in Africa than in Asia.

Another point, however, is that young children – whether boys or girls – seem to be generally disfavored in the allocation of family food. In recent studies from Kenya and the Philippines, preschool-aged children had a lower level of dietary energy adequacy than the household as a whole. In Kenya, average household calorie adequacy was 94 percent of requirements, but the energy adequacy of the child's diet was only between 60 and 70 percent, depending on age. Similarly, in the Philippines, although household calorie adequacy was in the 85 to 95 percent range, it was only 70 percent for preschoolers (Kennedy and Haddad 1992).

It is important to note, however, that the allocation bias of food tends to disappear for boys as they get older, but not for girls. Females tend to meet a smaller percentage of their energy requirements than do males in the same households (McGuire and Popkin 1990), in part because of a biased allocation of food away from women, and in part because of the energy intensity of women's activities.

This combination of women's reproductive role, heavy workload, and inadequate diet contributes to a series of nutritional problems for developing-country females, not least among them that they live shorter lives by about 10 years when compared to women in the industrialized world (Ghassemi 1990). A majority of the world's women are anemic; nonpregnant women are 2 to 3 times more likely to be anemic than men, whereas pregnant women are 20 times more likely to be anemic (McGuire and Popkin 1990).

To some extent, the poor nutritional status of women is due to differences in bargaining power and productivity across household members. For instance, if one individual in a household has better nutritional status than the remaining household members, is this attributable to his or her superior bargaining power, or is it simply an efficient allocation of resources to the individual best able (now or later) to raise household income? The primary determinants of bargaining power and productivity are cultural phenomena on the one hand (discrimination in, for example, education, time burdens, health care) and randomly distributed initial endowments of physical and cognitive abilities on the other hand.

Link 6: Women's Time Allocation and Preschooler Nutritional Status: Female-Headed Households

In many countries, the pattern of bias in the allocation of food to young children is influenced by the gender of the head of household. Recent studies in Kenya, Malawi, and the Dominican Republic, for example, find that at very low levels of income, some types of female-headed households – those in which the male head of household is absent for more than 50 percent of the time – have lower levels of preschooler malnutrition than male-headed households at comparable income levels (Kennedy and Peters 1992). This finding tends to buttress our earlier assertion that women may allocate proportionately more of their incomes to food and more of the household calories to children.

Other types of time-intensive nurturing behavior, such as feeding children more frequently, are also more common in some types of female-headed households. Such behavior is important to understand, because interventions that can promote appropriate nurturing behavior for children may be quite effective in enhancing nutritional status.

The successful food security and nutrition coping mechanisms exhibited in some types of female-headed households have limits, however. The growing number of female-headed households in developing countries is of concern because these households tend to be more vulnerable to poverty, and in Latin America, a growing number of women and children are living in poverty because of the increase of such households (Buvinic 1990). Women in female-headed households tend to be poorer because they have less access to labor, land, credit, and government resources (Rosenhouse 1989). In addition, as already mentioned, where women can participate in the labor force, they tend to do so with low-paying jobs (Buvinic 1990).

Link 7: Preschooler Nutritional Status and Women's Time Allocation: Intergenerational Effects

The nutritional status and morbidity levels of preschoolers will help determine the transmission of nutritional status across generations. Studies cited under Link 4 demonstrate the importance of early nutrition on later physical and cognitive performance. An additional pathway is through role-model formation and expectation setting. Better-educated parents, who promote better nutritional status for their children, will tend to expect enhanced school performance, which, in turn, will promote enhanced adult productivity. This is one way of breaking the intergenerational cycle of poverty and poor nutritional status.

Evidence of intergenerational transmission effects is provided by M. Buvinic (1990): Abandoned mothers in Santiago, Chile, tend to come from female-headed households. Moreover, D. Thomas (1991) has shown, with data from Ghana, the United States, and Brazil, that the intergenerational effects tend to run along gender lines: The father's education has a stronger effect on the son's anthropometric status, and the mother's education has a stronger effect on the daughter's anthropometric status.

Other intergenerational effects include (1) the impact healthier infants have on reduced health expenditures later in life and (2) the improved provision of old-age security for parents from healthier children.

Link 8: Women's Nutritional Status and Their Time Allocation and Energy Expenditure: A Zero-Sum Game?

Non-income-mediated pathways may be as important, or in some cases more important, than income alone in improving or maintaining child nutritional status. Almost all the non-income links to nutritional status are time-intensive. Links 2, 4, and 6 discuss the impact of women's time allocation decisions on household income, household food security, and preschooler nutritional status. Link 8 suggests that these relationships are not without cost (and are, therefore, unsustainable) in terms of women's nutritional status.

Time allocation studies indicate that, on average, women in developing countries put more hours per day into nonleisure activities than do men (Juster and Stafford 1991). Not only are women actively engaged in agriculture and wage-generating activities, but a substantial amount of their day is devoted to home production activities such as getting water and fuel wood, preparing meals, and child care. In many rural areas, domestic activities account for the largest proportion of women's time in any given day. Unfortunately, low-income women have even longer working days than their higher-income counterparts, further exacerbating the poverty–malnutrition cycle.

In addition, many of the health-promoting strategies advocated as part of the child survival revolution – breast feeding, growth monitoring, oral rehydration therapy – add to the time constraints of women. Indeed, the low level of utilization of these child survival strategies may be related to the lack of time of the mother (Leslie 1989).

Women's time constraints have a negative effect on their own nutritional status. As already indicated in the previous section, biased allocation of food away from women in many countries, particularly in South Asia, combine with long hours of labor to work a decidedly negative impact on women's nutritional status. Thus, the few studies on women's nutritional status that exist indicate that malnutrition is more common in women than in men (McGuire and Popkin 1990).

Conclusions

The major links between women's nutritional status, household food security, and infant–child nutritional status have been discussed. In the past great attention has been focused on the effect of nutritional status during pregnancy and lactation on neonatal and perinatal nutritional status. Yet the prepregnant weight of the mother influences birth weight more than weight gain during pregnancy. Unfortunately, few interventions have addressed nutritional status issues related to nonpregnant women. A potentially cost-effective nutrition intervention, however, would be one aimed at improving the nutritional status of high-risk female adolescents.

Any intervention designed to improve the nutrition of women must take their time constraints into consideration. Failure to ensure regular participation of women was one reason for the lack of any robust effects of prior dietary supplementation schemes. Time-saving, and thus energy-saving, programs offer a greater potential than other types of interventions for improving women's nutrition. Since the greatest portion of the day for rural women is devoted to home production activities – getting water and fuel, housework, cooking, and so forth – any program that can decrease this time may have a significant nutrition benefit.

Much of the discussion in the literature stresses the improvement of women's nutrition as an equity issue. However, there are strong efficiency reasons why policy makers would want to improve women's nutrition. Better-nourished women are more economically productive. Thus, because women are major actors in developing-country agriculture – particularly in Africa – interventions that improve their nutritional status also offer the potential of ensuring a more productive agricultural sector.

VI.7 Infant and Child Nutrition

Infant Feeding in Prehistory

Prehistoric patterns of human infant feeding are important for understanding the forces that have shaped the nutritional requirements of today's infants and the biological capacities of their mothers to satisfy these requirements through lactation. The primary sources of data to reconstruct such patterns are observational studies of nonhuman primates in the wild, particularly the great apes, and ethnographic studies of contemporary peoples whose nomadic lifestyle and level of material culture probably approximate those of the first humans.

As a mammalian class, virtually all primates – prosimians, monkeys, and apes, as well as humans – follow a *k*-strategy of reproduction. That is, they have a small number of infants, most born as singletons, in whom considerable parental attention and effort are invested. The consequence is that a relatively high number of offspring live to adulthood, with the success of such a strategy depending on close physical contact for protection. Thus, nonhuman primate parents carry, rather than cache, their infants – a constant contact that is reinforced by primate milks. These are uniformly high in sugar and low in satiety-producing fat – a milk composition more suited to a frequent-snacking pattern of eating than to one of large, isolated meals. Frequent nursing episodes enhance the amount and, possibly, the energy density of milk (Quandt 1984a). They also delay the return of ovulation, leading to longer birth intervals. Such a biobehavioral complex involving infant feeding, infant care, and birth spacing was doubtless encouraged by the selection process in primate evolution, and consequently, infant feeding became an integral part of the reproductive process, as is demonstrated by studies of human foragers.

The infants of the latter are normally kept in skin-to-skin contact with the mother, and nursing takes place frequently upon demand. Observational studies of the !Kung San of the Kalahari Desert, for example, show that mothers nurse their infants only briefly, but as often as four times per hour during the daytime for an average of two minutes per feeding. Cosleeping of mothers and infants is the rule, and infants also nurse at will during the night (Konner and Worthman 1980). Birth intervals in this noncontracepting group average 44 months (Lee 1979). Weaning among hunter-gatherers is generally gradual, with complete severance not occurring until the next child is born. Premasticated foods are gradually added to the diet, because there are few available foods that can be otherwise managed by very small children.

Infant Feeding in the Historical Period

From the Neolithic to the Renaissance

The Neolithic Revolution brought significant alterations in infant- and child-feeding practices. This transition from a foraging subsistence base to one that incorporated a variety of food production techniques began some 8,000 to 10,000 years ago and was first accomplished in at least six places, including Egypt, Mesopotamia, highland Peru, Mesoamerica, the Indus Valley, and China. Accompanying these changes in food sources were the origins of urbanism, stratified social organization, and writing and record-keeping, along with a host of other cultural traits that joined to comprise what we regard as civilization.

Data on infant-feeding practices come from a variety of artifacts of these civilizations. In addition to archaeological data, there are documentary sources, including art, inscriptions, and early writings. Interpretation of these data is aided by ethnographic analogy with contemporary nonindustrialized societies.

Food production, as opposed to foraging, brought two major changes in the feeding of young children. One of these was the addition of starchy, semisoft foods to the infant diet as a complement to breast milk. Food production meant that the grains or tubers from which such foods could be made were now dependable staples. Cooked into gruels of varying consistency, these foods offered infants and young children relatively innocuous flavor, readily digestible carbohydrate composition, and concentrated energy. Such foods, however, could lead to infectious diseases when contaminated and to equally serious undernutrition, as vegetable foods are deficient in essential amino acids. Consequently, if they were given in place of breast milk, they made for a protein-deficient diet.

With the second change, which came with the domestication of such animals as cows, sheep, goats, and camels, nonhuman milks became available to supplement or even to replace breast milk and to serve as nutrient rich foods for children after weaning. Although there is no record of such milks in the New World or in the civilizations of eastern Asia, their use is well documented elsewhere.

Together these changes in feeding were closely linked to the population explosion that accompanied the Neolithic. The newly available infant foods could shorten the period of intensive breast feeding, leading to shorter periods of postpartum infecundability and, thus, shorter intervals between births. The latter requires substitute foods for infants abruptly displaced from the breast by subsequent newborns, and the milks and cereals were such substitutes.

This does not, of course, mean that breast feeding was abandoned. Early civilizations of the Near East (c. 3000 B.C.) left abundant evidence of their infant-feeding attitudes and practices. Sculptures, paintings, and inscriptions all indicate that mothers were highly regarded and that breast feeding was practiced. For

Egypt, medical papyri from about 1550 B.C. contain remedies and recommendations for a variety of nursing problems still addressed today. These include ways to increase milk supply, to ease breast pain, and to evaluate milk quality. Ointments, incantations, and magico-religious spells are also included.

Wet nursing seems to have been a well-accepted practice in Egypt and Mesopotamia. Among the ancient Egyptian royalty, wet nursing was apparently the usual method of feeding highborn infants, with the nurses accorded high status in the royal court (Robins 1993). During periods of Greek and Roman rule in Egypt, the practice changed so that wet nursing became even more widespread and was frequently performed by slave women. In addition to wet nursing, there is pictorial evidence of infants being fed animal milks from horn-shaped and decorated vessels. We cannot know how frequently such artificial feeding was practiced, but it seems likely that most infants were breast-fed. In the case of wet nursing, there were contracts that specified how long a wet nurse should suckle a child and how the child should be weaned before being returned to the parents (Fildes 1986).

Near Eastern texts also prescribed the weaning diet of young children. After several months of exclusive breast feeding, it was recommended that animal milks and eggs be added to the diet and that animal milks become the principal food after weaning, which occurred at 2 to 3 years of age. Other foods were not introduced until teeth were cut, and these were primarily fruits and vegetables. The feeding of corn and pulses to weaning infants is described in the Old Testament.

There is limited mention of infant feeding in the writings of the philosophers of ancient Greece. These make it clear that infants were breast-fed, usually from the first day after birth, but there is no indication if this initial feeding was done by the mother or another woman. (In this connection, Aristotle noted that the early milk is salty.) Wet nurses were used by the wealthy, but there was regional and temporal variation in whether they resided with the family and whether they were slaves. We have little evidence to indicate when children nursed by their own mothers were weaned or how, although it is probable that animal milks, cereals, and honey were employed in the task. Pottery feeding vessels of various designs have been found that were probably used during and after weaning to feed animal milks to children.

Roman physicians from the first and second centuries A.D. were the first to focus significant attention on the health of infants. The most influential of these, Soranus of Ephesus, wrote on gynecology in the second century, and his works were translated and circulated throughout Europe during medieval times (Atkinson 1991). The writings of Soranus and his contemporaries indicate some controversy over whether new arrivals should be given the mother's breast immediately, or whether a wet nurse should substitute until the mother's mature milk came in. There was also disagreement about whether or not newborns should be given purgatives to help remove the meconium.

Physicians discussed the personal qualities of wet nurses in their writings because there was widespread belief that those qualities could be transmitted via the nurses' milk. Thus, Spartan nurses were highly valued for their ability to transmit stamina and good physical and mental health (Fildes 1986). Despite the recommendation of physicians that other foods be withheld until teeth were cut, their writings indicate that women were feeding cereals to infants as young as 40 days. Writers disagreed over giving wine to infants, as well as over the value of prechewed foods. Although the literary sources do not mention their use, feeding vessels are common artifacts from Roman times. Ages recommended for weaning ranged from 2 to 3 years (deMause 1974).

Ancient Ayurvedic medical texts from the second millennium B.C. through the seventh century A.D. contain clear and consistent discussions of pediatrics and infant feeding in India. Practices in the first few days of life were ritualized and quite similar to those still employed in India and among those of Indian heritage elsewhere. These included the feeding of ghee (clarified butter) and honey mixed with other substances in a specific order and at regular intervals over three days. On the fourth day, milk was expressed from the mother's breasts, and then the infant was put to nurse. As in other civilizations, a wet nurse was employed if the mother was unable to nurse, and there is mention in the texts of the use of cow's and goat's milk if breast milk was insufficient. However, no feeding vessels are mentioned in the literature or have been found as artifacts from ancient India, so the extent (and method) of artificial feeding is unknown.

The concept of balance is found throughout the Ayurvedic writings on infant feeding. A wet nurse, for example, was to be neither fat nor thin, neither fickle nor greedy (Fildes 1986). The quality of milk could be disturbed by extreme emotions and could be brought back into balance with a specific diet. The first nonmilk baby food in India was rice. The timing of this feeding varied, but in many cases coincided with the eruption of teeth. Weaning from the breast occurred in the third year.

Although the texts from ancient civilizations do not link feeding practices to infant health, some of those mentioned, such as giving infants cereals or animal milks within the early weeks of life, must have led to illnesses. Contamination of these foods probably occurred with some frequency, as climates were hot and sanitary practices for food storage were not well developed. Preference for spring weaning in some places, for example, was probably based on seasonal patterns of disease and the known association of weaning and disease.

Careful study of populations undergoing the change from foraging to food production elsewhere indicate that an epidemiological transition also took place. The skeletal sequence from the Dickson Mounds, Illinois (A.D. 950 to 1300), for example, shows evidence of lower life expectancy at birth with the shift to food production (Goodman et al. 1984). Skeletons and dentition of adults bear evidence of infectious disease episodes and some deficiency diseases (Cassidy 1980). These same nutrition-related health difficulties probably characterized many populations of settled horticulturalists, with greater problems present among those who were most crowded and whose resources were seasonally strained.

From the Renaissance to the Eve of Industrialization

Most data bearing on infant and child nutrition during the centuries spanning the Renaissance and the beginning of industrialization are from Europe and its colonies. During this period, Europe was characterized by changing medical knowledge, social divisions, and cultural patterns. At the same time, great portions of the rest of the world were changed by the diffusion of European customs, much of this occurring within the context of slavery and colonial domination. In Europe and in the colonies, most infants of the sixteenth century were breast-fed by their mothers, and when mothers could not or did not nurse, wet nurses were employed. There were class differences in feeding practices throughout the period, with change coming sometimes from the upper and sometimes from the lower classes. There were regional differences as well, which make generalizations difficult and trends hard to describe in a simple fashion.

Neonatal feeding focused on the use of purgatives to help remove the fetal meconium from the intestines. It was believed that the consumption of milk before purging the meconium could lead to a dangerous coagulation in the bowels. The use of substances for purges such as almond oil, butter, and honey was continued from ancient times, and wine, pharmaceutical purges (such as castor oil), and others, like salt water or soap, became popular in the late seventeenth century. These were administered at regular intervals over the first few days of life, a period during which women were advised not to breast-feed their infants.

In fact, the period of withholding breast milk could range from a few days up to a month. This was in part because a mother was believed to need time to recover from the delivery and, also, to become "clean" after the vaginal discharge had stopped. But in addition, the infant was thought to be at risk of harm from the mother's impure colostrum and, as already mentioned, from the coagulation of colostrum and meconium (Fildes 1986). The effect of this delay in breast feeding was to deprive the infant of the immune properties of the colostrum and to cause dehydration and weight loss. In addition, it disrupted the supply and demand nature of lactation, so that mothers might lack sufficient milk to feed their babies properly.

But such ideas began to change in the mid-seventeenth century following the publication of a number of medical and midwifery texts that advocated the feeding of colostrum, although it doubtless took some time for such new notions to be put into practice. A major impetus for such change came from English lying-in hospitals, where, by 1750, purgative use was discouraged and breast feeding of infants within 24 hours was advocated to reduce the incidence of breast abscesses and infections, both of which were major causes of maternal mortality. However, an important by-product of this practice was a marked decline in infant mortality as well (Fildes 1980).

These lying-in hospitals were used by poor women for delivery and were the site of medical training for both physicians and midwives who became advocates of early breast feeding. At the same time, upper-class women were beginning to read and to be influenced by treatises on infant care that incorporated the new medical ideas about early feeding. These changes in neonatal feeding were probably more responsible for the decline in infant mortality observed in England from the late preindustrial to the industrial period than any other factor (Fildes 1980).

During the preindustrial era, maternal breast feeding was practiced by most mothers after the neonatal period. They nursed infants with no supplemental foods for at least one year and usually continued breast feeding well into the second year of life until the infant was capable of consuming the family diet. Weaning from the breast was sometimes gradual and sometimes abrupt, with bitter substances smeared on the breast to deter the child; or the child was sent to stay with friends until weaning was accomplished (Treckel 1989).

The actual timing of weaning was dictated by the seasons and by the dental development of the child. The fall and spring were believed to be the best seasons for severance from the breast, and weaning in the summer and winter months was discouraged. This was because of presumed dangers of summer infections and the perils of winter cold. Children were also believed to be at risk of illness and death until most of their teeth had erupted, and so weaning was postponed until this had occurred. Nipple shields were sometimes used to reduce discomfort for mothers.

Until the late seventeenth century, upper-class women were more likely to employ wet nurses than to breast-feed children themselves. Although this practice was rationalized by women as avoiding a delay in feeding the infant because of the avoidance of colostrum, it was probably mostly the result of ideas about sexuality and gender roles held by upper-class women. Because sexual intercourse was believed to hasten the resumption of menstruation and to impair both the quality and quantity of breast milk, sexual abstinence until weaning was encouraged by medical authorities. The employment of a wet nurse avoided this issue, and husbands were normally responsible for the decision to seek a wet nurse. In so deciding, husbands were able to assert patriarchal authority and establish "ownership" of the child. In other words, having a wet nurse rather than the mother feed the child (especially when the child was sent away to be nursed) focused attention on the woman as wife and diminished her identity as mother (Klapisch-Zuber 1985).

If wet nursing solved some problems, however, it brought with it others. Because breast milk was believed to transmit the characteristics of the woman who produced it, care had to be taken in choosing and supervising a wet nurse. The possibilities for the transmission of influences ranged from temperament to physical attributes such as hair color and complexion. It was best if a boy's wet nurse had herself borne a boy, and a girl's borne a girl, so that appropriate gender demeanor would be transmitted.

Earlier in this period, there was general acceptance throughout Europe of women who employed wet nurses, although many physicians and moralists condemned the practice. But after the Reformation, there was considerably more sentiment against wet nursing. Indeed, mothers who did not breast-feed were portrayed as evil and self-indulgent in both popular tracts and in sermons (Lindemann 1981), and there was concern that the practices of upper-class women might spread to the lower classes. In the American colonies, wet nursing was deplored because of the Puritan ethic, which encouraged women to devote themselves to motherhood and not indulge their sensual urges. Women who placed their infants with wet nurses were criticized for being vain and sinful (Treckel 1989).

Such sentiments apparently also resulted in a reduced use of wet nurses among members of the stricter Protestant sects in England and in some countries on the Continent (Lindemann 1981; Fildes 1986). However, in other places, most notably France, wet nursing continued at all levels of society. Elsewhere, by the late eighteenth century, upper-class women had begun to nurse their own infants. But in France, the use of wet nurses began to spread from the upper to the lower social strata, resulting in an increasing reliance on rural wet nurses by the lower and working classes of growing urban populations (Sussman 1982; Fildes 1988). Infants were sometimes sent a considerable distance into the countryside to live with a wet nurse, not returning until the prescribed age of weaning, which could be several years of age. This brought with it considerable infant mortality, as there was little supervision of wet nurses to ensure that infants were fed and cared for.

It is the case, however, that perhaps because of its prevalence wet nursing was more regulated in France than elsewhere. Starting in the seventeenth century, a number of *recommandaresses* were authorized in Paris by local judiciaries to require registration of those wet nurses who took infants home with them to rural parishes. These *recommandaresses* were later consolidated and regulations added to protect the lives of the children in question. For example, nurses were forbidden to take on more than two infants at a time, and still later, additional regulations set the prices for wet nursing. In 1769, the *recommandaresses* were abolished and replaced with a single authority that was designed to enhance communication between parents and nurses and to enforce the payment of the wages to the nurse. Although the intentions of these regulations may have been good, the wet-nursing business was, in fact, highly entrepreneurial, with individuals contracting to bring infants to nurses in the countryside, competing against one another to do so, and more concerned with profits than with the welfare of parents, nurses, or infants. Infant mortality rates were extremely high.

One of the reasons wet nursing flourished in France was the doctrine of the Catholic Church, which solved the problem of the taboo on sexual intercourse during breast feeding by recommending that infants be placed with a wet nurse so that husbands could enjoy the conjugal relations they felt were owed to them. Other factors also contributed to the extensiveness of wet nursing. As we just noted, by the eighteenth century, large numbers of urban Frenchwomen had entered the workforce, and their work as artisans, shopkeepers, and domestics for upper-class families provided little opportunity to care for a baby. The crowded nature of living and working conditions in cities also made nursing a baby difficult, and a lack of safe breast milk substitutes left wet nursing as the only alternative.

The decline in wet nursing in France and elsewhere has been attributed to a number of factors. The foremost cultural theory – that of the "discovery of childhood" – has been the subject of considerable debate (Bellingham 1988). Philippe Aries (1962) has argued that in the past, child mortality was so high that adults invested little money or interest in children, who were frequently neglected or abused; wet nursing was, according to Aries, one form of such neglect. However, Edward Shorter (1976) has viewed the maternal investment in children less than 2 years of age as a product of modernization. As Enlightenment philosophers and physicians began to attack wet nursing and other child-care practices, upper-class mothers began to devote themselves to feeding, rearing, and caring for their own children. Such concerns for the welfare of the child gradually trickled down to the lower classes.

Infant Feeding in the Industrial Era

The Industrial Revolution of the nineteenth century brought dramatic changes in lifestyle that had drastic effects on infant-feeding practices. People flowed from traditional towns and villages to large urban communities, and with the concentration of the population in cities came overcrowding, contaminated water and milk supplies, and infectious diseases spawned by poor sanitation and crowded living conditions. Women entered the labor force in large numbers and, for both men and women, work was no longer based at home.

Enhanced access to education increased the literacy level of the population, and magazines, newspapers, and books became widely available. Included among these were infant-care manuals and numerous advertisements for infant foods, all of which heightened public demand for new products and services that would benefit their children (Fildes 1991). Moreover, improvements in the recording of vital statistics in the second half of the nineteenth century increased awareness of high infant-mortality rates, and – as inadequate nutrition was seen as a cause of disease and death – this also stimulated interest in infant feeding.

Research-oriented physicians and scientists developed theories of infant nutrition, and both practitioners dealing with breast-fed infants who were not thriving and mothers having problems with breast feeding sought nutritional solutions (Apple 1987). Although mothers' milk was recognized as the best food for infants, that milk had to be of optimal quality, and this, both physicians and mothers believed, was not always the case. Breast milk quality might be compromised by the mother's health, her behavior, even her disposition. Factors alleged necessary to the production of adequate milk ranged from consuming a good diet and getting sufficient rest to avoiding strong emotions and physical labor. Because these factors were thought to compromise the milk of wet nurses as well as mothers, wet nursing increasingly fell into disfavor.

Because wet nurses were used less, and women were working outside the home in large numbers, infants were fed foods other than breast milk by their caretakers (often, young girls) during the working day. Paps and porridges were made, frequently with bread and water flavored with a little milk and sugar, and kept warm all day on the stove to be fed as needed. When this food failed to soothe an infant, commercial baby tonics were given. Containing laudanum, these were probably very successful at quieting a hungry or fretful baby.

The infant-feeding practices of working-class Europe spread to other parts of the world as populations came under the economic domination of England and the other colonizing countries. Plantation systems and other labor-intensive industries needed a constant supply of workers, and returning mothers to work as soon as possible after giving birth was in the interest of the dominating powers. In the English-speaking Caribbean, for example, the African practice of prolonged breast feeding was discouraged among slaves. After returning to work, mothers left their infants in creches where they were fed paps and panadas by elderly caretakers in between nursing breaks (King and Ashworth 1987). These early supplemental foods were very similar to those fed in England at the time (Fildes 1986).

Such economic and social changes in the last half of the nineteenth century, as well as research into the chemical composition of milk in Europe and the United States, paved the way for the use of artificial milks or formula milks. Certainly, women were ready to adopt such milks. Most middle-class households could not afford a servant to breast-feed infants while the mother was engaged in activities outside the home, and working-class women had to wean their infants at a very young age to enter the labor force.

The earliest scientists to make a substantial impact on feeding practices through the development of formulas were Philip Biedert in Germany and Arthur Meigs in Philadelphia (Wood 1955). Biedert was the first to suggest modification of cow's milk, noting its high protein content and hard-curd consistency relative to human milk. He recommended the addition of cream, whey, and sugar to make cow's milk more digestible for human infants. Meigs published nutrient analyses of human and cow's milk in 1884, which showed the higher carbohydrate and lower protein and fat content of human milk. He was able to demonstrate that the protein of human milk formed a softer curd than cow's milk and thought that the addition of lime water was important to make cow's milk more alkaline. In combining the work of Biedert with his own, Meigs was able to produce what was to be one of the most popular formulas for the transformation of cow's milk into an approximation of human milk.

The problem of infant diarrhea provided the research impetus for therapeutic artificial milks, and two schools of thought developed. In the United States, that thought was complex, as Thomas Morgan Rotch (a professor of pediatrics at Harvard University) and his followers developed the "percentage method," based on Meigs's recommendations. Rotch advocated individualized infant-formula prescriptions that required considerable mathematical calculation and a hospital laboratory to produce.

In Europe at the same time a "caloric method" was developed by Heinrich Finkelstein, who hypothesized that infant diarrhea resulted from the fermentation of carbohydrates in the intestine. This theory led to the invention of "Eiweissmilch," a low-carbohydrate, high-protein milk produced by a process of sieving curdled casein back into artificially soured milk. In contrast to Finkelstein, Adalbert Czerny concluded that infant diarrhea resulted from an intolerance of milk fat. Almost simultaneously, he developed a mixture of butter and flour that was added to milk.

By 1910, the percentage method had fallen into disfavor, and pediatricians were noting a disturbing number of occurrences of deficiency diseases, such as scurvy, among infants fed the artificial milks. These infants also suffered high rates of mortality (Levenstein 1983). Reformers advocated a series of different measures, ranging from educating the poor to breast-feed to regulating the milk supply so as to guarantee its cleanliness. But while physician-scientists were developing formulas that could be prescribed to mothers for home preparation, chemists were devising other alternatives to breast milk, and the success of these products indicated the existence of a previously unrecognized market. The subsequent commercial marketing of formulas, in contrast to their prescription by physicians, once again gave control of infant-feeding decisions to mothers, as in the past when they had decided between breast-feeding or employing wet nurses. By the end of the nineteenth century, mothers could choose from viable alternatives to breast feeding, and in the twentieth, their preferences made artificial feeding a cultural norm.

Such changes in infant feeding were part of the transformation of medicine into a scientific profession, and at the turn of the century, science was highly valued and viewed as the key to resolving numerous important problems (Rosenberg 1976). As physicians obtained more and more scientific knowledge, they became increasingly regarded as experts with privileged information (Apple 1987).

The "Scientific" Era

Infant feeding in the 1930s and 1940s differed somewhat from earlier practices; there was a general acceptance of simpler infant formulas, and researchers themselves were involved in the commercialization of formulas. Thereafter, as the dangers and difficulties of artificial feeding lessened, the flurry of research on infant nutrition declined as well (Apple 1987). By the middle of the twentieth century, most babies in the United States were bottle-fed with artificial milks, as were a high percentage of babies in the industrialized countries of Europe and in those under European influence. The belief was that artificial feeding, with its scientific basis and medical direction, was equal or superior to breast feeding.

No wonder then that survey data from the United States, Europe, and European-influenced countries showed a consistent decline in breast feeding during the twentieth century. The number of breast-fed infants born in the United States dropped from 77 percent between 1936 and 1940 to 25 percent by 1970. Duration of breast feeding also declined from a 1930s average of 4.2 months to 2.2 months in the late 1950s (Meyer 1958, 1968; Hirschman and Hendershot 1979; Hendershot 1980, 1981).

There were striking demographic patterns of breast feeding during this period (Table VI.7.1). Although breast feeding was more common among blacks than whites earlier in the twentieth century, its subsequent decline was greater among blacks so that only 14 percent breast-fed by 1970, compared with 29 percent of whites and 35 percent of Hispanics. The relationship of education to breast feeding changed as well. In the early 1950s, the practice was most common among women with lower educational levels; better-educated mothers were less likely to breast-feed. But this trend was reversed by the 1970s – a phenomenon interpreted as a "trickling down" of values and behaviors from upper- to lower-class women (Salber, Stitt, and Babbott 1958; Meyer 1968). The incidence of breast feeding in the United States reached a low of 22 percent in 1972 – a downward trend paralleled in England (Newson and Newson 1963) and elsewhere.

Table VI.7.1. *Percentage of first-born infants ever breast-fed between 1951 and 1970 in the United States, by ethnic group and education*

Category	1951–5	1956–60	1961–5	1966–70
Ethnic group				
White	49	43	39	29
Black	59	42	24	14
Hispanic	58	55	39	35
Education				
< 9 yrs	62	53	40	32
9–11 yrs	50	40	29	17
12 yrs	45	40	32	23
13–15 yrs	57	48	50	35
>15 yrs	46	50	69	57

Although recommendations from professional medical groups stressed breast feeding throughout this period, a variety of factors worked against it. One was the continued high value placed on science and technology and their applications to medicine (Apple 1987), as physicians and nurses learned more and more about artificial feeding and less and less about breast feeding. Moreover, birth became more of a medical event, and mothers who delivered in hospitals frequently stayed as long as two weeks. During that time, infants were often artificially fed because they were separated from their mothers and only brought to them to be nursed at fixed intervals. Mothers were instructed to wear face masks while breast-feeding, their nipples were washed before feeding, and they were not allowed to hold their babies afterward. All these practices virtually guaranteed that mothers' milk supplies would be inadequate and that their babies would require formula to supplement or replace breast milk.

That such hospital practices contributed to breast-feeding problems was recognized by some physicians (for example, Aldrich 1942). However, professional medical journals included recommendations from other practitioners who advised mothers to feed thickened cereal and other foods from an early age (Clein 1943; Stewart 1943). Others advocated feeding schedules, and some even recommended reducing the number of feedings to match family mealtimes (Clein 1943), reflecting cultural themes of regimentation and discipline applied to the infant (Millard 1990).

As already noted, by the 1970s the downward trend in breast feeding was reversed in the United States. More mothers initiated breast feeding, and they breast-fed for longer periods of time (Martinez and Nalezienski 1979; Hendershot 1981). This return to breast feeding paralleled the earlier decline, although now it was women of higher socioeconomic status who rediscovered the practice. As with the development of formula in the first half of the century, popular books and pamphlets stressed the scientific aspects of the "new" feeding method, which with breast feeding focused on greater disease resistance, prevention of allergies, and enhanced mother–infant bonding.

The return to breast feeding in Western countries in the 1970s was fueled by growing health activism and advocacy by women. As women discovered that they knew relatively little about their bodies and that they were dependent on the largely male medical community, lay efforts of women educating women grew (Boston Women's Health Book Collective 1976). La Leche League had been founded in 1956 as an organization focused on providing mothers with practical knowledge of breast feeding (La Leche League International 1963). The league filled a void. Few physicians had received any training in breast feeding, and lay breast-feeding knowledge had been lost as women turned to bottle feeding.

Breast feeding as promoted by La Leche League clashed sharply with other aspects of American culture. The League's promotion of extended breast feeding until a child weaned itself, often at 2 or 3 years of age, was at odds with cultural values of fostering independence. Infant-centered feeding patterns, with frequent nursing during the day and nighttime nursing, contrasted with the prevailing norm of scheduled feedings and use of the clock (Millard 1990). Comparing studies of League and non-League mothers shows the sharp contrast in feeding styles. Whereas League mothers nursed an average of 15 times per day (Cable and Rothenberger 1984), non-League mothers averaged only 7 (Quandt 1986).

The upward trend in breast feeding reached a peak in 1982 with 61 percent of newborns breast-fed and two-thirds of those still breast-feeding at 3 months of age (Martinez and Krieger 1985). But as the decade wore on, interest in breast feeding once again eroded, and by its end only 52 percent of newborns and 18 percent of 6-month-olds were breast-fed. The decline in initiation and duration was greatest among nonwhite mothers, younger mothers, and those with less education (Ryan et al. 1991). A similar decline in breast feeding was recorded in Great Britain for the same period (Emery, Scholey, and Taylor 1990).

There are several possible explanations. Alan S. Ryan and colleagues (1991) suggest that there was a decline in attention given breast feeding in the public press at the same time that manufacturers of formula began to aggressively market their products through television and direct mailings to new parents. Economic pressures may also have contributed, because mothers in the labor force breast-fed less (Ryan and Martinez 1989). Indeed, even those not working outside the home expressed the need to be unencumbered by breast feeding if the need or opportunity to work arose (Wright, Clark, and Bauer 1993).

In addition to this cultural explanation of a decline in breast feeding, other scientists combined biological and behavioral perspectives into explanatory models that drew on rapid advances (during the 1980s) in knowledge of the hormonal control of milk production and milk volume (Stuart-Macadam and Dettwyler 1995). They pointed to the need for frequent stimulation of the nipple to maintain milk production (Quandt 1984b) and for baby-led feeding schedules to allow infants to regulate their own hunger and satiety levels through fat intake (Woolridge 1995). Sara A. Quandt (1984b) demonstrated that the introduction of beikost (nonmilk foods) to the diet of infants in the first 3 months of life resulted in declines in the number of breast feeds per day and, ultimately, in the duration of breast feeding. Thus, shorter durations of nursing at the population level appear to have a biobehavioral basis and are not simply the result of marketing of formula or women working outside the home.

Twentieth-Century Infant Feeding in the Developing World

In the second half of the twentieth century, considerable concern arose over changes in infant-feeding patterns occurring in developing countries. This was especially the case with changes thought to be the result of the marketing malpractice of multinational corporations (Chetley 1986). Scores of reports documented the promotion and sale of infant formula in developing countries, often to mothers who could not afford formula and who lived in circumstances where it could not be hygienically prepared. As a result, it was charged, low-income families were spending a large proportion of their incomes on products that were actually dangerous to the health of infants and also, because of the availability of breast milk, unnecessary. Indeed, dependence on formula meant erosion of breast-feeding knowledge and practices and increased poverty and infant mortality. Horror stories of "bottle babies" fed contaminated and overdiluted formula drew international attention, and pictures of infant graves marked by nursing bottles aroused anger toward the companies promoting the products.

After the publication, in 1974, of *The Baby Killer* (Muller 1974) and its German translation, Nestlé filed a libel suit against the Third World Action Group responsible for the translation. Although the group was found guilty of misrepresenting the formula manufacturer, it was assessed only a nominal fine, whereas the conduct of the formula manufacturer drew considerable public outcry. A number of public action groups joined to form the Infant Formula Action Coalition (INFACT), and in 1977, INFACT began to promote a consumer boycott of all Nestlé products. The boycott was extremely successful, with participation by large numbers of citizens as well as governmental agencies in the United States and Canada (Van Esterik 1989). In 1981, the World Health Organization (WHO) and the United Nations International Children's Emergency Fund (UNICEF) adopted a code of marketing with which Nestlé agreed to abide. INFACT called off the boycott in 1984.

Scientific research on infant-feeding patterns in developing countries, however, provides a more complex picture than that conveyed by the problems arising from the simple substitution of bottled formula for breast feeding. In some areas, new feeding modalities and products were added to existing breast-feeding practices. The contents of infant-feeding bottles were highly varied. There was inter- and intracultural variation in how breast feeding was practiced before the promotion of formula by multinational corporations. For example, mixed breast and artificial feeding had been common in the Caribbean for centuries, whereas extended breast-feeding had been the norm in Africa and Asia (King and Ashworth 1987).

Data gathered around 1980 from large, nationally representative samples for the World Fertility Survey in 17 countries make possible some tentative generalizations about the state of breast-feeding practices in the second half of the twentieth century (Popkin et al. 1983). In Asia and the Pacific Islands, the practice continued to be very common, with virtually all mothers initiating breast feeding. Over 90 percent of infants were still breast-fed at 3 months of age and between 60 and 90 percent at 12 months. Breast feeding was slightly more common and of longer duration in rural than in urban areas. Supplementation of breast feeding was often delayed until after 12 months.

In Latin America, by contrast, as many as 20 percent of infants were never breast-fed, and by 6 months of age, less than 60 percent were breast-fed. The vast majority were weaned by 12 months. Rural–urban differences were pronounced, with more and longer duration of breast feeding in rural areas.

African breast-feeding rates were intermediate between those of Asia and Latin America. Overall, these findings indicate that a general decline in breast-feeding duration, but not breast-feeding incidence, had occurred. This change is probably tied to overall patterns of modernization (for example, changes in women's participation in the labor force and changes in postpartum sex taboos) and not exclusively to the promotional effects of formula manufacturers.

International interest in infant-feeding practices in developing countries stems from a broader and longstanding concern about child survival and the effects of malnutrition on the long-term functional development of children (Mosley and Chen 1984). The link of breast feeding of short duration and abrupt weaning to kwashiorkor and extended, unsupplemented breast feeding to marasmus was established by the 1960s (Williams 1955; McLaren 1966; Cravioto et al. 1967) and attributed to a variety of adverse biological and social factors. Both human and animal studies demonstrated that the long-term consequences of these severe forms of protein–energy malnutrition included impaired mental development (Pollitt 1969; Winick 1969). More recently, a series of intervention and observational studies has shown that even marginal malnutrition results in growth stunting in early life and continued functional impairments later in life (Allen 1995). The results of such studies make it clear that achieving adequate nutrition for infants is the foundation for optimal health in whole populations.

VI.8 ~ Adolescent Nutrition and Fertility

The relationship between nutrition and adolescent fertility has been a topic of much discussion in recent research on human biology. The apparent increase in the incidence of teenage pregnancy in Western societies has led some researchers to wonder whether there are biological as well as cultural factors that influence this phenomenon (Vinovskis 1988). Studies of adolescents in different geographic and socioeconomic settings have demonstrated that the age at which sexual maturity is reached is not fixed but is heavily shaped by numerous influences, such as fatness at adolescence, physique, health status, genetics, degree of physical activity, and socioeconomic status (Maresh 1972; Johnson 1974; Short 1976; Zacharias, Rand, and Wurtman 1976; Frisch 1978; Meyer et al. 1990; Moisan, Meyer, and Gingras 1990; Wellens et al. 1990).

Since the reproductive process requires energy, reproductive ability is curtailed in times of food scarcity or when calories burned through physical exertion or exercise exceed the amount provided by food intake. Undernourished women, for example, reach menarche later and experience menopause earlier than do well-nourished ones. Poorly nourished women also have higher frequencies of irregular menstruation and anovulatory menstrual cycles, with menstruation and ovulation disappearing entirely if malnutrition is severe. During pregnancy, malnourished women have a greater likelihood of miscarriage, and if they do carry the infant to term, they experience a longer period of lactational amenorrhea. In men, severe malnutrition leads to loss of libido, a decrease in prostate fluid and in sperm count and mobility, and, eventually, the loss of sperm production altogether. For children and adolescents, undernutrition delays the onset of puberty in both boys and girls, and limits the fecundity of those who have achieved sexual maturity (Frisch 1978).

Researchers disagree, however, on the precise way to measure adequate nutritional status. Some, most notably Rose Frisch (1978), argue that achievement of a critical weight is the major factor in achievement of sexual maturity. Others argue that body composition, particularly the percentage of body fat, is the most important determinant of sexual maturity (Crawford 1975).

Much more is known about the effects of nutrition on adolescent fertility in girls than in boys (Boyd 1980). Fertility in girls is usually based on age at menarche, although even this event is not a foolproof measure because adolescent girls experience a number of anovulatory cycles before establishing regular menstruation (Short 1976). Nevertheless, researchers have clearly established that poorly nourished girls, female athletes, and girls with anorexia nervosa and other eating disorders reach menarche at later ages, have higher incidences of amenorrhea, and have a greater frequency of anovulatory cycles than do girls who have adequate dietary intake relative to calories expended (Frisch 1978; Wyshak and Frisch 1982).

Fertility in boys, however, is much harder to determine. The main indicator of male fertility is spermatogenesis, determined by measuring the amount of sperm contained in the seminal fluid. But data on the beginning of spermatogenesis is more difficult to obtain because there is no clearly visible sign, as is the case in menarche. Moreover, it is not clear whether the appearance of spermatozoa in the urine is a reliable measure of fertility in adolescent boys (Baldwin 1928; Short 1976). Some researchers have attempted to use age of first ejaculation (Kinsey 1948) as an indicator of male fertility, but this, too, is unreliable (Brown 1966; Short 1976). Consequently, less is known about the factors that influence adolescent male fertility.

The Secular Trend in Sexual Maturity

One of the more controversial issues in the history of adolescent sexuality is whether the age of sexual maturity has declined over time. Nearly all of the discussion in this area centers around the apparent declining age of menarche, particularly among young women in Europe and the United States. G. von Backman (1948) and J. M. Tanner (1962) were among the first to suggest that the age of menarche has declined precipitously over the past several hundred years, from a high of 17 or 18 in early modern times to an average age of 12 in contemporary Western societies.

Most historians and researchers in human biology have accepted this model of a secular trend in age at menarche (Zacharias et al. 1976; Frisch 1978; Shorter 1981). Some scholars, however, have questioned the methodology employed in determining the age of menarche in the past. It has been argued that the evidence for Tanner's secular trend is based on extremely small samples of young women, and some have questioned whether these findings can be applied to larger populations (Brown 1966; Bullough 1981). In addition, others have pointed out that the way in which age at menarche is usually determined is flawed, for it relies on the recollected memory of women who were interviewed much later in life. It has been suggested that during the nineteenth century, an early age of menarche was often associated with sexual promiscuity and/or working-class status. Therefore, some women may have stated a higher age of menarche than they actually experienced, in order to maintain an image of middle-class respectability (Brown 1966; Bojlén and Bentzon 1968; Diers 1974; Bullough 1981). Even Tanner admitted that "the early studies of age of menarche suffered from disadvantages of both sampling and technique" (Tanner 1968, 1973, 1981b).

Another troubling aspect of historical research on the secular trend is the fact that age of menarche appears to be younger in both ancient and medieval times than in the nineteenth century. Reviews of Greek and Roman textbooks, for example, indicate that the average age of menarche in the ancient world was about 13.5 years (Amundsen and Diers 1969; Diers 1974), and evidence from medieval textbooks indicates that the age of menarche varied from 13 to 15 years (Post 1971; Amundsen and Diers 1973; Diers 1974). Researchers are cautious about this evidence, however, because it comes from medical textbooks, rather than from direct observations of young women (Diers 1974).

Some historians have even suggested that there might be ideological reasons for placing so much faith in a secular trend in age at menarche. Both Vern L. Bullough (1981) and Maris A. Vinovskis (1988), for example, have argued that the secular trend is often linked with the increasing problem of teenage pregnancy in contemporary American society and is used to justify very stringent policies regarding teenage sexuality.

Despite these criticisms, however, most researchers do agree that there has been some decrease in the age of menarche over time. Even Bullough states: "Undoubtedly there has been some drop in menarcheal age in the United States since the 19th century, to under 13 in the 1980s" (Bullough 1981: 366). The consensus in recent research on the secular trend is that there has been a statistically significant decline in age at menarche, but the drop has been much less precipitous than that suggested by Tanner and Backman (Frisch 1978; Wyshak and Frisch 1982; Golub 1983).

The History and Geography of Studies on Adolescents

Scientific interest in the fertility and growth of young men and women dates back to at least ancient Greece. Aristotle was among the first to observe the negative effect of excessive training and undernutrition on young boys. He also warned of the dangers of precocious sexuality, claiming that "the physique of men is also supposed to be stunted when intercourse is begun before the seed has finished its growth" (quoted in Tanner 1981a: 8).

During Roman imperial times, Soranus noted that vigorous exercise could inhibit menstruation, but he stated that this was normal and did not require intervention. Like Aristotle, Soranus noted that precocious "excretion of seed is harmful in females as well as males," and that "men who remain chaste are stronger and bigger than others" (quoted in Tanner 1981a: 10). As a result of these warnings about precocious sexuality, Roman law linked the age of marriage with the age of puberty, which was believed to be 14 for boys and 12 for girls (Amundsen and Diers 1969; Tanner 1981a).

In the Middle Ages, the Renaissance, and the early modern period, medical texts tended to echo the writings of ancient authors on the subject of adolescent growth and development. Among them, as among the ancient authors, there seems to have been at least some understanding that the onset of puberty, and particularly the onset of menarche, was linked with nutritional status. G. Marinello, for example, observed in the sixteenth century that some girls menstruated earlier than others. He stated that "the cause of variation is [differences in] the natural composition of the body, or complexion or habits; thin and long girls [menstruate] later[,] fat and strong ones earlier" (Marinello 1574, quoted in Tanner 1981a: 21). Similarly, Hippolytus Guarionius (1571–1654), a contemporary of Francis Bacon, noted that peasant girls in seventeenth-century Germany menstruated later than the daughters of townsfolk or aristocracy. Guarionius noted that "the cause seems to be that the inhabitants of the town consume more fat (moist) foods and drink and so their bodies become soft, weak, and fat and come early to menstruation, in the same way as a tree which one waters too early produces earlier but less well-formed fruit than another" (quoted in Tanner 1981a: 29).

During the eighteenth and nineteenth centuries, ideas about adolescent growth and development shifted as a result of contemporary debates about the place of so-called inferior races in the natural order. The egalitarian rhetoric of the Enlightenment called into question earlier ideas of racial inferiority, implying that the "natural rights of man" applied to men and women of all races, classes, and ethnic origins. But many scientists at this time endorsed racist ideas about human difference and looked for physical traits that would demonstrate that working-class Europeans, Africans, Asians, and Native Americans were inferior to white, middle-class Europeans (Stepan 1982; Schiebinger 1993). One of the physical signs that was used to "prove" the inferiority of nonwhite and working-class individuals was early age of menstruation and physical maturity, because such traits seemed to place these groups closer to animals.

Scientists attributed the allegedly early age of puberty in nonwhite and lower-class individuals to two causes: precocious sexual activity and warm climate. Both of these factors, it was argued, caused a buildup of heat in the body. Because many believed that heat was the engine of growth, anything that caused an accumulation of heat would lead to an early age of puberty. Albrecht von Haller (1775), for example, claimed that girls in the southerly regions of Asia, where the climate was warm, were marriageable in their eighth year and gave birth in their ninth or tenth year; conversely, women in Arctic regions did not menstruate until age 23 or 24. This view was shared by other eighteenth-century writers, most notably J. F. Freind (1738), Herman Boerhaave (1744), and Montesquieu (1751). Similarly, Martin Schurig (1729), a Dresden physician, noted that bodily maturation in girls could be accelerated by indulging in conversations with men, kissing, and other sorts of sexual encounters. Schurig claimed that indulgence in sexual activity was why prostitutes and lower-class women had an earlier age of menarche than did gentlewomen (Tanner 1981a).

To be sure, some authors, most notably George-Louis Leclerc de Buffon (1749–1804) and John Roberton (1832, 1845), continued to argue that nutritional status was the most important factor in determining age of puberty. During the middle-to-late nineteenth century, Charles Darwin (1868) also tried to postulate a relationship between food supply and fertility, observing that domestic animals with a regular, plentiful food supply were more fertile than corresponding wild animals. Moreover, reformers who were interested in improving the plight of the laboring classes argued strongly against the idea that lax morals caused an early age of puberty among working-class girls. On the contrary, they argued that difficult living conditions delayed puberty in the working classes (Whitehead 1847).

Climatic theories about puberty persisted well into the twentieth century. As late as the 1950s, some medical writers were still claiming that women from the tropics matured much earlier than those from temperate or cold climates (Peters and Shirkande 1957; Shaw 1959).

As a result of the views described above, middle-class parents in Europe and the United States viewed precocious puberty with a certain degree of alarm. Nineteenth-century medical-advice literature cautioned mothers to prevent all children, but especially daughters, from masturbating, reading romantic novels, and indulging in any activity that might excite the sexual passions (Neuman 1975). Many physicians also believed that too much consumption of meat contributed to precocious sexual longings and sexual development in young girls and could even cause insanity and nymphomania. Doctors, therefore, advised mothers to restrict their daughters' intake of meat in order to prevent such disasters (Brumberg 1988). In retrospect, this advice may have contributed to the perceived secular trend in the age of menarche.

During the mid-twentieth century, a number of developmental studies uncovered the methodological flaws in earlier studies of the effect of sexual activity and climate on age of puberty. Tanner (1962), for example, demonstrated that many of the studies of adolescents from tropical regions were performed on girls and boys from wealthy families who had access to abundant sources of protein-rich foods and, therefore, did not represent the average age of puberty in these societies. Moreover, researchers noted that the age of menarche in Eskimo girls was actually earlier than that of western European girls, a phenomenon that resulted from the Eskimos' meat-rich diet (Bojlén and Bentzon 1968).

The most definitive studies on the relationship between nutrition and adolescent fertility were performed during and after World War II. Studies of children who had experienced famine, illness, and other harsh conditions during the war years showed a definite link between poor nutrition and age of physical maturity (Ellis 1945; Markowitz 1955; Krali-Cercek 1956; Maresh 1972; Wellens et al. 1990; Murata and Hibi 1992). Likewise, cross-cultural studies of women in both Western and non-Western countries have demonstrated that socioeconomic status and, hence, nutrition, are much more important than climate in determining age of puberty (Kolata 1974; McBarnette 1988; Brink 1989; Riley, Huffman, and Chowdhury 1989). These discoveries have completely undermined earlier notions about the effect of climate or sexual activity on age of puberty and have established once and for all that nutritional status is the determining factor in age of sexual maturation.

VI.9 Nutrition and Mental Development

Most research on nutrition and human mental development has focused on protein–energy malnutrition (PEM), which consists of deficits in energy and protein as well as other nutrients (Golden 1988). But there is also an extensive literature on the importance to mental development of trace elements and vitamins, as well as the impact of short-term food deprivation. Thus, although the bulk of this essay focuses on PEM and mental development, we begin with an examination of these other areas of concern.

Vitamins and Trace Elements

General Vitamin and Mineral Deficiencies

It is well understood that severe vitamin deficiencies may have drastic effects on mental development. Serious thiamine and niacin deficiencies, for example, as well as those of folic acid and vitamin B_{12}, can cause neuropathy (Carney 1984). But milder, subclinical vitamin deficiencies are much more common, and thus their influence on mental development is presumably of much greater importance. Unfortunately, the extent to which multivitamin and mineral supplements influence intelligence in schoolchildren remains unknown, although this question has been the subject of at least five clinical trials (Schoenthaler 1991).

One study of 90 Welsh children using a multivitamin–mineral supplement over a nine-month period indicated that supplementation produced an increase in nonverbal IQs (Benton and Roberts 1988). A similar study of 410 children in the United States over 13 weeks also revealed an overall increase in nonverbal IQs (Schoenthaler 1991). However, in a Belgian study of 167 children who were supplemented for five months, only boys whose diets had previously been nutritionally deficient showed an increase in verbal IQs (Benton and Buts 1990). Other studies, one in London and the other in Scotland, reported no significant effects of supplementation (Naismith et al. 1988; Crombie et al. 1990).

Reasons for inconsistent findings may have to do with differences in the duration of the programs or may lie in the nature of the children's normal diets. Because supplementation is most likely to benefit children whose diets are deficient in one or more of the chief nutrients, more consistent results might have been obtained if the subjects had been restricted to children with deficient diets. Another problem with these studies is that a variety of vitamins and trace elements were administered in the supplements. Thus, it is not possible to single out those nutrients that may have played key roles in raising nonverbal IQs.

Trace Elements

Among the trace elements there are two that have been the subject of much research and are known to have a substantial influence on mental development.

Iodine. One is iodine, which is required for the production of thyroxine. Iodine deficiency during pregnancy can cause deficits in fetal brain maturation, resulting in cretinism. There are two types of cretinism, neurological and myxedematous; mental retardation is a symptom of both. Other symptoms of neurological cretinism include spastic diplegia and deaf-mutism, whereas dwarfism is symptomatic of myxedematous cretinism.

Cretinism, however, is not the only manifestation of iodine deficiency, and a number of others have been identified. These are referred to as iodine-deficiency disorders (IDD) (Hetzel 1983) and include goiter, neuromotor delays, deaf-mutism, and an increase in both pre- and postnatal mortality rates (Stanbury 1987).

Cretinism seems to be the extreme in a spectrum of cognitive and psychomotor deficits caused by iodine deficiency. Studies in Indonesia and Spain have indicated that village children living in iodine-deficient regions had poorer levels of mental and motor development than other village children who did not live in such areas (Bleichrodt et al. 1987). It may be that other disparities between the villages played a role in the differences. But, in a village in Ecuador, iodine supplementation of pregnant mothers reportedly led to improved motor development of the children, in comparison with children in a nonsupplemented village (Fierro-Benitez et al. 1986). Similar results were derived from a clinical trial conducted in Zaire (Thilly et al. 1980).

Yet in other studies, iodine supplementation seems to have been less effective. One of these, conducted in Peru, reported no effect on the development of the infants of mothers supplemented during pregnancy (Pretell et al. 1972). Two other studies involved schoolchildren. One, carried out in Bolivia, revealed no changes in school achievement and development despite iodine supplementation (Bautista et al. 1982), and a Spanish study discovered no effect on the mental or psychomotor development of supplemented children (Bleichrodt et al. 1989).

Clearly, more research of a conclusive nature is needed. There are some 800 million persons at risk of iodine deficiency in Asia, Africa, and Latin America;

close to 200 million persons in the world suffer from goiter, and more than 3 million are cretins (Hetzel 1987). This is especially tragic because iodine deficiency is so easily prevented by the consumption of iodized salt or iodized oil, or by iodine injection.

Iron. Iron is the second of the trace minerals that play a decided role in mental development. Its deficiency is the main cause of anemia, an important nutritional problem in both developed and developing countries. Because anemia symptoms include listlessness and lassitude, iron deficiency can and does negatively affect the cognitive processes.

Early investigations indicated associations between iron-deficiency anemia and poor levels of cognition in children. However, there were problems in eliminating social factors that could also be causal (see, for example, Webb and Oski 1973). Subsequent studies on iron-deficient children suggest, among other things, that the adverse effects of iron deficiency on the cognitive processes are most apparent when the deficiency is severe enough to cause anemia.

Age has much to do with such findings, as does the duration of the periods of iron supplementation. For example, in five studies, supplementation was given for periods of less than two weeks, and developmental levels assessed on infant scales were used as outcome measures. No significant gains from supplementation were discovered in four of the studies, which were conducted in Guatemala (Lozoff et al. 1982), Costa Rica (Lozoff et al. 1987), Chile (Walter et al. 1989), and North America (Oski and Honig 1978). A fifth study, in Chile, did find an improvement in developmental levels, although the absence of a placebo group compromised the results (Walter, Kovalskys, and Stekel 1983).

In another group of studies, however, children under two years of age were supplemented for longer periods. Two such studies were preventive trials in which high-risk children were supplemented from the age of 2 to 3 months and then tested at 12 months. In Chile, such supplementation produced better development (Walter et al. 1989), and in Papua New Guinea, supplemented children had longer fixation times than the controls (Heywood et al. 1989). On the other hand, in the United Kingdom, a group that underwent two months of supplementation did not produce better development scores than a placebo group, although a greater number of treated children achieved normal rates of development (Aukett et al. 1986). In Costa Rica, after three months of supplementation, children who experienced complete recovery of their iron status clearly benefited from the supplements (Lozoff et al. 1987). However, a study in Chile found no effect after three months of supplementation (Walter et al. 1989).

It appears that, as a rule, the longer the duration of treatment, the more likely there will be benefits in developmental levels. It has been suggested that iron deficiency affects such development because it reduces a child's span of attention (Pollitt et al. 1982). But children under two years of age are difficult to assess, and only one study thus far has attempted to look at the matter (Heywood et al. 1989).

Results seem to be more positive in children over two years of age. Indeed, 10 studies have reported improvement in mental functions after iron supplementation. Three of these were conducted in Indonesia, and improvements in both cognitive functions and school achievement levels were reported after two or three months' treatment (Soemantri, Pollitt, and Kim 1985; Soemantri 1989; Soewondo, Husaini, and Pollitt 1989).

In India, two studies found improved cognitive functions after three months of supplementation (Seshadri and Gopaldas 1989); another, in Egypt, reported the same after four months of treatment (Pollitt et al. 1985). In India, two additional clinical trials showed improvements in IQ scores after three months of supplementation with both iron and folic acid (Seshadri and Gopaldas 1989). In the United States, the results of two studies, which were not true clinical trials, indicated that supplementation produced improvements in the cognitive functions of anemic children (Pollitt, Leibel, and Greenfield 1983a), and similar conclusions were reached in Guatemala (Pollitt et al. 1986). But two other studies, in the United States and Thailand, showed no apparent improvements with iron supplementation (Deinard et al. 1986; Pollitt et al. 1989).

From the foregoing, then, it would seem that there is good evidence to indicate that iron-deficiency anemia has detrimental effects on the mental development of children over the age of two, and that supplementation will erase those effects. In younger children, however, the evidence is less conclusive. In fact, there is little or no evidence of benefits with supplementation lasting less than two weeks, and although investigations with longer-term treatment have yielded more positive findings, such findings are inconsistent.

Nonetheless, the evidence generated by such investigations is of vital importance because about 51 percent of preschool-age and 38 percent of school-age children in developing countries, and 10 percent of preschool-age and 12 percent of school-age children in developed countries, are anemic (DeMaeyer and Adiels-Tegman 1985).

Short-Term Food Deprivation

Although improvement in school achievement is one of the goals of school feeding programs, there have been few well-designed evaluations of their effectiveness (Pollitt, Gersovitz, and Gargicilo 1978). The best results are most likely to be derived from such programs in developing countries where the prevalence of undernutrition is greater. But, unfortunately, most investigations conducted in these countries have tended to be poorly designed (Levinger 1986).

One exception was a small Jamaican study using a matched control group. It related improvements in school achievement to the school feeding plan, but not to improvements in nutritional status as such (Powell, Grantham-McGregor, and Eston 1983). It was speculated that the mere alleviation of hunger during school hours produced improvements in cognitive functions and behavior.

The most sensitive method of examining the effects of short-term food deprivation on mental functions involves studies in which children are used as their own controls and in which their performance is compared with and without breakfast. Four such studies (including three from the United States) have reported detrimental effects on mental functions when breakfast was omitted. In one of these, the omission of breakfast showed a deterioration in cognitive functions only in children with low IQs (Pollitt, Leibel, and Greenfield 1981). When the investigation was replicated, deterioration was found in the cognitive functions of all children (Pollitt et al. 1983b). Another study indicated that the detrimental effect on cognitive functions became worse as the period of deprivation increased (Conners and Blouin 1983).

In Jamaica, an investigation into the effects of missing breakfast among both undernourished and adequately nourished children discovered that the cognitive functions of undernourished children deteriorated with the omission of breakfast, whereas those of adequately nourished children did not (Simeon and Grantham-McGregor 1989).

The reason for the impact of short-term food deprivation on cognitive functions is not clear. However, it likely has a metabolic basis, which may result in changes in arousal levels (Pollitt et al. 1981) or in neurotransmitter levels (Wurtman 1986). The relationship between arousal levels and performance is complex (Kahneman 1973) and varies with the nature of the task (Hebb 1972) and the subjects (Eysenck 1976).

It does seem clear that undernourished children are more susceptible to cognitive function impairment resulting from short-term food deprivation than are adequately nourished children. It is possible that malnutrition may serve to sensitize the children to the stress of the omission of food. In other words, they may appraise the situation as being more threatening than do better-nourished children (Barnes et al. 1968; Smart and Dobbing 1977). But the response of malnourished children may also be due to abnormalities in carbohydrate metabolism. Illustrative is the fact that, during severe PEM, children have low fasting glucose and insulin levels (James and Coore 1970; Alleyne et al. 1972).

In concluding this discussion of short-term food deprivation and cognitive functions, we should note that although the impact of such deprivation appears to be small, there may be important consequences. If, for example, food deprivation occurs frequently over a long period, the effects may be cumulative and lead to poor levels of development and school achievement. Indeed, food deprivation, which is hardly uncommon in malnourished children, may play a significant role in the low levels of mental development generally found in such children.

Protein–Energy Malnutrition

There have been three major classifications of PEM, with the Gomez classification being the first (Gomez et al. 1955): Children suffering from PEM were described as being mildly, moderately, or severely malnourished, depending on their deficits in weight compared to reference values for their sex and age. However, a second classification – the Wellcome classification – takes into account the presence of edema as well as weight deficits (Wellcome Trust Working Party 1970).

These two classifications are generally used in the identification of children with severe PEM. But the use of weight and age alone is not very useful in discriminating between different types of mild-to-moderate PEM. For example, a child with a low weight-for-age may be tall and thin or short and fat. To address this problem, J. Waterlow (1976) introduced a third classification, which employs height expressed as a percentage of the expected value for age and sex, and employs weight as a percentage of the expected value for the height and sex of an afflicted child. Low height-for-age, or stunting, is thought to reflect long-term PEM, whereas low weight-for-height, or wasting, is believed to reflect recent nutritional experiences.

The prevalence of mild-to-moderate PEM in developing countries ranges from 7 to 60 percent, whereas that of severe PEM is between 1 and 10 percent (Grant 1990). PEM has a decided impact on mental development, and with an estimated 150 million children suffering from the affliction worldwide, its potential cost in human, as well as social and economic, terms is staggering.

Mild-to-Moderate PEM

A number of observational studies have associated mild-to-moderate PEM with poor mental development. Yet PEM tends to occur amid economic deprivation that has its own deleterious effects on development. Because it is not possible to control for many of these factors, the most effective way to determine the impact of PEM lies in the use of experimental study designs.

Unfortunately, there have been only a few experiments in which at-risk children have been supplemented and their mental development compared with that of controls. What follows is a brief summary of the findings of observational studies and experimental studies, although only those in which there was statistical control of confounding background variables are mentioned.

Observational studies. Investigations examining associations between mild-to-moderate PEM and the mental development of preschool-age children have been conducted in Colombia (Christiansen et al. 1977), Guatemala (Lasky et al. 1981), and Jamaica (Powell and Grantham-McGregor 1985). The results of the three studies indicated that PEM was associated with poor development.

Another seven studies involved school-age children. Undernutrition in children was associated with poor school achievement levels in the Philippines (Popkin and Lim-Ybanez 1982; Florencio 1988), Nepal (Moock and Leslie 1986), and India (Agarwal et al. 1987), and with low IQs in Jamaica (Clarke et al. 1991). In Guatemala, a study showed a close association between undernutrition and low IQs, whereas in Kenya, malnutrition was correlated with poor levels of cognitive functions (Johnston et al. 1987; Sigman et al. 1989).

Experimental studies. There are two types of supplementation investigations: preventive and remedial. The former focuses on high-risk mothers who are supplemented during pregnancy, and on their offspring who are supplemented in early childhood to prevent them from becoming undernourished. By contrast, in remedial studies, the focus is on already undernourished children who are supplemented to improve their nutritional status.

The findings of experimental studies in developed countries are especially likely to be inconsistent. In one preventive investigation, carried out in North America, supplementation during pregnancy provided the infant with only small advantages in play, and none in development, during its first year of life (Rush, Stein, and Susser 1980). Two other trials revealed no apparent benefits for the infants whose mothers had received supplements (Osofsky 1975; Pencharz et al. 1983). In a fourth study in which supplementation began during pregnancy and continued during the first year of life, children experienced large gains in development, compared with their older siblings (Hicks, Langham, and Takenaka 1982).

One reason for the inconsistency in the findings of these four studies is that in a developed region like North America, the children under scrutiny would probably not have become malnourished, regardless of whether they had supplemented mothers.

A fifth supplementation study in the developed world was remedial. Carried out as a clinical trial in England (Lucas et al. 1990), it investigated the effects of an enriched formula on the development of small preterm children. Marked benefits were shown at 18 months, especially in motor development.

It is the case, however, that studies conducted in developing countries where malnutrition is endemic are much more useful in determining whether the association between PEM and mental development is causal. One from Colombia, in which the supplementation was preventive, produced evidence of beneficial effects, first in motor development (Mora et al. 1979) and later in language (Waber et al. 1981). In Taiwan, supplementation of pregnant mothers, but not of children, led to benefits in motor development when the children were eight months old, although there was no effect on mental development (Joos et al. 1983). Supplementation of both mothers and children, however, resulted in gains in mental and motor development in Mexico (Chavez and Martinez 1982), and in cognitive functions in Guatemala (Freeman et al. 1980).

As for remedial studies, in one conducted in Colombia, both malnourished and adequately nourished children were supplemented for one year. Only those who had been malnourished improved in their development (Mora et al. 1974). In a second such investigation in Colombia, a supplementation–stimulation program was found to encourage mental development and a subsequent improvement in school performance. Moreover, such positive effects increased with the duration of the program. However, supplementation alone had no effect on development (McKay et al. 1978).

Jamaica was the site of a third remedial study, in which children ages 9 to 24 months, with low heights-for-age, were given nutritional supplementation for two years. There was a beneficial effect on development. Locomotor development was affected first, followed by mental functions. This clinical trial also had a stimulation component, and the effects of supplementation and stimulation were additive and not interactive (Grantham-McGregor et al. 1991).

To sum up, in developing-world countries, improvement in mental development was found in studies in which supplementation was preventive. This was also the case in two of the three remedial investigations. There were design flaws in some of the investigations, but considering the consistency of the findings across developing countries, the evidence indicates that both remedial and preventive supplementation encourage development. In general, however, the benefits are small, perhaps because the gains in growth were also small in the supplemented children. Indeed, the actual levels of supplementation were less than intended because of the problems of food sharing and substitution that occur in supplementation studies (Beaton and Ghassemi 1982).

Finally, the importance of the cumulative effect of mild-to-moderate undernutrition (or its absence) throughout childhood cannot be accurately assessed in supplementation programs lasting a relatively short period of time and producing only small improvements in growth.

Severe PEM

The most common method of defining severe PEM in children is the Wellcome classification, which includes those suffering from marasmus, kwashiorkor, or marasmic-kwashiorkor.

Because it is not ethical to conduct experimental studies with severely malnourished children, investigations have been observational, and most of the children studied were treated in hospital in the acute stage. Early studies reported poor levels of mental development in children with severe PEM (see, for example, Gerber and Dean 1956). There followed a series of cohort studies of school-age children who survived severe PEM in early childhood.

As in examinations of mild-to-moderate PEM, a main problem was that the poor socioeconomic environment in which the victims lived tended to confuse the relationship between PEM and poor mental development. The use of well-matched controls was therefore essential and improved over time. Two strategies were employed to control for social background. The first was the use of siblings of the index children as controls, and the second included the use of children from similar socioeconomic backgrounds.

These strategies, of course, have inherent problems. Although it is reasonable to assume that both the index child and the sibling have lived under similar socioeconomic conditions, there are unavoidable biases when siblings are used as controls. It is not possible, for example, to control for age and birth order, both of which affect development. In addition, it is possible that a child who has become severely malnourished has not been treated the same way as a sibling who was not malnourished. Most importantly, it is probable that the siblings were also malnourished and, consequently, had lowered levels of mental development themselves. Finally, there is evidence that long-term PEM may have greater negative effects on mental development than an episode of severe PEM (Grantham-McGregor, Powell, and Fletcher 1989). Therefore, the true effects of severe PEM are likely to be worse than those determined from studies using sibling comparisons.

The use of nonsibling controls from the same socioeconomic class also presents problems. Families of children with severe PEM tend to be poorer (Richardson 1974) and to have less stimulating home environments (Cravioto and DeLicardie 1972) than their control comparisons, and both of these factors can affect mental development. In the following discussion, research on the effects of severe PEM on mental development during its acute phase will be discussed first, followed by a look at investigations of its long-term sequelae. Finally, the effects of severe PEM, as demonstrated by studies conducted in developed countries, will be reviewed.

Acute stage. In early reports, children suffering from severe PEM were described as apathetic (Williams 1933) and having poor levels of mental development (Cravioto and Robles 1965; Yatkin and McLaren 1970; Monckeberg 1979). Although there was some evidence of improvement after clinical recovery, these studies had no controls. But, in a controlled study in Jamaica, severely malnourished children were found to have lower levels of mental development when compared with controls hospitalized for other illnesses. The developmental levels of both groups improved during their hospital stay. However, the malnourished group failed to reduce their deficit relative to the controls. The children who had suffered from PEM were also less active, more apathetic, and less exploring than the controls (Grantham-McGregor et al. 1990).

Long-term effects with nonsibling controls. In examining the long-term effects of PEM, eight studies were identified in which school-age children who had previously suffered from the illness were compared with nonsibling controls. In seven of these efforts, the malnourished children had lower levels of mental development than the controls. One, conducted in India, indicated that the index children had lower scores in perceptual, abstract, and verbal abilities, as well as in memory and sensory integration (Champakam, Srikantia, and Gopalan 1968).

Two other studies were conducted in Jamaica. In the first, the index children were found to have lower IQs (Hertzig et al. 1972) and lower school achievement levels (Richardson, Birch, and Hertzig 1973) than controls. The second Jamaican study also found deficits in IQs (Grantham-McGregor, Schofield, and Powell 1987) and school achievement (Powell and Grantham-McGregor 1990). In Barbados, children who had previously been severely malnourished were found to have lower IQs than controls (Galler et al. 1983b), and more behavior problems (Galler et al. 1983a), learning disabilities (Galler, Ramsey, and Solimano 1984a), and motor delays (Galler et al. 1984b).

In Uganda, severe PEM was also found to be associated with deficits in mental and motor development (Hoorweg and Stanfield 1976), and in Nigeria, children who had been severely malnourished had lower scores in a number of tests of cognitive functions (Nwuga 1977). Similarly, in South Africa, children who had previously suffered from severe malnutrition had lower IQs, lower levels of school achievement, and more behavior problems than controls (Stoch and Smythe 1976). Another South African study, however, was the only one of the eight under discussion that reported no difference in development between survivors of severe PEM and controls (Bartel et al. 1978).

Long-term effects and sibling controls. The long-term effects of PEM have also been examined in eight studies in which the development of school-age children who had previously been severely malnourished was compared with that of their siblings. Five of these studies revealed deficits in development. In Nigeria, index children were found to have lower IQs than their siblings (Nwuga 1977), whereas in India they had poorer levels of school achievement (Pereira, Sundaraj, and Begum 1979). In Mexico, boys who were previously severely malnourished had lower IQs than their siblings, although no difference was found with girls (Birch et al. 1971). In Jamaica, index children had lower verbal IQs (Hertzig et al. 1972) and more behavior problems (Richardson et al. 1973) than siblings, but there was no difference in school achievement levels. In South Africa, there was no difference in IQs between previously severely malnourished children and their siblings. However, the index children showed lower school achievement and produced lower scores on a drawing test (Evans, Moodie, and Hansen 1971).

Yet, severe PEM was found to have no effect on children's school achievement in Peru (Graham and Adrianzen 1979), and none on motor development in South Africa (Bartel et al. 1978). Another South African study examined the impact, on young adults, of severe PEM in early childhood. No difference was found in school attainment or in social adjustment when compared with their siblings (Moodie et al. 1980).

Developing countries. As we have mentioned, in studies conducted in developing countries, it is difficult to separate the effects on mental development of severe PEM from those of poor environment. Therefore, investigations using subjects from developed countries can be helpful. Unlike the situation in developing countries, where poverty is the primary cause of malnutrition, children in developed countries generally become malnourished because of diseases, such as cystic fibrosis. Since the children's developmental state tends not to be associated with deprived social conditions, such cases present an opportunity to view the long-term effects of severe PEM from a fresh angle.

The results of these studies have been inconsistent. Small deficits in children's development were demonstrated in some instances (Klein, Forbes, and Nader 1975; Winick, Meyer, and Harris 1975; Carmona da Mota et al. 1990), but no deficits were found in others (Lloyd-Still et al. 1974; Valman 1974; Ellis and Hill 1975). It is possible that the findings in developed countries have not been as consistent as those in developing countries because the children in the former tended to have less severe episodes of PEM that continued for shorter periods.

It is also possible that the environments in which the children were raised after the episode of PEM had a modifying effect. Psychosocial stimulation can improve the development of severely malnourished children. Such improvements were only transient in the wake of short-term programs (McLaren et al. 1973; Cravioto and Arrieta 1979) but lasted for several years following a three-year program (Grantham-McGregor et al. 1987). This effect is consistent with animal studies in which stimulation has decreased the adverse effects of severe PEM on development (Levitsky 1979).

Clearly, then, there are problems with inferring a causal relationship between severe PEM and poor mental development on the basis of nonexperimental studies. Nonetheless, the results of the studies reviewed indicate that children who are severely malnourished in early childhood and are raised in deprived conditions usually have lower levels of mental development than similarly deprived children who are not severely malnourished. The effects have been more consistent in studies in which malnourished children were compared with nonsibling controls rather than with siblings. This may be because of overmatching in the latter studies.

The mechanism linking PEM to poor mental development is not clearly established, but there are several hypotheses that assume a causal relationship. Children who died from severe PEM have been found to have smaller brains than comparison children (Winick and Rosso 1969; Rosso, Hormazabal, and Winick 1970; Dickerson, Merat, and Yusuf 1982), and it is certainly possible that impairments in brain growth may have adverse effects on mental development. Although findings from animal studies indicate that the anatomical changes due to PEM are persistent (Bedi 1987), it is not clear if this is the case in humans. In addition, it is not known if children with mild-to-moderate PEM also experience impaired brain growth.

The brain function of severely malnourished children has also been investigated by using evoked brain potentials. However, here the findings have proven inconsistent. In Mexico, abnormal auditory evoked potentials were found in severely malnourished children when compared with matched controls, and the abnormality persisted after clinical recovery (Barnet et al. 1978). In South Africa, the results of electroencephalograph (EEG) measurements indicated that children who had previously been severely malnourished had delays in brain development when compared with their siblings, but there was no difference when compared with nonsibling controls (Bartel et al. 1979). On the other hand, two other South African studies found no difference in EEGs when previously severely malnourished children were compared either with their siblings (Evans et al. 1971) or with nonsibling controls (Stoch and Smythe 1976).

It has been speculated that malnourished children are less active, explore their environments less, and thus acquire skills more slowly than adequately nourished ones. It may well be that in addition, their caretakers become less responsive to them, thus exacerbating poor development. Yet, although malnourished children have been shown to have lower activity levels and poorer developmental levels than adequately nourished children (Chavez and Martinez 1982; Meeks Gardner et al. 1990), there is no evidence showing that reduced activity precedes poor development (Grantham-McGregor et al. 1990).

In conclusion, it seems clear that various nutritional deficiencies have adverse effects on mental development. There are concurrent deficits in development in the face of mild-to-moderate PEM, severe PEM, short-term food deprivation, and iron-deficiency anemia. Maternal iodine deficiency has long-term effects on development, and severe PEM, usually, has long-term effects on mental development, if the children live in poor environments. But it has not yet been established that less severe PEM has long-term sequelae.

VI.10 Human Nutritional Adaptation: Biological and Cultural Aspects

The extraordinary diversity of aboriginal food cultures testifies to the capacity of many combinations of foodstuffs to sustain human health and reproduction. From this diversity it is apparent that humans have no requirement for specific foods (with the qualified exception of breast milk, which can be replaced by the milk of other mammals but with less satisfactory results). Modern nutritional science has demonstrated that good health is dependent upon the consumption of a discrete number of biochemical compounds that are essential for normal metabolism but cannot be synthesized de novo in the body. These compounds or their metabolic precursors can be obtained from many different combinations of foods.

It is possible that there are still unidentified trace elements required in such small amounts that it has not yet been possible to demonstrate their essentiality, although it is unlikely that they are of any clinical importance in human nutrition. It is probable that current perceptions of the amounts of some nutrients required for optimal health – such as the relative amounts of various fatty acids necessary for the prevention of cardiovascular disease – will undergo further change, but the present state of nutritional knowledge is adequate as a basis for evaluating the quality of different food cultures in terms of their ability to provide the nutrients required for nutritional health.

This chapter evaluates two contrasting food cultures: the carnivorous aboriginal diets of the Arctic Inuit and the traditional cereal-based diets consumed by the inhabitants of Southeast Asia and of Central and South America. Also, the current nutritional health of these populations is evaluated in terms of their adaptation to a modern diet and lifestyle.

Biological Adaptation to the Intuit Diet

Although nutritional anthropologists have concluded that the diets of most hunting and gathering societies were more varied than those of early agricultural societies, this clearly was not true of the aboriginal diet of the Inuit inhabitants of the high Arctic. Although berries and the leafy parts of edible plants were available in the Subarctic region, the diet of the Inuit residing 300 miles above the Arctic Circle was, for all practical purposes, carnivorous (that is, they were hunters but not gatherers).

Current diet recommendations in industrial societies promote the consumption of a mixture of foods belonging to four or more food groups: cereals, fruits and vegetables, meat and fish, and dairy products. The native diet of the Arctic Inuit – caribou, seal, and whale meat, augmented with lesser amounts of fish, birds, eggs, and the meat of other land mammals – is composed of foods belonging to only one of these groups.

Meat consumption in modern societies is being discouraged because of its propensity to cause cardiovascular disease. Yet, when the Inuit were first examined by ships' doctors, they were found to be virtually free not only of vascular disease but of renal disease, hypertension, and diabetes as well (Thomas 1927; Robinhold and Rice 1970; Mouratoff and Scott 1973). These conditions are the main manifestations of malnutrition in modern societies. The factors underlying the successful adaptation of the Inuit to their extraordinarily narrow food base have been discussed elsewhere (Draper 1977) and are further examined in the context of current knowledge in the following sections.

Sources of Metabolic Fuel

The Inuit native diet frequently is characterized as being high in protein or high in fat, but from the standpoint of metabolic adaptation, its most important feature is its low content of carbohydrate. In the absence of plant sources of starch and sugars, carbohydrates in the diet were limited to small amounts of glycogen and the sugar moieties of the glycoproteins and glycolipids present in animal tissues.

The postprandial energy state following consumption of the modern mixed diet, in which carbohydrates constitute the main source of energy, is marked by the conversion of excess glucose to fat for energy storage. The postprandial state following consumption of a carnivorous diet is marked by the obligatory synthesis of glucose, which is essential for brain function and other metabolic processes. Inasmuch as fatty acids, the main source of energy in the diet, cannot be converted to glucose, most of the glucose required must be obtained from gluconeogenic amino acids. Glycerol, the backbone of dietary triglycerides (fat) and of phospholipids, is an additional but minor metabolic source of glucose.

Because of its low carbohydrate content, the native Inuit diet had to be sufficiently high in protein, not only to supply the amino acids required for the synthesis of body proteins but to maintain normoglycemia as well. In some Inuit food subcultures, such as that of the caribou eaters of the Arctic tundra, protein (rather than fat) probably constituted the main source of energy in the diet, because caribou is much lower in fat than is modern beef.

The high rate of gluconeogenesis in the Inuit requires large amounts of enzymes (which consist mainly of proteins) for the conversion of amino acids to glucose and for the conversion of waste amino acid nitrogen to urea. These processes, respectively, account for the large livers and urine volumes long associated with Arctic Inuit. Increased enzyme synthesis in response to an increase in substrate concentration (so-called feed forward regulation of enzyme reactions) is a major form of metabolic adaptation to changes in diet composition.

Sources of Vitamins

The vitamins of the large B-complex group function as cofactors for enzymes involved in the metabolism of many biochemical compounds, including amino acids, fatty acids, and glucose. Consequently, there is a natural association between the amounts of these vitamins and the amounts of enzyme proteins present in the tissues of animals. Most of the protein in the liver, where many of these transactions occur, consists of enzyme proteins. This association is most apparent in the case of vitamin B_6, which functions exclusively in enzymatic transformations of amino acids, such as the aminotransferase reactions required to remove their nitrogen groups before their conversion to glucose.

As a result, the requirement for this vitamin is proportional to protein intake. Although the high-protein Inuit diet generates a high B_6 requirement, the risk of B_6 deficiency fails to increase with protein intake because of the strong association between this vitamin and protein in the diet. There is a similar, though less strong, association between other B vitamins and dietary protein. In contrast to cereal-based food cultures, there is no history of deficiencies of the B-complex vitamins among carnivores. The adequacy of the aboriginal Inuit diet in these nutrients was further ensured by their custom of eating food in the fresh, frozen, or lightly cooked state.

The nutriture of the Inuit with respect to vitamin C, a vitamin generally associated with fruits and vegetables, has long held a fascination for nutritionists. As for other apparent mysteries about Inuit nutrition, however, their freedom from vitamin C deficiency is readily explicable in terms of current knowledge relative to the amount of vitamin C required for the prevention of scurvy, its concentration and stability in the diet, and the capacity for storage. Prevention of scurvy requires 10 milligrams (mg) or less per day, an amount available from the fresh or frozen raw tissues of animals that synthesize it. The liver of land and sea mammals, often eaten fresh while still warm, is a good source of vitamin C. Seal liver, an Inuit delicacy, contains about 35 mg per 100 grams (g), an amount sufficient to provide for significant storage (Geraci and Smith 1979).

The epidemics of scurvy among Europeans in the eighteenth and nineteenth centuries were caused by the oxidation of vitamin C in grains and salt meats during long sea and land voyages and by its leaching from foods during cooking in water. Further, it is not necessary, as a recent advertisement claims, "to get your vitamin C every day." The amount of vitamin C stored by a typical adult in the United States or Canada is sufficient to prevent a deficiency, in the absence of any intake, for about 30 days (Baker et al. 1971).

The need to envelop the body in heavy clothing against the cold during the long winter night deprives the Arctic Inuit of solar radiation, the main source of vitamin D in temperate and tropical climates. The Inuit experience demonstrates that at least in some environments, there is an absolute dietary requirement for vitamin D, a nutrient that some have proposed be reclassified as a hormone because it can be synthesized in adequate amounts in the skin with sufficient exposure to sunlight. The high concentrations of vitamin D in the oils of fish and fish-eating sea mammals make up for limited synthesis of vitamin D in the skin during the Arctic winter, as demonstrated by the lack of historical evidence of rickets in Inuit children and of osteomalacia in adults consuming the native diet. These oils also provide an abundance of vitamin A. The occurrence of toxic amounts of vitamin A in polar bear liver, accumulated through the fish and seal food chain of this species, forms the basis of one of the strongest Inuit food taboos.

The vitamin E nutriture of the Inuit is unusual because their carnivorous diet contains no cereal oils, the main source of vitamin E in the modern mixed diet. Further, the high concentration of polyunsaturated fatty acids from fish and marine mammals in this diet generates a high requirement for vitamin E to maintain their oxidative stability in the tissues. Nonetheless, analysis of the blood plasma of Northern Alaskan Inuit has revealed concentrations of vitamin E similar to those of the general U.S. population (Wo and Draper 1975).

The explanation for this finding lies in a difference in the forms of vitamin E present in carnivorous and mixed diets. Although the total amount of vitamin E present in the mixed diet is substantially higher than in the carnivorous diet, only about one-quarter of the total occurs in the form of alpha-tocopherol; the rest is present mainly as gamma-tocopherol, which has only about 10 percent as much biological activity. In contrast, animal tissues contain almost exclusively alpha-tocopherol. Consequently, the amount of vitamin E in the Inuit native diet, expressed as biological activity, is comparable to that in the mixed diet.

As is evident from the pungent odor of volatile products of lipid peroxidation that permeates Inuit villages in summer, the concentration of vitamin E in the highly unsaturated oils of aquatic species is inadequate to protect them from oxidative rancidity when they are exposed to an air environment, even though it is sufficient at the reduced oxygen tension and temperature of their natural aquatic environment. In general, the concentration of vitamin E in plant oils and animal fats is proportional to the amount necessary to stabilize the unsaturated fatty acids they contain. For example, the inheritance of vitamin E and polyunsaturated fatty acids in maize is genetically linked, so that varieties high in polyunsaturated fatty acids are also high in vitamin E (Levy 1973). Fish, seal, and whale oils, on the other hand, impose a burden on the vitamin E requirement that must be borne by other food sources of the vitamin. Although Canadian Indians consuming a diet high in fish have been found to have a plasma vitamin E level below that of the general population (Desai and Lee 1974), dietary vitamin E deficiency has not been documented.

Sources of Inorganic Nutrients

Human requirements for inorganic nutrients (often loosely referred to as minerals) are qualitatively similar to those of other mammalian species. Hence, the carcasses of animals are a good source of these nutrients in human diets, provided they are eaten in their entirety, as they were (less the skin and compact bone) by the Arctic Inuit. The inorganic elements most frequently at risk of deficiency in human diets are iron and iodine. Iron deficiency, often precipitated by intestinal infections and diarrhea, is most prevalent among malnourished consumers of low-protein vegetarian diets. Iron is accumulated in animal tissues in the iron-binding liver proteins hemosiderin and ferritin, which, together with hemoglobin and other iron-containing proteins, provide an abundance of bioavailable iron in a carnivorous diet. Risk of iron deficiency is reduced by an adaptive feedback mechanism that increases the efficiency of iron absorption on a low-iron diet. This mechanism also serves to prevent iron toxicity on the high-meat Inuit diet by suppressing the absorption of excess dietary iron.

Iodine deficiency is a prevalent problem in various human populations, arising in some cases from its deficiency in the soil (for example, the "goiter belt" around Hudson's Bay) and in other cases from the ingestion of plant goitrogens. Neither of these circumstances applies to the Inuit native diet, which is devoid of goitrogens and is high in iodine from foods of aquatic origin. This diet also contains an abundance of zinc, which is present in marginal amounts in cereal diets high in phytin, a component of fiber that inhibits zinc absorption.

Meat has a very low calcium content, and in the absence of dairy foods, which supply about 75 percent of the calcium in the food supply of most industrialized societies, the spongy trabecular bone of land and sea mammals and the soft bones of fish are an essential source of this element in the native Inuit diet. Bone chewing, a nutritional as well as a social custom, is now nearly extinct, and a low consumption of dairy products has resulted in a calcium intake among the Inuit that is both below the historic level and below intake level currently recommended in the United States for optimal development of the skeleton during growth and for its stability during aging. However, the intake is comparable to the amount delivered by cereal-based diets, and there is no clear evidence that the lowered intake results in a state of calcium deficiency.

The body has an ability to adapt to a range of calcium intakes by modulating the efficiency of calcium absorption from the intestine. This ability, which serves to protect against both calcium deficiency and toxicity, is one of the best understood of metabolic adaptations to a change in nutrient intake. It involves an increase in the synthesis of parathyroid hormone in response to a small decline in serum calcium concentration caused by a decrease in calcium intake. This hormone effects an increase in the renal synthesis of 1,25-dihydroxycholecalciferol, the active form of vitamin D, which, in turn, enhances the synthesis of a calcium transport protein in the intestinal epithelium that is required for the active absorption of calcium.

The result is an increase in the efficiency of calcium absorption following a reduction in intake that restores serum calcium homeostasis. Whether this mechanism is fully successful in enabling adequate amounts of calcium to be absorbed to maximize skeletal development during growth and minimize bone loss during aging is a question of current interest with respect to the relationship between calcium intake and the incidence of osteoporosis.

The Inuit of Northern Alaska and Canada undergo a more rapid rate of aging bone loss, a risk factor for osteoporosis, than Caucasians consuming the mixed diet (Mazess and Mathur 1974, 1975). The high-protein, high-phosphorus, low-calcium content of the native diet has been implicated in this phenomenon. However, the high rate of aging bone loss in the Inuit does not appear to be associated with a high incidence of osteoporotic bone fractures.

This may be explained by a difference in bone morphology between the Inuit and Caucasians; the shorter, thicker bones of the Inuit may have a greater weight-bearing capacity than the longer, thinner bones of Caucasians. The rapid bone loss in the Inuit, nevertheless, may have relevance for the high incidence of fractures among elderly consumers of the "Western diet," which contains about twice as much protein as necessary to meet the protein requirement and an excess of phosphorus arising from a natural association of this element with protein and from the widespread use of phosphate food additives.

Oxidation of excess sulfur amino acids present in high-protein diets generates hydrogen ions and sulfate (sulfuric acid) that is excreted in the urine. On a high-protein (usually high-meat) diet the urine consequently is acid, whereas on a low-protein (usually high-cereal) diet it is near neutrality or slightly alkaline. Unopposed acidification of the renal filtrate decreases the reabsorption of calcium and increases its loss in the urine.

In experiments on adults fed purified proteins, this loss was found to amount to 300 mg per day, indicative of rapid bone loss, at a daily protein intake of 95 g, an amount well within the range of intakes on the mixed diet and low by Inuit standards (Linkswiler, Joyce, and Anand 1974). The protein intake of aboriginal Inuit adults in northwest Greenland has been estimated at nearly 400 g per day (Bang, Dyerberg, and Sinclair 1980). On a high-protein diet composed of normal foodstuffs, however, the decrease in calcium reabsorption by the proximal renal tubules caused by urine acidification is not unopposed.

The increased intake of phosphorus on high-protein diets results in a depression of serum calcium and a consequent increase in the synthesis of parathyroid hormone, which stimulates calcium reabsorption from the renal tubules and thereby counteracts the calciuretic action of excess dietary protein. Whether these opposing effects of dietary protein and phosphorus on urinary calcium excretion are always fully offsetting is not clear. However, it has become apparent that the most important nutrient ratio, from the standpoint of bone homeostasis, is not the ratio of calcium to phosphorus, which has received most attention, but the ratio of protein to phosphorus, which is fundamental to the maintenance of calcium balance on a high-protein diet. Whether the increased rate of bone resorption associated with excess dietary phosphate and protein observed on the Inuit diet and on the high-protein modern diet (Calvo, Kumar, and Heath 1988) results in increased bone loss and risk for osteoporosis is still controversial.

Metabolic Adaptation to Dietary Lipids

Danish studies on nutritional adaptation among the Inuit of northeast Greenland undertaken in the late 1960s and early 1970s led to an explanation for their low incidence of cardiovascular disease and to important innovations in methods for its prevention and treatment in modern societies. These studies revealed a protective effect of the unusual fatty acids present in the fish and marine mammal oils consumed in large quantities by the Inuit. Such oils contain polyunsaturated fatty acids with extremely long carbon chains (up to 22 carbon atoms) and unusually large numbers of double bonds (up to 6), characteristics that confer on them a low melting point that enables aquatic species to maintain membrane fluidity at the temperature of their environment. In contrast, the polyunsaturated fatty acids of cereal oils, the main source of fat in the modern mixed diet, contain up to 18 carbon atoms and up to 3 double bonds.

Another important difference is that the first double bond in most of the highly unsaturated fatty acids in the Inuit diet occurs between the third and fourth carbon atoms (n-3 fatty acids), whereas the first double bond in most of the fatty acids in cereals occurs between the sixth and seventh carbon atoms (n-6 fatty acids). The metabolic significance of this distinction is that the n-3 and n-6 fatty acids are precursors of two distinct groups of hormones, the prostacyclins and the prostaglandins, that have significantly different effects on the metabolism of blood lipids. They therefore also differently affect the risk of heart attack. Prostacyclins reduce the plasma triglyceride (fat) level, as well as the propensity of the blood to clot (and hence the risk of an embolism). A negative effect of the high n-3 fatty acid content of the Inuit diet is its tendency to cause nosebleeds (Fortuine 1971).

As a result of these findings, increased consumption of fish has been recommended as part of the Western diet, and concentrates of n-3 fatty acids prepared from fish oil are used in the clinical management of cardiovascular disease. The n-3 fatty acids have become recognized as dietary essentials for both children and adults, and official recommendations have been issued relative to their desirable level of intake (National Research Council, U.S. Academy of Sciences 1989; Health and Welfare Canada 1990). This series of events serves as an example of the value of cross-cultural research as a source of information relevant to the nutritional health of all human societies.

There is little doubt that hypercholesterolemia is a risk factor for heart attacks, and a plasma cholesterol level of 200 mg per deciliter or less has been selected as a desirable goal. Diet recommendations for the prevention of heart disease in modern societies call for a reduction in cholesterol intake to 300 mg per day or less (National Research Council, U.S. Academy of Sciences 1989; Health and Welfare Canada 1990). In light of these recommendations, the rarity of cardiovascular disease among the Inuit (Thomas 1927), whose traditional diet is extraordinarily high in cholesterol, seems anomalous.

Electrocardiographic recordings made on Northern Alaskan Inuit adults in the 1970s (by which time only about 50 percent of their calories were derived from native foods) revealed an incidence of abnormalities only half that recorded in a reference population of U.S. Caucasian adults (Colbert, Mann, and Hursh 1978). Indigenous foods in the partially acculturated diet of a cohort of adult Inuit living in the northwest Alaskan village of Point Hope in 1970 averaged 918 mg per day (range 420 to 1650 mg) (Feldman et al. 1978).

Studies on the epidemiology of hypercholesterolemia carried out between 1937 and 1961 showed "a strong tendency towards normocholesterolemia . . . among the unacculturated Eskimo groups but increased rates of elevated serum cholesterol among modernized Eskimos" (Feldman et al. 1978: 174). It is noteworthy that the plasma cholesterol levels of the Inuit during that period were similar to those of adults in the general population of the United States, despite a twofold difference or more in cholesterol intake.

The explanation for this discrepancy has been provided by epidemiological and laboratory research on the relationship between the intake of cholesterol in the diet and the level of cholesterol in the plasma. The Inuit experience is consistent with the conclusion of A. Keys, J. T. Anderson, and F. Grande (1965), the originators of the connection between dietary fat and heart disease, and with the observations of subsequent investigators: In the normal, healthy, adult population, the level of cholesterol in the diet has only a minor influence on blood cholesterol.

The current public preoccupation with dietary cholesterol and the promotion of "cholesterol-free" foods is attributable to a seemingly logical assumption that lowering cholesterol intake should lower plasma cholesterol. This is often true in patients with clinical hypercholesterolemia, a condition associated with genetic and various metabolic disorders, including diabetes and obesity, in which the metabolic control mechanism that normally downregulates the synthesis of cholesterol in the body in response to a high intake in the diet is impaired.

This is, however, weak justification for imposing a limit of 300 mg per day on the intake of cholesterol by "the generally healthy population" for whom diet recommendations are issued (National Research Council, U.S. Academy of Sciences 1989; Health and Welfare Canada 1990). The "cholesterol free" label on foods has been used as a "red herring" to attract attention away from the more important characteristics of foods from the standpoint of their effect on plasma cholesterol, namely the amount and composition of the fat they contain.

Current nutrition recommendations in industrialized countries include a call for a reduced consumption of "red meat" as a means of lowering the risk of cardiovascular disease. This edict seems paradoxical in view of the reported absence of this disease among Inuit consumers of the native meat diet. It is aimed at the consumption of beef, which bears the stigma (no longer fully justified) that it is high in fat and saturated fatty acids and low in polyunsaturated fatty acids. (The term "red meat" itself seems anomalous, since the redder meat is, the lower it is in fat.)

Contrary to the general impression that all animal tissues are high in saturated and low in polyunsaturated fatty acids, the tissues of the fish and of the land and sea mammals that constituted most of the Inuit diet are the reverse. The lipids of seal, whale, walrus, and polar bear meat contain 15 to 25 percent polyunsaturated fatty acids, consisting mostly of fatty acids of the n-3 type (Wo and Draper 1975). In contrast to beef, caribou meat is so low in fat that the Inuit dip it in seal oil to improve its palatability. The lipids of caribou muscle have been found to contain 5.6 percent arachidonic acid and 15.4 percent linoleic acid of the n-6 polyunsaturated fatty acid series.

In contrast, values of 0.5 percent arachidonic acid and 2.5 percent linoleic acid have been reported for beef muscle (Link et al. 1970). Most of the polyunsaturated fatty acids in both caribou and beef muscle are located in the phospholipids of cell membranes. The phospholipids of beef muscle have a level of polyunsaturates comparable to that in caribou muscle (Link et al. 1970), but have been swamped by saturated fatty acids as a result of selection of beef animals for "marbling" with intramuscular fat to increase the palatability of their meat.

Current diet recommendations in the United States and Canada also call for a reduction in fat intake to 30 percent of calories or less as a further means of reducing the risk of cardiovascular disease (National Research Council, U.S. Academy of Sciences 1989; Health and Welfare Canada 1990). The experience of the Inuit, however, indicates that it is the composition of dietary fat, rather than its level in the diet, that is of primary importance in the prevention of heart disease.

This view is supported by the low incidence of cardiovascular disease among consumers of the "Mediterranean diet," which contains a preponderance of monounsaturated fatty acids derived mainly from olive oil used in cooking. These acids replace more saturated than polyunsaturated fatty acids in the diet, thereby shifting the ratio in favor of polyunsaturates. The role of this ratio is also indicated by an analysis of changes in the composition of dietary fat in the United States from the 1960s through the 1980s, an interval during which the death rate from heart disease declined by about 25 percent (Stephen and Wald 1990).

The data show that there was an increase in the ratio of polyunsaturated to saturated fatty acids in the diet over this period from about 0.25 to 0.50. This increase was due mainly to a decrease in the intake of total fat, which entailed a discrimination against "visible fat" (such as the peripheral fat around the outside of steak) that consists mostly of saturated fatty acids. These observations further indicate that it is the composition of dietary fat, rather than the amount of fat consumed, that is of prime importance in the prevention of cardiovascular disease. Reducing total fat intake, however, is the only practical means of increasing the ratio of polyunsaturated to saturated fatty acids in the modern diet of industrialized countries.

The ratio of polyunsaturates to saturates in the native Inuit diet is difficult to estimate with accuracy and is highly variable, but it clearly exceeds the ratio of 0.50 calculated for the U.S. diet in the 1980s (Stephen and Wald 1990) and probably exceeds the 1.0 ratio proposed in modern diet recommendations. Inuit diets in northwestern Greenland in 1976 were estimated to have a ratio of 0.84, compared to a ratio of 0.24 in the diet of Danes (Bang et al. 1980). In addition to a reduction in total fat consumption to 30 percent of energy intake, current recommendations call for a 1:1:1 ratio of polyunsaturates to saturates to monounsaturates (Health and Welfare Canada 1990). The protection from cardiovascular disease afforded by the profile of fatty acids in the native Inuit diet is encouragement that implementation of these recommendations will confer a similar benefit on modern societies.

Adaptation to Dietary Sugars

The Inuit of western Greenland and northwestern Alaska are uniquely susceptible to congenital primary sucrase-isomaltase deficiency, a condition presumably related to the absence of sucrose in their traditional diet over many centuries (McNair et al. 1972; Raines, Draper, and Bergan 1973). Its epidemiology is familial, and studies on Greenland Inuit have indicated that it is due to a deficiency of an autosomal recessive gene. Its incidence was estimated to be about 3 percent in northwestern Alaska and 10 percent in a sample of hospital patients and staff in northeast Greenland.

This deficiency has a major effect on the capacity of those Inuit affected to deal with the modern diet. For example, children are unable to eat an ice-cream cone or drink a bottle of carbonated beverage unless it contains a synthetic sweetener in place of sucrose. In this respect, sucrase deficiency differs from lactase deficiency, in which lactase production declines during growth but persists at a reduced level in adulthood. Sucrase deficiency, a recently recognized cause of diarrhea in Inuit children, is present in acute form from birth.

The options available for dealing with it include replacing sucrose with other sugars (such as invert sugar in honey), using synthetic sweeteners, or taking oral sucrase preparations made from the intestinal juices of animals. Sucrase-isomaltase deficiency appears to be absent among Alaskan Inuit residents of the Subarctic, where the traditional diet has contained sucrose present in fruits and berries.

As in most societies (excepting mainly those of northern European origin), Inuit children undergo a progressive decrease in the intestinal synthesis of lactase during growth to a level that limits the amount of milk and milk products that can be digested in adulthood (Kretchmer 1972). Based on the results of a standard lactose tolerance test – which involves administering 50 g of lactose (the amount present in a liter of cow's milk), measuring the subsequent rise in plasma glucose, if any, and recording any adverse clinical reactions, such as abdominal cramps or diarrhea – about 70 percent of Inuit adults have been characterized as "lactose intolerant" (Gudmand-Hoyer and Jarnum 1969). However, if given a dose of 10 g of lactose (the amount present in a cup of milk), a large majority of Inuit adults experience no adverse symptoms and, therefore, from a nutritional standpoint, may be regarded as "lactose tolerant."

With respect to their ability to digest lactose, the Inuit resemble a majority of the world's population.

Alaskan Inuit children routinely consume milk or other dairy products as part of a school lunch program. The breakpoint in lactose tolerance in adults typically falls between 10 and 20 g (Raines et al. 1973); intakes in this range can be repeated after an interval of several hours. Hence, for most individuals, lactose intolerance is not a serious impediment to the acquisition of the calcium and other nutrients present in dairy foods.

Adaptation to the Modern Diet

Historically, the greatest threat to the nutritional status of the Arctic Inuit was famine, triggered by failure to catch a bowhead whale or by the failure of the caribou to run. In such exigencies, seals were the most reliable dietary staple. The Inuit population was kept in balance with its food supply by periodic famines, by a high infant mortality, by an extremely high rate of fatal accidents among adults pursuing the hunting culture, and if necessary, by infanticide. They had no nutrition education and no need for it. Their custom of eating animals almost in their entirety provided them with all the nutrients necessary for nutritional health, assuming their foods were available in sufficient amounts. There were no "junk foods" in their diet. Food not eaten fresh was preserved in the frozen state in the ice cellars that are still prevalent in Arctic Inuit villages. The central nutritional imperative was simply to get enough to eat.

For the first time since they migrated across the Bering Strait several thousand years ago, the Inuit in the twentieth century have been confronted with the necessity of making significant food choices in order to be well fed. Fractionation of primary foodstuffs by the modern food-manufacturing industry has generated multitudes of products of highly variable nutritional quality that must be reassembled in specific combinations to ensure a balanced diet. This necessity has led to the development of a set of rules for selecting proper combinations of foods that are inculcated into children by their parents and teachers and communicated to the public through nutrition education programs. To assist consumers in following these rules, a list of the nutrients that processed foods contain must be put on their labels, including the contribution of one serving to the recommended daily intake of each nutrient. A large government bureaucracy is devoted to ensuring that foods actually contain the amounts of nutrients listed on the label, and another agency is responsible for determining whether claims made for their efficacy in the prevention of disease are valid.

To primitive peoples whose only previous nutritional imperative was to get enough to eat, dealing with the complexities of the modern diet presents serious problems of nutritional adaptation. These problems are reflected in the poor nutritional status of Inuit and Amerindian inhabitants of the urban centers of Alaska and Canada. The nutritional health of urban Inuits is inferior to that of their forebears, as well as to that of their Arctic contemporaries who still maintain a semblance of the traditional diet and lifestyle (Colbert et al. 1978).

The younger generation of Inuit, like younger generations of most other native minorities, has abandoned the traditional diet almost entirely. The incidence of obesity, hypertension, and cardiovascular disease among Alaskan Inuit follows an increasing gradient from the high Arctic to the Subarctic to the modern cities of the south (Colbert et al. 1978). The incidence of diabetes is also increasing, but is still substantially lower than in Caucasians (Thouez et al. 1990; Young et al. 1990).

The decline in the nutritional status of the Inuit in the second half of the twentieth century has more to do with psychosocial factors than with a lack of nutritious foods. Educational and technical deficiencies, loss of social status in the community, deterioration of cultural values, lack of a sense of community, and discrimination in employment are factors in their poor nutritional status. The modern Inuit are at a watershed in social acculturation, unwilling to revert to their traditional lifestyle, yet unable to cope successfully with the complexities of an industrialized society.

Metabolic Adaptation to Cereal-Based Diets

The cereal-based diets consumed by the inhabitants of Southeast Asia and of Central and South America are in direct contrast to those consumed by the Inuit; that is, they are high in carbohydrates and low in protein and fat, rather than vice versa. Consequently, the bioenergetic transformations imposed by this diet, are also reversed. Fat stored in the adipose tissues is formed primarily by lipogenesis from glucose released in carbohydrate digestion, rather than by the fatty acids released by fat digestion. As polyunsaturated fatty acids cannot be synthesized in the body, fat formed from glucose consists mainly of saturated and monounsaturated fatty acids. In contrast to the massive conversion of excess amino acids to glucose on the Inuit diet, most of the limited amounts of amino acids in cereal diets are used for the synthesis of tissue proteins.

In addition to food shortages caused by crop failures, cereal-based food cultures have been subject to epidemic deficiencies of specific nutrients, notably beriberi caused by thiamine deficiency in the case of rice diets and pellagra caused by niacin deficiency in the case of maize diets. These diseases have created a prevalent impression that cereal diets are low in nutritional quality, but, in fact, these afflictions were the result of a disruption of native food cultures by foreign influences or the failure of foreigners to adopt the native culture.

Replacement of brown rice with more prestigious polished rice, a minor food in Europe but the staple food in Southeast Asia, removed most of the thiamine from the diet and resulted in a classic example of so-called cultural malnutrition. The traditional method of preparing maize practiced by the Mexican Indians, which entailed grinding it in lime water, was not followed by the black and "poor white" populations of African and European origin who inhabited the southern United States.

Their maize diet had several nutritional liabilities. The niacin in maize is present in complex forms from which it must be released by some type of hydrolysis, which in the native Indian culture took the form of alkaline hydrolysis effected by grinding with lime water. Further, maize protein is low in tryptophan, an amino acid that can be converted to niacin in the body. Although pellagrins consumed substantial amounts of pork, it consisted mostly of fat ("sowbelly") that contained little niacin, protein, or tryptophan. The Indian practice of grinding maize in lime water presumably arose out of experience. Not only was it instrumental in protecting them from the ravages of pellagra but it also contributed substantially to their intake of calcium, which is low in cereal grains.

Cereal diets are lower in protein than modern mixed diets and tend to be associated with protein-deficiency diseases, such as kwashiorkor, a severe condition affecting impoverished children during the postweaning period. It is marked by an edema that wrongly gives the impression that the children are of normal weight. When their serum protein level is restored by providing enough dietary protein, the edema dissipates, revealing severe emaciation (marasmus) caused by inadequate energy intake. This condition of protein–calorie malnutrition can be prevented by providing an adequate cereal-based weaning diet, indicating that the main etiological factor is a lack of food, rather than a lack of protein specifically.

When sufficient calories are supplied to prevent the utilization of dietary amino acids for energy production, these acids become available for the synthesis of tissue proteins. Most cereal-based diets, particularly if they contain (as they usually do) small amounts of animal products, such as fish, chicken, eggs, or meat, provide enough protein to satisfy the requirement for this nutrient. Diets based on cassava, a root vegetable with no redeeming nutritional qualities other than as a source of calories, are an exception to this generalization.

Vitamin B_{12} occurs only in foods of animal origin, which, therefore, must be included in all so-called vegetarian food cultures. Strict vegetarian diets, such as that of the "vegans," can result in macrocytic anemia and irreversible neurological damage caused by a deficiency of this vitamin. On the other hand, most of the B-complex vitamins and vitamin E are plentiful in the bran and germ of cereal grains. The vegetables and fruits that normally constitute a major part of vegetarian diets provide folic acid, vitamin C, and vitamin K and are good sources of beta-carotene, a precursor of vitamin A in the body. Yet, until programs of vitamin A supplementation were instituted in the mid–twentieth century, vitamin A deficiency was the main cause of blindness among children in Indonesia and other Southeast Asian localities, despite the fact that edible plants capable of preventing it were readily available.

Cereal diets have been of particular interest from the standpoint of mineral nutrition. Phytin, a component of the fiber of cereals (particularly wheat), binds dietary zinc, preventing its absorption and, at high intakes, precipitating a zinc deficiency. Dwarfism among poor Middle Eastern children, long presumed to be of congenital origin, was found to be due to chronic zinc deficiency caused by the consumption of large quantities of unleavened wheat bread (Prasad et al. 1963). Yeast fermentation degrades phytin and, thereby, prevents zinc deficiency, a relationship that evidently escaped recognition in this food culture for generations, even though the relationship between fermentation and the production of alcohol (presumably a higher priority) was known and exploited. Phytin also binds calcium, but to a lesser extent, and the capacity to adapt to a low intake of this element aids in the prevention of calcium deficiency.

Unlike carnivorous diets, which in general contain adequate amounts of essential trace elements to meet human requirements (because these elements are also essential in the diet of food animals), the trace element content of plants often reflects the content of the soil on which they were grown. Keshan disease, an acute cardiomyopathy among children in the Keshan district of China, is caused by an extremely low concentration of selenium in local soils and, consequently, in the cereals grown on these soils. Locally grown plant foods constitute the bulk of the diet in this area. Such deficiencies are less likely to occur on mixed diets, which contain plant foods grown on a variety of soils, as well as foods of animal origin.

The low calcium content of cereal diets is of current interest with respect to the role of this element in the prevention of osteoporotic bone fractures in elderly adults. Paradoxically, the incidence of hip fractures associated with the cereal-based food cultures of Japan and other Asian countries appears to be lower than it is in Western countries where calcium intake, derived mainly from dairy foods, is substantially higher (Fujita 1992). Whether this apparent anomaly reflects a minor role of calcium in the prevention of hip fractures, a high calcium requirement generated by the high-protein Western diet, a difference in lifestyle, a difference in the incidence of falls, a genetic involvement, or the effect of some unidentified factor is a question raised by cross-cultural studies on the epidemiology of osteoporotic bone disease.

Adaptation to Dietary Toxins

Plants did not evolve with the idea that they should be good to eat. In fact, the synthesis by plants of substances toxic to their predators (humans, animals, insects, and microbes) has been a major factor in survival to the present day. Humans and animals have eaten them at their own peril, sorting out those that, based on experience, could be safely added to their diet. A. C. Leopold and R. Ardrey (1972) have developed the thesis that the presence of toxins in plants was an important determinant of the dietary habits of primitive societies.

In addition to natural insecticides and substances poisonous to animals, plants contain a multitude of compounds that make them unsafe for human consumption: hemagglutinins, enzyme inhibitors, cyanogens, antivitamins, carcinogens, neurotoxins, and allergens, among others. Accounts of their occurrence have been given elsewhere (Ory 1981; Lampe 1986). L. S. Gold and colleagues (1992) have argued that nearly all the carcinogens in the diet are of natural rather than – as widely perceived – industrial origin. Although rigorous toxicological testing of food additives on laboratory animals is required before they are approved for human consumption, no such tests have been applied to the natural toxins present in the diet. Broadening of testing for carcinogenicity to include these compounds recently has been recommended (Gold et al. 1992).

Compounds toxic to humans are more likely to be encountered in foods of plant origin because they have not been subjected to toxicological screening by first having been consumed by animals. Many toxins that are not overtly toxic to animals are at least partially catabolized by enzymatic detoxification systems present in animal tissues, notably the microsomal mixed-function oxidase system in the liver. Some toxins in plants are destroyed by cooking, but this method of food preparation appears to have been practiced only during the last 20 percent of human existence (Grivetti 1981).

Removal of toxins from plants by selective breeding and food processing has made it possible to add many new foods to the modern mixed diet. In addition, commerce in foodstuffs has diluted the high concentrations of toxins present in plants grown in specific localities. For example, the soil in some areas of the western United States contains high levels of selenium, an element that is accumulated in the seed of wheat and other cereals. When these locally grown grains constitute the bulk of the diet fed to farm animals, they can cause severe symptoms of selenium toxicity and even death. It must be presumed that they also caused at least mild toxicity among the early settlers in the same areas, for whom locally grown grains made up a major part of the diet. Modern commerce in foodstuffs has resulted in dilution of high-selenium foods and removed the risk of toxicity among consumers of the mixed diet.

Numerous substances have been added to the modern diet to improve its nutritional quality and safety. The required listing of these supplementary nutrients and additives on the label of processed foods has created a prevalent impression among consumers that some products consist mainly of synthetic industrial chemicals of questionable safety. In fact, nearly all food supplements and additives are either natural substances or exact replicas of natural substances already present in the diet or in the body (Branen, Davidson, and Salminen 1989). Most cases of food poisoning in modern societies are caused by microbial toxins formed as a result of careless handling and preservation in the home.

The few additives of purely synthetic origin have been subjected to the exhaustive life-cycle testing on laboratory animals required by food safety laws. Two such substances are the lipid antioxidants, BHA and BHT, used to prevent the oxidation of polyunsaturated fatty acids in foods, a widespread problem in the food industry resulting in flavor deterioration and the formation of products that pose a possible health risk. The synthetic sweeteners used in low-calorie beverages were approved only after years, or even decades, of safety evaluation. As indicated, there are several grounds upon which the modern diet can be criticized, but the common impression that it is less safe, in toxicological terms, than so-called natural diets is without foundation. Indeed, the reverse is the case.

The epidemiology of cancer in modern societies shows correlations of uncertain interpretation with diets high in fat and protein, but none with the use of food additives (Doll 1992; Lutz and Schlatter 1992). There are correlations, probably signifying causation, between the presence of certain substances in the diet and a high incidence of specific cancers. These include stomach cancer among Japanese and other Asians who consume large quantities of heavily salted foods, and liver cancer in Madagascans who consume moldy peanuts containing the potent carcinogen aflatoxin B_1. There is no current information as to the possible role of natural chemicals in the estimated 35 percent of cancers in industrialized societies that are "diet related" (Doll 1992). W. K. Lutz and J. Schlatter (1992) have pointed out that this figure is "provocatively close" to the prevalence of overnutrition (that is, obesity) in these societies.

There remain a number of toxicological risks associated with the modern diet that are preventable or avoidable: formation of microbial toxins in poorly preserved foods; overdosing or accidental poisoning with synthetic vitamins; ingestion of harmful bacteria, residual plant enzymes, and antinutrients resulting from inadequate cooking; consumption of carcinogenic amino acid derivatives produced by overcooking meats; and ingestion of natural toxicants in such foods as mushrooms. There are also numerous allergens present in foods that seriously affect food selection by individuals but which do not have an important influence on general food cultures. The occurrence of immunological toxicants in foods has been discussed by L. W. Mayron (1981).

Cultural Factors in Nutritional Adaptation

There are many dietary practices that are not explicable in terms of environmental, nutritional, or toxicological (that is, biological) determinants. They are attributable to traditions (religious, societal, and familial) that often distinguish one food culture from another, even when their practitioners share other common influences on food choices, such as food economics, social class, and occupational status. Traditional ceremonies surrounding the procurement of food are still in evidence among some hunting cultures, as exemplified in the ceremony held by the Arctic Inuit on the eve of the annual whale hunt, even though this hazardous undertaking is no longer necessary to meet their nutritional needs.

Religious prohibitions affect the consumption of beef, pork, dairy products, and fish, as well as processed foods that contain substances of animal origin. Adherents to some food cultures would rather starve than consume foods that are a common item in other cultures (for example, dog meat and insects). Food fads, prevalent in modern societies, have a major, but usually short-term, influence on food practices. The role of cultural factors as determinants of traditional and modern food habits is discussed in several reviews and books (Wing and Brown 1979; Grivetti 1981; Axelson 1986; Gordon 1987; Kittler and Sucher 1989).

Notwithstanding the strength of cultural traditions, studies on intersocietal migrants and aboriginal societies undergoing acculturation have shown that changes in food habits can occur relatively rapidly, particularly among the young. A diet survey conducted on the inhabitants of an Arctic Inuit village in the early 1970s showed that about 50 percent of calories were still derived from native foods in the diet of adults, compared to only about 25 percent in the diet of children, even though all foods were eaten at home (Raines and Heller 1978). A similar generation gap in the acceptance of new foods has been observed among Chinese immigrants to the United States (Axelson 1986).

Adaptation to a new food culture often begins with the preparation of new foods by traditional methods and by selection of commercially prepared facsimiles of traditional foods, such as prepared tortillas by Mexican Americans (Axelson 1986). P. G. Kittler and K. Sucher (1989) compared the traditional food cultures of Native Americans, that of the original European settlers, and that of recent immigrants from other countries. Further, they traced the changes in native and foreign food cultures that have taken place to the present time. They concluded that the modern mixed diet reflects a strong influence of European food traditions on the dietary habits of all segments of the population, but that there is also clear evidence of an influence of all the major food cultures brought to America, except those brought by blacks. Consumption of traditional Native American foods is confined mainly to Indian reservations. The decimation of the Amerindian food culture is reflected in an extraordinarily high incidence of diseases that are the modern hallmarks of malnutrition in America.

Paradoxically, overnutrition in industrialized societies is more prevalent among the poor than among the affluent. Analysis of the disposal of family income in the United States indicates that expenditures for food are not closely related to income (Popkin and Haines 1981). This finding is attributable to the low cost of food, which makes it possible for even the poor to conserve family income by buying inexpensive food items.

The relationship between the cost of food and its nutritional quality is also weak. The poor nutritional status of blacks and Native Americans is not due in any major degree to an inability to buy nutritious food. It is, more importantly, a reflection of a lack of education that precludes understanding the health risks associated with obesity, a low social status lacking the peer pressure to maintain normal body weight that prevails among the middle and upper classes of society, and incomplete emergence from the agrarian culture of the nineteenth and early twentieth centuries. It was only some 50 years ago that obesity was regarded as a sign of good health and a source of energy that could be called upon in times of ill health. Popular figures in Western social culture (Shakespeare's Falstaff and Santa Claus, for example) are portrayed as jolly, fat men. It is understandable, therefore, that the opposite perception of obesity has not yet permeated all levels of American society.

VI.11 The Psychology of Food and Food Choice

We can think of the world, for any person, as divided into the self and everything else. The principal material breach of this fundamental dichotomy occurs in the act of ingestion, when something from the world (other) enters the body (self). The mouth is the guardian of the body, a final checkpoint, at which the decision is made to expel or ingest a food.

There is a widespread belief in traditional cultures that "you are what you eat." That is, people take on the properties of what they eat: Eating a brave animal makes one brave, or eating an animal with good eyesight improves one's own eyesight (reviewed in Nemeroff and Rozin 1989). "You are what you eat" seems to be "believed" at an implicit level, even among educated people in Western culture (Nemeroff and Rozin 1989). It is an eminently reasonable belief, since combinations of two entities (in this case, person and food) usually display properties of both. Thus, from the psychological side, the act of eating is fraught with affect; one is rarely neutral about what goes in one's mouth. Some of our greatest pleasures and our greatest fears have to do with what we eat.

The powerful effect associated with eating has a strong biological basis.[1] Humans, like rats, cockroaches, raccoons, herring gulls, and other broadly omnivorous species, can thrive in a wide range of environments because they discover nutrients in many sources. But although the world is filled with sources of nutrition, there are two problems facing the omnivore (or generalist). One is that many potential foods contain toxins. A second is that most available (nonanimal) foods are nutritionally incomplete. An apt selection of a variety of different plant foods is required for the survival of omnivorous animals to the extent that they cannot find sufficient animal foods. Animal foods tend to be complete sources of nutrition, but they are harder to come by because they are less prevalent and because they are often hard to procure (for example, they move). Hence, the omnivore must make a careful selection of foods, avoiding high levels of toxins and ingesting a full range of nutrients. Any act of ingestion, especially of a new potential food, is laden with ambivalence: It could be a good source of nutrition, but it might also be toxic.

Specialist species, such as those that eat only insects, can identify food as small moving things; specialists that eat only one species or group of plants may identify food by some common chemical property of these plants. There is no simple, genetic way to program an omnivorous animal to identify food by its sensory properties, because anything might be food and anything might contain toxins (or harmful microorganisms). Hence, omnivores must basically learn what is edible and what is not and what constitutes a good combination of edibles. This learning is facilitated by a few biologically (genetically) based biases:

1. An innate tendency in many species (including rats and humans) to ingest things that taste sweet (correlated with the presence of calories in nature) and to avoid things that taste bitter (correlated with the presence of toxins in nature [Garcia and Hankins 1975]).
2. Conflicting tendencies to be interested in new foods and a variety of foodstuffs but to fear anything new. This results from what I have called the generalist's (omnivore's) dilemma; the importance of exploring new foods to obtain adequate nutrition across different areas and seasons and, yet, the dangers of ingesting toxins in doing so. The conflicting tendencies are manifested as a cautious sampling of new foods and a tendency to eat a number of different foods in any day.
3. Special abilities to learn about the consequences of ingestion. Here omnivores face a difficult challenge, because both the positive and negative effects of foods occur many minutes to hours or even days after ingestion. But omnivores, like rats and humans, can learn to associate a food with the consequences of ingestion even if they occur some hours later (Garcia, Hankins, and Rusiniak 1974; Rozin 1976).
4. A few special preprogrammed food selection systems. These include systems that signal to an animal that it is in need of energy (what we loosely call "hunger"), water ("thirst"), and sodium ("sodium appetite"). The sodium system, at least for the rat, is linked to an innate recognition of the taste of the needed nutrient. As shown originally by the great food selection psychologist, Curt Richter, rats deprived of sodium for the first time in their lives show an immediate preference for the taste of sodium (salt) (Richter 1956; Denton 1982; Schulkin 1991). There is some evidence for something that may resemble an innate sodium-specific hunger in humans (Beauchamp, Bartino, and Engelman 1983; Shepherd 1988).

The psychology of human food-related behavior falls naturally into two areas. One is concerned with how much is eaten (the starting and stopping of eating, defining the meal). Almost all psychological research is devoted to understanding what determines how much people and animals eat and the disorders of this process (such as obesity and anorexia). These issues are discussed elsewhere in this work. But this chapter focuses on the second area, what is eaten, that is, on food selection.[2]

The Human Omnivore

Food selection can be accomplished by genetic programming (for example, the avoidance of bitter tastes), by individual experience with foods (for example, learning that a certain food causes adverse symptoms), or by social transmission. Social transmission obviously has the virtue of sparing an organism the efforts and risks of discovering what is edible and what is not. In nonhuman animals, there is social transmission that can be called inadvertent; that is, animals may learn to eat what their parents or conspecifics eat by some sort of exposure to the conspecifics when eating (see Galef 1988, for a review). Humans, however, have two other powerful modes of transmission of food preferences and information (see Rozin 1988, for a review). One is an indirect social effect: social institutions, cuisines, and technological advances that make certain varieties of nutritious foods easily available (for instance, by agriculture or importation) and reduce the likelihood of contact with harmful potential foods (such as poisonous mushrooms). The second effect is explicit teaching about food preferences by example or by transmission of information (for example, "don't eat wild-growing mushrooms"). There is no firm evidence for any nonhuman species of explicit (intentional) teaching about appropriate foods (Galef 1988).

Humans share with animals both the nutritive need for food and the derivation of pleasure from ingestion. However, humans supplement these two functions of food with others as well (Rozin 1990b). Food and eating can serve a social function by providing an occasion for the gathering of kin at mealtimes. Food also acts as a vehicle for making social distinctions (as in serving certain foods to indicate high regard for a guest) and as culture-wide social markers (as when cuisines serve as distinctive characteristics of different groups). In the form of cuisine, food also produces an aesthetic response that extends well beyond animal pleasure. And finally, for many people in the world, most particularly Hindu Indians, food is a moral substance; eating certain foods and avoiding others is a means of preserving purity, avoiding pollution, and leading a proper life (Appadurai 1981). The multiple functions of food for humans make the understanding of human uses of food and attitudes to food an extremely complex task.

The Psychological Categorization of Food

We are accustomed to biological/taxonomic (species) and nutritional classifications of foods. But for a psychology of food, the important distinctions are those made in the human mind, and these are only weakly related to scientific classifications of foods.

The simplest approach to human food choice is to determine, for any group of people, the types and amounts of foods consumed (or more easily, purchased). We can call this measure food *use.* It is of special significance from the point of view of economics, but it has a major shortcoming as a measure of human food selection, since much food use is determined by its cost and availability. It would certainly be inaccurate to assume that because a group consumes more of X than Y, that they prefer X, when it may be that X is simply more available or less costly.

A more appropriate psychological measure is *preference,* which indicates, with price and availability controlled, which foods a person or group chooses. Yet it would be a mistake to assume that preference is a direct and infallible measure of liking for particular foods. A dieter, for example, might like ice cream better than cottage cheese but prefer (choose) cottage cheese. *Liking,* then, is a third way of describing food selection. It usually refers to attitudes about the sensory properties of foods, most particularly the oral sensations (tastes, aromas [flavors], "mouth feel"). Thus, a psychology of human food choice must address the question of why particular humans or groups of humans use, prefer, and like particular foods.

Further analysis suggests that there is a richer psychological categorization of foods for humans. Of all the potential edibles in the world (which essentially means anything that can be gotten into the mouth), a first simple division is between items that are accepted and those that are rejected by any individual or group. However, acceptance or rejection can be motivated by any of three reasons (or any combination of these) (see Table VI.11.1; Rozin and Fallon 1980; Fallon and Rozin 1983).

One reason is "sensory-affective." This has to do with liking or disliking the sensory properties of a food. Foods that are accepted or rejected primarily on sensory-affective grounds can be called "good tastes" or "distastes," respectively. If X likes lima beans and Y does not, the reason is almost certainly sensory-affective. Most of the differences in food likes within a well-defined cultural group have to do with differences in sensory-affective responses.

A second reason for rejecting a food is anticipated consequences. One may reject a food (which we call

Table VI.11.1 *Psychological categorization of acceptance and rejection*

	Rejections				Acceptances			
Dimensions	Distaste	Danger	Inappropriate	Disgust	Good taste	Beneficial	Appropriate	Transvalued
Sensory-affective	–			–	+			+
Anticipated consequences		–				+		
Ideational		?	–	–		?	+	+
Contaminant		–		–				+
Examples	Beer Chilli Spinach	Allergy foods Carcinogens	Grass Sand	Feces Insects	Saccharin Favorite foods	Medicines Healthy foods	Ritual foods	Leavings of heroes, loved ones, or deities

Source: From Fallon and Rozin (1983).

a dangerous food) because one believes ingestion will be harmful (it may be high in fats, or may contain carcinogens). Or one may accept a food (which we call a beneficial food) because it is highly nutritive or curative (perhaps a vitamin pill or a particular vegetable).

A third, uniquely human reason for food acceptance or rejection is what we call ideational; it is the nature of the food and/or its origin that primarily determines our response. Thus, we reject a very large number of potential foods because we have learned simply that they are not food: paper, tree bark, stones. These (inappropriate) entities may not be harmful and may not taste bad; they simply are not food. This inappropriate category is very large, yet there is a much smaller (appropriate) category on the positive side: foods that we eat just because they are food. Certain ritual foods might fall into this category.

We have now used three reasons to generate three categories of acceptance (good tastes, beneficial, and appropriate) and three of rejection (distaste, danger, and inappropriate). There remains one more major category of rejection that represents, like inappropriate, a fundamentally ideational rejection. We call this category disgust: Although it is primarily an ideational rejection, disgusting items are usually believed to taste bad and are often believed to be harmful. Feces seems to be disgusting universally; in American and many other Western cultures, insects fall within this category as well.

Disgusting items have the unique property that if they touch an otherwise acceptable food, they render that food unacceptable; we call this psychological contamination (Rozin and Fallon 1987). The category of disgusts is large. The opposite positive category, which we call transvalued foods, is very small. These are foods that are uplifting for ideational reasons and which are often thought to be beneficial and tasty. A good example is "prasad" in Hindu culture. Food that has been offered to the gods, and is subsequently distributed to worshippers who believe it to have been partly consumed by the gods, is considered especially desirable (Breckenridge 1986).

A psychological account of food choice would have to explain how foods come to be in any of the eight categories we have generated.

Accounting for Food Preferences and Likes

It must be true that human food attitudes result from some combination of three sources of information or experience: biological heritage (that is, our genes), cultural environment, and unique individual experience. I shall examine each of these contributing causes, with emphasis on the last, most psychological of the three. Of course, the distinction among genetic, cultural, and individual–psychological origins of human preferences is somewhat arbitrary, and there is a great deal of interaction among these forces. Nonetheless, the distinction is very useful.

Genetic Aspects of Food Selection

By their nature, omnivores carry into the world little specific information about what is edible and what is not. I noted taste biases, suspicion of new foods with an opposing tendency to seek variety, and some special abilities to learn about the consequences of food. However, there are individual differences among people that have genetic bases and that influence food selection. The small minority of these directly affect the nervous system and food choice. The best-investigated example is an inherited tendency to taste (or not to taste) a certain class of bitter compounds (identified by one member of this category, phenylthiocarbamide or PTC). This ability is inherited as a simple, single-locus, Mendelian recessive trait (Fischer 1967) and probably has some modest effect on preferences for certain bitter substances, such as coffee. The incidence of PTC tasting differs in different cultural groups.

More commonly, genetic differences in metabolism affect the consequences that different foods have and, hence, whether they might enter the beneficial or harmful category for any individual. A well-investigated example is lactose intolerance, but others include a sensitivity to wheat protein (gluten) and sensitivity to a potential toxin in fava beans (see Katz 1982; Simoons 1982, for reviews). In the case of lactose intolerance, the inability of most human beings to digest milk sugar (lactose) as adults (a genetically determined trait) accounts for the absence or minimal presence of raw milk and other uncultured milk products in the majority of the world's cuisines. Those who are lactose intolerant can develop lower gastrointestinal symptoms (cramps, diarrhea) upon ingestion of even relatively moderate amounts of uncultured milk.

The fact remains that although there are genetic influences on food choice, they are rather minor, at least at the individual level. An indication of this is that the food preferences of identical twins are not much (if at all) more similar than are the preferences of fraternal twins (Rozin and Millman 1987).

Culture and Food Selection: Cuisine

Although it has never been directly demonstrated, it seems obvious that the major determinant of any individual's food preferences is his or her native cuisine. Put another way, if one wanted to guess as much as one could about a person's food attitudes and preferences, the best question to ask would be: What is your native culture or ethnic group? Not only would this response be very informative but there is also no other question one could ask that would be remotely as informative. In terms of the taxonomy of food acceptances and rejections (Table VI.11.1), cultural forces generally determine the ideational categories and strongly influence the good tastes–distastes and danger–beneficial categories.
